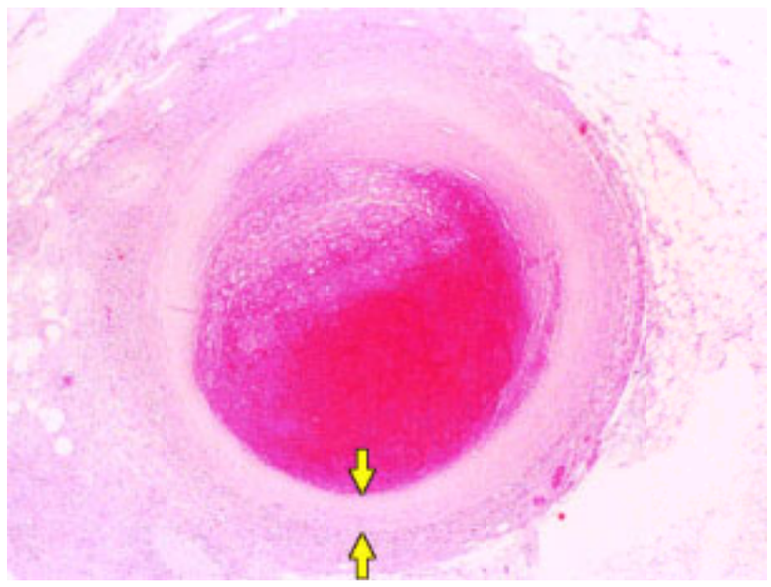
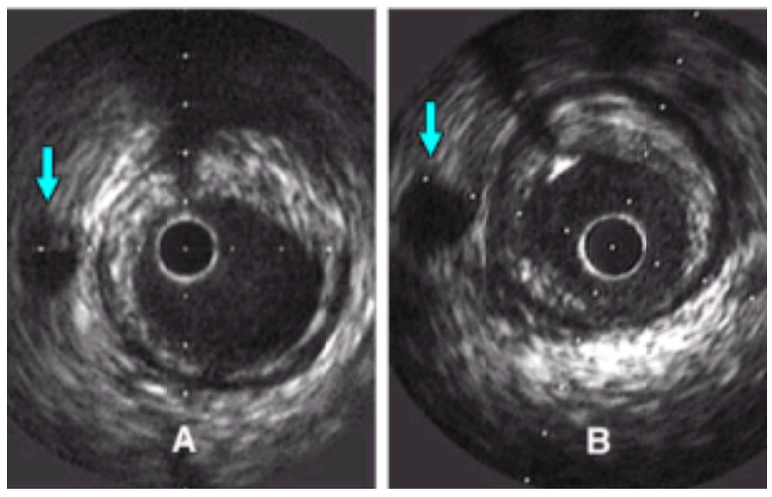
OVERVIEW

Despite major pharmacologic advances in the management of heart failure, cardiac transplantation is the most effective treatment for selected patients with end-stage heart failure. Sound, evidence-based immunosuppressive strategies have decreased morbidity and mortality, enabling the successful transplantation of even less than ideal candidates. Most infections and rejections are either preventable or treatable, and 1-year and 3-year survival rates exceed 85% and 80%, respectively. Cardiac allograft vasculopathy limits long-term survival and is the major cause of death after the first few years. Nonetheless, approximately 50% of recipients are alive 10 years after transplantation. Because of this success, the number of patients who could potentially benefit from cardiac transplantation is even greater than previously thought, which results in an ever-increasing donor to recipient disparity. Not only must every effort be made to increase the number of donors and use every appropriate donor heart, but care must be taken to ensure that individuals listed as candidates for cardiac transplantation are those who are likely to benefit the most. Potentially suitable candidates should be referred early in the course of their end-stage disease to heart failure and transplant specialists so that transplantation can be appropriately timed or alternative treatment options implemented. After transplantation, the care of recipients should be directed, at least in part, by transplant physicians.



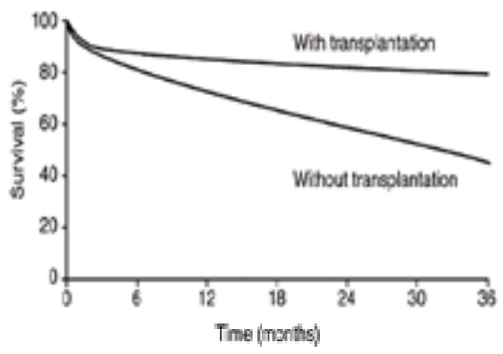
Acute thrombosis of the coronary artery in a transplant heart. The concentric thickening of the vessel wall is consistent with transplant associated vascular disease (*yellow arrows*).



Serial intravascular ultrasound study in transplant recipient. The baseline study (A, 2 months after cardiac transplant), shows an eccentric plaque in the left anterior descending artery. One year later (B), the same site is identified with the help of anatomic and angiographic landmarks (a branch vessel, *arrow*). This permits repeated imaging of the same site, which reveals no change over 1 year.

HISTORICAL PERSPECTIVE

Although much progress has been made in pharmacologic therapy for heart failure, the most effective treatment for selected patients with end-stage heart disease is cardiac transplantation. Patients with severe heart failure have a 1- to 2-year mortality approaching 50% despite appropriate and advanced medical treatment (1). Heart transplantation alters the course of end-stage heart disease, with 1-year, 3-year, and 10-year survival rates exceeding 85%, 80%, and 50%, respectively (2) (*e*Fig. 94.0.1). More than 55,000 procedures have been performed in over 330 centers worldwide, and nearly 3,000 additional procedures are performed each year (2). Although certain demographic variables influence the likelihood of survival after cardiac transplantation (e.g., retransplantation, older recipient and donor age, higher pulmonary vascular resistance, and longer duration of ischemia) (2) (*e*Table 94.0.1), survival and quality of life continue to improve (3,4,5 and 6). Heart transplantation is not experimental.



***e*FIGURE 94.0.1** Survival of cardiac transplant recipients. Moderate and severe congestive heart failure is associated with a poor prognosis. Without transplantation, candidates would likely survive as depicted in the lower curve. The poor prognosis contrasts with the survival achieved with transplantation, depicted in the upper curve, as reported to the International Society for Heart and Lung Transplantation, 1996–1999 (n = 11,844). During the first month after cardiac transplantation, donor heart dysfunction predominates as a cause of death. The propensity to reject the transplanted heart decreases over time. Consequently, the first few months after transplantation present not only the highest risk of rejection but also the highest risk of infection because of the higher doses of immunosuppressive agents used. Between 1 and 12 months after transplantation, not surprisingly, infection and acute rejection predominate as causes of death. After the first few years, cardiac allograft vasculopathy (CAV) and malignancy become the leading causes of death, the former accounting for a quarter of the deaths in transplant recipients (2,3 and 4) (*e*Fig. 94.0.2).

***e*FIGURE 94.0.2** Causes of death after heart transplantation: influence of time. Although infection, acute allograft rejection, and nonspecific (NS) cardiac allograft failure remain significant causes of mortality after heart transplantation, cardiac allograft vasculopathy (CAV) and malignancy become the leading causes of death after the first few years after heart transplantation. (Adapted from Hosenpud JD, Bennett LE, Keck BM, et al. The Registry of the International Society for Heart and Lung Transplantation: seventeenth official report—2000. *J Heart Lung Transplant* 2000;19:918, with permission.)

The quality of life achieved after transplantation is generally good (5). By 5 years, approximately 55% of survivors are employed or retired (2,6). Many of those who are not employed could be, but are prevented from working because of various societal factors. Hospitalization rates among survivors decrease over the first 5

years from approximately 40% in the first year to 20% in the fifth year (2).

The care of potential transplant patients and posttransplant patients is important to internists and cardiologists alike. Given the success of heart transplantation, knowing when to refer a patient to a heart failure and transplant specialist for evaluation is of paramount importance. Early referral of any patient who has persistent significant left ventricular dysfunction (ejection fraction <25%) despite appropriate medical therapy is warranted, not only for evaluation of the potential need for cardiac transplantation, but also for determination of whether alternative therapies might delay or even prevent the need for transplantation. In addition, many patients awaiting cardiac transplantation (more than 4,000 in the United States alone) and many cardiac transplant recipients are cared for, at least in part, by their primary physicians. Management of end-stage heart failure and cardiac transplant patients is challenging and requires vigilance and attention to detail.

CLINICAL PROFILE

Recipient Selection

Indications

Cardiac transplantation is indicated for one of the many reasons listed in Table 94.1 (1,7,8 and 9). Cardiac transplantation is not indicated, however, simply because of an ejection fraction of less than 20%, a past history of functional class III or IV symptoms of heart failure, or a previous history of ventricular arrhythmias. Also, before transplantation is considered, a thorough search for reversible or surgically amenable cardiac disease must be completed and optimal medical management implemented. Patients should either have failed to improve with a trial of beta-blocker therapy or have clear contraindications to beta-blocker use. Confidence that the medical therapy is optimal is increased when the therapy is directed or administered by heart failure specialists.

TABLE 94.1 INDICATIONS FOR CARDIAC TRANSPLANTATION CANDIDACY

Patients who require continuous intravenous inotropic support (e.g., dobutamine hydrochloride or milrinone lactate) or mechanical circulatory support (intraaortic balloon pump or left ventricular assist devices) despite maximal medical therapy for heart failure are likely to benefit from transplantation and should be evaluated. Whether less ill, ambulatory patients with heart failure will benefit from transplantation is more difficult to determine. Identifying all patients at high risk for death during continued medical therapy remains challenging. Individuals whose predicted chance of survival for 1 year is less than 80% without heart transplantation warrant consideration for transplantation. Most patients being considered for cardiac transplantation usually have New York Heart Association class III to IV symptoms despite receiving best medical therapy. Ambulatory candidates usually have peak oxygen consumption (VO_2) values of 14 mL per kg per minute or less when assessed by maximal exercise tolerance testing. Unless the test is terminated because of myocardial ischemia or ventricular arrhythmias, anaerobic threshold occurs at 50% to 70% of peak oxygen uptake. The effects of age, gender, and conditioning effects on maximal oxygen uptake must be considered in interpreting VO_2 data.

Assessment of Risk of Mortality and Morbidity after Transplantation

Patients meeting indications for cardiac transplantation are evaluated to determine whether they are at higher than acceptable risk for a poor outcome after transplantation (7,10,11,12,13 and 14). Anecdotal experience of successfully overcoming isolated risk factors should not justify ignoring known risks in the majority of situations. Table 94.2 lists characteristics that increase the risk of morbidity and mortality after cardiac transplantation. These risk factors do not necessarily represent absolute exclusionary criteria. For example, combined heart-liver or heart-kidney transplantation is feasible in selected patients with both end-stage heart and liver disease or end-stage heart and kidney disease (12,13).

TABLE 94.2 CHARACTERISTICS INCREASING THE RISK OF MORBIDITY AND MORTALITY AFTER CARDIAC TRANSPLANTATION

The use of standardized indications and risk assessment procedures assists physicians in (a) selecting appropriate transplant recipients by ensuring that transplantation is avoided or delayed for patients who are functioning well, (b) encouraging optimal medical or surgical management before considering transplantation, and (c) helping to avoid the transplantation of patients who are at high risk of a poor outcome. For high-risk patients, the use of a donor heart may not be justifiable, given the scarcity of donor hearts and the abundance of lower-risk patients. Older patients can be successfully transplanted, and any age limitation is obviously arbitrary (14). Even though, for recipients older than 50 years, increasing age increases the risk of mortality after transplantation, the effect is moderate, with a mortality risk 50% greater in a 70-year-old than in a 50-year-old candidate (2). Therefore, patients are probably best considered individually using criteria that contain as few arbitrary guidelines as possible.

Management of the Patient while Awaiting Transplantation

While the patient awaits transplantation, his or her general health and hemodynamic compensation must not be allowed to deteriorate without intervention. A low threshold for hospitalization and more intensive heart failure treatment are mandated for any hemodynamic deterioration that may manifest as significant azotemia, refractory salt and water overload, persistent hypotension, altered mental status, or even gastrointestinal distress. Signs and symptoms of low cardiac output should prompt escalation in therapy from intravenous diuretics to intravenous inotropic agents, and from intravenous inotropic agents to intraaortic balloon pump or left ventricular assist devices (see Chapter 95). Heart transplant candidates who nonetheless develop irreversible end-organ failure in other organ systems or who are likely to die despite transplantation are not transplanted. Therapeutic approaches to the prevention of sudden death, including the use of an implantable cardioverter defibrillator, as appropriate, are considered. The routine placement of an implantable cardioverter defibrillator in heart transplant candidates in the absence of standard indications for use has not been proven.

All patients awaiting transplantation are routinely tested and evaluated to insure that indications and risk assessments remain valid. Every 3 to 6 months, even stable patients undergo repeat right heart catheterization to insure acceptable pulmonary vascular resistance. Levels of panel-reactive antibodies (PRA) are periodically

monitored, particularly after any blood transfusions. If blood transfusions are needed, leukocyte-removing filters are used to minimize anti-HLA antibody formation. Various therapies may be used to decrease elevated PRA levels in sensitized patients, for example, administration of intravenous immunoglobulin, plasmapheresis, administration of immunosuppressive agents, or some combination of these. Patients are monitored for recovery of left ventricular function that would obviate or at least postpone the need for transplantation. Peak VO_2 is reassessed every 6 months and left ventricular ejection fraction is reassessed every 6 to 12 months. Peak VO_2 measurements of 15 mL per kg per minute or more generally allow deferment of transplantation. Transplantation is postponed if indications are no longer met.

Donor Selection

Donor selection is influenced by many factors, including ABO blood type compatibility, donor-recipient size disparity, presence of intrinsic cardiac disease, and presence of transmissible infectious or malignant diseases (15,16,17 and 18). The risk of using a specific donor heart is always balanced against the risk one is willing to take with regard to a particular recipient. A decision to use a marginal donor heart may sometimes be made if the condition of the potential recipient warrants the risk and the potential recipient consents.

The lowest donor weight deemed compatible is usually considered to be 80% of the recipient's weight. In adults, upper weight limits are only rarely needed, and then only in situations in which the size disparity is large. In recipients with significant (but acceptable) pulmonary hypertension, the lower donor weight limit is often increased in hopes of preventing acute right ventricular failure in the transplanted heart.

To avoid intrinsic cardiac disease, electrocardiography, echocardiography, and (at times) coronary angiography are used. Electrocardiographic abnormalities that generally preclude the use of a donor heart include evidence of myocardial infarction and significant ventricular arrhythmias. Echocardiographic abnormalities that generally preclude the use of a donor heart include significant global hypokinesis, significant valvular abnormalities, and moderate to severe left ventricular hypertrophy. In addition, evidence of a significant cardiac contusion with a significantly elevated troponin level generally precludes use of the donor heart. Although older donor hearts are associated with a higher risk (eTable 94.0.1), many have been successfully used (2,19). Even in the absence of risk factors for coronary artery disease, coronary angiography is recommended in male donors older than 45 years and in female donors older than 50 years. The presence of risk factors for coronary artery disease prompts coronary angiography in even younger donors. Some donor hearts with significant coronary artery or valvular disease have been transplanted successfully with simultaneous bypass surgery or valve replacement, but doing so is not yet standard care. Brain death can cause time-dependent changes in left ventricular function (20) that may be related to catecholamine release. Donor heart dysfunction may be reversible, and thyroid hormone is frequently administered to improve donor heart function. Clearly using an irreversibly damaged donor heart is to be avoided.

To avoid transmitting infectious disease with the donated heart, a series of tests are performed to determine the suitability for transplantation. A history of behaviors, especially recent, that predispose to human immunodeficiency virus (HIV) infection or viral hepatitis (e.g., intravenous drug use); positivity for HIV, hepatitis B surface antigen (HB_SAg), or hepatitis C; and uncontrolled gram-negative sepsis generally preclude donor use. The use of a heart from an HB_SAg-positive donor could be considered, however, if the recipient is also HB_SAg positive. Due to the differences in virulence of various hepatitis C subtypes, the use of hepatitis C–positive donors' hearts in hepatitis C–positive recipients remains controversial. Generally, if the donor has a malignancy not confined to the cranium, the donor heart is not used (16,17 and 18,21). The final decision to transplant a particular heart is made at the time of visual inspection.

An additional donor-related factor affecting survival after cardiac transplantation is the degree of HLA matching between donor and recipient. Time constraints affecting donor cardiectomy and implantation generally preclude prospective HLA matching. Retrospective evaluations suggest that improved matching would in fact lead to improved outcomes.

Donor Allocation

Given the increasing donor to recipient disparity, the procurement and methods of allocation of all solid organs are frequently debated. Of course, everything should be done to decrease candidate waiting time, increase the use of suitable donor hearts, and increase the willingness of the population at large to donate (16,21,22). Hearts are allocated based on mandated guidelines. In the United States, hearts are allocated to specific patients based on blood type, size, proximity of the donor to the candidate's transplant center, and the disease severity and waiting time of the candidate (23).

Flexibility in organ allocation is at odds with predictability and societal accountability. Flexibility in matching donors to recipients maximizes the use of donor hearts. For instance, marginal donor hearts can be transplanted into less than ideal candidates, which increases the use of altruistically donated hearts. Many older patients might be more than willing to accept a heart with less than normal coronary arteries or even a heart that requires bypass surgery. Granting unlimited flexibility to transplant surgeons and physicians is not socially acceptable, however, because the public generally requires predictability and accountability.

ANATOMIC CONSIDERATIONS

Donor Cardiectomy

In donor cardiectomy and transplant surgery, one key to successful transplantation is the minimization of donor heart ischemic time (24,25). Ischemic time (from the time of aortic cross-clamping in the donor to release of aortic cross-clamp in the recipient) of less than 4 hours is generally acceptable, although some risk is conferred by every hour of donor heart ischemia (risk = 1.0 + 0.26 per hour for each hour over 3 hours) (2) (eTable 94.0.1).

In multiorgan donor procurement procedures, a midline incision is extended from the sternal notch to the pubis. The sternum is incised longitudinally and the pericardium is opened. The superior and inferior venae cavae within the pericardium are dissected free, and the superior vena cava is encircled with transfixion sutures. Because the sinoatrial node is located at the atrial-caval junction, care is taken to avoid this area to minimize the risk of injury. The aorta and pulmonary artery are separated, and the pulmonary artery is dissected free to its bifurcation. A purse-string or horizontal mattress suture is placed in the adventitia of the aorta as far distal as possible. Heparin is administered (10,000 to 20,000 U intravenously), and the inferior vena cava is divided at or slightly cephalad to the diaphragm. Bleeding is allowed into the pericardium and the ascending aorta is cross-clamped as far cephalad as possible. Cardioplegic solution is infused through an angiocatheter placed through the purse-string suture. The superior vena cava is double-ligated by tying the transfixion sutures and dividing the cava between them. The right and left pulmonary veins are divided at their entrance into the pericardium. The left and right pulmonary arteries distal to the bifurcation of the main pulmonary artery are divided. The aorta is transected distal to the cardioplegic needle but proximal to the aortic cross-clamp. The excised donor heart is rinsed in saline at 4°C, placed into two concentric sterile plastic bags, and packed beneath crushed ice in a portable ice chest for transport.

Implantation Techniques

Lower and Shumway Technique

Three implantation techniques are available: the traditional Lower and Shumway technique, the bicaval technique, and the rarely used heterotopic technique (24,25,26,27 and 28). Concern about the loss of normal atrial anatomy using the Lower and Shumway technique has led to the more frequent use of the bicaval technique. The bicaval technique may result in a longer donor heart ischemic time but is associated with lower right atrial pressure, lower incidence of atrial tachyarrhythmias, lower diuretic dose, less need for pacing, less tricuspid valve incompetence, and shorter hospital stay. An improved atrial kick contribution to cardiac output may also decrease the incidence of thrombus formation in the left atrium (29). Heterotopic cardiac transplantation can be performed with the donor heart placed in the right lower thorax in parallel to the recipient heart, which is left in place.

In the traditional Lower and Shumway technique, the recipient is placed on cardiopulmonary bypass and cooled to 30°C as the diseased heart is removed. Atria are incised on the atrial side of the atrioventricular groove and the atrial septum is incised, with a large remnant left posteriorly. The great arteries are divided cephalad to the commissures of the aortic and pulmonic valves. The left atrium of the donor heart is opened by connecting the orifices of the pulmonary veins and trimming residual tissue to fit the remnant of the excised left atrium of the recipient. The left atria are connected with continuous suture. The right atrium of the donor heart is opened by incising the lateral wall beginning at the orifice of the inferior vena cava and continuing in the direction of the atrial appendage. The right atria are then connected. End-to-end anastomoses are made for donor and recipient aortae and donor and recipient pulmonary arteries. Air is evacuated from the heart and great vessels, and the aortic cross-clamp is released after rewarming. Cardiopulmonary bypass is discontinued, and temporary pacing wires are attached to both the right atrium and the right ventricle.

Bicaval Technique

In the bicaval technique, the right atrium of the recipient is excised, with a 2- to 3-cm cuff left around each cava (cavo-atrial cuff). The left atrial size and structure are

more or less normal because the recipient's atrial septum is resected, so that only the atrial roof is left *in situ*. This contrasts with the standard technique in which the atrial septum, as well as a large remnant of the recipient atrial mass, is left behind. The donor heart is excised with the right atrium intact and with long cavae. The donor left atrium is sutured to the recipient left atrium with continuous suture. Cardiac rewarming is avoided by venting the left atrium. The inferior vena cava opening is then sutured to the inferior vena cava cuff with continuous suture. The donor superior vena cava is similarly sutured to the recipient superior cavo-atrial cuff. The great arteries are then anastomosed in the usual fashion.

Heterotopic Technique

In heterotopic transplantation, anastomoses are made between donor left atrium and recipient left atrium, donor and recipient aortae, donor superior vena cava and recipient right atrium or superior vena cava, and donor pulmonary artery and recipient pulmonary artery or right atrium. Heterotopic heart transplantation accounts for less than 0.3% of all procedures. The indications for heterotopic cardiac transplantation include severely elevated pulmonary hypertension, a small donor heart, and a donor heart with anticipated poor initial function.

PATHOPHYSIOLOGY OF THE TRANSPLANTED HEART

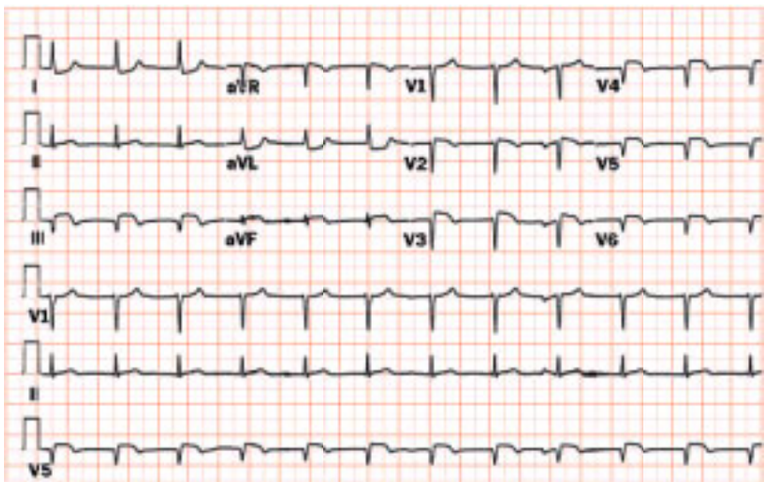
Cardiac Allograft Function and Inotropic Support

The function of the newly transplanted cardiac allograft is influenced by preexplant variables (e.g., degree of inotropic support, cardiopulmonary resuscitation, and trauma), the ischemic insult during explant and implantation, effectiveness of cardioplegia, and total denervation. Inotropic support (using isoproterenol, dobutamine, or milrinone) is usually required for 2 to 5 days, depending on donor heart function.

Ischemia induces diastolic noncompliance, which necessitates higher than normal filling pressures (right atrial pressures of 10 to 15 mm Hg and left atrial pressures of 15 to 20 mm Hg). Failure to maintain adequate preload results in increasing inotropic requirements and hemodynamic deterioration. Early on, impaired contractility and depressed systolic function may also be seen. Even with adequate preload, inotropic support is generally necessary to obtain sufficient cardiac output.

Agents such as isoproterenol (0.25 to 5.00 µg per minute) or dobutamine (2.5 to 20.0 µg per kg per minute) are indicated. In most adults, inotropic support with these agents maintains the heart rate between 110 and 120 beats/min, enhances diastolic relaxation, and insures adequate cardiac output. If further inotropic support is needed beyond isoproterenol or dobutamine, the agents may be combined, or milrinone (0.25 to 0.75 µg per kg per minute), epinephrine (1 to 10 µg per minute), or other inotropic agents may be used. Dopamine hydrochloride can be used to reverse moderate systemic vasodilation or to enhance renal blood flow. Profound systemic vasodilation, which may rarely be seen with the disruption of central aortic reflexes or with severe muromonab-CD3 monoclonal antibody (OKT3) first-dose reactions, responds well to phenylephrine or arginine vasopressin.

One of the most serious hemodynamic problems that can occur early after transplantation is acute distention and failure of the right ventricle. Right ventricular failure nearly always results from excessive right ventricular afterload. This may be due to preexisting pulmonary hypertension or severe reactive pulmonary vasoconstriction, caused by cardiopulmonary bypass or the administration of protamine sulfate or both. Although isoproterenol, nitroglycerin, sodium nitroprusside, milrinone, or amrinone may each dilate the pulmonary vasculature, the most effective agents are prostaglandin E_1, administered in incremental doses of 30 to 50 ng per kg per minute, or nitric oxide. Should prostaglandin E_1 or nitric oxide be ineffective, mechanical right ventricular support is indicated.



Right ventricular infarction. ST-segment elevation in leads V_4R and V_5R reveals right ventricular involvement complicating the inferior infarct.

If global ischemia is the cause of poor allograft function, recovery is likely. Even poorly functioning cardiac allografts can return to normal function after as little as 1 week. In most cardiac transplant recipients, measures of left ventricular function, such as ejection fraction, are normal within 1 to 2 weeks after transplantation. Resting hemodynamics tend to normalize over time as well.

Denervation and Reinnervation

Although the cardiac allograft is totally denervated at the time of transplantation, over a period of months to years it reinnervates at least partially in the majority of recipients (30,31,32,33 and 34). When totally denervated, the heart responds differently to many common cardiovascular medicines. The response to direct beta-adrenergic agonists (isoproterenol, dobutamine, epinephrine, norepinephrine) is qualitatively unchanged. The sympathomimetic amines that act indirectly by releasing catecholamines from nerve terminals (dopamine, ephedrine, metaraminol bitartrate, and mephentermine sulfate) are likely diminished, and supersensitivity to adenosine is occasionally seen.

Because of denervation, norepinephrine-induced hypertension does not cause reflex bradycardia. Oxymetazoline hydrochloride (Neo-Synephrine) would not be expected to cause reflex bradycardia. Similarly, atropine sulfate, edrophonium chloride, digoxin, and quinidine would not be expected to affect atrioventricular conduction.

Exercise Capacity

Despite demonstrably normal left ventricular function, most patients do not achieve a normal exercise capacity (32). Many patients are inadequately rehabilitated (33). In others, concomitant pulmonary or vascular disease limits exercise tolerance. Administered immunosuppressive agents, particularly corticosteroids, undoubtedly take their toll and likely affect even the structure of skeletal muscle in transplant recipients (34). Nonetheless, all recipients are encouraged to rehabilitate to the extent possible, preferably, at least early on, in organized cardiac rehabilitation programs.

Cardiac Arrhythmias

Sinus node dysfunction is common early after transplantation and appears to be more common when the traditional Lower and Shumway technique is used than when the bicaval technique is used. Transient bradycardia can be treated with temporary pacing or administration of theophylline. Permanent bradycardia, which can occur late after transplantation, eventually necessitates use of an electronic pacemaker in approximately 5% of patients.

A 55-year-old African-American male patient status post cardiac transplant. Note the accessory atrial rhythm as evidenced by the extra P waves in the inferior leads.

As with many other types of cardiac surgery, postoperative atrial tachyarrhythmias may occur and are generally approached as usual. Cardiac allograft rejection, however, is considered in the differential diagnosis, and the pharmacologic interventions need to take into account the denervation (35). Late after transplantation, recipient remnant atrial to donor atrial conduction (across the suture line) has been observed (36). Early on, postoperative ventricular ectopy can be seen, but it usually resolves without the need for long-term treatment. After the postoperative period, electrophysiologic disease may become manifest or may develop. Generally, traditional approaches are appropriate, including the use of antiarrhythmic agents, devices, or interventions.

CARDIAC ALLOGRAFT REJECTION

Pathophysiology of Cardiac Allograft Rejection (the Immune System)

Transplantation of an organ between members of the same species is known as allotransplantation; hence, the use of the term *cardiac allograft*. Alloantigens are molecules recognized as foreign (or nonself) by the recipient immune system. In the absence of immunosuppression, destruction of the organ bearing alloantigens occurs (37,38,39,40,41,42 and 43).

HLA antigens are serologically identified alloantigens that have been shown to correspond to the human major histocompatibility complex (MHC). These cell surface antigens are subclassified as MHC class I (HLA-A, HLA-B, and HLA-C) or MHC class II (HLA-DP, HLA-DQ, and HLA-DR) and have distinctly different roles in the rejection process.

The sequence of events leading to cardiac allograft rejection encompasses antigen recognition (Fig. 94.1A), primary and secondary (costimulatory) signals for T-cell activation (Fig. 94.1B), and T-cell proliferation and differentiation (Fig. 94.1C).

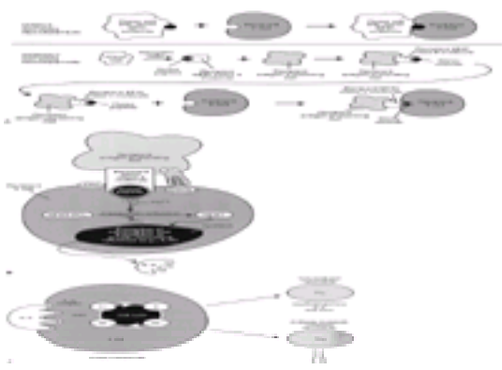


FIGURE 94.1 Sequence of events leading to cardiac allograft rejection, encompassing antigen recognition **(A)**, primary and secondary (costimulatory) signals for T-cell activation **(B)**, and T-cell proliferation and differentiation **(C)**. **A:** Antigen recognition. Direct recognition of alloantigen occurs when recipient T lymphocytes recognize major histocompatibility complex (MHC) molecules on the surface of foreign cells. Indirect allorecognition involves intermediate steps before T-cell recognition. Recipient cells take up foreign MHC molecules, degrade the protein into peptide antigens, and complex the resulting peptide with recipient MHC class II molecules. The recipient MHC class II molecule and the foreign peptide antigen complex are displayed on the cell surface of recipient antigen-presenting cells (macrophages, dendritic cells, or B cells), which enables recipient T-cell recognition of the foreign peptide and binding at the T-cell receptor. **B:** Primary and secondary (costimulatory) signals for T-cell activation. T-cell activation requires two signals. The first is the binding of the foreign peptide to the T-cell receptor (TCR). The second signal, shown here as a CD28/B7 receptor/ligand interaction, is an independent costimulatory signal. Together, the first and second signals trigger a series of calcium-dependent steps that lead to calcineurin dephosphorylation of a transcription factor, nuclear factor of activated T-cells (NFAT). NFAT binds to DNA elements in the promoter regions of many key cytokine genes [e.g., interleukin-2 (IL-2), interferon-g, and tumor necrosis factor (TNF)-a], which leads to the transcription and translation of growth-promoting cytokines. **C:** T-cell proliferation and differentiation. When growth-promoting cytokines (e.g., IL-2) bind to receptors on the surface of T lymphocytes, intracellular signaling occurs that allows the cell to enter the cell cycle and undergo mitosis (M) and clonal amplification. Undifferentiated T cells differentiate into Th_1 (cell-mediated cytotoxicity) or Th_2 [antibody (humorally)-mediated cytotoxicity] subsets depending on the influences of various cytokines. Both cell-mediated and humorally mediated cytotoxic immune responses may cause allograft destruction. G_1 and G_2, growth phases; S, synthesis phase; TOR, target of rapamycin.

Without an interaction of the T-cell receptor and antigen, T cells remain quiescent. The interaction with the T-cell receptor can be aided by a series of accessory molecules that alter the affinity, stability, and duration of the interaction. A number of intracellular signaling pathways are activated, which results in *de novo* expression of a range of genes, including those encoding cytokines [e.g., interleukin-2 (IL-2)] and new cell surface proteins.

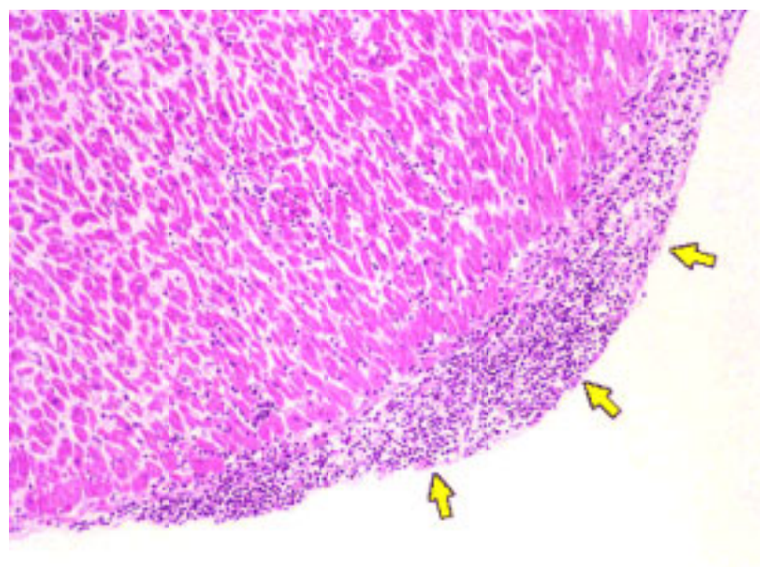
Once the primary signal is received, the destiny of a T cell depends on whether it receives a second signal (37). Without a second signal, a T cell may become apoptotic, anergic, or unresponsive, failing to progress through the cell cycle. Such a cell may inhibit the growth or activation of neighboring T cells in an antigen-specific fashion. Together, the first and second signals trigger a series of calcium-dependent steps that lead to calcineurin dephosphorylation of a transcription factor, nuclear factor of activated T-cells (NFAT). NFAT binds to DNA elements in the promoter regions of many key cytokine genes (e.g., IL-2, interferon-g, and tumor necrosis factor-a), which leads to the transcription and translation of growth-promoting cytokines.

When growth-promoting cytokines (e.g., IL-2) bind to their respective receptors on the surface of lymphocytes, intracellular signaling occurs via a number of tyrosine- and cyclin-dependent kinases, which allows the cell to enter the cell cycle and undergo mitosis and clonal amplification. Depending on the influences of various cytokines, undifferentiated T cells differentiate into T_H1 or T_H2 subsets. T_H1 cytokines (interferon-g, IL-2, tumor necrosis factor-b) are believed to promote cell-mediated and cytotoxic responses, and T_H2 cytokines (IL-4, IL-5, IL-6, IL-10, IL-13) promote humoral immune responses. Both cell- and humoral-mediated cytotoxic immune responses may then cause allograft destruction.

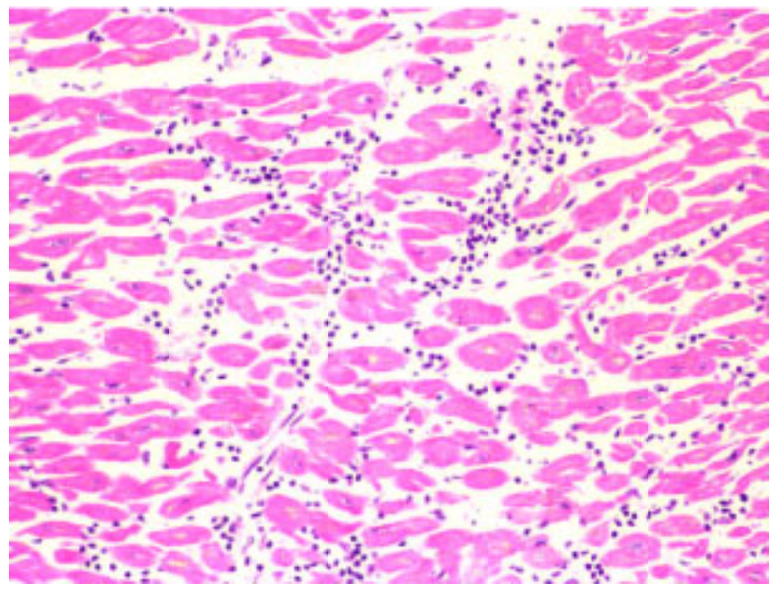
In brief, after the heart is transplanted, proinflammatory cytokines are elaborated and recipient inflammatory cells (e.g., macrophages) are recruited into the cardiac allograft. Donor passenger leukocytes migrate from the allograft into host lymphoid tissue, and recipient leukocytes enter the allograft. T-cell stimulation occurs via a T-cell receptor signal and a necessary costimulation signal. Cytokine production leads to the generation of effector cells for cell-mediated and antibody (humoral)-mediated immunity. Destruction of the allograft occurs via involvement of antibody, cytotoxic T lymphocytes, macrophages, and cytokines.

Types of Cardiac Allograft Rejection

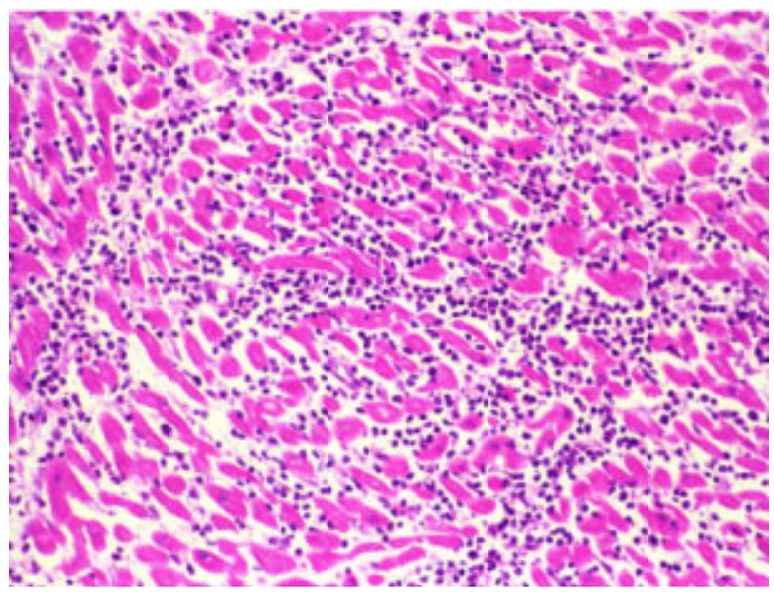
Cardiac allograft rejection is an immunologic process that, left unchecked, leads to allograft destruction. Rejection has been variously classified but may be defined histologically, functionally, or clinically. The most generally recognized categories are hyperacute, acute cellular, and acute vascular (humoral) rejection. In cardiac transplantation, the term *chronic rejection* generally refers to CAV.



“Quilty” lesion in a transplant heart. A benign infiltration of the endocardium (*yellow arrows*) with small lymphocytes can be seen in this section. The adjacent myocardium shows interstitial infiltration with lymphocytes, which is part of a multifocal acute rejection process seen elsewhere in the heart.



Mild acute rejection (grade 1A). Interstitial infiltration of lymphocytes with no myocyte damage in a transplanted heart.



Moderate acute rejection (grade 3A). Interstitial inflammatory infiltrate of large, aggressive lymphocytes in a transplanted heart.

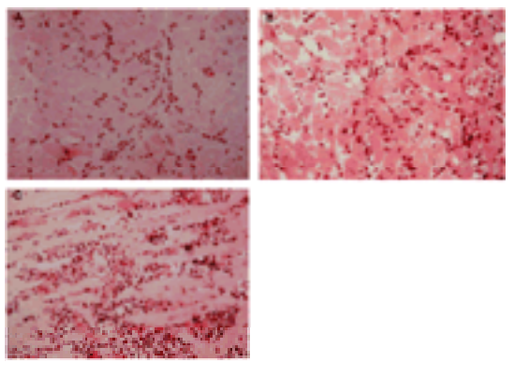
Although hyperacute rejection is due to preformed, donor-specific antibodies in the recipient, the presence of such antibodies does not always result in hyperacute rejection. When it occurs, hyperacute rejection is a vigorous immune response that takes place within minutes to hours. The outcome, without repeat transplantation or total artificial heart support, is uniformly fatal. The best method for avoiding hyperacute rejection is to avoid transplanting a donor heart into a patient who is sensitized to the donor (a positive donor-specific cross-match). Screening PRA is useful because prospective cross-matching is frequently impractical (44). PRA screening is performed by exposing recipient serum to lymphocytes from 50 or more random individuals. A normal result of 0% reactivity suggests a low risk that a retrospective cross-match would be positive. For PRA reactivity greater than 10%, prospective cross-matching is generally warranted (45,46).

Even a positive cross-match that does not result in hyperacute rejection may be associated with a more vigorous immune response (45). Patients with a positive cross-match generally require an increased intensity of immunosuppression or the initial use of plasmapheresis or both. Long-term survival, however, can be achieved with positive cross-match results in the absence of hyperacute rejection. Strategies for decreasing pretransplant PRA levels include use of intravenous gamma globulin or cyclophosphamide and plasmapheresis (46). Even in the absence of a positive cross-match, an elevated PRA level might by itself indicate a more challenging posttransplant course.

Acute cellular rejection is the most common form of rejection and occurs at least once in approximately half of heart transplant recipients (47). Even though the propensity toward allograft rejection decreases over time and nearly half of the rejection episodes occur in the first 2 to 3 months, late rejection can and does occur. Rejection occurring early after transplantation tends to be more aggressive and life-threatening than late-occurring rejection. Acute cellular rejection is most frequently diagnosed by endomyocardial biopsy graded in accordance with the International Society for Heart and Lung Transplantation (ISHLT) criteria (48) (Table 94.3 and *e*Fig. 94.1.1). Certain factors increase the risk for rejection. For instance, both increasing age and male gender appear to be associated with decreased cardiac allograft rejection (49,50). All patients are at risk for rejection, however, and are carefully followed regardless of demographic variables.

Grade	Finding	Rejection severity
0	No infiltrate, normal myocytes	None
1A	Focal perivascular or interstitial infiltrates without necrosis	Borderline mild
1B	Diffuse but sparse infiltrates without necrosis	Mild
2	One focus only with aggressive infiltrate and/or myocyte damage	Mild or focal moderate
3A	Multifocal aggressive infiltrates and/or myocyte damage	Moderate
3B	Diffuse inflammatory infiltrates with necrosis	Borderline severe
4	Diffuse aggressive polymorphous infiltrate with edema, hemorrhage, and vasculitis, with necrosis	Severe

TABLE 94.3 ENDOMYOCARDIAL BIOPSY GRADING SCALE USED BY THE INTERNATIONAL SOCIETY FOR HEART AND LUNG TRANSPLANTATION



***e*FIGURE 94.1.1** Lymphocytic infiltrate in endomyocardial biopsy specimens. Progressing from panel **A** to panel **C**, an increasing degree of lymphocytic infiltration is seen, indicative of worsening cardiac allograft rejection. These changes correspond to International Society for Heart and Lung Transplantation grades 1B **(A)**, 2–3A **(B)**, and 4 **(C)**.

Vascular rejection may be manifest by otherwise unexplained cardiac allograft dysfunction with or without histologic evidence. Histologic evidence is scant cellular infiltrate but abundant colocalized immunoglobulin and complement components in the allograft microvasculature seen on one or more biopsy specimens. In addition, vascular rejection may be manifest only histologically in the absence of allograft dysfunction (47).

Vascular rejection has been associated with a positive cross-match, the development of sensitization to OKT3, prolonged use of OKT3, female gender, and younger recipient age. Vascular rejection is more difficult to treat than acute cellular rejection and is more often accompanied by hemodynamic compromise or instability. As a result, vascular rejection is associated with a worse prognosis and appears to increase the risk of CAV nearly tenfold (47).

Diagnosis of Cardiac Allograft Rejection

Surveillance for allograft rejection generally centers on the routine use of endomyocardial biopsy (51). Endomyocardial biopsy is initially performed weekly (for the first 4 to 8 weeks) and then at gradually increasing intervals. Twelve to 24 months after transplant, biopsies are performed every 3 to 6 months. Over time, some patients are managed without routine endomyocardial biopsies (52). After the diagnosis of rejection, the endomyocardial biopsy interval is, of course, altered.

To perform an endomyocardial biopsy, venous access is obtained and an intravascular sheath is placed. A bioptome (either a disposable or a reusable Scholten bioptome) is directed under fluoroscopic or echocardiographic guidance to the right atrium with the tip pointing to the lateral wall. The handle is turned 180 degrees toward the interatrial septum and advanced through the tricuspid valve. Once the bioptome is in the right ventricle, the handle is rotated directly posteriorly, which directs the bioptome toward the right ventricular side of the interventricular septum. Only the septum is biopsied to prevent ventricular perforation. Biopsy specimens are obtained by opening the handle, advancing to the point of slight resistance or ventricular ectopy, closing the handles, and withdrawing the endomyocardial tissue. Four good specimens are usually required for adequate pathologic evaluation. Endomyocardial biopsy may also be performed via right subclavian vein and femoral vein approaches. Acute complications are rare but include cardiac perforation and pneumothorax. Inadvertent carotid puncture occurs occasionally and is generally benign. Long-term complications include occlusion of the jugular vein and damage to the tricuspid apparatus, which requires tricuspid valve replacement in some situations.

Clinically, most rejection episodes are detected by surveillance endomyocardial biopsies and manifest no signs or symptoms. If the episode is symptomatic, the most frequent symptom is fatigue. Later in the rejection process, exercise intolerance or frank heart failure symptoms may occur. Physical findings, if present, may include relative hypotension (decrease in systolic blood pressure of more than 20 mm Hg from baseline), elevated jugular venous pressure, or a third heart sound gallop. Symptoms or signs such as those mentioned prompt an urgent endomyocardial biopsy. An enlarging pericardial effusion or worsened indices of systolic or diastolic function determined by echocardiography may herald rejection. Fever is an infrequent manifestation of rejection. Atrial or ventricular arrhythmias are considered indicative of allograft rejection until proven otherwise. Clearly, if the patient has significant allograft dysfunction, signs of heart failure may be present.

Many noninvasive strategies for the early diagnosis of cardiac allograft rejection have been evaluated in an attempt to decrease the dependence on endomyocardial biopsy (53,54,55,56 and 57). Generally, sensitivities of 85% to 90% can be achieved with fair specificity. No technique has as yet eliminated the clinical practice of routine endomyocardial biopsy surveillance.

In infants, echocardiography almost completely supplants endomyocardial biopsy (53). In adults, echocardiographically derived indices, myocardial relaxation velocities determined by Doppler tissue imaging, integrated backscatter techniques, nuclear and magnetic resonance imaging, paced epimyocardial electrography, heart rate variability, measurement of immunologic markers, and many other methods have been evaluated (54,55,56 and 57).

Pharmacology of Immunosuppressive Agents

Suppression of the recipient immune system (Fig. 94.1) is necessary to prevent and treat cardiac allograft rejection. The pharmacology of currently available agents is summarized in Table 94.4. Polypharmacy is almost always used to minimize the toxicity of individual agents and to block the immune system in multiple locations (58,59,60,61,62,63,64,65,66,67,68,69,70,71 and 72). Immunosuppression is conveniently considered in three phases: early rejection prophylaxis (perioperatively and for the first several weeks after transplantation), long-term maintenance prophylaxis (immunosuppression in the absence of allograft rejection), and the augmentation in immunosuppression after the diagnosis of allograft rejection.

TABLE 94.4 PHARMACOLOGY OF IMMUNOSUPPRESSIVE AGENTS

Prevention and Treatment of Cardiac Allograft Rejection

Early Rejection Prophylaxis

To prevent cardiac allograft rejection perioperatively and for the first several weeks after transplantation, multiple agents are administered. Generally, “triple therapy” is used, consisting of (a) cyclosporine or tacrolimus; (b) azathioprine, mycophenolate mofetil, or sirolimus; and (c) corticosteroids (61,62,63,64,65,66,67,68,69,70,71 and 72). Although not perfect, triple therapy has proven to be simple and effective for most patients. In some patients with marginal renal function, early administration of cyclosporine or tacrolimus can lead to significant transient renal dysfunction and volume retention. To avoid the early use of cyclosporine or tacrolimus in patients at high risk of renal dysfunction (serum creatinine level higher than 2.0 mg per dL before transplant), OKT3, one of a variety of antilymphocyte globulins, or even IL-2 receptor blockers may be used perioperatively (67,68 and 69). Antilymphocyte antibody-based early rejection prophylaxis can safely delay cyclosporine or tacrolimus administration until after cardiac and renal function have stabilized. Disadvantages to using antilymphocyte antibody-based early rejection prophylaxis include first-dose reactions, greater expense, more complicated immunosuppression, and potentially more immunosuppressive side effects.

After binding to an intracellular binding protein (cyclophilin in the case of cyclosporine, FK binding protein in the case of tacrolimus), both cyclosporine and tacrolimus interfere with calcineurin and thus block the production of IL-2 in T lymphocytes (70). Disparate experience with the efficacy and tolerability of cyclosporine compared with tacrolimus is reported. In a U.S. multicenter trial, no clear advantage was seen with the use of tacrolimus (62). Rejection frequency, mortality, and degree of renal dysfunction were no different than with cyclosporine. In other trials tacrolimus has been found to be superior, especially when combined with mycophenolate mofetil (71). Tacrolimus therapy is associated with less hypertension, hirsutism, hyperlipidemia, and gingival hyperplasia but may have a higher incidence of neurotoxicity and glucose intolerance.

Both azathioprine and mycophenolate mofetil inhibit lymphocyte proliferation, but by different mechanisms. Azathioprine is metabolized to 6-mercaptopurine, which blocks DNA replication. Mycophenolate mofetil blocks the *de novo* pathway for purine biosynthesis by inhibiting the action of inosine monophosphate dehydrogenase. Lymphocytes rely almost exclusively on *de novo* biosynthesis for purines. Whether to use azathioprine or mycophenolate mofetil in early rejection prophylaxis depends on the interpretation of the findings of a multicenter trial comparing the two agents (64). However, interpretation of the results of the study is difficult. Eleven percent of transplant recipients in the study never received study medicine but were counted in the intent-to-treat analysis, and those in the group randomly assigned to receive mycophenolate mofetil experienced a higher mortality rate. No difference in rejection frequency, mortality, or morbidity is seen in the intent-to-treat analysis. On the other hand, if one analyzes data only for the patients actually taking at least one dose of study medicine, survival is better and rejection less frequent in the group randomly assigned to receive mycophenolate mofetil.

Trials with sirolimus and derivative of sirolimus (SDZ RAD) (72) are under way. Usually, these agents are substituted for the azathioprine or mycophenolate mofetil as part of triple therapy. After binding to the intracellular binding protein FK binding protein, they abrogate IL-2–driven effects by interfering with mitosis. Trials are also under way of basiliximab and daclizumab, monoclonal antibodies that block the IL-2 receptor (68,69). In cases of renal transplantation, both decrease rejection episodes by approximately one-third.

Long-Term Maintenance Immunosuppression

The majority of patients is maintained long term on triple therapy. Because the propensity to reject decreases over time, dosages of all three drugs may be decreased accordingly. Cyclosporine and tacrolimus are usually maintained long term at levels less than half of those used early after transplant. Similarly, although azathioprine may have been used early after transplant to target white blood cell counts in the 4,500 to 5,500 per mm^3 range, long-term doses larger than 2 mg per kg per day are generally not used. Long-term doses of mycophenolate mofetil generally decrease from 3,000 mg per day to 2,000 mg per day. Prednisone can safely be withdrawn in patients who demonstrate a low propensity to reject (73). Advantages of corticosteroid-free maintenance immunosuppression include reversal of most corticosteroid-induced side effects.

Treatment of Established Cardiac Allograft Rejection

The treatment of cardiac allograft rejection depends on several factors: severity of rejection (ISHLT grade of endomyocardial biopsy specimens), time since transplant, rejection and immunosuppressive history, and hemodynamic status of the patient. Even “mild” rejection (ISHLT grades IB and II) may warrant augmentation of immunosuppression in the setting of allograft dysfunction. In treating rejection, one generally optimizes or increases the dosages of maintenance immunosuppressors and markedly increases corticosteroid dosages. In corticosteroid-refractory rejection or in rejection episodes associated with hemodynamic instability, antilymphocyte antibodies such as OKT3 or one of a variety of antithymocyte globulins are added. Mild rejection in hemodynamically stable patients, those without evidence of allograft dysfunction, is not treated. Some data, however, suggest that occurrence of even mild rejection may increase the likelihood of CAV. Moderate rejection in the absence of hemodynamic instability is usually treated initially with a several-day course of either intravenous or high-dose oral corticosteroids. If a subsequent biopsy specimen shows resolution, the maintenance dosages are continued. If a subsequent biopsy specimen does not show resolution, however, then intravenous corticosteroids are used. Failure of a second course of corticosteroids to resolve the rejection episode generally leads to the use of antilymphocyte antibodies (*e*Fig. 94.1.2).

***e*FIGURE 94.1.2** Algorithm for the treatment of cardiac allograft rejection in patients taking cyclosporine and azathioprine as maintenance immunosuppression. Early: less than 3 months from transplant; hemodynamic instability: decrease in ejection fraction, elevated filling pressures, or hypotension; prednisone: oral corticosteroids, usually given as prednisone 1 to 2 mg per kg per day for 3 to 5 days followed either by an immediate return to maintenance doses or with a 1- to 2-week gradual

tapering to maintenance doses; methylprednisolone: intravenous corticosteroids, usually given as methylprednisolone 500 to 1,000 mg daily for 3 days followed either by an immediate return to maintenance dosages or by a 1- to 2-week gradual tapering to maintenance doses; MMF: mycophenolate mofetil; OKT3: muromonab-CD3 monoclonal antibody given for 7 to 14 days; ATG: antithymocyte globulin given for 7 to 10 days; thymoglobulin: thymoglobulin given for 7 to 10 days.

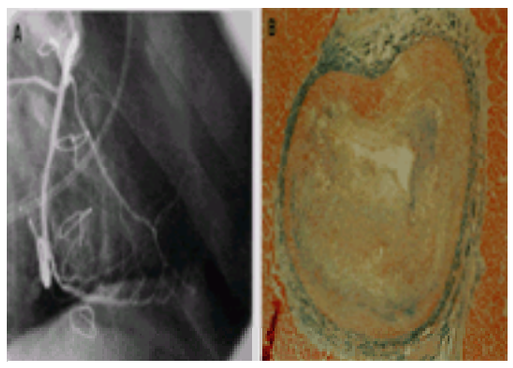
Rejection frequently may be treated by changing the maintenance immunosuppression. For instance, mycophenolate mofetil may be substituted for azathioprine, or tacrolimus for cyclosporine, or both substitutions may be made (74). Sirolimus may be added to or substituted into the regimen. The most vexing problem in immunosuppressive management is treating recurring or refractory rejection. Patients who require high dosages of maintenance immunosuppressive agents are at high risk of developing untoward, life-threatening immunosuppressive side effects. In difficult situations, one can add an agent to the treatment regimen (e.g., methotrexate sodium or sirolimus), consider the substitutions mentioned earlier, or even consider total lymphoid irradiation (75). An interesting new approach to dealing with rejection is photopheresis, which has been shown to decrease rejection when given as early rejection prophylaxis and may be able to treat ongoing rejection (76).

CARDIAC ALLOGRAFT VASCULOPATHY

Pathophysiology of Cardiac Allograft Vasculopathy

After the first few years posttransplantation, CAV is the leading cause of death and the cause of significant morbidity (2,77,78). The prevalence of angiographically detectable disease approaches 50% to 60% at 5 years. The prevalence of disease detected by intravascular ultrasonography or at autopsy is greater. Thus far, the improvements in immunosuppression have not greatly affected the incidence and morbidity associated with CAV development. CAV is not a homogeneous disease; rather, it changes over time. Early, CAV is characterized by diffuse and distal involvement, whereas later-onset coronary artery disease is more proximal, focal, and eccentric. Because the vasculopathy is localized to the vascular bed of the transplanted heart, CAV cannot be totally explained by any property of the medications used after cardiac transplantation.

Histologically, CAV is characterized by proliferation and migration of smooth muscle cells, proliferation and migration of macrophages, intact elastic lamina, increased ground substance and foam cells, and macrophage-engulfed cholesterol (*e*Fig 94.1.3) (79). Angiographically, several types of lesions have been described, as shown in Figure 94.2 (80).



***e*FIGURE 94.1.3** Right coronary artery 3.5 years after cardiac transplantation. **A:** Angiograph of the right coronary artery, taken 1 week before explantation for retransplantation in a 35-year-old man with unexplained allograft dysfunction, was relatively normal. **B:** Trichrome stain of the midportion of the right coronary artery of the explanted heart shows extensive allograft coronary artery disease.

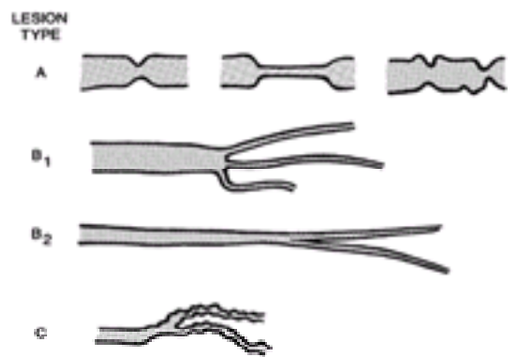


FIGURE 94.2 Types of lesion seen in cardiac allograft vasculopathy. Cardiac allograft vasculopathy can present with a variety of lesions, most of which are not amenable to revascularization. (From Gao SZ, Alderman EL, Schroeder JS, et al. Accelerated coronary vascular disease in the heart transplant patient: coronary arteriographic findings. *J Am Coll Cardiol* 1988;12:334–348, with permission.)

P>Various risk factors have been identified for the development of CAV diagnosed by angiography, intravascular ultrasonography, or angioscopy (2,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94 and 95). Although older donor hearts are associated with an increased risk of the development of CAV at 3 years after transplantation [risk = 1.0 + 0.073 per year for each additional year of donor age above 30 years; p <.0001 (2)], given the significant and growing donor to recipient disparity, older donor hearts will likely continue to be used with even greater frequency. Not surprisingly, coronary artery disease leading to the need for cardiac transplantation is associated with a 33% increased risk of developing CAV at 3 years (2). The influence on CAV of the more common risk factors for native coronary artery disease (e.g., hypertension, diabetes, cigarette use, hyperlipidemia, hyperhomocysteinemia, low folate and vitamin B_6 concentrations) is likely greater later after transplantation (82,83).

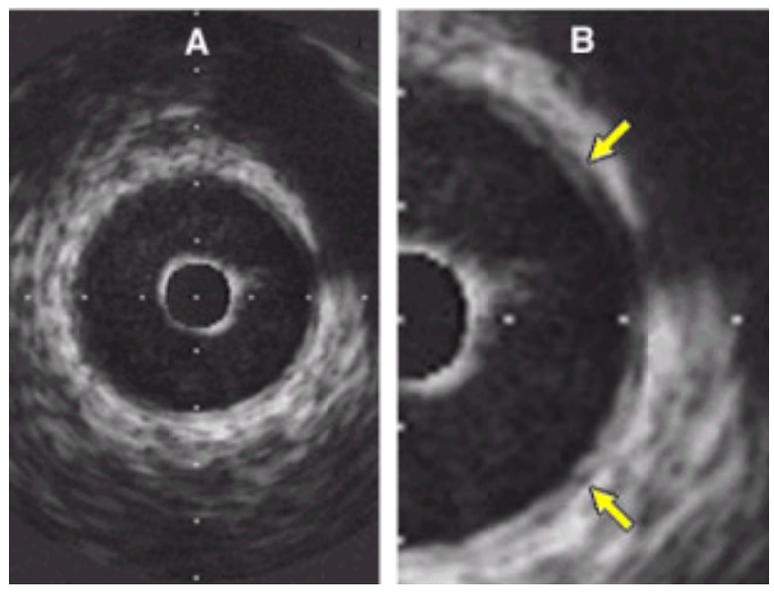
Many other possible risk factors for CAV have been evaluated. The frequency and type of rejection; the degree of HLA matching; increased levels of endothelin; the presence of endothelial cell–derived mesenchymal growth factors; cytomegalovirus (CMV) infection; the expression of various chemokines, cytokines, or serum cardiac troponin-T concentrations; the quantity of various apolipoproteins; MHC class II expression; gene polymorphisms for plasminogen activation factors; the quantity of various anticoagulation factors; and even race and ethnicity have been assessed as being potentially contributive (84,85,86,87,88,89,90,91,92,93,94 and 95).

Diagnosis of Cardiac Allograft Vasculopathy

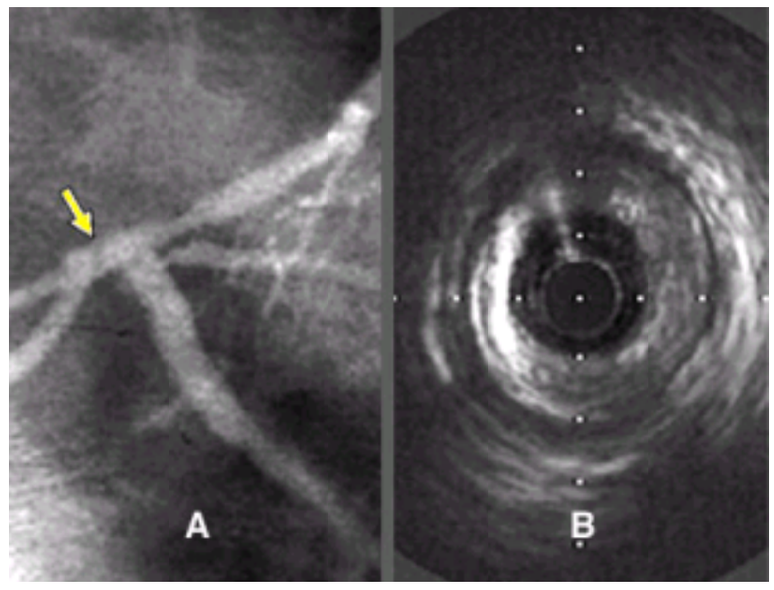
The clinical presentation of CAV early after transplant may be silent, manifesting as acute myocardial infarction, congestive heart failure, arrhythmias, wall motion abnormalities, or sudden death. Later, typical angina pectoris may occur due to focal, albeit incomplete, reinnervation. Most CAV is diagnosed by routinely scheduled yearly surveillance angiography, although many noninvasive techniques have been evaluated in an attempt to decrease the need for invasive testing (96,97 and 98).

Exercise or dobutamine stress echocardiography is frequently used to screen for disease and at times replaces routine surveillance angiography. Dobutamine stress echocardiography may also be able to track the progression of established CAV (96). A negative dobutamine stress echocardiogram is associated with a low risk of cardiac events. Nuclear techniques, for example, stress thallium scintigraphy and positron emission tomography, may also be used (97,98). Some characteristics of the endomyocardial biopsy specimen may predict the presence of CAV.

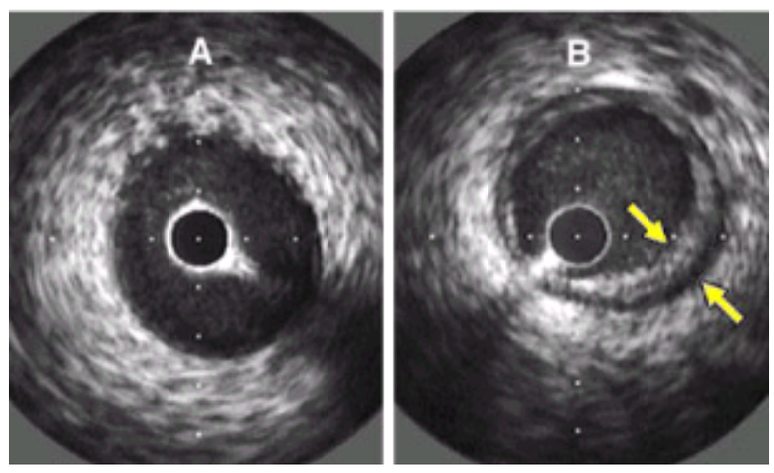
Regrettably, angiography is insensitive in detecting CAV (eFig. 94.1.3). Compared with angiography, intravascular ultrasonography (or other techniques, see Chapter 85) is more sensitive, detecting disease in a much larger percentage of patients (99,100). Intravascular ultrasonography predicts the development of angiographic coronary artery disease and is predictive of morbidity and mortality (99). However, early diagnosis of CAV has not been shown to affect long-term outcomes.



Normal coronary wall morphology by intravascular ultrasound. A trilaminar appearance is apparent with distinct layers representing the intima, media, and adventitia (B, *arrows*).



Limitation of angiography. The concentric plaque in the left main trunk (A) was not clearly defined by angiography because of the diffuse nature of the disease. Intravascular ultrasound examination demonstrates a major area reduction by concentric plaque (B).



Serial intravascular ultrasound study in a cardiac transplant patient. The baseline intravascular ultrasound study (A), 1 month after transplantation, shows a normal left anterior descending artery. After 1 year (B), there is obvious thickening of intima with a concentric distribution pattern.

Treatment of Cardiac Allograft Vasculopathy

Treatments need to be developed that prevent disease, halt disease progression, and effectively ameliorate significant CAV. For both primary prevention and the prevention of progression of established disease, conventional risk factors for coronary disease should be eliminated, minimized, or controlled. Although such risk factor reduction may not affect the early aggressive form associated with intimal hyperplasia, the later form may be impacted.

The treatment of established disease appears to be limited to retransplantation and revascularization techniques, because augmented immunosuppression has not been conclusively shown to prevent progression. Retransplantation is the only option for patients with type B and C lesions, especially because transmyocardial laser revascularization is unlikely to be beneficial in the long term with current techniques (101). Retransplantation for CAV can, if performed years after the initial transplantation, result in survival rates of nearly 80% at 1 year after retransplantation (2).

Percutaneous revascularization in the presence of distal disease, even for type A lesions, is associated with a poor outcome, whereas revascularization in the presence of angiographically normal distal coronary arteries is associated with better outcomes. The use of coronary artery bypass grafting is considered in some situations. Given the results seen with retransplantation and the current donor to recipient disparity, aggressive use of interventional or surgical treatment or both to prolong the life of the cardiac allograft, if possible, seems prudent.

COMPLICATIONS AFTER CARDIAC TRANSPLANTATION

The complications encountered after cardiac transplantation are legion. Recipients are at risk for cardiac, immunosuppression-related, and other complications. Although largely not preventable, most problems can be mitigated, at least in part. The cardiac complications have been addressed earlier in this chapter.

Immunosuppression-Related Complications

Infectious Complications

Infection is common in organ transplant recipients (102). The types of infections expected in cardiac transplant recipients vary depending on the time from transplantation. This is because the intensity of immunosuppression administered varies directly with the propensity for rejection, and the propensity to reject decreases over time. Figure 94.3 depicts the changing frequencies of bacterial, viral, protozoal, and fungal infections after transplantation (103).

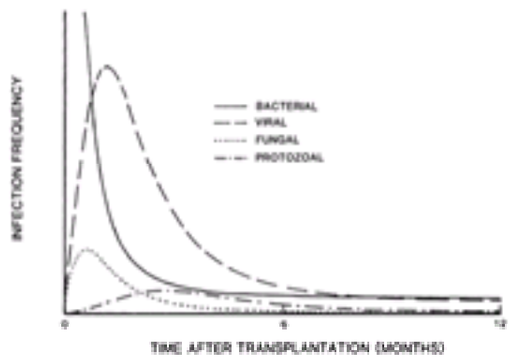


FIGURE 94.3 Risk of infection after cardiac transplantation. The risk of infection from various etiologic agents peaks at different times after cardiac transplantation. (Adapted from Miller LW, Naftel DC, Bourge RC, et al. Infection after heart transplantation: a multiinstitutional study. *J Heart Lung Transplant* 1994;13:384, with permission.)

Bacteria and viruses account for more than 80% of infections after transplantation. The most common bacterial infections early after transplantation are nosocomial, due to infected intravascular catheters or lines, or gram-negative pneumonias. As can be seen in Figure 94.3, the risk decreases rapidly over time. The most common viral infections are caused by herpes viruses, CMV, and herpes simplex. Although CMV infection used to be associated with significant morbidity and mortality, the use of ganciclovir has significantly improved the prognosis (104,105). However, ganciclovir-resistant CMV is occasionally seen. Patients who are CMV seronegative who receive a heart from a seropositive donor are at greatest risk for aggressive disease. Attempts to prevent CMV disease in these patients have been less fruitful than in patients who are seropositive before transplantation. Although fungi and protozoa account for less than 15% of infections after transplantation, such infections can be associated with the worst prognosis (106). Fungal infections occur in patients who require intensive treatment over a prolonged period before transplantation or in whom significant rejection occurs in the setting of a bacterial infection that requires the use of broad-spectrum antibiotics.

The overall incidence of infection is approximately 0.5 infections per patient, although as many as two-thirds of patients remain free from serious infections during the first year. The most common site of infection is the lung, accounting for up to one-third of all infections. Although most serious infections are treated successfully, infection remains a leading cause of death during the first year (103).

Given the potential morbidity and mortality associated with infections during the first posttransplant year, infection prophylaxis is common. This has reduced the morbidity and mortality after cardiac transplantation for CMV infection, *Pneumocystis carinii* pneumonia, and toxoplasmosis (107,108). Prophylactic regimens are commonly used against CMV (if either recipient or donor is seropositive), toxoplasmosis (especially if the recipient tests negative and the donor tests positive), *P. carinii*, *Candida albicans*, and herpes simplex (*e*Table 94.4.1). Whether or not influenza vaccines should be given is not entirely clear. Concern exists about administering them early after transplantation; however, they are given to recipients who are at high risk (109).

***e*TABLE 94.4.1** INFECTION PROPHYLAXIS AFTER CARDIAC TRANSPLANTATION

Organism	**Regimen**
Cytomegalovirus (recipient seropositive)	Ganciclovir 5 mg/kg i.v. b.i.d. for 2–4 wk, then 1,000 mg p.o. t.i.d. until 1 mo posttransplant, then acyclovir 800 mg p.o. q.i.d. until 2–3 mo posttransplant
Cytomegalovirus (recipient seronegative and donor seropositive)	Ganciclovir 5 mg/kg i.v. b.i.d. for 2–4 wk, then 1,000 mg p.o. t.i.d. until 3 mo posttransplant
Herpes simplex	Acyclovir 200 mg p.o. q.i.d. until corticosteroid dosage <20 mg prednisone/d
Epstein-Barr virus (recipient seronegative and donor seropositive)	Acyclovir 800 mg p.o. q.i.d. for 12 mo, then 200 mg p.o. q.i.d.
Toxoplasma gondii (donor or recipient seropositive)	Pyrimethamine 25 mg p.o. q.d. for 6 wk and leucovorin calcium 5–10 mg p.o. q.d. for 6 wk
Pneumocystis carinii	Trimethoprim maleate/sulfamethoxazole 160 mg/800 mg p.o. 3–7 times per wk or dapsone 75–100 mg p.o. q.d. if sulfa allergic
Candida albicans	Nystatin 10 mL swish and swallow q.i.d. or clotrimazole troche p.o. q.i.d. until corticosteroid dosage (prednisone) <20 mg/d

Renal Insufficiency

Five years after heart transplantation, 8.5% of recipients have a serum creatinine level higher than 2.5 mg per dL, and 1.9% require long-term dialysis (2). Although some renal dysfunction is related to preexisting renal disease, most is acquired. Cyclosporine and tacrolimus are nephrotoxic and probably account for the majority of renal problems (110,111,112 and 113). Minimizing the dosages of these and other nephrotoxins, avoiding dehydration, and searching carefully for nonimmunosuppression-related reversible causes are warranted (111).

Whether some individuals are at greater than usual risk for cyclosporine- or tacrolimus-related nephrotoxicity is not known (112). Once renal dysfunction occurs, the course is variable. Some patients progress quickly to dependence on dialysis, whereas others do not. Costs are likely increased and prognosis worsened in heart transplant patients with significant renal dysfunction (113).

Hypertension

After transplantation, hypertension occurs in approximately two-thirds of recipients (2). Hypertension is more prevalent in cyclosporine-treated recipients (70% to 90%) than in tacrolimus-treated recipients (30% to 50%). In nontransplant patients, hypertension is a significant risk factor for vascular disease and to assume otherwise in transplant recipients is unwise. The role of hypertension in the development of renal dysfunction and CAV among long-term survivors is not known.

Even though most hypertensive cardiac transplant recipients require pharmacologic treatment, moderate limitation of salt intake, maintenance of ideal body weight, and moderate exercise are encouraged. Generally, blood pressures consistently greater than 140/90 mm Hg are treated. Either angiotensin-converting enzyme (ACE) inhibitors or calcium channel blockers in conventional dosages are effective monotherapy for many patients (114,115). Some patients are prone to hyperkalemia due to the combined effect of cyclosporine and ACE inhibition on the kidney. Due to decreased metabolism of cyclosporine and tacrolimus, the use of either diltiazem or verapamil necessitates lowering of the dosages of cyclosporine or tacrolimus and initially more frequent cyclosporine or tacrolimus level monitoring. Use of both an ACE inhibitor and a calcium channel blocker is effective in many patients in whom neither class of drugs alone is sufficient. Diuretics are effective in some patients, although rarely as monotherapy. Dehydration should, of course, be avoided with the concomitant use of cyclosporine or tacrolimus.

In some patients, hypertension is inadequately controlled despite the use of maximally tolerated dosages of both calcium channel blockers and ACE inhibitors. Clonidine, beta-blockers, hydralazine, prazosin, or even minoxidil may be effective. In some patients, changing from cyclosporine to tacrolimus or minimizing the dosage of cyclosporine may be helpful.

Osteoporosis

By the time most patients undergo cardiac transplantation, the risk of osteoporosis and other skeletal complications is high. Prolonged inactivity and, in some cases, prolonged heparin administration can demineralize bone and put the patient at risk for complications. Further bone loss occurs due to high-dose corticosteroid therapy. Bone loss is rapid in the first 6 months after transplantation and is most marked in the lumbar spine. Vertebral compression fractures and aseptic necrosis of the femoral head are among the most common skeletal problems after heart transplantation. Due to the morbidity associated with osteoporosis, patients at risk are treated (116,117 and 118). Postmenopausal women are generally prescribed estrogen replacement therapy. Postmenopausal women and all patients with evidence of pretransplant osteoporosis receive calcium salts (e.g., calcium carbonate 1,000 to 1,500 mg per day in divided doses) and upwardly titrated doses of calcitriol (beginning at 0.25 µg every other day) while awaiting transplantation and indefinitely thereafter (116). Alendronate sodium (10 mg per day) may effectively increase bone density and can be safely added to calcium salts and calcitriol (117).

Treatment of bony complications of the spine is supportive. Clearly, maintaining physical activity and ideal body weight are important measures (118). Physical

therapy is helpful. Joint replacement is successful in the vast majority of posttransplant patients and should be recommended as indicated.

Hyperlipidemia

After cardiac transplantation, hyperlipidemia is common (119) and requires treatment in as many as 50% of recipients (2). All patients are encouraged to limit intake of cholesterol and other fats, maintain ideal body weight, and exercise. Minimization of corticosteroid dosage, when possible, is also generally helpful. Serum cholesterol levels greater than 200 mg per dL (or levels of low-density lipoprotein cholesterol above 100 mg per dL) are treated. If levels are not successfully lowered with dietary and other behavior modification, pharmacologic treatment is instituted. Although use of gemfibrozil (in doses up to 600 mg twice daily) can be successful is some patients with mild to moderate hyperlipidemia, particularly in the setting of hypertriglyceridemia, moderate to severe hypercholesterolemia generally requires the use of a 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor (119,120). The combination of cyclosporine or tacrolimus and an HMG-CoA reductase inhibitor increases the risk of rhabdomyolysis over that for the HMG-CoA reductase inhibitor alone. When used, HMG-CoA reductase inhibitors should be started at low dosage and the dosage should be increased periodically while levels of creatine kinase and liver enzyme are monitored. Combining an HMG-CoA reductase inhibitor with gemfibrozil or nicotinic acid in lipid-lowering doses (1 g per day or more) can cause rhabdomyolysis, and these combinations are used cautiously in transplant patients. Bile acid sequestrants, probucol, and fish oil (omega-3 free fatty acids) are infrequently used to treat hyperlipidemia after transplantation.

Preexisting hyperlipidemia, corticosteroid therapy, and the use of cyclosporine or tacrolimus play a role in the development of hyperlipidemia. Because it is a risk factor for vascular disease in nontransplant patients, hyperlipidemia could also be a risk factor for cerebrovascular and peripheral vascular disease in transplant patients. Hypertriglyceridemia has frequently been shown to be a risk factor for the development of CAV and hypercholesterolemia has occasionally been shown to be a risk factor, and aggressive treatment seems to lead to regression of existing disease.

Malignancy

After transplantation, cardiac allograft recipients have an increased risk of malignancy compared with the general population. The overall degree of immunosuppression may be more important than any intrinsic property associated with a particular drug. Care is taken to avoid overimmunosuppression. By 5 years after transplantation, nearly 10% of survivors have experienced a malignancy (2). Fortunately, nearly half are skin cancers, occurring predominantly in those who would otherwise be at risk (121). Because locally invasive skin cancer can be fatal if not treated promptly and adequately, routine screening is performed. Posttransplant lymphoproliferative disease (PTLD) occurs in less than 2% of patients (122). PTLD can be refractory to any treatment or relatively localized and benign, responding simply to reduction in immunosuppression (123). The Epstein-Barr virus (EBV), a lymphotropic virus that infects more than 90% of the population by adulthood, is thought to be the etiologic agent responsible for most cases of PTLD (123,124).

Among patients who are seropositive for EBV before transplantation, the incidence of PTLD is low, approximately 1%. The incidence of PTLD in patients who are seronegative for EBV before transplant and who receive an organ from an EBV-seropositive donor may be as high as 50%. Preemptive antiviral therapy may be helpful (124). Treatment of PTLD usually involves reduction of immunosuppression, administration of acyclovir, and chemotherapy for widespread disease.

Although other malignancies occur in heart transplant recipients, the behavior of prostate, breast, and cervical cancer and of other solid tumors seems no different than in the general population.

Glucose Intolerance

Although nearly 20% of cardiac transplant survivors develop frank diabetes within the first year, by 5 years after transplantation, only 15% would be classified as diabetic (2). This is likely related to the use of decreasing dosages of immunosuppressive agents, in particular, corticosteroids. No evidence exists that cardiac transplant recipients should be treated differently with regard to diabetic control in terms of target levels of blood glucose and glycosylated hemoglobin and the agents used to treat them.

Other Age-Related Complications

Other diseases that are associated with aging that likely have nothing to do with the events surrounding the management of transplantation should not be ignored. Usual health maintenance measures need to be carried out. Breast cancer, cervical cancer, and prostate cancer screening is recommended.

Biliary Disease

The incidence of biliary disease is greater in cardiac transplant recipients than in nontransplant patients (125). The incidence may be as high as 8%, which represents a 17-fold increase over the incidence in the general population.

During transplantation, the vagus nerve is transected. Because gallbladder emptying is controlled by both neural and humoral factors, the resulting gallbladder denervation increases the risk of cholelithiasis. Thus, after transplantation, patients depend solely on cholecystokinin to stimulate gallbladder contraction. Cyclosporine increases the risk of cholelithiasis because of its lithogenic and cholestatic properties.

Generally, presence of any abdominal symptoms coupled with cholelithiasis warrants surgical intervention. Laparoscopic cholecystectomy is the procedure of choice in uncomplicated situations (126).

Pregnancy

Successful pregnancies after heart transplantation have been reported (127). Maternal and fetal risk is undoubtedly higher than in the general population and transplant recipients are so counseled. Once the recipient is pregnant, close collaboration with an obstetrician knowledgeable with regard to high-risk cases is warranted to avoid teratogenic drugs and manage the pregnancy. Immunosuppressive drug levels are monitored frequently, as volume changes and metabolic changes occur during pregnancy. Radiation exposure can be minimized by using echocardiographically guided endomyocardial biopsies.

Management of the Cardiac Transplant Recipient Undergoing Surgery

Due to bone complications, biliary disease, and other surgically amenable problems, many cardiac transplant recipients undergo noncardiac surgery. In general, antibiotic prophylaxis is used for dental procedures and other procedures in which the risk of septicemia is high. The risk associated with noncardiac surgery depends on the status of the allograft. In patients without ongoing rejection, significant coronary disease, or left ventricular dysfunction, the risk is low. Before all elective procedures, an endomyocardial biopsy is performed, and the most recent angiogram is reviewed. Patients receiving corticosteroids within the preceding 9 months receive stress doses of corticosteroids. If intravenous immunosuppressants are to be needed due to prolonged ileus, appropriate dosage adjustments are made.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Controversies in Recipient Selection

The impact of cardiac transplantation on the mortality of patients with end-stage heart failure should not obfuscate the fact that the need for transplantation generally represents a failure of heart muscle disease prevention or early detection and treatment. Viewed simplistically, decreasing the number of patients who could benefit from cardiac transplantation by preventive and early treatment measures is of greater importance than perfecting cardiac transplantation for those who need it.

Medical advances have made it possible to successfully transplant patients who were previously considered inappropriate candidates. Although individual patient advocacy is admirable, physicians bear a responsibility in their stewardship over donor hearts. Physicians must balance two competing interests—those of individual patient advocacy and societal responsibility—to ensure that appropriate candidates are given donor hearts.

Controversies in Transplant Center Restriction

The United States currently has over 150 heart transplant centers. Given that just over 2,000 heart transplants are performed in the United States each year, the average is a little over one transplant per center per month. Data suggest that centers performing a low number of transplants do so with increased risk to recipient

survival. Therefore, reason suggests that the number of centers should be limited to improve overall patient survival, to ensure continued expertise, to further develop the science and art of transplantation, and to minimize cost.

Cost of Transplantation: Who Should Pay?

An unstated consideration in selecting a transplant candidate is the ability to pay. Many heart transplant centers will not list a patient unless funding for the procedure is secure. Patients from lower socioeconomic classes are not afforded the same opportunity for transplantation as others. The answer to the question of who should pay is not unique to transplantation but underlies much of the policy that governs health economics (128). The only resource scarcer than funding is donor hearts.

THE FUTURE

During the next decade, the induction of donor-specific tolerance will be furthered, which will decrease the need for pharmacologic immunosuppression. Because both xenotransplantation and permanent mechanical circulatory support systems will emerge as clinically appropriate, the donor to recipient disparity will stabilize as alternatives to allotransplantation are provided for selected patients with end-stage heart disease.

INTRODUCTION

Heart failure is a major epidemic. Patients who would have otherwise died after acute coronary events or patients with chronic ventricular dysfunction are surviving, albeit with reduced left ventricular (LV) function and diminished quality of life. Medical therapies for these patients have improved dramatically, but survival in patients with advanced heart failure remains poor. Similar to medical therapies, great strides have been made in the surgical treatment of patients with cardiac disease. Currently, the mortality for primary and reoperative coronary artery bypass grafting (CABG) at The Cleveland Clinic Foundation is less than 2%. Improvements in preoperative medical care, anesthetic management, perfusion technology, myocardial protection, inotropic agents, intensive care unit care, and postoperative medical therapy all have played important roles. These advances have encouraged the application of surgical techniques to patients with severe heart failure resulting in similarly low morbidity and mortality.

The goal of this chapter is to review the current state of surgical interventions for chronic heart failure. The focus is on surgical risk assessment, management of ischemic cardiomyopathy with revascularization and remodeling, mitral valve procedures, and LV assist devices (LVADs). Acute cardiogenic shock and mechanical complications of acute myocardial infarctions (MIs) are addressed in Chapter 19. Because the field is rapidly changing, an effort was made to summarize information published in the last decade, and references are limited to important contributions in each area during this time period. Surgical videos and illustrations of the various procedures described are present on the CD-ROM that accompanies this textbook.

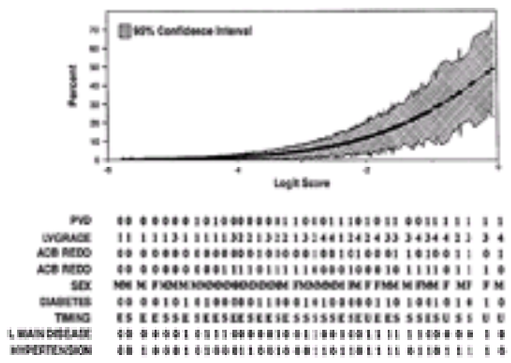
RISK ASSESSMENT

Patients at the highest risk for surgical morbidity and mortality are often the patients most likely to gain some improvement in quality of life or a survival benefit. Solid data are now available to estimate the risk of coronary revascularization and valvular intervention. What is often much more difficult is determining whether functional recovery of the ventricle will occur postoperatively and whether this is in fact a prerequisite for symptom resolution or has a survival advantage.

Series evaluating this early risk of coronary revascularization have concluded that the degree of LV dysfunction is no longer important. This is probably incorrect and reflects the practice of defining LV dysfunction at some arbitrary relatively high level of ejection fraction (EF). Rao et al. reviewed the Toronto General Experience in 4,558 CABG patients (1). The strongest predictor of mortality was LVEF less than 20%. When compared with patients with EFs between 20% and 40%, the mortality for patients with EF less than 20% increased from 3% to 11% (Table 95.1). The addition of advanced age, reoperation, and the need for emergency operation significantly increases the risk of revascularization. Using the equation generated by the analysis, an institution can input the variables and arrive at the patient's estimated risk (eFig. 95.0.1).

Variable	Odds ratio	95% Confidence interval
Left ventricular ejection fraction		
40–60%	1.62	(0.93–2.83)
20–40%	2.02	(1.11–3.68)
<20%	8.10	(3.91–16.80)
Repeat operation	4.86	(2.97–7.95)
Age ≥70 yr	2.79	(1.85–4.19)
Emergency operation	2.69	(1.25–5.79)

TABLE 95.1 ODDS RATIO FOR MORTALITY AFTER CORONARY REVASCULARIZATION



***e*FIGURE 95.0.1** Logit score for mortality after coronary artery bypass grafting as determined by Rao et al. ACB, arterocoronary bypass; E, elective; LV, left ventricular; PVD, pulmonary valve disease; S, semielective; U, urgent. (From Rao V, Ivanov J, Weisel RD, et al. Predictors of low cardiac output syndrome after coronary artery bypass. *J Thorac Cardiovasc Surg* 1996;112:38–51, with permission.)

Other risk factors in patients with ischemic cardiomyopathy include obesity, poor target vessels for revascularization, need for intraaortic balloon pump, and severity of congestive heart failure (CHF) symptoms or New York Heart Association (NYHA) functional class (2,3,4,5 and 6).

The presence of clinical heart failure deserves attention. In general, there is a poor correlation between EF and functional class. From the Duke database, approximately 20% of patients were in NYHA class IV in each quintile of EF below 55% (7) (Table 95.2). Olhshansky et al. reviewed data from the CABG Patch trial, which shows that when corrected for degree of CHF, EF failed to predict outcome across EF quartiles (eTable 95.2.1) (8). If they arbitrarily selected EFs above and below 0.27, then CHF predicted mortality in each group (eTable 95.2.2). These data support clinical experience that has found that the EF is at best a rough indicator of clinical well-being and that therapy to eliminate or reduce heart failure signs and symptoms before intervention may significantly affect early survival.

	Congestive heart failure class				
Ejection fraction (%)	0	I	II	III	IV
<0.25	1.1	10.8	5.0	6.0	18.2
0.25–0.35	6.5	14.9	15.0	26.5	29.5
0.36–0.45	15.8	29.7	21.7	22.9	22.8
0.46–0.55	28.0	20.3	25.8	26.5	22.8
>0.55	47.0	24.3	32.5	18.1	6.8

***e*TABLE 95.2.2** RELATIONSHIP BETWEEN LEFT VENTRICULAR EJECTION FRACTION (LVEF) AND CONGESTIVE HEART FAILURE (CHF) SYMPTOMS AND MORTALITY[a]

Quartile	LVEF <0.27	LVEF ³0.27
CHF present	2.72	2.06
CHF absent	1.31	1.00

[a] Values represent relative risk.
From Olshansky B, Telfer EA, Curtis AB, et al. Predictive value of preoperative left ventricular ejection fraction and functional class for mortality and morbidity after high-risk coronary artery bypass grafting. *Am J Cardiol* 2000;85:1489–1491, with permission.

Some data are available to assess the risk of valve interventions in patients with reduced LV function. In 257 patients with a mixture of aortic and mitral interventions, predictors of hospital mortality mirrored those of coronary revascularization and included lower EF, reoperations, ischemic mitral disease, and emergency surgery (9). Predictors of decreased 10-year survival were age greater than 60 years, aortic regurgitation, and diuretic use. The authors suggest that the more advanced the heart failure, as reflected by the diuretic use, the worse the prognosis. For patients with severe aortic stenosis and low gradients secondary to severe LV dysfunction, surgery has a relatively high published mortality with few defined risk factors except older age (10,11).

At The Cleveland Clinic Foundation, we have used a severity scoring system that uses many of the variables identified as risk factors after coronary bypass surgery. Compared with the early 1980s, the patients undergoing surgery a decade later are in higher risk groups, yet have lower risk adjusted morbidity and mortality. It is noteworthy that stroke mortality has declined substantially. This reflects use of a single cross-clamp technique, frequent use of transesophageal echocardiography, and avoidance of aortic manipulation if ascending atheroslerosis is present (*e*Fig. 95.0.2 and *e*Fig. 95.0.3, *e*Table 95.2.3) (12). Currently, isolated mitral valve operations at The Cleveland Clinic Foundation are now consistently performed with a less than 2% operative risk of death (Fig. 95.1).

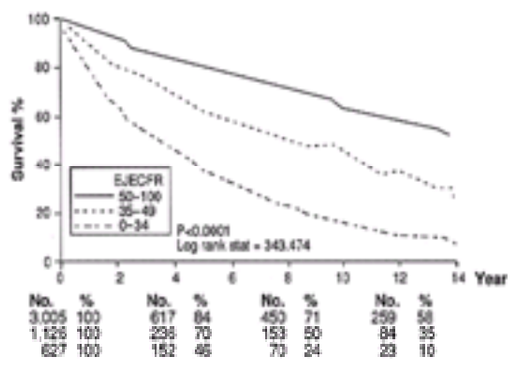
There lies the quandary. Surgical risk has been reduced substantially for even the highest risk subgroups, a result that is undoubtedly multifactorial and reflects improvements in preoperative preparation and management of heart failure, surgical techniques and myocardial protection, and intraoperative and postoperative care. Most patients survive the operation, but the real dilemma is identifying the patient most likely to benefit from the procedure.

ISCHEMIC CARDIOMYOPATHY: ROLE OF SURGICAL REVASCULARIZATION

The rationale behind revascularization is based on the concept that a chronically ischemic ventricle contains hibernating myocardium that will improve functionally with improvement of myocardial blood flow. This concept was first introduced by Rahimtoola (13,14). In a busy heart failure surgical section, the question of which patient with ischemic cardiomyopathy is a candidate for revascularization arises daily. The only randomized study to help with this decision is the Coronary Artery Surgery Study (CASS) study (15,16). It is important to note that the patients enrolled in this study had mild angina and were excluded if heart failure was present and if the EF was below 0.36. In the medically treated cohort excluded from surgery because of a low EF, survival was quite poor (17). It is true that these studies are nonrandomized, but it suggests that the subgroup of patients with the lowest EF have the poorest survival (*e*Fig. 95.1.1). Data supporting the value of surgical

revascularization in this subgroup of patients was presented by Alderman and colleagues (18). They reviewed these patients who were evaluated for the CASS study but excluded because the EF was less than 36%. Surgically treated patients had more angina, more left main stenosis, and less heart failure (18). In addition to these differences, there was crossover into the surgical group. Medically treated patients with severely reduced LV function and three-vessel disease had dismal survival over 8 years. Overall they showed that surgically treated patients did better and the greatest benefit was seen in the patients with the lowest EFs (Fig. 95.2).



***e*FIGURE 95.1.1** Medically treated CASS registry patients with three-vessel disease by ejection fraction (EJECFR). [From Emond M, Mock MB, Davis KB, et al. Patient Selection

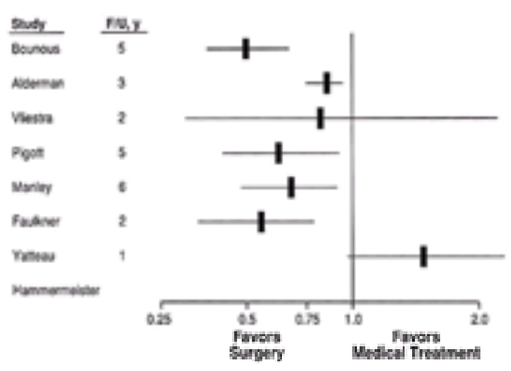
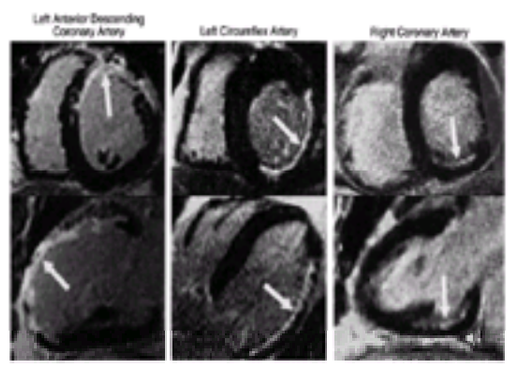
Patients with angina and severe LV dysfunction are candidates for surgical therapy assuming adequate targets for revascularization (19,20). Baker et al. concluded that this approach is favored by review of the literature, improves EF and angina by 30% to 50%, and reduces NYHA functional class by one (19). It must be noted, however, that these are nonrandomized trials, somewhat outdated, and with small numbers. However, clinical experience supports these findings (eFig. 95.2.1). The more difficult question is when to intervene in patients without angina. It is primarily in this group of patients in which viability and functional studies have their greatest impact. It is beyond the scope of this chapter to detail the utility of functional studies. In general, the greater the number of viable myocardial segments, the greater the increase in postoperative EF and exercise capacity. However, improvement in quality of life and functional class has not correlated with the volume of hibernating myocardium (21).



***e*FIGURE 95.2.1** Review of published papers supporting surgical or medical therapy for ischemic cardiomyopathy. F/U, follow-up; y, years. (From Baker DW, Jones R, Hodges J. The role of revascularization in the treatment of patients with moderate or severe left ventricular systolic dysfunction. *JAMA* 1994;272:1528–1534, with permission.)

To assess myocardial viability in patients with ischemic cardiomyopathy and heart failure, the author relies primarily on positron emission tomography (PET) and magnetic resonance imaging (MRI) scans. MRI has the advantage of assessing wall motion and perfusion, identifying scar distribution, and determining chamber volume and valve function. The study has its limitations, however. Approximately 10% of patients cannot tolerate the confined spaces of the MRI scanner and another 10% to 20% are excluded from the study because of the presence of pacemakers or internal defibrillators. The patient receives intravenous gadolinium, which is taken up by myocardial scar (eFig. 95.2.2 and eFig. 95.2.3). Kim et al. have shown that the absence of enhancement of the myocardium by gadolinium predicts improvement in wall motion after revascularization, whereas greater than 75% transmural uptake of gadolinium is indicative of scar and irreversible segmental dysfunction (22).



***e*FIGURE 95.2.2** Myocardial wall enhancement with gadolinium (*arrows*). The extent of wall enhancement predicts functional recovery after revascularization.

Impaired systolic function and necrosis delineation in a chronic myocardial infarction region (long-axis). The SPAMM (spatial modulation of magnetization) image (A) demonstrates contraction of the left ventricular inferior wall but akinesia of the anterior, apex, and infero-apical segments. The delayed-enhancement image (B) demonstrates transmural hyperenhancement of the segments with impaired systolic function.

DiCarli and colleagues have evaluated the utility of PET scans in conjunction with clinical symptoms. Patients with PET mismatch (greater than 5% of myocardium, which is a low percentage), with and without angina, have a survival advantage over medical therapy. Sudden death was a common event in the medically treated patients, supporting the thesis that hibernating myocardium is a more unstable substrate than scar. In patients without angina, the use of PET matching of low perfusion and no metabolic activity predicts no survival benefit with revascularization (23). Other studies confirm this but suggest that quality of life and exercise capacity increase in this group. Because the number of patients assessed is small, further studies are necessary to define the role of revascularization in patients with heart failure and limited amounts of viable myocardium.

The size or volume of the ventricle is another important variable predicting outcome. Yamaguchi et al. showed that in patients with EFs less than 30%, if the LV end systolic volume index was greater than 100 mL per m^2, those patients did not have an increase in EF postrevascularization and had significantly worse 5-year survival and event-free survival (Fig. 95.3, Fig. 95.4, and Fig. 95.5) (24). It is likely that, in the future, some assessment of ventricular volume will be used to determine the likelihood of functional recovery of the revascularization.

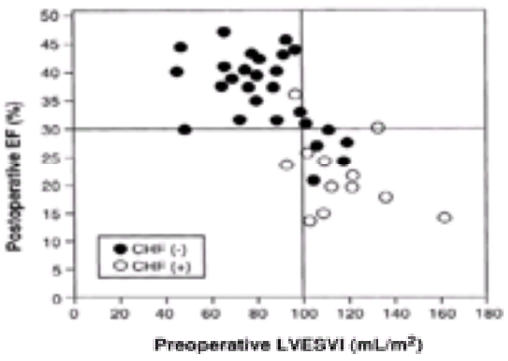

FIGURE 95.3 For patients with ischemic cardiomyopathy, ejection fraction (EF) less than 30% and left ventricular end systolic volume index (LVESVI) greater than 100 mL per m^2functional recovery was unlikely after revascularization. Left ventricular volume predicts postoperative course in patients with ischemic cardiomyopathy. *Ann Thorac Surg* 1998;65:434–438, with permission.)

Current Practice

Given the critical shortage of donor organs for transplantation, all patients with ischemic cardiomyopathy are assessed for nontransplant alternatives. For patients with angina, multivessel disease, and normal to mild chamber enlargement, revascularization can be expected to improve function and survival. A common clinical practice rarely described in the literature is to base revascularization decisions on target vessel quality. Langensburg et al. showed that in a small series of patients with ischemic cardiomyopathy, patients with vessels rated as poor had 100% mortality after revascularization (2). For patients with only heart failure symptoms, markedly enlarged ventricles, and previous operations (all predictors of increased operative risks), functional studies are obtained to help support surgical intervention. A PET scan showing mismatch of greater than 15% of the myocardial mass supports intervention. If PET corroborates extensive scarring, then isolated revascularization is not considered. A combination of anterior scar, ventricular enlargement, and lateral and inferior ischemia or hibernation directs the surgeon toward revascularization and a remodeling procedure.

Patients with a markedly enlarged ventricle, fair to poor targets, and limited viability, especially if the procedure is a reoperation, are at high risk for postcardiotomy pump failure and are assessed preoperatively for transplant candidacy. If postcardiotomy pump failure occurs, then an LVAD may be used to bridge the patient to transplantation.

SURGICAL TECHNIQUES

The goal of intervention is complete revascularization and meticulous myocardial protection. Because antegrade and retrograde blood cardioplegia provide outstanding protection of these marginal ventricles, an effort should be made to graft all bypassable targets. The approach of “get in and get out” is no longer supportable. The left internal thoracic artery should be used to bypass the left anterior descending artery and not avoided because it is a high-risk case. In fact, Leavitt et al. have shown in a large series of 21,873 consecutive patients that the use of the internal thoracic artery reduced in-hospital mortality and adverse events, especially in the higher risk patients (25). During reoperations the greatest risk is atheroembolization from diseased vein grafts. This would be potentially fatal in patients with marginal LV function. Gentle dissection, use of retrograde cardioplegia, and early ligation of diseased vein grafts all help minimize this problem.

For patients with more diffuse disease, coronary endarterectomy or laser transmyocardial revascularization have been employed. The efficacy and safety of these techniques are not known at this time.

Results

Most published results have focused on early mortality. In one series, mortality was been quite respectable at 1.8% to 6.9% (26,27,28,29 and 30). However, these results are published from centers with expertise in treating patients with reduced LV function, and patients are often carefully selected.

Longer term results also are quite good in patients with and without angina and match that of transplantation. Most studies have shown a 1-year survival of 75% to 80% with a 5-year (5) survival of 50% (*e*Fig. 95.5.1, *e*Fig. 95.5.2, and *e*Fig. 95.5.3) (29,30). These patients’ conditions are improved but not cured. Given the fixed number of donor hearts available, any reduction in the number of patients awaiting transplant or delaying transplantation is an important benefit of the procedures. Survival is good, but cardiac events continue to occur, indicating that medical therapy for heart failure must be diligently maintained. In the future, patients will be stratified by the volume of the ventricle, degree of dysfunctional myocardium, angina, and heart failure class, and results should assess, in addition to survival, quality of life, exercise capacity, and cause of death. Once these data are available, we will be able to better identify the patient with severe, chronic ventricular dysfunction most likely to benefit from surgical revascularization.

DIRECT VENTRICULAR REMODELING

Partial Left Ventriculectomy and Aneurysmorrhaphy

LV chamber enlargement is a compensatory response commonly seen after many forms of myocardial injury. Despite concomitant hypertrophy, wall stress remains excessive when compared with normal-sized ventricles. After infarction the progressive enlargement of the akinetic or dyskinetic segment places additional stress or afterload on the normal segments of the myocardium, which eventually fail, especially if ischemia is present. Early after acute MI a ventricular end systolic volume of more than 40 mL per m^2 is associated with significantly increased 1-year mortality, and massive ventricular enlargement significantly worsens survival in patients with chronic heart failure (*e*Fig. 95.5.4) (31,32). It is interesting that the volume of the ventricle early after the MI is predictive of future mortality. This also seen in patients with chronic CHF, although the size of the ventricle is much larger (*e*Table 95.2.4 and *e*Fig. 95.5.5). As is discussed later, this raises the question of at what size should surgical intervention be considered? Options in the future will include active remodeling of the ventricle as with the Dor procedure or passive restraints such as with the Acorn CS device. As discussed in the previous section, Yamaguchi et al. have shown that patients with LV end systolic volume index greater than 100 mL per m^2 do not respond to revascularization, and overall and event-free survival are poor (24). These findings support the concept of surgical remodeling to reduce the chamber volume and to decrease wall stress with the goal of improving overall cardiac performance, which then, it is hoped, will translate into improvement in functional status and long-term outcomes.

Partial Left Ventriculectomy

Randas Batista introduced partial left ventriculectomy (PLV) in late 1995 based on the law of LaPlace and the reduction of wall stress with a decrease in chamber radius. The procedure and its promoter drew a great deal of attention and interest from heart failure physicians and patients with end-stage heart disease. This procedure offered an alternative to patients who were not candidates for transplant or LV assist devices or preferred to avoid or delay transplantation. More important, it encouraged physicians to look for more unconventional approaches to end-stage heart failure, and along with the contemporaneous success with mitral valve repair in patients with end-stage cardiomyopathy, surgeons were emboldened to attempt surgery in these high-risk patients.

Patient Selection and Technique

In most published series, patients undergoing PLV had idiopathic dilated cardiomyopathy with or without mitral regurgitation. LV dimensions needed to be greater than 7.0 cm; at The Cleveland Clinic Foundation, all patients were transplant candidates (33).

A wedge of ventricular myocardium weighing an average 96 g (range, 30 to 290 g) was resected in the coronary distribution of the lateral circumflex artery. This removed the muscle between the papillary muscles. If this was thought to be insufficient for radius reduction, the papillary muscles were detached, more myocardium was resected, and the papillary muscles reattached. Mitral valve repair or replacement was performed in most patients. An incremental but potentially significant advance in patient selection was described by Suma et al. (34). Early in The Cleveland Clinic experience, the preoperative MRI scans suggested that the lateral wall was functioning the best and the anterior wall and septum were akinetic and scarred. After lateral wall resection, the anterior and septal walls sometimes had improvement in function, but often they did not. Suma et al. intraoperatively looked at regional wall motion of the decompressed ventricles (on partial bypasses) with transesophageal echocardiography. If all walls show improved motion while decompressed on partial cardiopulmonary bypass, the patient is not a candidate for PLV and undergoes mitral valve surgery alone. If the anterior wall and septum are akinetic with good lateral wall function, a modified endoventricular circular patch plasty is performed even for idiopathic dilated ventricles. For lateral wall akinesis, the standard PLV is done (34).

Results

There were astonishing successes and dismal failures after PLV, with an inability to predict outcomes (35) (Table 95.3). In general, ventricular volume and wall stress were reduced, EF increased, but central hemodynamics were unchanged. Surgical mortality was high, and longer-term results were poor (36,37,38,39,40 and 41). The experience of Suma et al. suggests that a more selective approach to resection in elective patients can be done safely with good results (Table 95.4).

Operative mortality	3–20%
Early left ventricular assist device (The Cleveland Clinic Foundation)	15%
2-year survival	50–60%
3-year event-free survival	30%

TABLE 95.4 RESULTS OF TARGETED VENTRICULAR REDUCTION[a]

The reason for the unpredictability of PLV remains unclear. Computer analysis has shown that volume reduction by wall segment resection improves end systolic elastance but worsens diastolic compliance (Fig. 95.6 and Fig. 95.7) (42,43 and 44). The net effect is a decreased slope of the Starling relationship and worse cardiac pump function. Additional factors such as coronary artery injury in the resection closure further compromise cardiac function.

The effect of ventricular volume reduction surgery in the dilated, poorly contractile left ventricle: a simple finite element analysis. *J Thorac Cardiovasc Surg* 1998;116:566–577, with permission.)

Currently, most centers have abandoned PLV as a therapy for idiopathic dilated cardiomyopathy. However, some European and Asian centers continue to pursue this approach in both ischemic and dilated cardiomyopathies. In general, early operative mortality is high (approximately 20%), and long-term results are not known. New devices such as the Myosplint (Myocor, Inc., Plymouth, MN) may accomplish the same stress reduction without the high morbidity and mortality (see New Surgical Therapies for Congestive Heart Failure).

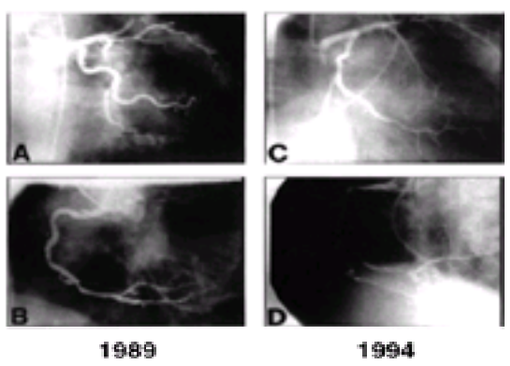
REMODELING THE ISCHEMIC VENTRICLE

The deleterious effects of a large dyskinetic ventricular wall have been known for over 50 years. Increased attention has been directed toward preventing ventricular enlargement and managing the enlarged ventricle with akinetic anterior walls. Traditionally, surgical intervention was reserved for symptomatic patients (angina, CHF, thromboemboli) with large aneurysms. Dor and colleagues directed attention to the deleterious effects aneurysmal segments have on the adjacent normal walls (45,46) and have argued for a more aggressive and early approach to akinetic segments to prevent irreversible damage. In some patients, over a relatively short time period after an acute anterior MI, patients remodel and enlarge the ventricle but also develop myocardial wall motion dysfunction remote from the area of infarct (*e*Fig. 95.7.1 and *e*Fig. 95.7.2). It is unknown how common this is. We have seen patients present with severe heart failure within months of an acute anterior MI from single-vessel disease and others who are followed for decades with large anterior and apical aneurysms before the signs and symptoms of CHF arise. It is worthwhile to note that in the review by Alderman et al. of the patients excluded from the CASS study for EF less than 36% that an LV aneurysm was present in 30% of the medical and surgical treatment groups. Most surgically treated patients had some form of aneurysmectomy (18). There was no surgical benefit in survival in this subgroup when adjusted for the degree of heart failure and wall motion scores. This does not negate the value of aneurysmectomy but supports the notion that early intervention is beneficial before heart failure and remote wall motion dysfunction is advanced.



***e*FIGURE 95.7.1 A–D:** Stable coronary anatomy over 5 years after an anterior infarct. (From Cox JI. Left ventricular aneurysms: pathophysiologic observations. *Semin Thorac Cardiovasc Surg* 1997;9:113–122, with permission.)

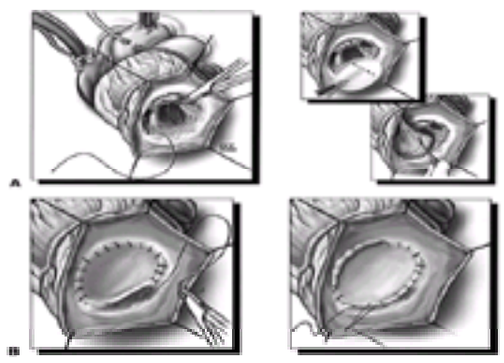
Indications for Ventricular Remodeling

As mentioned previously, traditionally patients have presented with symptoms of cardiac failure and have undergone aneurysm repair at this stage. Currently, asymptomatic patients with ventricular enlargement after an anterior MI should be considered for remodeling. Recommendations vary, but an end diastolic volume greater than 150 to 200 mL, end diastolic dimension of greater than 6.0 to 6.5 cm, or LV end systolic volume index of greater than 60 to 70 mL per m^2 are reasonable guidelines. In our ischemic remodeling group, the average end diastolic volume was 240 mL (end diastolic volume index = 97 mL per m^2) by three-dimensional echo or MRI, whereas Dor's patients had end diastolic volumes ranging from 205 to 246 mL by biplane cineangiography for akinetic and dyskinetic ventricles, respectively (47,48 and 49). We use MRI to assess regional wall motion abnormalities in conjunction with clinical status to exclude patients from remodeling. In patients with massively enlarged ventricles or those with extensive wall thinning with class IV symptoms and patients on inotropes, ventilators, or balloon pumps are considered for transplantation or LVAD.

Aneurysm repair in a patient with a recent lateral wall myocardial infarction. "Packing material" is evident overlying the area of repair (*yellow arrow*).

Techniques

Cooley is credited with performing the first open aneurysm resection in 1958. After 2,000 cases, he has modified the technique from linear closure to internal patch technique. Jatene and Dor nearly simultaneously described an internal remodeling technique that has the theoretical advantage of excluding the infarcted and nonfunctional septum from chamber pressures (45). This is our preferred technique. In brief, the operation consists of differentiating the infarcted or akinetic muscle from contractile muscle and placing two concentric purse strings to reapproximate the normal geometry of the ventricle (eFig. 95.7.3). An additional series of purse strings or a patch is used to exclude the remainder of the nonfunctional wall. CABG is performed in 98% of Dor's patients and 93% in our series, whereas mitral valve procedures were necessary in 54%.



***e*FIGURE 95.7.3 A,B:** Dor procedure: The border zone between scar and muscle is identified and encircled by two purse-string sutures. This excludes the infarcted anterior wall and septum. A patch of either mobilized scar or Dacron is used to close the defect.

Results

Operative mortality is 12.0% in Dor's experience and 1.5% at The Cleveland Clinic Foundation. Dor has shown that patients with akinetic ventricles do not do as well as those with dyskinetic aneurysms, and this is corroborated in our experience. Both survival and event-free survival are reduced in patients with akinetic anterior walls (eFig. 95.7.4, eFig. 95.7.5, and eFig. 95.7.6). The exact reason for this is not clear. It may be that, in general, the akinetic ventricles are larger and, if compared by size outcomes, would not be so different. Overall, the patients do quite well, and the results support the argument for an aggressive approach to ventricular reduction and preventing remodeling (see Acorn Cardiac Support Device, later in this chapter).

MITRAL VALVE SURGERY IN REDUCED LEFT VENTRICULAR FUNCTION

Historically mitral valve surgery in the setting of reduced LV function was thought to be associated with prohibitive perioperative mortality. The oft quoted mortality of

greater than 30% arose from papers published in the 1980s (50). Significant advances have been made since those series in the understanding of the mechanism of mitral insufficiency, the need to preserve papillary annular continuity, and improvements in myocardial protection and surgical techniques that have resulted in substantial improvement in survival. Currently, mitral valve interventions of all types including ischemic mitral regurgitation have an operative mortality of less than 10% (51,52 and 53).

Mechanism

Surgical dogma stated that replacement of the mitral valve in the setting of reduced ventricular function would eliminate the pop-off mechanism for the failing ventricle and result in deterioration in LV function (54). In fact, the mechanism for LV dysfunction was the common practice of excising both the anterior and posterior leaflets and chordal attachments. This loss of the papillary annular connection immediately worsened LV function and resulted in a more spherical ventricular shape with increased wall stress. As experience with mitral valve repair grew, it was demonstrated that when compared with mitral replacement LV function was maintained by repair. This led to the expansion of repair techniques in patients with LV dysfunction. It is worthwhile to note that mitral valve replacement that spares the subvalvular apparatus may be as useful as mitral replacement (55).

In patients with dilated cardiomyopathy, the mitral valve leaflets are usually normal and the mitral regurgitation is related to annular dilatation and apical displacement of the papillary muscles as the chamber enlarges. In ischemic cardiomyopathy, the pathology is much more varied (*e*Table 95.4.1) (56).

***e*TABLE 95.4.1** POTENTIAL CAUSES OF ISCHEMIC MITRAL REGURGITATION

Leaflet(s) prolapse
Transient ischemia
Papillary muscle rupture
Papillary muscle trunk
Papillary muscle head
Chordal avulsion
Papillary muscle elongation
Lack of coaptation of leaflets[a]
Transient ischemia
Annular dilation
Dyskinetic/akinetic wall with apical displacement of papillary muscle and leaflets
Distortion of papillary muscles

[a] Due to apical displacement of the papillary muscle.

From David TE. Techniques and results of mitral valve repair for ischemic mitral regurgitation. *J Cardiol Surg* 1994;9[Suppl]:274–277, with permission.

Ischemic injury to the papillary muscles results in regional wall motion abnormalities; muscle elongation and fibrosis lead to leaflet prolapse centrally and at the commissures. Postinfarction ventricular enlargement apically displaces the papillary muscles yet infrequently results in annular dilatation. Ischemic injury to the valve may cause morphologic changes similar to those seen with myxomatous valve disease. This results in reduced leaflet coaptation and restricted leaflet motion. These distinctions are important for determining repair techniques.

In general, patients with restricted leaflet motion have more severe reduction in LV function and significantly worse survival at 3 years (Fig. 95.8). Acute severe mitral regurgitation is usually seen after a limited transmural infarct with a ruptured papillary muscle head or an acutely torn chorda. These patients usually have preserved LV function (*e*Fig. 95.8.1). Patients with intrinsic mitral valve pathology usually have fairly normal LV function as compared with patients who have normal valves and poor LV function. Patients with normal mitral valves do well after interventions on the mitral valve (*e*Fig. 95.8.2).

If you do not have QuickTime you may download it here.*

Indications for Mitral Valve Repair or Replacement with Reduced Left Ventricular Function

Clinically, there are no published data available to separate out patients with heart failure and mitral regurgitation so advanced that the patients would be better served by heart transplantation. In general, patients requiring continuous intravenous inotropes are not considered for mitral valve surgery. Patients weaned from inotropes have been successfully operated on. On the other side of the coin, the best approach for patients with 2 to 3+ mitral regurgitation remains unclear. In general, if preoperative echoes have shown 3+ mitral regurgitation and revascularization is unlikely to eliminate the regurgitation, valve repair should be considered.

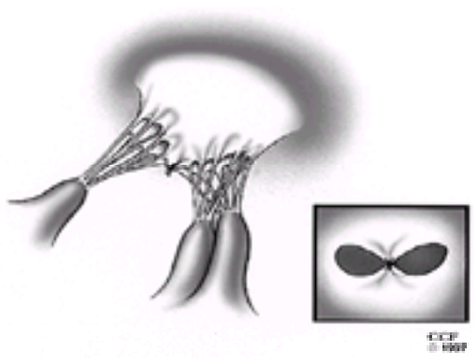
Techniques

For successful surgical results when operating on ventricles with severe reduction in LV function, meticulous attention to myocardial protection, complete revascularization, and knowledge of valve repair techniques is paramount.

Chapter 21 focuses on valve repair techniques, and details can be found elsewhere in this text. Annuloplasty is the main technique for patients with dilated mitral annuli (*e*Fig. 95.8.3 and *e*Fig. 95.8.4). The addition of a stitch to approximate the leaflets (Alfieri) (*e*Fig. 95.8.5) may help reduce late mitral regurgitation from apical displacement but this remains to be proven. Repair techniques such as leaflet resection for prolapse and flail segments, chordal transfer and shortening, papillary muscle plication, and commissural plication are used as necessary. In general, ischemic mitral regurgitation tends to be multifactorial and repairs more difficult. Chordal-sparing mitral valve replacement may be simpler, more effective, and result in similar short- and long-term outcomes.

***e*FIGURE 95.8.3** Operative photograph of a posterior annuloplasty band. By undersizing the band, the coaptation zone of the leaflets increases substantially. In some cases, it converts the mitral into a monocuspid (anterior leaflet) valve.

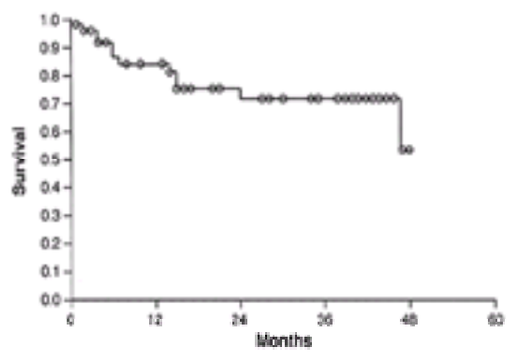
***e*FIGURE 95.8.4** A Carpentier's annuloplasty band. In degenerative mitral disease, only the posterior annulus dilates. The entire annulus dilates in patients with ventricular enlargement.



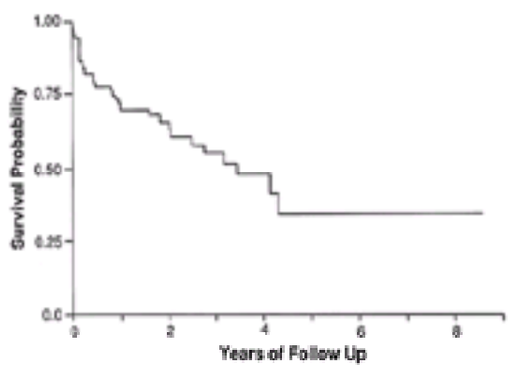
***e*FIGURE 95.8.5** An Alfieri's or bow-tie stitch directly increases leaflet coaptation. In large degenerative valves, there is little concern for causing mitral stenosis. However, in patients with apical displacement of the papillary muscles without annular enlargement, an undersized annuloplasty band along with this stitch may cause mitral stenosis.

Results

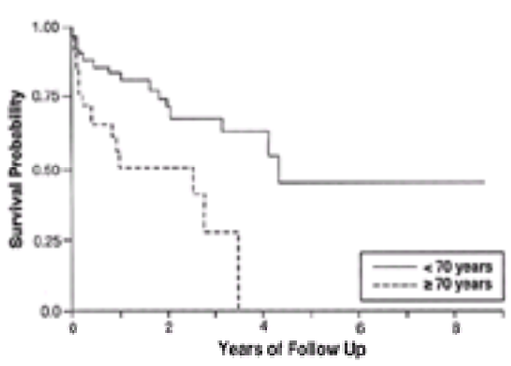
Early reports of mitral valve surgery for ischemic cardiomyopathy showed relatively poor results. Currently at The Cleveland Clinic Foundation, the overall mortality for mitral valve replacement and CABG has decreased over the past decade to less than or equal to 10%. Similar results have been published by Gangemi from the University of Virginia. In their experience, 16 patients with a mean EF of 23% and 4+ mitral regurgitation underwent CABG with mitral valve repair with a 6.3% operative mortality and a 87% 1-year survival (57). Bolling et al. studied 100 elderly patients with ischemic mitral regurgitation (52). There were four early deaths with six late deaths. NYHA class improved significantly with a reduction in hospital admissions for CHF. For patients with profound end-stage LV dysfunction (mean EF = 16%) and severe mitral regurgitation, Bolling et al. have successfully repaired the valve in 130 patients, with one death and a 1-year survival of 82%. Five-year survival is 56% (58,59) (*e*Fig. 95.8.6). Patients less likely to do well have an ischemic etiology of the mitral regurgitation, larger ventricles, and pulmonary hypertension. Chen et al. have reported similar results (*e*Fig. 95.8.7). Survival is much worse in patients over 70 years of age and those with preoperative CHF (*e*Fig. 95.8.8 and *e*Fig. 95.8.9) (51).



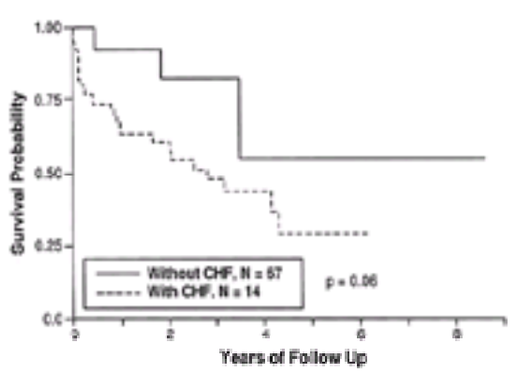
***e*FIGURE 95.8.6** Survival (*p*) after mitral valve repair in patients with end-stage cardiomyopathy. (From Bolling SF, Pagani FD, Deeb GM, et al. Intermediate-term outcome of mitral reconstruction in cardiomyopathy. *J Thorac Cardiovasc Surg* 1998;115:381–388, with permission.)



***e*FIGURE 95.8.7** Survival after mitral valve repair for cardiomyopathy. (From Chen FY, Adams DH, Aranki SF, et al. Mitral valve repair in cardiomyopathy. *Circulation* 1998;98:II-124–II-127, with permission.)



***e*FIGURE 95.8.8** Age again is associated with reduced survival after mitral valve repair in patients with cardiomyopathy. (From Chen FY, Adams DH, Aranki SF, et al. Mitral valve repair in cardiomyopathy. *Circulation* 1998;98:II-124–II-127, with permission.)



***e*FIGURE 95.8.9** Preoperative heart failure symptoms are associated with decreased survival after mitral repair for cardiomyopathy. CHF, congestive heart failure. The documented superiority of mitral valve repair over replacement in patients with degenerative disease is thought to apply to patients with advanced ventricular dysfunction. However, this may not be the case, especially in patients with functional ischemic mitral regurgitation (eFig. 95.8.10). Patients who undergo valve repair, often with an annuloplasty only, have significantly worse survival than valve replacement (eFig. 95.8.11). This reflects the functional state of the ventricle (worse with valve repair) and not the technique. However, for patients with functional mitral regurgitation (normal valves; apical displacement of papillary muscles), Cohn et al. have shown better survival and less morbidity and mortality in the valve replacement groups (eFig. 95.8.12) (55). These authors believe that chordal-sparing mitral valve replacement is likely to be as efficacious as valve repair, especially in patients with mitral regurgitation that has a multifactorial complex basis and may not be amenable to easy and durable repair techniques.

***e*FIGURE 95.8.10** Decreased survival in patients undergoing valve repair or replacement when the mitral regurgitation is based on ventricular dysfunction. *Structural* refers to valve abnormality as a mechanism for mitral regurgitation, whereas *functional* refers to normal valves with left ventricular dysfunction. MECHANICAL CIRCULATORY SUPPORT

A detailed discussion of mechanical circulatory support is beyond the scope of this chapter, but it is extremely important in the surgical management of patients with end-stage heart disease. Mechanical support can be categorized in multiple ways depending on the duration of support (acute or chronic), type of pump (pulsatile vs. continuous flow), completely implantable, implantable or external, total heart replacement, or ventricular assist devices (Table 95.5).

Device	Pulsatile	Short and long-term	Internal
Extracorporeal membrane oxygenation	No	Short	No
ABIOMED	Yes	Short	No
AB-180	No	Short	Yes
HeartMate	Yes	Long	Yes
Novacor	Yes	Long	Yes
Thoratec	Yes	Short/long	Yes
LionHeart	Yes	Long	Completely
Debakey	No	Long	Yes
Jarvik 2000	No	Long	Yes
ABIOCOR	Yes	Long	Completely

TABLE 95.5 CHARACTERISTICS OF MECHANICAL SUPPORT DEVICES

Currently, mechanical support is indicated for postcardiotomy pump failure, acute MI with cardiogenic shock, as a bridge to transplantation, and for patients with the potential for myocardial recovery. Permanent implant or destination therapy is the ultimate goal of mechanical support but has yet to be realized. The REMATCH trial may help define the role of implantable LVADs as an alternative for patients with end-stage cardiomyopathy (60).

Postcardiotomy Support

The need for postcardiotomy mechanical support is declining, despite increasing numbers of high-risk operations (61). To date, all short-term support devices have had equivalent outcomes with approximately 30% of patients surviving the hospitalization (62,63,64 and 65). Despite numerous advances in caring for these patients over the past 20 years, only the ability to convert these patients to an implantable LVAD has improved survival to nearly 50% (66,67). Samuels et al. have recommended that earlier initiation of mechanical support in the operating room to avoid the toxic effects of high doses of inotropes could improve outcome (68).

Bridge to Transplant

The largest collective experience worldwide with mechanical support has been in the group of patients bridged to transplant. The three most common devices are the TCI HeartMate (Fig. 95.9) (Thermo Cardiosystem, Woburn, MA), Novacor (WorldHeart Corp., Ottawa, Canada), and Thoratec VAD (Thoratec Laboratories, Berkeley, CA). A much smaller experience has accumulated with the Cardiowest (Cardiowest Technologies, Tucson, AZ) total artificial heart.

HEART SOUNDS

Auscultation performed in a 48-year-old male patient with end-stage cardiomyopathy after implantation of a Novacor pneumatic left ventricular assist device as a bridge to transplantation. Left lower sternal border. (The heart sounds were digitally acquired courtesy of equipment from Welch Allyn/Meditron and Cardionics Inc.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

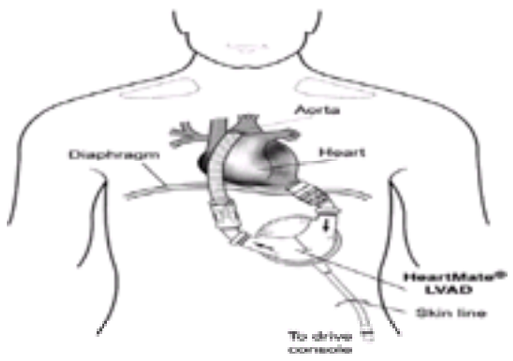

FIGURE 95.9 HeartMate left ventricular assist device (LVAD). (From Slaughter MS, Pappas PS, Tatooles AJ. Modified implant technique for the pneumatic HeartMate left ventricular assist system. *Journal of Congestive Heart Failure and Circulatory Support* 2000;1:123–125, with permission.)

In general, these pumps have worked quite well, with 60% to 75% of patients surviving to transplant (66,69,70). Complications are frequent, including thromboemboli, pump-related infections, and mechanical and valve dysfunction. It is hoped that the smaller axial flow pumps will reduce or eliminate some of these problems as the implantation is much simpler and the pumps are smaller so infection may be less (Fig. 95.10). There are no valves, which may reduce the risk of thromboemboli and eliminates the problem of valve failure.

FIGURE 95.10 A,B: Jarvik axial flow pump. The metal portion is inserted into the apex of the ventricle with the graft anastomosed to the descending thoracic aorta. (From Katsumata T, Westaby S. Implantable axial flow impeller pumps. *J Circ Support* 1998;1:13–19, with permission.)

Ventricular Recovery

It was noticed early in the LVAD bridge to transplant that many hearts had decreased in size, remodeled, and improved in function. Some worked so well that the pump was removed and transplant avoided.

In addition to macroscopic changes, neurohormonal and histologic changes supported the concept that unloading the ventricle may promote recovery. It has been more difficult to characterize ventricles and patients who may recover on support. Hetzer et al. reported the largest experience with 23 patients weaned from LVAD support (71). In general, only patients with idiopathic dilated cardiomyopathy, younger patients, those with shorter durations of heart failure symptoms, and those with greater and earlier remodeling while on support had lasting recovery. It is estimated that of the patients supported with LVADs for long-standing ischemic or dilated cardiomyopathies less than 10% will be recoverable. Given the declining number of donor hearts, identifying even a small group of potentially weanable patients is critical. Additionally, the best support parameters that rest the ventricle but also load it to promote recovery and avoid atrophy and fibrosis remain to be determined. Finally, adjuvant pharmacology, gene therapy, or myoblast transfer may be needed to increase the number of weanable patients.

Destination Therapy

The original purpose of mechanical support funding was to develop a permanent cardiac substitute. That dream remains elusive. Current LVADs work well as a temporary bridge to transplantation but are unlikely to provide the durability and quality of life necessary for more widespread application. The REMATCH trial will provide some insight into how close to the goal we are (60).

Future Devices

The next generation of devices will be the continuous flow pumps (72). These are either axial (straight) or centrifugal (right angle inflow and outflow relationship) miniature pumps that generate flow through high-speed revolution of an impeller blade (Fig. 95.10). The advantages of these pumps are they are much smaller and can be used in pediatric patients and small adults, limited dissection is needed to create a pump pocket, they are quiet, they work without valves, and they are technically easier to convert to a completely implantable design. They currently are in trial in Europe, and trials will begin soon in the United States. It is hoped that the smaller continuous flow pumps will have fewer complications with greater durability and provide an alternative for nontransplant candidates.

NEW SURGICAL THERAPIES FOR CONGESTIVE HEART FAILURE

Acorn Cardiac Support Device

Cardiomyoplasty was developed with the idea that the trained muscle would augment systolic function of the ventricle. Research showed this augmentation was infrequent and the major advantage was a result of a passive girdling of the LV that reduced wall stress, decreased future LV enlargement, and occasionally reversed remodeled the ventricle. This led to the development of a simple mesh-like jacket (Fig. 95.11 and Fig. 95.12) that is slipped around the heart with the hopes of preserving or improving myocardial properties.

FIGURE 95.11 Acorn mesh.

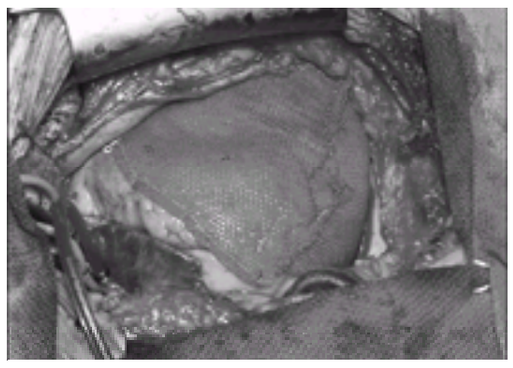

FIGURE 95.12 Acorn after placement around the left ventricle and right ventricle.

Animal studies are quite promising. In an ischemic heart failure model in dogs, the CSD after 3 to 6 months resulted in lower end systolic and end diastolic volumes, improved adrenergic reserve, and showed no evidence of constricting the myocardium. These investigators showed that the CSD attenuates cardiomyocyte stretch, limits cardiomyocyte hypertrophy, and improves sarcoplastic reticulum Ca^{2+} ATPase cycling (73).

In two small series published as abstracts, the Acorn CSD (Acorn Cardiovascular, St. Paul, MN) appears to reduce LV size and improve functional class. Currently, a randomized trial is under way that has two arms: CSD alone versus medical therapy, and CSD plus mitral valve surgery versus mitral valve surgery alone. The cardiomyoplasty experience has helped guide the selection of patients. This device will likely be most beneficial in retarding progression of chamber enlargement. This requires its application in patients with class II to III symptoms and moderate (6.0 to 7.5 cm) chamber enlargement. More advanced stages of heart failure are unlikely to benefit from the CSD and operative mortality will be substantially higher. An interesting application of this technology would be in patients after a large acute MI to prevent remodeling. Identifying patients at high risk for remodeling after an acute MI remains to be completely defined.

Myosplint

Unlike the Acorn CSD, which passively remodels the ventricle, the Myosplint (Myocor Inc., Plymouth, MN) actively and acutely reshapes the LV. Conceived after the Batista principle that geometric reduction in LV size should improve wall stress, the Myosplint is a transventricular splint with epicardial pads that reduce the LV radius by creating a bilobular or two-chamber LV (Fig. 95.13 and Fig. 95.14).

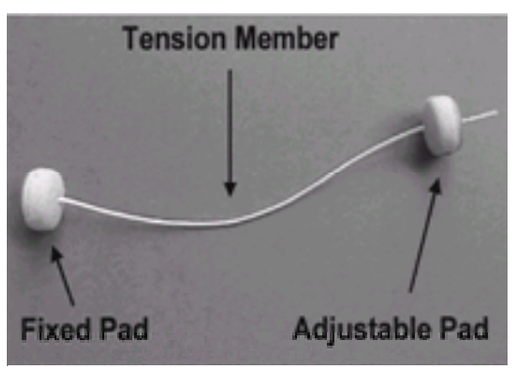

FIGURE 95.13 Myosplint tension member. This metal wire traverses the left ventricle in three spots from base to apex.

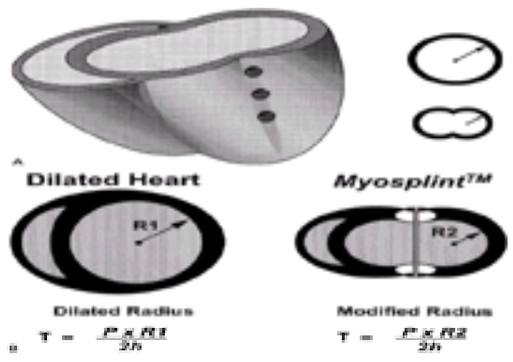

FIGURE 95.14 A,B: Myosplint concept. Stress reduction through ventricular shape change **(A)**.

In early animal studies, LVEF increased from 19% to 38% with significant decreases in end systolic volume (75). It is anticipated that this device will be applied to patients with more advanced heart failure symptoms and larger ventricular volumes.

CONTROVERSIES AND PERSONAL PERSPECTIVES

The statistics speak for themselves. An ever-growing pool of patients with heart failure, limited biologic replacement therapy, and an enlarging armamentarium of surgical therapies and devices suggest that surgery for heart failure will continue to play an important role in treating these patients.

The greatest difficulty in choosing a therapy is the rapidly changing landscape of heart failure medicine. In addition to angiotensin-converting enzyme inhibitors and beta-blockers, angiotensin-receptor blockers, anti–tumor necrosis factor, and other immunotherapy, biventricular pacing, automatic internal cardiodefibrillators, and gene and myoblast therapy are all being assessed in these patients and may affect ventricular remodeling, ischemia, arrhythmias, and mitral regurgitation such that they compete favorably with a surgical procedure. Conversely, waiting until the patient's disease is so far advanced before considering surgical therapy significantly increases the operative risk and most certainly diminishes the benefit. As this chapter outlines, operations for heart failure can be done with low mortality and the concerns that these are high-risk procedures and should be avoided are no longer true. The real question is whether they provide an improvement in the quality of life of the patient and, secondarily, whether they prolong survival at a reasonable cost.

Uncertainty remains as to the benefit of procedures with advanced heart failure. Patients with extensive myocardial ischemia or hibernation by functional studies should undergo revascularization. There is no justification to consider these patients for inclusion in a randomized trial. On the other hand, there is a great deal of uncertainty and conflicting information about the value of revascularization in patients with only heart failure symptoms, no ischemia or hibernation, and markedly enlarged ventricles. This group should and likely will be evaluated in a randomized trial that includes remodeling and revascularization versus medical therapy.

Other randomized trials are investigating the role of mitral valve repair in end-stage patients compared with medical therapy and the benefit of repair valves with lesser degrees of mitral regurgitation to prevent remodeling.

Assist devices are seen as the answer to end-stage heart disease. Some people say no one should die from heart failure without a trial on an assist device, probably with an AICD to reduce the risk of sudden death. It is hoped that the smaller rotary pumps will make the implant easier, be totally implantable, and run forever. The REMATCH trial may give us some insight into these issues. The profession and society as a whole will need to decide what cost we are willing to expend to improve

the quality of and, it is hoped, extend the duration of life in these patients. This undoubtedly will assume greater urgency in the next few years.

THE FUTURE

The lines between heart failure medicine and surgery will grow less distinct. Operations will be performed earlier to prevent the deleterious effects of remodeling and long-standing valve insufficiency. Adjuvant gene or myoblast therrapy along with tissue engineering may allow us to rebuild segments of damaged myocardium. Assist devices will get smaller, more durable, completely implantable, and less expensive, justifying a wider application of this technology.

HISTORICAL PERSPECTIVE

A series of critical experiments in the 1950s and early 1960s established what has come to be known as the central dogma of molecular biology. These experiments demonstrated that deoxyribonucleic acid (DNA) is the genetic material responsible for transmitting heritable information, that DNA is "transcribed" into messenger ribonucleic acid (mRNA), and that mRNA is then "translated" into proteins. However, several crucial discoveries were required before detailed analyses of these processes could be routinely made. One of these was the identification of a series of DNA-processing enzymes from bacteria and bacteriophages. These enzymes included restriction endonucleases, which cleave DNA at sequence-specific sites; polymerases, which synthesize new DNA from a DNA template; and ligases, which can join two pieces of DNA together. This technology ushered in the era of recombinant DNA, allowing small pieces of DNA to be isolated, sequenced, ligated to other pieces of DNA, radiolabeled, and used as molecular probes.

The discovery of the enzyme reverse transcriptase had a particularly great impact on the field of molecular biology. Reverse transcriptase synthesizes DNA from an RNA template, thus allowing one to make a strand of DNA that is complementary to the mRNA. The ability to synthesize complementary DNA (cDNA) from mRNA isolated from a specific tissue was critical to the development of cDNA libraries, ushering in the era of molecular cloning. Other important technical advances included the development of nucleic acid and protein gel electrophoresis to separate different species by size, systems for "blotting" nucleic acids and proteins on filters so that they can be subjected to a variety of analyses, the development of "hybridization" techniques to identify specific DNA and RNA molecules, and the advent of DNA sequencing. The development of viral and plasmid "vectors" that are designed to introduce DNA into a variety of cells where it can be transcribed into mRNA and then translated into proteins has provided powerful tools for the functional analysis of specific genes as well as the generation of recombinant proteins, a number of which are now routinely used in clinical medicine.

The development of appropriate experimental models was critical to the application of molecular techniques to basic investigation in cardiovascular disease. A critical breakthrough was the establishment of culture systems for studying the individual cellular components of the cardiovascular system. The ability to study each cell type as an essentially "pure" culture provided the initial stimulus for a vast array of studies that examined cell surface receptors, transmembrane signals, gene regulation, and the pathways involved in growth, migration, and control of shape. A variety of "coculture" models have been developed to examine interactions among cell types. The breakthroughs in tissue culture techniques have been paralleled by the development of a variety of animal models of cardiovascular disease. These include models of vessel injury, congestive heart failure, and dyslipidemia, as well as animals with genetic preponderance toward hypertension, atherosclerosis, and other cardiac diseases. These *in vivo* models have been complementary to cell culture and have allowed investigators to verify findings in culture using a more clinically relevant setting. The ability to generate "transgenic" animals—animals whose genetic makeup has been altered using recombinant DNA techniques—has allowed investigators to examine the functions of specific *in vivo* models and to develop small animal models that more closely mimic human pathology.

This chapter is designed as an overview of some of the major molecular and cellular techniques that are used in contemporary cardiovascular research. The revolution in molecular biology over the previous century has provided the tools to examine biologic processes at their most basic level. As is evident throughout this text, the application of molecular techniques to cardiovascular research has led to major advances in our understanding of the pathobiology of cardiovascular disease. Although the techniques described are widely used in many areas of biologic investigation, our focus is on their application to cardiovascular investigation; as such, we hope that it provides a frame of reference for understanding the experiments described in the other chapters of this book. The following sections of this chapter describe the cell culture and *in vivo* models that were developed to allow the application of basic molecular techniques to the study of cardiovascular diseases, the major methods used in the study of gene expression, the techniques for molecular cloning, and the methods used to alter gene expression.

MODELS USED IN CARDIOVASCULAR RESEARCH

The development of appropriate experimental models was critical to the application of molecular techniques to cardiovascular research. Hundreds of models have been developed over the past few decades to help further our understanding of cardiovascular pathology. This section provides an overview of some of the models that are most commonly used.

Cell Culture

Cardiovascular diseases involve complex interaction among multiple cell types. As is discussed in later sections, state-of-the-art techniques are being increasingly refined to allow gene expression to be monitored in individual cells in their natural milieu. In spite of these advances, the ability to examine pure populations of cells in

an environment that can be experimentally controlled has provided a wealth of information about the biologic properties of each cell type and continues to be a powerful approach. The relevance of data obtained from cell culture systems to the intact organism must be established experimentally. Hence, the ability to move rapidly from cell culture, to animal models, to clinical studies, and back is an important feature of contemporary molecular cardiology. The following paragraphs outline some of the procedures that are used to study cells in culture, the problems inherent in such cell culture systems, and more recent approaches to addressing cell-cell interactions.

Smooth Muscle Cell Culture

Smooth muscle cells have been cultured from a number of vascular beds (1), including aorta, carotid, mesenteric, pulmonary, and coronary arteries, as well as from veins. Although the most used system has been that of the rat, smooth muscle cells have been cultured from rabbit, bovine, primate, human, and, most recently, murine sources. The availability of explanted hearts from human cardiac transplant recipients has also led to a marked increase in studies that use human smooth muscle cell culture. The general approach to smooth muscle cell culture is to grow cells in plastic dishes in the presence of culture medium and 10% to 20% serum (usually fetal bovine serum). Two approaches have been used to obtain smooth muscle cells. For smaller animals and vessels, such as rat aorta or human coronaries, collagenase/elastase digestion accompanied by fine dissection has provided a means of obtaining essentially pure cultures of smooth muscle cells (1). For larger vessels with extensive media, such as human aorta, the use of explants (2) has proved to be more successful than enzymatic disruption. In this technique, the vessels are dissected free of adventitia and endothelium and cut into small chunks, and the cells are allowed to proliferate and migrate onto the culture dish. These preparations tend to have lower degrees of purity than enzyme digests but provide ample supplies of smooth muscle cells.

Although both techniques provide high yields of smooth muscle cells, they contain mixed populations of smooth muscle cell types. In most cases, the cells grow rapidly to cover the surface of the tissue culture plates and can then be passaged. In this process, the cells are removed from the plastic surface by trypsin digestion, diluted at ratios of 1:5 to 1:10, and transferred to an expanded number of new plates. This allows for large-scale and complex experiments that involve dozens, and sometimes hundreds, of plates. Cells can also be grown on slides or cover slips for specialized procedures. In addition, cells can be grown on or in a variety of matrices, such as those comprised of collagen, vitronectin, or mixtures of matrix proteins. Such matrices often affect the properties of the cultured cells (3). Ultimately, normal smooth muscle cells develop senescence and can no longer be passaged. Therefore, they are characterized as strains, rather than cell lines, which can be grown indefinitely.

A major drawback to the use of cell culture is the phenomenon characterized as *phenotypic modulation*. In the normal vessel, smooth muscle cells maintain a contractile phenotype in which their cytoplasm is largely comprised of actin and myosin filaments, and they do not divide in response to growth factors. In cell culture, smooth muscle cells quickly lose their filaments and modulate to a synthetic phenotype in which they no longer contract but divide rapidly in response to growth factors (4,5 and 6). To date, attempts to identify the genes for altering smooth muscle cell phenotype have proved unsuccessful, and the switch from the synthetic back to the contractile phenotype has not been observed. The two phenotypes described in cell culture mimic those seen in atherosclerosis, in which the medial smooth muscle cells modulate to a synthetic phenotype, migrate to the intima, and grow rapidly. In contrast to cell culture, these synthetic smooth muscle cells appear to be able to modulate back to the contractile phenotype under certain conditions. It should thus be stressed that studies that involve smooth muscle cell cultures focus on cells whose phenotypes are decidedly different from those of normal vessels but may be more representative of those found in injured or atherosclerotic vessels. This remains an important limitation in interpreting studies using cultured smooth muscle cells. Despite these limitations, considerable information has been obtained from the use of cell culture systems, and they remain a mainstay of smooth muscle cell biology. The use of smooth muscle cell culture has been extensively reviewed in a two-volume set edited by the Campbells (7).

Endothelial Cell Culture

Studies on vascular endothelium have also extensively availed themselves of cell culture. Unlike smooth muscle cells, endothelial cells are present as a single layer lining the intima. Therefore, smaller amounts of endothelial cells can be obtained from blood vessels. These cells also tend to develop senescence more quickly than smooth muscle and therefore provide a greater challenge in obtaining large numbers of cells. A favorite choice for endothelial cell culture has been the human umbilical vein endothelial cell. This cell can usually be passaged four to five times, and a large number of cells can be obtained from individual placentas (8). The ready availability of placentas has been instrumental in the popularity of these cells. Other sources include arterial endothelial cells from bovine, rat, and human sources. Unlike smooth muscle cells, endothelial cells grow poorly on plastic or glass and are usually grown on a matrix of gelatin, collagen, or fibronectin.

Two particularly important properties of cultured endothelial cells have received considerable attention. The first is the ability of endothelial cells to respond directly to shear or turbulence (9). This has led to the development of a variety of cell culture systems to study endothelial cell biology under various flow conditions. The second property is the ability of microvascular endothelial cells to form capillaries under appropriate cell culture conditions (10). This has allowed investigators to use cell culture to model capillary formation, such as that seen in tumor angiogenesis and in angiogenesis associated with ischemia.

Cardiac Myocyte Culture

Cardiac myocytes that are isolated by explant or enzymatic digestion of fetal and adult hearts maintain their contractile phenotype in culture on plastic and have been particularly useful for electrophysiologic as well as molecular biologic studies (reviewed in reference 11). Because they are at or near terminal differentiation, cardiac myocytes that are isolated from late stages of development do not divide in culture and, therefore, can only be used as primary cultures. Isolation of relatively pure populations of myocytes requires dissection to isolate the chamber of interest, mechanical and enzymatic disruption, and serial plating or density centrifugation to remove fibroblasts (which grow rapidly in culture and would quickly outnumber the myocytes). The passage of cardiac myocytes in serial culture has thus far been limited to transformed or cardiac tumor–derived cells that show varying degrees of differentiation in culture. The ability to expand large quantities of fetal cardiac myocytes in culture to repopulate damaged myocardium *in vivo* remains a major goal.

Coculture Techniques

As noted previously, a rational approach to vascular biology has been to use “pure” cell culture systems to study the biologic properties and responses of individual cell types. The next step in the process is to examine the effects of one cell type on another. A variety of systems have been used to raise the level of complexity and to address cell-cell interactions. The simplest has been the use of “conditioned” medium. In this approach, the culture medium that is collected after incubation with one cell type is added to another. The use of conditioned medium has been particularly important in examining stable humoral factors synthesized by one cell that have effects on the other. A second approach is to culture two cell types in chambers separated by a semiporous membrane. The rationale for this approach is to prevent direct cell contact but to allow humoral effects involving molecules with shorter half-lives. This approach also allows for cross talk, in which one cell may induce the other to synthesize a molecule, which then acts on the original cell. The third approach is to allow for direct cell contact, either by plating one cell on top of another or by plating one cell on plastic monolayers and the other on beads (12). The use of beads allows ready separation of one cell type from the other at the end of the experiment. The use of cocultures has provided important information on endothelial–smooth muscle cell interactions and has led to the discovery of a large number of important molecules that regulate endothelial and smooth muscle cell phenotype. In addition to endothelial–smooth muscle cell coculture, attention has focused on cocultures of endothelial cells and leukocytes. These studies have been stimulated by the discovery of families of molecules that mediate the interaction of leukocytes with the vessel wall and, specifically, with the endothelium. These studies have been reviewed (13).

Other Cell Types

The cell types described previously in this section represent some of the more commonly studied in the cardiovascular literature. The list is by no means exhaustive. Most of the cells types involved in the pathogenesis of cardiovascular diseases, including fibroblasts, lymphocytes, macrophages, and circulating stem cells, can be grown in culture.

In Vivo Models

Despite the invaluable contribution of cell culture, the utility of molecular cardiology to improve the treatment of human disease is dependent on the development of animal models that accurately mimic these diseases. Although naturally occurring animal models of cardiovascular disease have been exploited, many of the common human diseases are rarely seen in animals. In recent years, the increasing application of transgenic technology to cardiovascular research has allowed the development of more sophisticated mouse models of cardiovascular pathology. Although the small size of the mouse presents challenges, a variety of diagnostic techniques have been adapted for its use, including echocardiography (14), micromanometry (15), and *in vivo* magnetic resonance imaging (16).

Atherosclerosis

One model that is commonly used to study atherosclerosis and arterial injury involves the use of balloon catheters to denude the endothelium and to injure the media (17). The approach to catheterization is similar to that used in human angioplasties, involving cannulation of a distal artery and passage of a balloon-tipped catheter into the area to be injured. Injuries can range from gentle endothelial denudation to injuries that tear the internal elastic lamina and damage the media. Alternative approaches include external injury to the artery, for example, using a forceps to crush the artery (18,19), or internal injury using air (20) or electrical stimulation (21).

Such models have been used in rats, rabbits, transgenic mice, dogs, pigs, and nonhuman primates. The hallmark of this model is the development of intimal hyperplasia, characterized by the migration and proliferation of smooth muscle cells in the intima. An example is shown in Figure 96.1.

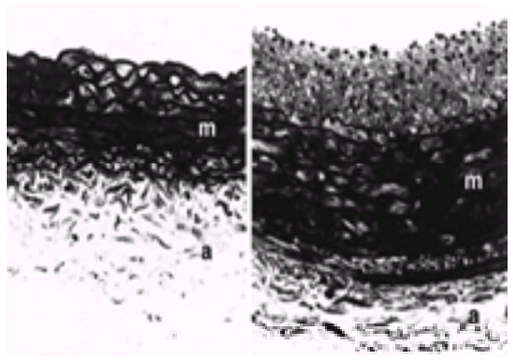

FIGURE 96.1 Intimal hyperplasia following balloon injury of the rat aorta. Cross section of a normal rat aorta **(left)** stained with hematoxylin and eosin and a rat aorta 2 weeks after balloon catheter injury **(right)** showing the development of a thickened intima (i). a, adventitia; m, media.

Balloon injury models have been instrumental in elucidating the early molecular and cellular events following vessel injury and have also been used widely for studying approaches to inhibit intimal hyperplasia. Because intimal hyperplasia is a major component of the atherosclerotic plaque and is thought to play a role in restenosis after angioplasty, balloon injury models have received considerable attention. One criticism of most models is that they involve the use of normal vessels, whereas atherosclerosis occurs and angioplasty is performed in the setting of abnormal vessels that contain lipid-rich, calcified plaques. Studies that use injury to normal vessels have contributed greatly to understanding cell biology *in vivo* but have been less useful for predicting the effects of pharmacologic interventions in human disease.

An alternative to injuring normal vessels is the use of double-injury models in which a second injury is performed several weeks after an initial injury (22). In rodents, double injury is associated with a more thrombotic response than that seen after single injury. Whether this model is more representative of human atherosclerosis remains to be determined.

In addition to acute arterial injury, a variety of *in vivo* systems have been used to model the more chronic development of atherosclerosis, such as that seen in human disease. These have included the use of high-fat/high-cholesterol diets in rabbits (reviewed in reference 23), pigeons (24), pigs (25), and nonhuman primates (26,27 and 28). Although these diets are often associated with the types of lesions that are seen in early atherosclerosis, they are not as severe as those seen in human disease (29). A variety of genetically engineered hyperlipidemic transgenic mice that more closely resemble the complex lesions of human atherosclerosis have been developed (30). The study of genetically altered mice has led to dramatic advances in the study of lipoprotein metabolism and atherosclerosis. (See reference 31 for an in-depth review.) In spite of these advances, challenges still remain. A critical feature of human unstable coronary syndromes is the rupture of atherosclerotic plaques, and the lack of plaque rupture is a shortcoming of the dyslipidemic animal models.

Congestive Heart Failure

A variety of large animal models that were developed to study the hemodynamic aspects of congestive heart failure have been modified for use in small rodents. Aortic banding is a well-established model of left ventricular (LV) hypertrophy due to pressure overload. The progression of LV hypertrophy to progressive LV dysfunction and overt heart failure has been documented in guinea pigs and rats. Similar effects have been observed following renal artery ligation (32) and after the administration of a high-salt diet to Dahl salt-sensitive rats (33). Surgical procedures are more technically challenging in mice because of their small size, but aortic banding can be accomplished via microsurgical techniques (34). Aortic banding leads to cardiac decompensation in mice that express specific transgenes (35,36) and in mice treated with cyclosporin (37). Coronary artery ligation as a model of myocardial infarction with subsequent LV failure has a long history in cardiovascular research and has been adapted to the mouse (38). Murine models of viral myocarditis with cardiac failure have been extensively studied (well reviewed in reference 39). A hereditary form of dilated cardiomyopathy occurs in a strain of Syrian hamsters (40); the underlying genetic defect has been identified (41,42). Although naturally occurring inherited cardiomyopathy models are lacking in the mouse, an array of transgenic models has been generated (see reference 43 for review). In addition to the models of dilated cardiomyopathy, an important model of hypertrophic cardiomyopathy has been developed by introduction of a missense mutation analogous to a mutation that causes familial hypertrophic cardiomyopathy into the murine alpha-cardiac myosin heavy-chain gene (44).

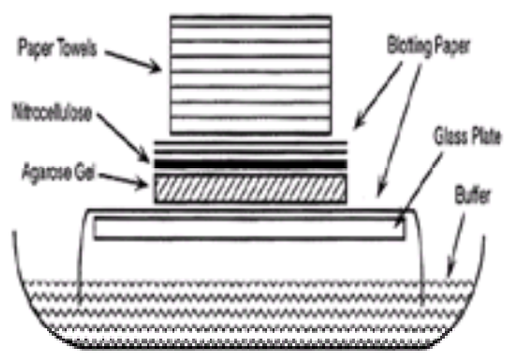
ANALYSIS OF GENE EXPRESSION

The central dogma in molecular biology is that the genetic information stored in DNA is transcribed to RNA and then translated to proteins. In strictest terms, *gene expression* refers to the process by which a gene is “turned on” to produce mRNA. However, it often is used to describe the entire process by which activation of a gene leads to an increase in its protein. This section describes approaches that are used to examine mRNA and protein.

RNA (Northern) Blot Analysis

RNA blot analysis (45) has been the most popular method for identifying and quantifying specific mRNAs. It is particularly useful for identifying mRNAs that are abundant (i.e., that are present in large enough quantities to be easily measured). This process involves size fractionation of RNA on formaldehyde/agarose gels, followed by transferring the RNA to filters and then hybridizing the filters with probes that recognize a specific mRNA.

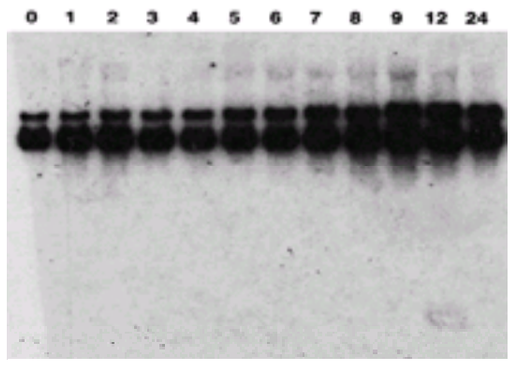
The basic principle underlying RNA blot analysis is that under denaturing conditions, in response to an electric current, RNA moves through an agarose gel at a rate inversely proportional to its size; that is, the largest RNA moves the least. This allows one to isolate total RNA from cells or tissues, apply small amounts (~10 µg) to the lanes of an agarose gel, and then separate the various RNA species by size. Because the vast majority of RNA is ribosomal RNA, the individual mRNA species cannot be seen directly. However, the RNA can be transferred to filters (usually composed of nitrocellulose or nylon) by the process of “blotting” (eFig. 96.1.1). The RNA is then baked onto the filter, where it can remain stable for months to years.



***e*FIGURE 96.1.1** Schematic representation of the blotting apparatus used to transfer RNA (or DNA) from agarose electrophoresis gels to nitrocellulose. Buffer placed in the bottom of the apparatus is drawn up through the layers of material to the paper towels by capillary action. RNA moves with the stream of buffer and becomes immobilized when it reaches the nitrocellulose membrane.

Specific mRNAs can be identified on the filters using the technique of hybridization. This is based on the ability of RNA to form hydrogen bonds with complementary strands of DNA (cDNA) or RNA (cRNA). The binding between mRNA and its exact complement is extremely tight, and therefore high-affinity probes can be designed to detect a specific mRNA. Various approaches have been used to label the probes, including phosphate-32 (P-32) nucleotides, fluorescent or biotinylated compounds, or

digoxigenin (46). The most common approach is to label cDNA with P-32 deoxynucleotides using either the technique of “nick translation” (47) or random oligomer priming (47,48 and 49). he hybridization protocol is carried out by incubating the blotted filter in a buffer containing the labeled probe. The filter is washed several times to remove the labeled probe and then processed based on the type of label used. The specific mRNA is detected as a band (eFig. 96.1.2). Most typically, radiolabeled bands are identified by autoradiography on x-ray film or using a phosphoimager.



***e*FIGURE 96.1.2** RNA blot analysis. To examine the effects of basic fibroblast growth factor (FGF) on the expression of messenger ribonucleic acid (mRNA) for the rat protein osteopontin, total RNA was isolated from cultured vascular smooth muscle cells following treatment with 50 ng/mL basic FGF. 10 µg per lane was loaded on a 1% agarose, 7.5% formaldehyde electrophoresis gel, and, following electrophoresis, the RNA was transferred to nitrocellulose using the apparatus depicted in *e*Figure 96.1.1. The nitrocellulose “blot” was hybridized with P-32–labeled complementary DNA probes for rat osteopontin and myosin light chain. Because myosin light chain is known to be constitutively expressed under these conditions, it was used as an internal control. The higher band in the autoradiogram above demonstrates hybridization to osteopontin mRNA, and the lower band demonstrates hybridization to myosin light-chain messenger RNA (mRNA). Levels of osteopontin mRNA rise after exposure to basic FGF, whereas levels of myosin light chain remain constant.

The specificity with which the cDNA or cRNA probes hybridize to the mRNAs contained on the filter is determined by the conditions of hybridization and of the washing, referred to as the *stringency*. Homologous probes (i.e., probes that correspond exactly to the specific mRNA being examined) bind most tightly to the target mRNA. As the degree of similarity between the probe and the target mRNA decreases (e.g., when probes from one species are used to identify mRNA from another, or when probes represent related but not identical molecules), the tightness of binding decreases. The higher the temperature of washing and the lower the salt concentration of the wash buffer (i.e., the higher the stringency), the more closely related the probe and mRNA must be to remain bound. The advantage of RNA blot hybridization is the ability to identify related but not identical signals by hybridizing and washing at low stringencies. The disadvantage is that the technique only identifies signals if the mRNA is abundant. Another disadvantage is that even under high stringency, a single probe can hybridize to several highly related mRNA species of similar size. Several alternative techniques have been designed to identify less abundant mRNAs and to provide a higher degree of specificity. One approach is to perform RNA blot hybridizations with poly A^+ RNA. Because mRNAs contain large tracts of poly A at their 3' ends, they can be purified from the ribosomal RNA on columns that contain oligo dT (47) or poly U. This purification results in an approximately 50- to 100-fold enrichment for mRNA and therefore allows for substantially more mRNA to be loaded on the agarose gels.

Ribonuclease Protection Assays

Ribonuclease (RNAse) protection assay uses a sequence-specific labeled cRNA molecule as a probe to hybridize with RNA in solution (50,51). Base pairing between the labeled probe and the mRNA of interest results in double-stranded cRNA-RNA hybrids that are resistant to digestion by RNAse. Following hybridization, samples are digested with RNAse to destroy the unhybridized, single-stranded probe and mRNA. The products of digestion are then run on a polyacrylamide gel. The gel is dried, and the “protected” bands are detected by autoradiography (Fig. 96.2). One advantage of this technique is the extremely high degree of base pairing that is needed to prevent RNAse from digesting the cRNA-RNA hybrids. Even two consecutive base pair mismatches are sufficient to allow the RNAse to digest the hybrid at the point of the mismatch. This technique thus allows for the identification of mRNA that is virtually 100% complementary to the cRNA probe. The area that corresponds to the alternative spliced exon is degraded by the RNAse. RNAse protection assays are usually more sensitive than RNA blot analysis and can therefore be used to detect lower levels of mRNA. Kits are commercially available to generate specific probes for the detection of multiple mRNAs in a single sample at one time.

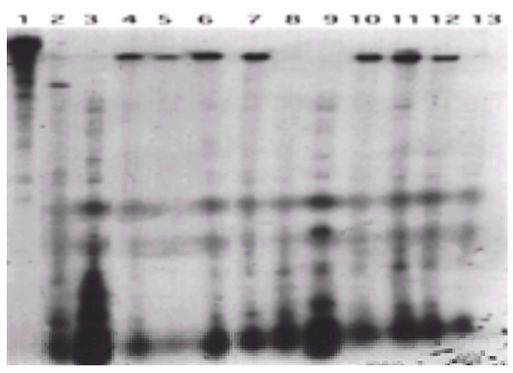


FIGURE 96.2 Ribonuclease (RNAse) protection. To examine the expression of the rat gene SM-20, an antisense P-32–labeled RNA probe was synthesized by *in vitro* transcription using a plasmid containing the rat SM-20 complementary DNA and the recognition site for T3 polymerase. The 420–base pair (bp) probe contained a 40-bp sequence from the plasmid vector and a 384-bp sequence complementary to SM-20 messenger RNA (mRNA). Total RNA, 10 µg per lane, from a variety of tissues was hybridized with the rat probe, incubated with RNAse, and then analyzed by polyacrylamide gel electrophoresis. Lane 1 of the autoradiogram shows the undigested probe. When the probe was hybridized to RNA from mouse heart (lane 2), part of the probe was protected from RNAse digestion, implying that there is partial sequence identity between the rat and mouse SM-20 mRNA. Rat tissues that express the SM-20 mRNA (lanes 4–7, 10–12) showed full protection of the complementary region of the probe. Yeast transfer RNA (lane 13) and RNA from tissues that do not express SM-20 (lanes 3, 8, 9) failed to protect the probe.

Unlike RNA blot hybridization, RNAse protection assays do not usually identify highly related isoforms unless they are generated by the process of alternative splicing, in which identical exons, representing regions of 100% identity, are spliced to different exons. This results in partial protection of the cRNA probe, corresponding to the area that contains the shared exon.

Polymerase Chain Reaction

The most sensitive approach for identifying and amplifying specific DNA or mRNA sequences is polymerase chain reaction (PCR) (Fig. 96.3). Standard PCR involves the synthesis of a set of primers (sense and antisense) that correspond to the 5' and 3' ends of the segment of DNA to be amplified. DNA (genomic DNA, or plasmid DNA) is used as a template. To amplify sequences from mRNA, a cDNA copy of the mRNA is generated by reverse transcription and used as a template in the PCR reaction. To begin the PCR, template DNA is incubated in solution with the primers, all four deoxyribonucleotides, and a temperature-stable DNA polymerase. Three reactions are performed in a thermocycler that allows for very rapid changes of temperature. The initial step is the denaturation of the double-stranded DNA template by heating to approximately 95°C. The next step is annealing (performed between 37°C and 65°C) of the primers to the denatured template. This is followed by synthesis of complementary DNA strands by the heat-stable DNA polymerase (performed at ~72°C). At the beginning of the next cycle, the newly synthesized DNA is denatured (at ~95°C) to produce new single-stranded templates. This cycle is repeated 20 to 40 times to achieve greater than 1 million–fold amplification of the sequence of interest. The products are then resolved on agarose or polyacrylamide gels. PCR can be used to identify and amplify a single molecule of viral DNA from a single cell. It can also be used to identify DNA that contains a specific mutation.

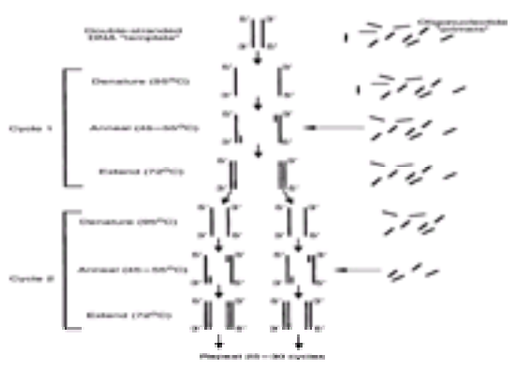

FIGURE 96.3 Polymerase chain reaction for amplification of DNA. The schematic shows two complete cycles of polymerase chain reaction. The procedure is repeated for a total of 25 to 30 cycles.

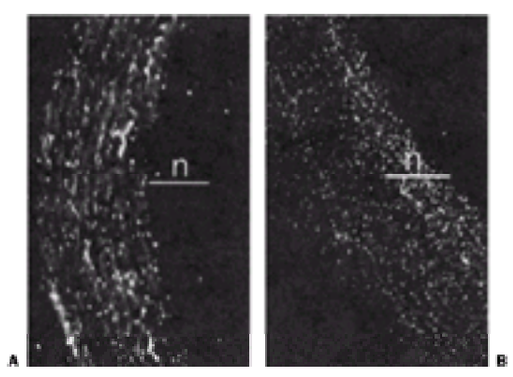
The sensitivity of reverse-transcription (RT)–PCR enables one to amplify from just a few molecules of mRNA. RT-PCR can therefore be used to examine mRNA from a single cell or from small tissue samples, such as those obtained from cardiac biopsies or coronary arthectomies. One disadvantage of RT-PCR is that it is difficult to use for quantitation. During the early cycles, there is exponential amplification and a direct relationship between the amount of original DNA template and the amount of product. As the number of cycles increases, the reagents in the reaction tube cannot sustain the continued exponential amplification. The rate of accumulation of PCR product falls off in an unpredictable way. Once this occurs, the final yield of product may have little relationship to the original amount of starting material. A variety of procedures involving the use of internal standards and varying cycle lengths have been used to allow “semiquantitation” of RT-PCR, but these techniques can be cumbersome. Real-time quantitative PCR is designed to circumvent these problems (reviewed in references 52 and 53). In this technique, the reaction is carried out in a thermocycler equipped with fluorescence detection and specialized software. The incorporation of dyes that are specific for double-stranded DNA or the release of fluorescence from specially designed primers is continuously monitored. The numbers of cycles that are required to permit fluorescence detection are then correlated to the quantity of starting material.

In Situ Hybridization

The above techniques involve the identification and measurement of mRNA from samples extracted from cells or tissues. *In situ* hybridization provides a method for identifying mRNA in intact cells or tissue samples (54). The general strategy is similar to that used for RNAse protection assays and involves the generation of single-stranded, labeled cRNA probes. Rather than being hybridized in solution, the probes are incubated with cells or tissue sections fixed on slides or cover slips. After hybridization, the slides are washed at high stringency. In the case of radiolabeled probes, the slides are covered with photographic emulsion for several weeks and then developed. For digoxigenin-labeled probes, the slides are analyzed using antibodies to digoxigenin and colorimetric detection. They are then examined by light- or dark-field microscopy. After detection of radiolabeled probes, mRNA appears as grains associated with cell bodies. After detection with digoxigenin-labeled probes, it appears as colored staining. With either labeling technique, slides can be counterstained such that the normal cellular architecture can be determined. This procedure thus allows one to identify specific cells that express mRNA. In the early stages of murine development, embryos are small enough to allow penetration of cRNA probes without sectioning. This allows intact embryos to be examined by light microscopy to determine the expression of developmentally regulated genes. Although *in situ* hybridization is excellent for localizing sites of mRNA expression, it is not ideal for quantitation. Nevertheless, semiquantitative approaches have been used based on the number of grains seen. The availability of increasingly sophisticated imaging systems should allow for more reliable quantitation. An example of the use of *in situ* hybridization to examine gene expression in an animal model of balloon arterial injury is shown in *e*Figure 96.3.1.



***e*FIGURE 96.3.1** *In situ* hybridization. Localization of messenger RNA (mRNA) expression for the rat gene SM-20 in balloon-injured rat aorta using ^{35}S–complementary RNA (cRNA) probes. **A:** The sense cRNA probe used as a negative control did not hybridize to an mRNA species. **B:** The antisense cRNA probe hybridized to SM-20 mRNA and was detected as small grains seen throughout the specimen, most strikingly in the neointima (n). (From Wax SD, Tsao L, Lieb ME, et al. SM-20 is a novel 40-kd protein whose expression in the arterial wall is restricted to smooth muscle. *Lab Invest* 1996;74:797–808, with permission.)

New Directions: Laser Capture Microdissection

As discussed in the section Models Used in Cardiovascular Research, cardiovascular diseases involve complex interaction among multiple types of cells, and the ability to culture pure preparations of these cells has been critical to work in molecular cardiology. Still, each of the cell culture models has inherent limitations. It would be ideal to be able to study the individual cell types within pathologic lesions. *In situ* hybridization and immunostaining allow gene expression to be examined in tissue sections but are of limited sensitivity and do not permit comprehensive analysis of gene expression. Laser capture microdissection (LCM) is a technique developed at the National Cancer Institute that allows pure cell populations to be microscopically dissected from tissue sections so that their DNA, RNA, and proteins can be analyzed (55). Briefly, a glass slide with a routine tissue section is overlain with a transparent thermal polymer film and placed on a microscope. Once the investigator visualizes the cells of interest, a brief burst of infrared laser light is directed at the area, causing the cells to adhere to the thermoplastic film. The cells can then be recovered from the film and subjected to molecular analysis, including RT-PCR followed by gene-array screening (56). The National Cancer Institute maintains a website devoted to LCM (http://dir.nichd.nih.gov/lcm/lcm.htm) to distribute information regarding the rapidly evolving uses of LCM. Figure 96.4 shows an application of LCM to isolate macrophages from an atherosclerotic plaque.

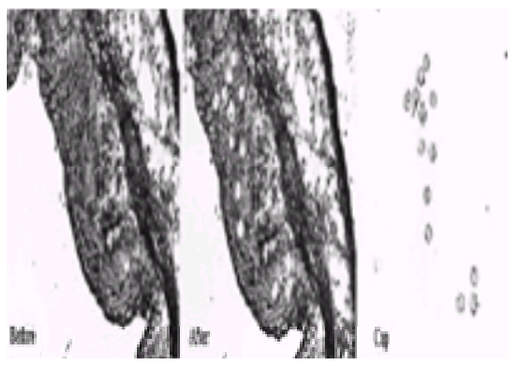


FIGURE 96.4 Laser capture microdissection (LCM) of atherosclerotic plaque. Sections of atherosclerotic plaque were immunostained to detect macrophage-derived foam cells and then covered with a thermoplastic film. Short bursts of infrared laser light were used to attach 15-µm circular fragments of macrophage-rich tissue to the film. Tissue section is shown before LCM **(left)** and after LCM **(middle)**. Analysis of Transcription

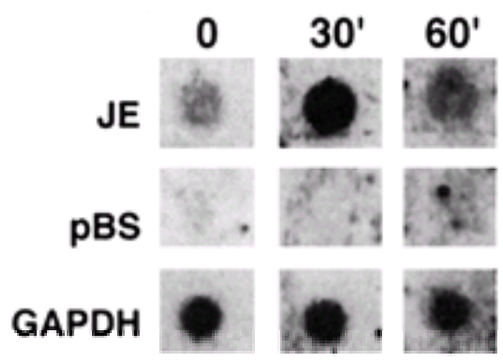
The above techniques measure steady-state levels of mRNA and can be used to assess the accumulation of mRNA in response to a particular stimulus, for example, arterial balloon injury or treatment with agonists. Steady-state mRNA levels represent a balance between transcription of new mRNA and changes in the stability of the transcribed message. It should be noted that the term *induction* has been most typically used to describe mRNA transcription. However, it is sometimes used to describe any increase in mRNA levels, whether it be due to changes in transcription, mRNA stability, or a combination of both. Several approaches have been used to examine specifically the transcriptional component.

Nuclear Run-On (or Run-Off) Analysis

Nuclear run-on (or run-off) analysis (57) has been the gold standard for examining mRNA transcription. This technique is based on the principle that isolated nuclei contain RNA that is in the process of being transcribed. One can complete this process (elongation) in a test tube by adding ribonucleotides. In contrast, transcription cannot be initiated in a test tube under the same conditions. By including a radiolabeled ribonucleotide in the reaction, one can measure the level of transcription that occurs at the moment that the nuclei were collected.

The technique for measuring transcription of specific mRNAs is essentially the reverse of RNA blot hybridization. The unlabeled specific probe is blotted onto the filter, and the filter is hybridized to the reaction mixture that contains the radiolabeled transcripts, representing all of the mRNAs being elongated in the *in vitro* reaction. Because one can blot dozens of probes on a single filter, it is possible to analyze levels of transcription for many different mRNAs at the same time (*e*Fig. 96.4.1).



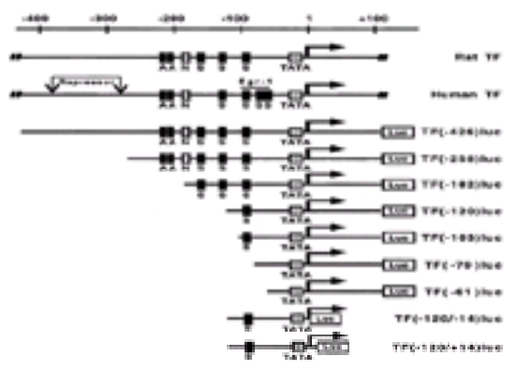
***e*FIGURE 96.4.1** Nuclear run-off analysis. Nuclear RNA was isolated and labeled as described in the text from quiescent VSMC and at 30 and 60 minutes after exposure to 10 ng per mL platelet-derived growth factor (PDGF). Linearized plasmid DNA containing complementary DNA (cDNA) from the rat called *JE*, empty plasmid vector (pBS), and plasmid containing the cDNA encoding glyceraldehyde phosphate dehydrogenase (GAPDH) were spotted onto a nitrocellulose filter (10 µg DNA per spot), and the filter was hybridized with the labeled nuclear fractions. The experiment demonstrates that there is a marked increase in *JE* messenger RNA (mRNA) transcription 30 minutes after PDGF exposure, whereas GAPDH mRNA is transcribed at a constant rate.

Because the elongation reaction is performed in a cell-free system for a short period of time, it should not be affected by changes in mRNA stability, most of which are mediated by cytoplasmic factors and occur over a longer time frame. Although nuclear run-on analysis remains the most rigorous approach for assessing the role of new transcription in the accumulation of mRNA, it is limited by the need to isolate nuclei from large numbers of cells and is poorly suited to examine transcription *in vivo* or in cell cultures, where only limited numbers of cells are available such as those derived from human coronary arteries. The advantage of the procedure is that it is measuring transcription of the target gene in its original environment in the chromosome.

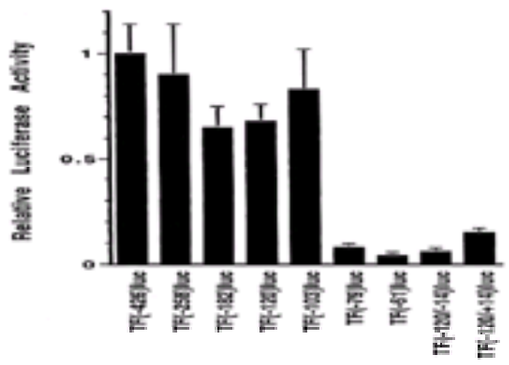
Promoter Analysis

A second approach to analysis of transcription is to isolate the transcriptional unit of the specific gene of interest and to examine its regulation in cell culture. This approach, referred to as *promoter analysis*, has been a major focus of research in molecular biology and has provided a wealth of information on the molecular events that are required for gene transcription. Transcription begins when RNA polymerase attaches to the promoter area of the gene being transcribed. In the presence of ribonucleotides, the polymerase then moves along the gene, linking ribonucleotides together in a pattern that is complementary to the antisense strand of DNA. In general, transcription begins 25 bases downstream from the promoter. Binding of the RNA polymerase to the promoter requires a very small amount of DNA sequence. However, regulation of polymerase binding and subsequent transcription involve a variety of sequences located apart from the promoter. Many of these sequences are found within 200 to 300 bases of the promoter. However, others can be located thousands of bases away.

Regulatory sequences may convey tissue specificity, developmental specificity, or agonist specificity to transcription. The sequences, referred to as cis-*acting elements*, can either be positive or negative regulators of transcription. A particular class of regulators, known as *enhancers* or *suppressors*, has the property of being able to act in an orientation- and position-independent fashion. For example, an enhancer can be turned around or placed thousands of bases away from the promoter (upstream or downstream) and still regulate transcription. For a *cis*-acting element to function in regulating transcription, it must be bound by a humoral "*trans*-acting" factor, usually a protein. Substantial progress has been made in identifying the *cis*-acting elements and *trans*-acting factors that are involved in gene regulation in a variety of cell systems. An example of the regulatory region of the human tissue factor promoter is shown in *e*Figure 96.4.2. This figure demonstrates binding sites for some of the most well-studied transcriptional factors in vascular biology, including NFkB, AP-1, and SP-1.



***e*FIGURE 96.4.2** Comparison of the known transcriptional elements in the proximal rat and human tissue factor (TF) promoters. The presumed transcription start site was assigned the number 1. Nucleotides located upstream of the transcription start site were assigned negative numbers, and nucleotides downstream of the start site were assigned positive numbers. The luciferase (Luc) reporter constructs used in *e*Figure 96.4.3 to examine the basal activity of the rat tissue factor promoter are also shown. A, AP-1 site; Egr-1, Egr-1 binding site; N, NFkB site; S, SP-1 site; TATA, TATA box. (From Taby O, Rosenfield C-L, Bogfanov V, et al. Cloning of the rat tissue factor cDNA and promoter: identification of a serum-response region. *Thromb Haemost* 1996;76:697–702, with permission.)



***e*FIGURE 96.4.3** Basal activity of the rat tissue factor (TF) promoter–luciferase constructs. Rat aortic vascular smooth muscle cells were transiently transfected with each of the luciferase constructs shown in eFigure 96.4.2. Luciferase activity was measured and expressed relative to the activity of the longest construct [TF(–426)luc]. Minimal activity was seen for constructs lacking the region between –79 and –103 and in constructs lacking the region between the transcription start site and the luciferase reporter [TF(–120/–14)luc and TF(–120/+14)]. (From Taby O, Rosenfield C-L, Bogfanov V, et al. Cloning of the rat tissue factor cDNA and promoter: identification of a serum-response region. *Thromb Haemost* 1996;76:697–702, with permission.)

The general approach to promoter analysis is to isolate the promoter region and "flanking sequences" (those that contain the putative *cis*-acting elements) from a genomic library. The entire region is then ligated to a "reporter gene," a gene whose product can be easily measured. Among the most common reporters are those that encode the bacterial enzyme, chloramphenicol acetyl transferase (58), or the firefly enzyme, luciferase (59). The activity of these enzymes can be easily measured (60,61) and used to monitor promoter activity. For these studies, the constructs that contain the promoter region and the reporter are ligated into a plasmid vector and transfected into cultured cells. Levels of the reporter gene product are measured and used to assess the rate of transcription of the promoter. Once the level of transcription has been assayed for the entire promoter region, serial deletions can be made in the promoter construct to identify specific areas that contain the *cis*-acting positive and regulatory elements. An example of deletion analysis is shown in eFigure 96.4.3.

The technically straightforward method for promoter analysis involves transient transfections (by any of the methods discussed in the section Functional (Expression) Cloning) of the construct into cultured cells followed by measurement of promoter activity. Although this *in vitro* approach has allowed the identification of regulatory elements in a multitude of genes, the elements that regulate transcription of a particular gene *in vivo* may be quite different, emphasizing the importance of confirming cell culture findings in the intact animal. Most often, this is accomplished by creating transgenic mice with a promoter construct driving expression of the beta-galactosidase gene as a reporter (used because it produces a blue color when the appropriate substrate is added). This approach has been used to identify the elements that are responsible for tissue-specific expression of smooth muscle alpha-actin (62) and to identify sequences responsible for the transcriptional regulation of smooth muscle genes following balloon angioplasty (63).

Protein Identification

A variety of approaches are used to identify proteins. In some cases, functional assays can be used, particularly in the case of specific enzymes. More often, antibodies are used to identify specific proteins.

Immunoprecipitation

For immunoprecipitation, extracts that contain the desired protein are incubated with a specific antibody. An antibody-binding reagent, complexed to beads, is then used to precipitate the complex by centrifugation. Two approaches can be used for quantitation. In the first, the protein is labeled *in vivo* using radiolabeled amino acids. Most commonly, sulfate-35 (S-35)–methionine is used. The labeled material can then be counted using liquid scintillography. To provide maximum specificity, the precipitated complex can be run on a sodium dodecyl sulfate polyacrylamide gel that separates proteins by size in a fashion similar to that described for mRNA. The gel is then subjected to autoradiography. After this, the protein of interest can be verified by its position relative to known-sized markers and the amount of protein assayed either by densitometric analysis of the autoradiogram, by cutting out the band and measuring radioactivity in a scintillation counter, or by the use of a phosphoimager. An example of autoradiography is shown in Figure 96.5.

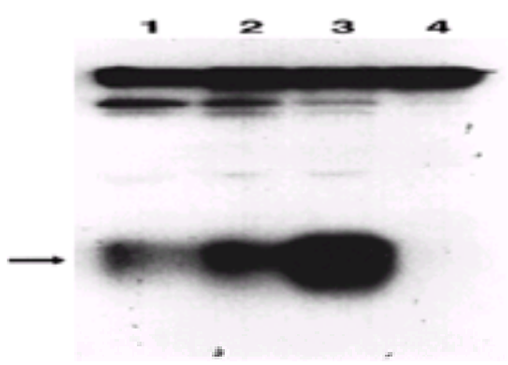


FIGURE 96.5 Immunoprecipitation. VSMC proteins were labeled *in vivo* by incubating cultured cells for 4 hours with sulfate-35–methionine. Protein lysates were isolated from cells that did not receive further treatment (lane 1) and cells labeled in the presence of 1 µM angiotensin II (lane 2) or 20 ng per mL platelet-derived growth factor (PDGF; lanes 3 and 4). Samples were precipitated with anti-JE antiserum (lanes 1–3) and preimmune serum (lane 4) and then analyzed by polyacrylamide gel electrophoresis followed by autoradiography. JE protein (*arrow*) was precipitated by the immune serum and showed elevated levels in cells exposed to angiotensin II or PDGF. [From Taubman M, Rollins B, Poon M, et al. JE mRNA accumulates rapidly after aortic injury and in platelet derived growth factor–stimulated vascular smooth muscle cells. *Circ Res* 1992;70(2),314–325, with permission.]

Western Blot Analysis

An alternative to immunoprecipitation is Western blot analysis (Fig. 96.6). In this technique, the protein extract is first run on a polyacrylamide gel. The proteins in the gel are then transferred to a membrane, and the membrane is incubated with an antibody that is specific for the protein in question. A variety of approaches can then be used to identify the antibody, most often involving the use of a secondary antibody, followed by enzymatic detection (see the section Enzyme-Linked Immunosorbent Assay). Western blot analysis has the same advantage as running immunoprecipitates on gels: It allows for confirmation of the desired protein by comparison with either size markers or by using purified protein as a control. In addition, it does not require prior labeling of the protein. Thus, Western blot analysis can be used to identify proteins in animal models of arterial injury, from cardiac biopsies, or from atherectomy samples.

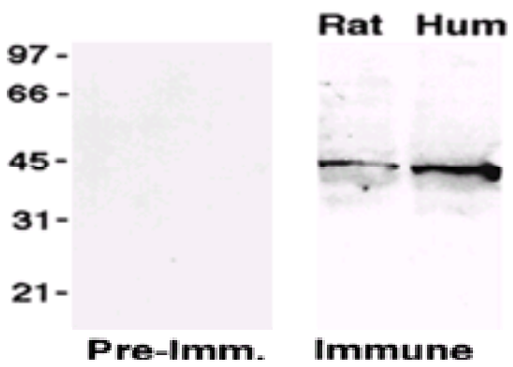

FIGURE 96.6 Western blot analysis. Protein lysates (25 µg per lane) of rat and human cultured vascular smooth muscle cells were loaded onto a 12% polyacrylamide gel. After electrophoresis and transfer to nitrocellulose, the blots were incubated with preimmune rabbit serum (Pre-Imm.) and antiserum against the rat protein SM-20. The blots were washed and then incubated with horseradish peroxidase–conjugated donkey antirabbit antibody. Detection of bound antibody was accomplished by exposing the blots to photographic film immediately after incubation with a chemiluminescent substrate for horseradish peroxidase. (From Wax SD, Tsao L, Lieb ME, et al. SM-20 is a novel 40-kd protein whose expression in the arterial wall is restricted to smooth muscle. *Lab Invest* 1996;74:797–808, with permission.)

Enzyme-Linked Immunosorbent Assay

Several approaches have been used for rapid large-scale quantification of protein. These approaches have been of particular import in clinical laboratories, where large-scale and rapid quantitation is required and very small amounts of protein need to be measured. The most common techniques involve enzyme-linked immunosorbent assay (ELISA). In one approach, samples coat the bottom of 96-well immunosorbent plates. Nonspecific binding is blocked by incubating wells with normal horse serum and albumin. Wells are then rinsed and incubated with specific antibody. The wells are washed and the antibody detected using a variety of enzyme-based procedures. A commonly used method involves incubating with a biotinylated secondary antibody (e.g., horse antimouse or antirabbit immunoglobulin G) followed by avidin-conjugated horseradish peroxidase and then a developing solution that contains the chromogenic substrate *O*-phenylenediamine dihydrochloride. Protein concentrations are determined by comparison of light absorption of the samples to a standard curve that is generated using purified protein. A variety of kits are commercially available, as are automated ELISA readers.

Radioimmunoassay

Radioimmunoassay requires the availability of purified protein and a specific antibody. The purified protein is radiolabeled, usually with iodine-125, and the radiolabeled protein is immunoprecipitated with a specific antibody and counted in a gamma counter. To quantify levels of the target protein from a solution, such as a cell extract, culture medium, or human serum, increasing amounts of the solution are incubated with a fixed amount of iodinated protein. If the solution contains significant amounts of the target protein, it will compete away the radiolabeled protein. A competition curve can be generated and compared to a standard curve made with purified protein. This is a particularly sensitive and reliable means for quantifying protein. Its one potential drawback is the ability of a closely related but not identical protein to compete effectively with the target protein.

Immunohistochemistry

Immunohistochemistry uses antibodies in a fashion analogous to that described for *in situ* hybridization. Specific antibodies can be used to identify proteins in cell culture or in tissue sections. These techniques have been particularly useful for localizing proteins in tissue sections from experimental animal models or human specimens. Like *in situ* hybridization, they are less useful for quantitation. Immunohistochemistry can be used with light microscopy, confocal microscopy, or electron microscopy, the latter allowing for precise cellular localization of proteins. Double- and triple-labeling techniques are available to colocalize proteins. In addition, immunohistochemistry can be performed together with *in situ* hybridization. Examples of immunohistochemistry of cultured cells and tissue are shown in Figure 96.7.

FIGURE 96.7 Immunohistochemistry. **A:** Immunohistochemical detection of tissue factor in cultured vascular smooth muscle cells. **B:** Immunohistochemical detection of the protein SM-20 in a section of an injured rat artery. Strongest immunostaining is seen in the intima (I) but is also seen in the media (M).

MOLECULAR CLONING

In molecular cloning, genetic information from a species or cell type of interest is expanded in bacteria (or other simple hosts) to allow the isolation of DNA containing a single sequence of interest. Foreign DNA is introduced into bacteria most commonly in the form of plasmids (small pieces of circular DNA that replicate within bacteria) or bacteriophage (viruses that infect bacteria). The plasmids or phage that are used have been extensively engineered to facilitate the process of molecular cloning and are referred to as *cloning vectors*.

To begin the process of cloning, known quantities of DNA and of the cloning vector are digested with a restriction endonuclease and joined together by the enzyme DNA ligase. The result is a collection of millions of copies of the vector, each containing a single DNA fragment, referred to as the *insert*. This collection is called a *DNA library*; a high-quality library is one in which all of the DNA sequences that are present in the starting material are represented in the final pool of ligated vector.

If the starting material for the library is genomic DNA, the library is referred to as a *genomic library*. Because each somatic cell in an organism contains a complete copy of the genome, the tissue chosen for generating a genomic library is based on convenience. Genomic libraries contain exons and introns and thus may not provide direct information about the sequence of the mRNA or the protein. They are particularly valuable for isolating the promoter and associated regulatory sequences involved in gene transcription. Most of the information that has been obtained on the regulation of gene transcription has required cloning the regulatory regions from genomic libraries. Fragments that are isolated from genomic libraries are also necessary for generating transgenic animals.

Often, the sequence of interest is the mRNA that encodes a particular protein. In this case, the library is designed to represent the unique set of mRNA species that are expressed in a specific tissue or cell type at the moment of isolation. To allow mRNA sequences to be cloned using the same powerful techniques as genomic DNA, a DNA copy is made of the single-stranded mRNA using the enzymes reverse transcriptase and DNA polymerase. The resulting library is known as a *cDNA library*. The cDNA represents a faithful copy of the mRNA and therefore can be used to determine the sequence of the mRNA and to deduce the sequence of the protein encoded by the mRNA. A high-quality cDNA library contains copies of all of the mRNA transcripts that are present in the starting material; a high proportion of the copies will be full length, and the number of cDNA copies of a particular transcript will be directly proportional to the mRNA transcript's abundance.

Screening Libraries

Once an appropriate library has been constructed, the actual cloning process takes place. In its simplest form this involves "screening the library" with a radioactive probe that has a sequence similar to that of the clone of interest. Briefly, the phage or plasmid library is introduced into bacteria and spread out on agar plates so that the individual clones are physically separated from each other. The bacteria are allowed to grow overnight, greatly amplifying the amount of plasmid or phage DNA that is present in each colony on the plates. The next day, sheets of nitrocellulose filter are briefly layered on top of the plates so that some of the DNA from each colony adheres to the nitrocellulose. The DNA that sticks to the filters is then denatured and "hybridized" by incubation with a solution that contains the radioactive probe. The nitrocellulose filters are washed and then subjected to autoradiography. Hybridizing clones are identified as spots on the autoradiogram and then recovered from the original agar plates by lining up the filters with the plates. The recovered clone is then amplified and spread onto agar plates, and the process is repeated until the clone is purified to homogeneity. The probe can be labeled to allow nonradioactive detection. Alternatively, the probe may be an antibody. In this case, the library can be introduced into bacteria that can express the protein sequences encoded by the cDNA. In cases in which no DNA or antibody probe exists, the cloning process is adapted to screen the library using a functional assay.

Constructing and Screening Complementary DNA Libraries

Although a plethora of cDNA libraries are now commercially available, the methodology for generating these libraries merits discussion. Total RNA is first isolated from the tissue or cell of interest. In the cellular processing of eukaryotic mRNA, long repetitive stretches of the ribonucleotide adenosine are added to the 3' end. To purify this poly A+ mRNA from total RNA in the laboratory, chromatography resins with synthetic oligonucleotides (short stretches of single-stranded DNA or RNA) that are complementary to this poly A tail are used. Single-stranded cDNA is generated using reverse transcriptase and either oligonucleotides to prime the poly A tail of the 3' untranslated end of the molecule or random oligonucleotides that may prime from anywhere along the mRNA, or primers designed for a specific mRNA or class of mRNAs. Double-stranded cDNA is then generated with DNA polymerase. After this, the cDNA is ligated into an appropriate cloning vector, usually derived from bacteriophage lambda. These vectors allow for the cloning of large pieces of cDNA that correspond to the full-length mRNA transcript. The bacteriophage is then used to infect *Escherichia coli* that is grown as lawns on large agar dishes. Infection of the *E. coli* results in plaques that contain large amounts of the bacteriophage bearing the cDNA inserts.

Screening of cDNA libraries is analogous to the techniques used for blot hybridization. Large nitrocellulose filters are placed on the bacterial lawns. DNA from each plaque will stick to the nitrocellulose, which is then lifted from the plates, washed, and baked. The filters can then be hybridized to labeled cDNA, cRNA, or oligonucleotide probes. After washing at appropriate stringencies, hybridizing plaques are identified as round dots after autoradiography on x-ray film. The appropriate plaques are then isolated from the original plate and purified.

When appropriate nucleotide probes do not exist, antibodies can also be used to identify plaques that contain the desired cDNA. To do this, the bacteriophage-infected *E. coli* must be induced to produce the protein that corresponds to the cDNA insert. Specific strains of *E. coli* are available for this procedure. Bacteriophage "expression vectors" contain an inducible promoter, such as the beta-galactosidase promoter, to drive the transcription of the cloned cDNA insert. If the insert contains the protein-coding region and is in the correct reading frame and orientation, induction of the promoter enables the bacteria to synthesize and accumulate large amounts of the protein that is encoded by the cDNA insert. Using procedures similar to those described for hybridization, filters impregnated with material to induce the promoter can be placed on the bacterial lawns and, after lifting, can be incubated with specific antibodies to identify the desired protein. The plaque that produces this protein can then be purified and the cDNA isolated and characterized.

An alternative to using bacterial systems is to generate cDNA libraries in baculovirus and to express them in insect Sf9 cells. Because these cells are more closely related to mammalian cells, they are more likely than simple bacteria to modify the synthesized peptides in ways that are similar to those of mammalian cells (e.g., by attaching sugar molecules) to produce mature proteins that can be recognized by mammalian antibodies.

It should be noted that because cDNA libraries are generated by reverse transcriptase from mRNA, the cDNA inserts represent the relative amounts of mRNA in a particular cell under particular conditions, for example, after treatment with a growth factor. Therefore, libraries that are made from different cells or in response to different treatments contain different cDNAs. The mRNAs expressed in a particular cell usually correspond to only 10% to 20% of the total number of genes.

Constructing and Screening Genomic Libraries

Genomic libraries are generated by isolating total DNA and mechanically or enzymatically disrupting it to generate 8,000 to 100,000 nucleotide fragments and ligating the fragments into bacteriophage vectors, cosmids, or bacterial artificial chromosomes. Genomic libraries from many species are commercially available. Unlike cDNA libraries, because each cell contains the same DNA, a high-quality genomic library generated from any cell type should contain inserts that are representative of all of the genomic material of a particular species. Genomic libraries are usually screened using labeled cDNA probes. In mammals, the genomic inserts contain exons (which encode mRNA) and introns (which are spliced out before the mRNA is generated). Therefore, genomic libraries cannot usually be used for expression cloning. As noted previously, genomic libraries are used for isolating the regulatory regions of genes (not present in the mRNA), for genome sequencing projects, and for generating transgenic animals.

Functional (Expression) Cloning

Many cloning projects involve isolating a cDNA encoding a protein of known function that has not been purified and whose sequence is unknown. Such cDNA cannot be isolated using antibodies (because they do not exist) or nucleotide probes (because the sequence is not known). Several approaches have been used to identify cDNA clones by expressing the protein in mammalian cells or frog (*Xenopus laevis*) oocytes and then assessing protein function. Examples of this have been the cloning of angiotensin II and thrombin receptors.

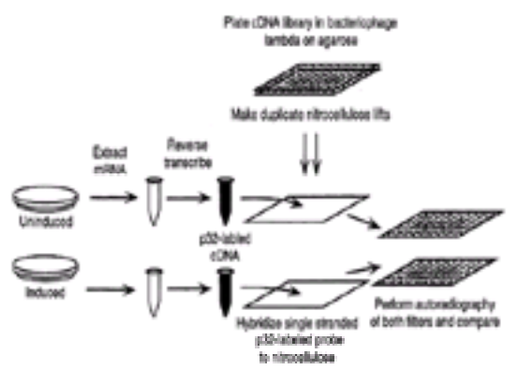
For expression cloning in mammalian cells, cDNA libraries are constructed in plasmid vectors containing a promoter that is active in mammalian cells. Examples of particularly active promoters include those derived from cytomegalovirus, SV40 virus, and adenovirus. The plasmids are then introduced into the mammalian cells by the process that is referred to as *transfection*. Approaches used for transfection include those using calcium phosphate precipitation, cationic liposomes, diethyl aminethyl–dextran, and electroporation. The most widely used cell lines for expression studies have been COS cells, derived from African green monkey kidneys, and Chinese hamster ovary cells. Once transfected, the cells are split into a large number of pools and assayed for the desired function. For example, in the cloning of the angiotensin II receptor, pools of transfected COS cells were assayed for their ability to bind radiolabeled angiotensin II (64). Once a pool was identified, it was split into smaller pools until a single clone of COS cells was isolated that bound radiolabeled angiotensin II. The plasmid was then isolated and the cDNA sequenced.

An alternative to expression cloning in mammalian cells is to use *Xenopus* oocytes. In this procedure, a cDNA library is generated in a plasmid vector, as has been described for mammalian expression studies. mRNA is then transcribed *in vitro* from pools of cDNA and microinjected into the oocytes. Next, oocytes are assayed for the biologic activity of interest. For example, in the cloning of the thrombin receptor (65), oocytes were injected with cRNA generated from pools from a plasmid library and assayed for mobilization of calcium in response to thrombin. Once a positive oocyte was found, the cDNA pool from which the cRNA was synthesized was split into smaller pools until a single cDNA clone was isolated (64,65).

Use of DNA Libraries for Comparing Expression of Multiple Genes

The above strategies all involve screening libraries for "known" genes or genes that encode known proteins or specific functions. A number of strategies have been designed to find novel genes or to identify sets of genes that have been induced by specific circumstances, for example, genes activated by treatment with platelet-derived growth factor or genes induced during muscle differentiation. Technical innovations have made these types of comparisons increasingly robust.

The earliest approach to large-scale comparisons of gene expression was differential screening of cDNA libraries (*e*Fig. 96.7.1). This was an extension of the standard methods described previously for screening libraries by hybridization. A cDNA library was generated from mRNA that was isolated from the cells or tissues of interest. After the library was plated, duplicate nitrocellulose lifts were made from the same bacterial lawn. The duplicate filters were then hybridized to labeled cDNA or cRNA probes made from RNA that was isolated under different conditions and subjected to autoradiography. If the duplicate membranes were nearly identical, a transcript present at high levels in one probe and at low levels in the other probe would be expected to show a corresponding difference of intensity after annealing to its corresponding clone on the two membranes. This somewhat crude technique has largely been supplanted by the use of arrayed libraries (discussed in the section Recent Advances in Molecular Cloning).



***e*FIGURE 96.7.1** Differential screening. Complementary DNA (cDNA) probes generated from cells or tissues grown under two different conditions are used to screen duplicate nitrocellulose lifts from a cDNA library. Hybridizing clones from genes that are more highly expressed under one of the two conditions show a stronger signal

on autoradiography (see text for details). mRNA, messenger RNA.

Subtraction Techniques

A limitation of the differential cloning approach outlined previously is that transcripts present at low levels may be difficult to detect because of their low signal intensity and may also be underrepresented in the cDNA library used for the screening or for the array. An alternative is to use “subtractive” strategies to enrich for differentially expressed genes. Single-stranded cDNA is synthesized from mRNA isolated under the condition in which the genes of interest are presumed to be induced. This cDNA is then hybridized in solution to an excess of mRNA isolated from the uninduced condition. The double-stranded DNA-RNA hybrids are then removed by hydroxyapatite column chromatography. The remaining cDNA should be enriched for transcripts that are present in the induced state. This enriched cDNA can be used either to generate a library for screening or to generate a probe for screening a more conventional cDNA library. This technique was used to identify the myogenic factor MyoD1 by using fibroblast mRNA to subtract cDNA from proliferating myoblasts (66). A variety of novel techniques are commercially available as kits to provide a similar type of enrichment with smaller amounts of starting material.

Differential Display of Messenger RNA

This is a PCR-based method used for identifying differentially expressed mRNAs. The basic strategy for this is to use RT-PCR (described in the section Polymerase Chain Reaction) to produce short cDNA fragments that correspond to every mRNA present. Because of the sensitivity of RT-PCR, even the least abundant mRNAs can theoretically be amplified. The amplified products from mRNA isolated from multiple different conditions can be separated on polyacrylamide gels and compared. Products that appear to be differentially regulated are recovered and sequenced.

Yeast Two-Hybrid System

The yeast two-hybrid system is a sophisticated expression cloning technique designed to identify genes encoding unknown proteins that interact with a protein of interest. The system takes advantage of the yeast protein GAL4, a transcriptional activator. The GAL4 protein has a binding domain that interacts with DNA and an activation domain that initiates transcription. These domains are structurally distinct and do not activate transcription unless they are associated. The yeast two-hybrid system exploits this property by separating the two domains in two different expression plasmids. One plasmid contains DNA encoding the known protein (referred to as the *bait*). The second plasmid contains a cDNA library generated from cells or tissues hypothesized to express proteins that bind to the bait. Both plasmids are introduced into yeast, where they generate “fusion proteins,” one containing the GAL4-binding domain fused to the bait, the others containing the activation domain fused to proteins encoded by the cDNA library. For example, if one wanted to clone genes encoding proteins that bind to the intracellular domain of a particular receptor, one could use DNA encoding the intracellular domain as the bait and generate a cDNA library from cells hypothesized to contain the binding proteins. When these plasmids are cotransfected into yeast, if a fusion protein from the library binds to the bait, the two GAL4 domains are brought together and the complex is able to activate the promoter of a reporter gene. cDNA encoding potential binding proteins is then isolated from yeast colonies that express the reporter gene.

Recent Advances in Molecular Cloning

Automation and new resources associated with the large-scale genome sequencing efforts have dramatically changed the common approach to molecular cloning. A limitation to the library screening approach is that each time the library is spread out onto agar plates, the identity of the millions of randomly dispersed clones is unknown. The only clones that are identified are those that are being specifically probed. In addition, the nitrocellulose filters can only be screened several times before new plates must be generated, creating a new array of millions of isolated colonies. Automation can improve this situation by arraying the library in a known configuration. Individual clones are picked off the plates and transferred to numbered wells on multiwell microtiter plates. The library is now “arrayed” and can be duplicated as many times as needed in this configuration. One way of screening an arrayed library is by having a robot “spot” an aliquot of each clone in an identifiable location on a membrane and then hybridizing the membrane with a labeled probe. Alternatively, the spots can be placed in a microscopic array for hybridization and detection using one of the microarray (“gene chip”) technologies. In either case, the location of the hybridizing signal tells the investigator which well of the microtiter plate contains the clone of interest. Taking this one step further, the array can be constructed entirely of sequenced clones so that after identifying the location on the membrane by hybridization, the investigator can immediately have access to information about the clone’s identity. When screening commercially available membranes (or microarrays), it is unnecessary for an investigator to actually possess the library—the individual clones of interest can be obtained from the vendor after their location is identified by screening.

In theory, hybridizing a gene array with a probe derived from the mRNA of a specific tissue identifies all of the arrayed genes that are actively expressed in the tissue. Thus, hybridizing duplicate arrays with probes derived from normal and diseased tissues can identify genes that are regulated in pathologic conditions. For example, a DNA array containing 6,000 genes was used to identify genes activated in a transgenic mouse model of lethal cardiomyopathy (67). Hybridization of identical arrays with probes derived from different tissues is essentially a modern version of the differential cloning strategy discussed previously except that now the identity of the clones has been established beforehand and there is no limit on the number of conditions that can be compared (other than the expense associated with acquiring the arrays).

Two types of resources generated through the publicly funded genome projects are particularly useful and, in many cases, can make the traditional techniques for molecular cloning unnecessary. The first applies to genomic cloning and the second to cDNA cloning. Each of the genome projects generates a library of overlapping, large genomic clones that are used in the sequencing process. In the early stages of a genome project, arrayed membranes produced from these libraries are usually available commercially. As the project progresses, vast amounts of sequence information from the individual clones is deposited in the public databases and is freely accessible via the Internet. By the time the genome project is completed, genomic library screening can be effectively accomplished “*in silico*” by searching the databases for the sequence of interest. If the actual genomic material is needed (e.g., for a promoter analysis or making a transgenic animal), a phone call or e-mail can replace the actual cloning process. The second resources are the expressed sequence tag libraries. These are cDNA libraries from a wide variety of tissues that are being systematically arrayed. Each clone is partially sequenced, and the sequence is deposited in the public databases. After an expressed sequence tag of interest is identified through a search of the public database, the actual clones can be obtained from a number of vendors. Certainly, these resources are evolving too rapidly for any printed source of information to be current. The National Center for Biotechnology Information maintains the public sequence databases in the United States, and its website is an excellent source of further information (http://www.ncbi.nlm.nih.gov/).

MOLECULAR METHODS FOR ALTERING GENE EXPRESSION

A major approach for studying protein function is to either overexpress a protein that is normally not present at high levels in a particular cell type or to decrease the expression of the protein. Many of the techniques are similar to those described previously, and studies that use these techniques are described in detail in subsequent chapters.

Overexpression in Cell Culture

The basic strategies are similar to those described in expression cloning. Plasmid vectors are constructed containing promoters that are active in mammalian cells. The cDNA that encodes the protein to be overexpressed is then ligated into the vector, and the vector is transfected into the cells. Two types of promoters are used. Constitutive promoters, such as the cytomegalovirus promoter, are always active and thus continually generate large amounts of the target protein. Inducible promoters, such as the metallothionein or mouse mammary tumor virus promoter, are relatively inactive until the cells are treated with specific inducers, such as divalent cations or glucocorticoids, respectively. The plasmids are introduced into the cells using a variety of techniques, including transfection with calcium phosphate, DEAE-dextran, cationic liposomes, or electroporation. A second approach is to use viral vectors, such as retroviruses or adenoviruses. These “infections” have higher efficiencies of DNA transfer into cells than transfections. Expression can either be transient or stable. In the latter, transfections or infections are performed with vectors that contain a selectable marker, such as neomycin or hygromycin resistance, and stable clones are isolated in the presence of high levels of the appropriate antibiotic. Stable overexpressing lines can be used to generate high levels of recombinant proteins for a variety of studies.

Overexpression in Animals

Two general approaches have been used to overexpress proteins in animals. The first mimics cell culture and requires the introduction of expression vectors into animals. Like cell culture, these studies can use transfections with liposomes or, more typically, viral vectors. A particular target for such work has been the arterial wall, where DNA can be introduced locally using catheters. Plasmids have also been injected directly into cardiac muscle, to overexpress proteins and to perform *in vivo* promoter analyses.

The second approach to overexpression uses transgenic animals. In this technique, a gene that encodes a desired protein is injected into embryos at the earliest stages of development. Animals that incorporate the gene into their germline transmit it to their offspring. The gene's product is expressed by the "transgenic" animal during development and at maturation. For such studies, the choice of promoters is critical. Nonspecific promoters drive the expression of the gene in virtually all types of cells and tissues. However, many tissue-specific promoters exist that target expression to a particular organ. For example, the cardiac myosin heavy-chain promoter directs expression largely to the heart. In this way, one can overexpress a particular protein in heart muscle.

Underexpression in Cell Culture

The inhibition of specific protein expression is more problematic than overexpression, although many of the techniques are analogous. One approach is to transfect or infect cells with plasmids that contain cDNA in the antisense orientation. On transcription, antisense mRNA is produced that specifically binds to the normal ("sense") mRNA. The double-stranded RNA either remains as a stable complex, unable to be translated into protein, or is rapidly degraded. An example of this approach was the generation of smooth muscle cell lines with abnormal adhesion properties because of decreased expression of the matrix protein, osteopontin (68). The technique depends on generating levels of antisense mRNA that are significantly in excess of the normal sense mRNA. It often results in decreased levels of specific protein synthesis but does not completely inhibit synthesis of the target protein. Such studies usually require stable transfections to analyze the results of protein inhibition adequately and to provide an environment in which all of the cells display lower levels of the target protein.

The use of antisense oligonucleotides has provided an important alternative to transfection of antisense cDNAs. These small fragments can bind to the target mRNA, destabilizing the mRNA or preventing it from binding to the ribosome and being translated. Antisense oligonucleotides may also affect transcription by binding to nuclear DNA. The advantage of this approach is that oligonucleotides can be easily synthesized and are taken up by cells in culture with much higher efficiency than large plasmids. Therefore, they can be used in transient transfection studies. Oligonucleotides can also be used in animal models and have been used extensively in attempts to inhibit gene expression in the arterial wall, where they can be delivered by catheters or by absorption from the adventitial surface. One concern about the use of antisense oligonucleotides is nonspecific effects that are unrelated to their binding to mRNA and the potential for more than one species of mRNA to be inhibited. Nevertheless, the use of antisense oligonucleotides, particularly in cell culture, has provided many insights into the importance of specific proteins in a variety of cell processes.

Alternatives to antisense oligonucleotides are ribozymes, RNA molecules with enzymatic activity (see reference 69 for review). Like protein enzymes, ribozymes cleave RNA at specific sites. However, because of the ability of RNA to form complementary base pairs with other RNA, ribozymes can be synthesized to cleave a particular mRNA species. Ideally, this cleavage is catalytic, thereby allowing a small number of ribozyme molecules to cleave, and thus inactivate, a large number of mRNA molecules. In most cases, ribozymes are believed to act catalytically as well as like antisense oligonucleotides. Ribozymes are usually synthesized in the form of their corresponding cDNAs and introduced into cells via plasmids. Their uptake into cells thus follows the same rules as those of transfection or infection of vectors that contain sense or antisense cDNAs. Like other antisense strategies, ribozymes can often decrease levels of protein synthesis but do not fully "knock out" gene expression.

Underexpression in Animals

As noted previously, antisense oligonucleotides have been used to reduce gene expression in animal models. However, the most effective way to inhibit gene expression is to generate transgenic animals in which the gene of interest has been knocked out (reviewed in reference 70). In this approach, the gene is first isolated from a genomic library. It is then altered to produce a nonfunctioning gene, usually through the introduction of a premature stop codon, resulting in a truncated nonfunctioning protein. The gene, coupled to a selectable marker, is then introduced into embryonic stem (ES) cells; by the process of "homologous recombination," a small number of stem cells replace their native gene with the genetically altered one. This process of recombination is not significantly different from that which occurs in nature during meiosis, leading to genetic variation and sometimes serious abnormalities. By growing cells in the selection medium, the appropriate ES cells can be isolated. These are then used to generate mosaic animals whose germ cells contain one chromosome that lacks a functioning gene. After mating, these animals transmit the targeted allele to their offspring, who then are heterozygous for the targeted allele. By crossing these heterozygotes, one can generate mice that are homozygous for the nonfunctioning gene. The generation of knockout mice has produced a revolution in molecular biology, in that it has created hundreds of different animals that lack a specific gene product. Unlike all of the previously mentioned approaches, these animals can potentially be completely deficient in the target gene. In addition, one set of knockout mice can be bred with another to examine the interactions between two specific gene products. Although current work has used mice (because of the ease of generating mouse ES cells and of injecting mouse oocytes), knockout strategies are now being applied to other mammals as well and offer great promise for examining gene expression *in vivo*.

Disrupting a gene by homologous recombination in the manner described removes the gene from all tissues throughout the entire life of the organism. Knocking out a gene that is required at an early stage of development is likely to cause lethality at the earliest point in development that its protein product is required, eliminating the opportunity to determine the protein's function in tissues that appear at later points in development. To circumvent this problem and to allow the function of a gene to be examined in a specific tissue, conditional knockouts can be generated using the Cre/lox site-specific recombination system (reviewed in reference 71). In this technique, a gene encoding the site-specific recombinase "Cre" is attached to a promoter that drives expression in the tissue to be studied and is introduced into a mouse by transgenic techniques. Another mouse, in which the gene to be disrupted is flanked by specific recognition sequences for the recombinase ("lox" sites), is generated by homologous recombination in ES cells. The mice are crossed to produce offspring that carry the Cre recombinase transgene and the targeted gene (flanked by lox sites). When the tissue-specific promoter is turned on during development, the recombinase is expressed and causes the gene between the two lox sites to be efficiently removed. The resulting animal is a genetic mosaic in which the majority of cells that express the Cre recombinase are missing the targeted gene.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Mouse Models of Cardiovascular Disease

The powerful techniques for targeted gene disruption that have been described are critical to contemporary biomedical research. Because knockout mice have phenotypes that closely resemble a number of human cardiovascular diseases, they are widely used as models. This is particularly true of mice with targeted disruptions of genes involved in lipoprotein metabolism that develop arterial lesions very similar to those seen in human arteriosclerosis. Despite the utility of these powerful models, there are several theoretical and practical considerations that should be kept in mind.

When targeting a gene by homologous recombination, there is an assumption that targeting will result in specific loss of the gene's product and will not directly affect the expression of other genes. Although the loss of the gene's product can be verified, the upregulation of another gene in the vicinity of the targeting can occur (72) and may readily escape detection. Such upregulation could have an important effect on the observed phenotype. In addition, the genetic background of the mice may have a profound effect on the observed phenotype. A particularly striking example is the vast difference in the extent of atherosclerosis observed in apolipoprotein E knockout mice based on their genetic background (73). To circumvent these concerns, one would ideally disrupt a gene using several different targeting strategies and then test the mutants to see if they are allelic (or use a transgene to "rescue" the mutant phenotype). The resultant knockouts could then be crossed onto several different genetic backgrounds. However, the time and expense of generating a mouse knockout are considerable, and seldom are different knockouts intentionally made for the same gene. Where they exist, subtle differences in the mutant phenotypes are not uncommon.

The standard approach to gene targeting by homologous recombination involves targeting the gene of interest in ES cells derived from one mouse strain and then transferring the targeted allele into a specific inbred strain by mating. Multiple rounds of backcrossing the targeted allele into the inbred strain are repeated until (after more than ten generations) the resulting mice are considered to be *congenic*, meaning identical to the inbred strain at all loci except for the targeted allele. Although the initial generations of targeted animals may be useful as experimental subjects, background genetic heterogeneity is high, and littermates must be used as controls. From a practical viewpoint, the investigator must be able to genotype the animals readily and to maintain a large enough colony of animals to ensure that adequate numbers with each genotype are available. In congenic strains the genetic background is uniform, but it is important to recognize that this "identity" is transient. Carrying a deleterious mutation in the homozygous state for multiple generations will favor the accumulation of new mutations over time that will tend to mitigate the severity of the mutant phenotype. Thus, even when using congenic strains, the "cleanest" experiment from a genetic perspective is one in which the homozygotes have had minimal opportunity for genetic drift from the control animals.

Gene Expression and Molecular Cloning

A major focus of cardiovascular research (and of this chapter) is the analysis of gene expression in normal and diseased tissues and the cloning of individual genes. Until recently, technical constraints limited most studies to the examination of only a few genes at a time. In the "postgenome era," there has been a shift toward performing far more comprehensive analysis of arrays that may include thousands of genes at one time. When studying such large sets of genes, each experiment produces a wealth of information that is then subjected to computational analysis. In previous investigations that focused on a single gene at a time, there was a natural tendency to study those genes that demonstrated the greatest difference in expression among conditions. In the large data sets generated by array screening, large numbers of genes with relatively modest degrees of regulation will be identified. If these robust analyses are to live up to their full promise, a major challenge for investigators will be to identify the underlying patterns and biologic significance of these more subtle forms of gene regulation. The rapidly developing field of

proteomics should help provide rapid ways of determining whether subtle changes in mRNA are translated into important changes in protein levels and activity. Undoubtedly, exciting new approaches will be developed to combine experimental and computational biology.

THE FUTURE

The complete sequencing of the human genome is a critical milestone in the history of molecular biology, not only for the wealth of information that it provides but as a stunning example of how high-throughput techniques can be used to tackle basic problems in biology. As these technologies continue to evolve, the same trends toward miniaturization, increased speed, and decreased cost that are seen in other industries can be anticipated in molecular biology. The ability to characterize gene expression extensively in progressively smaller samples will permit wider application of these techniques to clinical medicine, further narrowing the gap between the clinical and basic sciences.

OVERVIEW

Finding the gene(s) for a disease is considered a breakthrough discovery because it defines the genetic pathway and molecular basis underlying the pathogenesis of the disease and raises hopes that knowledge of the disease-causing genes and their functions may soon lead to accurate genetic testing, effective therapy, and prevention or cure for the disease. Identification and characterization of disease-causing genes is the central theme in the field of human molecular genetics. It usually starts with definition of the chromosomal location (disease locus) of a disease gene by cytogenetic analysis or gene mapping studies. Genes located within that chromosomal region can then be identified or cloned and become candidate genes for the disease. Mutation analysis of the candidate genes is then performed. Identification of disease-causing mutations in one of the genes implicates that gene in the disorder. Functional characterization of the mutations using transgenic/knockout mouse technology as well as biochemical, cell biologic, and molecular biologic studies can reveal pathogenic mechanisms underlying the disorder. The use of DNA microarrays and other related new technologies to determine genome-wide expression profiling of a disease offers a new avenue for identification of disease genes and is providing a wealth of new information for diagnosis and ultimate prevention or cure of cardiovascular disease.

GLOSSARY

Bioinformatics: Computational molecular biology.

Contig: A stretch of overlapping genomic clones such as yeast artificial chromosomes (YACs), bacterial artificial chromosomes (BACs), and cosmids that provide a continuous representation of a genetic locus or a genomic region defined by markers, sequence tagged sites (STSs), or genes.

Embryonic stem cells: The preimplanted embryo-derived pluripotent cells that maintain an unlimited differentiation potential and normal karyotype during the cell culture.

Expressed sequence tag (EST): A partial single-pass sequence from either end of a cDNA clone.

Functional cloning: A technique used for cloning human disease genes based on the availability of information on the target gene and its corresponding protein product.

Genome: All of the genes in an organism.

Genotype: Genetic makeup of an individual, often at a single locus.

GRAIL: Gene Recognition and Analysis–Internet Link software used to predict genes embedded in genomic DNA sequence.

Heterogeneity: If diseases or other phenotypes have multiple causal factors, they are considered heterogeneous. Allelic or intragenic heterogeneity refers to different genotypes at the same genetic locus that cause a similar phenotype. Locus heterogeneity refers to a situation in which a disease is caused by defects at different genetic loci.

Linkage analysis: Analysis to determine whether alleles at two or more genetic loci (usually a disease locus and one or more marker loci) are cosegregating within a pedigree.

Pedigree: Illustration of the relationships among family members.

Penetrance: Probability that a genotype will yield the predicted phenotype.

Phenotype: An observable biochemical, cellular, or clinical characteristic that is associated with the expression of a gene.

Polymorphisms: If there are at least two identifiable alternative gene forms (alleles) at a locus and none with frequency greater than 0.99, the locus is considered polymorphic. Commonly, any allele with a population frequency greater than 0.01 is termed a *polymorphism*. Any allele with a population frequency less than 0.01 is often called a *mutation*.

Positional cloning: A technique used to identify the underlying genetic cause of a disease based primarily on finding the location of the defective gene.

Segregation analysis: Analysis to determine the most likely genetic model for an observed trait in a pedigree: autosomal dominant, autosomal recessive, X-linked, or polygenic.

Sequence tagged site: A unique site in the genome defined by two oligonucleotide primers for polymerase chain reaction. STSs have become the common currency of physical mapping.

Simple tandem repeat markers: Polymorphic microsatellite markers that are ideal for genotyping and linkage studies. Simple tandem repeat markers can be dinucleotide, trinucleotide, or tetranucleotide repeats. Simple tandem repeat markers are widely and evenly distributed across the human genome and can be typed using polymerase chain reaction amplification.

Single nucleotide polymorphisms (SNPs): SNPs are single nucleotide changes or substitutions that are highly abundant and are perceived as the basis for the high-density genetic marker maps required for unraveling complex genetic traits.

Transcriptome: A set of genes that are expressed or transcribed from genomic DNA.

INTRODUCTION

Genetic factors have long been recognized to contribute to human phenotypes and disease. As the incidence of nutritional and infectious diseases markedly decreases, there has been an increasing awareness of the role of genes in the pathogenesis of human disease. Some human diseases, such as long QT syndrome and hypertrophic cardiomyopathy, are strongly determined by genes. Other diseases, such as infectious diseases, are strongly determined by nongenetic or environmental factors, although it is now realized that host defense protein factors encoded by genes play an important role in susceptibility to infection (1). Many of the most prevalent diseases, such as coronary artery disease, hypertension, diabetes mellitus, and cancer, are determined in varying degrees by both genetic and environmental factors. Therefore, all diseases are to some extent genetic.

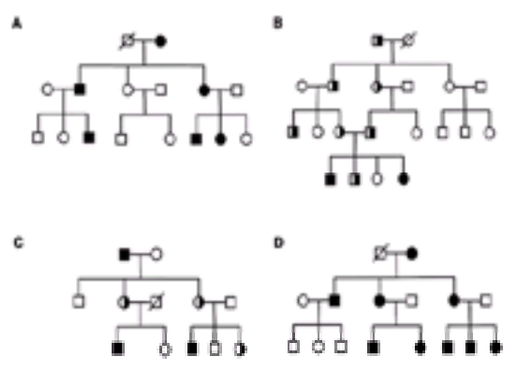
Advances in human molecular genetics, coupled with exponential growth in genomic research, have led to the development of a variety of technologies for identification of human disease genes. Positional cloning, a primary tool used for finding disease genes, has become far easier over the years. Newly developed DNA microarray technology offers a new alternative for identification of disease genes. Transgenic and knockout mice and other technologies have been developed to assess how a mutation in a given gene affects the function of the protein product and so defines the functional role of a novel gene. The new discipline of bioinformatics, or functional genomics, has become an important tool for the rapid computer-based screening of DNA and protein databases, identification of novel genes from genomic DNA sequences, and the prediction of gene function. The purpose of this chapter is to review the theory and practice of these key molecular genetic technologies.

MAJOR TYPES OF GENETIC DISEASES

Genetically determined diseases can be broadly classified into four groups: chromosomal disorders, single gene disorders, polygenic or multifactorial diseases, and mitochondrial disorders (2).

Chromosomal disorders are the result of deletions, duplications, or other alterations of entire chromosomes or large segments of them. These disorders include Down syndrome and DiGeorge syndrome.

Single gene disorders are caused by single mutant genes. Human diseases caused by single genes are inherited in a simple mendelian fashion and are often referred to as *mendelian disorders*. More than 4,000 mendelian disorders are now known that are inherited in autosomal dominant, autosomal recessive, or X-linked fashion (eFig. 97.0.1). The characteristics of autosomal dominant inheritance include vertical transmission of the disease phenotype, a lack of skipped generations, and approximately equal numbers of affected male and female subjects. Father-to-son transmission may be observed, which is a feature that can be used to exclude X-linked inheritance. Autosomal recessive inheritance is characterized by clustering of affected individuals in the same generation, absence of disease among parents of the affected, and approximately equal numbers of affected male and female subjects. Consanguinity is often a factor in recessive diseases. A major distinction between dominant and recessive disorders is that heterozygotes are clinically affected in most cases of dominant diseases, whereas they are clinically normal in the case of recessive disorders.



***e*FIGURE 97.0.1** Inheritance patterns of genetic disease. **A:** Autosomal dominant inheritance. **B:** Autosomal recessive inheritance. **C:** X-linked recessive inheritance. **D:** Mitochondrial inheritance. Affected individuals are shown as filled circles (female subjects) or squares (male subjects), and unaffected individuals as empty symbols. Heterozygous carriers in **B** and **C** are shown as half-filled symbols.

The first human gene to be mapped was the color blindness gene, deduced to be on the X chromosome by the distinct features of X-linked inheritance. In a pedigree with X-linked recessive inheritance, father-to-son transmission is absent; affected individuals are more frequently of the male gender; and the disease phenotype skips generations when genes are passed through female carriers. Approximately 50% of sons from the female carrier with a mutant X chromosome develop the disease phenotype.

Polygenic or multifactorial diseases such as coronary artery disease, heart failure, and hypertension result from the joint action of multiple genes and environmental factors. They are the most common human genetic diseases and pose a major challenge to contemporary human geneticists owing to their complex nature in which additive, interactive, or both effects of many genes and environmental factors create predisposition to the disease.

Mitochondrial diseases are caused by mutations on the mitochondrial genome. This group of diseases is inherited in a maternal fashion [i.e., only affected female subjects can transmit the disease mutation (phenotype) to their offspring] (eFig. 97.0.1).

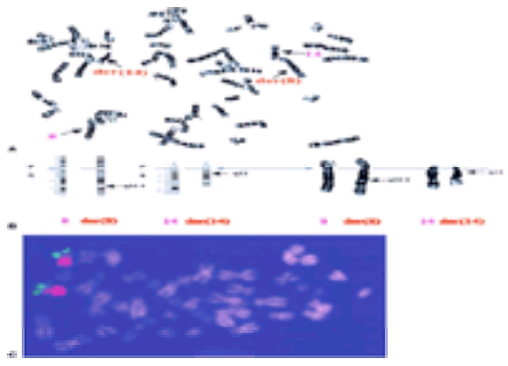
All the diseases discussed previously are associated with genetic abnormalities in the DNA of all cells in the body and can be transmitted to future generations. However, a new paradigm of diseases called *somatic cell genetic disorders* caused by mutations in specific somatic cells has been recognized. Examples of such diseases include cancer and some vascular disorders.

CYTOGENETICS IN GENETIC RESEARCH AND MOLECULAR DIAGNOSTICS

Chromosomal (or cytogenetic) abnormalities account for at least 50% of spontaneous abortions or miscarriages and cause congenital malformations, mental disability, infertility, and certain cancers (3). Chromosomal abnormalities involving one chromosome include a deletion or duplication of a portion of a chromosome, a pericentric (involving the centromere) inversion or paracentric (not involving the centromere) inversion, or the formation of a ring chromosome or isochromosome. When two or more chromosomes are involved, a translocation or exchange of chromosomal materials between the chromosomes occurs. The chromosomal abnormalities associated with cardiovascular disease include Down syndrome, DiGeorge syndrome or velocardiofacial syndrome, congenital heart defects, and Williams syndrome.

Karyotype Analysis

Karyotyping from peripheral blood is a standard technique used for examining human chromosomes and for identifying chromosomal abnormalities (4). A small amount of anticoagulated blood is centrifuged to isolate white blood cells, to which are added tissue culture medium containing plant lectins such as phytohemagglutinin to stimulate them to divide. The dividing cells are then arrested at metaphase with mitotic spindle inhibitors such as colchicine and lysed in hypotonic buffers to prepare metaphase chromosomes. Preparations of metaphase chromosomes are then stained with dyes such as Giemsa (G-banding) and examined under a microscope. G-banding involves a series of acid, heat, or gentle trypsin treatment of chromosome preparations followed by staining with Giemsa. The alternation of chromosomal regions with high or low G/C content results in a pattern of light and dark bands that is unique for each human chromosome (*e*Fig. 97.0.2A). The unique pattern for each human chromosome allows the unequivocal definition of each chromosome, and any deviations from this typical pattern may indicate occurrence of chromosomal abnormalities (*e*Fig. 97.0.2B). Other chromosome banding techniques producing quinacrine (Q) bands, reverse (R), or centromeric (C) bands can be used to examine special chromosomal domains.



***e*FIGURE 97.0.2** Examples of karyotype analysis **(A,B)** and fluorescence *in situ* hybridization analysis **(C)**. **A:** A metaphase spread prepared from blood samples of a patient with Klippel-Trenaunay syndrome and stained by Giemsa banding. A translocation involving chromosomes 8 and 14 (*arrows*) was identified. **B:** Translocation t(8;14)(q22.3;q13) with centromeres at the solid line and breakpoints marked. Ideograms of normal chromosomes 8 and 14 and derivative chromosomes 8 and 14 are shown at the left, and G-banded chromosomes are shown at the right. **C:** Fluorescence *in situ* hybridization analysis to map the human myotrophin gene to chromosome 7q36. The painting probe (*red*) is for the short arm (p) of chromosome 7. The signals from the test probe, a bacterial artificial chromosome containing the myotrophin gene, are in green. (**A** and **B**, unpublished data from Azita Sadgephour and Qing Wang; **C**, unpublished data from Ayse Anil Timur and Qing Wang.)

Fluorescence *In Situ* Hybridization

Fluorescence *in situ* hybridization (FISH) technology is a major tool for gene mapping and for identifying chromosomal abnormalities (5,6). In FISH analysis, DNA probes (any cloned DNA sequences, genes, microdissected fragments, or flow-sorted chromosomes) are labeled by incorporation of chemically modified nucleotides (e.g., BrdU) that fluoresce directly or can be labeled by incorporation of reporter molecules (e.g., DIG or Biotin). The DNA probes are then hybridized to metaphase or interphase chromosomes. Chromosomes are then counterstained with 4,6-diamino-2-phenyliodole (DAPI) to provide high-definition banding of the chromosomes, and hybridization signals are detected by binding a fluorescently tagged molecule to reporter molecules (e.g., anti-DIG-FITC). Chromosomes are then photographed under a fluorescence microscope (*e*Fig. 97.0.2C). FISH can allow rapid mapping of any gene or DNA sequence cloned into cosmids, BACs, or YACs to a particular chromosome (*e*Fig. 97.0.2C). FISH can also be used to detect numerical chromosomal abnormalities, including the small deletions involved in DiGeorge syndrome and supravalvular aortic stenosis and Williams syndrome.

Advances in FISH technology include chromosome painting, which allows the entire chromosome to fluoresce with the chosen color (*e*Fig. 97.0.2C), and multicolor FISH, which allows each human chromosome to be painted in up to 12 different colors (5). Both chromosome painting and multicolor FISH can be used to identify complex chromosomal rearrangements or abnormalities rapidly.

In conclusion, both karyotype analysis and FISH are powerful technologies that can be implemented in many research and diagnostic fields of human genetics.

OVERVIEW OF STRATEGIES FOR DISEASE GENE DISCOVERY

Functional Cloning

Until the mid-1980s, the primary approach to identify the gene responsible for a human disease was through careful analysis of biochemical and physiologic differences between healthy and affected individuals. The deficient protein or enzyme from patients can be purified, and partial amino acid sequences can be obtained or antibodies against the protein can be raised. The antibodies, degenerate oligonucleotides derived from the partial amino acid sequences, or tagged fusion proteins, can then be used to screen various cDNA libraries to identify the disease gene. The approach moving from the basic biochemical defect to the disease gene is referred to as *functional cloning*. Sickle cell anemia caused by mutations in the hemoglobin gene was the first human disease characterized by human molecular genetics. Initially, red blood cells from affected individuals were noticed to be abnormally shaped. Later, it was found that hemoglobin from patients was electrophoretically different from normal hemoglobin, and this difference was due to the substitution of valine for glutamic acid at the sixth amino acid position of the beta chain of hemoglobin (7). Subsequently, the gene for beta-hemoglobin was cloned and the mutation of a single base substitution of A to T was identified at the nucleic acid level (8). However, the genetic etiology of most diseases cannot be tackled using functional cloning due to lack of information on biochemical defects.

Candidate Gene Approach

With the candidate gene approach, potential known candidate genes for a disease are chosen based on the assumption of physiologic mechanisms of the disease and are assessed using mutation analysis to verify the candidacy of the gene. The candidate gene approach was used to establish that mutations in the cardiac sodium channel gene *SCN5A* cause idiopathic ventricular fibrillation with right bundle branch block and ST-segment elevation (known as *Brugada syndrome*) (9).

POSITIONAL CLONING

The development of genetic markers, together with the availability of efficient and accessible statistical methods for analyzing the segregation of markers and disease genes, made it possible to locate and clone the gene responsible for a human disease solely on its map position, without any prior knowledge of the function of its protein product. This approach is referred to as *positional cloning* (originally referred to as *reverse genetics*) (10). The first disease gene cloned by positional cloning was chronic granulomatous disease in 1986 (11) (*e*Table 97.0.1). By 1989, positional cloning had led to cloning of only four disease genes. A similar approach was used to clone *KvLQT1* on chromosome 11p15.5 that causes long QT syndrome (12). By 1998, more than 100 disease genes had been cloned by positional cloning (*e*Table 97.0.1). Although positional cloning has become much easier, it is still a difficult and time-consuming approach.

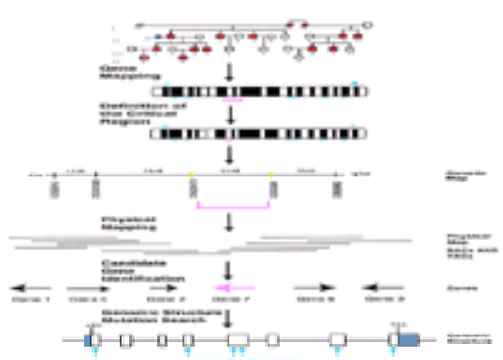
[a] Based on information from http://genome.nhgri.nih.gov/clone/. Genes identified by a (positional) candidate gene approach are excluded.

The overall strategy for positional cloning is illustrated in eFigure 97.0.3. Positional cloning includes five major steps: gene mapping, definition of the critical region, physical mapping, identification of candidate genes, and mutation analysis. Each step is discussed in detail later in this chapter.



***e*FIGURE 97.0.3** Positional cloning. The five major steps are shown schematically. BAC, bacterial artificial chromosomes; YAC, yeast artificial chromosomes.

Positional Candidate Gene Approach

This approach is a shortcut to positional cloning. When a disease gene is mapped by linkage analysis or cytogenetic abnormalities, known genes located near the disease gene become candidate genes for the disease. Mutation analysis is then used to verify the candidacy of each gene. The positional candidate gene approach was used to identify the chromosome 7–linked long QT gene (*HERG*) and the chromosome 3–linked long QT gene (*SCN5A*) (13,14 and 15). The completion of the Human Genome Project will make the positional candidate gene approach the predominant method to identify disease genes in the coming decade.

Genetic Mapping

The first step in positional cloning is to determine the map position of the disease gene of interest by linkage analysis (*e*Table 97.0.2). Occasionally, a cytogenetic abnormality associated with the disease can provide the first clue. However, increasingly, disease genes are mapped by performing genome-wide linkage analysis.

***e*TABLE 97.0.2** STRATEGIES FOR MAPPING DISEASE GENES

Strategy	Disease
Model-based linkage analysis	Single gene disease (e.g., long QT syndrome, dilated cardiomyopathy)
Model-free linkage analysis	Complex genetic disease (e.g., coronary artery disease, hypertension)
Variance component linkage analysis	Polygenic disease (e.g., coronary artery disease, hypertension)
Cytogenetic abnormalities (chromosomal breakpoints)	Single gene disease

Linkage is the location of two loci sufficiently close together on a pair of homologous chromosomes that they do not segregate independently. Linkage occurs because alleles on the same chromosome at loci that are close to each other tend to be transmitted together. Consider two diallelic loci, one with alleles *A* and *a*, the other with alleles *B* and *b*. Suppose a person inherited *A* and *B* from one parent and *a* and *b* from the other parent. We denote the person's genotype *AB/ab*, where the slash separates the two parental contributions. If this person transmits a gamete with haplotype *Ab* or *aB*, a recombination has occurred. The proportion of gametes in which a recombination has occurred, q, is known as the *recombination fraction* between the two loci. The four different haplotypes that a person with genotype *AB/ab* can transmit, together with their probabilities, are given in eTable 97.0.3. If q = 1/2, these four probabilities are each equal to 1/4, and the alleles at the two loci segregate independently.

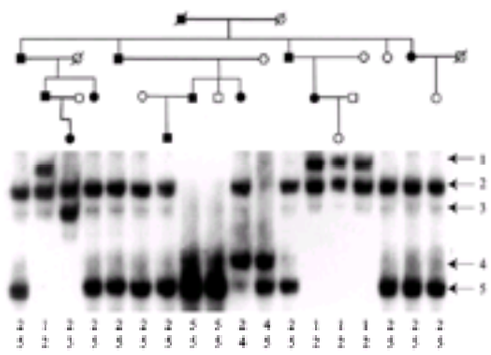
***e*TABLE 97.0.3** THE FOUR POSSIBLE GAMETES, AND THEIR PROBABILITIES, TRANSMITTED BY A PERSON WITH GENOTYPE AB/AB

Gamete	Probability
AB	1/2(1–q)
Ab	1/2q
aB	1/2q
ab	1/2(1–q)

Linkage leads to an intrafamilial association between the two phenotypes determined by the genotypes at the two loci. Furthermore, unless the two loci are so close together that recombination has not destroyed the association formed between them at the time a mutant allele first appeared at one of the loci, the two phenotypes are not associated in a random sample of unrelated persons from the population. It is difficult to conceive of any environmental factor that could simulate the typical result of genetic linkage between the two traits: lack of association at the population level, but association within families. This is especially the case if one of the two traits is known to be genetically determined. For this reason, evidence of linkage between a known genetic marker and a putative gene for a disease is usually taken to be the "ultimate" statistical evidence for the existence of that disease gene.

Markers

A genetic marker is a polymorphic trait that is genetically determined in a simple mendelian manner. The first markers were the blood cell antigens, red cell antigens such as the ABO and Rhesus blood groups and the HLA white cell antigens. About 40 years ago, enzyme polymorphisms were discovered that could be determined as bands on electrophoresis. In 1980 (16) the era of DNA polymorphisms began. At first, the DNA polymorphisms were restriction fragment length polymorphisms, but these were soon followed by variable number tandem repeat polymorphisms and short tandem repeat polymorphisms, or microsatellites (*e*Fig. 97.0.4), easily typed by use of the polymerase chain reaction (PCR). The newest markers are diallelic SNPs.



***e*FIGURE 97.0.4** Genotyping analysis using a simple tandem repeat marker. The pedigree is shown above, and the actual results of genotyping are shown below. Each of the alleles (1 to 5) for this simple tandem repeat or microsatellite marker carries a different number of copies for the simple repeated sequence, GATA. The marker was amplified using polymerase chain reaction as described (13), and products were separated by electrophoresing through 6% denaturing polyacrylamide. Each family member has two alleles at this locus, which are scored as 2/5, 1/2, 2/3, and so on.

Genetic Map

To use linkage analysis to place trait genes on the genome, we need a genetic map, a linearly arranged set of loci with known distances between them. Whereas a physical map gives the distances between loci in physical units (numbers of base pairs), a genetic map gives the distances in genetic units. At the beginning of meiosis, the pairs of homologous chromosomes line up alongside each other, and each chromosome duplicates into two identical sister strands, or chromatids. At this stage, crossing over between nonsister chromatids occurs at one or more points along the chromosome; crossing over is a reciprocal event resulting in each of two chromatids switching their DNA from being maternal to paternal in origin, or vice versa. It follows that a recombination occurs whenever there is an odd number of crossovers between the two loci on a particular gamete. The genetic map distance is measured in Morgans: 1 Morgan is the distance in which we expect exactly one crossover event to occur. The unit usually used is the centiMorgan (cM) (i.e., one-hundredth of a Morgan). Between loci that are separated by a small distance, only 0 or 1 crossover can occur; it follows that map distance and the recombination fraction are then the same. For loci that are far apart, the distance between them in centiMorgans will be larger than the recombination fraction expressed as a percentage, because only an odd number of crossovers leads to recombination between the two loci. The recombination fraction depends on the sex and other characteristics of the transmitting parent; on average, the human autosomal genome is approximately 3,600 cM long (17), and so approximately 180 markers are required to span it at 20-cM intervals.

Methods of Linkage Analysis

There are two main types of linkage analyses, model-based and model-free (18). Every statistical analysis requires a probability model to make inferences, and in both types of analyses the marker's mode of inheritance is specified. The terms *model-based* and *model-free*, when used to describe linkage analysis, refer specifically to the trait one is trying to map. In model-based analysis, the genetic model for the mode of inheritance of the trait must be completely specified, whereas in model-free linkage analysis, it does not have to be specified. We focus first on classical model-based linkage analysis. This is often called *parametric*, or *lod score*, linkage analysis, but these terms are equally applicable to model-free linkage analysis.

Model-Based Linkage Analysis

Given the trait and marker modes of inheritance, one can calculate the likelihood for a particular set of pedigree data that have been randomly sampled from a population. In general, to do this we need to specify (a) founder genotypic frequencies, (b) transmission probabilities, and (c) penetrance functions.

The founders of a pedigree are those members who have neither parent in the pedigree, and it is usually assumed that their genotypes are sampled at random from a particular population. If we consider two alleles at each of two loci, say *A* and *a* at one locus and *B* and *b* at the other locus, then four haplotypes, those indicated in eTable 97.0.3, are possible. When these are paired, they give rise to (5 × 4)/2 = 10 distinct unordered pairs that can be called *diplotypes*. eTable 97.0.4 shows what are often called the nine two-locus genotypes formed by two-diallelic loci, but genetically the double heterozygote *AaBb* corresponds to two different genotypes: *AB/ab* and *Ab/aB*. These are different two-locus genotypes, but they are often called the two phases of the same two-locus genotype. Use of the word *diplotype* (which unfortunately is not yet in common usage) avoids the ambiguity that often occurs whenever the term *multilocus genotype* is used.

***e*TABLE 97.0.4** THE NINE GENOTYPES AT TWO DIALLELIC LOCI, CORRESPONDING TO TEN TWO-LOCUS GENOTYPES, OR DIPLOTYPES

Genotypes at the first locus	Genotypes at the second locus		
	BB	*Bb*	*bb*
AA	*AABB*	*AABb*	*AAbb*
Aa	*AaBB*	*AaBb*	*Aabb*
aa	*aaBB*	*aaBb*	*aabb*

Unless all founder diplotypes are known, their relative frequencies in the population must be specified. It is usually assumed that the genotype frequencies at each locus are in Hardy-Weinberg equilibrium proportions, that the genotype distributions at the two loci are independent, and that each phase is equally frequent in the population.

The transmission probabilities (19) determine, conditional on the genotypes of their parents, the genotype probabilities of all nonfounders (i.e., of those individuals who have both parents in the pedigree). Transmission is usually assumed to be mendelian at each locus individually. The transmission of haplotypes from each double

heterozygote diplotype depends on the recombination fraction. The transmission probabilities from the double heterozygote *AB/ab* are the probabilities listed in *e*Table 97.0.3. Those from the double heterozygote *Ab/aB* are the same except that 1 – q replaces q.

Each penetrance function is a probability distribution, the distribution of phenotype given a particular genotype. In model-based linkage analysis we usually assume

P(trait phenotype, marker phenotype | diplotype) = P(trait phenotype | trait genotype) P(marker phenotype | marker genotype)

The second factor is usually assumed to be 0 or 1 for all phenotypes and genotypes, corresponding to a marker whose alleles are all codominant and at which there are no genotyping errors. The first factor is taken to follow a model estimated by segregation analysis or guessed, and, except as noted in the following discussion, is assumed to be known without error.

Calculation of Likelihoods and Lods

In terms of the three kinds of probability functions just described, the probability of observing the phenotypes Y on pedigree members can be expressed as a function of the recombination fraction q. This probability is calculated for various values of q, and each resulting probability is divided by the probability that results when we set q = 1/2. The ratio of these two probabilities, considered as a function of the unknown recombination fraction q, is a likelihood ratio. The logarithm to base 10 of the likelihood ratio is called a lod (20), or lod score, and is denoted *Z(q)*. The calculation of the likelihood ratio usually requires a computer. The value of q that maximizes Z(q), $\hat{\theta}$, is the maximum likelihood estimate of the recombination function, and Z($\hat{\theta}$) is the maximum lod.

Interpretation of Lods

Traditionally, when a single recombination fraction is estimated, a maximum lod Z($\hat{\theta}$) greater than or equal to 3 has been taken to be good evidence for linkage, whereas Z($\hat{\theta}$) less than or equal to –2 has been taken to exclude linkage within a recombination fraction of q (21). If there is no linkage, P(Z($\hat{\theta}$) ³3) £10^{-3}, so 10^{-3} is an upper bound for the probability of type I error, or *p* value. Furthermore, as the number of informative meioses becomes large, the corresponding *p* value becomes equal to 10^{-4}. The original reason for requiring a lod greater than or equal to 3 (in large samples equivalent to *p* £10^{-4}) before concluding that a linkage exists was to control to approximately 5%, not the probability of a type I error when there is *no* linkage (the null hypothesis), but rather the *posterior* probability of type I error when concluding that there *is* linkage (21). This follows from the fact that two loci picked randomly from the genome have a small prior probability, approximately 1/20, of being linked. It has been argued that this is an unsatisfactory assumption in the case of a complex trait for which the very existence of genetic involvement may be in doubt. Lander and Kruglyak (22) have therefore advocated a somewhat more stringent criterion, reasoning that, because we are testing for linkage at all locations along the genome when performing multipoint linkage analysis (i.e., using the information from multiple markers spread out over each chromosome), we must allow for the multiple tests being performed. However, they state that this same more stringent criterion should be met whether a part or whole genome scan is actually performed. This is illogical, if the reason for the criterion is based on a need to correct for multiple testing, for then the criterion should depend on how many tests are performed. Morton (23) has pointed out that the very fact that a linkage study is being performed indicates that one has a prior belief that a gene must be involved and that the criterion for accepting linkage must logically depend on how many data are available, which determines the power of the analysis.

When more than one parameter is estimated, it is common to derive the (larger) lod that then corresponds in large samples to a *p* value of 10^{-4} and require that the observed lod be this large to have good evidence for linkage.

Robustness

When using model-based linkage analysis, errors in the assumed trait model (the number of loci involved, the number of alleles at each locus, the allele frequencies, and the penetrances) can lead to inconsistent estimates, invalid tests, or lack of power. Furthermore, the pedigree data analyzed are not usually obtained by randomly sampling pedigrees, and in general the appropriate likelihood depends on the mode of ascertainment of the families in the study. However, provided any assumption errors concern only one of the variables involved, trait *or* marker, the results will be validity robust (i.e., the probability of coming to an erroneous conclusion when the null hypothesis of no linkage is true will not be inflated; and by the same token, lod scores do not depend on the mode of ascertainment if ascertainment is through only one of the variates, trait *or* marker) (24,25). Furthermore, in the case of a rare disease, the disease allele frequency assumed in the analysis, provided it is less than 0.01, is not critical; and provided all founder genotypes are known without error (or can be deduced without error from their relatives), the likelihood ratios, and hence also the lods, do not depend on the marker allele frequencies assumed for the analysis.

Model-Free Linkage Analysis

If a trait locus is linked to a marker locus, relatives such as siblings who have similar trait phenotypes tend to have similar marker phenotypes, whereas relatives who have dissimilar trait phenotypes tend to have dissimilar marker phenotypes. All methods of model-free linkage analysis test for a correlation between two such measures of similarity among relatives, because in the absence of linkage there is no reason for such a correlation to exist. The relatives may be chosen to be similar (e.g., they may all have a particular disease), in which case the test is to determine whether their marker phenotypes are more similar than expected by chance; they may be chosen to be dissimilar (e.g., discordant sibling pairs), in which case the test is to determine whether their marker phenotypes are less similar than expected by chance; or they may be chosen to include both these types, in which case we test whether their degree of similarity or dissimilarity is correlated with their marker similarity or dissimilarity. The most powerful of such tests measure marker similarity in terms of identity by descent (ibd). Two alleles at a marker locus are ibd if they are copies of the same ancestral allele. In a random sample from a random mating population, unrelated persons share no alleles ibd, parent–offspring pairs share one allele ibd, and monozygotic twins share two alleles ibd, at every autosomal locus.

The earliest model-free method of linkage analysis based on marker ibd is that of Haseman and Elston (1972) (26). In this method, the probabilities that two siblings share zero, one, or two alleles ibd at a marker are calculated, using parental marker information, population marker allele frequencies, or both, if how many alleles they share ibd cannot be determined exactly. The proportion of marker alleles each sib pair shares ibd is estimated as the probability they share two alleles ibd plus one-half the probability they share one allele ibd. Then the sib pair squared trait difference is linearly regressed on this estimate, $\hat{\pi}_j$ for the *j*th sib pair. A significantly negative regression coefficient is taken as evidence for linkage. If markers spanning the whole genome have been typed, ibd sharing can be calculated in a multipoint fashion and a test performed at every point in the genome (27).

In the case of a dichotomous disease trait, most of the information often comes from affected sib pairs. This has led to a sampling design in which only affected sib pairs are collected and model-free methods of affected sib pair analysis used. (It should be noted that the same sample can undergo model-based linkage analysis, but the term *affected sib pair analysis* is usually used to denote model-free methods). This design is analogous to performing an experiment without controls, which in this case would be discordant sib pairs. Especially when parental genotypes are not known, a comparison between affected sib pairs and discordant pairs is advisable because the estimates of marker allele sharing are then dependent on the marker allele frequencies, which may be only poorly known, and are assumed in the analysis.

Another type of model-free linkage analysis, which may be thought of as a hybrid between model-based and model-free analysis, is variance component linkage analysis. This method is model-free in that it does not require one to specify the allele frequencies and penetrance functions at the trait locus, but a model is built in which the trait variance is decomposed into components due to individual marker locations and residual polygenic and environmental components. In particular, the trait covariance between a pair of relatives is modeled, assuming multivariate normality of the trait across family members, as a function of locus-specific trait variance components. In this type of analysis the assumption of multivariate normality can be critical if the resulting lods are to be interpreted in large samples as *p* values (28). Elston et al. (29) have proposed changing the Haseman-Elston regression procedure in a manner that makes it analogous to the usual variance component method of linkage analysis in that it models the sib covariance, rather than the squared sib-pair difference; but the fact that it is done by linear regression makes it much less dependent on any assumption of normality.

Finally, it should be pointed out all methods of linkage analysis depend critically on correct knowledge of the relationships among the pedigree members whose data are being analyzed. When the results of a whole genome marker scan are available, it is possible to detect, for example, unrelated persons or half-sibs who have been misclassified as full sibs (30).

DEFINITION OF THE CRITICAL REGION

After an initial linkage is obtained, multiple new markers in the region of interest are genotyped to assign the target gene to a critical interval by identifying two flanking genetic markers. The flanking markers are markers at either side of the critical interval (region) that demonstrate recombination events with the disease phenotype. In genetically homogeneous populations, the critical region for a disease gene can be narrowed with the study of linkage disequilibrium (LD) (i.e., the identification of a specific haplotype segregating with the disease in affected individuals). For diseases with cytogenetic abnormalities, the landmarks of the critical region for the target disease gene are chromosome breakpoints. The chromosome breakpoints can be defined using FISH analysis or somatic hybrid analysis, thus providing the precise

location of the disease gene.

PHYSICAL MAPPING

After the critical region for a disease gene is narrowed to the order of 2 cM or less, the next critical step in positional cloning is the characterization and cloning of large segments of human DNA from the critical region in specialized vectors such as the YAC cloning system (31) and the BAC system (32). This is achieved by the construction of an overlapping series of genomic YAC and BAC clones (a clone contig) across the critical region. YACs contain DNA inserts up to 1 Mb and are the best currently available tool for cloning large genomic regions. For many chromosomes, large uninterrupted YAC contigs with few gaps have been constructed, and the YAC contig information is available from http://www-genome.wi.mit.edu/. The relevant YAC clones can be purchased from commercial suppliers such as Research Genetics or Incyte, Inc. The YAC system is an excellent tool to construct physical maps and YAC contigs provide a framework on which to map other sequences or candidate genes. However, owing to difficulty in isolating and purifying YAC DNA and the chimerical nature of most YAC clones, YAC contigs are not ideal for identifying all genes across the critical region. Therefore, the YAC contigs are usually converted into BAC/PAC/P1 or cosmids contigs. The cloning capacity for the bacteriophage P1 system, the PAC system, the BAC system, and cosmid are 70 to 100 kb, 60 to 300 kb, 120 to 300 kb, and 40 kb, respectively (31,32,33 and 34). The high-density STSs on the YAC contigs can be used to screen BAC, PAC, P1, or cosmid libraries that are commercially available.

Identification of Candidate Genes (General Techniques)

Based on the high-resolution physical maps, novel genes in the region can be identified using several strategies. The principles of each gene identification method are discussed here. The technical details can be found in *Current Protocols in Human Genetics* (34a).

Exon Trapping

The exon-trapping technique was used to identify the chromosome 11–linked long QT gene, *KVLQT1* (12). Exon trapping relies on functional sequences required for RNA splicing and flank exon-coding sequences (35,36). Cloned genomic DNA fragments in BACs, PACs, P1s, or cosmids are ligated into a plasmid vector that contains consensus-splicing sequences. If the genomic fragment insert ligated in the vector contains an exon, then the exon can be spliced properly into the mature mRNA after expression in mammalian cells in culture. Trapped exons can then be amplified by reverse transcription PCR with primers flanking the consensus splice sites and used to screen cDNA libraries to identify the full-length cDNA corresponding to the new gene.

Complementary DNA Selection

The cDNA selection method captures cDNA sequences directly on the basis of their hybridization to target genomic DNA (37). The cDNA molecules are amplified from a cDNA library and hybridized to biotinylated genomic DNAs (YACs, BACs, PACs, P1s, cosmids) after suppression of repeated sequences. The cDNAs are then captured using streptavidin-coated magnetic beads. The cDNAs that specifically hybridize to genomic DNAs are then eluted and amplified by PCR; this process is repeated two or three times before cloning the selected cDNAs and sequencing them. This method is dependent on the choice of cDNA sources and the predicted pattern of expression of the target gene.

Cloning CpG Islands

The CpG islands are the GC-rich regions in the genome that are usually located at the 5' end of genes, somewhere around the first exon, and act as signposts for the 5' end of genes (38). Thus, finding CpG islands can lead to identification of novel genes. The CpG islands can be identified by analyzing results from digestion of genomic clones with restriction endonucleases recognizing CG sequences for clustering of CpG-rich sites.

Testing for Cross-Species Conservation

The rationale for cross-species conservation is that protein-coding sequences (genes) rather than intronic sequences are conserved to varying degrees across species (39). The evolutionary conservation of DNA fragments can be identified by hybridizing radioactively labeled DNA fragments from genomic clones to Southern blot filters containing genomic DNA from multiple species (“zoo” blot). If a DNA fragment demonstrates cross-hybridizing bands in several distantly related species, it may indicate that the DNA fragment contains coding sequences.

Identifying Expressed Sequence Tags

ESTs are partial, single-pass sequences from either end of clones (representing individual genes) that are randomly selected from cDNA libraries. Extensive databases of ESTs exist for finding ESTs or genes mapped to a disease locus (http://www.ncbi.nlm.nih.gov/UniGene; http://corba.ebi.ac.uk/RHdb/species/HUMAN/gm99.html). The National Center for Biotechnology Information also provides a map viewer that provides displays of the human genome sequence data and the location of genes, STSs, and SNPs on finished and draft sequences (http://www.ncbi.nlm.nih.gov/). ESTs located within the disease locus are then characterized as candidate genes for the disease.

Direct Screening of Complementary DNA Libraries

Screening cDNA libraries is the final step required to identify the corresponding genes and to obtain the full-length cDNA for most gene identification strategies. Screening cDNA libraries can also be used as a direct approach to find novel genes from genomic DNA fragments. DNA inserts in genomic clones such as BACs, PACs, P1s, and cosmids can be radioactively labeled and hybridized directly to cDNA libraries blotted on nylon filters after suppression of repetitive sequences. Positive cDNA colonies are then picked up and sequenced to find the novel genes.

Strategies for Sequence-Based Gene Discovery and Mapping (Bioinformatics)

Genomic sequencing, coupled with bioinformatics that allows for faster and more accurate recognition of coding sequences in long stretches of genomic DNA sequences, is becoming the ultimate gene identification method. Advances in automation and robotics for faster and cheaper long-range sequencing have made it possible to sequence the genomic clones (YACs, BACs, or cosmids) isolated from the critical disease region. Moreover, a “working draft” of sequences covering 90% of the human genome has been determined and is freely available to the community via the Internet. Thus, a significant number of sequencing data for the critical disease gene region may be already available or obtainable quickly. All sequence data from a project can be used to explore the GenBank or other databases (discussed in the next section) for new genes with bioinformatics tools.

Databases

Entrez ties together several linked databases (http://www.ncbi.nlm.nih.gov/):

- Nucleotide sequence database (GenBank): National Center for Biotechnology Information maintains and updates GenBank, a comprehensive repository of sequence data and associated annotation. GenBank contains sequences from GenBank, European Molecular Biology Laboratory Data Library, and DNA Database of Japan.
- PubMed database: The biomedical literature (PubMed) contains bibliographic information and journal abstracts indexed from more than 4,300 biomedical journals.
- Protein sequence database.
- Structure: A database for three-dimensional macromolecular structures.
- Genome: The genomes of over 800 organisms, both completely sequenced organisms and those for which sequencing is in progress.
- PopSet: A set of DNA sequences that have been collected to analyze the evolutionary relatedness of a population.
- Taxonomy: The names of all organisms that are represented in the genetic databases with at least one nucleotide or protein sequence.
- Online Mendelian Inheritance in Man database: A catalog of human genes and genetic disorders.

Information on the human genetic map (primer sequences, chromosomal locations, PCR profiles of polymorphic markers) and the physical map (contigs, YACs, BACs, genes, STSs, ESTs) can be obtained at the following locations: http://www.gdb.org//; http://www.genlink.wustl.edu/genethon_frame/; http://www.genethon.fr/genethon_en.html; http://www-genome.wi.mit.edu/; http://research.marshfieldclinic.org/genetics/; http://www.chlc.org/; and http://www.sanger.ac.uk/.

Bioinformatics Tools

Bioinformatics (computational molecular biology) has become a major research tool to identify and characterize genes implicated in human diseases. Putative genes in stretches of raw genomic DNA sequences can be identified by two primary approaches: homology-based methods [searching for related sequences in GenBank using computational programs such as Basic Local Alignment Search Tool (BLAST)] and feature-recognition methods [finding regions with protein-coding potential using tools such as Gene Recognition and Analysis–Internet Link (GRAIL)].

Homology-Based Methods (Basic Local Alignment Search Tool)

Database sequence similarity searching has become a valuable research tool for all molecular biologists and can be accomplished with the BLAST programs (40,41). In brief, users can access the National Center for Biotechnology Information Web page, click “BLAST” to open the program, input a nucleotide or amino acid query sequence, and search a nucleotide or amino acid sequence database. The program returns a list of sequences that are identical or homologous to the query sequence. The BLAST programs consist of BLASTP, BLASTN, BLASTX, TBLASTN, and TBLASTX, which differ on the query sequence and database sequence (*e*Table 97.0.5).

***e*TABLE 97.0.5** BASIC LOCAL ALIGNMENT SEARCH TOOL PROGRAMS

Program	Query sequence	Database sequence
BLASTP	Protein	Protein
BLASTN	Nucleotide (both strands)	Nucleotide
BLASTX	Nucleotide (six-frame translation)	Protein
TBLASTN	Protein	Nucleotide (six-frame translation)
TBLASTX	Nucleotide (six-frame translation)	Nucleotide (six-frame translation)

BLAST, Basic Local Alignment Search Tool.

If input is a genomic DNA sequence, and returned sequence hits are ESTs, other mRNA sequences, or protein sequence motifs or profiles, it suggests that the genomic DNA sequence contains the new gene(s) and the EST hits highlight the location of exons.

Feature-Recognition Methods (Gene Prediction)

Computer programs have been developed to predict and identify a DNA sequence that is likely to encode a protein by identifying patterns that exist in protein coding DNA sequences such as splice-donor and splice-acceptor junctions. The GRAIL software package is the most widely used system for recognizing portions of a sequence that have the potential to encode a protein (42). Besides GRAIL, a number of other programs have been developed. All these programs are available as stand-alone programs or via e-mail or the World Wide Web listed here, and instructions for using them are easily accessible via the Internet.

- GRAIL: http://compbio.ornl.gov/tools/index.shtml
- GeneID: http://www1.imim.es/geneid.html
- GeneParser: http://beagle.colorado.edu/~eesnyder/GeneParser.html
- FGENEH: http://genomic.sanger.ac.uk/gf/gf.shtml
- GENSCAN: http://genes.mit.edu/GENSCAN.html
- MZEF: http://www.cshl.org/genefinder
- PROCRUSTES: http://www-hto.usc.edu/software/procrustes

DNA sequences predicted to encode proteins are further characterized using Northern analysis or reverse transcription PCR to verify whether they are true protein-coding sequences. If positive, the DNA sequences are used as probes to screen cDNA libraries to isolate the full-length cDNA.

Sequence Motifs and Profiles

Sequence motifs or profiles are derived from the statistical analysis of amino acid residue conservation in aligned families of sequences with a particular biologic function. Identification of sequence motifs is usually indicative of the potential function of proteins encoded by novel genes. The sequence motifs can be identified by using a target sequence to query key databases providing collections of motifs such as BLOCK (http://www.blocks.fhcrc.org/), PROSITE (http://www.expasy.ch/prosite/), PRINTS (http://www.bioinf.man.ac.uk/dbbrowser/PRINTS), PFAM (http://www.sanger.ac.uk/Pfam), and TRANSFAC (http://transfac.gbf.de/TRANSFAC/).

Mutation Detection

Once a candidate gene has been identified, mutational analysis is performed to determine whether this gene, when mutated, causes a mutant phenotype or disease state. The presence of multiple mutations in the same gene in different families or patients is generally accepted as evidence that the mutant gene causes the disease. This section discusses types of mutations and several methods for detecting mutations.

Overview of Mutations

A *mutation* is defined as a change in DNA sequence. Mutations can occur in germline cells (germline mutations) or somatic cells (somatic mutations). Some mutations alter the number or structure of chromosomes. These major chromosomal abnormalities, such as aneuploidy, deletions, duplications, inversions, and translocations, have been discussed earlier. Here we list mutations that are not microscopically observable and affect single genes.

1. Base pair substitutions may or may not result in amino acid changes. Base pair substitutions can be divided into missense mutations that result in a change in a single amino acid, and nonsense mutations that produce a stop codon.
2. Deletions or insertions of one or more base pairs can result in extra or missing amino acids as well as frameshift mutations when the number of missing or extra base pairs is not three.
3. Mutations can occur in promoters (promoter mutations), enhancers (enhancer mutations), or intron-exon boundaries (splice site mutations or splicing mutations).
4. Trinucleotide repeat expansions have been shown to cause anticipation (earlier age of onset, more severe expression, or both in more recent generations of a pedigree) in some genetic diseases such as Huntington’s disease, myotonic dystrophy, and fragile X syndrome (43).

Methods for Detecting Mutations

Many techniques have been developed to detect or identify mutations (*e*Table 97.0.6). Here we discuss only a few of the most commonly used techniques.

***e*TABLE 97.0.6** TECHNIQUES FOR DETECTING MUTATIONS

Category (mechanisms)	Method	Reference
Gel electrophoresis mobility alteration techniques	Single strand conformation polymorphism analysis	44
	Denaturing gradient gel electrophoresis	93
	Heteroduplex analysis	45
	Restriction enzyme fingerprinting	94
	ddNTP fingerprinting	95
	Southern analysis	93
	Constant denaturant gel electrophoresis	96
Sequencing techniques	Direct sequence analysis of uncloned polymerase chain reaction products	—
	Sequence analysis of cloned polymerase chain reaction products	—
Mismatch cleavage/recognition techniques	RNAse A cleavage	93
	Chemical mismatch cleavage	93
	Bacteriophage T4 endonuclease VII cleavage	97
	MutY cleavage	98
	Mismatch repair detection	99
Cytogenetic techniques	Fluorescence *in situ* hybridization	93

High-performance liquid chromatography	Transgenomic WAVE DNA fragment analysis	47
DNA chip–based techniques	Oligonucleotide microarray hybridization	46
Protein truncation technique	Protein truncation analysis	100

Fluorescence *In Situ* Hybridization

Large deletions or insertions (greater than 300 kb) can be detected by the use of FISH analysis. FISH is particularly useful for detecting aneuploidy, deletions, duplication, complex arrangements, or loss of heterozygosity.

Southern Blot Hybridization or Restriction Fragment Length Polymorphism Analysis

Large deletions or insertions can be identified by the presence of junction fragments. Point mutations, microdeletions, or insertions (less than 300 bp) can be identified by altered restriction sites.

Single-Strand Conformation Polymorphism Analysis

Single-strand conformation polymorphism is the most commonly used method for identifying mutations. The single-strand conformation polymorphism method relies on the fact that single-strand DNA in solution, under certain conditions, has a defined secondary structure (44). This secondary structure can be altered when one of the bases is changed; the alteration in secondary structure can be detected by electrophoresis in nondenaturing polyacrylamide gels because normal and mutant strands have different mobilities (9,12,13,14 and 15).

Heteroduplex Analysis

Heteroduplex analysis relies on the fact that heteroduplex molecules, hybrids between wild-type and mutant DNA fragments, may show differential mobility from homoduplexes through polyacrylamide (45) or other gel matrices such as MDE (BioWhittaker Molecular Applications).

Sequencing Methods

PCR products used to be cloned into a bacterial vector, and multiple clones were then sequenced from each individual. Development of cycle sequencing eliminates the cloning step and makes it possible to directly sequence uncloned PCR products. Direct sequencing of uncloned PCR fragments has become a common technique for searching for mutations in candidate genes.

DNA Chips

DNA chips are high-density arrays of oligonucleotides. The labeled test DNA probe is hybridized to one or more DNA chips. Mutant and wild-type oligonucleotides may show differential intensity of hybridization to the test DNA (46). The DNA chip method is ideal for genetic diagnosis to detect known mutations in new patients.

Transgenomic WAVE DNA Fragment Analysis System

The Transgenomic WAVE System is a rapid and automated scanning method to detect mutations. It separates heteroduplexes from homoduplexes using denaturing high-performance liquid chromatography (47). The running time per sample in the Transgenomic WAVE System is short (approximately 10 minutes), and the method is automated; thus, the potential to analyze many samples rapidly is high. Although the Transgenomic WAVE System can be used to identify novel mutations, it is best suited for genetic diagnosis to detect known mutations in new patients.

GENE IDENTIFICATION FOR COMPLEX DISEASE

Many of the genes causing mendelian diseases have been identified, but genetics has yet to make a significant impact on common multifactorial disorders such as coronary artery disease, hypertension, and heart failure. It is thought that the availability of highly polymorphic markers and dense linkage maps will enable genetics to identify the constituent genes of complex diseases on the basis of their genomic locations. Once linkage analysis has identified these locations, the genetic dissection of a complex disease can be accomplished with one of the following approaches.

Association Studies (Case-Control Studies)

In association studies, affected individuals (cases) and matched controls are genotyped at test loci, and the resultant genotypes are analyzed. An allele is associated with the disease if it occurs in a collection of patients with a frequency significantly higher than that in a control population. If the disease-associated allele is within the coding sequence or promoter region and affects the physiologic function and expression of the coded protein, it may directly cause susceptibility to the disease. However, it is equally possible that the association occurs because of LD between the marker locus and the disease susceptibility locus. In this case, further studies are required to identify the susceptible gene near the marker. Until now, population-based association studies have been limited to a few candidate genes with disease. Associations can also occur because of population stratification and confounding, and care must be taken to avoid such ‘‘spurious’’ associations.

Linkage Disequilibrium Mapping Using Single Nucleotide Polymorphisms

On average, sequence variants occur every 1,000 bp in the human genome (48). Approximately 90% of sequence variants are single-base substitutions, referred to as *SNPs* (49,50). SNPs that occur within genes or in regulatory elements may affect the function or expression of a gene, which in turn may be responsible for disease susceptibility or drug response. Construction of human SNP maps is currently under way. The SNP Consortium Ltd. has identified and mapped more than 100,000 SNPs (http://snp.cshl.org/) and aims to expand the number to 300,000 at the beginning of 2001. High-throughput genotyping technologies (e.g., Affymetrix microarrays) have been developed for SNP genotyping. The advantages of SNPs have attracted attention for their use in whole-genome LD analysis to map common disease genes (50). The primary objective of LD analysis is to use a dense map of SNPs to detect association between an SNP and disease. If the disease-associated SNP identified is a functional variant, it becomes a mutation causing susceptibility to disease. Otherwise, the disease-associated SNP acts as a marker that allows mapping of a disease-susceptible gene. Positional cloning focusing on the disease-susceptible region can then lead to identification of the causative gene, a situation analogous to the use of linkage analysis to identify disease-related genes in families. Computer simulations (but not empirical evidence) have predicted that LD is unlikely to extend beyond 3 kb in the general human population, and approximately 500,000 SNPs will be required for whole-genome LD analysis. Because many types of LD analyses merely detect association, which is then assumed to be due to LD, they leave open the possibility of spurious results.

PHARMACOGENOMICS

The genetic study of drug response is referred to as *pharmacogenomics*. It is a newly developed field, and its principal objective is to understand the genetic basis of patients’ responses to medicines so that treatments can be targeted to those most likely to benefit.

SNPs that occur within genes or in regulatory regions may affect the function or expression of the gene. These functional SNPs may be responsible for the genetic component of phenotypic variables, including drug response. A major goal of pharmacogenetics is to identify the functional SNPs and then to determine how a specific allele contributes to patients’ responses to medicines (50). Novel drug target candidate genes can also be identified using transcriptome and proteome analysis (51). In summary, pharmacogenomics aims to identify multiple susceptible genes that are involved in determining a patient’s response to a given drug. These studies will eventually allow physicians to determine a patient’s likely response to a medicine before it is prescribed.

Gene Chip Technology and DNA Arrays (Transcriptional Profiling)

One of the most powerful and versatile tools developed for functional genomics is the high-density DNA or oligonucleotide arrays or gene chip technology. As previously mentioned, DNA arrays can be used both to perform mutational analysis and also to measure levels of gene expression (mRNA abundance). In this section, we focus on this latter use. A set of genes expressed or transcribed from genomic DNA is referred to as the *transcriptome* (52), the expression profile or transcriptional profile. Transcriptional profiling allows massively parallel analysis of gene expression. Here we use a study on heart failure using oligonucleotide arrays to demonstrate the principles and applications of this approach.

The basic premise for using this type of high-throughput approach to measure changes in gene expression is that each protein within the cell functions as part of an extended network with other proteins (i.e., each protein is part of a “functional module”) (53). It is rare that a particular cell function can be ascribed to a single molecule; much more likely, a functional effect is due to a collection of proteins that make up a functional group. Thus, to truly understand the complex changes in gene expression that occur during development of heart failure, we need to measure the expression of a large number of genes, and then cluster the results into functional gene families (54). The benefits of this approach have been succinctly stated by Weinstein (1998) (55): “We will have to understand our favorite biological molecule in the context of many thousands of others . . . a wide net must be cast to be sure that we have, in fact, found the important ones. . . .”

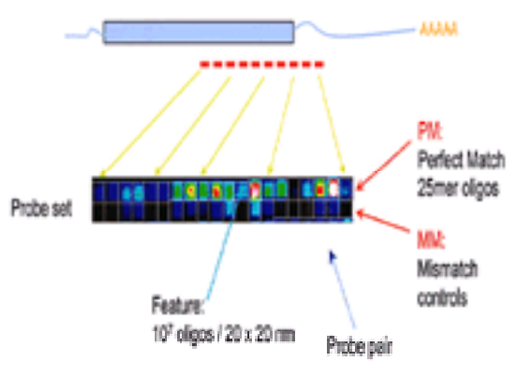
High-Throughput Methods of Gene Expression Analysis

With the working draft of the human genome now complete, the rate at which we identify new human genes is rapidly accelerating. Out of a total of approximately 30,000 to 40,000 genes predicted to make up the human genome, more than 12,000 full-length human genes (open reading frames) have already been sequenced. Partial DNA sequences of many more thousands of genes are represented by ESTs. As a result of the rapid increase in our knowledge of the repertoire of human genes, we now have the unprecedented opportunity to analyze the expression levels of thousands of genes by high-throughput gene-profiling technologies. These approaches permit an unbiased assessment (i.e., no preselection of genes is required) of expression levels of thousands of full-length genes, ESTs, or both. By simultaneously measuring changes in expression of hundreds or even thousands of genes, we can for the first time identify changes in whole classes or clusters of genes that do not function normally in failing hearts. This represents a giant leap forward in our ability to sort out all the different pathways in the heart muscle cells where changes in gene expression, and thus, most likely, changes in protein expression, have occurred.

The earlier methods that permitted simultaneous analysis of expression levels of large numbers of cDNAs included differential display, subtractive hybridization, and serial analysis of gene expression. More recently, microarray technologies have rapidly achieved popularity. These may consist of cDNAs printed or spotted onto a solid support, often called *spotted arrays* or *cDNA arrays* (56,57). Commercially available cDNA arrays may include large numbers of cDNAs within a gene family (e.g., genes involved in apoptosis) or members of cytokine gene families. Alternatively, arrays customized by robotic array makers can now be produced in house or purchased from a vendor. A variant of this approach, pioneered by Affymetrix, is to synthesize short oligonucleotides directly onto a glass substrate using photolithography techniques. We discuss in greater detail the use of oligonucleotide arrays and provide an example of the power of microarray technology to shed light on the large number of changes in gene expression that take place in the failing heart (58). Detailed information on methods of array manufacture, sample preparation, and data analysis can be found in original publications (46,59).

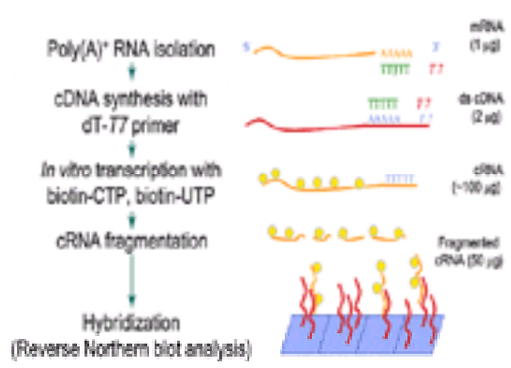
Oligonucleotide Arrays

An oligonucleotide array consists of a gene chip with many thousands of oligonucleotides synthesized on its surface using a photolithographic mask, as used in the semiconductor industry. Each of the cDNA sequences on the array is represented by one probe set containing approximately 20 different 25-mer oligonucleotides, chosen from unique regions of the nucleotide sequence of the gene. Each of these “perfect match” probes has a mismatch control (59) that serves to control for nonspecific hybridization to the chip (eFig. 97.0.5).

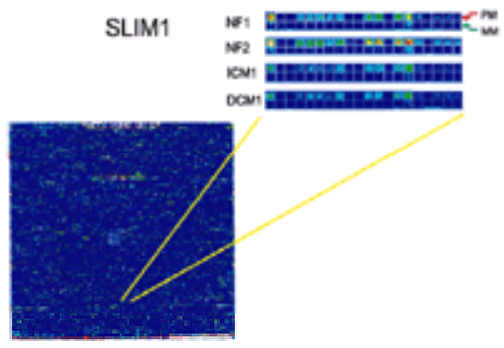


***e*FIGURE 97.0.5** Example of a probe set on a gene chip representing one particular gene. Each feature on the chip represents approximately $10^7$25-mer oligonucleotides, representing a unique region of the sequence of that gene (PM, perfect match oligonucleotides) or the same sequence but with a mismatch nucleotide (MM, mismatch) to control for nonspecific hybridization. Together, each PM and MM pair makes up a probe pair. A probe set represents a set of probe pairs that should uniquely identify a particular gene. Thus, when complementary RNA prepared from myocardium hybridizes to the probe set, after subtracting the nonspecific hybridization to the MM oligonucleotides, the relative extent of hybridization is a quantitative indication of the expression level of that gene (or, for some chips, of an expressed sequence tag). (Figure prepared by Jiacheng Yang, PhD.)

From a starting material of approximately 2 g of myocardium from the ventricular free wall, the main steps involved in sample preparation for analysis by oligonucleotide arrays or gene chips are (a) preparation of total RNA from tissue or cell homogenate, (b) purification of poly(A)$^+$ RNA, (c) double-stranded cDNA synthesis using poly(A)$^+$ RNA as a template and a *T7*-(dT)$_{24}$ oligonucleotide as initial primer; then (d) amplification by *in vitro* transcription to produce biotin-labeled cRNA; and (e) approximately 50 µg of fragmented cRNA plus control cRNAs hybridized to the chips (eFig. 97.0.6). More recent protocols eliminate the poly(A)$^+$ RNA step. After subtracting nonspecific hybridization due to cRNA binding to mismatch oligonucleotides, the intensity of fluorescence averaged over all of the probe pairs representing each gene is then determined. This is proportional to the level of expression of the gene in the tissue being assayed. An example of a gene chip showing a sample of cRNA from a human heart hybridized to a gene chip, highlighting hybridization to the probe set representing the gene *SLIM1*, is shown in eFigure 97.0.7.



***e*FIGURE 97.0.6** Sequence of steps to isolate complementary RNA (cRNA) from heart homogenate for hybridization to a gene chip. The initial starting material is total RNA. Either poly(A)+ RNA is then isolated from the total RNA, or, more commonly, total RNA is used as the starting material. Single-chain complementary DNA (cDNA) and then double-stranded (ds) cDNA is prepared by reverse transcription using a dT-T7 primer. The amplification step is next: This involves *in vitro* transcription performed in the presence of biotinylated CTP and UTP. The cRNA obtained is then fragmented to optimize hybridization to the oligonucleotides on the chip. The final step is fluorescent labeling of the hybridized biotinylated sample to quantitate the extent of hybridization. mRNA, messenger RNA. (Figure prepared by Jiacheng Yang, PhD.)



***e*FIGURE 97.0.7** Fluorescent image of biotinylated complementary RNA (cRNA) hybridized to high-density oligonucleotide arrays (gene chips). This demonstrates the result of hybridization of biotinylated cRNAs prepared from failing and nonfailing human hearts (NF1, NF2) to Affymetrix gene chips. The entire image of the chip (1.3 cm × 1.3 cm) containing oligonucleotides representing approximately 7,000 full-length human genes is shown at left. Magnified images compare the fluorescent intensity of biotin-labeled cRNAs hybridized to the perfect match (PM) and mismatch (MM) oligonucleotide probes specific for the striated muscle LIM protein-1 (*SLIM1*) gene. Expression of *SLIM1* was decreased in the failing human hearts. DCM, dilated cardiomyopathy; ICM, ischemic cardiomyopathy. (From Yang J, Moravec CS, Sussman MA, et al. Decreased SLIM1 expression and increased gelsolin expression in failing human hearts measured by high-density oligonucleotide arrays. *Circulation* 2000;102:3046–3052, with permission; figure by Jiacheng Yang, PhD.)

The Next Step

A unique problem that DNA array studies present is sorting out the vast array of data obtained. Sophisticated computer programs and advances in the burgeoning field of bioinformatics are needed to facilitate the data analysis and help identify the gene families that show altered expression in heart failure. We also need to determine whether the changes that we identify are initial triggering events or compensatory changes; the latter may be good for the failing heart, whereas the former changes may be bad. The next step is to go back to animal models of heart failure, manipulate the expression level of these same genes shown to have altered expression levels in failing hearts, and find out if, by mimicking the changes in the failing human heart, we either exacerbate disease development or ameliorate impaired cardiac function.

How will gene chip technology ultimately find its way into the heart clinic? There is potential for gene chip technology to help people who demonstrate an increased likelihood of developing heart failure, or it could be of use even earlier in the disease process (e.g., to forewarn of increased risk of ischemic cardiomyopathy as a result of an early triggering event, blockage of coronary arteries with secondary ischemic damage to the heart muscle cells). In the one instance, the goal would be to help identify that subset of genes that shows altered expression in groups of people with an increased risk of heart disease; in the second case, in view of the range of successful surgical and medical treatments now available, it may be even more timely to use gene chip technology to identify people who are “good responders” to a particular therapy versus poor responders. What differences in gene expression distinguish these people? Gene chip arrays could help to predict these individual differences.

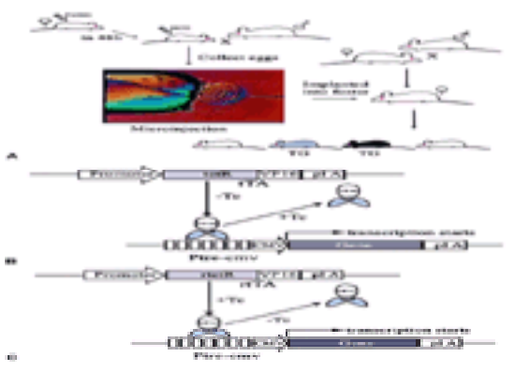
ANIMAL MODELS (TRANSGENIC AND EMBRYONIC STEM CELL TECHNOLOGIES)

Transgenic and embryonic stem (ES) cell (gene-targeting) techniques have become essential tools in modern molecular genetics to define normal physiologic function of new genes, to assess how a mutation can affect its protein functions, and to create animal models for human genetic diseases. Here we review the principles and applications of transgenic and ES cell technologies.

Transgenic Animal Technology

In 1980, the first transgenic mouse was generated by microinjecting DNA into the pronucleus (60). The foreign DNA could be transmitted into the descendants. The animal carrying the foreign DNA (transgene) in its genome is referred to as the *transgenic animal*. The transgene, which can be integrated as a cluster (head to head, head to tail, or tail to tail) at a single site and rarely at multiple sites on the chromosome(s) (61), can function as an endogenous gene (62). To date, besides transgenic mice, transgenic rats, rabbits, sheep, pigs, goats, and cows have been successfully generated (63,64,65,66 and 67).

The transgenic animals can be generated by various methods. The conventional procedure is to microinject DNA into the pronuclei of the fertilized eggs at the one-cell stage (*e*Fig. 97.0.8A) (67,68). Other methods include the infection of blastocysts with retrovirus vectors (69), sperm-mediated DNA transfer (70), and ES cell–mediated DNA transfer (71).



***e*FIGURE 97.0.8 A:** Generation of transgenic (TG) animals by microinjection. Different colors in TG represent the fact that the TG founders carry various copies of the transgene, and they are usually chimeric to different degrees. **B,C:** Tet-off and tet-on systems, respectively. CMV, human cytomegalovirus promoter; HCG, human chorionic gonadotropin; pl A, poly A adding signal; PMSG, pregnant mare serum gonadotropin; Tc, tetracycline; VP16, herpes simplex virus VP16 activation domain.

Design of Transgenic Constructs

A transgene consists of three parts: a promoter region, a structural gene (target gene), and a poly A adding signal.

Overexpression

The transgene can be overexpressed in the specific tissues (organs), in the whole body, or in the tissues where it is natively expressed. The tissue overexpression can be achieved by using a tissue- or organ-specific promoter to direct the expression of the transgene. There are many tissue-specific promoters available, such as cardiac myosin heavy chain-a promoter specific for cardiac tissues (both ventricles and atria) (72), cardiac myosin light chain-2 promoter specific for ventricles (73), and *TIE* (*TIE1* and *TIE2*) promoters specific for endothelial cells (74,75).

Some promoters, such as the CMV and RSV promoters, are strong but of less selectivity in tissue expression, and give high expression levels in most parts of the body. The high expression of a gene in various tissues or organs can allow one to investigate a spectrum of functions of the gene.

The enhanced expression of a gene in its natively expressed tissues can be accomplished by using its genomic DNA, including BACs, PACs, and YACs (76) or its natural promoter-directed cDNA as the transgene.

Inducible Expression

The tetracycline-resistance operon was modified and used in the regulation of a transgene's expression, a system referred to as *tet-off/tet-on*. In the tet-off system (eFig. 97.0.8B), the tTA, a fusion protein that consists of the tet repressor (tetR) protein (1-207 aa) and the C-terminal region (127 aa) of the herpes simplex virus VP16 activation domain (VP16), activates transcription by binding to the adapted tet operator (Ptre-cmv, tet response element plus the minimal CMV promoter) (77). The tetracycline (Tc or doxycycline, Dc) can remove tTA from the binding site, and therefore turn off the Ptre-cmv–directed transcription.

In the tet-on system (eFig. 97.0.8C), the tTA has been modified, and the modified tTA (rtTA) reverses the binding property of tTA, and therefore permits binding only in the presence of Tc or Dc. When Tc or Dc is present, rtTA binds to the Ptre-cmv and turns on the transcription (78).

The transgenic animals with the tet-on/tet-off system carry two transgenes: one is the tissue-specific promoter-directed rtTA/tTA, and the other is the Ptre-cmv–directed transgene. The expression of the transgene can be initiated when the animal is treated with Tc or Dc (79).

Reporter Gene

The spatial and temporal expression pattern of a given gene during embryogenesis as well as adulthood can be analyzed by using its promoter to drive the expression of a reporter gene, such as *Lac Z* or *GFP* in transgenic animals. The expression pattern of the interest gene can be mapped by determining the expression of reporter genes (73).

Dominant Negative and Antisense

The functions of an interest gene can be arrested if a dominant negative mutant is used as the transgene. The dominant negative mutant is usually a truncated fragment of the interest gene that can antagonize the normal function of the endogenous gene (80). In addition, the function of a gene can also be suppressed by using an antisense construct as the transgene (81).

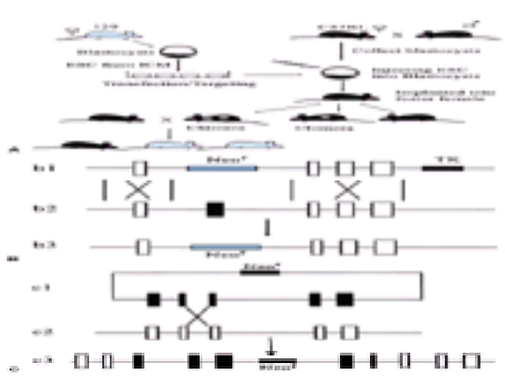
Embryonic Stem Cell Technologies

Embryonic Stem Cell

The ES cells are the preimplanted embryo-derived pluripotent cells that maintain an unlimited differentiation potential and normal karyotype during cell culture (82,83). Several ES cell lines have been generated from various mouse strains. The ES-like cell lines have been isolated from other species, but the murine species is currently the only laboratory animal whose ES cells can be genetically manipulated both *in vivo* and *in vitro*.

Gene Targeting

By homologous recombination, a specific gene can be modified in ES cells when they are transfected with a proper construct. This process is referred to as *gene targeting* (84,85). The genetically manipulated ES cells are injected into blastocysts, and the blastocysts are then transferred into the uteri of the foster female mouse where they develop into chimeric mice. The chimeric mice can transmit the ES cell genotype if the modified gene is integrated into the germline cells (eFig. 97.0.9A) (68).



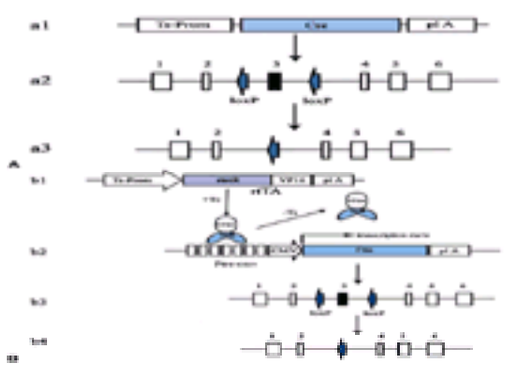
***e*FIGURE 97.0.9 A:** Scheme for gene targeting. Spots on the animals' coats indicate that the animals have different degrees of chimerism. Gray indicates that the animals are homozygous. **B,C:** Replacement and insertion vectors, respectively. The vertical open or filled bars are the exons of a gene. b1 and c1, targeting vectors; b2 and c2, wild-type alleles; b3 and c3, targeted alleles; ESC, embryonic stem cell; ICM, inner cell mass.

Targeting Vectors

Replacement vectors are used to replace a certain region of an endogenous gene with the DNA fragment from a targeting vector. The DNA fragment can be a reporter gene, the selective marker such as a neomycin-resistant gene (Neo^r), or the same endogenous gene, but with subtle mutations. The replacement vector usually has positive and negative markers, such as Neo^r and the herpes simplex virus-1 thymidine kinase gene (*HSV-1tk*), allowing the selection of correctly targeted ES clones (eFig. 97.0.9B).

Insertion vectors are used to introduce the subtle mutations or to duplicate the gene *in vivo* (eFig. 97.0.9C). Several targeting systems have been designed, respectively, for these purposes: gap-repair gene targeting (86) as well as hit-and-run gene targeting (87).

The *Cre-loxP system* is developed for tissue-specific targeting. Two components are needed in the Cre-loxP system: bacteriophage P1 Cre recombinase and loxP sites. The loxP site is a 34-bp DNA sequence consisting of two 13-bp inverted repeats, the binding sites for the Cre, and an 8-bp asymmetric core sequence. The core sequence determines the orientation of the loxP. When Cre is present, the DNA sequence between two loxP sites that are in the same orientation can be efficiently excised (eFig. 97.0.10A) (88,89). For example, if the target gene is to be deleted in cardiac ventricles, two types of mice are needed; one is the transgenic mouse in which the Cre is specifically expressed in the ventricles, and the other is the knockout mouse in which certain exons of the target gene are flanked by the loxP sites (but the gene's function is still normal) by means of regular gene targeting. Because the Cre is specifically expressed in ventricles, it deletes the targeted gene (locked exons of this gene) only in the ventricles in their offspring when the two strains are bred together (90).



***e*FIGURE 97.0.10 A:** Cre-loxP system. The vertical open or filled bars are the exons of a gene, and the arrows are the loxP sites. Cre produced by a1 acts on a2, and exon 3 is then removed in a3. **B:** Inducible gene-targeting system. The fusion protein, rtTA, is expressed under the control of a tissue-specific promoter (b1). If Tc exists, rtTA can bind to Ptre-cmv, leading to the expression of CRE (b2). CRE then removes the loxed exon 3 in the gene of interest (b3 and b4). CMV, human

cytomegalovirus promoter; pl A, poly A adding signal; Ts-Prom, tissue-specific promoter; VP16, herpes simplex virus VP16 activation domain.

In combination with the tet-on/tet-off system, the Cre-loxP system has been used to create inducible gene targeting that deletes the target gene only when the animals are treated with tetracycline or doxycycline (eFig. 97.0.10B) (91,92). The inducible targeting strategy is particularly useful in characterizing genes that cause embryonic lethality when deleted in mice.

Transgenic and ES cell technologies have been widely used to characterize the genes causing cardiovascular diseases. In addition, gene trapping, the other ES cell–based technique, has been developed to identify the novel genes involved in developmental processes, such as the formation of the heart. As the majority of human genes is identified in the near future, transgenic and ES cell technologies will remain the major tools in genetic research over the next decade.

CONTROVERSIES AND PERSONAL PERSPECTIVES

The Human Genome Project has already led to a rapid acceleration in the pace of disease gene discovery. Linkage analysis is still the key to positional cloning. The physical mapping phase of positional cloning will eventually be eliminated. Candidate gene identification will rely on ESTs and genes available in the critical disease region, and on bioinformatic programs that can predict genes from raw genomic DNA sequences. The current mutation detection methods are sufficient for finding novel mutations in candidate genes.

Gene chip technology and transgenic and gene-targeting technologies will remain predominant approaches in finding the physiologic function of human genes, all of which will be identified in the next few years. However, gene chip studies create an enormous number of data. Sophisticated computer programs and advances in the burgeoning field of bioinformatics are needed to sort out this vast array of data. We also need to determine whether the changes that we identify are initial triggering events or compensatory changes. The next step is to go back to animal models, manipulate the expression levels of these same genes, and find out if the changes in human disease can be mimicked. At the present time, the ES cell–based gene-targeting technique can only be performed in mice, but it is expected that the same technique will be developed for other species that may serve as better animal models to study cardiovascular disease. Transgenic congenic animals may become particularly useful in characterizing complex cardiovascular diseases.

The genetic studies of cardiovascular disease will go through four paradigm shifts: disease gene identification, genetic testing, pharmacogenomics, and therapy. We are currently at the peak of the gene discovery phase. In 5 to 10 years, genetic testing will start to truly benefit many patients by providing risk assessment and allowing implementation of medical surveillance and lifestyle planning programs to reduce risks. Many policy issues need to be resolved for genetic testing. Current mutation detection technologies are not sufficient for fast and low-cost genetic testing because many genes are usually involved in the pathogenesis of a disease, and most of the mutations are isolated or individual mutations. High-throughput and low-cost technologies need to be developed to make massive genetic testing possible. The field of pharmacogenomics has just started, and therapies based on disease gene discoveries may take an unpredictably long time to reach and benefit patients. The future challenge will be to develop new technologies for pharmacogenomics and better therapies.

THE FUTURE

Positional cloning will remain as a dominant strategy for genetic dissection of human disease over the next 5 to 10 years. Many genes for single gene disorders will be quickly identified, and some susceptibility genes for complex diseases will be discovered. The completion of the Human Genome Project, coupled with increasingly more powerful bioinformatic tools, will speed up positional cloning significantly. The focus of genetic research in human disease is gradually shifting from single gene disorders to complex diseases and pharmacogenomics. Sib pair linkage analysis, case-control studies with candidate genes, and LD analysis with SNPs will be the key technologies used in finding genes for complex diseases and drug response. Another focus of research in the next decade will be functional genomics. The goal of functional genomics is to assign a function to each human gene. Ultimately, individual genes will be integrated together to form networks, thus forming networks of proteins that regulate genes. Transgenic and ES cell technologies (gene targeting), as well as finding human disease genes, will be the most informative approaches to identify or assign functions to genes. However, we expect that the main strategy to accumulate functional information for all human genes will be the whole genome approaches, in the form of expression profiles (gene chip technology), computational molecular biology, protein–protein interactions, proteomics, and comparative genomics.

GLOSSARY

Allele: One alternative form of a gene.

Candidate gene: A gene that, by virtue of its known properties, could contribute to a genetic disease.

Dominant: A trait that is expressed in a heterozygote (such as familial hypercholesterolemia).

Genotype: Either the genetic constitution of an individual or the alleles that are present at a particular locus.

Heritability: The proportion of variance of a trait (such as blood pressure or myocardial infarction) explained by genetics.

Linkage: The tendency of genes that reside near one another on a chromosome to be inherited together.

Locus: A unique chromosomal location that defines the position of a gene.

Modifier gene: A gene whose expression can modulate a phenotype.

Multifactorial: A trait determined by multiple factors, usually including genetic and environmental factors.

Phenotype: The physical characteristics of an individual determined by his or her genetic constitution (e.g., the phenotype of high levels of plasma cholesterol result from low-density lipoprotein receptor mutations).

Polymorphism: A genetic variation that occurs relatively frequently (>1%) in the population.

Restriction fragment length polymorphism: A polymorphism recognized by a difference in the size of hybridizing fragments following digestion of deoxyribonucleic acid.

INTRODUCTION

Atherosclerosis, the primary cause of heart disease and stroke, is a disorder with multiple genetic and environmental contributions. Epidemiologic studies have identified a surprisingly long list of genetic and nongenetic risk factors (eTable 98.0.1). Within populations, genetic differences appear to be of primary importance in determining those in whom significant atherosclerosis will and will not develop clinically. Between certain populations, particularly those with different levels of dietary fat consumption, environmental influences predominate. A number of mendelian disorders that are associated with atherosclerosis, such as familial hypercholesterolemia (FH), have been characterized, but such genetic disorders explain only a small fraction of disease susceptibility (less than a few percent). The vast majority of cases of coronary artery disease (CAD) and stroke result from the interactions of multiple genetic and environmental factors, none of which is able to cause disease by itself. As yet, we have little understanding of the genes that are involved in such "complex" or "multifactorial" forms of atherosclerosis. Many association studies and linkage studies for CAD and its risk factors have been reported, but most such studies have been able to provide only suggestive evidence for the involvement of certain candidate genes, and our understanding is very incomplete. New approaches for the dissection of complex genetic traits, including novel analytic methods, large-scale sequencing of candidate genes, and the use of animal models, are being applied to atherosclerosis and its risk factors. The Human

Genome Project, now nearing completion, is a crucial resource for such studies. The identification of genes involved in common forms of atherosclerosis should lead to improved prevention, control, and cure of the disease. In this chapter we present a geneticist's perspective of atherosclerosis and review the current state of knowledge of the simple and the complex forms of the disease and its risk factors. Several previous reviews of the genetics of atherosclerosis are available (1,2,3,4,5 and 6).

***e*TABLE 98.0.1** GENETIC AND ENVIRONMENTAL RISK FACTORS ASSOCIATED WITH ATHEROSCLEROSIS AND CORONARY ARTERY DISEASE

Factors with strong genetic component	
Elevated levels of LDL/VLDL	Associations have been demonstrated by numerous epidemiologic studies and are supported by studies of genetic disorders and animal models. Small, dense LDL particles are particularly strongly associated with CAD. Clinical trials have shown benefits of cholesterol reduction.
Reduced levels of HDL	Associations have been demonstrated by numerous epidemiologic studies, studies of genetic diseases, and studies of animal models. The relationship is complex, however, because HDL is heterogeneous and exhibits different functional states.
Elevated levels of Lp(a)	Associations with CAD have been observed in many but not all epidemiologic studies. Animal studies have yielded positive as well as negative results.
Elevated blood pressure	Associations with CAD and stroke have been observed in numerous epidemiologic studies. Clinical trials have demonstrated benefits of blood pressure reduction, with a particularly strong effect on stroke.
Elevated levels of homocysteine	Associations have been observed in epidemiologic studies, and homocystinuria results in severe occlusive vascular disease. Animal studies have been inconclusive.
Family history	When all known risk factors are controlled for, family history remains a very significant, independent factor in nearly all studies reported.
Diabetes and obesity	Associations have been observed in epidemiologic studies and in studies with animal models. Atherosclerosis is accelerated in part through interactions with other risk factors.
Elevated levels of hemostatic factors	Significant independent associations have been observed with elevated levels of fibrinogen, plasminogen activator inhibitor type 1, and platelet reactivity.
Depression and other behavioral traits	Associations have been observed in several studies. The results are complicated due to associated traits; for example, depressed people are more likely to smoke.
Gender (male)	Under age 60 yr, CAD develops in men at more than twice the rate of women. A recent trial has raised concerns about the benefits of postmenopausal estrogen replacement.
Systemic inflammation	Elevated levels of inflammatory molecules such as C-reactive protein are associated with CAD, as are inflammatory diseases such as rheumatic arthritis.
The "metabolic syndrome"	This cluster of metabolic disturbances, with insulin resistance as a central feature, is strongly associated with CAD.
Environmental factors	
High-fat diet	Population migration studies have revealed very strong associations with lifestyle, and diet appears to be the most significant factor. High-fat, high-cholesterol diets are usually required for development of atherosclerosis in experimental animals.
Smoking	Strong associations have been observed in numerous epidemiologic studies. It has been estimated that approximately 30% of CAD deaths are due to smoking. Clinical trials have demonstrated benefits of cessation of smoking.
Low antioxidant levels	Results of clinical trials with antioxidants have yielded mixed results and are as yet inconclusive. However, fat-soluble antioxidants protect against atherosclerosis in experimental animals.
Lack of exercise	This is associated with many other risk factors, such as diabetes, obesity, and smoking, but a significant independent relationship has been observed.
Infectious agents	Epidemiologic studies have provided suggestive evidence for associations with various infectious agents, such as *Chlamydia pneumoniae*. Preliminary animal studies have supported the relationship.

CAD, coronary artery disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein; Lp(a), lipoprotein(a); VLDL, very-low-density lipoprotein.
Adapted from Lusis AJ. Atherosclerosis. *Nature* 2000;407:233–241, with permission.

An understanding of the genetic aspects of CAD and stroke is becoming increasingly important to the clinician who is concerned with the management of patients with CAD. For example, an appreciation of the nature of genetic-environmental interactions that are involved in the disease is essential in assessing risk and advising patients of lifestyle changes. Moreover, knowledge of the genetics of CAD allows optimal use of the family history for counseling patients and other family members who may be at risk for CAD later in life. Genetically based classifications for various risk factors for atherosclerosis—including plasma lipid variations, hypertension, and diabetes—will become possible as our knowledge of the genetic factors that underlie these traits expand.

OVERVIEW: GENETICS OF ATHEROSCLEROSIS

Atherosclerosis Has an Important Genetic Component

With the exception of rare mendelian forms, CAD does not exhibit obvious genetic patterns of inheritance. Because the disease is so common, with an incidence of more than 50% in some populations, it is not surprising that in some families there are multiple affected individuals. How, then, can we estimate the influence of genetic factors on disease susceptibility or even be sure that atherosclerosis has an important genetic component?

First, family studies have clearly shown a clustering of atherosclerosis, and there is a very significant increase in mortality in first-degree relatives of men and women with CAD compared to control subjects. The familial effect of CAD appears to be particularly strong for early-onset disease, approximately 50 years of age or less (1,2,7). For example, one study analyzed first-degree relatives of 121 men and 96 women with CAD and an approximately equal number of control subjects. When deaths in men under 55 years and in women under 65 years were considered, the relatives of female patients showed a sevenfold increased risk and the relatives of male patients showed a fivefold increased risk (8).

Second, twin studies strongly support a genetic component, because monozygotic twins, who share 100% of their genes, have a much higher concordance rate for CAD and stroke than do dizygotic twins, who share approximately 50% of their genes (1,4,9). *e*Table 98.0.2 shows concordance data from a Norwegian twin study. A very large twin study, which included 21,004 Swedish twins, yielded similar results. Among men, the relative hazard of death from CAD when the twin died of CAD before the age of 55 years, as compared with the hazard when the twin did not die of CAD before the age of 55 years, was 8.1 for monozygotic twins and 3.8 for dizygotic twins. Among women, when the twin died of CAD before age 65, the relative hazard was 15.0 for monozygotic twins and 2.6 for dizygotic twins (10). Family studies and twin studies are both confounded by the effects of common environmental factors. Although it seems that monozygotic and dizygotic twins should share the environment to about the same extent, there are likely to be subtle differences.

***e*TABLE 98.0.2** NORWEGIAN SAME-SEX TWIN PAIRS: CONCORDANCE RATES FOR CORONARY ARTERY DISEASE

Category	Monozygotic pairs	Dizygotic pairs
All affected pairs	0.66[a]	0.25
Affected pairs, 60 yr or younger	0.83	0.22

[a]Concordance rates are expressed as correlation coefficients. Individuals were determined to be affected if they experienced myocardial infarction or angina pectoris.
Data from Berg K. Genetics of coronary heart disease. In: Steinbert AG, Bearne AG, Motulsky AR, Childs B, eds. *Progress in medical genetics.* Philadelphia: WB Saunders, 1983:35–90.

The fact that certain atherosclerosis risk factors (*e*Table 98.0.1) are clearly heritable provides additional strong evidence for a genetic component in atherosclerosis (11). For example, *e*Table 98.0.3 shows the heritability of plasma lipoprotein levels and blood pressure in one study. Many other studies have revealed similar results, and other atherosclerosis risk factors, such as obesity and type II diabetes, also exhibit high degrees of heritability as evidenced by higher concordance rates in monozygotic twins compared to dizygotic twins (*e*Table 98.0.4). In addition to heritability estimates from family and twin studies, candidate gene studies have identified a number of genes contributing to various risk factors. Some examples are shown in *e*Table 98.0.5.

***e*TABLE 98.0.3** HERITABILITY OF BLOOD LIPIDS AND RELATED TRAITS FROM MULTIGENERATIONAL UTAH PEDIGREES[a]

	Correlation coefficients (*r*)		Heritability estimates (%)		
Trait	MZ	DZ	Twin H^2	Pedigree H^2	Pedigree C^2
Total cholesterol	0.80	0.49	61	42	8
Total triglycerides	0.68	0.28	81	37	6
High-density lipoprotein cholesterol	0.75	0.39	74	45	15
Body mass index	0.68	0.41	54	24	0
Diastolic blood pressure	0.46	0.16	60	22	3

[a]Shown are correlation coefficients in monozygotic (MZ) and dizygotic (DZ) twins, gene heritability (H^2) calculated from twins or pedigrees, and percentage of variance attributable to common household (C^2).

Data from Ma J, Stampfer MJ, Hennekens CH, et al. Methylenetetrahydrofolate reductase polymorphism, plasma folate, homocysteine, and risk of myocardial infarction in US physicians. *Circulation* 1996;94:2410–2416.

***e*TABLE 98.0.4** CONCORDANCE RATES IN MONOZYGOTIC (MZ) AND DIZYGOTIC (DZ) TWINS FOR SELECTED TRAITS RELEVANT TO ATHEROSCLEROSIS

	Concordance rates		
Trait or disease	MZ twin	DZ twin	Heritability
Blood pressure (diastolic)	0.58	0.27	0.62
Blood pressure (systolic)	0.55	0.25	0.60
Body fat percentage	0.73	0.22	>1.0
Diabetes mellitus (type II)	0.70–0.90	0.25–0.40	0.9–1.0
Myocardial infarction (men)	0.39	0.26	0.26
Myocardial infarction (women)	0.44	0.14	0.60

From Jorde LB, Carey JC, Bamshad MJ, White RL. *Medical genetics*. St. Louis: Mosby, 1999:249.

***e*TABLE 98.0.5** COMMON GENETIC VARIATIONS CONTRIBUTING TO CORONARY ARTERY DISEASE AND ITS RISK FACTORS[a]

Trait	Gene	Variation
LDL/VLDL	ApoE	Three common missense alleles explain ~5% of variance of cholesterol
	ApoAI-CIII-AIV-AV cluster	Multiple polymorphisms
HDL levels	Hepatic lipase	Promoter polymorphism
	ApoAI-CIII-AIV cluster	Multiple polymorphisms
	ApoAII	Multiple polymorphisms
	Cholesteryl ester transfer protein	Common null mutations (Japanese); missense polymorphisms
	Lipoprotein lipase	Missense polymorphisms
Lp(a)	Apo(a)	Many alleles of apo(a) explain >90% variance
Homocysteine	Methylenetetrahydrofolate reductase	Missense polymorphism
Coagulation	Fibrinogen B	Promoter polymorphism
	Plasminogen activator inhibitor type 1	Promoter polymorphism
	Factor VIII	Common missense
Blood pressure	Angiotensinogen	Missense and promoter polymorphisms
	$Beta_2$-adrenergic receptor	Missense polymorphism
	Alpha-adducin	Missense polymorphism; support from studies in rats
CAD	Angiotensin-converting enzyme	Insertion-deletion polymorphism
	Serum paraoxonase	Missense polymorphism affecting enzymatic activity; animal studies support
	Hemochromatosis-associated gene	Missense polymorphism
	Endothelial nitric oxide synthase	Missense polymorphism
	Factor XIII	Missense polymorphism
	Fibrinogen cluster	Various polymorphism
	Interleukin-1 receptor antagonist	Missense polymorphism
	P-selectin	Missense polymorphism
	CD14	Promoter polymorphism
	Mannose-binding lectin	Missense polymorphism
	Plasminogen-activated inhibitor type 1	Insertion/deletion polymorphism

Apo, apolipoprotein; CAD, coronary artery disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein; Lp(a), lipoprotein(a); VLDL, very-low-density lipoprotein.
[a]Only genes exhibiting evidence of linkage or association in two or more studies are cited. See text for discussion.
Adapted from Lusis AJ. Atherosclerosis. *Nature* 2000;407:233–241.

The strongest evidence for a genetic component in CAD is the identification of genes that contribute to the disease. Striking progress has been made in characterizing the mendelian forms of the disease (*e*Table 98.0.6), but few genes have been conclusively implicated in the common forms of CAD (*e*Table 98.0.5).

***e*TABLE 98.0.6** MENDELIAN DISORDERS RELEVANT TO ATHEROSCLEROSIS

Trait	Disease (gene)	Characteristics
Elevated LDL/VLDL levels	Familial hypercholesterolemia (LDL receptor)	Dominant disorder characterized by very high LDL-cholesterol levels and early CAD
	Familial defective apoB-100 (apoB)	Dominant disorder due to apoB mutations that affect binding to LDL receptor; less severe than FH
Low HDL levels	ApoAI deficiency (apoAI)	In the homozygous state, null mutations of apoAI result in the virtual absence of HDL and early CAD
	Tangier disease (ABCA1 transporter)	This recessive disorder results in the inability of cells to properly efflux cholesterol and phospholipids, resulting in very low levels of HDL
Coagulation	Various genetic disorders of hemostasis	Unlike rare disorders of lipid metabolism in which atherosclerotic disease is a primary manifestation, genetic disorders of hemostasis usually present either as increased risk of bleeding or thrombosis (usually venous), with no outstanding effect on atherogenesis
Elevated homocysteine	Homocystinuria (cystathionine beta-synthetase)	Recessive metabolic disorder resulting in very high levels of homocysteine and severe occlusive vascular disease
Diabetes, type II	MODY1 (hepatocyte nuclear factor 4a), MODY2 (glucokinase), MODY3 (hepatocyte nuclear factor 1a)	MODY1, 2, and 3 are characterized by the development of non–insulin-dependent diabetes mellitus in young adults
Hypertension	Glucocorticoid-remediable aldosteronism (hybrid gene from crossover of 11-b-hydroxylase and aldosterone synthase)	Dominant disorder with early-onset hypertension and stroke
	Liddle's syndrome (epithelial sodium channel)	Dominant disorder with hypertension and metabolic alkalosis

Apo, apolipoprotein; CAD, coronary artery disease; FH, familial hypercholesterolemia; HDL, high-density lipoprotein; LDL, low-density lipoprotein; MODY, maturity-onset diabetes of the young; VLDL, very-low-density lipoprotein.

Atherosclerosis Is Etiologically Very Complex

The number of different genetic factors that contribute to the common forms of atherosclerosis is unknown, but it is likely that dozens of different genes, each acting on the background of important environmental influences, are involved. It is evident from the numerous genetic risk factors associated with the disease that the number of genes involved must be large (*e*Table 98.0.1). With the exception of gender and lipoprotein(a) [Lp(a)] levels, each genetic risk factor is multifactorial. Studies with animal models indicate that traits such as plasma cholesterol levels, diabetes, obesity, and blood pressure are genetically very complex. It is also clear that atherosclerosis can result from different sets of genetic factors. Classically, such "genetic heterogeneity" has been found to result from mutations of genes that encode either different enzymes in the same metabolic pathway or different proteins in a multiprotein complex. The heterogeneity of atherosclerosis is probably due in large part to the fact that many different processes contribute to the disease (e.g., pathways for cholesterol homeostasis, blood pressure regulation, and artery wall cell interactions). Furthermore, the heterogeneity of atherosclerosis is also evidenced by the numerous different transgenes or gene knockouts that influence lesion formation in mouse models (see the section Dissection of Genetic Factors in Atherosclerosis).

Atherosclerosis Involves Genetic-Environmental Interactions

Atherosclerosis is not a function of genetics alone or environment alone but, rather, the interaction of the two. Between certain populations, environmental factors predominate; for example, the Japanese have a much lower incidence of CAD than do Americans, but Japanese-Americans who have adopted an American lifestyle, including diet, have about the same incidence of disease as European-Americans. On the other hand, within populations, genetic factors are likely to be most important; thus, numerous twin studies and family studies in the United States and in Europe argue that genetic factors outweigh environmental influences. In populations that consume low-fat diets, CAD tends to be relatively uncommon, irrespective of genetics, although rare individuals with very strong genetic predisposing

factors, such as FH, still have a high probability of developing the disease. In populations that consume high-fat diets, CAD is very common (up to approximately 50% of the population), but a large fraction of the population remains resistant to the disease or at least to its clinical consequences. Within a population, whether premature CAD does or does not develop in an individual is determined in large part by genetic factors, presumably because within a population most people experience a similar environment. The environmental factor that appears to be of greatest importance is dietary fat, although smoking, stress, lack of exercise, and other factors are clearly involved as well (*e*Table 98.0.1).

Genetic-environmental interactions have been studied in most detail for lipoprotein metabolism. The influence of environmental factors on lipoprotein metabolism and CAD has been most dramatically revealed by studies of different populations. The Seven Countries study (12,13) demonstrated strong positive correlations between the consumption of saturated fats, serum cholesterol levels, and CAD mortality among different populations. Migration studies suggested that such differences between populations are due primarily to environmental rather than genetic factors (although important genetic differences undoubtedly do exist between populations). For example, one study compared Japanese individuals living in Japan, Hawaii, and the mainland United States with total fat consumption progressively increasing among the three groups. Corresponding to the increases in fat consumption were increases in serum cholesterol levels and the incidence of CAD and stroke (14,15). Nevertheless, hereditary factors are primarily responsible for the plasma lipid differences within populations (1,16). This is most likely due to the fact that most individuals in a population tend to consume relatively similar diets and lead similar lifestyles.

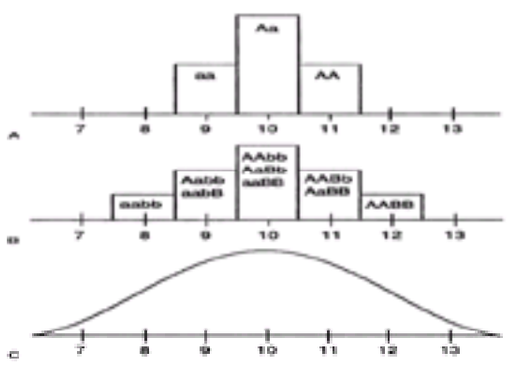
In some instances, genetic-environmental interactions are also known for certain other atherosclerosis risk factors. For example, a common polymorphism of the fibrinogen gene appears to influence myocardial infarction (MI) primarily in individuals who smoke (17,18). In addition, a common polymorphism of methylenetetrahydrofolate reductase (MTHFR), an enzyme in the folate cycle that precedes methionine synthetase, appears to cause high levels of homocysteine if the intake of folate is low (19,20). This latter polymorphism provides a potential paradigm for genetic screening and risk assessment for CAD; thus, if individuals who exhibit the polymorphism could be identified, they could be advised about the importance of folate intake.

An important but poorly understood aspect of the genetics of atherosclerosis involves how genes contribute to the *response* to dietary, or other environmental, changes. It is well known, for example, that different individuals respond very differently to challenge with a high-fat diet. Some striking ethnic differences are also seen in dietary responses. For example, the Masai, a Nilo-Hamitic tribe of East Africa, have extremely high fat intake, with their diet consisting almost entirely of animal products, but they appear to maintain low blood cholesterol levels by unusually efficient negative feedback regulation of cholesterol synthesis (21). On the other hand, Arctic Eskimos have relatively poor repression of cholesterol synthesis in response to dietary cholesterol, and their serum cholesterol levels are roughly proportional to their daily intake (22). Berg (4) has distinguished between “level” genes, which set the level of expression of a protein irrespective of environment, and “variability genes,” which influence how the expression of a protein changes in response to an environmental challenge. Using pairs of identical twins who exhibit various alleles of certain candidate genes, such as apolipoprotein (apo) B, he has obtained suggestive evidence for variability genes. For example, certain alleles of apoB resulted in larger differences in low-density lipoprotein (LDL) levels *within* a pair of twins than did other alleles. Because the twins are genetically identical, the alleles of apoB presumably determined the response to the environment.

Genetic-environmental interactions are very difficult to study in detail in humans. In particular, it would be very difficult to determine the relationship between a quantifiable phenotype, such as blood cholesterol, and various environments. One problem relates to our inability to control the environment carefully. However, the major problem is that a genotype cannot be replicated in humans (except in identical twins), and, therefore, it is almost impossible to examine the effect of a number of different environments on a phenotype while holding the genotype constant. Consequently, the data that are available for humans represent average results over many different genotypes. An excellent potential model for detailed studies of genetic-environmental interactions is the mouse, because many different inbred strains, each representing a unique gene pool, have been derived by brother-sister mating. Numerous differences in dietary responsiveness have been observed among strains of mice, affecting traits such as plasma lipoproteins and lesion development (23,24).

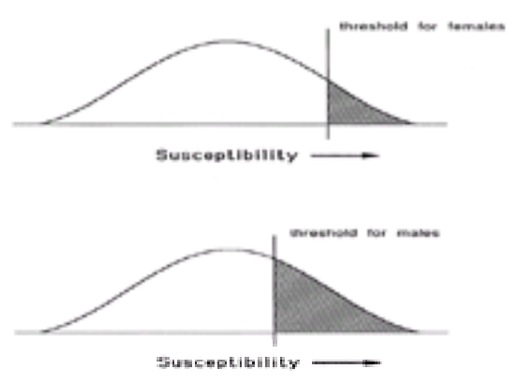
Models for the Inheritance of Atherosclerosis

As discussed in the Introduction, most forms of atherosclerosis are multifactorial, being governed by the simultaneous action of numerous gene loci. Traits that are controlled by a small number of loci yield discontinuous distributions, although the various classes may be obscured by environmental influences. Traits that are determined by the additive actions of a large number of different loci are distributed in a normal, or Gaussian, distribution in the population (*e*Fig. 98.0.1). Height is an example of such a trait. The smooth normal distributions of various risk factors for CAD, such as plasma cholesterol levels or blood pressure, suggest the involvement of a large number of loci. Such distributions are specified by two parameters—the *mean* and the *variance*. The variance is a statistic to quantify the dispersion about the mean. When variances are due to independent causes, they are additive. Thus, the overall variance of a phenotype (V_P), such as cholesterol levels or blood pressure, is the sum of the individual causes. These can be divided into the environmental variance (V_E) and the genetic variance (V_G). The heritability (h^2) of a trait is the proportion of total variance that is genetic (V_G/V_P). Heritabilities of human traits can be estimated from family studies or twin studies (e.g., *e*Table 98.0.3). The genetic variance V_G can be partitioned into components with additive, dominant, and epistatic influences (9,25). The mathematical modeling of complex traits has provided information about the existence of “major genes,” with relatively large effects on a trait and their modes of inheritance (26,27). For very complex traits such as atherosclerosis, or even blood pressure or cholesterol levels, it is very difficult to construct realistic models, because the observed phenotypes depend on so many unknowns, including the number of genes involved, the number of alleles of each gene and their frequencies, the impact of each allele on the trait, gene-environment interactions, and gene-gene interactions.



***e*FIGURE 98.0.1** Distribution of quantitative traits determined by one, two, or many additive gene loci. The graph shows the distribution in a population of a hypothetical trait determined by the effect of one **(A)**, two **(B)**, or many **(C)** loci. In this example, the trait has a mean value of 10; each lowercase allele subtracts 0.5 units, and each uppercase allele adds 0.5 units. (Modified from Strachen T, Read AP. *Human molecular genetics.* New York: Wiley-Liss, 1996.)

Unlike cholesterol levels and blood pressure, CAD and stroke are not continuously variable, or even quantitative, traits (although the area or size of atherosclerotic lesions in the population is continuously variable and may even have a Gaussian distribution). Traits such as MI or stroke are discontinuous: They are either present or not. The theory of polygenic inheritance was extended to discontinuous non-mendelian traits by postulating a continuously variable *susceptibility* and the existence of a threshold, beyond which the development of the disease would occur (28) (*e*Fig. 98.0.2). Thus, affected people would have inherited an unfortunate combination of susceptibility genes, pushing them beyond the threshold. The relatives of affected people would, on average, also tend to inherit genes that raise susceptibility, explaining the inheritance of the trait. The greater susceptibility of men to early CAD can be explained by a higher threshold in women than in men (*e*Fig. 98.0.2). A corollary of this is that, because a woman requires more susceptibility alleles for development of the disease than does a man, the children of an affected woman (or other first-degree relatives) have a higher likelihood of developing the disease than do the children of an affected man.



***e*FIGURE 98.0.2** A threshold model for coronary artery disease and stroke. See text for discussion.

The heritability of CAD can be estimated from twin studies and family studies. For example, using twin studies, the heritability *h* can be estimated using the simple formula

$$h = 2(C_{MZ} - C_{DZ})$$

where C_{MZ} is the concordance of the disease among monozygotic twins and C_{DZ} is the concordance among dizygotic twins. *e*Table 98.0.4 lists heritabilities for CAD and a number of related traits. The formula provides only a very rough estimate, however, because it assumes additive inheritance and the absence of genetic interactions (neither of which is realistic). The heritability of atherosclerosis, examined in numerous studies, frequently exceeded 50% but varies depending on the age (heritability tends to be larger for "early" CAD) and the sex of the subjects.

Dissection of Genetic Factors in Atherosclerosis

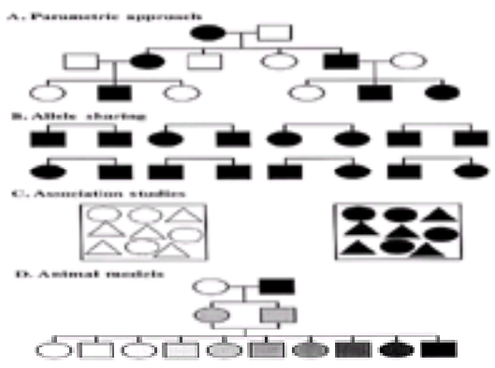
Very rapid progress is being made in identifying the genes in mendelian traits that are relevant to heart disease, using candidate gene and positional cloning approaches (*e*Table 98.0.6). Such studies often have relevance to understanding the complex forms of heart disease. The most outstanding example of this is FH. The genetics of FH were first elucidated in the 1930s by Carl Miller, a physician at a county hospital in Oslo. Miller's studies showed that the triad of very high plasma cholesterol, tendon xanthomas, and early heart disease tended to segregate together in a dominant fashion in families. This conclusively established the link between cholesterol and atherosclerosis. The classic studies of Brown and Goldstein, beginning in the early 1970s and continuing to the present day, have established the basis of the disease and, more important, have defined mechanisms that govern cholesterol homeostasis. This knowledge has formed a scientific cornerstone for further understanding of the common forms of hypercholesterolemia, and it has contributed to the development of powerful new therapies, such as the family of statins. Mendelian forms of high-density lipoprotein (HDL) deficiency, hypertension, and cardiomyopathies have similarly clarified the common complex forms (*e*Table 98.0.6).

A starting point for the dissection of atherosclerosis, as is the case for most other complex diseases, is genetic epidemiology (27). Epidemiology reveals associations between subclinical traits and clinical disease, and it can help divide complex diseases into different forms. A list of genetic and environmental risk factors identified by epidemiologic studies is presented in *e*Table 98.0.1. A classic example of the utility of epidemiology in revealing disease heterogeneity is diabetes. Diabetes used to be considered a single disease, characterized simply by high blood sugar. Epidemiologic studies, however, revealed that one form of diabetes, termed *type I*, tended to occur in early childhood and was associated with a lean body mass, whereas another form, termed *type II*, tended to occur in adulthood and was associated with obesity. It is now clear that type I and type II diabetes are separate diseases, resulting from very different genetic and environmental contributions. This is, of course, crucial for further understanding of the diseases. When a complex disease process such as atherosclerosis is considered as a single disease entity, genetic and biochemical dissection is enormously complicated. Just as in diabetes, various forms of hypertension and hypercholesterolemia and CAD have different causes, and defining the various forms is an important step toward deeper understanding.

Genetic dissection of atherosclerosis has built on the foundations provided by epidemiology, focusing on the various risk factors that are known to contribute to the disease. By analyzing the genetics of plasma lipoprotein levels, blood pressure, and other risk factors, we are dissecting the resulting diseases, CAD and stroke. Clearly, it is much simpler to analyze such quantitative traits that underlie atherosclerosis than the disease itself, particularly because the clinical disease is difficult to diagnose and to quantitate. On the other hand, the known systemic risk factors for atherosclerosis explain only part of its genetic component. To understand genetic factors that act at the level of the artery wall, it is necessary to assess the disease itself. Markers of the disease, such as C-reactive protein (CRP) or various noninvasive techniques for measuring lesion development, should be useful in such efforts.

Most of the genetic studies related to atherosclerosis that have been performed thus far have tested for associations between polymorphisms of "candidate genes" (known genes likely to contribute to processes involved in atherosclerosis) and various risk factors, such as lipoprotein phenotypes (29). Systematic searches for polymorphisms of hundreds of candidate genes for atherosclerosis, hypertension, and related disorders have been reported (30), and a complete catalog of all known human polymorphisms (variations with frequency >1%) is expected in the next few years. Because most deoxyribonucleic acid (DNA) polymorphisms are unlikely to be functionally relevant (i.e., the cause of differences in gene expression), associations in general depend on the phenomenon of "linkage disequilibrium." This refers to the fact that various polymorphisms of a particular gene are nonrandomly associated with one another as a result of the evolutionary history and population genetics of a gene. Thus, when a mutation of a gene that results in an altered phenotype occurs, it tends to remain associated with whatever polymorphisms were present at the ancestral locus as it spreads through the population. Only fragmentary data are available, but such linkage disequilibrium should in many cases be detectable in the general population for markers as far away as approximately 10 kilobases or more (31). Association studies are subject to various artifactual problems, such as the ethnic composition of the populations being examined. Thus, if the population consists of two or more ethnic groups, one of which differs from the others in a phenotype and also the frequency of a particular polymorphism, an association could be detected between the phenotype and the polymorphism. In such a case, the association would reflect population admixture rather than linkage. One means of controlling for admixture is to examine associations within families using "transmission distortion" (27). Hundreds of association studies have been reported for traits that are relevant to atherosclerosis, but almost all of these require further confirmation.

With the development of thousands of informative genetic markers, linkage studies involving complete genome scans are being performed for traits that are relevant to atherosclerosis. Classic linkage analysis, involving the construction of a model for the transmission of the trait, has proved useful for certain complex diseases, such as breast cancer, but has not been applied to complex forms of CAD. Linkage analysis with complex traits has been performed primarily using robust sib-pair analysis (32) (*e*Fig. 98.0.3), although other methods, including the variance component approach, have also proved useful (26,27,33,34). The advantage of allele-sharing approaches, such as sib-pair analysis, is that they make no assumptions about the mode of inheritance and the types of gene interactions. Sib-pair analysis suffers from relatively low power as compared to parametric methods, perhaps explaining in part the relatively disappointing results of genome scans for hypertension and other atherosclerosis-related risk factors (31). One study that involved a genome scan of families from the Finnish isolate identified several suggestive loci for CAD (34). Many other genome scans have been conducted for CAD risk factors (see the section Metabolic Syndrome).



***e*FIGURE 98.0.3** Four approaches to the dissection of complex genetic traits. Lander and Schork (Genetic dissection of complex traits. *Science* 1994;265:2037–2048) have critically reviewed the four approaches to the mapping and identification of genes that contribute to complex genetic traits such as atherosclerosis, hypertension, and diabetes. The first, classic linkage analysis **(A)**, involved the construction of a model for the segregation of genes that contribute to the trait. The model includes parameters such as the number of genes, the mode of inheritance (recessive, dominant, codominant, X-linked, etc.), the distance between genetic markers and the gene, and nongenetic contributions. Such models are straightforward to construct for mendelian traits but have proved difficult to devise for most multifactorial traits. Allele-sharing methods **(B)** provide a model-free approach for linkage analysis of complex traits. Usually, pairs of siblings are studied, although the method can be extended to various relations. The basic concept of the method is that affected pairs tend to have increased sharing of chromosomal regions (as recognized by genetic markers) that contain genes contributing to the trait. Allele-sharing methods have much less power to detect linkage than does classic linkage analysis. The third approach is association **(C)**. This involves testing whether particular polymorphisms occur more frequently in affected individuals than in controls. As discussed by Risch (31), association is more powerful than allele-sharing methods, but it is dependent on the identification of candidate genes. A complete catalog of all common polymorphisms in the human genome will be generated within the next year or two, and it may be possible to conduct whole-genome studies, but some important issues must still be resolved (31). The fourth approach uses animal models, which provide much greater power to detect linkage than do human studies **(D)**. Rats and mice are the most useful mammals of genetic studies, and different strains of these rodents exhibit many variations relevant to atherosclerosis, including differences in susceptibility to arterial lesions in the presence of hyperlipidemia and variations in lipid metabolism, blood pressure, obesity, insulin resistance, and artery wall functions (7). Genetic crosses of such strains can produce hundreds of unique progeny that inherit different parental alleles contributing to the trait. In the case of complex quantitative traits, the progeny would exhibit a continuum rather than discreet groupings, as in the case of a mendelian trait. The regions that contain genes contributing to the trait can be recognized using statistical methods. For such regions, progeny inheriting marker alleles from one parent would differ in phenotype from progeny

inheriting alleles from the other parent.

Because of the difficulty of assessing lesion development in humans, animal models have been especially important for understanding the biology of atherosclerosis. During the last 15 years, the mouse has been developed as a particularly important model for identifying genetic factors in atherosclerosis and for examining pathways that lead to the disease (35,36 and 37). Rats are also useful genetic models, particularly for studies of hypertension and insulin resistance. Because the environment can be controlled and large numbers of animals can be studied, genetic mapping of the underlying genes is much simpler with mice or rats than with humans. Perhaps most importantly, the individual genetic loci that contribute to the complex traits can be isolated as congenic strains, making fine structure mapping and gene identification feasible. Finally, the pathways involved can be examined through the use of transgenic and gene-targeted animals (38). *e*Table 98.0.7 summarizes some results from studies with transgenic and gene-targeted mice for various candidate genes. Of course, mice differ in a number of respects from humans, and studies with mice cannot lead to a complete understanding of the genetics of the human disease. Nevertheless, many processes and genetic factors that are relevant to atherosclerosis are likely to be shared between the two species. Thus, studies in mice will elucidate a subset of genes involved in the human disease. Fixing on these will in turn simplify the analysis of the remaining human genes.

***e*TABLE 98.0.7** *IN VIVO* ANALYSIS OF CELLULAR AND MOLECULAR INTERACTIONS IN ATHEROSCLEROSIS USING TRANSGENIC AND GENE-TARGETED MODELS IN MICE[a]

Process in atherogenesis	Gene: transgene (tg) or knockout (KO)	Effect on lesion size: decrease (↓), increase (↑), or no change (↔)
Lesion initiation	Apo-I tg	↓
	Apo-II tg	↑

Apo, apolipoprotein; ICAM, intercellular adhesion molecule; LDL, low-density lipoprotein; Lp(a), lipoprotein(a); MCP, monocyte chemotactic protein.
[a]Reviewed in Lusis AJ. Atherosclerosis. *Nature* 2000;407:233–241, and references therein. Mice are relatively resistant to the development of atherosclerosis. When fed a high-fat, high-cholesterol diet containing cholic acid, certain strains, such as C57BL/6J, develop fatty streak lesions of the proximal aorta. More advanced lesions develop in mice with null mutations of apolipoprotein (apo) E or the low-density lipoprotein (LDL) receptor, because these result in extreme hyperlipidemia. Many of these studies tested the effect of the transgenes or null mutations in the presence of null mutations of the apoE gene or the LDL-receptor gene.

LIPOPROTEIN METABOLISM

The most significant risk factors for CAD and stroke are related to lipoprotein metabolism. Twin studies and family studies indicate that the heritability of most lipoprotein traits within populations is greater than 50%, indicating that genetic rather than environmental factors are of primary importance. A number of rare mendelian disorders affecting lipoprotein metabolism have been characterized (*e*Table 98.0.8 and *e*Table 98.0.9). However, most forms of hyperlipidemia or low HDL levels are due to a combination of multiple genetic and environmental factors.

***e*TABLE 98.0.8** RARE MUTATIONS AFFECTING APOLIPOPROTEIN B–CONTAINING LIPOPROTEINS AND CELLULAR CHOLESTEROL METABOLISM

Sitosterolemia	A rare, autosomal recessive disorder that results in greatly increased absorption of plant sterols and an increase in cholesterol absorption. Total plasma cholesterol levels are elevated in the disease; tendon xanthomas develop in affected individuals by 10 yr of age and severe atherosclerosis as early as age 5. The genes underlying sitosterolemia have been identified.
Abetalipoproteinemia	Characterized by the failure to secrete either chylomicrons or VLDL, resulting in fat malabsorption, retinitis pigmentosa, and ataxic neuropathy. It is due to a defect in the expression of microsomal triglyceride transfer protein, which appears to be involved in the assembly of triglycerides and cholesteryl esters into growing triglyceride-rich lipoproteins in hepatocytes and enterocytes.
Anderson's disease	Also termed *chylomicron retention disease*, it is characterized by the failure of intestinal mucosal cells to secrete chylomicrons. The genetic defect is unknown, although the apoB gene appears normal.
Chylomicronemia	Due to LPL or apoCII deficiencies. Recessive mutations of the LPL gene lead to massive accumulation of chylomicrons (and VLDL) in the circulation. Interestingly, the incidence of CAD is not strikingly elevated in LPL deficiency, although one study suggests that LPL deficiency can cause premature CAD. ApoCII is an essential cofactor for LPL, and recessive mutations of the apoCII gene produce symptoms very similar to those of homozygous LPL deficiency.
Hypobetalipoproteinemia	A relatively rare disorder, characterized by low levels of VLDL, IDL, and LDL resulting from defects of the apoB gene. If the mutations affect the expression of apoB48, chylomicron expression is also decreased. Many of the mutations of the apoB gene that occur in hypobetalipoproteinemia result in truncated forms of the protein. In contrast to abetalipoproteinemia, hypobetalipoproteinemia shows additive inheritance.
Hepatic lipase deficiency	A very rare, recessive disorder resulting in the accumulation of triglyceride-rich LDL and HDL particles. Some forms of the deficiency result from HTGL gene mutations.
CESD and Wolman's disease	Very rare autosomal recessive diseases resulting from mutations of lysosomal acid lipase, leading to the intracellular accumulation of cholesteryl esters and triglycerides. CESD patients are characteristically hypercholesterolemic, and premature CAD develops before the fourth decade of life.
Cerebrotendinous xanthomatosis	A rare, autosomal recessive disorder resulting in deposition of cholesterol and cholestanol in multiple tissues, including the central nervous system. The disorder is caused by mutations of sterol-27-hydroxylase, an enzyme that hydroxylates a variety of sterol substrates, and the disorder impairs the ability to convert cholesterol to bile acids. Early diagnosis of the disorder is important, because treatment with chenodeoxycholic acid reduces the progression of the disease.
Smith-Lemli-Opitz syndrome	Caused by a block in the last reaction in the cholesterol biosynthetic pathway, catalyzed by 7-dehydrocholesterol delta 7-reductase. This results in low plasma and tissue cholesterol in homozygotes, who show mental retardation and facial dysmorphism. Feeding of cholesterol to homozygotes appears to improve symptoms.

apo, apolipoprotein; CAD, coronary artery disease; CESD, cholesteryl ester storage disease; HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LPL, lipoprotein lipase; VLDL, very-low-density lipoprotein.

TABLE cellSpacing=0 cellPadding=0 width="100%" border=0> ***e*TABLE 98.0.9** RARE MUTATIONS AFFECTING HIGH-DENSITY LIPOPROTEIN (HDL) Familial hypoalphalipoproteinemia Although most individuals with low HDL levels simply reflect the low end of the normal distribution, certain pedigrees appear to exhibit an apparent autosomal dominant factor determining low HDL levels, termed *familial hypoalphalipoproteinemia*. Some such families appear to have mutations in the ABCA1 transporter that is mutated in Tangier disease. ApoAI deficiency Several mutations of the apoAI gene resulting in greatly diminished or totally absent plasma apoAI levels have been characterized. All result in the virtual absence of HDL, and the affected individuals exhibited a high prevalence of premature CAD, although the clinical manifestations are highly heterogeneous. ApoAI structural variants Approximately 20 different mutations affecting the structure of apoAI have been reported. Some significantly reduce HDL-cholesterol levels, several are defective in LCAT cofactor activity, and one results in lethal amyloidosis. It is noteworthy that individuals with certain apoAI structural defects resulting in very low HDL-cholesterol levels (in some cases, <10 mg/dL) do not exhibit premature CAD. The explanation is probably related to HDL functional heterogeneity or to compensatory genetic variations. Tangier disease Characterized by very low levels of plasma HDL cholesterol, apoAI, and apoAII. It results from the inability of cells to donate cholesterol to apoAI and other acceptors, producing very small HDL particles that are rapidly catabolized. The gene for Tangier disease has been identified and shown to be an ABC transporter. LCAT deficiency LCAT is responsible for the esterification of HDL cholesterol, and deficiencies result in lamellar HDL particles containing primarily unesterified cholesterol, low HDL-cholesterol levels, and abnormalities of other lipoprotein classes. Although LCAT deficiencies are accompanied by large reductions in HDL cholesterol (<10 mg/dL), they do not appear to accelerate CAD dramatically. The explanation is unclear but is probably related to HDL functional heterogeneity. Hyperalphalipoproteinemia due to CETP deficiency CETP transfers cholesteryl esters from HDL to very-low-density lipoprotein and IDL, with a reciprocal transfer of triglycerides to HDL. CETP deficiency results in substantial elevations of HDL-cholesterol levels, often exceeding 150 mg/dL. Such mutations are rare in white populations but relatively common in Japanese. ApoAII deficiency A family with total apoAII deficiency due to a splice junction mutation of the apoAII gene exhibited unremarkable lipoprotein profiles, indicating that apoAII is not required for HDL assembly and that its absence does not profoundly affect other aspects of plasma lipid transport. Nevertheless, several independent studies indicate that common variations of the apoAII gene influence apoAII levels and HDL composition (67,70).

Apo, apolipoprotein; CAD, coronary artery disease; CETP, cholesteryl ester transfer protein; IDL, intermediate-density lipoprotein; LCAT, lecithin-cholesterol acyl transferase; VLDL, very-low-density lipoprotein.

Genetic Classification of Lipoprotein Variations

The clinical classification of lipoprotein disorders has been based largely on the plasma lipid and lipoprotein phenotypes. For example, an early classification of hyperlipidemias, known as the *Frederickson classification* (39), is based on electrophoretic lipoprotein phenotypes. With the exception of type III hyperlipidemia, each of the classes is now known to include multiple, genetically distinct disorders. Similarly, HDL deficiencies have been lumped together as "hypoalphalipoproteinemia," although they clearly result from different genetic factors. We have suggested that an alternative classification, based on the underlying genetic factors, provides a more useful subdivision of lipid disorders, because it allows the targeting of therapies based on mechanisms and it facilitates assessment of risk to the patient and his or her relatives (40). The inheritance patterns include "simple" (or mendelian) and "complex" disorders. The mendelian disorders can be further subdivided into those that exhibit recessive, dominant, or codominant patterns of inheritance. As yet, analysis at the level of DNA is of little value for the screening or classification of common dyslipoproteinemias, although in some cases, such as apoE alleles in type III hyperlipidemia, genotype analysis can be useful for family studies and genetic counseling (40).

Common Hyperlipidemias and Other Variations Affecting Metabolism of Apolipoprotein B–Containing Lipoproteins

Complex Hyperlipidemias

Most moderate hyperlipidemias are multifactorial in nature and simply reflect the high end of the normal population distribution. Some are associated with other conditions, such as type II diabetes, obesity, alcoholism, hypothyroidism, pregnancy, renal failure, or drug use, and hence are termed *secondary*. Primary and secondary hyperlipidemias can have a strong genetic component. Many of the genes for apolipoproteins, lipoprotein receptors, and enzymes in plasma lipoprotein metabolism have been examined as "candidate" genes to test for possible associations or linkages with levels of plasma lipoproteins and lipids (38). Most of the observed effects on lipoprotein metabolism are relatively small and require confirmation. Three common variations of apoE, however, exhibit marked effects on plasma cholesterol levels as well as contributing to type III hyperlipidemia (*e*Table 98.0.10). In Western populations, it has been estimated that the apoE alleles explain 4% or more of total plasma cholesterol levels (41).

***e*TABLE 98.0.10** EFFECT OF COMMON APOLIPOPROTEIN E (APOE) ALLELES ON PLASMA CHOLESTEROL LEVELS IN TWO POPULATIONS

ApoE isoforms	U.S. population		German population	
Frequency (%)	Mean cholesterol (mg/dL)	Frequency (%)	Mean cholesterol (mg/dL)	
4/4	0.9	207	2.8	197
4/3	23.9	193	22.9	189
3/3	59.5	192	57.4	184

The apoE-system: genetic control of plasma lipoprotein concentration. *Adv Exp Med Biol* 1986;201:261–272.

Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCH) is a common disorder (approximately 1% of the European population but also common in other populations) that is characterized by elevations of very-low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), and LDL. FCH can best be distinguished from other forms of primary hyperlipidemia by family studies, because it exhibits an apparent dominant mode of inheritance. Among survivors of premature MI (<60 years), FCH is the most common familial lipid disorder, with a frequency of approximately 10% to 20% (42,43). The primary defect in FCH appears to involve an increased production of apoB and VLDL (44). Population association and family linkage studies have suggested that certain alleles of the apoAI-CIII-AIV gene cluster may contribute to familial forms of hypertriglyceridemia (45), and this cluster is also associated with FCH (46). Hypertriglyceridemia develops in transgenic mice that overexpress apoCIII (47). Heterozygosity for null mutations of lipoprotein lipase (LPL) may also contribute to certain forms of FCH (48). None of the candidate genes that have been studied thus far is likely to be the primary cause of FCH. One possible explanation for FCH is a "double hit" hypothesis. This hypothesis states that the primary defect in FCH is an increased production of apoB and VLDL and that a variety of secondary defects that inhibit lipolysis (apoCIII overexpression, LPL deficiency, certain apoE alleles) add to the burden, resulting in dramatic elevations in VLDL and IDL. This might appear to be inconsistent with the apparent dominant mode of FCH inheritance, but the hypothesis could explain the observed inheritance patterns if the secondary defects are quite common (49).

Familial Hypercholesterolemia

FH is caused by mutations of the LDL-receptor gene that affect receptor function. FH is extremely heterogeneous at the molecular level, and dozens of mutations of the LDL-receptor gene with variable effects on plasma cholesterol levels have been characterized. Because of the heterogeneity of LDL-receptor mutations, molecular diagnosis of the disorder is difficult. Certain populations, including French-Canadians, Afrikaners, and Lebanese, exhibit an increased incidence of FH due to a high frequency of specific mutations in each population. This is the result of a founder effect involving the rapid expansion of a population, and in such populations, molecular screening for FH is probably feasible (50).

Analysis of a large pedigree that exhibits FH has revealed the existence of a dominant, mendelian genetic factor capable of suppressing FH (51). Thus, obligate FH individuals who carried the factor exhibited relatively normal LDL-cholesterol levels, whereas other FH family members not carrying the factor had the highly elevated LDL-cholesterol levels that are typically associated with heterozygous FH. The factor does not significantly influence lipoprotein metabolism in non-FH individuals. The identity of the genetic factor is unknown, but a number of candidate genes (including the LDL receptor) have been excluded. Presumably, the factor is rare, and the fact that it can only be observed on the background of FH makes its study difficult.

Familial Defective Apolipoprotein B100

Familial defective apoB100 is due to a mutation in the coding sequence of apoB100 that substitutes glutamine (Gln) for arginine (Arg) at amino acid 3,500 of the polypeptide. This region serves as the ligand for binding to the LDL receptor, and the mutant form exhibits only a few percent of normal receptor-binding activity. Heterozygous familial defective apoB100 individuals exhibit cholesterol levels of approximately 300 mg per dL because of defective LDL clearance (52,53). The frequency of the disorder is approximately 1 in 500 to 1,000 in white populations.

Familial Dysbetalipoproteinemia or Type III Hyperlipidemia

Familial dysbetalipoproteinemia or type III hyperlipidemia is a relatively rare (approximately 1 in 5,000 in white populations) recessive disorder that is characterized by the accumulation of chylomicron remnants and IDL due to impaired clearance, resulting in cholesterol levels of greater than 300 mg per dL and even higher triglyceride levels. In the majority of cases (approximately 90%), type III is associated with homozygosity for a common allele of apoE, designated *E2*. The properties of various apoE alleles are given in *e*Table 98.0.11. Homozygosity for the E2 allele is, in most cases, necessary but not sufficient for the development of type III, because the vast majority (approximately 95%) of individuals who are homozygous for E2 do not exhibit the disorder and, in fact, tend to have low cholesterol levels (*e*Table 98.0.10). Thus, there are additional genetic or environmental predisposing factors, possibly relating to obesity or type II diabetes (approximately 50% of patients have glucose intolerance).

***e*TABLE 98.0.11** MUTATIONS AND COMMON VARIATIONS OF APOLIPOPROTEIN E

Phenotypic designation (charge)	Structure	Frequency[a] (%)	LDL receptor–binding activity (%)	Association with hyperlipidemia
Common alleles				
E3	“Wild type”	77	100	No
E4	Cys_{112}→Arg	15	100	Multigenic hypercholesterolemia
E2	Arg_{158}→Cys	8	2	Type III
Rare alleles				
E1	Arg_{158}→Cys, Gly_{127}→Asp		4	Type III
E2	Arg_{136}→Ser		n.d.	Type III
E2	Arg_{145}→Cys		45	Type III
E2	Lys_{146}→Gln		40	Type III
E3	Cys_{112}→Arg, Arg_{142}→Cys		<20	Type III
$E3_{Leiden}$	No Cys		~50	Type III
Null	No protein			Type III

LDL, low-density lipoprotein; n.d., not determined.

The utility of a genetic classification for lipoprotein disorders is nicely illustrated by type III hyperlipidemia. Because the disorder overlaps with several other hyperlipidemias in terms of cholesterol and triglyceride levels, definitive classification is best made by characterizing inheritance patterns and testing for apoE alleles. The latter is now widely performed using polymerase chain reaction amplification of DNA, although it should be noted that apoE genotyping can have some ethical considerations, because a relatively common allele of apoE (E4) is strongly associated with late-onset Alzheimer’s disease. A definitive classification of type III is important in at least two respects. First, because the disorder is highly responsive to diet and, if untreated, strongly predisposes to clinical disease, the diagnosis significantly influences therapy. Second, knowledge of the genetic nature of the disease allows determination of other family members at risk.

Lipoprotein(a)

Like LDL, Lp(a) contains a cholesteryl ester–rich core surrounded by a single molecule of apoB100, but it contains an additional polypeptide, termed *apo(a)*, that is disulfide bridged to apoB. The levels of Lp(a) differ greatly among individuals, ranging from undetectable to approximately 200 mg per dL. Significant differences are also found between populations; for example, Chinese and whites exhibit highly skewed distributions, with most individuals having relatively low levels (less than approximately 10 mg per dL), whereas black populations have more normal distributions with higher mean levels. Since the discovery of Lp(a) (59), numerous epidemiologic studies have indicated an association between high Lp(a) levels and CAD (60,61). Several prospective studies with Lp(a) and CAD have, however, yielded negative results. Most likely, these are related in part to differences in methodologies or the cohorts studied. Structurally, the apo(a) polypeptide exhibits remarkable sequence homology with plasminogen, and it is very likely that apo(a) evolved by a duplication and modification of the plasminogen gene. A striking characteristic of apo(a) is the presence of numerous repeats (in somewhat different versions) of the plasminogen kringle IV domain. The number of these repeats differs among individuals and results in genetic variation in the length of the apo(a) polypeptide. More than 30 different alleles of apo(a) have been identified, each differing by a single kringle IV repeat. Analysis of Lp(a) levels using the sib-pair method indicated that more than 90% of the variance of Lp(a) levels is determined by genetic variations of the apo(a) gene (62,63 and 64).

Common Genetic Variations of High-Density Lipoprotein

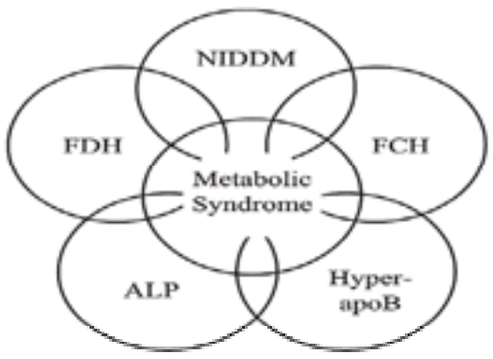
The majority of variation in HDL levels and structures is multifactorial in nature. Included in this are most forms of *hypoalphalipoproteinemia*, arbitrarily defined as HDL concentrations of less than the tenth percentile. Thus far, a variety of candidate genes have been examined in various populations, and several have been confirmed in multiple studies (*e*Table 98.0.5). High triglyceride levels and low HDL levels are frequently associated with abdominal obesity and type II diabetes (16). The mechanisms involved are unclear but may be related to changes in the expression of LPL (positively correlated with HDL) and hepatic lipase (negatively correlated), because both are altered in obesity.

It is clear that HDL is structurally and functionally heterogeneous. The levels of the various-sized classes of HDL differ among individuals, and this is determined in part by genetic factors (65,66). Polymorphisms of the apoAII gene in humans and in mice influence the ratio of apoAII to apoAI in HDL and the levels of plasma free fatty acids and triglycerides (67,68,69 and 70).

The composition of HDL can also be dramatically altered as the result of infections or various chronic inflammatory processes. In particular, acute or chronic inflammatory processes can cause hepatic serum amyloid A expression to increase to the point at which it becomes a major protein component of HDL. Such HDL, termed *acute-phase HDL*, has altered functional properties and, with respect to atherosclerosis, is likely to be proinflammatory rather than antiinflammatory (71).

METABOLIC SYNDROME

The metabolic syndrome, also called the *insulin resistance syndrome*, is in reality not a single disease but a combination of several disorders. It is characterized by the presence of hyperinsulinemia; obesity; decreased HDL-cholesterol levels; small, dense LDL particles; hypertriglyceridemia; hypertension; and hypofibrinolysis, all of which contribute to an increased risk of heart disease (72,73). Genetic studies of pedigrees from Utah defined a similar condition, termed *familial dyslipidemic hypertension*, involving a clustering of central obesity, lipid abnormalities, hypertension, and elevated fasting insulin levels (74). In addition, there is considerable phenotypic overlap between the metabolic syndrome and other disorders, such as non–insulin-dependent diabetes mellitus (NIDDM), FCH, and ALP (75,76) (*e*Fig. 98.0.4). Diabetes and obesity are risk factors for premature CAD, and it appears that they accelerate the atherosclerotic process, in part through interactions with other risk factors (77,78 and 79). It is not certain whether these disorders are different entities or just different definitions of the same underlying metabolic defect. Although the aggregate of the abnormalities in the metabolic syndrome clearly results in an unfavorable atherogenic risk profile, the mechanistic link with atherosclerosis is not entirely understood. Evidence from familial aggregation, twin studies, ethnic predilection, and animal studies suggests that genetic and environmental factors contribute to the abnormalities observed (80). Because the metabolic syndrome and the diseases with which it overlaps are complex, there will most likely be multiple genes, but it is not certain whether there will be specific susceptibility genes or an overlapping set of genes. Identification of the genetic factors that underlie the component abnormalities of the metabolic syndrome may elucidate the mechanism by which there is an increased risk for development of CAD.



***e*FIGURE 98.0.4** Overlap of the metabolic syndrome with other disorders. See text for discussion. ALP, atherogenic lipoprotein phenotype; apoB, apolipoprotein B; FCH, familial combined hyperlipidemia; FDH, familial dyslipidemic hypertension; NIDDM, non–insulin-dependent diabetes mellitus. (Adapted from Kwiterovich PO. Genetic and molecular biology of familial combined hyperlipidemia. *Curr Opin Lipidol* 1993;4:133–143.)

Low-Density Lipoprotein Particle Size

Small, dense LDL particles, as characterized by either a low ratio of LDL cholesterol to apoB, a plasma LDL apoB above 130 mg per dL but an LDL-cholesterol level below the ninetieth percentile (termed *hyperapobetalipoproteinemia*), or rapid polyacrylamide gel electrophoretic mobility [termed *atherogenic lipoprotein phenotype* (ALP)] are commonly associated with increased CAD, FCH, low HDL levels, and elevated triglyceride levels (54). The size of LDL is determined by environmental as well as genetic influences, and whether it contributes to atherosclerosis or is simply associated with other aspects of lipoprotein metabolism is unclear. Some studies have suggested that small, dense LDL particles are particularly susceptible to oxidation, providing a potential causal link to atherosclerosis (55). Family studies suggested linkage of the ALP to the LDL-receptor locus on chromosome 19 (56), and more recent studies with pedigrees enriched for heart disease suggested a complex pattern of inheritance with contributions from several loci, including a locus on chromosome 6 linked to the manganese superoxide dismutase (MnSOD) gene, a locus on chromosome 11 linked to the apoAI-CIII-AIV gene cluster, a locus on chromosome 16 linked to the cholesteryl ester transfer protein gene, and a locus on chromosome 19 linked to the LDL-receptor gene (57). In a subsequent study, the AI-CIII-AIV, MnSOD, and cholesteryl ester transfer protein gene loci were also found to segregate with ALP in FCH families, supporting the previous results (58). Interestingly, this latter study also demonstrated that small, dense LDL particles were tenfold more prevalent in FCH probands than in control subjects, lending support for the association between FCH and ALP (58).

Non–Insulin-Dependent Diabetes Mellitus

NIDDM (type II) is associated with obesity and is characterized by the presence of peripheral insulin resistance or a relative decreased insulin secretory capacity, or both. Diabetes is discussed in Chapter 7, and we review here only certain genetic aspects. Studies in monozygotic twins have demonstrated concordance rates of up to 90%, indicating a strong genetic determinant of susceptibility (81,82). Physiologic and genetic studies indicate heterogeneity in the pathogenesis of NIDDM and are most consistent with a multifactorial mode of inheritance. Several inbred rat and mouse strains exhibit NIDDM (83), providing useful models for identifying susceptibility genes. A large number of candidate genes have also been tested in population association studies and in linkage studies. Among those that have shown significant associations to NIDDM or glucose and insulin levels are the following: insulin and insulin-receptor genes (84), the glycogen synthase gene (85), the glucokinase gene (86), the $beta_3$-adrenergic receptor gene (81), and the apoAI and apoB genes (81). The gene for the intestinal fatty acid–binding protein (FABP2) on chromosome 4q exhibited linkage in Mexican-Americans and in Pima Indians (87,88). Mutations in the glucokinase, hepatocyte nuclear factor-4a, and hepatocyte nuclear factor-1a genes cause different forms of maturity-onset diabetes of the young (MODY), in which the NIDDM phenotype develops in young adults and segregates in a dominant fashion within families (89,90 and 91). However, it appears that these genes are not the cause of the more common forms of diabetes. Point mutations and deletions within the mitochondrial genome have been shown to result in specific maternally transmitted syndromes in which diabetes is a significant element (92). Several syndromes of marked insulin resistance are caused by mutations in the insulin-receptor gene (93). Finally, a common polymorphism in the peroxisome proliferator-activated receptor gamma gene has also been associated with diabetes, although the effect does not appear to be very strong (94).

As with other complex diseases, the use of genome-wide searches for NIDDM is proving to be an important tool in identifying additional genetic loci. Numerous genome scans have now been conducted in a variety of ethnic populations, including European whites, Mexican-Americans, and Pima Indians (95,96,97,98,99 and 100). The first genome scan identified a major NIDDM susceptibility locus, designated *NIDDM1*, on chromosome 2q in a Mexican-American population from Texas with a high rate of diabetes (95). Using high-resolution linkage disequilibrium mapping, the critical region was narrowed and an intronic polymorphism in the calpain-10 gene was identified that was more frequent in affected individuals than in normal control subjects (101). Calpain-10 is a cysteine protease and is ubiquitously expressed in all tissues. Although the intronic polymorphism is associated with NIDDM, it is not clear how it plays a functional role in the development of diabetes. Studies in the Pima Indians suggest that this variant alters expression of calpain-10 in muscle and leads to lower glucose oxidation rates, lending support for its role in glucose metabolism (102). Ultimate proof of whether this is an NIDDM susceptibility gene will rely on more detailed functional experiments and the development of animal models. Although the NIDDM1 locus has been identified in Mexican-Americans, it does not appear to contribute significantly to diabetes in other ethnic populations.

A locus for diabetes was identified on the long arm of chromosome 1, near the apoAII gene, in the Pima Indian population of Arizona (96). Subsequently, this locus was also linked to diabetes in two independent sets of white pedigrees from Utah and France (98,100). Of particular interest is the fact that the chromosome 1 locus was originally linked to the FCH phenotype in a set of Finnish families (103). This locus is also syntenic to a region on mouse chromosome 3, where a gene for combined hyperlipidemia was mapped (104). Thus, given the phenotypic overlap between NIDDM and FCH, the results from these studies raise the possibility that the same gene in this locus contributes to the development of FCH and NIDDM. Identification of the gene should be easier in the mouse. Whether the same gene gives rise to hyperlipidemia or diabetes, or both, remains to be determined.

Obesity

Obesity exhibits considerable metabolic overlap with the abnormalities that are present in diabetes and is associated with hypertension. Numerous family studies have shown that measures of obesity such as body mass index are significantly correlated between parents and their children (105), and concordance rates in monozygotic twins are much greater than those in dizygotic twins, supporting a strong genetic component contributing to these phenotypes. Adoption studies have confirmed these results. Furthermore, obesity is a characteristic feature of several genetic syndromes (106).

A variety of candidate genes have shown associations with various measures of obesity in human populations (107). These include the sodium–potassium–adenosine triphosphatase genes on chromosome 1, the $alpha_2$-adrenergic receptor on chromosome 10, the beta-hydroxysteroid dehydrogenase gene on chromosome 1, and the brown adipose tissue uncoupling protein gene on chromosome 4. A mutation within the coding region of the $beta_3$-adrenergic receptor may be associated with the propensity to gain weight in a French population (108). Last, obesity in Pima Indians has been linked to a marker near the tumor necrosis factor-a gene on chromosome 6 (109).

Genetic studies in mutant mouse strains have led to the identification of several genes that contribute to obesity (110). These include the dominant Agouti (*A*) gene on chromosome 2 and several recessive genes, including diabetes (*db*) on chromosome 4, obese (*ob*) on chromosome 6, tubby (*tub*) on chromosome 7, and fat (*fat*) on chromosome 8. The *ob* and *db* genes have proved to be particularly interesting, contributing directly to an understanding of body fat homeostasis. The *ob* gene is expressed in adipocytes and encodes the hormone leptin, which plays a role in regulating metabolism and satiety (111,112 and 113). The *db* gene encodes the leptin receptor (Ob-R), which is expressed in many tissues including the hypothalamus (114). The Ob-R gene undergoes alternative splicing, and only one of the splice products, expressed primarily in the brain, is capable of signal transduction following leptin binding. These findings demonstrate that the regulation of fat metabolism involves an important feedback loop between adipocytes and the hypothalamus. Leptin mutations in obese humans are extremely rare, however, suggesting that leptin resistance may cause obesity. Additional genetic loci that contribute to obesity and body fat measures have been identified in humans and mice through the use of quantitative trait locus mapping, although the underlying genes are unknown (107,115,116,117,118,119,120,121 and 122).

Hypertension

A number of studies have revealed associations between elevated blood pressure, hyperlipidemia, insulin resistance, and coronary atherosclerotic disease (123). Thus, identification of genes that contribute to blood pressure variation will also increase our understanding of the relationship between hypertension and atherosclerosis.

Significant progress has been made in elucidating the genetic basis for certain mendelian forms of hypertension, but the genetic factors that contribute to essential hypertension are largely unknown (124,125). Ample evidence from twin studies and family studies has shown that the patterns of familial aggregation of the common

forms of hypertension have a very significant genetic component (126). A number of candidate genes, particularly members of the renin-angiotensin system, have been investigated in humans and animal models. Linkage and association studies have provided relatively strong evidence for the role of the angiotensinogen gene in hypertension in white and African-Caribbean populations as well as in pregnancy-induced hypertension (127,128,129 and 130). The angiotensin-converting enzyme (ACE) gene has been found to be associated with coronary heart disease, but this appears to be a mechanism that is independent of the effects on blood pressure (131). In addition to candidate gene studies, several genome scans for essential hypertension and blood pressure have now been reported in various populations (132,133,134,135 and 136). However, unlike the results of the NIDDM genome scans discussed above, there is no overlap between the loci identified in these genome scans for hypertension/blood pressure. One explanation for the variation in these results could be the different racial makeup of the study populations. Another potential reason is the underlying genetic heterogeneity, because numerous genetic factors contribute to variation in blood pressure. One strategy for reducing this confounding factor may be to stratify the study population. For example, gene-finding efforts for blood pressure may yield better results if they are conducted in a study sample that is restricted to hypertension within the context of other pathophysiologic processes. In this manner, a more homogeneous hypertensive group can be selected, potentially reducing the problem of genetic heterogeneity. This strategy is exemplified by one study in which a genome scan for blood pressure was conducted in families with insulin-resistant dyslipidemia (136). In that study, systolic blood pressure and free fatty acid levels were mapped to the same locus on the short arm of chromosome 4. Although it is possible that there are two different genes in the region, a more attractive hypothesis is that there is a single gene at that locus contributing to blood pressure and to free fatty acids, supporting the notion that common loci underlie the clustering of traits in the metabolic syndrome.

Conclusions

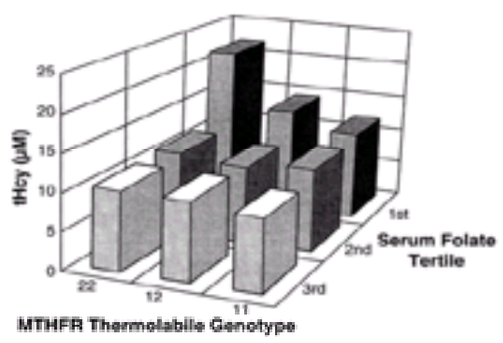
In summary, the strong clustering of insulin resistance, hyperlipidemia, and hypertension in the metabolic syndrome (and other related disorders) suggests that these traits have common genetic determinants. Some studies support this hypothesis, but genes that are specific to each component most likely exist as well. How the abnormalities in the metabolic syndrome exacerbate the atherosclerotic process is poorly understood. Metabolic derangements in diabetes consist of hyperglycemia, hyperinsulinemia, insulin resistance, and lipid abnormalities. Hyperglycemia has been shown to cause increased nonenzymatic glycation of proteins, resulting in the production of advanced glycation end products and the formation of reactive oxygen species (137). Such advanced glycation end products may damage the artery wall, perhaps contributing to the accelerated atherosclerosis that is observed in diabetics. The role of hyperinsulinemia and cellular insulin resistance on atherosclerosis development is less clear but may potentially involve its association with blood pressure (138). For example, it has been shown that insulin resistance (defined by hyperinsulinemia) in Mexican-Americans not only precedes the development of hypertension but also is predictive of it and that insulin resistance and blood pressure cosegregate in hypertensive families (139,140). Furthermore, elevated insulin levels may result in increased expression of endothelin, a vasoconstrictive protein produced by the endothelium (141). Insulin also appears to suppress C-type natriuretic peptide, an endothelial-derived vasodilatory molecule, and has been shown to decrease plasma vitamin E levels (142,143). Although these latter effects need to be examined in the hyperinsulinemic state, they provide potential mechanisms that could accelerate the atherosclerotic process.

HOMOCYSTEINE METABOLISM

The consideration of homocysteine as a risk factor for atherosclerosis derives from elucidation of the autosomal recessive disorder homocystinuria, characterized by the presence of highly elevated levels of homocysteine in plasma and a high frequency of occlusive vascular disease accompanying other manifestations. Subsequent studies have established that total plasma homocysteine (tHcy), at levels present in the general population, is an independent and significant risk factor for coronary artery, cerebrovascular, and peripheral arterial atherosclerotic disease.

Highly elevated levels of tHcy are found in patients with homocystinuria, which most commonly results from homozygosity for cystathionine beta-synthase (CBS) and much less often from homozygous deficiency of MTHFR or enzymes in cobolamin metabolism. Homocystinuria is relatively uncommon, with incidence rates varying from 1 in 50,000 to 1 in 1,000,000 in different countries (it is approximately 1:400,000 in the United States). Heterozygosity for classic homocystinuria due to CBS deficiency is typically associated with disproportionate elevation of plasma tHcy after a methionine load, but fasting levels are near normal in most individuals (144). Whether the heterozygous state is also associated with an increased risk of atherosclerotic or thrombotic disease is not established, as limited data are available from studies of obligate heterozygotes. A survey of such individuals found no increased incidence of vascular disease (although relative risk of <5 could not be excluded), and two reports of carotid ultrasound assessment of intima-media thickening found no increases compared to those of normal control subjects (145,146 and 147).

Individuals whose plasma tHcy levels exceed the ninetieth or ninety-fifth percentile of the population for fasting or postmethionine load are defined as having moderate (sometimes termed *mild*) hyperhomocysteinemia. General evidence for a genetic basis comes from family studies that have shown an increased frequency of moderate hyperhomocysteinemia among relatives of affected individuals (148,149 and 150). Genetic analyses have clearly shown that heterozygosity for classic CBS deficiency does not account for any significant fraction of moderate hyperhomocysteinemia in the general population (151,152), contradicting earlier reports suggesting that it did (153,154 and 155). However, substantial data have accumulated indicating that a common mutation in the MTHFR gene is the underlying cause of moderate hyperhomocysteinemia in approximately half the cases. In 1988, Kang and colleagues (156) described a biochemically variant form of MTHFR, which was unstable at elevated temperatures (thermolabile), and later noted an increased frequency in CAD patients (157). This phenotype has subsequently been shown to be due to homozygosity for a point mutation ($C_{677}T$) in the coding region of MTHFR that decreases enzyme activity (158,159). The frequency varies among different ethnic groups, being relatively common in various white populations (10% to 15%) but less so in some others (160). Although the majority of individuals who are homozygous for the thermolabile mutation do not have hyperhomocysteinemia, half or more of individuals with basal plasma tHcy concentrations that exceed 20 µM are homozygous for the mutation. The most important known factors in determining whether the presence of the mutation will result in elevated homocysteine levels are the intake and availability of folic acid (19,20). When plasma levels of folate are above 4 µM, homocysteine levels in patients with the mutation are no different on average from those of unaffected individuals. At lower concentrations of folate, the likelihood of having increased basal homocysteine goes up in all persons, but to much higher levels in individuals with the mutation (*e*Fig. 98.0.5). The mutation has no effect on postmethionine load tHcy concentrations. Although the thermolabile mutation clearly is associated with moderate hyperhomocysteinemia, the frequency of homozygotes is not increased in most atherosclerotic disease populations compared with that of control subjects (161). This may be because most individuals have adequate folate intake, nullifying the potential atherogenic effect of the mutation and leaving too few individuals to contribute sufficiently to the risk of being detected statistically. An alternative interpretation is that elevated plasma homocysteine is not a causative factor in atherosclerosis but rather a marker of another as yet unidentified process.



***e*FIGURE 98.0.5** Gene-environment interaction in the determination of plasma homocysteine levels. Homozygosity for the methylenetetrahydrofolate reductase (MTHFR) thermolabile mutation has a significant effect on plasma homocysteine levels, but only among individuals with relatively low folate levels (unpublished data). tHcy, total plasma homocysteine.

Additional genetic determinants of plasma tHcy remain to be identified. Up to half of the cases of moderate hyperhomocysteinemia are not associated with the MTHFR thermolabile mutation, and the underlying cause is not known (162). Within the normal range of basal plasma tHcy, several twin and family studies, although not all, have shown a fairly strong hereditary component that is unlikely to be due to the MTHFR $C_{677}T$ mutation (163,164 and 165). This has stimulated the search for additional common mutations/polymorphisms in the MTHFR, CBS, and methionine synthase genes. Although a number has been identified in each of these, their effects on plasma tHcy or association with disease are negative or, at best, inconsistent (166,167,168,169 and 170).

HEMOSTATIC FACTORS

Thrombosis triggered by atherosclerotic plaque rupture is the proximate cause of the majority of morbidity and mortality associated with atherosclerotic vascular disease. Nonocclusive thrombosis with organization of the thrombus is also believed to be an important mechanism of plaque enlargement. Thus, factors that are involved in thrombus formation and persistence must be considered as potential risk factors and, correspondingly, the genetic regulation of these as a part of the genetic basis of atherosclerotic vascular disease. Epidemiologic studies have evaluated a number of the blood hemostatic factors. Of these, fibrinogen, plasminogen activator inhibitor type 1 (PAI-1), and factor VII (FVII) have shown significant independent associations with arterial vascular disease, most consistently for fibrinogen

and PAI-1; platelet hyperactivity has also been observed (171). Substantial data have accumulated showing that each of these is regulated in part by common genetic variations in the population (172).

The hemostatic system encompasses the multitude of cellular and fluid phase constituents, which interact to prevent bleeding and limit intravascular fibrin formation. In pathologic settings, this same system is responsible for thrombosis. It can be viewed as a tripartite system composed of (a) fibrin as the central structural molecule of the thrombus and fibrinogen, from which fibrin is formed by the proteolytic action of thrombin; (b) a procoagulant protease cascade resulting in thrombin generation, composed of a series of cellular and fluid phase molecules; and (c) a fibrinolytic cascade resulting in plasmin generation that proteolytically degrades fibrin, composed of another series of cellular and fluid phase molecules. The procoagulant and the fibrinolytic arms have constituents that promote or participate in thrombin or plasmin generation and constituents that inhibit the processes. Endothelial cells and platelets (and in some cases monocytes) participate in both systems by either the cell surface expression or release of constituents. Fibrinogen, in addition to its central role as the precursor of fibrin, is a multifunctional molecule that contributes to blood viscosity and cell adhesion phenomena. Thus, the levels of hemostatic factors that are present in blood represent only one compartment of the hemostatic system, which almost certainly does not reflect the full activity of the system. The fact that elements from each of these arms are independently associated with arterial disease suggests that vessel wall components in each of them that have not been accessible to study may ultimately contribute as well.

Mendelian disorders that affect fibrinogen and most of the plasma constituents of the procoagulant and fibrinolytic systems have been described. These are all relatively rare, and for most there is little information concerning their effects on atherosclerotic disease risk. Unlike the rare disorders of lipid metabolism in which atherosclerotic disease is a primary manifestation of the disease, genetic disorders of hemostasis present either as increased risk of bleeding or thrombosis (usually venous), with no outstanding effect on atherogenesis. In general, the little evidence there is suggests that mutations manifesting as increased bleeding risk do not absolutely protect against atherosclerotic disease. Conversely, the mutations that manifest as increased venous thrombotic risk (prothrombin 20210, factor V Leiden, antithrombin III deficiency, and protein C deficiency) do not appear to predispose significantly to increased arterial thrombotic risk in the general population (171,172 and 173).

Fibrinogen

A genetic effect on plasma fibrinogen levels has been found in linkage and association studies. Heritability estimates from twin and family studies range from approximately 20% to 50% (174,175,176,177 and 178). One family-based study found that the impact of heritability varied with age, decreasing from approximately 50% at age 20 to 20% at age 60 and over (176). Most studies of plasma fibrinogen levels in offspring of CAD patients compared with control subjects have been consistent with this, showing increased levels in offspring of affected parents (179,180 and 181). Similar findings are observed in offspring of persons with essential hypertension or with NIDDM, conditions that are also associated directly with higher plasma fibrinogen levels (182).

A number of studies have examined the association of specific common polymorphisms in the fibrinogen genes with plasma fibrinogen levels, and the majority have found significant associations (17,18,183,184,185,186,187 and 188). Fibrinogen is composed of two identical subunits, each consisting of three polypeptide chains (alpha, beta, and gamma). These are encoded for by separate genes (FGA, FGB, and FGG) that are clustered adjacent to one another on chromosome 4. Because transcription of the beta chain is the rate-limiting step in fibrinogen biosynthesis, interest has focused on polymorphisms in FGB, and in particular on those in the promoter region of the gene. At present none of the polymorphisms has been documented to be functionally significant. The HaeIII polymorphism in the FGB promoter region (G/A at –455) has been studied most thoroughly and is associated with modest differences in plasma fibrinogen levels, ranging from 1% to 10% in different studies. This allele has a frequency of 20% to 25% in white populations but is less common in some others such as the Japanese (189). *e*Table 98.0.12 shows representative findings of the effect of the HaeIII genotype on plasma fibrinogen from a relatively large, European multicenter study of patients with MI (Etude Cas-Temoins de l'Infarctus du Myocarde; ECTIM), with comparable data in the same population for polymorphisms of the FVII and PAI-1 genes, discussed in the section Plasminogen Activator Inhibitor Type 1. Several studies have observed that the effect of the polymorphism is only, or more noticeably, present in individuals who smoke (17,18). This is consistent with a proposed biologic process of fibrinogen synthesis being responsive to smoking-induced mediators such as interleukin (IL)-6, as is well demonstrated in acute-phase reactions. Support for this comes from studies showing that the HaeIII genotype influenced the acute-phase fibrinogen response (190,191). The other FGB polymorphisms are in close linkage disequilibrium with the HaeIII polymorphism, and some may provide an additive effect (18,192,193). Because the overall heritable contribution is estimated to be 20% to 50%, additional genes beyond the fibrinogen gene itself are likely to be involved in determining plasma fibrinogen concentrations.

***e*TABLE 98.0.12** FREQUENCY OF HEMOSTATIC GENE POLYMORPHISMS IN MYOCARDIAL INFARCTION PATIENTS (ECTIM STUDY) AND THEIR EFFECT ON CIRCULATING LEVELS OF RESPECTIVE HEMOSTATIC PROTEINS

Fibrinogen beta	**HaeIII (G/A-455)**		
Genotype	H1H1	H1H2	H2H2
Frequency (n = 533)	0.66	0.30	0.04
Fibrinogen (mg/dL)	338	351	380
PAI-1	**4G/5G (–675)**		
Genotype	4G4G	4G5G	5G5G
Frequency (n = 476)	0.31	0.48	0.21
PAI-1 (AU/mL)	14.2	12.2	12.1
FVII	**Arg/Gln 353**		
Genotype	Arg/Arg	Arg/Gln	Gln/Gln
Frequency (n = 461)	0.80	0.19	0.01
FVIIc (%)	116	103	78

Arg, arginine; FVII, factor VII; Gln, glutamine; PAI-1, plasminogen activator inhibitor type 1.

Results of studies that attempt to establish a direct association of fibrinogen polymorphisms with clinical disease have been mixed (172). The largest study to date that has examined this is the ECTIM study, which found no difference in allele frequency overall between MI patients and control subjects (187,192). Similar findings were obtained in a Swedish study of men with MIs before age 45 (184). However, a separate case-control study of individuals undergoing coronary angioplasty found patients to have the HaeIII polymorphism significantly more frequently than did the control population (194), and in a prospective study of patients with established CAD, this polymorphism was more common in those patients who showed progression (195). Similarly, two studies of patients with peripheral vascular disease reported a positive association with disease (196,197), as have several studies of stroke patients (198,199 and 200). Several studies have examined the relationship of genotype with severity of CAD, assessed angiographically, with mixed results. A positive association was observed in the French arm of the ECTIM study, but none was found in an Australian arm (192,201). Given the numbers of patients studied and the fact that these polymorphisms contribute to only a portion of fibrinogen variability (which, in turn, contributes a small portion to vascular disease risk), these data are not unexpected or inconsistent with the hypothesis that one or more common mutations in the fibrinogen gene(s) contribute incrementally to overall cardiovascular disease risk.

Plasminogen Activator Inhibitor Type 1

Genetic regulation of PAI-1 is supported by twin studies, suggesting a moderate degree of heritability (202,203). Additionally, two family studies found a significant correlation of PAI-1 activity among first-degree relatives, with one showing strong correlation with lipid and body mass phenotypes (204,205). A large European cooperative study of offspring of men with premature CAD found no evidence of increased PAI-1 compared with control subjects (179).

Several polymorphisms have been described in the PAI-1 gene, one of which appears to be functionally significant (206,207 and 208). The latter is an insertion/deletion polymorphism in the promoter region, consisting of either four or five guanine nucleotides (4G/5G). The 5G allele has been shown to bind a repressor protein, whereas the 4G allele does not, thus reducing transcriptional activity. Clinical studies are consistent, finding that individuals who are homozygous for the 4G allele have increased PAI-1 in plasma (ranging from 15% to 50% greater than that of individuals with the 5G5G genotype; *e*Table 98.0.12) (208,209,210,211 and 212). Several of these have found evidence that the polymorphism affects the relationship of PAI-1 to triglycerides (209,210 and 211). These two traits are positively correlated in all genotypes, but among individuals with the 4G4G genotype, the slope of the regression curve is much steeper. Thus, the extent to which PAI-1 is elevated secondary to genetic or environmental influences acting on triglycerides is regulated in part by PAI-1 genotype. This is consistent with the observation that PAI-1 concentrations increase significantly after a fat tolerance test in individuals who have at least one 4G allele compared to 5G/5G homozygotes (213). However, association studies with the 4G/5G PAI-1 polymorphism and clinical disease have been mixed. Several large studies in which the risk of MI was examined (the European collaborative ECTIM study and the U.S.-based Physicians Health Study) found no significant association, whereas other studies have (208,210,212,214,215).

Factor VII/VIIa

The information that is available on the heritability of FVII is limited. One study of monozygotic twins with NIDDM reported a significant twin intrapair correlation coefficient (*r*) of 0.69 for FVII levels. Two studies of offspring of parents with premature CAD examined FVII levels, but opposing conclusions were reached (179,180).

Nevertheless, there is direct and convincing evidence that a moderately common MspI polymorphism in the FVII gene (causing a Gln substitution for an Arg) is

associated with plasma levels of FVII in men and in women (216,217,218,219,220 and 221) (*e*Table 98.0.12). Numerous studies have demonstrated a consistent decrease in FVII activity with the Gln allele, ranging from 11% to 38% for Gln heterozygosity compared with the homozygous Arg genotype. The relative frequency of the Gln allele ranges from 0.06 to 0.25, being less common in some nonwhite populations (222). Homozygous Gln individuals had levels of FVII activity that were 32% to 62% of standard and FVII antigen levels that were approximately 50% of normal. Subsequently, a 10–base pair insertion polymorphism in the FVII promoter region has been found that is in close linkage disequilibrium with the Arg/Gln polymorphism (223,224). In at least one study, this shows even stronger association with FVII levels. Studies of the functional consequences of these polymorphisms are in progress. FVII, like PAI-1, is strongly correlated with plasma triglyceride levels, and one group has observed an effect of FVII genotype on the relationship between FVII activity and triglycerides (223). Association of FVII gene polymorphisms with CAD incidence has not been demonstrated in the several studies, but a relatively large study would be required due to the high prevalence of the genotypes that are associated with higher FVII levels (201,218,221).

Platelets

Platelet function has been evaluated in fewer epidemiologic studies than plasma coagulation proteins, although enhanced platelet reactivity has been observed in several cross-sectional studies of CAD patients (171,225). This is a complex phenotypic trait with many possible causes. No data on traditional heritability measures are available, and there are no established syndromes of hereditary thrombotic disease caused by intrinsic platelet defects.

Because of the key role that platelets play in thrombosis, the potential functional and clinical consequences of common polymorphisms in the major platelet surface receptors have been investigated. These include the glycoprotein (Gp) IIb/IIIa complex, critical for platelet aggregation; the Gp Ib-V-IX complex, involved in adhesion; and the Gp Ia/IIa complex, involved in collagen binding. For each of these, there are studies that show functional and clinical associations and others that show no such associations.

The most thoroughly studied of these is the PI^{A2} polymorphism of the platelet Gp IIIa gene, which in white populations has an allele frequency of approximately 20%. Some *in vitro* studies have shown that the presence of the PI^{A2} allele is associated with a prothrombotic phenotype (226). Overall, clinical studies with relatively large numbers of subjects have not confirmed the initial observation of an association with MI or other manifestations of atherosclerotic disease, although it may play a role in some clinical settings (172,227,228 and 229).

Assessment of polymorphisms in other platelet-receptor proteins is an active area of research (172). Several polymorphisms have been identified in the gene for Gp Ia that are associated with altered Gp Ia/IIa receptor complex density. However, it is unclear whether these influence platelet functional properties. Likewise, polymorphisms are described that affect the Gp Iba gene. Although one or more clinical studies suggest an association with atherosclerotic disease for each of these, they have yet to be confirmed in larger prospective study sets (172).

Conclusions

Fibrinogen, PAI-1, and FVII are implicated as risk factors for CAD, and there is strong evidence that genetic factors moderately contribute to the overall interindividual variability in levels. Common polymorphisms in each gene have been identified that influence levels to varying degrees. Because these account for only a portion of the estimated genetic contribution to variability, it is likely that common polymorphisms in other genes will be identified. A common theme, shared with the thermolabile mutation of MTHFR affecting homocysteine levels, is that these mutations influence the response to, or their effects are potentiated by, environmental factors (fibrinogen and smoking, PAI-1 and triglycerides, MTHFR and folate) (230). Individually, these appear to contribute only a relatively small fraction to overall disease risk, such that statistical association with disease incidence or severity is frequently not observed when sought. This is an active area of research, and preliminary studies of other hemostasis-related genes have been reported in addition to those discussed here (see reference 172 for a detailed review). Genes that determine the expression and function of hemostatic elements of the vessel wall compartment also likely contribute to vascular disease, and genetic-epidemiologic studies to test for these are needed. With the advent of the complete human genome sequence and the intense search for clinically significant polymorphisms, there will undoubtedly be many more candidate polymorphisms to be evaluated. As demonstrated by the divergent results obtained in studies of the platelet PI^{A2} allele as well as those of the fibrinogen polymorphisms, these should be evaluated in multiple, large-scale, and preferably prospective studies. However, it may be premature to discount the importance of polymorphisms that have equivocal associations with disease despite confirmed functional effects. Inability to identify relevant patient subsets or the presence of as yet unrecognized gene-gene or gene-environment interactions may be reasons for false-negative results, even in large clinical studies.

INFLAMMATION

Inflammation and the immune system have been identified as important contributors to the pathogenesis of atherosclerosis. For example, premature atherosclerosis is recognized as the one disease-related complication in systemic lupus erythematosus (231). The inflammatory and immune system proteins can be classified into the acute-phase proteins, cytokines, cell adhesion molecules, and autoantibodies. In addition, an increasing role for T cells has been identified (232). Thus, the genes that encode these inflammatory and immune mediators can be considered as potential candidate genes for atherosclerosis. The focus of this section is on heritable features of these inflammatory and immune system proteins.

Acute-Phase Proteins

C-Reactive Protein

CRP is an acute-phase pentameric protein synthesized by the liver and lymphocytes that was initially identified as a protein able to bind the somatic C-polysaccharide of the pneumococcus (233). It can bind to various infectious agents, damaged cell membranes, lymphocyte Fc receptors, and LDL/VLDL particles. Hepatic synthesis can increase its concentration 1,000-fold during inflammation (234), and CRP appears to play a role in complement activation, antigen clearance, tissue factor production by macrophages, and platelet aggregation (235,236). These properties of CRP can result in damage to the endothelium, thereby contributing directly to atherosclerosis.

Many studies have examined the relationships between CRP levels and cardiovascular disease (237,238,239 and 240). Elevated CRP levels are associated with an increased risk of unstable angina in individuals with underlying CAD, an increased risk of CAD development in healthy subjects with CAD risk factors, and an increased risk for peripheral vascular disease development. Whether CRP is a marker for inflammation in atherosclerosis or plays a direct role in its pathogenesis is unclear. CRP has been shown to induce the expression of cellular adhesion molecules on human endothelial cells *in vitro*, suggesting a more direct pathogenic role (241).

The genetic determinants of CRP levels and function are poorly understood. CRP levels are increased in first-degree relatives of CAD patients who have had an MI. Although these individuals tended to be older, hypertensive, and homozygous for the 4G allele of the PAI-1 gene, elevated CRP levels (>0.33 mg per L) were still independently associated with a family history of MI (242). This association may represent an inherited predisposition to elevated CRP levels but may also represent shared atherosclerotic risk factors within families. To date, only one variation in the coding region has been identified (243). Because IL-6 increases the production of CRP (244), it is possible that polymorphisms within the IL-6 promoter, which increase IL-6 expression (245), could result in an inherited predisposition to elevated CRP levels. If CRP plays a direct role in atherosclerosis, inherited differences in its interaction with the FcgRIIa receptor on human monocytes and neutrophils may also be important. For example, CRP was found to bind to a much greater extent to monocytes and neutrophils from individuals who were homozygous for the R-131 allele of FcgRIIa compared to cells from individuals homozygous for the H-131 allele. As monocyte FcgRII receptors have been shown to play a role in LDL uptake and foam cell formation (246), the binding of CRP to monocyte receptors could influence the development of foam cells.

Mannose-Binding Lectin

Mannose-binding lectin binds to mannose and *N*-acetylglucosamine carbohydrates on infectious organisms, playing a role in opsonization and complement activation (247). Three polymorphic sites have been associated with decreased levels of expression and increased risk of infection (248,249). In a small Norwegian study, homozygosity for the rarer alleles at these three polymorphic sites was associated with patients who require coronary artery bypass surgery (250). In a study of white Canadian patients (men <55 years of age, women <60 years of age) with clinical CAD (angina, MI, coronary revascularization), heterozygosity for one of the alleles at these three sites was associated with increased carotid plaque area (251). This relationship remained significant when controlled for age, hyperlipidemia, hypertension, and smoking. The association of mannose-binding lectin polymorphisms with atherosclerosis is of particular interest given the postulated role that infectious agents, such as *Chlamydia pneumoniae*, may play in atherosclerosis.

CD14

CD14 is expressed on the surface of macrophages, monocytes, and activated neutrophils (252). Two soluble isoforms are also found in the serum (253). Binding of bacterial lipopolysaccharide to the membrane and the soluble forms of CD14 leads to cellular activation. The soluble form of CD14 is responsible for endothelial and smooth muscle cell activation (254,255). As inflammation secondary to bacterial infection has been postulated to be a mechanism that contributes to the pathogenesis of atherosclerosis, polymorphisms in the CD14 gene that may affect responsiveness to lipopolysaccharide have been tested for association with CAD. The T allele of a

T-C transition polymorphism at position –159 in the CD14 promoter region was found to be associated with MI in patients older than 62 years of age who did not have smoking or a history of hypertension as a risk factor. Homozygosity for the T allele at this locus resulted in an odds ratio of 3.8 for MI in this group (256). In another study, the frequency of the T allele at position –260 in the CD14 promoter region was found to be elevated in subjects who had experienced an MI. It was also shown in the study that healthy volunteers who were homozygous for the T allele had higher levels of CD14 on the surfaces of their monocytes (257). Similarly, in a Japanese population, the T allele of the –260 polymorphism was associated with MI (258). Thus, these studies suggest a role for CD14 in plaque stability.

Cytokines, Growth Factors, and Adhesion Molecules

Transforming Growth Factor-b

The transforming growth factor-b (TGF-b) family consists of three genes, each encoding a distinct isoform (TGF-b1, TGF-b2, and TGF-b3). With respect to atherosclerosis, TGF-b1 is of particular interest, because it is expressed in endothelial cells, connective-tissue, and hematopoietic cells. TGF-b1 exists as a latent complex that is proteolytically activated and plays an immunosuppressive role in the inflammatory process by inhibiting proliferation and activation of leukocytes. It can promote apoptosis of T and B cells, and it also plays a role in chemotaxis and cell localization through adhesion molecule regulation (reviewed in reference 259). TGF-b1 exerts antiproliferative and antimigratory effects on endothelial cells, smooth muscle cells, and macrophages (reviewed in reference 260); thus, functional polymorphisms may play a role in atherosclerosis. The TGF-b1 gene has eight known polymorphisms. A leucine-to-proline substitution at position 10 within the signal sequence of the TGF-b1 protein was examined for its association with MI in a Japanese population (261). The polymorphism was found to be associated with MI in men and with altered serum concentrations of TGF-b1. In a similar study performed in populations from France and Northern Ireland, a polymorphism that resulted in an Arg-to-proline substitution was found to be associated with MI, but the position 10 polymorphism failed to show any association (262). In contrast to the above-mentioned studies, five polymorphisms in the TGF-b1 gene failed to show any association with angiographically identified CAD or hypertension in an English population (263). Differences in the background genes of the study populations may also account for the differences in these results.

Interleukin-1 and Interleukin-1–Receptor Antagonist

IL-1 is an inflammatory mediator with a wide range of effects, including leukocyte chemotaxis, T- and B-cell activation, increased endothelial cell adhesion molecule expression, increased prostaglandin E_2 production, increased metalloproteinase production, and fever (264). In addition to playing a role in infection and autoimmune/inflammatory diseases, these mechanisms are important in the pathogenesis of atherosclerosis. The IL-1 genes (IL-1a and IL-1b) and the IL-1–receptor gene (IL-1RN) are located in a cluster on the long arm of chromosome 2. Several polymorphisms have been identified in these genes (265), and some are associated with differences in IL-1 production in response to lipopolysaccharide and with differences in IL-1–receptor antagonist levels (266,267). Polymorphisms of IL-1b and IL-1RN were found to be associated with angiographically demonstrated CAD (268,269). In a study that examined carotid artery wall intimal-medial thickness in African-Americans, an IL-1RN allele exhibited altered frequency in subjects with increased wall thickness (270). The same IL-1RN allele was also found to be associated with angiographically confirmed single-vessel CAD in an English population from Sheffield (271). Last, an Italian study demonstrated that the same IL-1RN allele was associated with MI in patients under 40 years of age (272).

Cellular Adhesion Molecules

Adhesion molecules mediate interactions between leukocytes and endothelium that result in the binding and diapedesis of leukocytes. Given the role that monocytes and lymphocytes play in atherosclerotic plaque development, these molecules could have an important role in genetic susceptibility to atherosclerosis. Polymorphisms have been identified in several of the cellular adhesion molecules, including E-selectin, P-selectin, L-selectin, VCAM-1, and ICAM-1 (273). Genetic studies in mice have shown that deficient expression of P-selectin, ICAM-1, and $beta_2$-integrin (CD18) resulted in atherosclerotic fatty streak reduction of 50% to 75% in mice fed a high-fat diet (274). In another study, P-selectin deficiency in apoE-deficient mice resulted in a decrease in monocyte recruitment into lesions, delayed plaque formation, and smaller and less calcified lesions in the aortic sinus (275). Similarly, P- and E-selectin–deficient mice bred onto an LDL receptor–deficient background exhibited delayed fatty streak development and smaller lesions in the aortic sinus (276). These results indicate that variations in expression or function of cellular adhesion molecules can affect the development of atherosclerosis.

E-selectin is expressed on activated endothelial cells, contributing to leukocyte adherence in inflammatory states. An association of a Ser-to-Arg substitution at position 128 in the epidermal growth factor–like domain of E-selectin was found to be associated with angiographically confirmed severe CAD in patients aged 50 years or younger (277). This Arg substitution was found to result in decreased adhesion strength in COS cells and in stimulated human umbilical vein endothelial cells *in vitro* (278).

P-selectin is expressed primarily on activated platelets and endothelial cells. In a study involving populations from France and Northern Ireland, a P-selectin allele with a proline substitution at position 715 (pro715) was found less frequently in patients with MI (279), suggesting a protective effect of this allele. The protective effect of this pro715 allele was confirmed in a Northern Irish population, although the effect was modest (280).

Conclusions

Most of the current human studies are preliminary, requiring confirmation in larger independent studies. The role of genetic susceptibility to infection and risk for atherosclerosis development will be an important area of investigation given the postulated mechanisms of infection in the pathogenesis of atherosclerosis. The ability to identify patients who carry functional polymorphisms in inflammatory genes that increase their risk of developing atherosclerosis or MI may permit such patients to be targeted for antiinflammatory therapy.

GENETIC FACTORS: THE VESSEL WALL

As atherosclerosis involves an interaction of arterial cells with blood elements, it stands to reason that genetic factors acting at the level of the artery wall play an important role in genetic control of susceptibility to CAD and stroke. Evidence for the existence of such factors is based in part on the finding by some, but not all, studies that the known risk factors do not fully account for the familial clustering of CAD (2,7). An interesting study bearing on this point showed that intimal thickening of coronary arteries in infants who had died before 1 year of age was significantly associated with a family history of CAD (281). As yet, little is known of such putative genetic factors, although a large number of candidate genes for processes such as cellular growth, inflammation, and oxidative stress have been identified. The genetic complexity of atherosclerosis, however, makes it difficult to test the role of these genes directly, because only relatively major genes are likely to be identified in population association and family studies. Moreover, the difficulty of quantitating lesions in humans presents a problem for human genetic studies, and the end points that are most often used, such as MI, are relatively crude. For these reasons, studies in animal models have proved particularly informative. Animal studies have provided conclusive evidence that genetic variations in vascular cell functions can profoundly influence susceptibility to atherosclerosis (282,283). In this section, we discuss some of the processes and candidate genes that may influence atherogenesis at the level of the vessel wall.

Lipoprotein Entry and Retention

Vascular permeability is increased at anatomic sites of atherosclerosis predilection, and the composition of the intimal matrix can influence LDL binding and retention (284). These processes suggest various candidate genes that could be examined in genetic studies, such as matrix proteins, but no definitive reports have been published. In studies of mice, it is clear that genetic factors can influence not only the development and size of lesions but also the sites of lesion development. For example, when fed a high-fat diet, certain strains of mice develop fatty streak lesions predominantly in the proximal aorta, whereas others develop lesions in the coronary arteries (285).

Oxidation

Abundant evidence has been found that oxidation within the vessel wall is central to at least the early stages of atherogenesis (286), but the evidence that genetic factors contribute to such oxidation is derived largely from studies with animal models (282,287,288). Molecular studies and studies with transgenic mice have suggested a variety of processes and candidate proteins that could contribute to lipoprotein oxidation (*e*Table 98.0.7). These include the levels of metal ions, thiols, superoxide, lipoxygenase, glucose, nitric oxide, myeloperoxidase, antioxidants, and HDL-associated enzymes that protect against oxidation. It is likely that some of these processes are determined in part by common genetic variations. Polymorphisms of some genes that are likely to influence oxidative stress or lipoprotein oxidation, including serum paraoxonase (PON1), nitric oxide synthase, and the hemachromatosis-associated gene, have been associated with CAD in population studies (*e*Table 98.0.5).

The evidence that PON1, a protein carried on HDL that inhibits the accumulation of oxidized lipids, plays an important role in genetic susceptibility to atherosclerosis is particularly convincing (reviewed in reference 289). Stimulated by observations that PON1 could inhibit the oxidation of LDL *in vitro*, a large number of association studies of PON1 gene polymorphisms have been conducted. Two common missense polymorphisms, a leucine-to-methionine substitution at amino acid 55 and a

Gln-to-Arg substitution at amino acid 192, have been most extensively studied. At present, more than 40 PON1 association studies with many different populations, including many European groups, Japanese, Chinese, Asian Indians, and American Indians, have been conducted. As expected for a trait as complex as CAD, results have differed between studies. However, taken together, the data are quite impressive, as more than half of the studies yielded significant results. In particular, studies that involved the Gln-to-Arg polymorphism, which clearly affects the activity of the enzyme, have consistently shown that the Arg allele is associated with increased risk. Some studies also suggest that PON1 could contribute to diabetes (reviewed in reference 289). Supporting the human data are studies in PON1 knockout mice that have conclusively shown that the enzyme can inhibit the development of atherosclerotic lesions (290,291).

Inflammation

In response to lipoprotein oxidation or other influences, monocytes are recruited to the artery wall. This involves the expression of adhesion molecules, chemotactic proteins, and growth factors for monocyte-macrophages. A number of inflammatory genes have been shown to contribute to atherogenesis in studies with transgenic mice (*e*Table 98.0.7). Among the many potential candidate genes that could contribute to vascular inflammation, several have been examined in human association studies (discussed earlier in the section Inflammation). Results with some, including TGF-b1 and IL-1–receptor antagonist, are at least suggestive.

Foam Cell Formation

Foam cells, the hallmark of early atherosclerosis, are also of importance in advanced lesions, because they contribute to lesion growth and possibly lesion stability. The growth and differentiation of macrophages appear to be importantly influenced by macrophage colony-stimulating factor (M-CSF), and much smaller lesions develop in mice with a null mutation of the M-CSF gene than in their normal littermates (292). A key process in foam cell formation is the uptake of oxidized lipoproteins, mediated by cell surface receptors that recognize oxidatively modified LDL. One study with two rabbit strains selected by breeding for either resistance or susceptibility to atherosclerosis revealed an association between the expression of receptors for modified lipoproteins and lesion susceptibility (293). Null mutations of CD36, an important receptor for uptake of oxidized lipoproteins, occur commonly in the Japanese population, but the effect on atherosclerosis has not been investigated (294). However, CD36-deficient mice exhibit smaller lesions compared to control mice, suggesting that CD36 could play a role in the development of CAD (*e*Table 98.0.7).

Smooth Muscle Proliferation

Many growth-promoting molecules for vascular smooth muscle cells have been recognized as possible contributing factors in atherosclerosis, including platelet-derived growth factor and angiotensin II (295). Inhibitors of smooth muscle cell proliferation, such as TGF-b, have also been considered in the context of atherosclerosis (296), discussed in the section Inflammation. Studies also suggest that apoptosis of human vascular smooth muscle cells may be significant in the development of fibrous plaques (297). Polymorphisms of the ACE gene have been associated with CAD in several populations (298,299 and 300). Certain common alleles of the ACE gene are associated with differences in plasma levels of ACE, which converts angiotensin I to angiotensin II and also degrades the vasodilator bradykinin. Angiotensin II promotes smooth muscle cell proliferation, whereas bradykinin is a growth inhibitor. It is likely that the ACE variation contributes to artery wall metabolism, because it is not associated with differences in blood pressure. An insertion/deletion polymorphism of the ACE gene was also strongly associated with CAD in NIDDM, providing a possible link between diabetes and CAD (301).

Monoclonal Proliferation

One possible explanation for the proliferation of smooth muscle cells in atherogenesis is a nonmalignant transformation of the cells, resulting from mutations of genes that are involved in growth control. Such a mechanism would predict that atherosclerotic lesions would show monoclonal proliferation; that is, all the smooth muscle cells in a lesion would be derived from the same transformed cell. Benditt and Benditt (302) tested this hypothesis more than 25 years ago, making use of females who were heterozygous for a genetic marker on the X chromosome. As a result of X-chromosome inactivation, women are chimeric with respect to the active X chromosome. Some cells have the paternal copy of the X chromosome active, and other cells have the maternal copy of the X chromosome active. Furthermore, because X-chromosome inactivation is stable during mitosis, all the progenitors of a particular cell have the same X chromosome active. Surprisingly, Benditt and Benditt (302) observed that small sections of coronary atherosclerotic lesions taken from deceased women who were heterozygous for the X-chromosome marker glucose 6-phosphate dehydrogenase expressed predominantly one allele of the marker or the other. More recent studies, however, have indicated that this monoclonal proliferation results from normal development (303).

Some evidence has been found that cells in lesions may undergo elevated mutation rates. In the mid-1980s, it was reported that DNA extracted from human atherosclerotic lesions exhibited the ability to transform NIH/3T3 cells (304), consistent with the activation of an oncogene, but a subsequent study failed to confirm those results (305). More recently, evidence for loss of heterozygosity and microsatellite instability in human atherosclerotic plaques has been reported (306). The significance of these findings is unknown.

Calcification

Arterial calcification is a very common occurrence in advanced human atherosclerotic lesions, and such calcification may contribute to lesion rupture (307). Because of the complexity of arterial calcification, which is clearly age and gender dependent and strongly promoted by atherosclerosis, it has been difficult to examine the genetics of the process in humans, and as yet familial clustering of calcification has not been demonstrated. Cell biology studies have suggested that arterial calcification is an active process akin to bone formation, suggesting potential candidate genes. Studies with mice have confirmed that arterial calcification is promoted by atherosclerosis, and they have also revealed the existence of distinct genetic factors (i.e., factors not involved in atherosclerotic lesion development) that contribute to the occurrence of arterial calcification and the sites of arterial calcification (285,292). Genetic studies in mice indicate that one mechanism that contributes to arterial calcification involves chondrocyte metaplasia. Some evidence also suggests that M-CSF, involved in the development of osteoclasts as well as macrophages, may contribute to arterial calcification (292). Genetic studies in mice have also resulted in the mapping of loci contributing to myocardial cell calcification (308), and these genes may also be involved in arterial calcification.

Lesion Rupture and Thrombosis

As discussed in the section Hemostatic Factors, association studies have shown that levels of various proteins involved in hemostasis, such as fibrinogen, are associated with polymorphisms of genes encoding the proteins. Epidemiologic studies have, in turn, correlated the levels of some such proteins with CAD and MI. Thus, we can conclude that common variations of certain genes for hemostasis contribute to the genetic component in CAD. Undoubtedly, this correlation is due in part to thrombosis following plaque rupture. Genetic factors may also influence the likelihood that a plaque will rupture. Clearly, the composition of a plaque, particularly whether it is primarily fibrous or fatty in nature, influences the probability of rupture. Fatty lesions are much more likely to rupture, and rupture frequently occurs at the lesion edges that are fatty in nature and contain foam cells, suggesting that the same factors that contribute to early atherosclerosis may promote rupture as well (309). It has also been suggested that certain metalloproteinases expressed in lesions, and produced in part by macrophages, may weaken lesions and increase the probability of rupture (310). One study produced suggestive evidence that a polymorphism of the gene for stromelysin-1, a metalloproteinase with broad substrate activity and expressed in atherosclerotic plaques, is associated with CAD (311). Some evidence has also been shown that polymorphisms of genes for proteins involved in host defense (such as CD14) may influence plaque stability (258).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Identification of the genes that contribute to atherosclerosis will help to unravel its complex nature and may provide insights into the interrelationship between the component traits. The successful discovery of these genetic factors will rely on the use of complementary approaches with animal models, large-scale human genetic studies, and functional experiments.

Genetic approaches are likely to have far-reaching effects on the diagnosis and treatment of heart disease and stroke. Molecular-genetic studies of mendelian disorders, such as FH, have contributed greatly to our understanding of disease processes, and the resulting knowledge has been important to the development of therapeutic strategies. For example, the knowledge of pathways for cholesterol homeostasis from studies of FH has contributed to the development of drugs such as bile acid chelators and statins (50). An outstanding example of the value of a genetic approach is the cloning of the mouse *ob* gene, which encodes the hormone leptin (111). This discovery has virtually revolutionized the field of obesity research. Clearly, understanding the underlying etiology of a disease is the best means of prevention and cure. The power of a genetic approach in providing an understanding of complex as well as simple diseases is that it leads to the identification of the primary causes. This contrasts with biochemical approaches, which frequently reveal only secondary consequences.

As yet, most of the primary causes of common forms of atherosclerosis, and of its associated risk factors, are totally unknown. Even for a process as carefully studied as lipoprotein metabolism, genetic studies suggest that many of the important genes and pathways have not yet been identified (312). Common forms of atherosclerosis present a particularly challenging problem because they are due to multiple genetic factors in combination with specific environmental contributions. Although many formidable problems remain, powerful new approaches and resources, such as those developed as part of the Human Genome Project, have created

optimism about the possibility of identifying the individual contributing genes in multifactorial diseases.

Although there is no guarantee that the identification of pathways that contribute to atherosclerosis will rapidly translate into useful new forms of pharmacologic intervention, the prospects seem excellent. Unlike most mendelian diseases, common forms of atherosclerosis depend heavily on environmental interactions. The fact that atherosclerosis progression can be modified by environmental factors, such as diet, suggests that pharmacologic intervention may be developed more readily than in the case of diseases such as sickle cell anemia, cystic fibrosis, and cancer. Although excellent pharmacologic interventions for hypercholesterolemia and hypertension are available, no effective treatments for any of the other risk factors have been developed. Of particular interest would be intervention at the level of the artery wall, perhaps complementing interventions directed at systemic factors such as cholesterol levels. Although not discussed here, genetic approaches may also be useful in dissecting pathways that contribute to restenosis, atherosclerosis following heart transplantation, plaque formation in coronary artery bypass grafts, or calcification of bioprosthetic valves. In addition to traditional drug intervention, gene therapy efforts for atherosclerosis have already been initiated, and several promising strategies have been developed. With the fundamental advances in gene delivery and gene expression that are likely to occur during the next decade, mendelian and complex forms of CAD and stroke are likely to be important targets. It may seem that gene therapy for complex forms of the disease would not be effective because there are so many contributing factors. This need not be the case, however. Even though a disease has multiple causes, altering just one can, in some cases, have a significant clinical effect. For example, simply lowering blood lipids, despite the presence of other risk factors, has proved to be very beneficial. The generation of mouse models has created many excellent opportunities for developing such therapies.

Another important consequence of understanding the genetics of atherosclerosis in more detail will be the ability to distinguish different forms of the disease for purposes of targeting pharmacologic intervention. Atherosclerosis is heterogeneous with respect to genetics and to environment. Different patients have, in a sense, different diseases, and the most appropriate therapy will differ depending on the particular variety of disease. Such classification is already used clinically, where patients are grouped according to the variety of risk factors that they display. A patient with high cholesterol is treated with a statin, whereas an individual with high blood pressure is given another drug. However, understanding the genetics of atherosclerosis, and the development of protein- or gene-based diagnostic tests, may greatly expand the possible subdivision of disease. It may also make it possible to help decide between different pharmaceuticals for treatment of a particular risk factor. For example, the differences in the responses of patients to various blood pressure medications are undoubtedly due to the fact that the patients have high blood pressure caused by different sets of genetic and environmental factors. If the patients could be classified according to genetic causes, effective medications could be identified with less trial and error. In summary, genetic approaches are likely to lead to more individualized therapy for CAD, stroke, and other common diseases.

A potential long-term benefit of genetic approaches is susceptibility testing for CAD and stroke. Cholesterol testing has been advocated for a number of years as a means of identifying individuals at increased risk, and more recently components such as HDL levels, Lp(a) levels, and homocysteinemia have emerged as indicators of risk. Once the genes that contribute to common forms of the disease have been identified, along with the specific nucleotide changes involved, DNA-based tests may greatly add to our ability to assess risk. It is clear that complexity of the genetic etiology of CAD and stroke will make it difficult to implement efficient screening procedures, and the development and validation of comprehensive test panels to assess risk profiles represent a very large challenge. Nevertheless, the potential benefits are great. Because CAD and stroke are disorders of adult onset, knowledge of disease propensity could be available many years before the development of clinical disease, permitting early intervention.

THE FUTURE

Although as yet we have relatively little understanding of the genetic causes of the common complex forms of atherosclerosis, rapid progress is now being made. This progress is dependent on new technologies, such as rapid genotyping, new analytic approaches, new information about the genome (generated in large part by the Human Genome Project), and the development of genetic animal models, particularly the mouse. Genetic approaches, by their nature, will reveal the underlying etiology of the disease. This knowledge will translate into new forms of intervention and new diagnostic tests that are capable of distinguishing different forms of the disease, allowing better targeting of intervention. A potential long-term benefit of genetic studies of the disease is risk assessment.

ACKNOWLEDGMENTS

The authors are grateful to colleagues at the University of California at Los Angeles and elsewhere for discussions on the genetics and biochemistry of atherosclerosis. They also thank Rosa Chen for her help in the preparation of the manuscript. Work in the authors' laboratory was supported by National Institutes of Health grants HL28481, HL30568, and HL60030 and by the Laubisch Fund, UCLA. H.A. was supported by an NIH Postdoctoral Training Grant in Endocrinology, Metabolism, and Diabetes.

OVERVIEW

Ever since blood pressure could first be reliably measured, studies have been carried out on the population distribution and hereditary nature of hypertension. Blood pressure is a quantitative trait that varies continuously throughout the whole population, and its regulation is controlled by a variety of mechanisms that involve several genetic loci and environmental factors in conjunction with unmodifiable parameters such as age and sex. Despite this complexity, several genetic approaches have been used to unravel the molecular mechanisms responsible for arterial hypertension in the population. The first one, called the *candidate gene approach*, corresponds to the analysis of genes coding for enzymes, receptors, and proteins known to be involved in blood pressure regulation and genes shown to be involved in blood pressure level in experimental animal models. Numerous candidate genes have been investigated in different settings such as case-control and sibling pair studies. Among genes encoding the renin-angiotensin system, interesting polymorphisms of the angiotensinogen (AGT), angiotensin I–converting enzyme (ACE), and angiotensin II type 1 receptor (AT_1) genes have been identified and have been suggested to increase the activity of the renin-angiotensin system and to play a role in human hypertension. Other important results have been found with other candidate genes such as the a-adducin, the G-protein b3 subunit, the adrenergic receptors, and the subunits of the epithelial sodium channel.

Thanks to the progress made in mapping the human genome and to several groups of clinicians who have collected data from large samples of families characterized with regard to blood pressure, the genome-wide scan strategy has been used in the recent years. This approach aims at identifying loci involved in blood pressure regulation or arterial hypertension without any a priori hypothesis as to the pathophysiologic pathway(s) that might be involved. Although no major gene has been found that could explain a large part of hypertension, several loci have been suggested. Among them, a locus on the long arm of chromosome 17 seems one of the most promising.

Finally, genes responsible for several rare mendelian forms of hypertension have also been identified. Most of them correspond to defects related to increased renal salt reabsorption and volume expansion. This is especially the case for glucocorticoid-remediable aldosteronism, due to an abnormal production of aldosterone in the adrenal zona fasciculata caused by a chimeric 11-b-hydroxylase/aldosterone synthase gene; for Liddle syndrome, due to mutations leading to increased activity of the epithelial amiloride-sensitive sodium channel; and for the syndrome of apparent mineralocorticoid excess, which is caused by a defect in 11-b hydroxysteroid dehydrogenase type 2, the enzyme inactivating cortisol in the kidney. Two genes responsible for pseudohypoaldosteronism type 2 (or Gordon syndrome) have also been identified, opening the possibility of new molecular pathways regulating renal ionic exchange and blood pressure.

GLOSSARY

Association studies: The concept behind association studies is the presence of susceptibility alleles for a given disease, which is reflected by a linkage disequilibrium with a polymorphism or a series of polymorphisms (haplotype). The statistics are based on the comparison of genotype frequencies for affected and unaffected individuals (cases and controls) either in retrospective or in prospective studies. These studies, which do not require any genetic model, are in principle able to detect susceptibility alleles—even those with a minor role on the disease. They have numerous pitfalls, however. Negative results can be the consequence of insufficient power or insufficient molecular analysis of the locus—failure to test the right polymorphism—and no conclusion can be drawn from a negative result. Positive study results can be due to a true positive association, an epigenetic effect, or a false-positive finding arising from the incorrect choice of cases and controls. This last possibility is probably the main problem raised by association studies, which too often are performed using inadequate controls (small number, population admixture). The second problem involves the choice of statistical significance level in populations in which the testing of multiple loci enhances the probability of detecting, by chance, a positive result. Results obtained by association studies need to be replicated and complemented by family-based association studies and by linkage studies.

Candidate gene approach: Most of the studies conducted so far concerning human complex traits are based on the candidate gene strategy. Due to the difficulty of mapping the gene, the idea is to test genes whose products have been proven to be important in the pathophysiology of the trait or that have been identified in animal experimental models as linked to the disease. This method has the advantage of maintaining maximal statistical power for the studies, with zero recombination between the marker and the locus tested.

Complex inherited disease: A disease arising due to a trait or phenotype that does not exhibit a classic mendelian transmission (autosomal, X-linked, recessive, dominant) is known as a *complex inherited disease*. At the opposite end of the spectrum from mendelian diseases, which are usually the consequence of alterations at a single gene locus, complex diseases such as essential hypertension are the consequences of the interaction of both environmental and multiple genetic influences.

Genome-wide scan: The strategy of genome-wide scan relies on the tremendous power of linkage analysis and the very impressive progress made in human genome mapping. The genes involved in a large number of monogenic diseases have been mapped by this method, once informative families have been collected. Mapping the locus involved in a complex trait is a much more difficult task, based on more robust but less powerful methods, such as the affected sibling pair method. The density of polymorphic genetic markers and the connections between the genetic and physical human genome maps, however, make such a genetic approach feasible, as has been already demonstrated with regard to diabetes and asthma.

Sibling pair linkage analysis: For complex traits, one cannot expect a simple cosegregation of a gene locus and a disease within a large multigenerational pedigree. There are several reasons: in particular, the age-related phenotype, the effect of the environment, the multiplicity of the susceptibility loci, and their high frequency in the population. Linkage analysis based on a specified genetic model and applied to large pedigrees is therefore problematic. Affected sibling pair analysis is a nonparametric method that is based on the number of alleles shared by affected siblings. If a locus is linked to the disease, the affected pairs will share more than the 50% distribution expected from mendelian inheritance. This methodology offers several advantages: (a) it does not assume any specific mode of inheritance at the test locus and looks only for a distortion of segregation between a genetic marker and the disease; (b) the use of a single adult generation decreases problems due to the age-related increase in blood pressure; and finally, (c) analysis of hypertensive sibling pairs can partly resolve the problem of genetic heterogeneity generated by the analysis of extended multigenerational families. The method has low statistical power, however, and requires highly polymorphic markers and a large number (several hundred) of affected sibling pairs. Increased power can be obtained by selecting individuals at the extreme (i.e., in the highest and lowest deciles of a continuous trait

such as blood pressure). This type of analysis has been widely used, with some success, in identifying loci involved in complex diseases.

BACKGROUND

A number of epidemiologic studies have shown that individual blood pressure levels result from both genetic predisposition and environmental factors. The heritable component of blood pressure has been documented in familial and twin studies and in studies such as those performed in Montreal, where blood pressure levels were documented in families with natural and adopted children (1). That approximately 30% of the variance of blood pressure is attributable to genetic heritability and 50% to environmental influences is generally accepted (2) (eTable 99.0.1).

***e*TABLE 99.0.1** MECHANISMS IMPLICATED IN BLOOD PRESSURE VARIANCE

Genetic heritability	30%
Allelic effect on a single gene	
Gene-gene interactions	
Gene-environment interactions	
Environmental influences	50%
Cultural heritability	10%
Residual variance	10%

From Ward R. Familial aggregation and genetic epidemiology of blood pressure. In: Laragh JH, Brenner BM, eds. *Hypertension: pathophysiology, diagnosis and management.* New York: Raven Press, 1990:81–100.

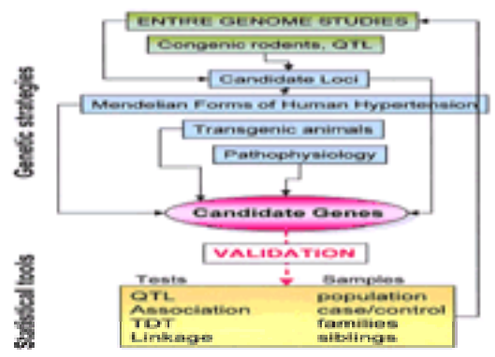
The familial component of high blood pressure can also be estimated by the use of self-questionnaires answered by hypertensive patients. Although this approach is recognized as having limited value (3), it allows screening of hypertensive patients with a putative family history of hypertension. Review of the Artemis data bank from the Hypertension Clinic of the Broussais Hospital showed that 13% of hypertensive patients reported at least one parent and one sibling with hypertension (4). Interestingly, a family history of hypertension was associated with a marked increase in the incidence of cardiovascular death of both parents before the age of 65 years and also with an increase in the prevalence of cardiovascular accidents in both parents, again before the age of 65 years. High blood pressure was detected at a younger age in patients without an apparent genetic component.

A positive family history of hypertension has a practical clinical application in identifying persons at high risk of hypertension. As reported by Williams et al. (5) in a Utah epidemiologic study, normotensive persons aged 20 to 49 years with at least two hypertensive first-degree relatives, who were observed for 7 years, had a four times higher risk of developing high blood pressure than persons without a family history of hypertension. In older adults, the relative risk of high blood pressure depends less on a positive family history of hypertension, probably because of the more prominent role of environmental factors at this age. Therefore, the finding of a strong positive family history of hypertension, especially in a young hypertensive patient, should encourage physicians to search for high blood pressure in first-degree relatives and to strongly advocate risk-factor treatment.

With the notable exception of a few autosomal forms of hypertension for which the molecular basis has been elucidated, no indication has been found regarding the number of genetic loci involved in the regulation of blood pressure, the frequency of deleterious alleles, their mode of transmission, and the quantitative effect of any single allele on blood pressure. The unimodal distribution of blood pressures within each age group and in each sex strongly suggests, but does not definitively prove, that several loci are involved. Because of the likely etiologic heterogeneity of the disease, a single biochemical or DNA genetic marker cannot be expected to help the clinician in the management of most hypertensive patients. However, genetic markers, alone and in combination, will probably be useful indicators for elucidating the various genetic loci linked to high blood pressure through intermediate phenotypes and for predicting the sensitivity to antihypertensive agents.

ANALYSIS OF CANDIDATE GENES IN ESSENTIAL HYPERTENSION

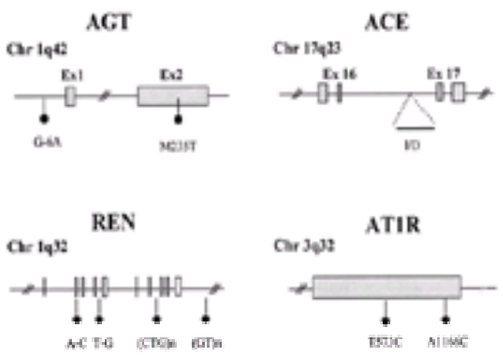
For studying the genes that might be involved in common forms of familial hypertension, the first logical approach used by researchers in the field has been to investigate genes that likely contribute to the variance of blood pressure because of their well-known effect on the cardiovascular system (eFig. 99.0.1). These candidate genes have been selected on the basis of the well-known physiologic effects of the corresponding encoded proteins or experimental results, especially in rodent models, due to their location within a quantitative trait locus or their effects on blood pressure in transgenic animals (6,7,8 and 9).



***e*FIGURE 99.0.1** Schematic diagram of the candidate gene approach. QTL, quantitative trait loci; TDT, transmission disequilibrium test.

Renin-Angiotensin System

The genes of the renin-angiotensin-aldosterone system are a good illustration of the use of the candidate gene approach because this system is well known to be involved in the control of blood pressure and the pathogenesis of several forms of experimental and human hypertension. This system consists of four main proteins: renin, AGT, ACE, and angiotensin II receptors. During the past years, considerable progress has been achieved, since all these genes have been cloned for humans and informative genetic markers have been identified (eFig. 99.0.2). Since very complete reviews on that matter by the authors' group (10) and others (11,12 and 13) have already been published, only the main findings that concern essential hypertension and blood pressure regulation are summarized here.



***e*FIGURE 99.0.2** Main polymorphisms of the renin-angiotensin system genes. ACE, angiotensin I–converting enzyme gene; AGT, angiotensinogen gene; AT1R, AT_1 receptor gene; Chr, chromosome; EX, exon; REN, renin gene.

Renin Gene

Activation of the renin system depends on the renin-AGT reaction, which is the first and rate-limiting step leading to angiotensin II production. Numerous studies have linked renin to some degree with experimental forms of hypertension and human hypertension. A fulminant hypertension develops in transgenic rats harboring the mouse Ren 2 gene (14). Even more interesting was the pioneering observation by Rapp et al. (15) of a cosegregation between a renin gene polymorphism and blood pressure level in an F2 population issued from crosses between inbred salt-sensitive and salt-resistant Dahl rats. In humans, approximately 30% of subjects with essential hypertension have higher renin levels than do normotensive subjects of the same age when examined under the same metabolic conditions (16). Interestingly, renin levels seem at least partly heritable, as observed by Grim and colleagues (17) in twins submitted to well-standardized conditions of posture and sodium diet, and more recently by Rossi et al. (18). The analysis of 175 sibling pairs and trios who participated in a multicenter trial showed very significant correlations between a familial aggregation of low-renin hypertension and plasma renin levels on either a high-salt diet (r = .36, p <.001) or a low-salt diet (r = .46, p <.001) (X. Jeunemaitre, N. D. L. Fisher, A. Vuagnat, and G. H. Williams, *unpublished data*, 1998).

The human renin gene is located on the short arm of chromosome 1 (1q32–1q42) (19). Several restriction fragment length polymorphisms (RFLPs) have been located throughout the renin gene: *Taq*I and *Bgl*I polymorphisms in the 5' region, *Hind* III in the 3' region, and *Hinf* I in the first intron. In a single large Utah human pedigree with high prevalence of coronary disease and hypertension, no significant association was found between the renin RFLPs and blood pressure or plasma renin activity (20). Interpretation was limited, however, by the very low number of patients studied. In another preliminary report, Morris and Griffiths (21) compared the renin RFLPs of 29 subjects under antihypertensive treatment with those of 202 adult patients. No association was found between hypertension and the renin gene allele but, again, no definite conclusion could be drawn because only a few patients with hypertension were studied, clinical data were not available, and the renin gene polymorphism was defined by a single and weakly informative RFLP.

Soubrier et al. (22) reported a study comparing the frequency of renin RFLPs in a large and contrasted population of normotensive and hypertensive subjects. A group of 102 hypertensive patients was selected according to strict criteria of age (between 20 and 60 years), established essential hypertension, and familial history of hypertension (defined as hypertension occurring before age 65 years in at least one parent and one sibling). A group of 120 normotensive subjects without a personal history of high blood pressure or a family history of hypertension was matched for age, sex ratio, and body mass index. In all cases, patients presenting other hypertensive risk factors such as elevated body mass index, excessive alcohol use, oral contraceptive use, or diabetes mellitus were excluded. Renin gene allele and haplotype frequencies were similar in the hypertensive and the normotensive groups.

To explore further the potential role of the renin gene as a genetic determinant of hypertension, the hypertensive sibling pairs approach was used (23). When the same clinical criteria and the same renin gene haplotypes as in the association study were used (22), no linkage was found between the renin gene and hypertension, which suggests again that the renin gene does not have a frequent or important role in the pathogenesis of essential hypertension. The definitive exclusion of a contribution of the renin gene in the heritability of essential hypertension, however, would require more powerful linkage studies, such as the use of a reliable renin intermediate phenotype and a more polymorphic marker of the renin locus. Of interest, some of the genome scans conducted since then have found the chromosome 1q32 region to be a possible hypertension-related locus.

Angiotensin I–Converting Enzyme Gene

ACE is a zinc metalloproteinase whose main functions are to convert angiotensin I into angiotensin II and to inactivate bradykinin. This step of the renin-angiotensin system is assumed not to be limiting in plasma, and indeed no indication exists that plasma ACE levels are directly related to blood pressure levels. The local generation of angiotensin I and the degradation of a bradykinin, however, might depend on the level of ACE expressed in tissues.

The enzyme consists of two highly homologous and functionally active domains resulting from a gene duplication (24). Two ACE promoters are found, a somatic promoter localized on the 5' side of the first exon of the gene and a germinal, intragenic promoter located on the 5' side of the specific testicular ACE messenger RNA (25,26 and 27). The two alternate promoters of the ACE gene exhibit highly contrasting cell specificities: the somatic promoter is active in endothelial, epithelial, and neuronal cell types, whereas the germinal promoter is active only in a stage-specific manner in male germinal cells (27). Plasma ACE concentration is thought to reflect the level of the synthesis of the somatic enzyme.

Relationship between Plasma Levels of Angiotensin I–Converting Enzyme and Genotype

From a geneticist's point of view, plasma ACE concentration is an interesting marker, as it varies considerably between individuals (from 1 to 8 at the extremes of the distribution) but remains remarkably constant when measured repeatedly in a given subject (28). This important variability is due, in large part, to a major genetic effect, as shown by Cambien et al. (29) in a family population study in which an intrafamilial resemblance was found between plasma ACE levels. This effect accounted for approximately 30% and 75% of the ACE variance in parents and in offspring, respectively.

The role of the ACE gene in the genetic control of plasma ACE was assessed using several genetic polymorphisms. The most studied is an insertion/deletion (I/D) of a 287–base pair DNA fragment in intron 16 of the gene, which corresponds to an Alu sequence. In their seminal observation of 80 healthy subjects, Rigat and colleagues showed that the serum ACE concentration of DD subjects was almost twice as high as that observed in patients homozygous for the I allele, whereas heterozygous patients were intermediate (30). In this study, the ACE I/D polymorphism accounted for 47% of the total variance of serum ACE level. As are serum ACE levels, T-lymphocyte ACE levels are significantly higher in patients homozygous for the D allele than in the other subjects (31). Another study combining segregation and linkage analysis in 98 healthy nuclear families showed that the ACE I/D polymorphism is only a neutral marker in strong linkage disequilibrium with the putative functional variant (32). Soubrier's group performed an extensive analysis of eight new polymorphisms in 95 healthy nuclear families (33). After adjustment for the I/D polymorphism, all polymorphisms of the 5' group remained significantly associated with ACE levels, which suggests the existence of two quantitative trait loci that act additively on ACE levels and account for 38% and 49% of the ACE variance in parents and offspring, respectively. More recently, Rieder and colleagues determined the complete genomic sequence of the ACE gene from 11 individuals, which represents the longest contiguous scan (24 kilobases) for sequence variation in human DNA (34). They identified 78 varying sites in 22 chromosomes that resolved into 13 distinct haplotypes. Seventeen were in absolute linkage disequilibrium with the ACE I/D polymorphism, producing two distinct and distantly related clades. The investigators suggested that the causal variant should be located within the 3' part of the gene. Despite these efforts, the causative variant or variants responsible for the increase in ACE has yet to be found, which might foreshadow the difficulty of identifying causal molecular variants in complex traits.

Angiotensin I–Converting Enzyme Gene Polymorphism and Hypertension

The observation that plasma ACE levels are under the direct control of an ACE gene variant, coupled with the linking of the ACE enzyme to two main enzymatic cascades (renin-angiotensin system and kallikrein-kinin system) implicated in cardiovascular physiology, rapidly made the ACE I/D polymorphism one of the most popular markers tested in cardiovascular diseases. The first genome scans performed in genetically hypertensive rats from an F2 rat population generated from stroke-prone spontaneously hypertensive rats (SHR/SP) and normotensive (WKY) rats rendered this hypothesis even more attractive: two groups of investigators found a significant linkage between sodium chloride–increased blood pressure and a gene locus on rat chromosome 10 (35,36). This locus—which contains ACE—contributed as much as 20% of the blood pressure variance of SHR/SP rats compared to WKY rats under conditions of high salt intake. A very large number of reported and unreported studies have been performed since then (11,12 and 13). Only some of the main findings of studies using the ACE gene as a candidate gene for human essential hypertension are summarized here.

One association study comparing a normotensive Australian population with a population of hypertensive individuals who had two hypertensive parents showed an association of hypertension with ACE gene polymorphism (37). In fact, the significant difference among the I/D genotype originated only from a subgroup of patients aged 50 years or older, in whom the D genotype was less frequent than in normotensives. This finding was interpreted as due to an increased risk of cardiovascular events in hypertensive patients carrying the D allele (38). Harrap et al. (39) investigated the distribution of the ACE I/D gene polymorphism described earlier in young adults with contrasting genetic predispositions to high blood pressure (40), using a "four corners" approach: young adults with high blood pressure and two parents with high blood pressure did not show any significant difference in frequencies of the I/D allele of the ACE gene compared to adults of the same age who had low blood pressure and no genetic predisposition to high blood pressure. Other association studies also yielded negative results (41,42). In a large series of hypertensive sibling pairs from Utah, no evidence was found of a linkage between hypertension and a growth hormone gene polymorphic marker in complete linkage disequilibrium with the ACE gene (43). Taken together, these results suggest that the ACE gene does not play a major role in blood pressure variance in these populations.

Some positive results, however, suggest that the ACE locus might influence blood pressure variability in a sex-specific manner. In a logistic regression analysis of 3,095 participants in the Framingham Heart Study (44), the adjusted odds ratios for hypertension among men with the DD and DI genotypes versus the II genotype were 1.59 and 1.18, respectively, whereas no effect was observed in women. Positive results were also reported by Fornage et al. in the analysis of a large population-based sample of 1,488 siblings having a mean age of 15 years and belonging to the youngest generation of 583 randomly ascertained three-generation pedigrees from Rochester, Minnesota (45). In sex-specific analyses, genetic variation in the region of the ACE gene explained as much as 35% of the interindividual blood pressure variation—again in males but not in females. Finally, Julier et al. (46) conducted an affected sibling pair analysis in families of France and the United Kingdom and explored chromosome region 17q23–32, based on the location of the ACE locus and on the quantitative trait loci observed in rats on the homologous region of chromosome 10. Significant evidence of linkage was found near two closely linked microsatellite markers, D17S183 and D17S934, that reside 18

centimorgans (cM) proximal to the ACE locus in the homology region.

Taken together, these results suggest that the ACE gene does not play a major role on blood pressure variance in the overall population. It may influence it in a sex-specific manner, however, in combination with other polymorphisms (47). Its role in the function of different organs (kidney, heart, vessels) has been suggested in different studies (10,11,12 and 13). Its influence on physical endurance and exercise, left ventricular mass, and renal and cardiovascular diseases has also been suggested, and excellent reviews of this topic are available (48,49,50 and 51).

Angiotensinogen Gene

Angiotensinogen, the renin substrate, is mainly synthesized by the liver and is the unique substrate for renin. In humans, AGT plasma concentration is within a range in which variations of concentration directly affect the angiotensin I production rate. Indeed, AGT levels are around the Michaelis-Menten dissociation constant of renin, and therefore to suspect that a chronic state of increased plasma AGT might increase angiotensin I levels and facilitate hypertension or cardiovascular diseases is logical. The role of AGT in human hypertension had been suspected in an epidemiologic study in which a strong correlation was found between plasma AGT concentration and blood pressure (52) as well as in another study in which offspring of hypertensive patients had elevated plasma AGT levels (53).

Angiotensinogen and Essential Hypertension

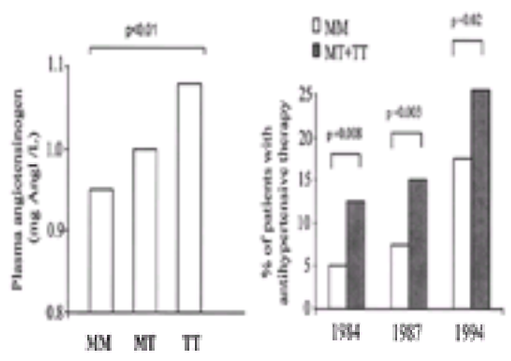
The human AGT gene belongs to the superfamily of serpins (54) and is localized to chromosome region 1q42.3, in the same region as human renin (55). With the group of J. M. Lalouel, the authors reported discovery of the first molecular elements suggesting a role for the AGT gene in human essential hypertension (56). An extensive study was performed involving two large series of hypertensive sibships yielding a total of 379 sibling pairs (Salt Lake City, UT, and Paris, France) and using a highly polymorphic microsatellite marker at the AGT locus. An excess of AGT allele sharing was found mainly in severely hypertensive sibling pairs and in men. Other linkage studies have since been reported with controversial results. Caulfield et al. showed a strong linkage and an association of the AGT gene locus to essential hypertension in a set of British families (57,58). To the contrary, no evidence for linkage was found in a large European study involving 630 affected sibling pairs, either in the whole panel or in family subsets selected for severity or early onset of disease (59). Linkage of the AGT gene to essential hypertension was also found in 63 affected African Caribbean sibling pairs (60). Similarly, positive albeit modest significant excess of AGT allele sharing was found in 46 extended Mexican-American families (61). No linkage was found between the AGT locus and hypertension in 310 hypertensive Chinese sibling pairs (62).

A strong effect of race is seen on the allele frequency of most of the polymorphisms found at the AGT locus. For example, the 235T allele frequency varies from 40% in whites to 80% in the Asian and African-American population and was even 93% in Nigerians (63). This high prevalence of the 235T allele may explain why no relation between 235T or 174M allele frequencies and hypertension was observed in a study of African-Americans (63). In the Japanese population, a significant association between this allele and high blood pressure was found in several separate case-control studies (64,65,66 and 67). These differences in allele frequencies might also facilitate false-positive results in case of admixture in case-control studies.

The association between the M235T polymorphism and essential hypertension has been tested in a large number of case-control studies that have been reviewed (68). A metaanalysis of case-control studies representing 5,493 white patients showed that the 235T allele was significantly but mildly associated with hypertension (odds ratio, 1.20; 95% confidence interval, 1.11 to 1.29; p <.0001), an association that increased in studies of individuals with a positive family history (odds ratio, 1.42; 95% confidence interval, 1.25 to 1.61, p <.0001) (69). Another metaanalysis that included 10,720 white individuals showed a 32% increase in the risk of elevated blood pressure associated with the 235T allele (70). More recently, Sethi et al. studied 9,100 men and women from the Danish general population (71). On multifactorial logistic regression analysis, women homozygous for the 235T allele, when compared to noncarriers, had an odds ratio for elevated blood pressure of 1.29, which increased to 1.50 if they were also homozygous for the T174 allele. No significant association was found in men. Altogether, these results probably highlight the modest effect of the AGT locus in the overall population and the difficulty of identifying susceptibility genes by linkage analysis for complex diseases.

Angiotensinogen Gene and Plasma Angiotensinogen

Among the 15 polymorphisms initially identified (56), two leading to amino acid changes, 174M and M235T, were found to be associated with hypertension and plasma AGT concentration. This association between plasma AGT level and the M235T genotype was further confirmed in white children (72). In this study, a strong and independent relationship of serum AGT level with body mass index (p = .0001) and race (p = .0003) was also observed. In young African-American individuals, Pratt's group showed an association between a haplotype containing the T235 allele and a polymorphism located in the promoter region of the gene (73). In a large sample of the MONICA Augsburg cohort, a mild codominant and significant increase of plasma AGT concentration associated with the M235T polymorphism was also observed (74) (*e*Fig. 99.0.3). In the Danish general population, homozygosity for both the 235T and T174 alleles was associated with a 10% increase in plasma AGT level (71). Because of the intra- and interassay variability of the plasma AGT measurement and the mild association with the M235T polymorphism, a large number of individuals are required to detect this relation.



***e*FIGURE 99.0.3** Relationship of the M235T polymorphism of the human angiotensinogen gene, plasma angiotensinogen level, and need for antihypertensive therapy in the Monica Augsburg cohort. AngI, angiotensin I. (Adapted from Schunkert H, Hense HW, Gimenez-Roqueplo AP, et al. The angiotensinogen T235 variant and the use of antihypertensive drugs in a population-based cohort. *Hypertension* 1997;29:628–633.)

Confirmation of the impact of an increased expression of AGT on blood pressure was obtained by Smithies and colleagues, who performed genetic manipulations in mice that resulted in animals with several functional copies of a given gene (9). Mice bearing one, two, three, or four functional AGT copies displayed a gene-dosage effect on plasma AGT concentration and blood pressure level that paralleled the M235T variant effect observed in humans (9,75). The amino acid residue at position 235 is not conserved across species and is in complete linkage disequilibrium with another nucleotide substitution at position –6 in the promoter of the gene with the same allele frequency (76). Lalouel's group was able to show that this variant is associated *in vitro* with an increased expression of the AGT gene, and this probably explains the association with increased plasma AGT levels (77). The true biologic effect may be more complex, however, because other polymorphisms such as C-532T, C-18T, A-20C, T+31C that are also in linkage disequilibrium with G-6A and M235T might play a role in the variation of transcription of the gene (68,78,79 and 80).

Angiotensinogen and Pregnancy-Induced Hypertension

One of the possibilities is that molecular variants of AGT might also represent a susceptibility allele for pregnancy-induced hypertension, for which a familial tendency has been documented (81,82). Two reports have suggested that the AGT locus could play an important role in the occurrence of pregnancy-induced hypertension. Ward et al. (83) found a significant association between the AGT 235T variant and preeclampsia in both white and Japanese samples. Using another strategy, analysis of the allelic inheritance of the GT repeat in 52 sibling pairs of preeclamptic sisters, Arngrimsson et al. (84) showed a significant linkage between the AGT locus and preeclampsia in Icelandic and Scottish families. Thus, although different mechanisms have been proposed for preeclampsia and essential hypertension, these results suggest that some common variants of the AGT gene could predispose to both diseases. Other studies, however, found no indication of association or linkage between preeclampsia and the AGT gene, and genome-scan studies have reported possible loci on chromosome arms 4q (85) and 2p (86,87).

Some of the contradictory results of the case-control studies could be explained by the difficulty of distinguishing between preeclampsia and other hypertensive disorders of pregnancy, which are likely to be caused by different mechanisms. The AGT gene could predispose to hypertension in only one subset of the women with pregnancy-induced hypertension. Two molecular mechanisms could explain this relationship. First, in heterozygous women, AGT expression of the T235 allele seems higher than that of the M235 allele in decidual spiral arteries (88), and nulligravid women homozygous for T235 have a lower plasma volume during the follicular phase of the menstrual cycle than those bearing the MT or MM genotype (89). Among normal volunteers receiving 50 mg of ethinyl estradiol for 1 week, homozygous TT

subjects had higher peak plasma AGT concentrations than MM subjects, a finding that confirms the influence of the genotype on the estrogen-induced stimulation of the renin substrate (90). Second, research has shown that the presence of a Met or Thr at position 235 could interact with the Cys at position 232 of the mature protein and thus favor or inhibit the formation of a disulfide bond with pro–major basic protein (91). Because hydrolysis of the AGT–pro–major basic protein complex is approximately seven times slower than that of the monomeric form of AGT and the proportion of the latter was found to be higher with the T235 recombinant AGT *in vitro*, women bearing this allele could therefore possess a more active renin substrate in the amniotic fluid and placenta. Both mechanisms acting together, an increased AGT expression due to the G-6A variant and an increased proportion of the active monomeric form of AGT, could increase the local formation of angiotensin II and facilitate hyperplasia of the spiral arteries and thus a reduction of the uteroplacental blood flow.

Other studies have tested the influence of the AGT gene on various pathologic conditions, such as coronary heart disease and diabetic nephropathy, of which reviews are available (9,13,68,92,93).

Angiotensin II Type 1 Receptor Gene

Angiotensin II receptors that mediate all the biologic and physiologic effects of the renin-angiotensin system are also candidate genes for essential hypertension. The AT_1 subtype is a G-coupled receptor inserted into the plasma membrane of angiotensin II target cells, vascular smooth muscle cells, renal vasculature and mesangial cells, adrenal gland, and brain. The human gene has been cloned and is located on chromosome region 3q21–3q25 (94,95).

No evidence was seen of linkage between a microsatellite marker of the AT_1 receptor gene and hypertension in a hypertensive sibling pair study, but an informative diallelic marker A1166C present in the 3' untranslated region of the AT1R gene was found significantly more frequently in 206 hypertensive subjects than in 298 normotensive control subjects, which suggests that a variant of AT_1 receptor exerts a small effect on blood pressure (96).

Other polymorphisms have been described, especially at the promoter region of the AT1R gene. None of these newly characterized polymorphisms has shown evidence for association with hypertension in a large white population-based sample (97). Results of studies performed in Finland, however, favor linkage between hypertension and the AT1R locus and an association with the A1166C polymorphism (98,99). In 218 white hypertensive patients, a positive relationship was found between the acute blood pressure response to angiotensin II and the AT1R locus (100). Of interest, the A1166C polymorphism of the AT1R gene has also been associated with aortic stiffness (101), left ventricular mass (102), coronary vasoconstriction (103), increased response to angiotensin II in isolated human arteries (104), and myocardial infarction in interaction with the ACE I/D polymorphism (105). These associations have been disputed in other studies, however; for example, no relation was found between AT1R density in platelets and the A1166C genotype (79).

Other Candidate Genes in Human Hypertension

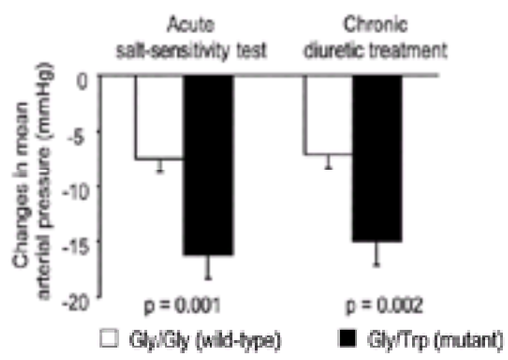
Several candidate genes have been evaluated in human hypertension using the affected sibling pair methodology or the case-control approach or both. Three of these are discussed here.

a-Adducin Gene

For more than 10 years, Bianchi's group in Milan has extensively studied the possible role of a- and b-adducin genes in rat and human hypertension (106,107). Adducin is a ubiquitously expressed membrane-skeletal protein that binds calmodulin and favors the association between spectrin and actin. Thereby, it interacts with membrane cytoskeletal proteins that affect ion transport across the cell membrane and may also be involved in cell motility. Adducin is a tetramer comprised of either a/bor a/gheterodimers (108). Each of the a,b,and g subunits is composed of two distinct domains: an N-terminal globular hydrophobic domain and a carboxy-terminal tail responsible for its interaction with actin and spectrin. The a-adducin gene is located at human chromosome band 4p16 and was originally identified due to its proximity with the gene responsible for Huntington disease. The a-adducin is widely expressed but predominates in brain and kidney. The b-adducin gene is 50% identical and is expressed with different tissue-specific isoforms. Thus, quantitative and qualitative physiologic differences exist in assembly of these subunits according to the tissue in which they are expressed.

Bianchi and co-workers put forward the hypothesis that variations in adducin could lead to variations in the activity of ionic transporters or channels, especially the Na-K-Cl cotransporter in the thick ascending limb and the Na-K–adenosine triphosphatase cotransporter all along the renal tubule, and thus lead to increased salt reabsorption and hypertension. The Milan strain of hypertensive rat (MHS) has characteristics that suggest a renal abnormality of sodium handling: increased glomerular filtration rate during the first weeks of life, low renin level, and greater sensitivity to furosemide than the normotensive strain (MNS) (106). ifferences in the amino acid sequence of the adducin genes between the MHS and the MNS strains could explain a significant part of the blood pressure difference between these two strains (107). Indeed, two amino acid changes were found in the a (F316Y) and b (Q529R) adducin genes. The transfection of wild or mutant subunits in renal epithelial cells showed that these mutations induce an increased activity of the Na-K pump, which provides a possible pathophysiologic link with increased renal sodium handling and with high blood pressure.

In humans, several studies have provided evidence in favor of a relationship between the a-adducin gene, salt sensitivity, and blood pressure level, even though the effect is probably mild at the population level. In a study involving French and Italian hypertensive sibling pairs, significant linkage was found between several markers surrounding the a-adducin locus and essential hypertension (109,110). A positive association was also found when the genotype frequencies of the G460W polymorphism of the a subunit of the adducin gene was studied in 190 hypertensive patients and 126 controls. Among 822 white and 572 African-American subjects participating in the HyperGEN Network in the United States, the 460W allele was associated with an increased risk of hypertension only in white subjects (odds ratio, 1.73; p <.01) and appeared particularly important for subjects older than 60 years (111). The blood pressure response to the long-term administration of hydrochlorothiazide was also significantly more important in subjects bearing the G460W allele, which suggests that this variant could predispose to salt sensitivity and hypertension (110) (eFig. 99.0.4). Since then, other studies have been performed that yielded negative results. This was the case, for example, in the linkage and association study examining the white population of Rochester, Minnesota (112), and the association study involving two large U.S. samples, one from an urban African-American population (Maywood, IL) and another from a rural white population (Tecumseh, MI) (113). Conversely, the association with low-renin status was confirmed in a multicenter international study investigating intermediate phenotypes in hypertension (114). Determination of the exact importance of the adducin locus in human hypertension will probably require large-scale studies as well as a search for interaction with other genes and sodium status (115).



***e*FIGURE 99.0.4** Blood pressure effect of acute and chronic salt depletion in hypertensive subjects by a-adducin G460W polymorphism. (Adapted from Cusi D, Barlassina C, Azzani T, et al. Polymorphisms of alpha-adducin and salt sensitivity in patients with essential hypertension. *Lancet* 1997;349:1353–1357.)

Protein b3 Subunit Gene

Several studies have suggested an increased activity of the sodium-proton exchanger in approximately 50% of the subjects with essential hypertension. Increased ion transport activity has also been found in immortalized lymphoblasts and in fibroblasts from hypertensive subjects, which might be due to altered intracellular signal transduction and enhanced activation of pertussis toxin–sensitive G-proteins (116). The heterotrimeric G-proteins are formed by the assembly of several subunits a,b and g. After excluding mutations of several of these subunits, Siffert et al. (117) found a very interesting genetic polymorphism (C825T) in exon 10 of the gene coding for the b3 subunit (GNB3). This polymorphism is not a missense mutation but favors the use of an alternative splicing of exon 9 of the gene and thus the expression of a protein with a deletion of 41 amino acids. The expression of the deleted protein in insect cells showed that it was functional but that it presents an enhanced reactivity to pharmacologic activators. Finally, in this pioneering study, the 825T allele was found to be present more frequently in 426 hypertensive subjects (0.31) than in 427

controls (0.25), which suggests a role as a susceptibility factor for essential hypertension.

This association with essential hypertension has since been debated, however. In a population-based study at Augsburg, Germany, selected from the Monitoring Trends and Determinants in Cardiovascular Diseases (MONICA) survey (118), the C825T polymorphism showed a weak, albeit significant, association with diastolic blood pressure (CC, 88.6 mm Hg; CT, 90.1 mm Hg; TT, 91.8 mm Hg; p <.02). Interestingly, plasma renin levels were lower in individuals bearing the 825T allele, which suggests that it might be associated with a low-renin profile. An association study involving 110 Australian white hypertensive individuals, each of whom was the offspring of two hypertensive parents, and 189 controls whose parents were both normotensive beyond the age of 50 years, found a significant difference in frequency of the 825T allele (0.43 vs. 0.25; p <.001), a finding which supports a role for this variant (119).

Results of several subsequent studies failed to confirm the association of this polymorphism with essential hypertension. Brand et al. (120) analyzed the GNB3 variant in two large case-control studies in which patients were selected for essential hypertension (Projet d'Etude des Gènes de l'Hypertension Artérielle Severe à Modérée study) and myocardial infarction (Etude Cas-Témoins de l'Infarctus du Myocarde study). The odds ratios for hypertension and myocardial infarction associated with presence of the T allele were 1.23 (95% confidence interval, 0.94 to 1.62; p = .13) and 1.11 (95% confidence interval, 0.88 to 1.39; p = .37), respectively. No association was found between the GNB3 polymorphism and early onset of hypertension, familial history of hypertension, or blood pressure. In a German case-control study involving 479 hypertensive persons and 1,000 sex- and age-matched controls, presence of the 825T allele was associated with an odds ratio for the qualitative trait of "hypertension" of 1.5 (95% confidence interval, 1.1 to 2.2) (121). In both the group as a whole and the untreated group, however, blood pressure levels were virtually identical for all genotypic groups. In a study involving 447 Indians of the Oji-Cree tribe in Canada, the frequency of the 825T allele was found to be 0.50, much greater than the frequency usually observed in whites (122). Surprisingly, the 825T allele was associated with a lower mean systolic blood pressure (CC, 126.7 mm Hg; CT, 123.5 mm Hg; TT, 119.6 mm Hg; p <.05) and was not associated with a significant difference in diastolic blood pressure. A Japanese study confirmed these negative results (123). In this study, the frequency of the 825T allele was very similar (0.49) in 718 subjects with confirmed essential hypertension, 191 subjects with borderline hypertension, and 515 controls, all from the Tokyo area.

In conclusion, the impact of the genetic polymorphism of the GNB3 subunit on blood pressure in the general population needs be assessed in large epidemiologic prospective studies. The hypothesis is attractive because of the possible ubiquitous effect of this protein, especially on vascular tone and renal sodium handling. If the role of this genetic polymorphism is confirmed, it may have some therapeutic implications, because the genotyping of 197 African-Americans and 190 non-Hispanic whites who underwent monotherapy with hydrochlorothiazide for 4 weeks revealed that 825TT homozygotes showed a greater response of both diastolic and systolic blood pressure than did the CC homozygotes (124).

Genes for Subunits of the Epithelial Sodium Channel

The amiloride-sensitive epithelial sodium channel (ENaC) is the rate-limiting step of Na^+ reabsorption by the kidney distal tubule. As discussed in the subsection on Liddle syndrome, the presence of gain-of-function mutations in the genes coding for the b and g ENaC subunits suggests the possibility of more subtle polymorphisms at those genes that might modify ENaC activity, especially in salt-sensitive patients or those with a low-renin profile. Several groups have therefore extended the screening for mutations in essential hypertension to bENaC and gENaC. In a series including more than 400 hypertensive subjects, seven missense mutations were found at the gene coding for the bENaC subunit, almost all of them in patients of African descent (125). Whereas these variants led to no significant increase in Na^+ current after expression of the corresponding complementary DNAs in *Xenopus* oocytes, data obtained in human B lymphocytes (126) suggest that at least one of them (T594M) could have an effect on Na^+ reabsorption. In a case-control study involving black residents of London, Baker et al. (127) found a significantly greater frequency of T594M in 206 hypertensive patients (8.3%) than in normotensive subjects (2.1%); the statistical significance persisted after adjustment for sex and body mass index. In the subset of patients in whom plasma renin activity was measured, the T594M polymorphism was also associated with a low renin profile, which suggested that it could raise blood pressure in affected people by increasing renal tubular sodium reabsorption. However, the impact of this polymorphism is still debated.

Several polymorphisms have also been detected on gENaC. The authors found four neutral polymorphisms, three in the third exon of the gene (T387C, T474C, C549T) and one in the last exon (C1990G) (128). These four variants occurred with similar frequencies in 453 hypertensive and 245 normotensive white subjects as well as in patients with a low renin profile. In three hypertensive subjects, two rare mutations, 594insP and R631H, were also found that produced no significant increase in Na^+ current in *Xenopus* oocytes. Together with the results obtained by other groups (129), these data suggest that this subunit is not frequently involved in essential hypertension.

The analysis of aENaC showed an interesting missense polymorphism (W493R) located in the extracellular loop of the subunit and in a rather well-conserved sequence not far from the amino acids responsible for the sensitivity to amiloride. In whites, however, this polymorphism was found at similar allele frequencies in hypertensive and normotensive individuals and did not change the amiloride-sensitive current when expressed in *Xenopus* oocytes (130). Other polymorphisms, G442V at bENaC and T663A at aENaC, have been shown to be associated with changes in the ratio of aldosterone to potassium in urine and with essential hypertension (131). Also of interest, a sibling pair linkage study involving 286 white Australian families showed significant linkage between systolic blood pressure and microsatellites at chromosome band 16p12, located in the vicinity of the genes encoding the b and g subunits of ENaC (132).

Other Candidate Genes

Many other genes can be considered as attractive candidates for essential hypertension. In large projects aimed at systematic investigation of genes that may act directly or indirectly on blood pressure, a list of more than 100 genes can be easily established. Among them are genes coding for proteins of the adrenergic systems (dopamine receptors, alpha-and beta-adrenergic receptors, in particular), proteins involved in salt-water homeostasis (natriuretic peptides and their receptors, subunits of the epithelial sodium channel, renal transporters, kallikrein-kinin system, etc.), proteins involved in hormonal regulation of blood pressure (enzymes and receptors of the mineralocorticoid and glucocorticoid pathways), and proteins involved in the structure or the regulation of vascular tone (endothelins and their receptors, adrenomedullin).

Of course, to summarize here the studies that have been performed for all these candidate genes is impossible, except to mention that none of the polymorphisms found within or near these genes has been definitively associated with significant changes in blood pressure in the general population. For example, the gene coding for endothelial cell nitric oxide synthase was very attractive because nitric oxide plays an important role in regulating blood flow and pressure, and because several reports have suggested that hypertensive subjects have a blunted endothelium-dependent vasodilatation that might be secondary to decreased nitric oxide production. Linkage and case-control studies involving French hypertensive and normotensive subjects, however, failed to show association or linkage with essential hypertension (133), which suggests that common variants of this isoform of nitric oxide synthase are not involved in common hypertension. Similar negative results were obtained in humans for the SA locus (134), which has been linked to blood pressure levels in several crosses involving different strains of genetically hypertensive rats (135).

The CYP 11B2 gene coding for aldosterone synthase is also an attractive candidate gene. It has been tested for its possible association with essential hypertension (136,137 and 138) and primary aldosteronism (139). A polymorphism in the promoter region of the gene (C-344T) is located at a steroidogenic transcription factor SF-1 binding site and could play a role in the expression of the gene. Despite the fact that the angiotensin II, K^+, and cyclic adenosine monophosphate signaling pathways *in vitro* use a cAMP-responsive element–like *cis* element and another SF-1 binding site that is located closer to the transcription start to regulate human CYP 11B2 expression (140), the C-344T polymorphism has been associated with variations in plasma aldosterone (136,141), which suggests that it could favor sodium retention and high blood pressure. Contradictory results have been obtained depending on the populations and the clinical and biochemical parameters studied (138,142,143,144 and 145).

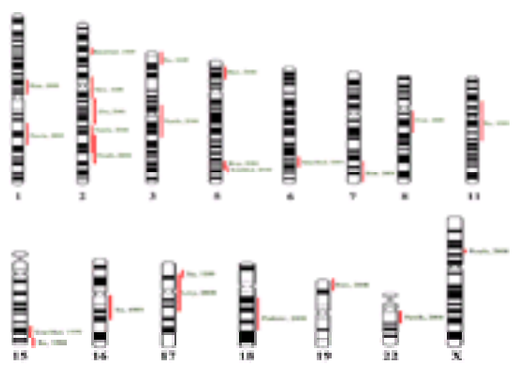
Finally, one should note that most of the studies performed so far on candidate genes have been conducted using a very simple design, by testing the role of each candidate one by one. However, several genes are recognized to control blood pressure level in an additive or interactive manner, together with environmental factors. A more integrated approach needs to be developed in which several genes and some environmental factors can be tested with or without a specific *a priori* hypothesis (146). In that regard, the study performed by Staessen and colleagues (47) showed the combined effect of the ACE I/D, the a-adducin Gly460Trp, and the aldosterone synthase C-344T polymorphisms on blood pressure level.

GENOME-WIDE SCANNING

Given the major advances over the last few years in developing the genetic and physical map of the human genome, the genome-wide scan (GWS) approach has become another important strategy for identifying major loci implicated in complex traits. Once the regions of interest are identified, a positional candidate gene approach can be used initially on the most promising genes (147). Because it does not make any *a priori* assumption regarding the genes to identify, this strategy appears very promising for discovering new pathways involved in blood pressure regulation.

This approach has strong statistical limits, however, that have been well delineated by several authors (148,149,150 and 151). Among them are (a) the problem of insufficient power to identify loci that have only a small influence on blood pressure level; (b) the use of nonparametric methods that require inclusion of hundreds of sibling pairs or the use of particular study designs, such as discordant sibling pairs, or both; (c) the need to adjust the statistical significance for multiple testing to

prevent the identification of genes with mild effects on the trait; (d) the requirement of replication of any positive result in another sample with the same characteristics using either the same design or a complementary approach such as family-based association studies or case-control studies; (e) the low power of replication for loci with only a small effect on blood pressure; and (f) the possible heterogeneity of genes causing essential hypertension depending on ethnic background and confounding factors such as obesity or associated diseases like dyslipidemia and diabetes. Finally, one must be aware that GWS, at least in the first stage, does not take into account the interaction between genes and between genes and the environment, which are the mechanisms at work in determining blood pressure level. Thus, negative results can be obtained for a locus with a true biologic and clinical effect that would have been detected only if analyzed in combination with other loci or with environmental factors. Despite these limitations, several GWS studies have been reported that provide interesting although contradictory results. A nonexhaustive summary of these studies is given below and in eFigure 99.0.5.



***e*FIGURE 99.0.5** Schematic representation of the susceptibility loci found in human hypertension. Each quantitative trait locus is represented as a vertical line, and the corresponding source is indicated.

White Individuals

One of the first published GWS studies was that performed by the group of Boerwinkle based on the Family Heart Program in Rochester, Minnesota, which included 3,974 subjects from 583 families. A first study (152) was based on the selection of 69 sibling pairs highly discordant with regard to blood pressure level (above the 80th percentile or below the 20th percentile). Four genomic regions (2p22, 5q33, 6q23, 15q25) were suggested to be linked with systolic blood pressure. In a second study (153), the investigators analyzed the candidate genes contained in the most promising region (5q33), among them those for dopaminergic receptor type 1A, the $alpha_{1B}$-adrenergic receptor, and the $beta_2$-adrenergic receptor. For each of those, an extensive search for polymorphisms was performed followed by the genotyping of the population. Most data did not show any consistent association between these polymorphisms and blood pressure. The polymorphism (Arg16Gly) of the $beta_2$-adrenergic receptor was the most interesting because of its association with significant although minor changes (2 to 3 mm Hg) of systolic blood pressure.

Another study was performed in the United Kingdom involving 119 white families selected for the presence of at least three hypertensive subjects in the same sibship (154). The genome scan used 262 markers and pointed out a suggestive region on chromosome arm 11q. An analysis of 124 additional families, however, did not confirm that location. A statistical simulation confirmed the genetic complexity of essential hypertension with a multipoint exclusion-linkage analysis showing that at least three genetic loci were necessary to explain the familial aggregation of the trait.

The Amish population may appear ideal for genetic studies examining blood pressure because of the size of the families and the standardized environment that largely prevents alcohol consumption and obesity. A study reported by Hsueh et al. (155) examined 694 subjects from 28 Amish families, each containing from 3 to 69 individuals. A total of 357 microsatellite markers were genotyped in 436 parent-sibling couples, 1,326 sibling pairs, 1,342 first-degree relatives, and 1,311 first cousins. In these families, blood pressure heritability was 0.23 for systolic pressure and 0.29 for diastolic pressure, estimates similar to those generally reported in the literature. The only chromosomic region that was linked to the trait was located in 2q31–34, with lod scores of 1.64 for systolic and 3.36 for diastolic blood pressure.

One of the most recently published GWS studies is also probably one of the most convincing (156). It involved 1,702 subjects from 332 families selected from the Framingham survey. For each individual, blood pressure was averaged on measurements taken at least three times over at least 10 years and adjusted for age and body mass index. A 10-cM genome scan was performed that allowed the analysis of the following relative pairs: 1,545 sibling pairs, 933 parent-offspring pairs, 742 cousin pairs, and 468 pairs of other first-degree relatives. The statistical analysis showed only one region of interest—chromosome 9—for diastolic blood pressure. For systolic blood pressure, a suggestion of linkage was found for several regions on chromosomes 5, 10, and 17. On this last chromosome, two regions were suggested, with the one located on 17q12–21 giving the most promising multipoint lod score (4.7).

This chromosome 17 region corresponds to one also found earlier by Julier et al. (46). In this study involving French hypertensive sibling pairs, French diabetic pairs with hypertension, and United Kingdom families, significant linkage and association were found using markers of the same region that contains the ACE locus at its telomeric end. No particular gene has yet been shown to be the one responsible for this statistical association, however, because the ACE gene seems excluded. Other arguments make this region of interest. First, it corresponds to the main quantitative trait loci found in the rat genome (35,36). Second, this region also contains one of the genes responsible for Gordon syndrome [pseudohypoaldosteronism (PHA2B)] (157). Finally, a missense polymorphism (Gly40Ser) at the glucagon receptor gene located at this locus has been shown to be associated with hypertension. This association, however, was detected in a limited set of white hypertensive patients with two hypertensive parents, with an allele frequency of 0.08 compared to only 0.01 in normotensive controls (158). It was not detected in a sample of 741 French hypertensive subjects who were compared with 412 controls (159). One might argue that this chromosome 17 region contains several important genes for blood pressure control that are not sufficient individually but could predispose to hypertension in the presence of several interacting molecular variants.

The Finnish Twin Cohort Study has also been used for a GWS analysis of blood pressure (99). The strategy was to study a limited number of pairs with an early-onset phenotype (mean age at discovery of 38.3 years) and to diminish the effect of possible confounding factors (at least one sib with body mass index less than 27, exclusion of diabetes). Only 47 sibling pairs were studied in stage 1 of the analysis, 36 dizygotic twins and 11 nontwin siblings. In stage 2, genotyping was densified for the regions suggestive of linkage with the addition of all available family members of the 47 probands (total of 138 subjects). Despite these relatively small numbers, several regions gave a maximum likelihood score higher than 1.5 (1q, 2q, 22q, and Xp). The most significant result was obtained on 3q21–25 (maximum lod score = 3.38 on the entire sample). This region contains the AT_1 receptor gene, and the stronger result was obtained with the intragenic CA repeat at this locus. An analysis of candidate genes in a German population, using blood pressure as a quantitative trait, also suggested linkage with the AT_1 receptor gene (160).

A GWS was also performed of 125 randomly selected and 81 obese families participating in the Québec Family Study (161). Multiple linkage regions were suggested for systolic blood pressure, especially on chromosome arms 1p, 2p, 5p, 7q, 8q, and 19p. One of the main aims of this study was to show the importance of gene–gene and gene–environment interactions, because most of the regions that were suggested in lean families did not show any linkage when analyzed in families in which one or more members had a body mass index greater than 32.

Finally, the GWS analysis of pulse pressure in 10 families (440 individuals) in the San Antonio Family Heart Study showed a heritability of 0.21 of this trait and suggested four regions of importance on chromosomes 21, 7, 8, and 18 (162). Suggestive evidence for linkage on chromosome arm 18q was found with postural systolic blood pressure in 498 white sibling pairs from the Hypertension Genetic Epidemiology Network (163). Using creatinine clearance measurements for a large biracial sample of hypertensive siblings from the same network (466 African-American subjects and 634 white subjects), DeWan et al. (164) showed that a locus on chromosome arm 3q may contribute to the degradation of renal function.

Asian Individuals

A remarkable effort has been made by Xu and colleagues to characterize a large population from the Anqing region in China (165). A GWS using 367 markers was performed for sibling pairs (207 discordant, 258 high concordant, and 99 low concordant) selected from a blood pressure screen of more than 200,000 Chinese adults (166). Although no regions achieved a 5% genome-wide significance level, maximum lod score values were over 2.0 (unadjusted p <.001) for five markers (D3S2387, D11S2019, D15S657, D16S3396, and D17S1303). Of interest, the suggestive regions identified depended on the design of comparisons and were different for systolic and diastolic blood pressure. By refining the trait definition and genotyping additional markers, the investigators highlighted a region on chromosome arm 15q with a maximum lod score of 3.8 near D15S203 in sibling pairs at the lower extreme of diastolic blood pressure (166).

A three-stage GWS study was carried out with 240 microsatellite markers, initially in 283 Chinese sibling pairs with hypertension, then in 637 pairs, and finally in 777 pairs (167). Multipoint linkage analysis showed lod score higher than 2.0 throughout a 5-cM region on chromosome band 2q14–2q23 (D2S112–D2S2370).

Nonparametric analysis also revealed positive linkage to this region (maximum Z-score = 3.27; p = .00086).

MONOGENIC FORMS OF HYPERTENSION

The molecular basis of several rare mendelian forms of hypertension has been elucidated. These forms are usually characterized by an early onset of hypertension, a frequent familial history of cerebrovascular accidents, and a strong penetrance. Most are related to abnormal sodium retention, which leads to volume expansion accompanied by suppression of plasma renin activity.

Glucocorticoid-Suppressible Hypertension

Glucocorticoid-suppressible hypertension (GSH; also called *dexamethasone-suppressible aldosteronism* or *glucocorticoid-remediable aldosteronism*) is characterized by a variable degree of hyperaldosteronism and an increased urinary excretion of 18-hydroxylated and 18-oxo-cortisol metabolites, 18-hydroxycortisol, and 18-oxocortisol. These abnormalities, including hypertension, can be corrected by the suppression of adrenocorticotropic hormone (ACTH) by dexamethasone. The proposal had been made that the disease was due to an abnormal expression in the zona fasciculata of aldosterone synthase, CYP 11B2, the enzyme responsible for the conversion of corticosterone into aldosterone. Lifton et al. (168) showed that this disorder was linked to an abnormal aldosterone synthase gene. They studied a large affected kindred and found a gene duplication arising from an unequal crossing over, resulting in a fusion of the 11b-hydroxylase (CYP 11B1) promoter with the coding sequence of aldosterone synthase. The chimeric gene encodes a protein that can hydroxylate cortisol (the steroid substrate present in the zona fasciculata) in the 18 position. This gene is under the control of the 11b-hydroxylase gene regulatory region, whose expression is under ACTH control and can be downregulated by exogenous glucocorticoid administration. All the phenotypic abnormalities of GSH can be explained by this mutation.

Since this original description, several other families affected with this syndrome have been identified. In a patient with GSH with an adrenal tumor, the chimeric gene was found to be expressed in the tumoral tissue and in the zona fasciculata of the surrounding adrenal tissue, and sensitivity of the corresponding adrenal cells to ACTH was observed (169). In all families reported so far, the chimeric gene derives from unequal homologous recombination between exons 2 and 4 of the 11b-hydroxylase and aldosterone synthase genes, respectively. It has been shown by site-directed mutagenesis that such hybrid genes expressed in heterologous eukaryotic cells are able to encode chimeric proteins that hydroxylate cortisol in the 18 position (170). More recently, the transfection into COS-7 cells of a series of CYP 11B1 complementary DNAs containing various regions of CYP 11B2 sequence showed that two amino acid changes, Ser288Gly and Val320Ala, are sufficient to convert CYP 11B1 into an efficient aldosterone-producing enzyme (171). Although these results suggest that a gene conversion involving exons 5 and 6—in which these residues are encoded—could cause a novel form of GSH, no such molecular abnormality has yet been found in a series of patients with essential hypertension and primary aldosteronism (172).

GSH is probably very rare. The possible locations of the unequal crossover between the CYP 11B1 and CYP 11B2 genes allow its molecular diagnosis by a simple Southern blot analysis or a long-range polymerase chain reaction assay (173). In the authors' own hypertension clinic, no case of GSH could be found in a systematic analysis of more than 200 patients with primary aldosteronism without overt tumoral primary aldosteronism (X. Jeunemaitre et al., *unpublished data*, 2000), and only four French families have been diagnosed with GSH up to now. One of the major interests of this diagnosis is its therapeutic implication, however, because low dosages of dexamethasone improve the clinical and biologic features of this syndrome (173,174).

Gordon's group described another form of familial primary aldosteronism, called *type II* (FH-II), that is found in a few families. Approximately 30% of the affected patients present with an aldosterone-producing tumor. The inheritance pattern is probably autosomal dominant (175,176). The screening of the entire genome in a large family with FH-II showed linkage with chromosome 7p22 (177).

Liddle Syndrome

In 1963, Liddle et al. (178) described a family with hypertension and an abnormality of Na^+ reabsorption at the level of the renal distal tubule that simulated primary aldosteronism but showed negligible basal and stimulated aldosterone secretion. Blood pressure and hypokalemia were not influenced by spironolactone treatment but triamterene, a specific inhibitor of the distal renal epithelial sodium channel, corrected these abnormalities. The authors proposed that the primary abnormality was a constitutive activation of the epithelial sodium channel. Some 30 years later, this hypothesis was reinvestigated in the proband and in the originally described pedigree. The index case developed renal failure. Renal transplantation corrected the aldosterone and renin responses to salt restriction, which demonstrated the involvement of the kidney in the disease (179). Thus, the gene for the ENaC located in the collecting cortical tubule is a logical candidate gene for this disease. This channel constitutes at least three homologous subunits, a,b and g which act together to confer its low sodium conductance and its high selectivity for sodium and amiloride (180).

Analyzing the original Liddle pedigree, Shimkets et al. (181) showed complete linkage of the gene encoding the b subunit of this channel, located at 16p13–12. In this pedigree and in other unrelated kindreds, a premature stop codon, a frameshift mutation, and other deleterious mutations were found, all located in the last exon of the gene encoding for the intracellular carboxy-terminal domain of the b subunit (181). These mutations were shown to be gain-of-function mutations, with an increased amiloride-sensitive Na^+ current after transfection of the corresponding mutant subunits together with a and g wild-type subunits. In a Portuguese family affected with this syndrome, a 32–base pair deletion was found leading to a premature termination of the carboxy end of the same subunit (182). Investigation of the epithelial nasal sodium-chloride conductance instead of the kidney conductance showed the presence of an increased amiloride-sensitive conductance in the three affected patients but not in their unaffected sister (183). A point mutation affecting the same region of the g subunit has also been found to cause Liddle syndrome (184), but no mutation of aENaC has been discovered in this syndrome as yet.

Comprehensive studies (185,186 and 187) have shown that the mechanism by which the truncation of the carboxy terminus of the b and g subunits alters the function of the epithelial sodium channel corresponds to an alteration of a conserved motif (PPxxY) in the carboxy terminus of all three subunits of the sodium channel. Normally, a specific interaction between this PY motif and cytosolic proteins (Nedd4 isoforms 1 and 2, and other related WW proteins) leads to ubiquitination and then degradation of part of the newly synthesized subunits (188). Both truncation or punctual mutation of this PY motif increase surface expression of the mutant proteins and thus increase the number of sodium channels in the apical membrane (189), which favors renal sodium absorption and hypertension.

Gain-of-Function Mutation in the Mineralocorticoid Receptor

One case of a new monogenic form of hypertension, which could be called *pseudoaldosteronism type II*, has been reported by Geller et al. (190). It is characterized by an early onset and severe form of hypertension associated with low plasma levels of renin and aldosterone. It is caused by an activating missense mutation (Ser810Leu) of the human mineralocorticoid receptor. This mutation is located within the hormone-binding domain and results in a constitutive mineralocorticoid receptor activity and in an alteration of the receptor specificity. The receptor becomes abnormally activated by progesterone and other steroids lacking 21-hydroxyl groups that normally act as antagonists. In the family described by Geller and coworkers, all women bearing the mutation had severe pregnancy-induced hypertension with hypoaldosteronism, which was caused by the massive increased production of progesterone during pregnancy. These original findings open the possibility of discovering other cases of similar types of mutations in pregnancy-induced hypertension.

Apparent Mineralocorticoid Excess (Ulick Syndrome)

The syndrome of apparent mineralocorticoid excess is a rare autosomal recessive form of hypertension diagnosed in children and characterized by a very early and severe hypertension associated with hyporeninism and hypoaldosteronism (191). It corresponds to a defect of the 11b-hydroxysteroid dehydrogenase type 2 enzyme that is expressed in the kidney. This enzyme inactivates glucocorticoids by converting cortisol into cortisone and corticosterone into 11-dehydrocorticosterone. Deleterious mutations have been found in affected patients, who are either homozygous for the mutation, especially in consanguineous families, or composite heterozygous (192,193 and 194).

The enzymatic defect leads to increased renal concentrations of cortisol and corticosterone, which are themselves powerful agonists of the human mineralocorticoid receptor, contrary to cortisone and 11-dehydrocorticosterone. Thus, affected patients are characterized by high ratios of cortisol to cortisone in plasma and urine, and by arterial hypertension, which mimics a primary aldosteronism (195). The genetic diagnosis can be obtained rapidly by direct sequencing of the five exons of the gene.

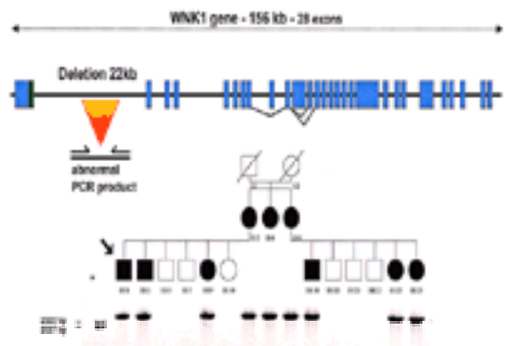
Pseudohypoaldosteronism Type 2 (Gordon Syndrome)

Pseudohypoaldosteronism type 2 (PHA2), also known as *Gordon syndrome*, is an autosomal dominant form of volume-dependent hypertension characterized by hyperkalemia and hyperchloremic acidosis without glomerular insufficiency (196). The low renin levels are thought to be the consequence of volume expansion, whereas plasma aldosterone levels are variable depending on the opposite influences of low renin and high potassium levels. At least two features suggest a primary renal tubular defect along the convoluted distal tubule: affected patients are highly sensitive to small doses of thiazide diuretics, and the clinical and biochemical features of PHA2 are the mirror image of those of Bartter-Gitelman syndrome, in which inactivating mutations in the thiazide-sensitive sodium-chloride cotransporter (SLC12A3) gene have been demonstrated (197). The pathophysiology of PHA2 is certainly more complex, however, as in some cases an associated reduced proximal

reabsorption, a chloride reabsorption defect, and an altered sensitivity to mineralocorticoids have been shown (198).

Examining eight affected but limited families, Mansfield et al. (157) have identified two loci on the long arm of chromosomes 1 and 17 named, respectively, PHA2A and PHA2B. The locus on chromosome 17 was confirmed in another Australian kindred (199). The direct implication of SLCA12A3 was excluded by genetic linkage analysis. The selection and genetic analysis of a large French pedigree led to identification of a third chromosomal region on chromosome arm 12p, designated PHA2C (200). Exclusion of linkage for these three chromosomal regions in two additional affected pedigrees suggests further genetic heterogeneity (201). Thus, the molecular genetics of this syndrome is expected to lead to a variety of molecular defects revealing the role of either several new components of the same pathway or of direct or indirect partners of the sodium-chloride cotransporter.

Lifton's laboratory and the authors' own group identified the genes corresponding to the PHA2C (chromosome 12) and PHA2B (chromosome 17) loci (202). Both genes are members of a particular family of serine-threonine kinases, called *WNK1* and *WNK4*, and the corresponding proteins localize to the distal nephron. Disease-causing mutations in the WNK1 gene are large deletions in the first intron, which lead to increased gene expression of the kidney isoform (eFig. 99.0.6). Mutations in the WNK4 gene are missense mutations clustering in a highly conserved domain among these types of kinases. Altogether, these findings implicate these kinases in a previously unrecognized signaling pathway likely to be involved in the control of sodium reabsorption in the distal nephron and blood pressure regulation.



***e*FIGURE 99.0.6** Mutation of the WNK1 gene in one family affected with Gordon syndrome. The mutation corresponds to a deletion of 22 kilobases (kb) in intron 1 of the WNK1 gene. An abnormal amplification product can be generated from peripheral DNA of affected patients. bp, base pairs; PCR, polymerase chain reaction. (Adapted from Disse-Nicodème S, Achard JM, Desitter I, et al. A new locus on chromosome 12p13.3 for pseudohypoaldosteronism type II, an autosomal dominant form of hypertension. *Am J Hum Genet* 2000;67:302–310; and Wilson FH, Disse-Nicodème S, Choate KA, et al. Human hypertension caused by mutations in WNK kinases. *Science* 2001;293:1107–1112.)

As already discussed, the WNK4 gene lies within the largest genetic linkage peak for blood pressure variation observed in the Framingham Heart Study population (156). Two studies of European hypertensive sibling pairs have also found evidence of linkage to this region (46). Searching for polymorphisms of that gene that might be implicated in essential hypertension is therefore of interest.

Syndrome Associating Arterial Hypertension and Brachydactyly

A rare form of autosomal dominant syndrome associating arterial hypertension and brachydactyly has been reported in a few families, especially one extended Turkish pedigree (203,204). In 100% of the affected patients, hypertension is accompanied by a short stature and brachydactyly but with no other special biologic or hormonal phenotype (205). A particular defect of cerebral vascularization—loops in the posterior inferior cerebellar artery—has been discussed as the possible origin of neurovascular compression and high blood pressure (206). In addition, abnormalities of autonomic function tests suggest an alteration of the baroreflex (207). The locus responsible for the disease has been mapped to chromosome arm 12p (208), in a region that is more centromeric than the PHA2C locus, but the gene has not yet been identified.

THE FUTURE

Several strategies have been used to identify genes involved in hypertension, from experimental models of rodent hypertension to multiple studies involving various human populations. These investigations have now shown that not a single gene but, rather, combinations of several susceptibility genes are involved in blood pressure regulation, although no clear picture emerges as to precisely which ones. The most remarkable results so far have been obtained in the rare cases of monogenic forms of hypertension. The attractive hypothesis that some genes directly implicated in monogenic forms of hypertension may also be involved in essential hypertension has not yet been confirmed. The discovery that WNK1 and WNK4 are responsible for two genetic forms of Gordon syndrome, however, leaves open the possibility that this family of genes may be implicated in essential hypertension.

Future directions might take advantage of the analysis of the present data:

1. An important effort needs to be made to define more accurate phenotypes than just hypertension per se. When possible, blood pressure (systolic, diastolic, pulse pressure) should be considered as a quantitative trait. Many variables that affect blood pressure should be taken into account, such as age and sex of the patient, the presence or absence of a documented family history of hypertension, and precisely estimated environmental factors (tobacco smoking, obesity, alcohol consumption, estrogen treatment). Better clinical and biochemical descriptions of hypertensive (and normotensive) populations should allow the description of intermediate phenotypes and the study of more homogeneous populations providing increased statistical power. A detailed investigation of the physiologic and biochemical parameters of well-characterized patients, in relation to gene variants, might thus provide evidence for a functional link between genotypes and phenotypes. Such studies could reveal unsuspected and interesting relationships between gene variants and intermediate phenotypes.
2. Ongoing genetic studies in hypertensive rodents should further contribute to the analysis of human genetic hypertension. GWS analyses revealed that several genetic loci are linked to hypertension or to hypertensive phenotypes in various strains of rats and mice. Although no candidate gene has yet been discovered using this approach, one hopes that in the near future several genes will be identified and will be tested for their potential contribution to human genetic hypertension.
3. A large effort has already begun on the systematic search for common molecular gene variants likely involved in blood pressure regulation and in cardiovascular diseases. Essential hypertension is a complex phenotypic trait that is influenced by several (or many) genetic factors and several (or many) environmental stresses. Thus, one cannot expect a restricted number of gene variants to influence blood pressure in individuals of different ages, in different environments, and of different ethnic origins in the same manner. As reported in the present review, some limited studies have already shown that a combination of gene variants is associated with an increased risk of cardiovascular complications. A systematic search for polymorphisms at candidate genes should be extremely useful for the identification of susceptibility genes through association and linkage studies. One must emphasize that testing hundreds of different genetic markers on large sample populations is now feasible. Two comments must be made, however: (a) because the allele frequencies may vary considerably by population, the frequency of the allelic variants in each ethnic group must be determined. To minimize the difficulty of obtaining strictly homogeneous patients with regard to ethnicity, several genetic-epidemiologic studies have been performed in well-defined and limited geographic areas such as Iceland, Finland, and other genetically isolated areas to obtain maximal control of this parameter. (b) Analysis of the effect of the combination of several gene polymorphisms might require very large population samples, especially because some of them may have a low allelic frequency. Such studies will require national and international collaboration.
4. Thanks to the tremendous efforts of the laboratories involved in the human genome project, a complete gene map of approximately 30,000 genes should be available within the next 5 years. This will have important consequences in the search for the genes of interest. In particular, a positional candidate cloning approach is now more and more feasible, with a test of different candidate genes once a chromosomal region has been determined to influence the level of blood pressure. Therefore, a strategy of positional cloning using random markers evenly distributed all along the genome appears increasingly as one of the strategies that can bring new insights into the primary causes of essential hypertension. The first attempts in that direction, however, have shown its limits and difficulties. The absence of replication from one sample to another demonstrates the importance of the type of population analyzed and possibly the fact that there is no major gene regulating the trait but rather many genes with mild effects that may play a role in determining basal blood pressure or its evolution with age, reactivity to different stimuli, or complications.
5. The time is too early to propose dietary recommendations and specific drug treatment according to a patient's genotype, although a few preliminary reports have been published suggesting relationships between a given polymorphism and the blood pressure response to antihypertensive therapy. Clearly, defining the subset of individuals in whom a gene or a combination of genes might play a role is one of the important tasks for the near future.

6. Finally, clinicians working in the field should be aware of the potential of molecular genetics and thus of the discovery of new genetic syndromes associated with hypertension. The exact prevalence of the mendelian forms of hypertension might have been underestimated due to the difficulty of establishing the diagnosis by classical biochemical approaches. It should be facilitated by further clinical attention and genetic testing. In this regard, the fact that the authors were able to collect more than 15 independent PHA2 families within the last 4 years in France is of interest.

Using these different approaches, our knowledge of the molecular defects involved in different forms of hypertension is likely to be improved. This should have a large impact on the strategies aimed at preventing and treating this common and complex disease.

OVERVIEW

Genetic factors contribute to the pathogenesis of a wide variety of disorders that affect cardiac and vascular structure and function. Advances in molecular genetics since the 1980s have provided remarkable insights into the genes responsible and pathogenic mechanisms of cardiovascular disease. Disease-causing genes have been identified for cardiac arrhythmic disorders [e.g., long QT syndrome (LQT), idiopathic ventricular fibrillation (IVF)], congenital heart disease [e.g., Holt-Oram syndrome, Ellis-van Creveld syndrome, atrial septal defect (ASD) with atrioventricular (AV) block, cardiac myxoma], hypertrophic cardiomyopathy, dilated cardiomyopathy, arrhythmogenic right ventricular dysplasia, and familial vascular anomalies [e.g., Marfan syndrome (MFS), patent ductus arteriosus, supravalvular aortic stenosis, lymphedema]. Genetic studies of human cardiovascular disorders continue to provide insight into molecular mechanisms underlying morphogenesis, development, and physiologic function of the cardiovascular system. Molecular genetic analysis of cardiovascular disease permits DNA-based diagnosis, which will promote new approaches to risk stratification and therapy. These exciting molecular discoveries have raised the hope of genetic testing, drug development, and gene-based therapies for a variety of cardiovascular disorders. In this chapter, we discuss major advances in the genetics of myocardial and vascular disease.

GLOSSARY

Allele: Alternative forms of a gene or a genetic locus.

Allelic: A condition in which two phenotypically different traits are the result of different mutations in the same gene.

Compound heterozygote: An individual with one mutation in one allele of a given gene and a different mutation in the other allele of the gene. Compound heterozygous mutations are usually associated with autosomal recessive disease.

Heterogeneity: *Allelic* or *intragenic heterogeneity* is different genotypes at the same genetic locus that cause a similar phenotype. *Locus heterogeneity* refers to a situation in which a disease is caused by defects at different genetic loci.

Heterozygote: An individual with a mutation in one copy of a given gene but without a mutation in the other copy. Heterozygous mutations are usually associated with autosomal dominant disease.

Homozygote: An individual with the identical sequence in both alleles of a given gene. Homozygous mutations are usually associated with autosomal recessive disease.

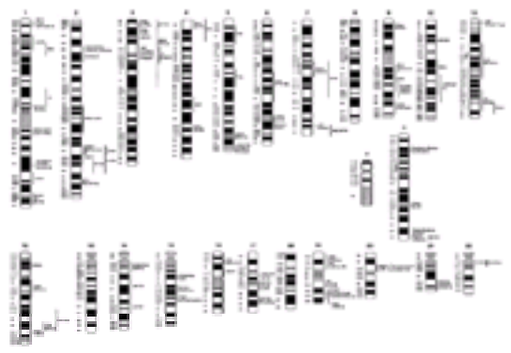
Linkage analysis: Analysis to determine whether two or more genetic traits (a marker locus and a disease trait) are cosegregating within a pedigree.

Positional cloning: A technique used to identify the underlying genetic cause of a disease based primarily on finding the location of the defective gene.

INTRODUCTION

Cardiovascular disease is the leading cause of death in developed countries. Genetic factors play an important role in the pathogenesis of cardiovascular disease. Each human being is variably estimated to have at least 30,000 to 40,000 different genes (1,2 and 3). Mutations in single or multiple genes can cause cardiovascular disease. The revolutionary advances in molecular genetics over the past 15 years have provided new insights into the responsible genes and pathogenic mechanisms of cardiovascular disease (eFig. 100.0.1). Some of these diseases are individually quite prevalent. Many of the most common diagnoses, such as "stroke," "heart attack," "hypertension," or "heart failure," subsume several distinct disorders. Other cardiovascular conditions are quite rare but have proven instructive in terms of the etiology and pathogenesis of common disease processes, such as atherosclerosis, aneurysms, and dysrhythmia. Mendelian disorders may be rare and can be caused by mutations in a single gene with profound consequences. Many of the more common disorders are not simply inherited, yet have a few or perhaps many genes that

stochastically interact with each other and the environment to produce pathology.



***e*FIGURE 100.0.1** Inherited disorders of the cardiovascular system. Ideograms of the 22 autosomes and the X and Y chromosomes are shown with their Giemsa banding patterns. Bands are numbered to the left of each ideogram. Known loci for autosomal dominant, autosomal recessive, and X-linked cardiovascular disorders are shown to the right of each ideogram. When disease-causing mutations have been identified in specific genes at a given locus, the gene is written in parentheses below the locus name. AF, familial atrial fibrillation; ARLK1, activin receptor-like kinase 1; ARVD, arrhythmogenic right ventricular dysplasia; AT, ataxia-telangiectasia; ATM, ataxia-telangiectasia mutated gene; AVSD, atrioventricular septal defect; beta-MHC, beta-myosin heavy chain; CACNL1A4, calcium channel, L type, alpha-1 polypeptide, isoform 4; CCM, cerebral cavernous malformations; COL3A1, collagen type III alpha 1 gene; DCM, dilated cardiomyopathy; EDIV, Ehlers-Danlos type IV; EDVI, Ehlers-Danlos type VI; EvC, Ellis-van Creveld syndrome; FHC, familial hypertrophic cardiomyopathy; FHM, familial hemiplegic migraine; FrA, Friedreich's ataxia; HERG, human ether-a-go-go-related gene; HMID, hereditary multi-infarct dementia; HOS, Holt-Oram syndrome; JAG1, Jagged-1 gene; JUP; plakoglobin; KVLQT1, potassium voltage-gated long QT syndrome 1 channel; LQT, long QT syndrome; MYBPC, myosin binding protein C; MYL2, regulatory ventricular myosin light chain; MYL3, essential ventricular myosin light chain; NF1, neurofibromin; ORW, Osler-Rendu-Weber syndrome; PPH, familial primary pulmonary hypertension; RyR2, ryanodine receptor; SCN5A, sodium channel, voltage-gated, type V, alpha polypeptide; SVAS, supravalvular aortic stenosis; TAPVR, total anomalous pulmonary venous return; TBX5, T-box 5 transcription factor; TIE2, endothelial cell specific receptor tyrosine kinase; VCFS, velocardiofacial syndrome; VHL, von Hippel-Lindau syndrome/gene; WH, Wolf-Hirschhorn syndrome; WPW, Wolff-Parkinson-White syndrome.

Monogenic cardiovascular disorders can be inherited as autosomal dominant, autosomal recessive, or X-linked traits. A rapidly increasing number of the genes responsible for such disorders have been mapped to specific chromosomal regions by linkage analysis and identified by candidate gene or positional cloning approaches (eFig. 100.0.1) (4,5). The "working draft" of the human genome sequence will greatly facilitate identification of additional genes. A recent tabulation of genes that have been mapped and are associated with human phenotypes numbers just more than 1,000; just over one-fourth involve the cardiovascular system (5).

Analysis of the genetics of common disease is far more complicated, whether in terms of populations, families, or molecules, than that for simply inherited conditions. Nonetheless, considerable progress has been made, both in experimental animals and in humans, in identifying genes that contribute to the cause, pathogenesis, or both of common diseases such as coronary artery disease and hypertension. In many instances, specific genetic variations that confer an increased risk of developing a condition can now be identified before symptoms develop. The challenge is to devise approaches to modulating the risk in those so identified.

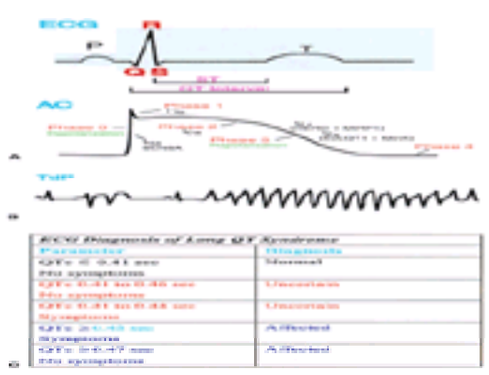
This chapter reviews the major advances in the molecular genetics of single gene disorders of the cardiovascular system. The genetics of complex diseases, such as coronary artery disease and hypertension, is covered in other chapters in this textbook.

DISORDERS OF CARDIAC RHYTHM AND CONDUCTION

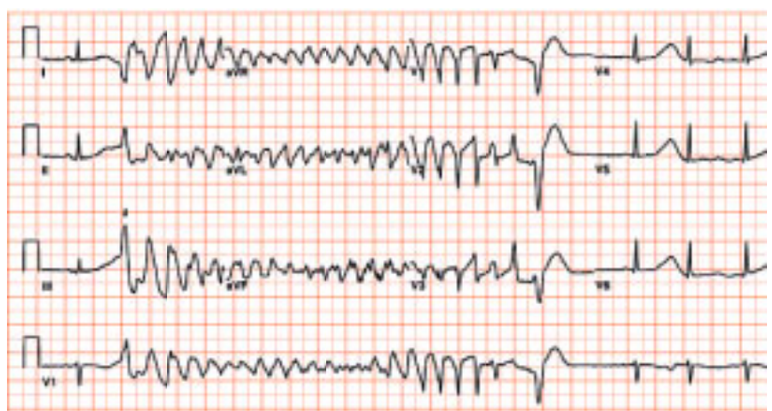
Cardiac arrhythmias are a common cause of morbidity and mortality, accounting for 300,000 to 400,000 sudden deaths each year in the United States alone (6,7). A number of mendelian conditions account for an unknown but clearly underestimated fraction of this mortality.

Long QT Syndrome

LQT is characterized by prolongation of the QT interval and T-wave abnormalities on electrocardiograms (ECGs) and symptoms of syncope, seizures, and sudden death, usually from a specific ventricular arrhythmia, *torsades de pointes* (8,9 and 10). Two inherited forms of LQT have been reported: autosomal dominant LQT (Romano-Ward syndrome) with normal hearing (8,9) and the much rarer autosomal recessive LQT (Jervell-Lange-Nielsen syndrome) associated with congenital deafness (9,11). It appears that patients with Jervell-Lange-Nielsen syndrome have a more adverse course and higher rate of sudden death. The primary defect at the tissue level involves cardiac repolarization, and the prolonged QT interval, when corrected for heart rate, is usually (but not always) evident on standard 12-lead ECG (*e*Fig. 100.0.2). Autosomal dominant LQT has an incidence of approximately 1 per 10,000, without apparent ethnic or geographic predilection (12,13). A set of clinical criteria to assist in diagnosis has been developed (*e*Fig. 100.0.2) (14). Although most clinical events are "triggered" by excitement, exercise, emotional upset, and the like, sudden death can occur during sleep. Some have suggested LQT as a cause of sudden infant death syndrome (15,16 and 17).



***e*FIGURE 100.0.2 A:** Temporal relationship between the electrocardiogram (ECG) and the cardiac action potential (AC). **B:** A representative ECG pattern for torsades de pointes (TdP). **C:** A conservative diagnostic criterion for long QT (LQT) syndrome. This diagnostic system has been successful in identification of LQT genes (18).



A 51-year-old female patient with torsades de pointes.

Molecular Genetics

The first LQT gene was mapped to chromosome 11p15.5 (*LQT1*) in 1991 (18). Since then, at least five other genetic loci for LQT have been identified on chromosome 7q35–36 (*LQT2*) (19), 3p21–24 (*LQT3*) (19), 4q25–27 (*LQT4*) (20), 21q22 (*LQT5*) (21), and 21q22 (*LQT6*) (22), and further locus heterogeneity exists. Five disease genes have been cloned or identified, and mutations have been described in each gene. *KVLQT1* (*LQT1*), *HERG* (*LQT2*), *KCNE1* (*LQT5*), and *KCNE2* (*LQT6*) all encode potassium channel subunits. *SCN5A* (*LQT3*) encodes the cardiac sodium channel protein. Heterozygous mutations in these genes cause autosomal dominant LQT. Homozygous or compound heterozygous mutations in *KVLQT1* and *KCNE1* cause Jervell-Lange-Nielsen syndrome. The LQT gene on chromosome 4q25–27 has been mapped in one family, but it has not been cloned yet.

Cardiac Potassium Channel Gene KVLQT1

KVLQT1, the LQT1 gene on chromosome 11p15.5, is the first novel gene cloned for LQT (23). This gene encodes a potassium channel alpha-subunit with a conserved potassium-selective pore-signature sequence flanked by six transmembrane-spanning segments (S1 to S6). People who are heterozygous for mutations in *KVLQT1* are at risk for autosomal dominant LQT. However, people who have mutations in both of their *KVLQT1* alleles have the more severe disease, autosomal recessive LQT with congenital deafness (24,25). Mutations in *KVLQT1*, when heterozygous, cause loss of channel function, altered channel gating, and/or a dominant-negative effect (26) in which the mutant form of the channel subunit interferes with the function of the normal form. The KVLQT1 protein normally functions by interacting with MinK, a short potassium channel subunit with a mere 130 amino acids and only one transmembrane-spanning segment (27,28). The physical interaction between KVLQT1 and MinK produces the slowly activating potassium current (I_{Ks}) in cardiac myocytes.

Various ion currents such as I_{Ks} are responsible for the different phases of the cardiac action potential (CAP) (eFig. 100.0.2). One CAP corresponds to one heart beat. The time course of one CAP can be divided into five phases: upstroke of rapid depolarization (phase 0); rapid repolarization following the peak (phase 1); a plateau (phase 2); rapid repolarization (phase 3); and the period between the maximum negativity (maximum diastolic potential) and the upstroke of the next action potential (phase 4) (eFig. 100.0.2) (29,30). The I_{Ks} potassium current acts at the repolarization phase (phase 3). KVLQT1 mutations reduce the repolarizing cardiac I_{Ks} current, causing delayed repolarization and prolongation of the CAP duration, and prolongation of the QT interval on ECG.

Cardiac Potassium Channel Gene *HERG*

The *LQT2* gene on chromosome 7q35–36 was identified as *HERG*, which encodes a cardiac potassium channel core–forming subunit with six transmembrane segments (31). This channel ordinarily generates the rapidly activating delayed rectifier potassium current (I_{Kr}) in the heart. LQT-associated mutations in *HERG* act through either a loss-of-function or a dominant-negative mechanism (32). The I_{Kr} potassium current is a major current at the repolarization phase of CAP. HERG mutations reduce the repolarizing cardiac I_{Kr} current, thus causing prolongation of the CAP duration, leading to prolongation of the QT interval on ECG.

Cardiac Sodium Channel Gene *SCN5A*

The gene associated with LQT3 on chromosome 3p21–24 is the cardiac sodium channel gene, *SCN5A* (12,33). It encodes a large protein of 2,016 amino acids with a putative structure of four homologous domains (DI-DIV), each of which contains six membrane-spanning segments (S1 to S6) (34). The sodium current I_{Na} generated by this channel is responsible for the depolarization phase of the CAP and contributes some current at the plateau phase. LQT-causing mutations in *SCN5A* act through a gain-of-function mechanism, in which the mutant channel functions, but with altered properties. Four *SCN5A* mutations (DKPQ, N1325S, R1644H, E1784K) generate the persistent noninactivated sodium current in the plateau phase of the CAP (35,36,37,38 and 39). One *SCN5A* mutation (D1790G) shifts steady-state inactivation by –16 mV in the presence of the $beta_1$-subunit (40). The E1784K mutation shifts the voltage dependence of steady-state inactivation toward more negative potentials (5 mV), and coexpression with the $beta_1$-subunit exaggerates the negative shift. The mutation R1623Q increases the probability of long openings and causes early reopenings, producing a threefold prolongation of sodium current decay (41,42). Although the LQT-causing mutations in *SCN5A* produce variable degrees of altered channel function, they all lead to the increase of inward plateau sodium current, prolonging the action potential duration and the QT interval on ECG.

Cardiac Potassium Channel Gene *KCNE1* (*MinK*)

As in *KVLQT1*, heterozygous mutations in *MinK* cause autosomal dominant LQT, but homozygous or compound heterozygous mutations in *MinK* cause autosomal recessive LQT (21,43). MinK interacts with KVLQT1 and HERG, recapitulating I_{Ks} with KVLQT1 and augmenting the amplitude of I_{Kr} generated by HERG (44). Different MinK mutations appear to have different effects on KVLQT1 and HERG (44). Mutation V47F alters I_{Ks} currents, and increases the HERG current. W87R alters I_{Ks} currents only. D76N suppresses both KVLQT1 and HERG currents. Mutant L51H channels are processed improperly and interact with neither KVLQT1 nor HERG.

Cardiac Potassium Channel Gene *KCNE2*

This gene, also called *MiRP1*, for minK-related peptide 1, encodes an integral component of a potassium channel. This gene has high homology with KCNE1; their close linkage (70 kb apart on chromosome 21q22) suggests that one arose as a result of gene duplication of the other. Mutations in *KCNE2* cause LQT6 (22). MiRP1 is a small integral membrane subunit that assembles with HERG to form I_{Kr}. Recently, MiRP1 was shown to interact with KVLQT1, resulting in a great change of the amplitude and gating properties of the KVLQT1 current (45).

The KCNE family includes another member, *KCNE3* (46), but no mutations in *KCNE3* were reported in LQT patients.

Potassium Channel Gene *Kir2.1* and Andersen's Syndrome

Mutations in the Kir2.1 inward rectifier potassium channel were recently identified in patients with Andersen's syndrome, which is characterized by QTc prolongation, periodic skeletal muscle paralysis, and mild dysmorphic features (46a). Kir2.1 mutations act by either loss-of-function mechanism or a dominant negative mechanism. Kir2.1 consists of only two transmembrane segments, M1 and M2, flanking a pore region and may generate the I_{K1} potassium current at the terminal repolarization phase (phase 3) and for maintenance of the cardiac resting potential.

Genotype-Phenotype Correlation in Long QT Syndrome

Mutations in *KVLQT1* and *HERG* cause approximately 40% of LQT cases, respectively, whereas mutations in *SCN5A* are associated with 10% of cases (47). Mutations in *KCNE1* and *KCNE2* are rare. Patients with LQT1 tend to have frequent exercise-related cardiac events, whereas most with LQT3 experience cardiac events during sleep or at rest. Patients with LQT2 may experience cardiac events both at rest and during exercise. The risk of cardiac events is higher in LQT1 and LQT2 than in LQT3; however, the likelihood of dying during a cardiac event is significantly higher among LQT3 patients (48). LQT1, LQT2, and possibly LQT3 genotypes are associated with different but typical ST-T–wave patterns on ECG (49).

Diagnosis, Genetic Testing, and Treatment

LQT can be diagnosed with reasonable certainty if QTc is 0.47 second or longer for asymptomatic individuals or if QTc is 0.45 second or longer for symptomatic individuals (29,30). LQT is not likely if QTc is less than 0.41 second in males and less than 0.43 second in females. Many mutation carriers as well as normal people have QTc ranging from 0.41 second to 0.46 second, which significantly limits the power of ECG diagnosis of LQT patients. Sudden death occurs in 10% to 30% symptomatic LQT patients (13), and it may occur with the first syncope. These factors make genetic testing extremely important. Current genetic testing for LQT patients is carried out only in research laboratories. Only positive results—that is, identification of a mutation—confirm the diagnosis.

The identification of LQT genes has led to the development of gene-specific therapies for LQT patients (30). Sodium channel–blocking agents such as mexiletine and flecainide can shorten QTc for LQT3 patients (50,51). Raising the serum potassium concentration shortens QTc for LQT2 patients (52). Potassium channel–opening agents and verapamil may be beneficial to patients with potassium channel mutations (13). All these therapies are at the investigational stage, and it is not clear whether these therapies can eliminate life-threatening ventricular arrhythmias.

All symptomatic patients as well as all asymptomatic children require treatment (13). For most LQT patients, administration of a beta-blocker is the initial choice of therapy. Beta-blockers are effective in patients with KVLQT1 and HERG mutations. Other therapeutic options include pacing and implantation of a cardioverter-defibrillator in combination with beta-blockers.

Idiopathic Ventricular Tachycardia and Ventricular Fibrillation

Idiopathic Ventricular Fibrillation with Right Bundle Branch Block and ST-Segment Elevation ("Martini"-Brugada Syndrome)

IVF is ventricular fibrillation without underlying structural heart disease and other electrolyte disorders such as LQT. IVF can be classified into two types: IVF with normal ECG and IVF with an ECG feature of right bundle branch block and persistent ST-segment elevation (STE) in leads V1 to V3 (IVF with STE) (Fig. 100.1), which was first described by Martini et al. and is now often referred to as *Brugada syndrome* (53,54 and 55). In a small percentage of patients with IVF, a family history of sudden death or even IVF can be found, with inheritance as an autosomal dominant pattern (56).

FIGURE 100.1 Twelve-lead electrocardiograms (ECGs) showing typical features of idiopathic ventricular fibrillation with right bundle branch block and ST-segment elevation (STE) ("Martini"-Brugada syndrome). **A:** ECG recorded immediately after the patient arrived at the emergency room because of an episode of syncope and seizures. The episode was triggered by cold-related fever. Note the presence of STE and development of polymorphic ventricular tachycardia (VT) after a ventricular premature contraction. **B:** ECG recorded 11 hours after the syncopal episode. The patient recovered after a cardioversion. Note the typical STE (mainly in lead V2). After the episode, a defibrillator was implanted in the patient. (Unpublished data, Carlos Oberti, Palmira Vanzini, Alvaro Rivara, and Qing Wang.)

In 1998, the first gene for IVF with STE (Brugada syndrome) was identified as *SCN5A*, the cardiac sodium channel gene (56). *SCN5A* mutations were also identified in IVF patients without STE on ECG (56,57). The IVF mutations are functionally different from *SCN5A* mutations associated with LQT. The IVF mutations act by a loss-of-function mechanism (16,56,58,59). *SCN5A* mutations may account for 15% to 35% of IVF patients (56,60), and other genes are involved and remain to be identified.

Catecholaminergic Ventricular Tachycardia

Families with stress-induced ventricular tachycardia [catecholaminergic ventricular tachycardia (CVT)] occurring in the structurally intact heart have been reported (61). Clinical symptoms of CVT include a family history of juvenile sudden death and stress-induced syncope. The inheritance pattern appears to be autosomal dominant, and a genetic locus for CVT was mapped to 1q42–q43 (61). The gene for CVT has recently been identified as the cardiac ryanodine receptor gene (*RYR2*) (62,63). Mutations in *RYR2* (62,63) were identified in autosomal dominant families presenting with bidirectional ventricular tachycardia that was reproducibly induced by exercise stress testing and/or isoproterenol infusion without structural heart abnormalities. As discussed later, *RYR2* mutations also cause arrhythmogenic right ventricular dysplasia (ARVD).

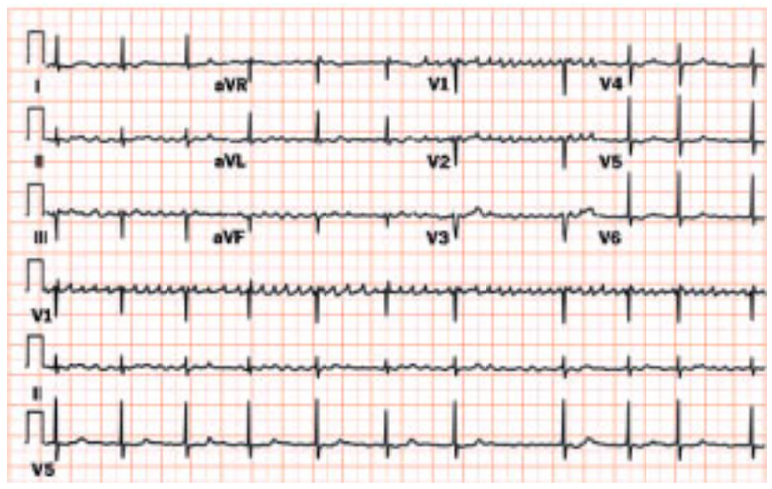
Polymorphic ventricular tachycardia can segregate in families as an autosomal recessive trait, and an autosomal recessive polymorphic ventricular tachycardia gene was mapped to 1p13–21 (64); however, the gene remains to be cloned.

Right Ventricular Outflow Tract Tachycardia

Right ventricular outflow tract (RVOT) tachycardia is a paroxysmal IVT with the focal origin localized to the RVOT. A functional mutation of F200L in the guanosine triphosphate binding protein inhibitory subunit alpha-i2 gene (GNAI2) on chromosome 3p21 was identified in a patient with RVOT tachycardia (65). Mutation F200L is a somatic mutation because it was identified in a biopsy sample from the arrhythmogenic focus but not from peripheral lymphocytes or the sample distant from the arrhythmogenic focus. This finding raises the possibility that common RVOT tachycardia is a somatic cell genetic disorder caused by mutations in specific somatic cells.

Atrial Fibrillation

In atrial fibrillation (AF), the atrial rate is very fast, typically more than 400 beats per minute; intermittent conduction across the AV nodes leads to an irregular ventricular rhythm. The characteristic ECG features include irregular atrial activation and a lack of a repetitive pattern of coordinated atrial activity. The overall prevalence rate of AF is 0.89% in the United States, but the rate increases to 5.9% among individuals older than age 65 (66). The clinical manifestations of AF range from thromboembolism, reduced left ventricular function, palpitations, dizziness, breathlessness, and chest pain to cardiac failure and stroke. AF is the cause of stroke for 30% of victims older than age 65 years (67). AF is associated with changes in distribution of ion channels such as reduction of calcium current I_{CaL} and transient outward potassium current I_{TO}, loss of atrial myocytes, and increasing fibrosis (68). Familial instances of AF are rare. An autosomal dominant AF gene has been mapped to chromosome 10q22–24 (69), but the gene remains to be cloned.



Atrial fibrillation. Narrow complex QRS with irregular RR intervals. Ventricular rate is controlled.

Conduction Defects

Interference with conduction across the AV block results in delayed, intermittent, or absent conduction of electrical impulses from the atria to the ventricles. AV conduction can be impaired in either the AV node or His-Purkinje system (AV bundle and bundle branches). If complete heart block (third-degree AV block) occurs, the ventricles can no longer be activated by impulses propagated from the atria, leading to syncopal episodes, Stokes-Adams seizures, or sudden death. The first gene for progressive familial heart block (PFHBI) was mapped to chromosome 19q13.2–13.3 (70), but the gene remains to be cloned. PFHBI is characterized by right bundle branch block and/or left anterior hemiblock with broad QRS complexes and progression to complete heart block. Inheritance is autosomal dominant. The second genetic locus for progressive familial heart block or progressive cardiac conduction defect was mapped to 16q23–24 (71), but the gene remains to be cloned.

Two *SCN5A* mutations (a splicing mutation at the splice donor site of intron 22 and a 1-bp deletion at position 5280 that creates a premature stop codon) were

identified in two separate families with progressive cardiac conduction defect, also referred to as *Lenègre* or *Lev disease* (72). Close examinations of the reported ECGs revealed mild STE in two of the patients and suggest the possibility that the two mutations reported by Schott et al. (72) may be associated with a variant of IVF with STE (Brugada syndrome).

Wolff-Parkinson-White Syndrome

The Wolff-Parkinson-White syndrome (WPW) is cardiac conduction defect characterized by a short PR interval, an increased duration of QRS complex, and a delta wave on ECG, and supraventricular tachyarrhythmias. A single mutation (R302Q) in the gamma$_2$-subunit of AMP-activated protein kinase was identified in two families with WPW, establishing a molecular basis for WPW (72a).

CONGENITAL STRUCTURAL HEART DISEASE

Many structural congenital cardiac anomalies have anatomic and physiologic manifestations that can be diagnosed at birth or even prenatally. Such anomalies occur in more than 5% of all live births and 10% of stillborns (73,74). Although some of these are sporadic events that result from somatic or *de novo* germline mutations, a significant portion represent familial transmission of disease. The increased risk of structural congenital heart disease in the first-degree relatives of patients with structural cardiac anomalies has long been recognized (75), and autosomal dominant, autosomal recessive, and X-linked modes of transmission have all been reported (5,75).

Mendelian patterns of inheritance can also vary in some disorders with a recognized heritable genetic basis. For instance, situs inversus can occur as an isolated heritable finding or as a component either of visceral heterotaxy syndromes (X-linked or autosomal recessive) or of autosomal recessive Kartagener syndrome. Molecular genetic analysis of such disorders has been limited by kindred size and low penetrance. Insights may be gleaned, however, from murine models (e.g., mutations in the *iv* and *inv* genes can produce murine *situs inversus*) (76,77). Macroscopic chromosomal aberrations and rearrangements (including trisomies of chromosomes 13, 18, and 21) have been associated with variable forms of congenital structural heart disease in the context of complex extracardiac abnormalities. Subtle mutations occur more often, however, and can cause discrete congenital cardiac malformations as well as syndromes with cardiac components. Recent advances in molecular biology have begun to elucidate the fundamental genetic mechanisms underlying such heritable cardiac disorders.

Septation Defects

Defects in the atrial and ventricular septa are the most commonly reported congenital cardiac anomalies. Studies have reported an incidence of greater than 5% of live births (74,78), and this is likely to be an underestimate given that both ventricular septal defects (VSDs) and ASDs may occur in isolation and may close spontaneously during infancy. Many VSDs as well as ASDs occur in the setting of other cardiac and extracardiac anomalies and can have grave physiologic consequences such as the development of Eisenmenger syndrome.

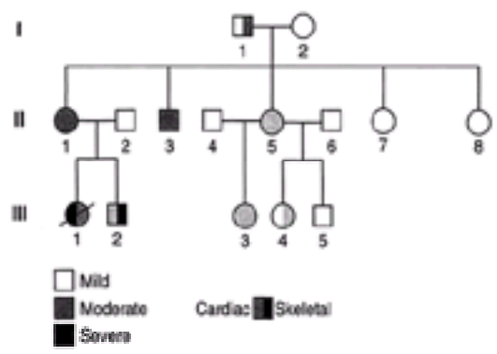
Holt-Oram Syndrome

Clinical Manifestations

Holt-Oram syndrome is characterized by cardiac septation defects in the setting of upper limb deformity (79). It is the most common form of “heart-hand syndrome” and occurs in at least 0.95 per 100,000 individuals (80). All individuals affected by Holt-Oram syndrome exhibit some degree of malformation of the arms or hands (*e*Fig. 100.1.1); such malformation is frequently asymmetric and may be unilateral. Although the initial descriptions of this syndrome focused on abnormalities of the thumb (typically triphalangism or aplasia) (*e*Fig. 100.1.1A), the most common manifestations are carpal bone malformations or fusions (5,79,80). These may be evident only radiographically and in fact may be the only clinical evidence of Holt-Oram syndrome in a given patient. On the other hand, limb malformation may be sufficiently severe for individuals to present with phocomelia (*e*Fig. 100.1.1B), and the syndrome has been called a “pseudo-thalidomide syndrome.”

***e*FIGURE 100.1.1** Skeletal manifestations of Holt-Oram syndrome. **A:** This individual exhibits a minimally deforming triphalangeal thumb on her right hand. Her left thumb is mildly displaced because of carpal bone malformation. Note the bilateral acrocyanosis secondary to her Eisenmenger’s syndrome from her uncorrected ventricular septal defect. **B:** This individual exhibits severe bilateral skeletal deformity. Such phocomelia found in individuals affected by Holt-Oram syndrome prompted some clinicians to call it a “pseudo-thalidomide” syndrome.

Approximately 75% of Holt-Oram syndrome patients (81) have some cardiac abnormality (*e*Fig. 100.1.2). In most cases, these defects are ASD or VSD, which range in size, number, and location. Most ASDs are ostium secundum defects, and most VSDs are muscular. Severely affected individuals may present with multiple VSDs (sometimes termed “Swiss cheese septum”) as well as ASDs, and rare individuals with AV canal defects have been reported. Many Holt-Oram syndrome patients will present with conduction disease (ranging from sinus bradycardia and first-degree AV block to AF and high-grade AV block). Conduction disease occurs independent of the presence or size of septation defects in a given patient. Other cardiac anomalies, including anomalous pulmonary venous drainage, abnormal isomerism, mitral valve prolapse, as well as persistent left superior vena cava and more rarely hypoplastic left heart syndrome and tetralogy of Fallot, have all been reported to occur in some patients with Holt-Oram syndrome (5).



***e*FIGURE 100.1.2** Variable expression of a TBX5 mutation in the Holt-Oram syndrome. Holt-Oram syndrome in Family F is caused by a premature stop codon in the TBX5 gene (2). Despite all individuals being affected by the same DNA mutation in TBX5, the manifestations of the disease vary considerably from individual to individual. Square symbols denote males, and circles females. A slash denotes a deceased individual. Symbols are filled on the left to denote the cardiac manifestations and on the right to denote the skeletal manifestations of the TBX5 mutation in the particular individual. Severity of the cardiac or skeletal malformations are shown by the density of shading as indicated in the key. Note that the severity of cardiac and skeletal malformations are often not equivalent in any individual. Moreover, a particular individual’s phenotype severity does not predict how his or her offspring will be affected.

Genetic Studies

Holt-Oram syndrome is an autosomal dominant disorder. Sporadic disease may represent a *de novo* germline mutation—that is, individuals who present with sporadic disease usually can transmit the disorder to their offspring. Despite its highly variable pattern of expression, Holt-Oram syndrome is highly penetrant in affected families.

Initial linkage analysis studies (82,83) revealed that the gene defect for Holt-Oram syndrome resides on the long arm of chromosome 12 (although this locus does not account for all other heart-hand syndromes). Recent studies (84,85) have demonstrated that Holt-Oram syndrome is caused by mutations on chromosome 12q24.1 that inactivate the *TBX5* gene. TBX5 is a member of the T-box family of transcription factors, and it is expressed in the embryonic human heart and forelimb (86,87). Atrial expression is much greater than ventricular expression in humans, mice, and chicks (86,87,88,89 and 90). It is currently unknown which genes are activated by this transcription factor, and the precise mechanism whereby *TBX5* haploinsufficiency causes cardiac and limb malformation is under active investigation. Studies correlating *TBX5* genotypes with Holt-Oram syndrome phenotypes suggest that mutations that produce truncation of the TBX5 protein have a higher incidence of both severe cardiac and severe limb malformation than less common missense mutations, which only alter a single amino acid (91). In the case of missense mutations, their location within the T-box appears to mediate the severity of cardiac versus limb malformations (91,92 and 93). The role of *TBX5* mutations in isolated septation defects and common atria syndromes also remains to be demonstrated. Detection of *TBX5* mutations in the families of Holt-Oram syndrome patients now permits accurate diagnosis of the syndrome even in subtly affected individuals (eFig. 100.1.2). In the future, delineation of TBX5-mediated regulation of cardiac development may provide new approaches to gene therapy for septation defects.

Ellis-van Creveld Syndrome

Like Holt-Oram syndrome, Ellis-van Creveld syndrome represents an association of cardiac septation defects with skeletal abnormalities (94). Transmitted in an autosomal recessive pattern, Ellis-van Creveld syndrome is most obviously characterized by dwarfism with particularly evident shortening of the distal extremities. Other features include polydactyly, carpal bone abnormalities, nail dystrophy, upper lip deformity, and premature dental eruption. Cardiac abnormalities typically include ASDs and common atrium. Linkage analysis (95) of interrelated Amish families and unrelated Hispanic kindreds affected by Ellis-van Creveld mapped the genetic defect to a locus at chromosome 4p16. More recently, positional cloning studies have identified disease-causing mutations in the novel *EVC* gene, whose function remains unknown (96). Cytogenetic abnormalities of distal chromosome 4p have been associated with ostium secundum ASDs in the setting of craniofacial abnormalities in the Wolf-Hirschhorn syndrome (97). The relationship (if any) of the chromosome 4p Ellis-van Creveld locus to this syndrome is as yet unknown.

Familial Atrial Septal Defects with Atrioventricular Block

In the syndrome of familial ASD with AV block, ASDs occur without associated skeletal malformation, as seen in Holt-Oram or Ellis-van Creveld syndrome. Some individuals exhibit conduction delay manifest as progressive AV block. This condition is transmitted in families as an autosomal dominant trait. Schott et al. (98) used linkage analysis to study families with this disorder and demonstrated that the disease gene mapped to chromosome 5q35. They subsequently applied a candidate gene strategy to identify the disease gene as the *NKX2.5* gene at this locus. *NKX2.5* is a member of the large NK homeobox transcription factor gene family. The prototypical member of this family is the *Drosophila* tin man gene, without which the fly heart fails to develop.

Schott et al. (98) and Benson et al. (99) demonstrated a number of mutations in the *NKX2.5* gene that cause familial ASD with AV block. These mutations include not only nonsense and other mutations that are predicted to result in *NKX2.5* haploinsufficiency but also a number of missense mutations. Recently, Kashahara et al. (100) studied a number of truncated forms of NKX2.5 as well as mutant NKX2.5 isoforms resulting from missense mutations observed in humans. They observed decreased NKX2.5 activity in all cases not only via NKX2.5 haploinsufficiency but also through impaired DNA binding or defective protein-protein interactions with essential cofactors.

Of note, although Lyons et al. (101) had initially noted that knockout mice who were homozygous null for *NKX2.5* died during embryogenesis with a failure of cardiac looping, subsequent analyses (101,102) have demonstrated both ASDs and conduction disease in mice heterozygous null for *NKX2.5*. Benson et al. (99) noted a number of protean manifestations of *NKX2.5* mutations in human patients. Not only do individuals with *NKX2.5* mutations exhibit ASDs, but also they may be affected by a number of other forms of congenital structural heart disease, including VSDs, tetralogy of Fallot, subvalvular aortic stenosis, pulmonary atresia, double-outlet right ventricle, and Ebstein's anomaly. However, no genotype-phenotype correlations have been observed (98,99,103) to allow the association of any particular form of congenital heart disease with any given single or group of *NKX2.5* mutations. Thus, the mechanism whereby *NKX2.5* mutations result in ASDs versus other forms of congenital heart disease remains unknown.

Familial Atrioventricular Defects

Isolated AV canal defects may also occur as sporadic or familial disease. These defects have most commonly been associated with trisomy of chromosome 21 in Down syndrome. From a cardiac perspective, Down syndrome frequently manifests as an AV septal defect in association with a cleft mitral valve. Although fertility is often impaired in such individuals, the disorder is heritable. Moreover, somatic mosaicism is the rule, and thus there is considerable tissue-to-tissue variation in the effects of the trisomy 21. Although investigators have tried to identify "cardiac critical" regions on chromosome 21, no consensus has been reached; it is generally accepted that the syndrome reflects the effect of abnormalities in the copy number of multiple genes (104).

Familial AV defects can occur without trisomy 21. The disorder can be transmitted in pedigrees in an autosomal dominant fashion, and linkage analysis (105) of some such pedigrees has excluded the presence of any gene defect on chromosome 21. A genetic locus for this disorder on chromosome 1p has been described (106), but no specific gene mutation has yet been identified.

McKusick-Kaufman Syndrome

Only females express the full spectrum of abnormalities in autosomal recessive McKusick-Kaufman syndrome: postaxial polydactyly, cardiac septation defects, and hydrometrocolpos (a congenital vaginal web) (5). Originally identified in Old Order Amish, the locus for McKusick-Kaufman syndrome was mapped to 20p12 (107). The disease-causing gene (*MKKS*) was a previously unknown gene and encodes a protein homologous to the chaperonins (108). These proteins are involved in determining the three-dimensional structure of other proteins and could play important roles in development.

Total Anomalous Pulmonary Venous Return

Total anomalous pulmonary venous return (TAPVR) may occur in the setting of isolated or complex septation defects and isomerism as in Holt-Oram syndrome or cat-eye syndrome (see below). However, TAPVR can present as an isolated finding. Incidence of TAPVR may be as high as one per 15,000 live births (109). If the anomalous pulmonary venous drainage is total (vs. partial), unrepaired TAPVR can lead to progressive heart failure and pulmonary hypertension during the first year of life, with a consequent high mortality rate.

Nonsyndromic familial TAPVR can be transmitted as an autosomal dominant trait. Its expression is highly variable, and the disease penetrance is low, confounding genetic analysis. Nevertheless, genetic analysis (110) has demonstrated that the gene defect in some families localizes to the pericentromeric region of chromosome 4. A founder effect appears to account for the common locus in at least some of these families. However, the specific mutated gene has yet to be identified. In addition, it is clear that the disorder is genetically heterogeneous, and gene defects at other as-yet unidentified loci can also cause TAPVR. In one case, TAPVR in the setting of a variety of extracardiac malformations has been associated with a chromosome 2q31–q33 deletion (111).

Conotruncal Abnormalities

Conotruncal abnormalities may account for more than 15% of congenital heart disease (112) and include malformation of the ventricular outflow tracts or the developing branchial arches. On the basis of animal studies in which neural crest cells have been experimentally ablated, defects in neural crest cell function/migration in the primitive contruncus are thought to be at the root of these abnormalities. Despite reports of autosomal dominant and recessive transmission (5), genetic investigation of many human conotruncal disorders has generally been limited by the impaired survival of affected individuals. With the advent of modern surgical repair of such disorders, however, improved survival of individuals affected by conotruncal malformations, including transposition of the great vessels, truncus arteriosus, and double-outlet right ventricle, has aided molecular genetic studies of these disorders, particularly velocardiofacial syndrome (VCFS) and tetralogy of Fallot.

Velocardiofacial Syndrome

Clinical Features

Individuals affected by VCFS or Shprintzen-Goldberg syndrome present with characteristic abnormal facies (including an elongated nose and face with almond-shaped eyes and low-set ears) in the setting of cleft palate and velopharyngeal incompetence. Many VCFS patients exhibit developmental delay as well as a variety of axial skeletal abnormalities, genitourinary defects, gastrointestinal motility disorders, and ophthalmologic difficulties. Approximately one-third of VCFS patients present with structural cardiac disease (5), including tetralogy of Fallot, VSDs, and right-sided aortic arch. When individuals present as well with hypocalcemia and immunologic impairment (particularly T cell–mediated immunodeficiency) secondary to absent or hypoplastic thymus and parathyroid glands, the disorder is referred to as *DiGeorge syndrome*. DiGeorge syndrome and VCFS are now thought to represent variation within a single clinical disorder. The reported incidence is on the order of 1 per 4,000 births (113).

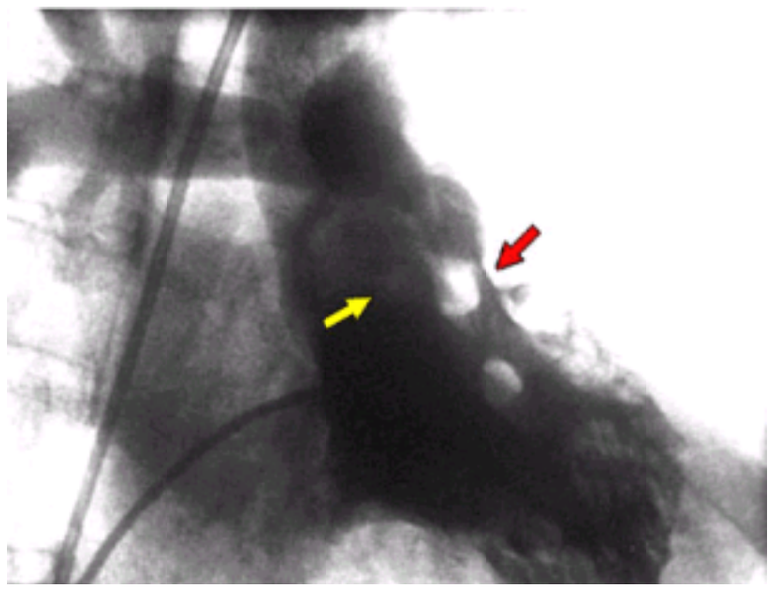
Genetic Studies

VCFS is an autosomal dominant disorder with both variable expression and decreased penetrance. Cytogenetic analyses of VCFS/DiGeorge syndrome patients led to its association with chromosome 22q11.2 deletions (114,115). Subsequent investigation demonstrated that even affected individuals without obvious cytogenetic abnormalities had microscopic deletions when they were evaluated by fluorescent *in situ* hybridization (FISH) with DNA probes specific to this region (114,115). A number of genes have been isolated from the 22q11.2 locus, but no single gene defect has yet been identified to cause VCFS. In fact, VCFS may reflect deletion of several contiguous genes at this locus, and the variation in the chromosomal abnormalities between patients may account for the differing clinical presentations. Recent efforts have sought to identify genes at chromosome 22q11.2, whose defect may specifically account for the cardiac versus the cranial malformations in VCFS. Deletion analyses of this region in mouse models (116) identified several critical genes that may contribute to the VCFS phenotype, including *Tbx1*, a T-box transcription factor gene with homology to the TBX5 gene mutated in Holt-Oram syndrome. Recent mouse knockout models of *Tbxl* haploinsufficiency have demonstrated that a 50% reduction in the *Tbxl* gene dose is sufficient in the mouse to produce aortic arch defects similar to VCFS in humans (116a,116b and 116c). Ongoing human analyses seek to identify TBXl-specific human mutations that might cause VCFS.

Establishment of densely spaced DNA probes at the 22q11.2 locus has made FISH an important diagnostic modality in this disorder (115). FISH analysis can be applied not only to blood samples from adults with equivocal diagnoses, but also to amniocentesis samples to provide prenatal diagnosis. Given the inability of current knowledge to predict structural disease manifestations from a given genetic defect, it will remain important, as with other DNA-based diagnoses, to follow FISH analysis with careful imaging studies of the affected adult or fetus.

Tetralogy of Fallot

Tetralogy of Fallot was initially thought to be a multicomponent disorder including a malalignment VSD with pulmonic stenosis, overriding aorta, and right ventricular hypertrophy. More recent nosology has considered tetralogy of Fallot a “monology”: failure of right ventricular infundibulum development with the other anatomic abnormalities secondary to this embryonic defect. This concept has been supported by experimental manipulation of the conus in chick embryos, which suggests that tetralogy of Fallot is one form of aberrant conotruncal development (117). Tetralogy of Fallot accounts for approximately 10% of congenital heart disease (118) and may occur in isolation or in association with other cardiac anomalies—for example, ASDs, AV septal defect, and persistent left superior vena cava, as well as complex syndromes such as Holt-Oram, Noonan’s, and Down. Tetralogy of Fallot frequently occurs in patients with noncardiac malformations that comprise the CHARGE association (*c*olobomata, *h*eart defects, cho*a*nal atresia, *r*etardation, *g*enital hypoplasia, and *e*ar abnormalities). Tetralogy of Fallot has been suggested to be transmitted in families in both autosomal dominant and recessive patterns (5).



Tetralogy of Fallot. This right anterior oblique right ventriculogram demonstrates some of the findings of tetralogy of Fallot with subpulmonic or infundibular stenosis (*red arrow*) and overriding aorta (*yellow arrow*) and prominent trabeculation of the right ventricle consistent with right ventricular hypertrophy.

Evaluation of patients with tetralogy of Fallot and/or CHARGE association by a variety of investigators has shown that a variable but significant portion of these individuals has chromosome 22q11 microdeletions like VCFS patients (119). In one series, chromosome 22q11 microdeletions were present in 15% of tetralogy of Fallot patients as well as in 50% of interrupted aortic arch patients, 35% of truncus arteriosus patients, and 33% of posterior malalignment VSD patients (120). Although these microdeletions may be *de novo* events, they may be inherited from parents, and they can certainly be transmitted to offspring in an autosomal dominant fashion. In addition, individuals affected by the rare cat-eye syndrome (abnormal facies, inferior iris coloboma, preauricular pits or tags, anal deformity, and renal malformation), which shares features of the CHARGE association, also exhibit abnormalities of chromosome 22q that usually include a duplication of the 22q11 region (121,122 and 123). Cat-eye syndrome patients more often exhibit TAPVR than tetralogy of Fallot. Although 22q abnormalities certainly do not account for all conotruncal abnormalities, their high prevalence in this patient population mandates FISH evaluation of chromosome 22 in such individuals and their first-degree relatives for diagnostic and counseling purposes.

Single gene mutations have occasionally been identified in tetralogy of Fallot patients. As described above, *NKX2.5* mutations may be associated with tetralogy of Fallot (98,99,103). Additionally, mutations in the *JAG1* gene have also rarely been observed (124,125) in tetralogy of Fallot even in the absence of findings of Alagille syndrome, more commonly caused by *JAG1* mutations (see the section Pulmonic Stenosis). Mutational analysis of these genes in tetralogy of Fallot remains available only through research laboratories (see http://www.genetests.org/).

Cardiac Looping Defects (Heterotaxy, or Left-Right Malformations)

Many genes implicated in defining the left-right plan have been identified. Seminal discoveries were made by exploring two mouse mutants, *iv* (*inversus viscerum*) and *inv* (*inversion of embryonic turning*) (126). Homozygous *iv* mice display randomized left-right development of heart and viscera, whereas in mice homozygous for the *inv* mutation, the reversal of left-right asymmetry and cardiac looping is nearly 100% (*situs inversus*), and cysts are formed in the kidneys. The *iv* gene was cloned and named as *lrd* (left-right dynein), which encodes a protein homologous to the sea urchin axonemal dynein heavy chain, a minus-end directed microtubule-based motor protein (127,128). The *inv* gene encodes inversin, which contains 15 consecutive repeats of an Ank/Swi6 motif at its amino terminus (129).

Humans born with altered left-right asymmetry are said to have heterotaxy. Randomization (*situs ambiguus*) and complete reversal (*situs inversus*) of the normal left-right position of the organs (*situs solitus*) are forms of heterotaxy. *Situs inversus* is often not associated with any pathologic abnormalities, but *situs ambiguus* is almost always associated with abnormal visceral organs. Familial heterotaxy can occur as autosomal dominant, autosomal recessive, and X-linked disorders. Several genes have been identified for heterotaxy. In 1995, mutations in connexin 43 (*cx43*), a gap junction gene, were proposed in six patients associated with *situs ambiguus*, but these findings have not been confirmed (130). Mutations were also identified in the human *EBAF* (*LEFTY A*, chromosome 1q42.1) gene coding for a protein with homology to the members of transforming growth factor-b superfamily, the *ACVR2B* gene (chromosome 3p22–21.3) encoding the type II receptor for activins, gonadal polypeptide hormones (131,132), and EGF-CFC encoding a cofactor for Nodal-related signals among some left-right malformation cases (4,133). Mutations in the *ZIC3* gene, located on Xq24–27.1, cause X-linked heterotaxy. *ZIC3* codes for a putative zinc-finger transcription factor (134).

Familial Valvular Disease

Abnormalities of the aortic, pulmonic, mitral, and pulmonic valves are common associations of a variety of complex cardiac malformation syndromes. These syndromes exhibit all modes of transmission. Examples of heritable entities of which valvular abnormalities are major components are highlighted below.

Bicuspid Aortic Valve

Bicuspid aortic valve is a common isolated finding; one series reported an incidence of 0.9% in 1,440 autopsies (135). In addition, this congenital malformation is an important cause of progressive aortic stenosis. At least 17% of cases of isolated bicuspid aortic valve have a familial occurrence (136). A reduced penetrance (particularly in females) for this heritable disorder has confounded genetic analysis. Nevertheless, identification of some families affected by bicuspid aortic valve has suggested an autosomal dominant mode of transmission (135). No autosomal chromosomal locus or gene defect has been associated with this disorder. Bicuspid aortic valve is, however, an important cardiac manifestation of Turner's syndrome (characterized by karyotype 45,XO), which affects approximately 3% of female fetuses (although few of these survive to term). As many as 50% of Turner's syndrome patients have bicuspid aortic valve and are at high risk for progressive aortic root dilatation and aortic valvar stenosis. Approximately 20% of Turner's syndrome patients also present with coarctation of the aorta (137).

Pulmonic Stenosis

Several examples of isolated familial pulmonic stenosis have been reported without a clear pattern of inheritance. However, valvular pulmonic stenosis is an important component of Noonan's syndrome. Noonan's syndrome, which like Turner's syndrome presents with lymphedema as well as skeletal and facial abnormalities, also presents with a variety of congenital cardiac abnormalities, most important, myxomatous degeneration of the pulmonic valve, causing stenosis and abnormal left ventricular hypertrophy (5). Noonan's syndrome is an important cause of infantile hypertrophic cardiomyopathy. Recent evidence (138) has demonstrated that this autosomal dominant syndrome is caused by a genetic defect that maps to chromosome 12q2. Tartaglia et al. (138a) have now demonstrated that mutations in the *PTPN11* gene, which encodes the protein tyrosine phosphatase SHP-2, cause Noonan's syndrome. *PTPN11* mutations account for approximately half of Noonan's syndrome.

VIDEO

Video 100.7 Transesophageal echo of a patient with congenital pulmonary stenosis. Note the severe hypertrophy of the right ventricular outflow tract, causing infundibular pulmonary stenosis as well as valvular pulmonary stenosis. The pulmonic leaflets are thin and pliable; however, there is marked doming caused by tethering of the leaflet tips. *This video must be viewed with QuickTime. Some patients with pulmonic stenosis present with café au lait spots, short stature, and decreased intelligence, and this syndrome has been given the eponym of Watson syndrome. Watson syndrome is an autosomal dominant disorder. Despite the absence of neurofibromata in patients with Watson syndrome, this syndrome is allelic to neurofibromatosis and has been associated with both deletions and duplications within the neurofibromin (NF1) gene on chromosome 17q11.2 (139,140 and

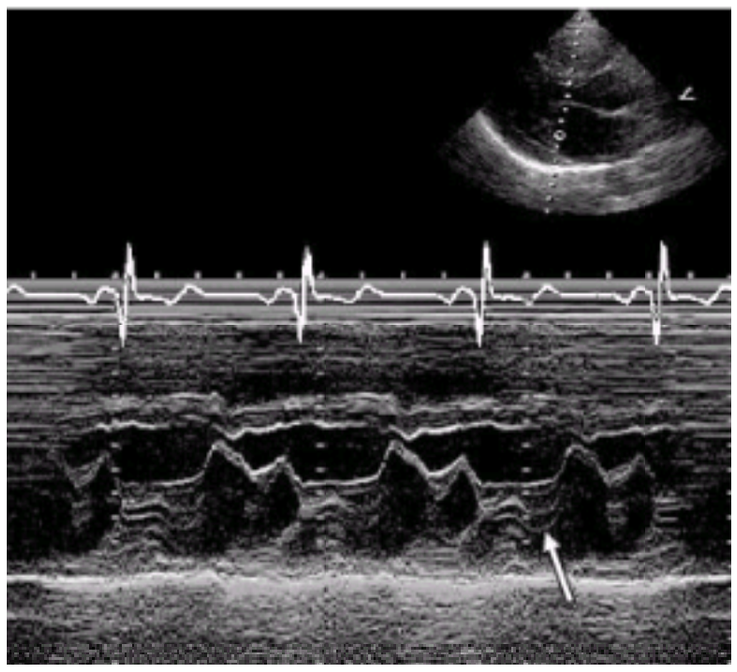
141).

Pulmonic valvular and peripheral pulmonic arterial stenosis are also major components of Alagille syndrome, which is also characterized by abnormal facies, anterior chamber ocular abnormalities, and bile duct hypoplasia with resultant cholestasis. Cytogenetic analysis of chromosomal rearrangements in sporadic patients (142), as well as analysis of families that transmit Alagille syndrome in an autosomal dominant fashion (143), have demonstrated that the gene defect resides on chromosome 20p11.2. Recent investigation has mapped the human homologue of the Jagged-1 gene (*JAG1*) to this 20p locus, and mutations secondary to submicroscopic rearrangements in JAG1 have been shown to cause Alagille syndrome (144,145). The JAG1 protein is thought to be a ligand for Notch1, a member of a transmembrane receptor gene family shown to be important in cell fate commitment in a variety of species. As described above *JAG1* mutations have also rarely been associated with tetralogy of Fallot (124), but no specific genotype-phenotype correlations have been observed.

Familial Mitral Valve Prolapse

Although mitral valve prolapse is an extraordinarily common finding in the general population and is associated with a variety (5) of complex congenital syndromes [e.g., Holt-Oram syndrome (see above), MFS and MASS phenotype (see below), as well as pseudoxanthoma elasticum], familial isolated mitral valve prolapse and myxomatous degeneration are rare. Nonetheless, familial occurrence is an important observation because it is the only known significant predictor (146) of the rare but devastating sudden death events in isolated mitral valvular abnormalities. Although some investigators have reported an autosomal dominant mode of transmission (146,147), a low and age-related penetrance of familial mitral valve prolapse has made thorough genetic analyses difficult. In some cases, concomitant abnormalities of other valves (especially the tricuspid valve) have given rise to the diagnosis of a multiple floppy valve syndrome.



M-mode tracing of posterior leaflet mitral valve prolapse. Note the posterior displacement of the posterior mitral leaflet after the leaflets close in systole.

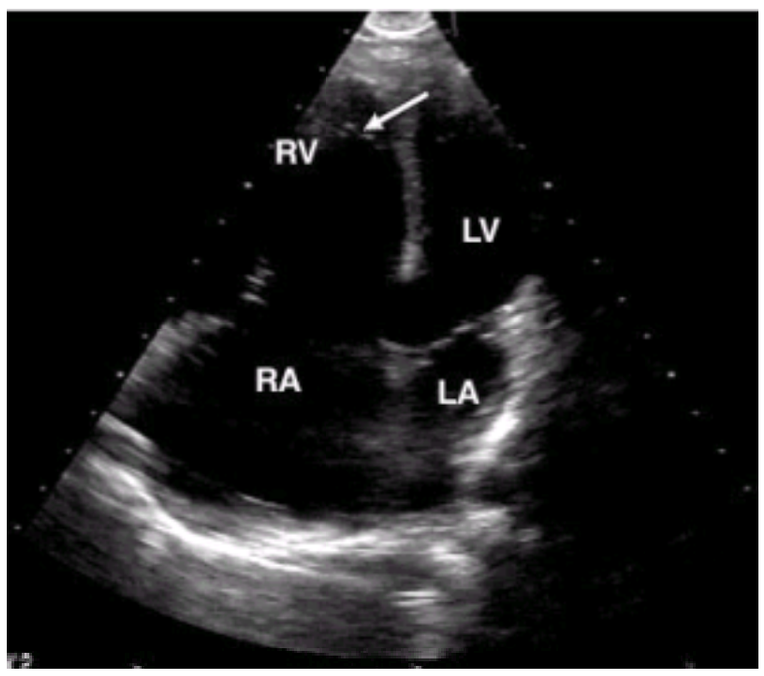
Recently, genetic analysis of families with myxomatous valvular disease has begun to shed light on the bases of mitral valve prolapse. Kyndt et al. (148) studied a large family affected by X-linked myxomatous valvular disease, sometimes referred to as *cardiac valvular dysplasia*, most commonly manifest as mitral valve prolapse, and mapped the as-yet unidentified gene defect to chromosome Xq28. Disse et al. (149) studied four families with autosomal dominant myxomatous mitral valve prolapse and mapped that as-yet unidentified gene defect to chromosome 16p11.2–p12.1. The etiology of sudden death in mitral valve prolapse remains controversial, and both exercise testing and electrophysiologic study are important diagnostic modalities for individuals with a diagnosis of familial mitral valve abnormalities. In the future, identification of the specific gene defects on chromosomes X, 16, and others that lead to mitral valvular defects may assist in risk stratification of individuals with mitral valve disease.

Ebstein's Anomaly

Ebstein's anomaly is characterized by an apical displacement of the tricuspid valve leaflets with an "atrialization" of the right ventricular myocardium superior to the deformed valve leaflets. Although the atrialized right ventricular myocardium is part of the atrium from a hemodynamic perspective, this region of myocardium retains ventricular electrophysiologic properties. An ASD is often present as well. Approximately 0.5% of congenital heart disease patients have Ebstein's anomaly, and there is no obvious gender predilection (150,151). Familial cases have been reported, but no mode of transmission has been documented, although male-to-male transmission has been noted. Most recently, Benson et al. (99) have observed *NKX2.5* mutations in rare individuals with Ebstein's anomaly, but the applicability of this finding to Ebstein's patients in general remains to be determined. Conduction abnormalities, including right bundle branch block, AF, and preexcitation, have been associated with Ebstein's anomaly; active investigation of the genetics of preexcitation syndromes such as Wolff-Parkinson-White syndrome (see the section Wolff-Parkinson-White Syndrome) may eventually contribute to our understanding of the genetic etiology of Ebstein's anomaly.



Ebstein's anomaly of the tricuspid valve. Note marked apical displacement of the tricuspid leaflets, especially the septal leaflet. The arrow designates the septal leaflet of the tricuspid valve.

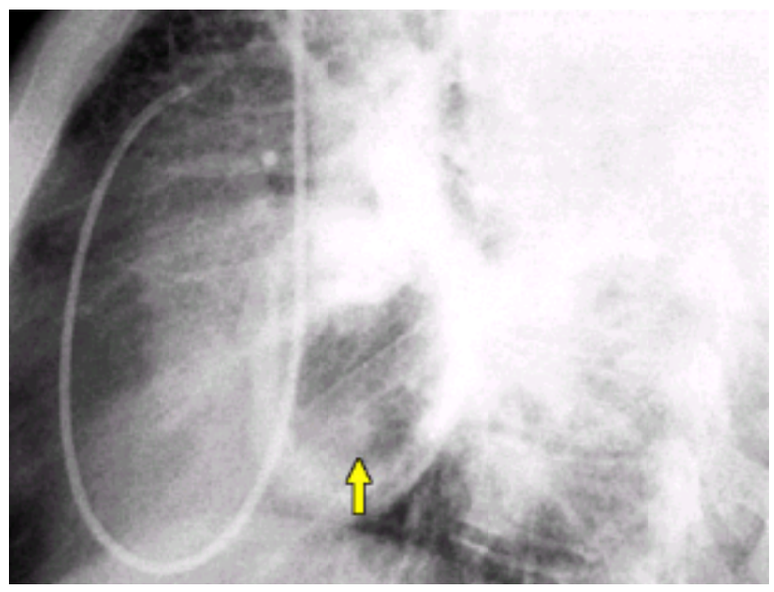
Familial Cardiac Myxoma

Clinical Manifestations

Intracardiac tumors are themselves rarely evident at birth, although they may be features of complex syndromes whose signs and symptoms can be observed immediately postpartum. Intracardiac myxomas account for one-third to one-half of all primary cardiac tumors and are generally regarded as isolated benign tumors of the left atrium of middle-aged women; they are amenable to surgical resection and rarely recur or metastasize. Approximately 7% of individuals with intracardiac myxomas have a familial history of intracardiac myxoma (Fig. 100.2), and these individuals are often young and as likely to be male as female. Tumors in such individuals may occur in any cardiac chamber (although atrial involvement is more common than ventricular), may be multicentric, and frequently recur at intracardiac sites distant from the original tumor despite complete surgical resection (152,153). Moreover, familial atrial myxomas (Fig. 100.2A) usually occur as part of a complex syndrome. Previously referred to by acronyms such as *NAME* (*n*evi, *a*trial myxoma, *m*yxoid neurofibromata, *e*phelides) and *LAMB* (*l*entigines, *a*trial myxoma, *m*ucocutaneous myxoma, *b*lue nevi), these syndromes are encompassed by the eponym Carney complex. Carney complex is characterized by not only intracardiac myxomas, but also by extracardiac myxomas in the setting of lentiginosis (Fig. 100.2B) and endocrine dysfunction. This syndrome is transmitted in an autosomal dominant fashion, and although it is highly penetrant, disease manifestations are highly variable even among individuals within a given family (153). Although at least one-third of individuals will ultimately present with an intracardiac tumor, diagnosis is facilitated by the fact that almost all individuals will exhibit some abnormal form of hyperpigmentation even in infancy (154,155).

FIGURE 100.2 Cutaneous and cardiac involvement in the Carney complex. **A:** An apical four-chamber, two-dimensional echocardiographic view of the heart from an individual affected by Carney complex. Although the ventricular myocardium is structurally normal, a large mass arising from the interatrial septum can be seen in the

left atrium. Histopathology of this mass after surgical removal demonstrated that it was an atrial myxoma. Cutaneous findings in this individual were similar to those seen in **B**. **B:** This child, a cousin of the individual illustrated in **A**, exhibits the typical cutaneous hyperpigmentation of the Carney complex. His face illustrates the excessive and atypical freckling pattern in this syndrome, including freckles on his lips. Note, as well, the large nevi on his right ear and between his right ear and right eye. In adulthood, he developed an atrial myxoma. Individuals in this family carry the haploinsufficient DFSterGly208 mutation in the PRKAR1a gene.



Left atrial myxoma. This left anterior oblique projection depicts the left atrial filling phase of a pulmonary angiogram performed via a pulmonary artery catheter inserted into the right jugular vein. A large contrast free space (*yellow arrow*) depicts a space occupying mass within the left atrial cavity, which surgical pathology confirmed to be a myxoma.

Video 100.10 Atrial myxoma (long-axis). A myxoma attached to the interatrial septum is seen. During diastole, the myxoma moves through the mitral orifice into the left ventricle. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 100.11 An 80-year-old male patient with weight loss, fever, and dyspnea for 2 months. Angiography revealed vascular tumor, which received blood supply from the right coronary artery. Echocardiograph confirmed location of the tumor in the left atrium with appearance consistent with myxoma. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Genetic Studies

Linkage analyses (155) demonstrated that a gene defect at a locus on chromosome 17q caused Carney complex in several families. Subsequent candidate-positional cloning studies (156,157) demonstrated that mutations in the gene encoding the R1a regulatory subunit of cyclic adenosine monophosphate–dependent protein kinase A (*PRKAR1*a) cause Carney complex. All of the *PRKAR1*a mutations identified to date (156,157,158 and 159) result in haploinsufficiency. Although development of some tumors may be associated with loss of heterozygosity at the *PRKAR1*a locus (157), other tumors (156) maintain the wild-type allele and continue to synthesize the PRKAR1a subunit. Thus, *PRKAR1*a may function as a tumor suppressor gene in the heart, but tumorigenesis may be the result of a constitutional mutation in *PRKAR1*a along with acquired mutation of other tumor suppressor genes as has been demonstrated for the NF1 gene in neurofibromatosis (160,161).

Carney complex is likely genetically heterogeneous (158,162). A minority of families have been described in whom mutational analysis has failed to demonstrate *PRKAR1*a mutations and in which potential recombination exists between the Carney complex phenotype and the *PRKAR1*a gene. A second locus (154) has been described on chromosome 2p, but thus far, the statistical significance of this locus remains unclear. Ongoing investigation will likely identify at least one other Carney complex disease gene. In the interim, for those families in whom linkage can be demonstrated of Carney complex to chromosome 17, DNA-based testing may help identify individuals at risk for cardiac myxoma formation and who will benefit from annual surveillance echocardiography (156,163).

CARDIOMYOPATHIES: ADULT-ONSET DEFECTS OF CARDIAC STRUCTURE

Cardiomyopathies are a heterogeneous group of primary myocardial disorders characterized by impaired ventricular function. These are traditionally classified as dilated, hypertrophic, or restrictive, based on anatomic and hemodynamic features. With an estimated prevalence of 36.5 per 100,000 individuals, dilated cardiomyopathies occur most commonly (164,165) and are associated with cardiac chamber dilation and depressed ventricular contractility. Hypertrophic cardiomyopathies are defined by an increase in myocardial mass with myocyte and myofibrillar disarray and abnormalities of both diastolic and systolic function (164). Although the incidence of familial hypertrophic cardiomyopathy (FHC) is unknown, an echocardiographic survey demonstrated unexplained hypertrophy in 1 of 500 young adults (166). Restrictive cardiomyopathies are the least common of these disorders; these are characterized by normal cardiac dimensions and abnormal ventricular diastolic function with preserved systolic function.

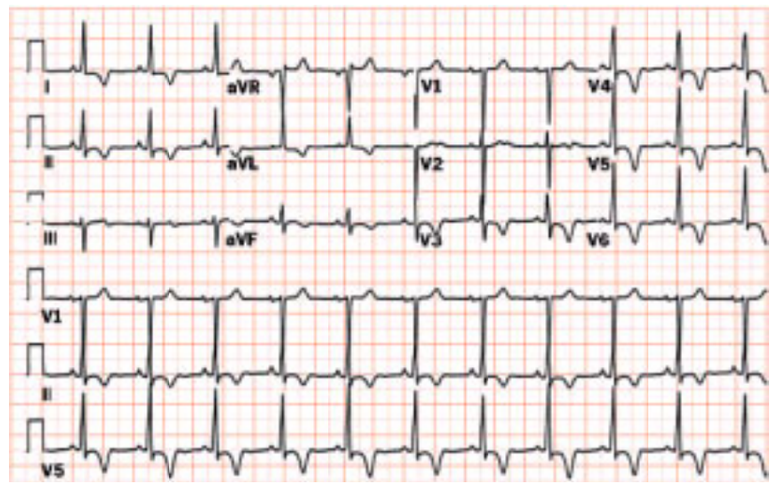
Clinical and research efforts have demonstrated that both dilated and hypertrophic cardiomyopathies are often familial. By contrast, restrictive cardiomyopathies are rarely inherited. Familial cardiomyopathies have been reported to be inherited as autosomal (dominant or recessive), X-linked, and matrilinear (presumably mitochondrial) disorders (167,168). Combined with recent advances in human molecular genetics, these observations have permitted significant progress toward identifying the genetic etiology of inherited cardiomyopathies. These endeavors will have a substantial impact on clinical medicine, including the immediate opportunity for accurate diagnosis. Such gene-based diagnosis also creates a scaffolding for ongoing analyses of clinical outcomes and therapies. In the future, understanding genetic mechanisms of cardiomyopathies may provide optimally targeted therapy instead of the currently available palliative therapy or cardiac transplantation. In this section, we explore in more detail current understanding of genetic etiologies of each form of cardiomyopathy and how they may relate to clinical presentation and management.

Familial Hypertrophic Cardiomyopathy

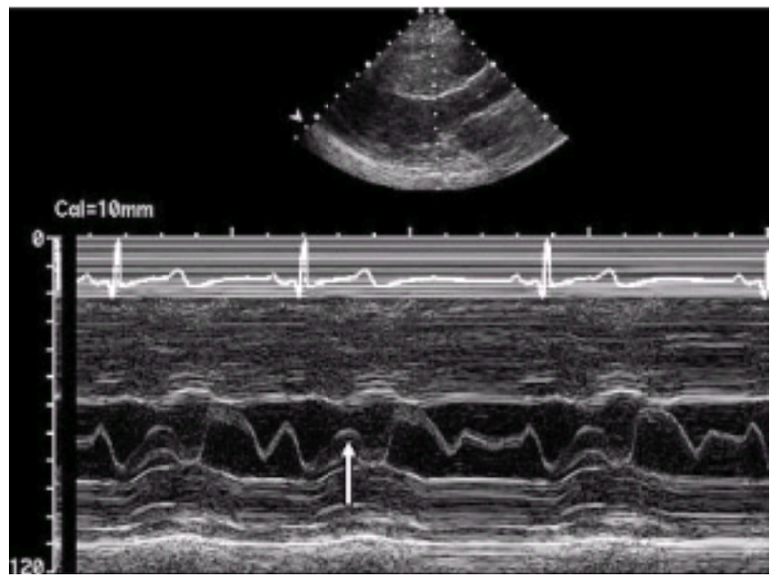
Clinical Features

FHC is an autosomal dominant disorder characterized by increased ventricular mass, hyperkinetic systolic function, and impaired diastolic relaxation. The cardiac hypertrophy found in this inherited disorder may affect either ventricle but usually involves the left ventricle and is often predominant in the interventricular septum (169,170). Histologic examination of affected myocardium reveals myocyte and myofibrillar disarray, which, if extensive, is pathognomonic (170). Symptoms of FHC are diverse and variable, including exertional dyspnea, angina pectoris, and sudden death, which can occur even in asymptomatic individuals (169). Hypertrophic cardiomyopathy is clinically significant because it is one of the most commonly recognized causes of sudden death in apparently healthy young adults (169,171,172). Hypertrophic cardiomyopathy can occur as a sporadic disease, but affected individuals can be shown to have familial disease with echocardiographic features of cardiac hypertrophy in first-degree relatives. Penetrance in familial disease is age-related, with the clinical manifestations of the disease typically developing in adolescence. In adults, penetrance may not be complete, although estimates of penetrance depend on the diagnostic criteria used. Although several studies of the natural history of FHC have demonstrated an annual mortality rate of 2% to 4% from sudden death (171), reports on ambulatory FHC patients suggest a more benign prognosis (169). The mechanism for sudden death is often unknown, and both primary arrhythmias and hemodynamic factors have been proposed. Atrial

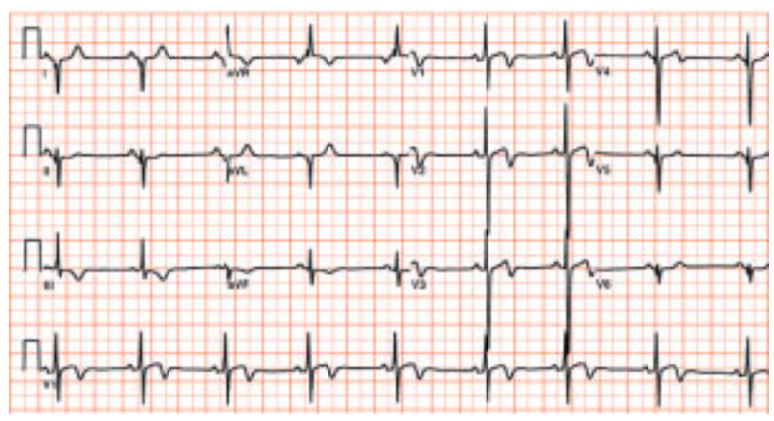
dysrhythmias, particularly fibrillation, are frequently problematic in FHC patients independent of their history of sudden death.



Yamaguchi's disease. Note anterior precordial T wave inversion in this Asian patient with apical hypertrophy.



M-mode tracing of hypertrophic cardiomyopathy with severe septal hypertrophy seen at the top of the trace and systolic anterior motion (SAM) of the mitral valve in systole seen in the middle of the trace (designated by the arrow).



A 28-year-old Caucasian male patient with hypertrophic obstructive cardiomyopathy.

Physical findings (particularly a systolic murmur that increases with maneuvers that decrease preload) or ECG abnormalities (e.g., inferior Q waves and left ventricular hypertrophy) may suggest FHC. However, the mainstay of diagnosis in the adult is the observation by two-dimensional echocardiography of left ventricular hypertrophy (*e*Fig. 100.2.1) without obvious explanation (e.g., aortic stenosis or long-standing hypertension). Associated echocardiographic findings include asymmetric hypertrophy (particularly of the interventricular septum), a dynamic left ventricular outflow tract pressure gradient, and systolic anterior motion of the anterior mitral valve leaflet. With the discovery of genetic causes of hypertrophic cardiomyopathy, the natural history of disease has been expanded to include a preclinical stage. Most often this occurs in the young because hypertrophy may not develop until after adolescent growth has been completed (173). However in some adults, development of the morphologic features of disease may not be manifest until late in life. Although echocardiograms are, by definition normal throughout this preclinical stage, these individuals sometimes show ECG abnormalities.

***e*FIGURE 100.2.1** Echocardiographic manifestations of familial hypertrophic cardiomyopathy. A parasternal long-axis two-dimensional echocardiographic view of the heart from this individual with familial hypertrophic cardiomyopathy is shown. Note the marked thickening of the left ventricular walls, particularly the interventricular septum.

Video 100.12 A four-chamber transesophageal echo (TEE) of a patient with hypertrophic obstructive cardiomyopathy before myectomy **(A)**. Note the mitral regurgitation due to systolic anterior motion of the mitral valve leaflets. Intraoperative TEE after myectomy **(B)** for hypertrophic cardiomyopathy. Note that there is no longer mitral regurgitation from systolic anterior motion of the mitral valve leaflets, and the left ventricular outflow tract is opened up compared with the preoperative TEE. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 100.13 A four-chamber transesophageal echo (TEE) of a patient with hypertrophic obstructive cardiomyopathy before myectomy **(A)**. Note the mitral regurgitation due to systolic anterior motion of the mitral valve leaflets. Intraoperative TEE after myectomy **(B)** for hypertrophic cardiomyopathy. Note that there is no longer mitral regurgitation from systolic anterior motion of the mitral valve leaflets, and the left ventricular outflow tract is opened up compared with the preoperative TEE. Video 100.14 Intraoperative transesophageal echo of a patient with hypertrophic obstructive cardiomyopathy and left ventricular outflow tract (LVOT) obstruction. The septum is hypertrophied, and the mitral leaflets show some systolic anterior motion of the mitral valve leaflets. An accessory mitral leaflet is located on the left ventricular septum. Note the independent motion of this leaflet in the LVOT. The pressure gradient across the LVOT/AV was greater than 100 mm Hg; however, the aortic valve opens freely. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Genetic Studies

Molecular genetic analyses have demonstrated that FHC is a disease of the sarcomere. Linkage analyses and positional cloning studies of kindreds with FHC have demonstrated that hypertrophic cardiomyopathy is a genetically heterogeneous disorder; a mutation in one of many sarcomeric genes can produce a clinically indistinguishable phenotype. To date, studies have demonstrated that mutations in genes for beta-myosin heavy chain (MHC) (chromosome 14q1) (174), cardiac troponin T (chromosome 1q31) (175), alpha-tropomyosin (chromosome 15q2) (175), myosin-binding protein C (chromosome 11p13–q13) (176), ventricular myosin regulatory light chain (chromosome 12q2) (177), ventricular myosin essential light chain (chromosome 3p) (177), cardiac actin (chromosome 15q14) (178), and titin (chromosome 2q31) (179) can all produce FHC.

Beta-cardiac MHC mutations are detected in approximately 35% to 40% of FHC patients, and extensive analyses of FHC patients have led to the identification of more than 50 mutations in the beta-cardiac MHC gene (180,181 and 182). The gene defects that cause FHC are typically family-specific—that is, unique mutations are found in different families (termed *allelic* or *intragenic heterogeneity*). All mutations are missense; the nucleotide change results in the replacement of the normally encoded amino acid with a different residue. Mutations are all localized to the globular head or head-rod junction in the molecule (183).

Different beta-cardiac MHC gene mutations appear to correlate with survival in patients with FHC (181,183,184). Several mutations have been identified that are associated with a significant risk of sudden and/or premature death (malignant mutations), whereas other mutations correlate with long-term survival (benign mutations). Kaplan-Meier curves for survival with FHC illustrate these different profiles (Fig. 100.3). For instance, near-normal survival is found in individuals with the Val606Met (benign) beta-MHC mutation. In contrast, approximately half of individuals with the Arg403Gln (malignant) beta-MHC mutation are dead by age 50 years. Because there are no good clinical predictors of risk for premature death in hypertrophic cardiomyopathy, acquisition of more survival data from the full spectrum of sarcomere mutations may be extremely useful for stratifying patient risk and allowing appropriate intervention.

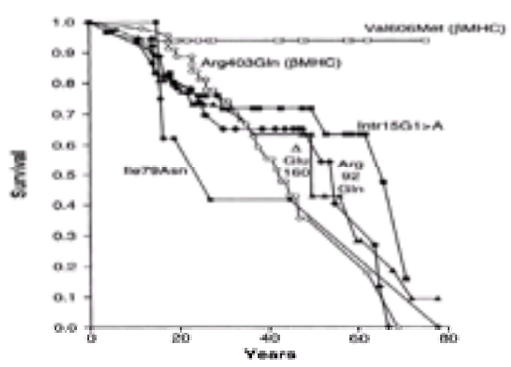

FIGURE 100.3 Kaplan-Meier product-limit curves for survival in patients with hypertrophic cardiomyopathy caused by different mutations. Survival data are plotted for all persons carrying a given mutation. The survival of individuals with hypertrophic cardiomyopathy caused by cardiac troponin T mutations [Intron 15 $G_1 \rightarrow A$ (■), Ile79Asn (●), DGlu160 (▲), and Arg92Gln (✚)] is similar to that in persons with a malignant beta-cardiac myosin heavy chain mutation (Arg403Gln) but significantly shorter than that in persons with a benign myosin mutation (Val606Met). (p <.03 for the comparison with each troponin T mutation and p = .006 for the comparison with all troponin T mutations.) Myosin mutations are shown in □ and ○. (From Watkins H, McKenna W, Thierfelder L, et al. Mutations in the genes for cardiac troponin T and alpha-tropomyosin in hypertrophic cardiomyopathy. *N Engl J Med* 1995;332:1058, with permission.)

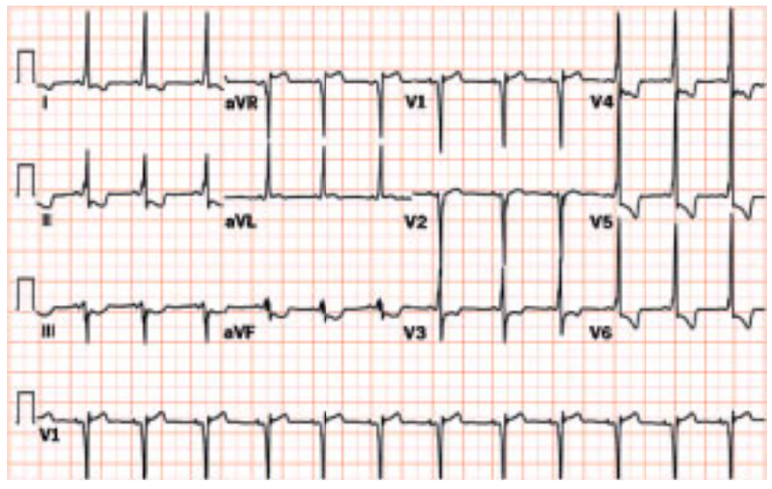
Despite this correlation between survival and alteration in charge of the mutated amino acid, considerable variation remains in the extent and distribution of hypertrophy even within a given family, all of whom have the same genetic basis for FHC. Recent analyses (185) of the anatomic features of FHC categorized according to different genetic etiologies have confirmed earlier work, thereby suggesting that other factors (genetic or environmental, or both) are important in modulating the hypertrophic phenotype. In addition, such factors undoubtedly also modulate the frequency of sudden death in FHC. Studies that correlate the clinical features of FHC in individuals with distinct genetic etiologies are an area of active research, and assessing various factors' impacts in light of the genetic background on which they occur will, it is hoped, improve risk stratification in patients.

In addition to beta-cardiac MHC mutations, mutations in other sarcomere components can also produce FHC (175,177,186). Defects in cardiac troponin T (175,187) and myosin-binding protein C (188,189) each account for approximately 15% of all cases of FHC. A wide range of different defects cause FHC in these genes, including missense mutations, insertions, deletions, and defects in splice signals. FHC caused by mutations in cardiac troponin T often has reduced penetrance, and the hypertrophic phenotype associated with these mutations can be subtle—that is, affected individuals appear to have modest increases in the maximum left ventricular hypertrophy (detected by echocardiography). Despite this, survival of individuals with FHC caused by cardiac troponin T mutations is often quite poor and comparable to that seen with malignant beta-cardiac MHC gene mutations. These findings suggest that genetic diagnosis may be particularly important in families with mutations in cardiac troponin T. A very different clinical profile is produced by cardiac myosin-binding protein C mutations (188,189). Hypertrophic cardiomyopathy caused by these defects can exhibit delayed expression, such that hypertrophy does not become manifest until middle age. Survival with myosin-binding protein C mutations is variable; some defects have near normal survival, whereas others have a poorer prognosis.

Other gene mutations are rarer causes of hypertrophic cardiomyopathy. Alpha-tropomyosin mutations account for approximately 5% (175), and a few mutations have been defined in the genes encoding the ventricular myosin regulatory and essential light chains (177), cardiac actin (178), and titin (179) in patients with FHC. Individuals with mutations in alpha-tropomyosin appear to have a variable presentation of FHC; severity of hypertrophy among families with unique mutations differs. Nonetheless, survival among such individuals is good, with only rare sudden death. Ongoing evaluations are needed to better assess the disease phenotype in individuals with mutations in ventricular myosin regulatory and essential light chains, cardiac actin, and titin.

Current research also centers on identification of other genetic causes of cardiac hypertrophy. For instance, clinicians have recognized an association between cardiac hypertrophy and electrical abnormalities, including Wolff-Parkinson-White syndrome and progressive atrioventricular block (190). Recent investigations (72a,190a) have established that defects in the gene encoding the $gamma_2$ regulatory subunit of AMP-activated protein kinase (*PRKAG2*) on chromosome 7q3 cause this phenotype. Although this disorder was initially felt to be a variant of hypertrophic cardiomyopathy, histopathology and biochemical features of *PRKAG2* defects indicate this to be a novel glycogen storage disease of the heart (190b). Similarly, hypertrophic cardiomyopathy has been associated with the autosomal dominant Noonan's syndrome (craniofacial malformation, axial skeletal abnormalities, pulmonic stenosis, and hypertrophic cardiomyopathy) as well as the neuromuscular disorder Friedreich's ataxia (191). Mutations have recently been identified (192) in the novel frataxin gene on chromosome 9q from individuals with Friedreich's ataxia. At this time, however, no physiologic function has yet been ascribed to the frataxin gene, and the mechanism by which these mutations cause the cardiac manifestations of

this syndrome are unclear. A hypertrophic cardiomyopathy occurs also in the context of multisystem neuromuscular disease. These disorders result from mutations in mitochondrial proteins encoded within the nuclear and mitochondrial genomes (reviewed in reference 172 and not discussed further in this chapter).



Wolff-Parkinson-White syndrome. Eleven-year-old patient with manifest preexcitation consistent with Wolff-Parkinson-White.

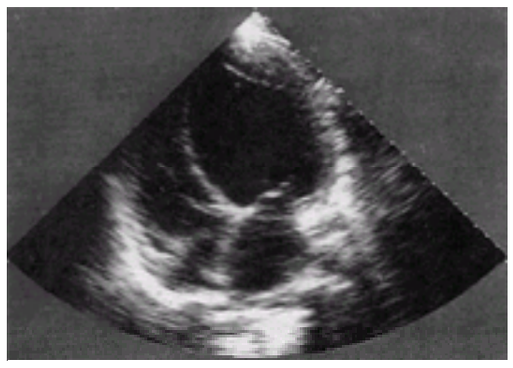
Strategies for understanding how sarcomere mutations result in cardiac hypertrophy are an avenue of active investigation. Mutated sarcomeric proteins are generally thought to produce disease via a dominant negative effect—that is, the mutated protein directly alters sarcomeric function. *In vitro* analysis of mutated myosins has suggested altered biochemical and biophysical properties of the protein. Although early data suggested that mutations in myosin caused a loss of function (193), more recent data indicate the opposite. *In vitro* analyses (194) of single molecule mechanics of Arg403Gln myosin showed supranormal actin-activated adenosine triphosphatase activity, increased generated force, and accelerated sliding with respect to actin filaments. These data indicate a gain in function resulting from this missense mutation. Ongoing evaluation of models (195,196,197,198 and 199) in which human mutations have been engineered into the mouse or rabbit genomes has helped define the physiologic and cellular consequences of FHC-causing mutations. These models also provide the opportunity to define intracellular signals and pathways that respond to perturbation in sarcomere structure or function, or both. Such data may provide a new framework for the rational design of therapeutic agents.

More immediately, the definition of distinct genetic etiologies for FHC permits gene-based diagnosis in some families. As noted, FHC is an autosomal dominant disorder that is equally inherited by men and women. Because only one mutated gene is sufficient to cause autosomal dominant diseases, 50% of the offspring of an affected individual will inherit the disease-causing mutation. In individuals for whom a sarcomere mutation has been identified, gene-based diagnosis of all family members is now possible. Gene-based diagnosis can be particularly beneficial to families with a high incidence of sudden death. Not only can this information target longitudinal evaluation to children who are genotype positive (200,201), but in addition these data can prevent unnecessary restrictions on children who are not at risk of developing FHC.

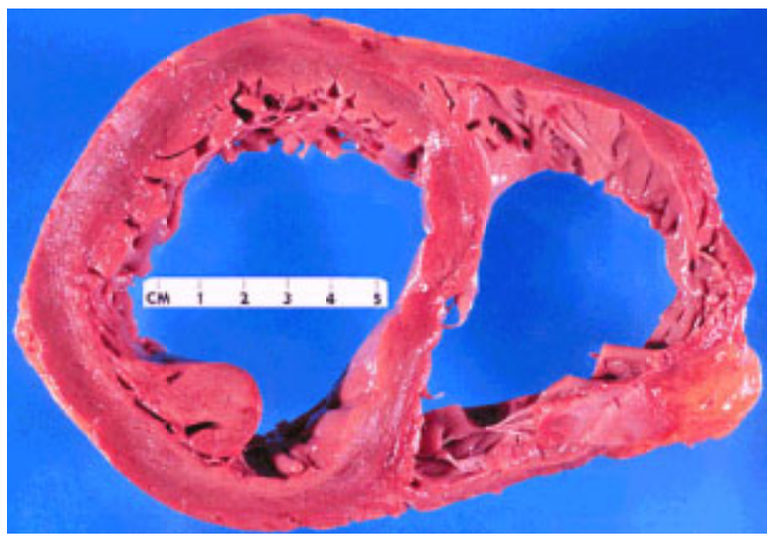
Familial Dilated Cardiomyopathies

Clinical Features

Dilated cardiomyopathy occurs as a primary disorder of the myocardium characterized by cardiac dilation (eFig. 100.3.1) and impaired ventricular function or secondary to toxic, metabolic, or infectious agents (reviewed in reference 164). The incidence of dilated cardiomyopathies is approximately 37 per 100,000 individuals (164,202), and these prevalent disorders contribute substantially to overall incidence of heart failure in the United States (164,165,202). Indeed, dilated cardiomyopathy accounts for up to one-third of heart failure in individuals between the ages of 25 and 65 (164,202), and is the most common indication for heart transplantation. In addition to signs and symptoms of congestive heart failure, pericardial effusion and conduction disturbances are often observed. Thromboembolic events, syncopal episodes, and unexplained sudden death further contribute to substantial morbidity and mortality associated with dilated cardiomyopathy.



***e*FIGURE 100.3.1** Echocardiographic manifestations of familial dilated cardiomyopathy. In this apical four-chamber, two-dimensional echocardiographic view of the heart from an individual affected by a familial dilated cardiomyopathy, the left ventricle chamber can be seen to be markedly enlarged without change in wall thickness.



Dilated congestive cardiomyopathy. Both the left and right ventricles are significantly enlarged. In this example, the left ventricular wall thickness falls within normal limits.

Pathologic findings also suggest that familial dilated cardiomyopathy is heterogeneous. Myocyte necrosis in the absence or presence of inflammation, fibrosis, and/or conduction system disease have all been noted (203). Cellular studies have identified a variety of physiologic defects (172,204) in dilated cardiomyopathy, including impaired sarcoplasmic reticulum calcium handling, atypical myocyte potassium currents, and autoantibodies to a variety of cardiomyocyte antigens, but have not provided a unified pathophysiologic or molecular mechanism (205). These data suggest that multiple gene defects individually or together may cause myocardial dysfunction that results in chamber dilation and dysfunction.

Genetic Studies

Primary dilated cardiomyopathy occurs as sporadic disease. Although elucidation of the initiating cause for idiopathic dilated cardiomyopathy in a single affected individual is often impossible, several studies have demonstrated that more than 25% of affected probands have an affected relative (202,206). Familial dilated

cardiomyopathy can be inherited as a matrilinear, X-linked, autosomal recessive, or autosomal dominant trait (167,168). Dilated cardiomyopathy due to mitochondrial mutation is one component of multisystem disease (164); these disorders are not discussed further. Autosomal dominant transmission is the most prevalent mode of transmission that has fostered application of molecular genetic approaches to identify gene defects that cause dilated cardiomyopathy. Premature morbidity and mortality in familial dilated cardiomyopathy initially hindered genetic studies of this disorder but with advances in the genome project, issues such as small family size have become less significant obstacles. Increasingly genetic loci and disease genes have been defined. Identification of the full complement of mutations that cause familial dilated cardiomyopathy is also likely to provide insights into the causes of sporadic disease; in some instances these may be due to *de novo* mutations in genes that also cause heritable disease.

Familial dilated cardiomyopathy (5,204,206) can be associated with a variety of cardiac findings, including atrial cardiomyopathy, conduction system abnormalities (particularly AV block), valvular disease, and ventricular tachycardia. Extracardiac manifestations are sometimes present; the coexistence of subclinical or overt skeletal myopathy is particularly common (167).

Mutations in three X-linked genes cause dilated cardiomyopathy. In addition to cardiac disease, these defects cause muscular dystrophy (Duchenne's or Becker's muscular dystrophy and Emery-Dreifuss muscular dystrophy) or the complex phenotype of Barth's syndrome.

In Duchenne's/Becker's muscular dystrophy, proximal muscular atrophy is the most striking feature, but most patients will exhibit some degree of cardiac involvement (207). Ninety-five percent of Duchenne's patients will exhibit some manifestation of dilated cardiomyopathy by the end of their lives, and in many, signs and symptoms appear before the age of 6. Cardiomyopathy tends to present after puberty in Becker patients. In some Duchenne's/Becker's patients, dilated cardiomyopathy is the dominant clinical finding. These cardiomyopathies result from deletions of the 5' muscle promoter of the dystrophin gene (208). Such individuals exhibit pathologic findings of dystrophy on skeletal muscle biopsy, but they may remain subclinical. A similar phenotype has been demonstrated in a recently described family with a premature stop codon and consequent dystrophin protein truncation (209). However, when the dystrophin promoter region in a large series of patients with idiopathic cardiomyopathy was examined, no mutations were identified (210). Thus, it is thought that this is a relatively rare etiology for adult-onset sporadic dilated cardiomyopathy.

Emery-Dreifuss muscular dystrophy often presents with dilated cardiomyopathy and AV conduction abnormalities in the setting of progressive skeletal muscle dysfunction and contractures. Although atrial dysrhythmias (paralysis, fibrillation, and flutter) are common, infranodal disease with slow junctional rhythms and AV block frequently causes symptoms. Mutations in the emerin gene cause this disorder (211), but the precise function of this protein as well as the contribution of emerin mutations to more common adult-onset cardiomyopathy remains unknown.

Barth's syndrome is a frequently lethal infantile disorder in which patients exhibit dilated cardiomyopathy associated with short stature and neutropenia. Although the genetic locus established by linkage analyses overlaps with the Emery-Dreifuss locus, recent positional cloning studies (212) have demonstrated that Barth's syndrome is caused by mutations in a distinct gene called *tafazzin*. Investigation of alternative splicing of tafazzin transcripts is an area of active research and may help explain the variable phenotypes in Barth's syndrome.

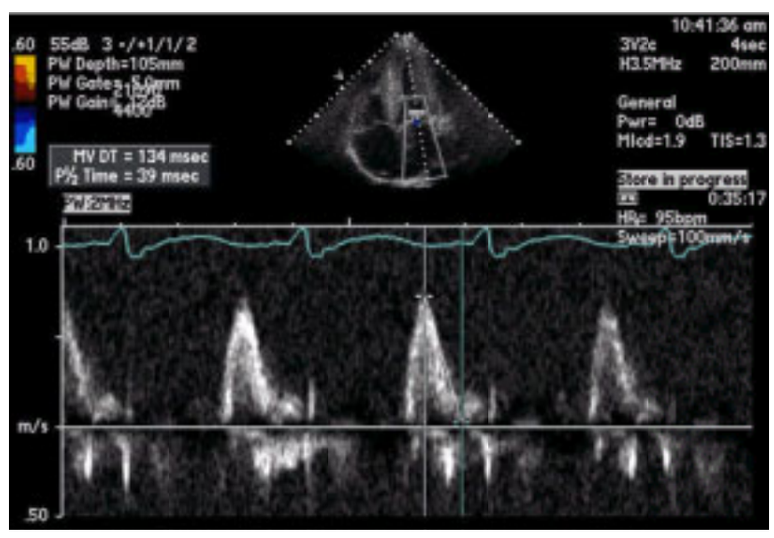
Autosomal dominant dilated cardiomyopathy is the most common form of hereditary primary dilated cardiomyopathy. To date, 17 distinct chromosomal loci have been reported (5) and more will likely be identified in the future. Disease genes that map to chromosomes 1q32, 2q31, 6q12–16, 9q13–q22, 14q11, and 15q14 cause isolated cardiac disease. Loci on chromosomes 1q21, 2q11–q22, 3q22–p25, 6q23, and 19q13.2 cause dilated cardiomyopathy in association with conduction system disease (5,70,213,214,215,216 and 217). Dilated cardiomyopathy that is caused by a mutated gene encoded on chromosome 10q21–q23 (216) is associated with mitral valve prolapse, whereas dilated cardiomyopathy due to mutation on chromosome 6q23–24 (218) is associated with sensorineural hearing loss. In several instances, these genomic locations have been defined by analyses of a single family, and in many instances specific gene defects have not yet been identified. In addition to the considerable variation in associated clinical manifestations, the age of onset of ventricular dilatation, systolic dysfunction, and frank heart failure can vary considerably. Early-onset disease that affects children and young adults characterizes some gene mutations, whereas others often present in middle-aged and older adults.

Conduction abnormalities are particularly prevalent in some families with autosomal dominant dilated cardiomyopathy. Individuals typically present early in life (before overt chamber dilatation) with sinoatrial node dysfunction, which may progress to supraventricular tachyarrhythmias and His-Purkinje system conduction delay. Pacemaker implantation is often required. Although mutations at three distinct loci are known to produce this phenotype, only one disease-causing gene has been identified. Mutations in the gene encoding lamin A and C isoforms (on chromosome 1q21) can cause this disease (219). Missense mutations that perturb the structure of the alpha-helical domain of these peptides usually cause dilated cardiomyopathy and conduction disease. Other mutations (missense and nonsense) in lamin can produce two different diseases, Emery-Dreifuss syndrome (220) or familial partial lipodystrophy (221). Emery-Dreifuss is a childhood-onset muscular dystrophy with contractures and adult-onset cardiac conduction abnormalities. Familial partial lipodystrophy (Dunnigan-type) is a metabolic disorder characterized by abnormal deposition of fat, insulin-resistant diabetes, and cardiac conduction system disease. The mechanisms by which distinct mutations in lamins cause these three different clinical phenotypes is unknown. Lamins are components of the nuclear envelope and may both contribute to the integrity of the nucleus; these may also participate in nuclear-cytoplasmic trafficking and in transcriptional regulation.

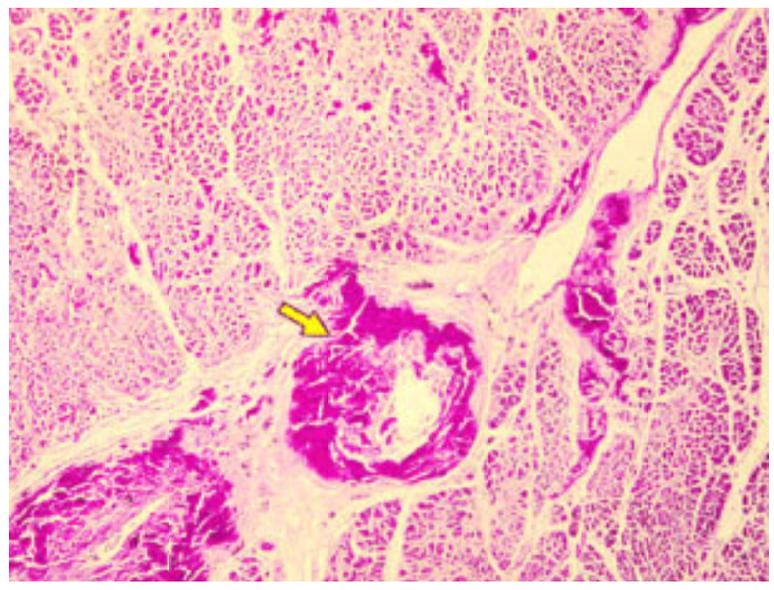
Dilated cardiomyopathy that occurs in isolation can be due to mutations in sarcomere protein genes. Although most mutations in these proteins cause hypertrophic cardiomyopathy, some missense mutations in cardiac actin (222) or the beta-cardiac MHC gene (223) and a deletion in cardiac troponin T (223) cause cardiac dilatation and dysfunction. Presumably these have distinct effects on the biophysical properties of the sarcomere than do mutations that result in cardiac hypertrophy. Although understanding the mechanisms by which different mutations produce these different cardiac morphologies is an area of active research, an important clinical observation came from this genetic research. The onset of cardiac failure occurs early in those individuals with dilated cardiomyopathy due to sarcomere gene mutations. Signs and symptoms of heart failure and even sudden death may present during childhood.

Restrictive Cardiomyopathy

Restrictive cardiomyopathies are a rare group of disorders characterized by abnormal diastolic function resulting from impaired ventricular filling and preserved systolic function. Restrictive cardiomyopathy often accompanies genetic conditions, such as amyloidosis, hemochromatosis, and Fabry's disease, and eosinophilic disorders, including myeloproliferative, vasculitic, and parasitic disease. Familial restrictive cardiomyopathy is exceedingly rare (5), and although one report (224) suggests dominant transmission, virtually nothing further is known about the genetic etiology of this condition.



Pulsed wave Doppler of the mitral valve inflow in a patient with amyloidosis demonstrating a short deceleration time (134 ms) consistent with restrictive physiology.



Amyloidosis of the heart. This is cresyl violet stain of the left ventricular myocardium. The yellow arrow indicates a metachromatic red-violet homogenous deposit around an intramyocardial arteriole with similar interstitial deposits.

Arrhythmogenic Right Ventricular Dysplasia

Clinical Features

ARVD refers to a condition of progressive atrophy of the myocardium with fatty or fibrofatty tissue replacement (225,226 and 227). Although this primary myocardial disorder typically involves the right ventricle and pathologic findings are initially found there, left chamber involvement is not uncommon. The pathology can be segmental or diffuse and transmural. Right ventricular wall thickness can be normal or increased by fatty infiltration, but replacement of myocardium by fibrofatty tissue usually results in marked thinning of the right ventricular wall, often with aneurysmal dilatation. Histologic features include myocardial necrosis and focal inflammation (lymphocytic infiltrates). Pathologic specimens that demonstrate greater than 3% fat and greater than 40% fibrosis tissue have been considered pathognomonic for suggested ARVD.

VIDEO

Video 100.15 Arrhythmogenic right ventricular dysplasia (transaxial). Thinning the right ventricular wall with dyskinesia of the right ventricular free wall during systole is due to fibrous replacement of the myocardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Focal chronic inflammation in a case of arrhythmogenic right ventricular dysplasia. (Courtesy of Norman Ratliff, M.D., and Marc Smith, M.D., Cardiac Pathologists at The Cleveland Clinic Foundation.)

Clinical recognition of the disease involves demonstration of perturbed structure and function. Endomyocardial biopsy should evidence the histopathology discussed above. Angiography and magnetic resonance imaging can be particularly helpful for defining right ventricular dilatation and/or aneurysm and diminished function (segmental or global dyskinesis/akinesis). Two-dimensional echocardiography has limited sensitivity in defining right ventricular abnormalities and may therefore be most helpful in longitudinal assessment rather than initial diagnosis. ECG findings of ARVD include right ventricular T-wave inversion, an epsilon wave, ventricular conduction delays, and ventricular tachycardia with left bundle branch block morphology (5).

Symptoms in ARVD can be absent during childhood and young adulthood, and in these ages the first manifestation of disease is often sudden death (228,229). Life-threatening arrhythmias characterize the disorder and appear to increase with disease duration. Affected adults can also develop symptoms of heart failure.

Genetics

Seven genetic loci have been mapped for autosomal dominant ARVD (230): *ARVD1* on chromosome 14q23–24 (231), *ARVD2* on 1q42–43 (232), *ARVD3* on 14q12–22 (233), *ARVD4* on 2q32.1–32.2 (234), *ARVD5* on 3p23 (235), *ARVD6* on 10p14–12 (236), and *ARVD7* on 10q22.3 (237). Recently, the ARVD2 gene has been identified as the cardiac ryanodine receptor gene (*RYR2*) (238). Tiso et al. (238) identified four missense mutations in *RYR2* in four ARVD families. The RYR2 protein induces the release of calcium from the sarcoplasmic reticulum into the cytosol and is involved in excitation-contraction coupling of myocardial cells. As discussed previously, mutations in RYR2 also cause catecholaminergic polymorphic ventricular tachycardia (62,63). Therefore, catecholaminergic polymorphic ventricular tachycardia and ARVD are allelic disorders. Other causative genes for autosomal dominant ARVD remain to be cloned or identified.

ARVD with an autosomal recessive inheritance pattern has also been reported in the setting of Naxos disease. Naxos disease was first reported in families on the Greek island of Naxos (239), and it is the triad of autosomal recessive ARVD, palmoplantar keratoderma, and woolly hair. The genetic locus for autosomal recessive ARVD (Naxos disease) was mapped to chromosome 17q21 (240). Recently, a homozygous 2-bp deletion in the plakoglobin gene was identified in patients with Naxos disease (241). The 2-bp deletion is located at the 3' end of the plakoglobin gene and causes a frameshift and creates a premature stop codon, leading to truncation of the plakoglobin protein by 56 amino acids. Plakoglobin is a major protein in the desmosomes and the intermediate junctions. Plakoglobin interacts with other desmosomal proteins, such as desmoglein I (242), and cell-cell adhesion proteins, such as E- and N-cadherin (243), linking it to the actin-based cytoskeleton. As discussed previously, mutations in the cardiac actin gene cause both dilated and hypertrophic cardiomyopathies. Thus, ARVD, dilated cardiomyopathy, and hypertrophic cardiomyopathy may share the same genetic pathogenic pathway—that is, mutations in a network of proteins in the cytoskeleton.

VASCULAR DISEASE

The vascular system is composed of four types of vessels based on anatomic and functional differences: arteries, capillaries, veins, and lymphatics. Blood vessels are composed of two cellular layers: an inner layer of endothelial cells lining the lumen and an outer layer of smooth muscle cells. During embryogenesis, blood vessels are formed via two processes: vasculogenesis and angiogenesis [reviewed by Risau (244)]. *Vasculogenesis* is defined as the process in which mesoderm cells are induced to differentiate into angioblasts (vascular endothelial cells that have not yet formed a lumen), which then assemble into a reticulum of primitive blood vessels called the *primary capillary plexus*. The primary capillary plexus later undergoes a remodeling and sprouting process called *angiogenesis*, which involves the sprouting, branching, and differential growth of blood vessels to form the more mature-appearing vascular patterns within almost all tissues of the mammalian body. In addition, during angiogenesis, the endothelial cells recruit smooth muscle cell precursors from mesenchymal and neural crest cells to ensheathe them. These precursor cells eventually differentiate into the smooth muscle cell layers of blood vessel walls. Further development accompanied by changes in size and mural structure leads to the formation of arteries, capillaries, veins, and lymphatics, each with its own function and characteristics. Studies in transgenic mice have established that vascular endothelial growth factor and its receptors, angiopoietin-1 and angiopoietin-2 and their receptors (Tie1, Tie2), the endothelin receptor-A, and the ephrin-B2 ligand and the Eph-B4 receptor are involved in the cascade of developmental processes leading to the formation of the vascular network (245).

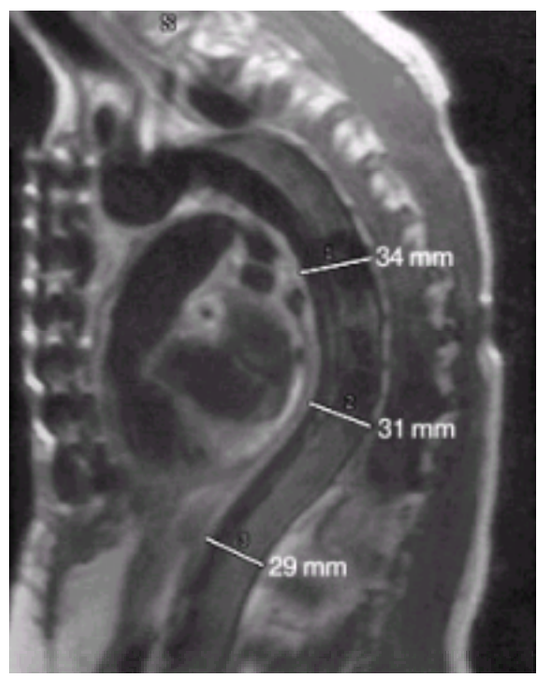
Marfan Syndrome

MFS is an autosomal dominant disorder of fibrous connective tissue with manifestations in the cardiovascular, skeletal, and ocular systems (246). Cardiovascular features include mitral valve prolapse, mitral regurgitation, dilatation of the aortic root, and aortic regurgitation (Fig. 100.4). The major life-threatening cardiovascular complications are aneurysm of the aorta and aortic dissection (4). The gene for MFS was mapped to chromosome 15q21.1 and identified as *FBN1*, which encodes fibrillin-1, the principal component of the extracellular microfibrils (247,248 and 249). Microfibrils are present in extracellular matrices in early mammalian development and later throughout the body, which helps explain the extensive pleiotropic features of MFS. Life expectancy in MFS, which previously averaged in the third to fourth decades, has been considerably extended by a combination of advice against vigorous exertion, chronic beta-adrenergic blockade, and prophylactic aortic root repair when the diameter reaches 50 to 55 mm in the adult (250,251). More than 300 distinct mutations in *FBN1* have been found in MFS patients, but clinical utility of mutation searching is limited (252,253). Mutations in this gene also cause related conditions, such as MASS phenotype and familial aortic aneurysm (FAA) (4).

FIGURE 100.4 Aortic root dilatation in Marfan syndrome. A parasternal long-axis two-dimensional echocardiographic view of the heart from an individual affected by Marfan syndrome is shown. Note the marked dilatation of the aortic root, particularly at the sinuses of Valsalva (*dashed line*). The maximal measurement of the width of the aortic root at the sinuses in this individual was 5.09 cm.

Ectopia lentis. This lens dislocation is associated with Marfan syndrome.

Arachnodactylia in Marfan syndrome. The ratio of finger length to hand size is markedly increased.

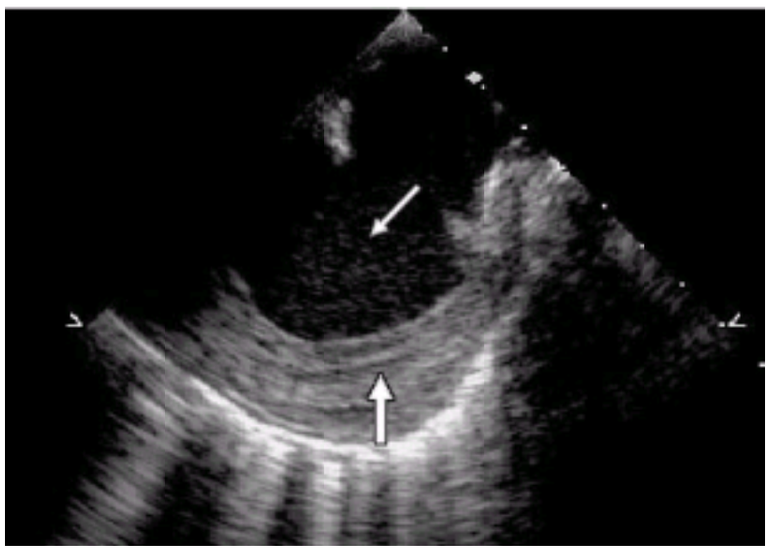


Magnetic resonance scan of the thoracic aorta in Marfan syndrome. There is dilation of the descending aorta with an average diameter of approximately 3 cm.

Mutations in the gene encoding fibrillin-2 (*FBN2*) on chromosome 5q23 have been identified to cause congenital contractural arachnodactyly, which shares skeletal abnormalities with MFS but is less commonly associated with cardiovascular abnormalities (254). Another gene has been mapped to chromosome 3p24.2–25 in a single family with marfanoid skeletal and vascular features (255,256).

Familial Aortic Aneurysm

Approximately 20% of aortic aneurysms have primary heritable etiologies, including the rare Marfan or type IV Ehlers-Danlos syndromes. Such FAA disease often presents with dissection and arterial pathology consistent with cystic medial necrosis. The disorder can affect all aortic segments—thoracic and abdominal—as well as other large arteries. Although thoracic aortic dilatation may be associated with bicuspid aortic valve, FAA also occurs in the absence of valvular abnormalities. In some cases, isolated thoracic aortic aneurysms (257) and FAA (258,259) have been associated with mutations in the FBN1 gene, although affected individuals have no other stigmata of MFS. These findings suggest that aortic aneurysms can represent a fibrillinopathy distinct from MFS. A number of families have now been identified and studied who inherit aortic aneurysms in an autosomal dominant fashion but who do not meet clinical criteria of MFS and have no molecular evidence of fibrillin abnormalities. Vaughan et al. (259) identified one genetic locus for this disorder (FAA1) on human chromosome 11q23.2–q24. Similarly, Guo et al. (260) described a genetic locus for a more restricted form of this disorder that affects only the thoracic aorta at human chromosome 5q13–q14. Although specific gene defects at these loci remain to be identified, these clinical and molecular genetic studies highlight the necessity of procuring a careful family history and screening of first-degree family members of patients when probands with aortic aneurysms are identified.



Transesophageal view of the aortic arch demonstrating an arch aneurysm (*thin arrow*) with layering of thrombus inferiorly (*thick arrow*).

Patent Ductus Arteriosus

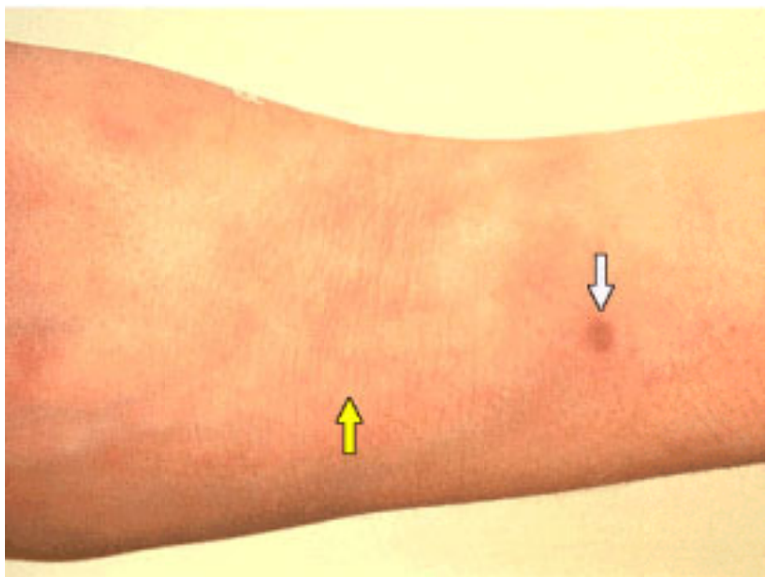
Failure of the ductus arteriosus to close at birth occurs in approximately 0.05% of all full-term infants; patent ductus arteriosus comprises approximately 10% of all congenital heart defects (5). A small fraction of patent ductus arteriosus occurs in variable association with abnormal facial and hand development in the autosomal dominant Char syndrome. This condition was mapped to 6p12–p21, and the gene was recently shown to be a transcription factor, *TFAP2B*, that is expressed in neural crest cells (261).

Supravalvular Aortic Stenosis and Williams Syndrome

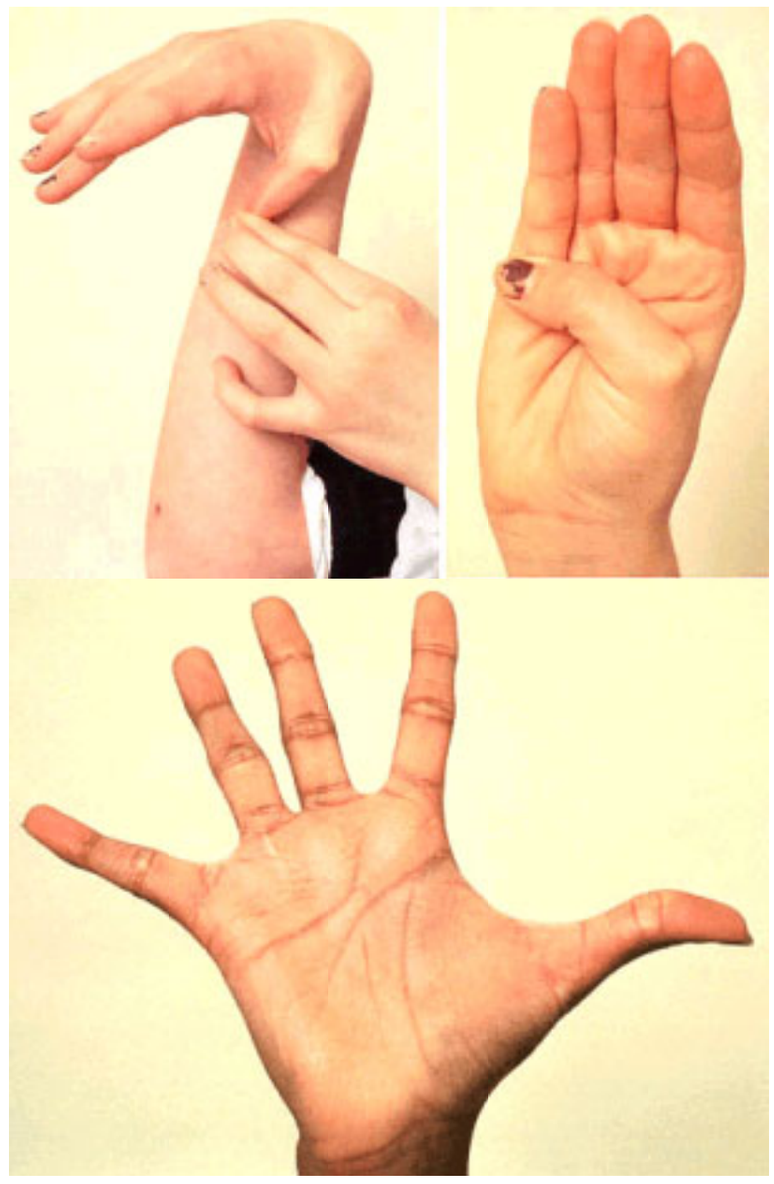
Supravalvular aortic stenosis is characterized by localized or diffuse congenital narrowing of the ascending aorta most pronounced just distal to the aortic valve (262). This is a common finding in Williams syndrome but can occur as an isolated autosomal dominant trait (263). In both instances, the supravalvular aortic stenosis is due to defects (often deletion) of one copy of the tropoelastin gene (*ELN*), which maps to chromosome 7q11.2 (262). Williams syndrome is characterized by infantile hypercalcemia, a face reminiscent of an elf, mental retardation but a gregarious personality, and dental abnormalities (264). The additional defects in Williams syndrome are due to deletion of genes surrounding *ELN*, making this condition a “contiguous gene deletion syndrome” (263). The cardiovascular defects in Williams syndrome, which include peripheral pulmonic stenosis, tend to be severer in males for unclear reasons (265). In both supravalvular aortic stenosis and Williams syndrome, the arterial constriction is not limited to the proximal aorta. Over time, a diffuse arteriopathy develops, which predisposes to stroke, myocardial infarction, and hypertension. The developmental impact of deletion of one *ELN* allele has been examined in mice made hemizygous at this locus. A loss of 50% of normal tropoelastin mRNA and protein was compensated by a 35% increase in the number of elastic lamellae and smooth muscle in arteries (266).

Ehlers-Danlos Syndrome

The Ehlers-Danlos syndrome group of conditions shares features in the skin and joints. Patients with all of the various types have hyperelastic skin and hyperextensible joints (267). The one form with high mortality was previously termed *Ehlers-Danlos syndrome type IV* and is now termed the *vascular type* (268). This condition is due to mutations in *COL3A1*, the gene that encodes type III collagen (269). Arterial walls ordinarily contain both types I and III collagen. In the vascular form of Ehlers-Danlos syndrome, muscular arteries are susceptible to spontaneous rupture, usually without preceding dilatation or dissection. Other organs, such as the bowel and uterus, are also prone to potentially catastrophic rupture (268).



Skin changes of Ehlers-Danlos syndrome. There is thin, velvety appearance of the skin (*yellow arrow*), as well as easy bruisability (*white arrow*).



Ehlers-Danlos syndrome. There is severe joint laxity and hypermobility that may produce joint dislocations (A–C).

Mucocutaneous Venous Malformations

Mucocutaneous venous malformations is a vascular anomaly associated with gastrointestinal bleeding. A gene for mucocutaneous venous malformations was mapped to chromosome 9p21 and cloned (270). The mutated gene codes for the receptor kinase *TIE2*, which is expressed specifically in endothelial cells. The *TIE2* mutations caused a six-to tenfold increase in the phosphorylation activity or ligand-independent hyperphosphorylation of the receptor (270), suggesting a gain-of-function mechanism for development of venous malformations.

Cutaneous Venous Malformations with Glomus Cells

Glomus tumors, or glomangiomas, are benign cutaneous neoplasms derived from specialized arteriovenous shunts (5). Glomus tumors are a clinical and radiologic subtype of venous malformations. The distinctive feature is the presence of undifferentiated smooth muscle cells (glomus cells) surrounding convoluted venous channels. A genetic locus for cutaneous venous malformations with glomus cells was mapped to chromosome 1p22–21 (271), and the specific mutated gene has been identified as a novel gene named glomulin (271a).

Lymphedema

Hereditary primary lymphedema is a developmental disorder of the lymphatic system that leads to a chronic tissue swelling resulting from deficient lymphatic drainage (5,272). A gene for hereditary lymphedema was mapped to chromosome 5q35.3 and identified (273,274). The mutated gene, the *FLT4* gene, encodes vascular endothelial growth factor receptor-3, a receptor for the vascular endothelial growth factor C (274).

An autosomal dominant condition of lymphedema of variable age of onset coupled with a double row of eyelashes (distichiasis) is due to mutations in a gene, *FOXC2*, that encodes a transcription factor (275).

Lymphedema. There is edema of the entire leg with induration and fibrosis of tissues, creating a woody texture.

Cerebral Cavernous Malformations

Cerebral cavernous malformations, or cavernous angiomas, are vascular malformations that may involve any part of the central nervous system and sometimes cause seizures, hemorrhage, or focal neurologic deficit (5). Three genetic loci for cerebral cavernous malformations have been identified: CCM1 on chromosome 7q11.2–21 (276,277), CCM2 on 7p15–13 (278), and CCM3 on 3q25.2–27 (278). The *CCM1* gene has been identified, and it encodes KRIT1, a protein that interacts with RAP1A (KREV1), which is a member of the RAS family of GTPases (279). The CCM2 and CCM3 genes remain to be identified.

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HTT), or Rendu-Osler-Weber syndrome, is a vascular dysplasia leading to telangiectases and arteriovenous malformations of skin, mucosa, and viscera (the lung, liver, and brain) (5). The frequent complications of mucosal involvement are epistaxis and gastrointestinal bleeding. Two genes for

HHT have been identified: the endoglin gene on chromosome 9q34.1 and the *ACVRL1* gene on 12q11–14 (280,281). The endoglin gene encodes a transforming growth factor-b binding protein, its mutations cause HHT1, which is associated with a high frequency of pulmonary arteriovenous malformations (280). The *ACVRL1* gene codes for an activin receptor–like kinase, also a transforming growth factor-b binding protein. The *ACVRL1* mutations cause HHT2, which rarely have pulmonary arteriovenous malformations (281).

Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia). Multiple dark red and slightly elevated telangiectasia in the back (*left panel*) and hands (*right panel*) are shown. These represent arteriovenous malformations of dermal microvasculature.

CONTROVERSIES AND PERSONAL PERSPECTIVES

As increasing numbers of genes associated with cardiovascular diseases are identified, accurate adult and prenatal diagnoses of these conditions become technically feasible. Although few such tests are currently available on a routine clinical basis, we can certainly anticipate commercial application of such testing in the future. In addition, although most research efforts have in the past focused on less common monogenic disorders, more recent studies have begun to identify genetic abnormalities that confer risk for common polygenic cardiovascular disorders such as hypertension and atherosclerosis. Clearly, definition of DNA-based diagnosis for both monogenic and polygenic disorders will be of great interest to patients and their physicians.

As with any clinical test, however, guidelines need to be developed for when to conduct and how to apply DNA testing. In some cases, preliminary genotype-phenotype studies have shown that certain mutations can predict an increased risk of mortality (e.g., sudden death in FHC and the beta-MHC Arg403Gln mutation) or morbidity (e.g., severe cardiac and limb malformation in Holt-Oram syndrome and *TBX5* mutations, which produce protein truncation). However, such DNA-based pre- and postnatal prognostication is limited by the variable expression of disease gene mutations; even within families that inherit “malignant” mutations, there are individuals who show minimal disease manifestations. Moreover, management options (including both currently available standard pharmacologic therapy and anticipated gene manipulation therapy) derived from DNA-based risk stratification have yet to be elucidated. Although studies (282) of at least one disease gene, huntingtin, have demonstrated that there are few significant negative psychological consequences to preclinical diagnosis, outcomes of studies demonstrating a universal benefit to such testing are not yet available.

Thus, we believe that at this time, DNA-based diagnosis should be selectively applied. Frequently, establishment of familial disease patterns by history is more than adequate for diagnosis and management when coupled with routine physical examination and imaging modalities. In fact, because a thorough family history and noninvasive evaluation may often be sufficient, they should always be carefully performed. Thorough consideration must be given to each patient’s cultural, social, and financial situation, as well as his or her medical condition. In addition, before DNA-based testing, the physician should conduct a careful discussion with each patient regarding the reliability, medical risks, and clinical, social, and financial implications of both positive and negative test results and how they might have an impact on the patient’s medical and personal decision making. To facilitate the appropriate application of DNA-based diagnoses, all candidate patients should be counseled both before and after testing by a physician with experience in both clinical genetics and the disease state in question.

In summary, genetic studies will have far-reaching effects on the diagnosis, treatment, and prevention of heart disease. They will lead to precise and definitive genetic diagnoses (including prenatal diagnosis), early detection of persons at high risk for disease development (even in the absence of symptoms), ore rational and specific therapeutic intervention, and ultimately, prevention of many cardiovascular disorders.

ACKNOWLEDGMENTS

This work was partly supported by a Scientist Development grant from the American Heart Association National Center (QW), Grant-In-Aid from the American Heart Association Ohio-Affiliate (QW), a grant from CCF Lerner Research Institute (QW), the Fourjay Foundation Cardiovascular Research grant (QW), a Doris Duke Charitable Foundation Innovation in Clinical Research Award (QW), NIH grants HL65630 (QW), NHLBI ROI HL66214 (CTB), NHLBI ROI HL61785 (CTB), and P50HL52320 (CES), the Edward Mallinckrodt, Jr. Foundation (CTB), the March of Dimes Birth Defects Foundation (CTB), and Howard Hughes Medical Institute (CES). We apologize to those authors whose work is either not cited or is cited in review papers due to strict space limitation.

THE FUTURE

The genetic studies of cardiovascular disease will go through multiple phases, including disease gene identification, diagnostic genetic testing, pharmacogenomics, and therapy. We are currently at the peak of the gene discovery phase. Genes for many rare monogenic cardiovascular disorders have been identified. Study of common diseases is progressing, both in animals and in humans. Future studies will continue to identify new genes for the monogenic forms of cardiovascular diseases as well as the primary genetic causes for complex and polygenic disorders such as coronary artery disease, heart failure, and hypertension. Ultimately, genetic testing will benefit many patients by providing risk assessment and allowing implementation of medical surveillance and lifestyle planning programs to reduce risks. The novel field of pharmacogenomics has just started, and therapies based on disease gene discoveries may take an unpredictable length of time to reach and benefit patients. The completion of the sequencing of the human genome and the development of new bioinformatic tools promise rapid progress in all these four fields in the near future.

OVERVIEW

Gene transfer is the introduction and expression of recombinant genes in mammalian cells. Although the field of human gene therapy is young, having its origins in the mid-1980s, major advances in the past 20 years have been in scientific principles, vectors, and delivery systems, development of animal models, and applications to specific diseases. Genetic models of human disease have been created using gene transfer techniques, and these models have been used to understand the pathophysiology of cardiovascular diseases as well as to develop new therapies. The concept that one might use a recombinant gene, rather than a drug, to treat a cardiovascular disease is relatively straightforward. However, the technical difficulties of selecting the appropriate gene and expressing it in a sufficient number of cells to achieve the appropriate biologic effect have been the major challenges in the field. In this chapter, the field of gene transfer in relation to cardiovascular disease is reviewed. The principles of gene therapy are defined. Viral and nonviral vectors used for cardiovascular gene transfer are reviewed. Animal models of cardiovascular disease based on gene transfer approaches are discussed. Finally, prospects for gene therapy of cardiovascular diseases are critically analyzed.

GLOSSARY

Antisense RNA: A single strand of RNA that is complementary to RNA sense strand. Binding of antisense to sense strand creates a double-stranded RNA hybrid that is not translated into protein.

Coding region: The portion of the gene or messenger RNA (mRNA) that contains the base pair sequences that are translated into protein.

Complementary DNA (cDNA): A single-stranded DNA sequence that is synthesized from the RNA strand by reverse transcriptase and is complementary to an mRNA coding region.

Electroporation: A method to transfect cells that employs an electrical field to affect the entry of DNA into cells.

Episomes: Genetic sequences that exist in stable form separate from the chromosome.

Exons: The segments of a gene that remain after splicing of the primary RNA transcript and make up mature mRNA, which in turn encodes protein.

Expression, stable: Expression of a gene that has been transfected into cells and is maintained long term in the target cell.

Expression, transient: Expression of a gene that has been transfected into target cells and is maintained short term in the cell.

Homologous: Common structural features found in two separate genes, which suggest a common ancestor gene.

Intron: Noncoding gene sequences. The segments of a gene that are transcribed into the primary nuclear RNA transcript but are excised during RNA splicing.

Oligonucleotides: A short polymer of DNA that is synthesized to perform studies of gene expression and function.

Plasmids: Naturally occurring circular DNA molecules that replicate in bacteria, which can be modified for use as vectors.

Promoter: The region of a gene that binds RNA polymerase and initiates gene transcription. Promoters can be constitutive-active in all cell types, cell-specific-active only in a specific cell type, or inducible switched on or off.

Recombination: The joining together of different segments of identical DNA sequence into a single continuous piece of nucleic acid sequence.

Reporter gene: A gene that is employed to assess the relative activity of a promoter or to encode a protein that is normally not found in the target cell, thereby allowing assessment of the promoter or gene expression in a target cell.

Reverse transcriptase: An enzyme that catalyzes the synthesis of DNA from an RNA template.

Sense strand: The single strand of DNA that gives rise to the RNA from which protein can be translated.

Transcription: The synthesis of mRNA from a DNA template by RNA polymerase.

Transfection: A technique that is used to transfer naked DNA to the nside of the cell, resulting in the expression of the gene in the target cell.

Translation: The synthesis of protein from the mRNA template by ribosomes.

Vector: A genetic carrier used to deliver exogenous DNA fragments into a host cell.

HISTORICAL PERSPECTIVE

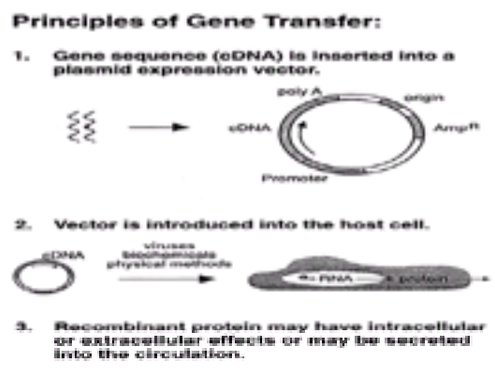
The field of human gene therapy has its origin in molecular biology and recombinant DNA technology. Major discoveries in molecular biology since 1950 have laid the foundation for the scientific basis for current molecular approaches to studying human disease. DNA was first discovered in 1944 as the genetic material in bacterial

cells (1). Watson and Crick determined the double helical structure of DNA in 1953 (2). Nirenberg and Leder elucidated the genetic code by 1964 (3), and the first recombinant DNA molecules were synthesized using molecular biology techniques by 1972 (4,5). The scientific basis for gene therapy was developed in the 1970s, based on knowledge of the mechanisms of cell transformation by tumor viruses (6). The principles of gene transfer are based on the entry of foreign recombinant DNA into a host cell. Cells are resistant to the uptake of foreign genes, and viruses have adapted methods to gain entry into the cell. Early gene transfer methods adapted viruses (modified to be replication incompetent) to carry recombinant genes into cells (7,8). Basic investigations of tumor viruses, particularly retroviruses, laid the scientific foundation for the development of gene therapy in the 1980s. In the early 1990s, investigators used their knowledge of viral vectors and gene delivery to develop animal models of human disease (9,10,11 and 12). These experimental models evolved into the development of human gene therapy protocols in the United States. The first approved trial of gene transfer in humans was performed in May 1989 (13). A human gene therapy trial was initiated in 1990 for adenosine deaminase deficiency, which used *ex vivo* delivery of retroviral vectors encoding the human *ADA* gene into lymphocytes (14). In the early to mid-1990s, the approval process for human gene therapy trials consisted of two components: first, approval by the Recombinant DNA Advisory Committee (RAC) of the National Institutes of Health (NIH); and second, approval by the U.S. Food and Drug Administration (FDA). The RAC was established to review the risks and benefits of the use of recombinant DNA in institutions receiving support from the NIH. Approval from the RAC was required since recombinant genes were being used in human subjects. Through 1996, more than 100 protocols were presented for approval to the RAC and FDA (11). The majority of these protocols was directed toward treating cancer, acquired immunodeficiency syndrome, and single-gene inherited disorders. In 1995, Dr. Harold Varmus, then Director of the NIH, appointed an ad hoc committee to assess the current status and promise of gene therapy. The report of this committee, chaired by Drs. Orkin and Motulsky, led to a general review of the field of gene therapy in the United States. Many of their recommendations are discussed later in this chapter in the section Controversies and Personal Perspectives. One outcome of their report was reconfiguration of the RAC, since in its role as evaluating risk, it was not judging scientific merit of the proposals. The FDA now must approve all proposals for human gene therapy trials in the United States. In addition, the tragic death of a young man in a gene therapy trial has appropriately led to a critical reevaluation of the conduct of clinical gene therapy studies in the United States.

PRINCIPLES AND CONCEPTS OF GENE TRANSFER

Gene therapy is a set of approaches to the treatment of human disease based on the transfer of genetic material into an individual. Gene delivery can be achieved either by direct introduction of vector or DNA to blood or tissues, or indirectly through the modification of cells that have been transduced to carry the foreign DNA. Gene therapy treats a disease in an individual by the administration of DNA rather than a drug. Somatic cells, not germ cells, are the target of these efforts. Therefore, gene therapy affects only individuals and not their offspring.

An initial step in the delivery of genes to individuals is the construction of gene transfer vectors (eFig. 101.0.1). A vector carries the recombinant gene (or DNA or RNA) into cells within a tissue. Vectors are used to transfer genes into cells because most cells are resistant to the uptake of foreign DNA. Vectors penetrate host cells with varying efficiency, depending on the cell type and the vector. Current viral vectors include retroviral vectors, adenoviral vectors, adeno-associated vectors, and herpes simplex viruses. Nonviral vectors include plasmid DNA, cationic liposomes, and biolistics (15).



***e*FIGURE 101.0.1** Delivery and expression of a recombinant gene within an individual. The complementary DNA (cDNA) is ligated into a plasmid expression vector. This vector may be introduced into the host cell alone or with a shuttle vector, such as a virus or lipid. Once within the cell, the recombinant gene is expressed and may exert autocrine or paracrine effects. (From Nabel EG, Pompili VJ, Plautz GE, et al. Gene transfer and vascular disease. *Cardiovasc Res* 1994;28:445–455, with permission.)

After construction of a vector, the vector is generally tested in the laboratory in cultured target cells. If the gene is adequately expressed in these target cells, then animal models are developed *in vivo*. Gene delivery can be achieved by two methods: *ex vivo* and *in vivo* approaches. *Ex vivo* gene transfer involves the removal of autologous cells from the individual, genetically modifying or transducing the cells in culture, and returning the genetically modified autologous cells to the individual (16,17). *Ex vivo* gene transfer permits the introduction of recombinant genetic material into a particular cell type (e.g., a smooth muscle cell), and analysis of gene expression within that cell type (18). *Ex vivo* gene transfer, however, is a cumbersome and costly procedure, requiring the establishment and modification of cells in the laboratory. *In vivo* gene transfer, on the other hand, is a relatively straightforward approach by which the vector harboring the foreign DNA is directly inserted into host cells *in vivo*. This might be achieved by direct injection (19) or catheter-mediated gene delivery (20). After *in vivo* gene transfer, recombinant genes are generally expressed in multiple cell types. Both *ex vivo* and *in vivo* gene transfer approaches have been used to develop animal models of cardiovascular disease (21). *In vivo* approaches using catheter-mediated gene delivery have gained attention more recently (22,23).

The fate of recombinant DNA, once inside host cells, has been difficult to regulate and control. Considerable efforts have been devoted to developing methods for retaining the correct function of the gene and for regulating the gene so that the physiologic effects of gene expression can be evaluated.

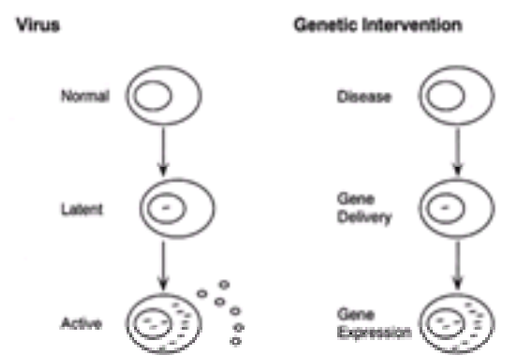
As the field of gene therapy has grown and seasoned, several important concepts have emerged. First, genetic defects contribute to the pathophysiology of many human diseases. Alterations or mutations in human genes result in abnormal phenotypes and disease. For example, an inherited mutation in the cystic fibrosis transmembrane regulator gene (*CFTR*) results in the disease cystic fibrosis (24). There are many acquired diseases in which genetic mutations contribute to the pathophysiology of the disease. Colon cancer is one example in which many individuals have inherited mutations in a gene that regulates cell growth and DNA repair, known as *p53* (25). Likewise, an individual can acquire genetic changes within cells due to viral infections, which in turn lead to serious disease. For example, infection of T-lymphocytes by human immunodeficiency virus results in alterations in T-cell genome and abnormal T-cell function (26,27). Many acquired diseases are characterized by normal genetic structure but abnormal expression of genes. For example, in atherosclerosis, normal repair of an injured artery leads to abnormal expression of cytokine and growth factor genes (28). Therefore, many human diseases, both inherited and acquired, are characterized by genetic mutations that result in abnormal gene expression and pathophysiology.

Second, the fields of genetics and gene therapy, in the past, have developed in parallel, but there is increasing recognition of the interdependence of the two areas. The human genome has been mapped (29). The fields of genomics and proteomics are emerging. Studies of gene expression and protein mapping will influence the diagnosis and treatment of cardiovascular diseases. Genomics, proteomics, and gene therapy do indeed go hand in hand and must be developed together.

Third, DNA is a drug that is being used to treat human disease. Therefore, the evolution of DNA as a drug is analogous to traditional drug development in the pharmaceutical industry. However, there are unique features that require special attention, including a greater understanding of the introduction and expression of genes within cells, host–cell interactions, and dose-response studies to determine the optimal concentrations of DNA that will achieve maximal biologic effect with minimal toxicity.

VECTORS FOR GENE THERAPY

Gene transfer vectors have relied on normal mechanisms of viral infection of human cells. For example, viruses have evolved mechanisms for receptor-mediated entry into human cells (6,30). Once within a cell, a virus, such as human immunodeficiency virus, may reside latent for long periods of time. On viral activation by cytokines or other host genes, active viral replication occurs. In a similar manner, researchers have modified viruses to become vectors that carry a recombinant gene into a cell, but cannot replicate within the cell (eFig. 101.0.2). The recombinant gene resides within the nucleus where it either integrates into host genome or undergoes episomal replication.



***e*FIGURE 101.0.2** Viral infection as a paradigm for gene therapy. Genetic interventions are modeled after viral infection of human cells, in which a virus gains entry into a cell and is expressed using host cellular factors.

An increasing number of vectors have been developed and evaluated for cardiovascular gene therapy. These vectors are summarized in *e*Table 101.0.1. Viral vectors (retroviruses, adenoviruses, adeno-associated viruses, and herpes simplex viruses) have been the predominant methods for delivery of genes into cells. In response to growing concerns about the safety of viral vectors, considerable effort has been expended to optimize nonviral vectors (plasmid DNA, DNA liposome complexes, and biolistics). These endeavors have succeeded in providing a safer alternative for a number of applications. There are advantages and disadvantages to each vector, dependent in part on the particular application, including cell type and organ system. These vectors differ in efficiency, integration, stability, and potential for immunogenicity (*e*Table 101.0.2). As each of these vectors is discussed, several concepts should be kept in mind. When selecting a suitable vector, certain features are desired. First, specificity to target tissues is critical. The vector should achieve local gene expression within an organ without systemic shedding and widespread toxicity. The vector should be delivered to host cells in sufficient quantity to result in high-level gene expression. Expression of the gene should persist for a sufficient period of time to treat the disease. Gene expression preferably is regulated through tissue-specific promoters or inducible or repressible promoters, or both. Finally, regulatory concerns about possible vector and gene toxicity should be kept in mind.

***e*TABLE 101.0.1** SOMATIC GENE TRANSFER VECTORS

Vector	Advantages	Disadvantages	Applications
Viral			
Retrovirus	Biology well understood	Low titer	Marker studies
	Stable integration into host cells	Infection limited to dividing cells	*Ex vivo* treatments
	Efficient entry	Expression difficult to control and stabilize	Vaccines
	No viral genes in vector	Expensive and complex to prepare	
Adenovirus	High titers	Vectors contain viral genes	Localized *in vivo* treatments: cystic fibrosis, short-term treatments such as cancer and cardiovascular disease
	Efficient entry into most cell types	Immunogenic, stimulating T- and B-cell responses	
	High level of expression	Generation of replication-competent virus	
	Infection of nondividing cells	Factors controlling tropism not well understood	
Adeno-associated virus	Integration at specific sites	Requires replicating adenovirus to grow	Similar to adenovirus
		No helper cell line	
		Limited insert size	
Herpesvirus	High titers	Complex construction	Neurologic diseases
	May be neurotropic	No packaging cell lines	
Pseudotyped retrovirus	High titers	Similar to retrovirus	Not established; may be similar to retrovirus
	Higher efficiency of retrovirus infection		
	Broader host range		
Nonviral			
Naked DNA	Easy to prepare	Inefficient entry and uptake	Topical or mechanical applications, or both, including skin and vasculature
	No size constraints	Limited persistence and lack of stability	
	High level of safety		
	No viral genes		
	Lack of integration		
DNA liposomes	Same as naked DNA	Limited persistence and lack of stability	Direct *in vivo* applications, cancer, cardiovascular disease, cystic fibrosis
	More efficient uptake of DNA		
Adenoviral polylysine DNA conjugate	Same as DNA liposomes	Requires adenovirus	Same as DNA liposomes
	Targetable to specific cell types	Complex to construct	

Modified from Nabel EG. Introduction to vectors for gene therapy. *Curr Protocols Hum Gene* 1996;[Suppl 10]:Unit 12.0.

***e*TABLE 101.0.2** COMPARISON OF GENE TRANSFER VECTORS

Vector	Efficiency	Integration	Stability	Immunogenicity
Viral				
Retrovirus	+	+	+	±
Adenovirus	+++	–	–	++
Adeno-associated virus	+	±	±	–
Herpes simplex virus	++	±	±	++
Nonviral				
Plasmid DNA	+	–	±	–
Cationic liposomes	+	±	±	–
Microparticle DNA	+++	+	+	–

Several approaches have been developed to achieve site-specific gene expression. These include ligand-directed vectors, targeted gene expression using cell-specific promoters, catheter-mediated gene delivery, and direct injection (31). In the cardiovascular system, catheter-mediated gene delivery has been used most often to achieve site-specific gene expression within focal segments of blood vessels (20,21). Direct injection may be a feasible approach for gene delivery into the myocardium (32). Cell-specific gene expression may be desirable for selected approaches to vascular gene transfer, such as inhibition of inflammatory cells or smooth muscle cell proliferation. Although a number of laboratories have identified smooth muscle (33,34) and endothelial (35) cell-specific promoters, these promoters have not been extensively evaluated yet in gene transfer vectors.

Viral Vectors

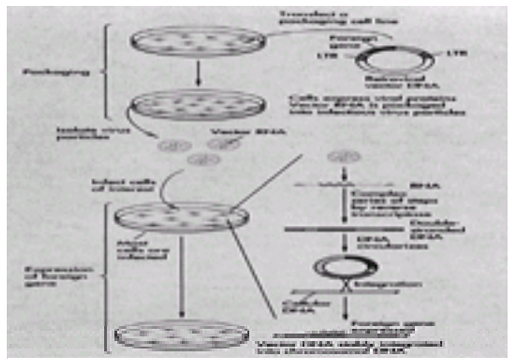
Retroviral Vectors

Retroviral vectors were the first viral vectors developed for gene transfer (9,36). These vectors promote efficient gene transfer and expression in cultured primary cells from humans and other animals. The transferred genes are integrated at random sites in the host cell genome with minimal alteration of host cell genomic DNA. Retroviral vectors, however, are replication defective (i.e., they do not encode any viral proteins, and hence, they do not replicate within the host cell) (37,38). Therefore, when using a replication-deficient viral vector, the process of gene transfer and expression is called *transduction*, as opposed to infection, to differentiate this

process from viral infection, which implies further viral replication and spread.

The advantages of retroviral vectors include a well-understood biology (6). They produce stable integration into host cell genome. Entry into host cell is sufficient via receptor-mediated uptake. No viral genes within the vector result in enhanced safety for human use (39). Disadvantages of these vectors include low titer production (40). Transduction is limited to dividing cells, thus lowering the number of applications to human diseases (41). Gene expression after retroviral transduction is difficult to control and stabilize. Finally, retroviral vectors are expensive and complex to prepare.

Production of the retroviral vector consists of two steps, the construction of the vector in plasma DNA form, followed by production of the virus from cultured cells that express proteins required for viral replication (42). An overview of this process is shown in eFigure 101.0.3. Construction of replication-defective retroviral vectors relies on the use of retrovirus packaging cells that synthesize all of the retroviral proteins but do not produce a replication-competent virus. Many packaging cell lines have been constructed for mammalian cell gene transfer (43). The range of cells transduced by retroviral vectors depends on the retrovirus used to make the packaging cell line. Amphotropic retroviral vectors are the most commonly used packing cell line because of their wide host range. A detailed protocol for the construction of retroviral vectors is reviewed elsewhere (42).



***e*FIGURE 101.0.3** Construction of a retroviral vector. The recombinant gene is cloned into a retroviral plasmid, which lacks viral replication genes. The retroviral plasmid is transfected into a packaging cell line that contains a provirus with replication genes. Vector RNA is packaged into virions, capable of infecting target cells. LTR, long terminal repeat. [From Watson JD, Gillman M, Witkowski J, et al., eds. *Recombinant DNA.* New York: Scientific American Books (WH Freeman Co), 1992:227, with permission.]

The current applications of retroviral vectors include marking studies in which autologous cells are removed from an individual, transduced to express a reporter or marker gene *in vitro* using a retroviral vector, and given intravenously back to the individual. The fate of these cells *in vivo* can then be traced (13). In addition, retroviral vectors are also useful for other *ex vivo* treatments involving T cells (14), hematopoietic stem cells (44), and endothelial cells (45,46 and 47). Finally, retroviral vectors are being evaluated for use in cancer vaccines (48).

All packaging lines still have the potential to produce helper virus by recombination events between the vector, helper virus sequences in the packaging cells, and endogenous retroviral elements, but fortunately, the frequency of helper production in currently used packaging cells is low (39). No viral proteins are synthesized during viral entry and integration into target cells; thus all viral protein-coding regions can be removed from the retroviral vectors without altering gene transfer efficiency. Transient transfection of retroviral vectors in murine packaging cell lines generally results in viral titers of less than 10^5 units per mL. Stable cell lines typically produce viral titers in the 10^5 to 10^7 range. Generation of stable vector-producing clones usually takes 1 month.

Pseudotype Retroviral Vectors

A pseudotyped retrovirus is defined as a retrovirus that incorporates the envelope protein of a second virus. The host range of the pseudotype is that of the virus donating the envelope protein. The envelope glycoprotein (G) of the vesicular stomatitis virus (VSV), a member of the rhabdovirus family, can be efficiently incorporated into a retroviral particle. VSV-G pseudotype retroviral vectors have an increased host range, because VSV infects cells ranging from insects to primates, unlike the amphotropic virus. The VSV-G pseudotype vectors are also able to infect mammalian cells more efficiently than conventional amphotropic vectors. VSV-G pseudotyped retroviral vectors can be concentrated to titers greater than 10^9 CFU per mL. Therefore, VSV-G pseudotype retroviral vectors have gained favor because they extend the use of retroviral vectors for stable gene transfer into species not previously accessible to retroviral infection. Also, they allow more efficient gene transfer into mammalian cells for possible treatment of human diseases. The production of pseudotyped retroviral vectors is similar to retroviral vectors (49). The applications of pseudotype retroviral vectors are not well established, but may be similar to retroviruses (50,51).

Adenoviral Vectors

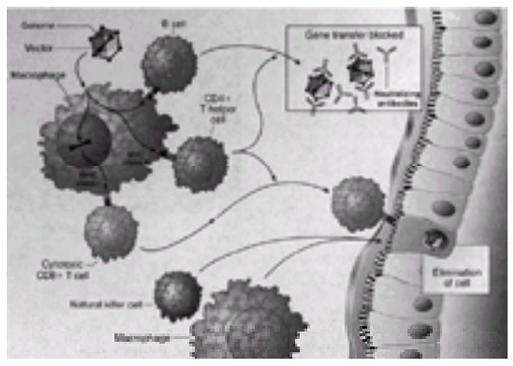
Viral vectors based on human adenoviruses have shown considerable promise for *in vivo* gene delivery compared with retroviruses, because they can transfer recombinant genes efficiently into a wide variety of dividing and nondividing cells. Adenoviral vectors are also attractive because large amounts of highly purified recombinant virus, 10^{12} particles per mL, can be produced from expansion of viral plaques. Human adenoviruses were initially evaluated as vectors to treat cystic fibrosis because of their tropism for pulmonary endothelial cells (52). The human adenovirus is a double-stranded DNA virus with a 36-kb linear genome that contains four early transcription units (E1 to E4), which are active at early time points after infection (3 to 12 hours), and five late transcription units (L1 to L5), which are active after 12 hours and produce the structural genes of the virus. Further details on the human adenovirus and its life cycle are reviewed elsewhere (53).

Adenoviral vectors are propagated in packaging cell lines, such as 293, which supply E1 function in trans. The final vector, however, is replication defective. Adenoviral vectors are constructed using a plasmid that contains the recombinant gene of interest and flanking adenoviral sequences. This adenoviral transfer plasmid is cotransfected with an adenoviral backbone into 293 cells. Recombination occurs in the region of overlap, in the E1 region between the restricted viral DNA or viral backbone and the plasmid. Viral plaques are produced, which then can be expanded. After further rounds of plaque purification, a stock of the adenoviral vectors is produced (54).

Transduction of host cells by adenoviral vectors follows the principles of adenoviral infection of epithelial cells. When the viral genome enters the cell, the early immediate genes (E1) are expressed. They activate other important regulatory early genes, E2 to E4. In the second phase of replication, late genes, L1 to L5, are expressed, leading to the production of more virus and cell death. The adenovirus has been engineered to be replication defective by deleting the early adenovirus genes that activate other viral genes (55). In the absence of these regulatory genes, the virus should not replicate *in vivo*, and the late viral genes should remain dormant. The first-generation adenoviral vectors have deletion of E1 genes and partial deletion of E3 genes, which renders them replication defective.

There has been extensive experience with first-generation adenoviral vectors in many cell types. Several themes have emerged. Concerns about the hazards of viral recombination, replication, and shedding have not been realized (56). Inflammation occurs with first-generation adenoviral vectors in a dose-dependent manner at the site of gene transfer, but there are differences among species and tissues within species in the quality and quantity of the inflammation (57). A consistent finding is that the expression of genes after adenoviral transduction is transient (58,59,60 and 61). Attempts to restore expression by the administration of a second dose using the same serotype of the vector are usually not successful. These limitations have tempered the initial enthusiasm for first-generation adenoviral vectors (56,62,63 and 64).

Transient expression of the therapeutic gene has been a major limitation of first-generation adenoviral vectors for application to many human diseases. Studies have elucidated possible mechanisms (65,66). There are humoral and cellular immune responses to the vector and vector-infected host cells (*e*Fig. 101.0.4). To overcome these immune problems, second-generation adenoviral vectors have been engineered to minimize the expression of viral antigens. Another approach is to prevent activation of T-helper cells by transient immunosuppression during the delivery of the adenoviral vector. Combining these approaches may prove useful in minimizing the immune reaction to adenoviral vectors. Current applications of adenoviral vectors include localized *in vivo* treatments, such as vascular diseases (67,68 and 69) and cystic fibrosis (57). Short-term treatments requiring transient expression of the gene are also likely approaches, including vascular diseases and cancer (70,71).



***e*FIGURE 101.0.4** Humoral and cellular immunity to adenoviral vectors. Vectors are taken up by macrophages where viral proteins are presented by class I major histocompatibility complex molecules to $CD8^+$ T cells. $CD4^+$ T cells also stimulate cytotoxic T-lymphocytes that destroy the genetically modified target cell and produce inflammation. In addition, B cells are activated to secrete humoral antibodies that neutralize the vector. These neutralizing antibodies then prevent subsequent administration of the same viral serotype. (From Wilson JM. Adenoviruses as gene-delivery vehicles. *N Engl J Med* 1996;334:1185–1187, with permission.)

The early experience with adenoviral vectors has been useful in defining many principles of *in vivo* gene transfer that are of general importance to other vector systems, including host responses to the vector and transgene. Broader applications of adenoviral vectors will require modifications that improve efficiency and promote targeting of vector uptake. Modifications in the vector to reduce viral antigen presentation, combined with transient immune suppression, may prove useful.

Adeno-Associated Viral Vectors

Adeno-associated viral (AAV) vectors have been explored for gene transfer. Recombinant AAV (rAAV) vectors are based on nonpathogenic human parvovirus, an adeno-associated virus (72). rAAV have two important advantages: their physical stability, which allows *in vivo* administration, and their ability to maintain stable gene expression.

rAAV can infect many cell types, including quiescent cells. Wild-type AAV infection results in integration into host chromosomes where it exists as a stable provirus. Wild-type AAV has preferences for insertion into certain chromosomal locations (73). If latently infected AAV-infected cells are subsequently infected with adenovirus, the AAV genome is rescued or excised from the chromosome, replicated, and packaged to produce progeny virions. This is the principle behind construction of rAAV vectors (74). The production of rAAV involves cotransfection of a rAAV-vector plasmid and the AAV-helper plasmid into 293 cells. These cells are subsequently infected with adenovirus to produce progeny virions. The rAAV virions are then separated from the adenovirus on cesium chloride gradients. rAAV stocks with titers as high as 10^{10} particles can be produced.

Transduction performed *in vivo* using rAAV factors has shown long-term gene expression; furthermore, the level of gene expression does not decrease substantially over time. Studies are in progress to evaluate the application of this vector to the vasculature and myocardium. There has been greater initial success in the myocardium (75), and limited to no success in the vasculature (76). The major advantage of rAAV is integration at specific sites in host cell genome as well as persistent expression (73). Major disadvantages of rAAV include the lack of helper cell lines, size limitation of the recombinant genome that can be packaged (4,681 bases), and a requirement for replicating adenovirus to grow. Eventual applications of rAAV vectors may be similar to adenovirus, including localized *in vivo* treatments.

Nonviral Vectors

Nonviral vectors offer safety advantages for a number of applications to human gene therapy. Nonviral vectors currently in development include plasmid DNA, DNA liposome complexes, and biolistics or particle-mediated DNA delivery.

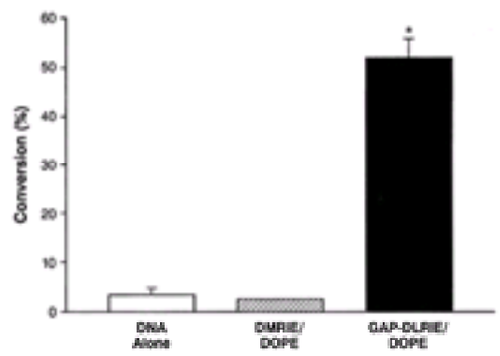
Plasmid DNA

Plasmid DNA can be delivered to cells, under certain conditions, in the absence of a vector shuttle. The use of plasmid DNA alone offers several advantages, including ease of preparation. There are no size constraints for insertion of the transgene into the plasmid backbone. Experience with laboratory preparation and use of plasmid DNA in human trials has demonstrated considerable safety and lack of toxicity (77). There are no viral genes within the plasmid backbone. Expression of plasmid DNA within host cells does not require integration into host genome. Disadvantages of plasmid DNA include inefficient entry and uptake into cells, as well as limited persistence and a lack of stability. The major applications of plasmid DNA include topical or mechanical applications, or both, including catheter-mediated gene delivery (78), direct injection into tumors (77), and vaccination by direct injection into skeletal muscle (79). Several human gene therapy trials have used direct injection of DNA to treat cancer (77), as well as catheter-mediated gene delivery of plasmid DNA to the vasculature (80).

DNA Liposome Complexes

Cationic liposomes are positively charged lipid molecules that complex with negatively charged DNA and facilitate entry into cells. The mechanisms by which cell entry occurs are not well worked out, but receptor-mediated endocytosis or fusion with cell membranes is most likely. Several generations of cationic lipid formulations have been constructed and tested (81,82 and 83). In general, newer formulations have improved uptake by cells and increased gene expression (84). After entry into the cell, the lipid DNA complex is engulfed by lysosomes. Dissociation of lipid from DNA occurs with escape of plasmid DNA that is transported by unknown mechanisms to the nucleus (85). A limitation of DNA liposome complexes has been endosomal degradation; current research on liposome technology has focused on mechanisms to enhance cell entry and reduce degradation in the cytoplasm.

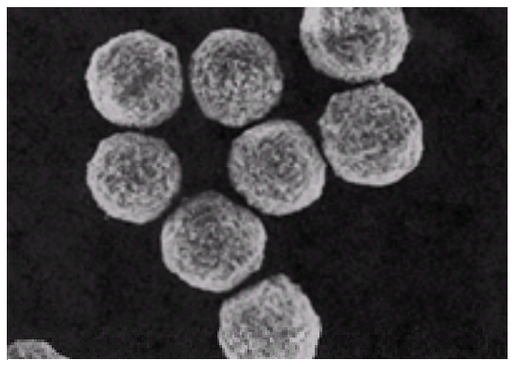
There are multiple advantages to using cationic DNA liposome complexes as a gene-delivery vehicle. These complexes are easy to prepare, and there are no constraints on the size of the transgene. Because no viral genes are present within the plasmid, these complexes are safe for human use. However, limited persistence and lack of stability are major concerns. More recently, a newer cationic liposome has been evaluated that results in 15-fold higher levels of gene expression in arteries *in vivo* compared with previous generations (eFig. 101.0.5) (84). Current applications for DNA liposomes include direct *in vivo* use in cardiovascular diseases (84), cancer (77), and cystic fibrosis (86).



***e*FIGURE 101.0.5** Comparison of gene expression with a newer formulation of cationic liposomes. Porcine arteries were transfected *in vivo* with a CAT reporter gene alone (DNA alone) or complexed with two lipids, DMRIE/DOPE or GAP-DLRIE/DOPE. Percent CAT conversion was measured 2 days later. Gene transfer with GAP-DLRIE/DOPE resulted in a 15-fold increase in gene expression. (From Stephan DJ, Yang ZY, San H, et al. A new cationic liposome DNA complex enhances the efficiency of arterial gene transfer *in vivo. Hum Gene Ther* 1996;7:1803–1812, with permission.)

Biolistics

Particle-mediated or gene gun technologies have been developed as a nonviral method for gene transfer into various experimental systems. A physical force is used to introduce plasmid DNA coated onto microscopic gold particles into target cells. This technology was initially developed in the agricultural industry for plant cell wall biology. More recently, there have been applications to human systems, such as the skin. Gene delivery is achieved by generating a strong shock wave to accelerate DNA-coated gold particles to high speeds, providing the momentum to penetrate the target cells. This concept has now been extended to the delivery of other molecules, including RNA and proteins. Before transfection, the plasmid DNA must be attached to the gold particles (eFig. 101.0.6). This is accomplished by precipitation of the DNA from solution in the presence of the gold particles by addition of polycations, spermidine, and $CaCl_2$. The particles are then resuspended in ethanol and coated onto the inner wall of tenzeo tubing. The DNA gold-coated tubing is cut into $^1/_2$-in. length cartridges, which are inserted into the cylinder of the gene gun device. Physical energy is generated by helium gas to shoot the particles into the tissue (87). The size of the gold particles is approximately 2.0 µm in diameter.



***e*FIGURE 101.0.6** DNA-coated gold particles. DNA is coated onto microscopic gold particles (2.0 µm), and the particles are shot into the target cell using a gun device driven by pressure from helium gas.

The major uses for particle-mediated gene delivery include epidermal skin and surgically exposed internal organs, such as the liver, pancreas, and skeletal muscle. *Ex vivo* applications include transduction of primary T cells, which are then returned to the patient for treatment of acquired immunodeficiency syndrome (88). With a helium pulse gene gun device, DNA-coded gold bead penetration and transgene expression has been detected 20 to 40 cell layers deep.

ANIMAL MODELS OF GENE TRANSFER

One of the major applications of gene transfer has been the development of animal models of cardiovascular diseases. This progress has been made in parallel with development of animal models of human disease created by germline manipulation of the mouse. Indeed, transgenic technology, including knockout of genes by homologous recombination, has gone hand in hand with gene transfer technology. The combination of these two methods has allowed for the development of powerful genetic models of complex cardiovascular disease. However, these models have largely been limited to the mouse. Due to the complexities of transgene technology, transgenics have been performed primarily in the mouse, with notable exceptions in the rat for studies of hypertension and the rabbit for studies of lipoprotein metabolism. Somatic gene transfer has been used in larger animal models, such as the rat, rabbit, and pig, to model focal vascular disease.

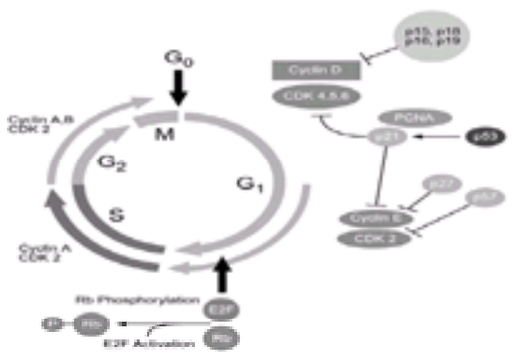
The initial animal models of cardiovascular disease emphasized *ex vivo* approaches, particularly in the vasculature (91). In these models, autologous endothelial cells (6,45,90) or smooth muscle cells (8,46,91) were derived from the host, genetically modified in culture, and then returned to intact blood vessels *in vivo*, where recombinant gene expression was monitored. Other applications included the seeding of vascular prostheses (17). Although these techniques were useful in the vasculature, to establish the principles and feasibility of gene transfer from a practical perspective, they proved to be complex and cumbersome, offering little short-term clinical applicability.

Direct *in vivo* transfer of genes has proven more useful for development of animal models of vascular and myocardial diseases. In the vasculature, these approaches have been used to study growth regulation, angiogenesis, lipoprotein metabolism, and thrombosis. The feasibility and principles of gene transfer have been well worked out in the vasculature by many investigators. These studies have generally used reporter genes to mark gene expression. Different animal models have been studied, including the rat, rabbit, dog, pig, and sheep, using primarily retroviral, liposome, and adenoviral vectors (89). Several themes have emerged. Initial studies of retroviral and liposome-mediated gene transfer in healthy arteries demonstrated low levels of gene expression, generally less than 0.01% of intimal and medial cells (20,92,93). Balloon injury of arteries increased gene expression (94). Gene transfer efficiency was improved after adenoviral-mediated gene transfer in many species (59,60 and 61,95,96). Adenoviral-mediated gene transfer of injured rat (96) and pig (67) arteries resulted in reporter gene expression in intimal endothelial and smooth muscle cells and medial smooth muscle cells, with an efficiency ranging from 10% to 75% (59). Gene expression after adenoviral delivery is transient, generally peaking at 1 to 2 weeks and lost by 1 month (60,61,95). Simple infusion of vector into an intact blood vessel generally results in transfection of endothelial cells (95,97). Manipulation of the artery, by mechanical stretch or pressure, results in gene expression in deeper layers of the vessel and mimics an angioplasty procedure (67,94,98). Several local delivery catheters have been tested for gene administration, each with its own unique features, advantages, and disadvantages (78,99,100).

Cell Cycle and Regulation of Cell Proliferation

Gene transfer is an approach to investigate the *in vivo* function of growth factor, receptor, signal transduction, and cell-cycle proteins. For example, several studies have examined the effects of overexpression of growth factor genes in normal arteries *in vivo*. These growth factor genes include platelet-derived growth factor-b, a secreted form of acidic fibroblast growth factor (FGF-1), and an active secreted form of transforming growth factor-b. Expression of these molecules produced intimal hyperplasia of smooth muscle cells, but the nature of the intimal lesions was different for each molecule. Overexpression of platelet-derived growth factor-b led to smooth muscle cell proliferation (101,102), FGF-1 produced intimal angiogenesis (103), and transforming growth factor-b stimulated procollagen synthesis (104).

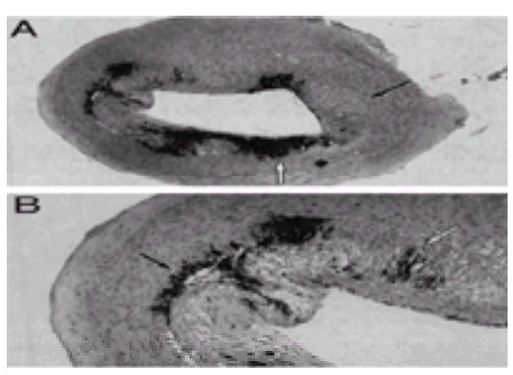
Because expression of multiple growth factor and cytokine genes can all lead to a common end point, intimal hyperplasia, a single inhibitor of one growth factor or its receptor, is likely not to have significant effects on limiting intimal size after arterial injury. Instead, many investigators have pursued regulators of the cell cycle as potential inhibitors of cell growth during vascular repair. When vascular cells are stimulated by mitogens to proliferate, they enter the cell cycle (eFig. 101.0.7) (105,106). The mammalian cell cycle consists of several sequential phases: G_1 or gap 1, S, during which DNA synthesis occurs, G_2 or gap 2, and M, when cells undergo mitosis. Progression through the cell cycle is tightly regulated by the sequential assembly and activation of cyclins and cyclin-dependent kinases (cdks). There are naturally occurring inhibitors of the cyclin-cdk complexes, called the *cyclin-dependent kinase inhibitors*, which arrest cells in G_1 and prevent cell proliferation. Several strategies have been devised to overexpress natural inhibitors of the cyclins and cdks, such as p21 (107,108) or to inhibit the cyclins or cdks directly by antisense oligonucleotides (109,110). Additional approaches include inhibition of protooncogenes, such as c-*myb* (111) and c-*myc* (112), or other cell-cycle proteins, such as proliferating cell nuclear antigen (113,114). These gene products have been tested in balloon-injured rat and pig arteries where they have resulted in a significant reduction in intimal smooth muscle cell proliferation and in intima to media area ratios. Whether these gene products are effective in the treatment of human vascular diseases awaits further testing.



***e*FIGURE 101.0.7** Regulation of the cell cycle. Progression of the cell cycle through G_1 is regulated by the assembly and activation of cyclins and cyclin-dependent kinases (CDKs). Naturally occurring inhibitors of cyclin-CDK complexes, termed the *cyclin-dependent kinase inhibitors*, arrest cells in G_1 and prevent proliferation.

(From Boehm M, Nabel EG. Cell cycle and cell migration: new pieces to the puzzle. *Circulation* 2001;103:2879–2881, with permission.)

Other cell inhibitors have relied on the secretion of cytotoxic molecules, which have paracrine effects on surrounding vascular cells. These approaches offer several advantages over the direct inhibitors of the cell cycle. A major advantage is that the gene product is secreted, and hence a greater number of cells are treated, compared with gene products that remain intracellular. Gene transfer efficiency is less critical when the gene product is secreted. Second, the timing of cell killing can be regulated by the administration of a prodrug. Third, these strategies are selective for dividing cells, and nondividing cells are not affected. Finally, local gene transfer without systemic toxicities can achieve high local concentrations. Two such strategies have been employed to inhibit vascular cell proliferation: a herpes simplex thymidine kinase gene (*HSV-tk*) and a cytosine deaminase gene (*CD*) gene, both of which are converted to active forms by the administration of a prodrug, ganciclovir (a nucleoside analog). *HSV-tk* gene transfer has been tested using adenoviral vectors in injured rat (69,115) and pig (67) arteries as well as injured atherosclerotic rabbit arteries (98) (eFig. 101.0.8). These treatments have been associated with 40% to 60% reduction in intimal cell proliferation and intimal area. A cytosine deaminase gene has also been evaluated in a rabbit model of restenosis in which effects on cell proliferation similar to those of *HSV-tk* were observed (116).



***e*FIGURE 101.0.8** Recombinant gene expression in atherosclerotic rabbit arteries. Peripheral arteries were denuded of endothelium, and the rabbit was lipid-fed for 3 weeks. A second angioplasty was performed, and adenoviral vectors encoding a marker gene were delivered to the injured vessel. Five days later, recombinant marker gene expression was observed in the atherosclerotic intima and media. **A:** Magnification ×100. **B:** Magnification ×250. The black arrows indicate the internal elastic laminae. The white arrows point to areas of recombinant gene expression in the media. (From Simari R, San H, Rekhter M, et al. Regulation of cellular proliferation and intimal formation following balloon injury in atherosclerotic rabbit arteries. *J Clin Invest* 1996;98:225–235, with permission.)

The role of growth inhibitors in the treatment of vascular proliferative diseases has yet to be established. These approaches are likely to be most effective in those settings in which cell proliferation plays a major role in the pathophysiology of the disease. For example, multiple components contribute to the pathophysiology of restenosis, including elastic recoil, thrombosis, and cell proliferation. Although the treatment of restenosis has improved with the use of stents (117,118), it is possible that the combination of a stent, a cell proliferation inhibitor, and an antithrombotic might be the optimal therapy. Stents coated with antiproliferative and antimitotic proteins are in clinical trials; if successful, the next generation of coated stents is likely to include DNA plasmid–coated stents.

Angiogenesis

Angiogenesis for peripheral vascular disease and myocardial insufficiency has been a focus of research efforts. Several candidate molecules have been identified, particularly vascular endothelial growth factor (VEGF) and FGF. VEGF is an endothelial cell-specific mitogen with a signal sequence, resulting in secretion of the active molecule. Plasmid DNA has been applied to an angioplasty catheter (the balloon is coated with a hydrogel polymer) and transferred to iliac arteries of rabbits with ischemic hind limbs. Significant improvements in angiographically proven collaterals, blood flow, and capillary density were observed (22,119). In additional studies, similar results have been obtained with a single intramuscular injection of plasmid DNA-encoding VEGF (120). These animal studies form the basis for a human gene therapy trial for therapeutic angiogenesis in patients with peripheral vascular disease (80). The improvement in collateral vessel formation and limb perfusion achieved with the VEGF gene is comparable with results achieved with a single infusion of recombinant VEGF protein (121). Whether one agent is preferable to another (the gene vs. the protein) will await further studies in humans. Continuous production of protein from a transgene, even in low doses, may be preferable than one or multiple larger doses of recombinant proteins from several perspectives, including safety, systemic toxicity, and production costs.

Methods have also been developed for intracoronary gene transfer of angiogenic genes to enhance coronary blood flow to ischemic myocardium. In a model of stress-induced myocardial ischemia, intracoronary (left anterior descending) infusion of an adenoviral vector encoding FGF-5 resulted in expression of FGF-5 mRNA and protein in ischemic and nonischemic regions of the left anterior descending territory. Expression of this angiogenic factor was associated with regional improvements in myocardial contractility and blood flow (122). Intracoronary infusions of recombinant basic FGF (123,124) and VEGF (125) protein have also enhanced myocardial collateral blood flow in ischemic myocardium of dogs.

Despite these notable results in animals, further evaluation is required. Whether these animal models faithfully reproduce the human disease is not known. The difference between the canine models and human peripheral, myocardial, or both kinds of ischemia may be significant, such that the duration of gene expression that was sufficient to induce collaterals in the animal model may not be so in human disease. Finally, whether these newly formed collaterals have vascular integrity to maintain significant improvements in blood flow and relief of clinical symptoms remains to be tested.

Lipoprotein Metabolism

The development of transgenic mouse technologies has provided a powerful animal model system for studies of the molecular and cellular pathophysiology of human atherosclerosis. Mice have now been produced that overexpress human apolipoprotein (apo)-E (126), human apoA-I (127), human and murine apoAII (128,129), human cholesterol ester transport protein (130), human lecithin-cholesterol acyltransferase (131), and human apoC-III (132). The results of these studies have provided important information on lipoprotein metabolism and atherosclerosis (133). In parallel with these transgenic models, a number of groups have demonstrated that adenoviral vectors can be used to program gene expression to hepatocytes in these animals. Specifically, the efficacy of adenoviral vectors encoding apolipoproteins and lipid-modifying molecules to alter lipid profiles and atherogenesis have been tested (134,135 and 136). For example, injection of adenoviral vectors encoding human lecithin-cholesterol acyltransferase into transgenic mice expressing human apoA-I resulted in elevation of plasma high-density lipoprotein-C levels and human apoA-I levels, which were associated with an increase in cholesterol efflux from serum (137). This study suggested that modifications of high-density lipoprotein composition by overexpression of apolipoproteins, for example, might prove useful as a gene therapy approach to modify atherosclerotic risk. Again, the therapeutic potential of this approach for inherited lipid disorders is unknown and awaits further study.

Thrombotic Disorders

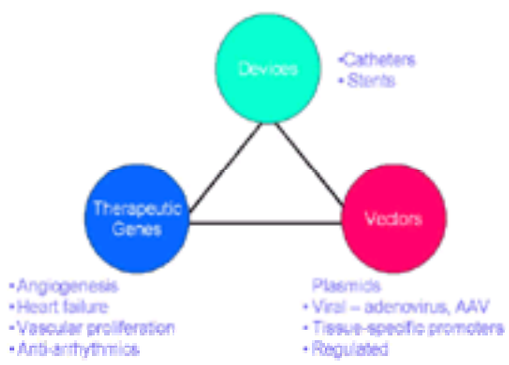
Transgenic technology, including knocking out of genes by homologous recombination, has also been a powerful tool for the analysis of thrombotic disorders and their role in the development of atherosclerosis and other vascular diseases. Murine models for a number of defects in the fibrinolytic and coagulation systems have been constructed, including mice deficient in plasminogen (138), urokinase plasminogen activator and tissue-type plasminogen activator (139), plasminogen activator inhibitor 1 (PAI-1) (140,141), a thrombin receptor (142), and thrombomodulin (143). These studies have provided important and surprising results. For example, mice deficient in thrombomodulin are embryonic lethal (143). Mice lacking a thrombin receptor have variable outcomes; approximately 50% die during embryonic development, whereas 50% survive to birth (142).

These animal models are currently being used to explore the genetic contributions to complex traits, such as atherosclerosis, and to dissect the pathophysiology of vascular diseases, such as the role of protease inhibitors to cell migration and proliferation. Adenoviral vectors have also been constructed to express fibrinolytic proteins, and the feasibility of these vectors infused into knockout mice to rescue the phenotype can be tested. For example, mice deficient in PAI-1 demonstrate accelerated intimal hyperplasia, whereas mice deficient in urokinase plasminogen activator have reduced neointimal formation after arterial injury. Adenoviral-mediated gene transfer of PAI-1 to PAI-1–deficient mice reverses the phenotype (i.e., neointimal formation is reduced) (144). Adenoviral gene transfer may also play a role in gene therapy approaches for the treatment of thrombotic disorders (145).

CLINICAL TRIALS

Cardiovascular diseases are ideal targets for gene therapy. Arterial lesions are focal, facilitating delivery of recombinant gene or protein directly into the site of disease. Devices can be adapted for delivery of gene products to the vasculature or myocardium. Short-term expression is sufficient to treat the disease, and this avoids systemic side effects.

Cardiovascular gene therapy can be thought of as a “three-legged” stool (eFig. 101.0.9). Three components are required: therapeutic genes, delivery device, and vectors. Considerable work by many investigators has identified a number of therapeutic candidate genes for angiogenesis and cell-inhibitor therapies. Only relatively recently has the need for delivery devices that are compatible with vectors been identified (146). Since the 1995 NIH review of the gene therapy field, many basic investigators have successfully improved viral and nonviral vectors, achieving tissue-specific expression and regulated expression.



***e*FIGURE 101.0.9** The three essential components to successful cardiovascular gene therapy. A successful clinical product must integrate a therapeutic gene with a vector and a delivery device. AAV, adeno-associated virus.

In the past 5 years, there has been an explosion in recombinant gene and protein phase I and II trials for cardiovascular diseases. Angiogenesis and cell-inhibitor therapies have been the major focus. VEGF and basic FGF are the two dominant growth factors delivered by recombinant gene or protein approaches for peripheral vascular disease and coronary artery disease. Recombinant genes have been delivered via adenoviral vectors or plasmid DNA. Direct injection into skeletal muscle or cardiac muscle, infusion into femoral coronary arteries, or injection into the left ventricle are the three major delivery approaches. This field is clearly in its infancy; however, there are several major lessons learned from the clinical trials to date: (a) VEGF and basic FGF delivered as plasmid DNA are safely tolerated in the peripheral and coronary vasculature and muscle; (b) the full safety profile on adenoviral vectors is not yet known; (c) after direct injection into skeletal and cardiac muscle, recombinant genes are expressed, although the duration of gene expression in human tissues is not known; (d) direct comparisons of recombinant protein and genes have not been made, and hence, we do not know whether one approach is preferable to the other; (e) demonstration of intact functional collaterals has not been made in any trial to date; and (f) therapeutic effectiveness has not yet been demonstrated and awaits randomized, controlled, multicenter phase III trials.

Cell-inhibitor therapies have been initiated to treat vascular proliferative diseases. Cell-cycle inhibitors, cytostatic and cytotoxic compounds, and secreted multifunctional proteins such as NOS have been tested in preclinical animal models and now are moving forward to phase I studies. The major indication is restenosis in the coronary and peripheral vasculature and in-stent restenosis. However, in the future, indications will be expanded to include bypass grafts, atrioventricular fistulas, transplant arteriopathy, and native lesions in the coronary and peripheral vasculature. A phase I and II trial to inhibit smooth muscle cells’ replication in saphenous vein bypass grafts has been reported (147). Cell-cycle progression was prevented by disrupting the E2F transcription factor by use of antisense oligonucleotides to E2F. Saphenous veins were incubated in the operating room with a solution containing E2F transcription decoys before placement as a bypass graft for peripheral artery stenosis. This trial demonstrated the safe delivery of a genetic factor in a lipid preparation into vessels before operative insertion. Clinical end points will need to be tested in a randomized, controlled, multicenter trial.

Several key issues must be resolved before broad implementation of cardiovascular gene therapies. Transfection efficiencies with most vectors remain low, and improvements in vector design are required. These vectors must be delivered by catheters to sites of disease. Many local delivery catheters have been designed, yet there is no consensus on the optimal configuration of a gene transfer catheter. Finally, interactions of host cells and vectors must be examined, and the risk of vectors must be sufficiently low to warrant use in cardiovascular diseases.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Tremendous early progress was made in the field of gene transfer and gene therapy in the late 1980s. Multiple new vectors were developed, including viral and nonviral vectors. These vectors were tested in cell lines *in vitro*, and recombinant gene expression was measured. The feasibility of expressing recombinant genes in many cell lines from multiple organs led to tremendous enthusiasm and speculation that gene therapy would have a ready-made niche in the therapeutic armamentarium of physicians. Based on these promising *in vitro* results, *in vivo* animal models of gene therapy were created. Although there were specific challenges related to vector, delivery, and expression for each organ system tested, the feasibility of expressing recombinant genes *in vivo* was established in the vasculature, heart, brain, lung, liver, skeletal muscle, bone marrow, skin, and tumors. The number of investigators in the field grew and so did the number of published studies. The number of applications to conduct human gene therapy trials also rose exponentially. More than 150 clinical protocols for gene therapy have been reviewed and approved by the FDA. The majority of the protocols involve cardiovascular diseases, cancer, inherited diseases, and infectious diseases (acquired immunodeficiency syndrome). Many of the early studies were gene-marking studies. Retroviruses have been employed in the majority of protocols, but quickly, phase I and II trials were initiated as well. Several observations were made on studies conducted up to the mid- to late 1990s: Recombinant genes are expressed in human cells *in vivo* in different organ systems; adverse side effects from the vectors vary, depending on the nature of the vector, the patient, and where it is administered; assessment of the results of gene therapy trials has been difficult because of the relatively low frequency of gene delivery to cells and often the lack of biochemical or other measurable end points; and efficacy has not been clearly established (nor was it explicitly tested).

There are several general goals for human gene therapy protocols. The appropriate disease target must be identified. A gene delivery system that programs temporal and spatial patterns of recombinant gene expression must be developed. Sufficient gene delivery and gene expression must be achieved within targeted cells to achieve long-term therapeutic benefits. Finally, little to no toxicity from the vector recombinant gene must be demonstrated in human studies *in vivo*. The *Report and Recommendations of the Panel to Assess the NIH Investment in Research on Gene Therapy*, prepared by Drs. Orkin and Motulsky, shaped the field in the mid-1990s. This panel has recommended that greater focus be placed on the basic science aspects of gene transfer, including improving vectors for gene delivery, increasing and maintaining high levels of gene expression, directing genes to specific cell types using cell- or tissue-specific promoters, and further developing animal models of gene transfer to study disease pathogenesis.

The field of gene therapy was turned upside down in the fall of 1999 when the first gene therapy–related death occurred in a young patient at the University of Pennsylvania. Further examination of this protocol revealed a lack of clinical oversight and financial disclosure. Public hearings ensued, followed by issuance of new regulations by the FDA. Investigators have responded appropriately with intensified efforts to improve vectors, thoroughly testing the efficacy and toxicity of vectors and genes in animals before proceeding to human trials, carefully weighing the nature and likelihood of clinical benefit against the risks, and explaining these benefits and risks to patients and family. Informed consent must be clear with oversight and monitoring by a data safety and monitoring board. Conflict of interest must be disclosed.

Improvements in vectors and gene delivery systems will play an increasingly important role in the further development of human gene therapies. Animal models of cardiovascular disease will be based on transgenic and gene transfer techniques. The initial limitations of low-efficiency vectors and inefficient delivery systems, it is hoped, will be overcome through focused research efforts. The most useful strategies will integrate refinements in vectors with improved delivery systems. For gene therapy to realize its clinical potential, there must be efficient and safe strategies for delivering therapeutic genes to somatic cells *in vivo*. Gene therapy is a unique case of drug delivery in which the therapeutic gene constitutes the drug. Although traditional drug development can take 10 years or more to market, human gene therapy products may require an equivalent amount of time, if not more. Yet the promise remains great.

THE FUTURE

Improvements in vectors and gene delivery systems will play an increasingly important role in the further development of human gene therapies. Future basic research in cardiovascular disease will be based on genetic technology. Clinical trials are proceeding, and it is likely that a gene therapy product for angiogenesis will reach the marketplace within the next 3 to 5 years.

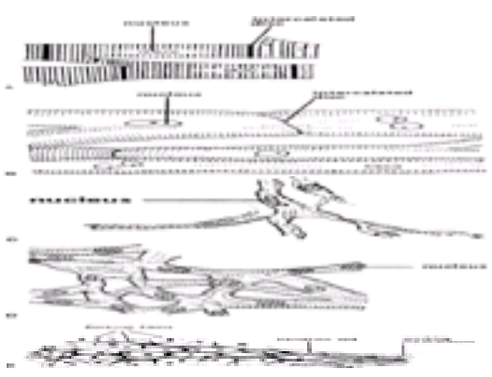
WHAT THE CARDIAC MYOCYTE DOES

The pumping action of the heart depends on interactions between the contractile proteins in its muscular walls. These interactions transform the chemical energy derived from adenosine triphosphate (ATP) into the mechanical work that moves blood under pressure from the great veins into the pulmonary artery, and from the pulmonary veins into the aorta. The contractile proteins are activated by a signaling process called excitation-contraction coupling, which begins when the action potential depolarizes the cell and ends when ionized calcium (Ca^{2+}) that appears within the cytosol binds to the Ca^{2+} receptor of the contractile apparatus. Movement of Ca^{2+} into the cytosol is a passive (downhill) process mediated by Ca^{2+} channels, whereas the heart relaxes when ion exchangers and pumps transport Ca^{2+} uphill, out of the cytosol. This chapter describes the mechanisms responsible for excitation-contraction coupling, contraction, and relaxation by the working cells of the atria and ventricles (for general reviews, see references 1,2,3,4 and 5).

MYOCYTE STRUCTURE

Several cell types are found within the myocardium. Most important are the *working myocardial cells* of the atria and ventricles, which are specialized for contraction (eFig. 102.0.1). *Nodal cells* of the sinoatrial and atrioventricular nodes are responsible for pacemaker activity and the atrioventricular conduction delay, respectively, whereas *Purkinje fibers* effect rapid conduction through the ventricular septum and throughout the ventricles. All of these myocardial cell types make up a functional syncytium in which cells are linked both electrically and mechanically by the *intercalated discs*. The latter contain low-resistance gap junction channels made up of connexin molecules that allow electrical current and small molecules to flow freely from one cardiac myocyte to another (6,7). Granules in the atrial myocardium contain biologically active atriopeptides; the latter, which are key regulators of vascular volume released in response to atrial stretch, promote smooth muscle relaxation and have natriuretic and diuretic effects.



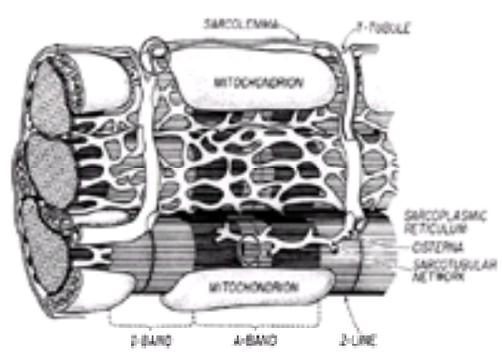
***e*FIGURE 102.0.1** Cells comprising the human heart. **A:** Working myocardial cell of the ventricle, showing intensely staining cross striations, central nuclei, and intercalated discs. **B:** Purkinje fiber, showing large, faintly staining cells with sparse cross striation. **C:** Sinoatrial node. **D:** Atrioventricular node. Both nodes have a network of small, sparsely cross-striated cells. **E:** Point of impingement of Purkinje fibers (*left*) on the working myocardium (*right*), showing transition cells. The scale for **E** is approximately half that for **A–D**. (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

Specialized Myocytes

The *His-Purkinje cells*, which are specialized for rapid conduction, are large, pale cells that contain more glycogen and many fewer contractile filaments than the cells of the working myocardium (eFig. 102.0.1). These cells make up the atrioventricular bundle and bundle branches, and course along the ventricular endocardium where they synchronize ventricular systole. Fast conduction by the His-Purkinje cells is made possible by the many large Na^+ channels in their plasma membranes (for review, see reference 8). The sinoatrial and atrioventricular nodes are made up of small *nodal cells* (eFig. 102.0.1), which, like the His-Purkinje cells, are rich in glycogen and contain few contractile filaments. Slow conduction by nodal cells reflects the dependence action of their potentials on Ca^{2+} channels (for review, see references 8 and 9). *Transition cells*, intermediate in appearance between the His-Purkinje cells and ordinary working myocardial cells, are found between these two cell types in the ventricles. They are also scattered in the atria, where they contribute to preferential atrial conduction pathways (the "internodal tracts"). The heterogeneity among these histologically different cell types is also apparent at a molecular level.

Working Myocardium

The cells of the working myocardium are filled with cross-striated *myofibrils* (eFig. 102.0.2). Excitation-contraction coupling and relaxation are regulated by the *plasma membrane*, which separates the cytosol from the extracellular space, and the internal membranes of the *sarcoplasmic reticulum*. As the latter is a specialization of the endoplasmic reticulum, the generic term for these internal membranes is *sarco(endo)plasmic reticulum*. The *mitochondria*, which generate ATP, contain enzymes responsible for aerobic metabolism and oxidative phosphorylation; the latter are located on the inner mitochondrial membrane, whose surface is increased by infoldings called *cristae*.



***e*FIGURE 102.0.2** Ultrastructure of the working myocardial cell. Contractile proteins are arranged in a regular array of thick and thin filaments (seen in cross section at left). The A-band represents the region of the sarcomere occupied by the thick filaments, whereas the I-band is occupied only by thin filaments that extend toward the center of the sarcomere from the Z-lines, which bisect each I-band. The sarcomere, the functional unit of the contractile apparatus, is defined as the region between a pair of Z-lines and contains two half I-bands and one A-band. The sarcoplasmic reticulum, a membrane network that surrounds the contractile proteins, consists of the sarcotubular network at the center of the sarcomere and the subsarcolemmal cisternae, which abut the T-tubules and the sarcolemma. The transverse tubular system (T-tubule) is lined by a membrane that is continuous with the sarcolemma, so that the lumen of the T-tubules carries the extracellular space toward the center of the myocardial cell. Mitochondria are shown in the central sarcomere and in cross section at the left. (From Katz AM. Congestive heart failure: role of altered myocardial cellular control. *N Engl J Med* 1975;293:1184–1191. Copyright 1975, Massachusetts Medical Society. All rights reserved.)

Myofibrils

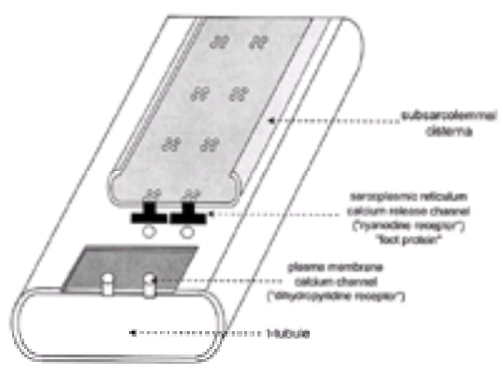
The organization of the *contractile proteins* gives rise to the characteristic pattern of light and dark striations (*e*Fig. 102.0.2). The more darkly staining bands are called *A bands*, whereas the lightly staining striations are called *I bands*. Each I band is bisected by a narrow, darkly staining *Z line*; a broad, dense *M band* is found in the center of the A band. The morphologic unit is the *sarcomere*, which lies between two Z lines (10); each sarcomere therefore consists of a central A band plus the two adjacent half I bands.

The A bands contain thick filaments that are composed largely of myosin, whereas the lightly staining half I bands at either side of the A band contain only thin filaments. The latter, which are strands of actin polymers, contain the regulatory proteins tropomyosin and the troponin complex. At physiologic sarcomere lengths in the resting heart, the thin filaments extend from the Z lines almost to the center of the A band, so that as the muscle shortens the extent of overlap between the thick and thin filaments increases. At short sarcomere lengths, double overlap is found between the thin filaments from the two adjacent I bands in the center of the sarcomere.

Sarcomere shortening occurs when the thin filaments are pulled toward the center of the A band by motion of the myosin *cross-bridges*, which project from the thick filaments to establish links with adjacent thin filaments. Like the oars of a racing shell, cross-bridge motion sweeps the thin filaments toward the center of the sarcomere in a reaction that is powered by energy released by ATP hydrolysis.

Membrane Structures

Contraction and relaxation in the adult human heart are regulated by the plasma membrane and sarcoplasmic reticulum (*e*Fig. 102.0.2). The plasma membrane is divided structurally into the *sarcolemma*, which surrounds the cell to separate the cytosol from the extracellular space, and the *transverse tubular (T-tubular) system* that penetrates the cell interior. The T tubules, whose lumens open to the extracellular space, rapidly transmit action potentials to the cell interior. Dyads, formed by the plasma membrane and sarcoplasmic reticulum (*e*Fig. 102.0.3), are composite structures that regulate the release of activator Ca^{2+} during excitation-contraction coupling.



***e*FIGURE 102.0.3** Schematic diagram of a dyad showing the Ca^{2+} release channels through which this cation leaves the subsarcolemmal cisternae of the sarcoplasmic reticulum, and their close approximation to the plasma membrane Ca^{2+} channels. (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

The heart's sarcoplasmic reticulum, which takes up, stores, and releases Ca^{2+}, can be divided into two regions. The *subsarcolemmal cisternae* contain Ca^{2+}-binding proteins that store this activator cation and Ca^{2+} release channels that release this activator cation into the cytosol to initiate systole. The more extensive *sarcotubular network*, which surrounds the contractile proteins in the center of the sarcomere, contains a densely packed array of Ca^{2+} pump adenosine triphosphatase (ATPase) proteins that transport Ca^{2+} out of the cytosol into the lumen of the sarcoplasmic reticulum to relax the heart.

MYOCYTE FUNCTION

Contractile Proteins

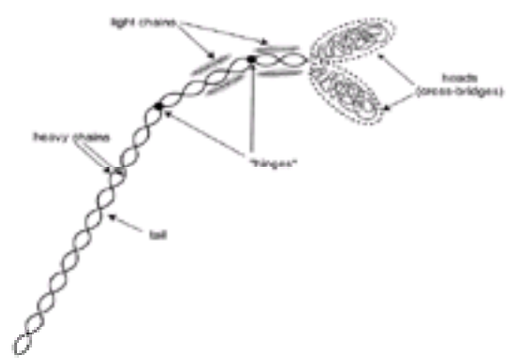
Myocardial contraction and its control can be understood in terms of the interactions between six proteins (1,10,11 and 12) (*e*Table 102.0.1) that, when assembled *in vitro*, hydrolyze ATP, undergo physicochemical changes that develop tension and cause shortening, and are controlled by Ca^{2+} in a manner that mimics physiologic excitation-contraction coupling.

***e*TABLE 102.0.1** CONTRACTILE PROTEINS OF THE HEART

Protein	Location	Salient properties
Myosin	Thick filament	Hydrolyzes adenosine triphosphate, interacts with actin
Actin	Thin filament	Activates myosin adenosine triphosphatase, interacts with myosin
Tropomyosin	Thin filament	Modulates actin-myosin interaction
Troponin C	Thin filament	Binds Ca^{2+}
Troponin I	Thin filament	Inhibits actin-myosin interactions
Troponin T	Thin filament	Binds troponin complex to the thin filament

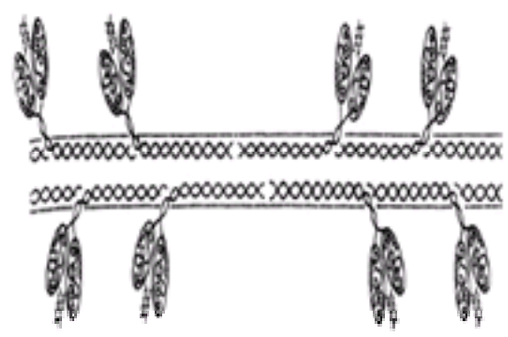
Myosin

Myosin, the major protein of the thick filament of muscle, is a large, elongated molecule with a filamentous "tail" and a globular "head" (*e*Fig. 102.0.4) that is able to hydrolyze ATP. When myosin interacts with actin, chemical energy is transduced into the mechanical energy used during contraction. Each myosin molecule contains two heavy chains and four light chains. The heavy chains extend into the cross-bridge and contain the sites responsible for both ATPase activity and the ability to interact with actin, whereas the light chains mediate responses of the contractile proteins to various signaling cascades. The myosin heavy chains and light chains differ among different muscle types, among different regions of the heart, and even among adjacent cells.

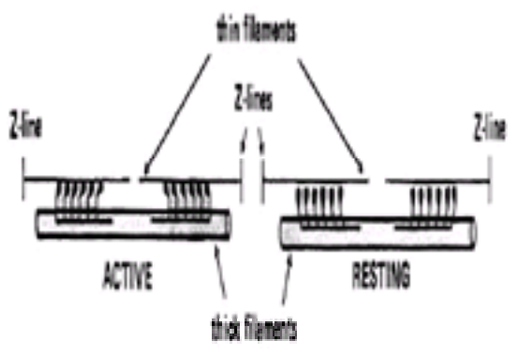


***e*FIGURE 102.0.4** Myosin is an elongated molecule consisting of two heavy chains and four light chains. The “tail” of the molecule, which is made up of a-helical regions of the heavy chains, extends into a paired globular “head” that makes up the cross-bridge. The hinges represent points of flexibility that allow for cross-bridge movement. (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

Myosin in the living muscle is aggregated in the *thick filament* in which the tails are wound together as a rigid backbone, and the heads project as the cross-bridges that effect contraction when they interact with actin (eFig. 102.0.5). In resting muscle the cross-bridges are perpendicular to the long axis of the thick filament, whereas in active muscle their tips shift toward the center of the sarcomere so as to “row” the thin filaments toward the center of the sarcomere (eFig. 102.0.6).



***e*FIGURE 102.0.5** Organization of the thick filament, in which the backbone—delineated by dashed lines—is made up of the tails of myosin molecules that have opposite polarities in the two halves of the sarcomere. The cross-bridges represent the heads of the individual myosin molecules, which project from the long axis of the thick filament. A bare area in the center of the thick filament, which is devoid of cross-bridges, occurs because of the tail-to-tail organization of myosin molecules unique to the center of the thick filament. (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

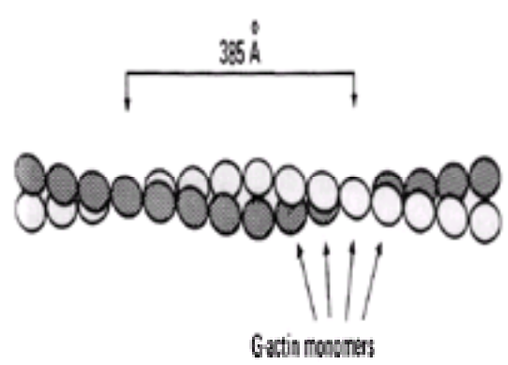


***e*FIGURE 102.0.6** In resting muscle (*right*), the cross-bridges project almost at right angles to the longitudinal axis of the thick filament. In active muscle (*left*), motion of the myosin cross-bridges pulls the thin filaments toward the center of the sarcomere. (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

The myosin heavy chains determine muscle-shortening velocity and myocardial contractility. A higher ATPase myosin heavy chain (called a) is associated with a rapid muscle-shortening velocity, high contractility, and efficient contraction against light load, whereas a lower ATPase myosin heavy chain (called b) is associated with lower contractility but greater efficiency of tension development at heavy loads. In the human heart, atrial myosin heavy chains are mostly a high-ATPase isoform, whereas the human ventricle contains only a small amount of the fast myosin heavy chain (13).

Actin

Actin is a globular protein that forms a double-stranded macromolecular helix which serves as the backbone of the thin filament (eFig. 102.0.7). Human hearts contain mainly a-cardiac actin, along with a smaller amount of a-skeletal actin.



***e*FIGURE 102.0.7** The F-actin polymer is composed of two strands of G-actin monomers (*ovals*) wound around each other. The G-actin monomers in the two strands are identical; one strand is shaded here only to illustrate the two-stranded structure of F-actin. (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

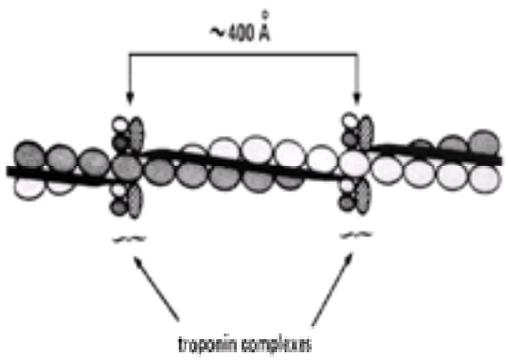
Tropomyosin

Tropomyosin is an elongated molecule made up of two helical peptide chains that is found along with actin in the thin filament, where one tropomyosin molecule lies in each of the two longitudinal grooves between the two strands of actin. Tropomyosin, which can contain either or both of two isoforms, a and b, regulates the

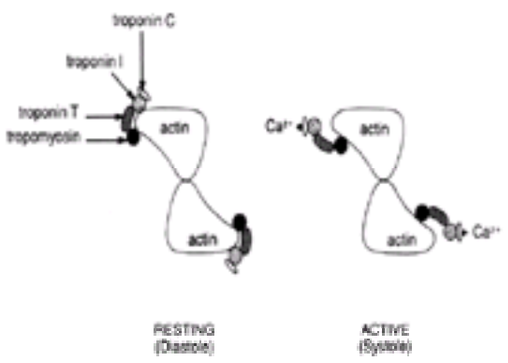
interactions between myosin, actin, and the troponin complex.

Troponin Complex

Troponin includes three discrete proteins (eFig. 102.0.8 and eFig. 102.0.9). *Troponin I*, in concert with tropomyosin, reversibly inhibits the interactions between actin and myosin; *troponin T* binds the troponin complex to tropomyosin; and *troponin C* contains the high-affinity Ca^{2+}-binding sites that recognize the appearance of Ca^{2+} in the cytosol as a signal to initiate contraction.



***e*FIGURE 102.0.8** Troponin complexes are distributed at approximately 400-Å intervals in the thin filament, along with actin and tropomyosin (dark lines in the grooves between the two actin strands). (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)



***e*FIGURE 102.0.9** Cross section of a thin filament in resting (*left*) and active (*right*) muscle. At rest, the troponin complex holds the tropomyosin molecules toward the periphery of the groove between actin strands in a manner that prevents actin from interacting with the myosin cross-bridges. In active muscle, Ca^{2+} binding to troponin C weakens the bond linking troponin I to actin, which causes a structural rearrangement of the regulatory proteins that shifts the tropomyosin deeper into the groove between the strands of actin. This rearrangement exposes active sites on actin for interaction with the myosin cross-bridges. (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

Troponin C is a member of a family of Ca^{2+}-binding proteins that includes the myosin light chains and calmodulin, a ubiquitous intracellular Ca^{2+}-mediated regulator. Troponin I, which inhibits actin-myosin interactions in resting muscle, allows actin to interact with the myosin cross-bridges when Ca^{2+} binds to troponin C. When phosphorylated by cyclic adenosine monophosphate–dependent protein kinase (PK-A), cardiac troponin I reduces the Ca^{2+} sensitivity of troponin C, which contributes to the lusitropic effect of beta-adrenergic stimulation. Troponin T binds the troponin complex to tropomyosin. Although troponin T itself does not bind Ca^{2+}, isoform switches can modify the Ca^{2+} sensitivity of tension development.

Interactions between the Contractile Proteins

The interactions of the contractile proteins are modified by the effects of Ca^{2+} described earlier, by changes in muscle length, and by an allosteric effect of ATP. The major determinant of contractility is the level of cytosolic Ca^{2+} achieved during excitation-contraction coupling. At the low Ca^{2+} concentrations found in resting muscle, actin-myosin interactions are inhibited by a blocking action of tropomyosin and the troponin complex. Ca^{2+} binding to troponin C reverses this inhibitory effect by initiating a series of cooperative interactions in the thin filament that shift the position of tropomyosin in the grooves between the double-stranded F-actin polymer (eFig. 102.0.9). In resting muscle, tropomyosin lies toward the outside of the grooves between the two actin chains, where it blocks the development of actin-myosin interactions. Ca^{2+} binding to troponin C shifts the elongated tropomyosin molecules toward the center of the groove between the actin chains, which initiates systole by allowing the myosin cross-bridges to interact with active sites on actin. The muscle returns to its resting state when Ca^{2+} dissociation from troponin C returns tropomyosin to its inhibitory position in the thin filament.

Regulation of cardiac performance by end diastolic volume (the Frank-Starling relationship) is due mainly to sarcomere length–dependent changes in both the Ca^{2+} sensitivity of the contractile proteins (14) and Ca^{2+} release from the sarcoplasmic reticulum (15). ATP, in addition to supplying energy for the interactions between myosin cross-bridges and actin, has important allosteric effects. At levels between 0.1 and 10.0 µM, ATP provides the substrate for energy-consuming reactions. The allosteric effects, which are seen at concentrations above 100 µM, facilitate relaxation by dissociating actin and myosin. ATP concentration in the living heart is well above 1 mM, more than three orders of magnitude higher than needed to saturate the catalytic site of myosin, so that the initial effect of energy starvation is to blunt this allosteric effect.

Excitation-Contraction Coupling and Relaxation

Excitation-contraction coupling in working myocardial cells begins when an inward Na^{+} current depolarizes the plasma membrane and ends when Ca^{2+} released from intracellular stores binds to troponin C. Relaxation, which is much more than reversal of the processes involved in excitation-contraction coupling, is brought about when energy-dependent Ca^{2+} pumps and exchangers lower cytosolic Ca^{2+} concentration.

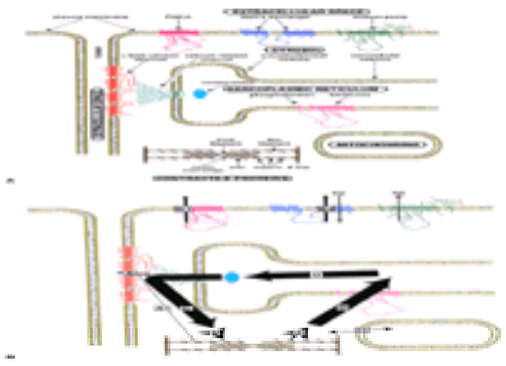
Energetics of Excitation-Contraction Coupling and Relaxation

Although energy is needed for both contraction and relaxation, energy is used in different ways and by different structures. During systole, energy released from ATP is used by the contractile proteins for tension development and muscle shortening, whereas the heart relaxes when energy-dependent ion pumps and exchangers remove Ca^{2+} from the cytosol. The Ca^{2+} concentration in the extracellular space and sarcoplasmic reticulum is approximately 1 mM, whereas much lower Ca^{2+} concentrations, approximately 10 µM, saturate troponin; both are much higher than the cytosolic Ca^{2+} concentration in the resting heart, approximately 0.2 µM. For this reason, the Ca^{2+} fluxes that activate contraction are passive, whereas those involved in relaxation require the expenditure of energy.

Ca^{2+} Cycles in Excitation-Contraction Coupling and Relaxation

The entry and removal of Ca^{2+} from the cytosol of working cardiac myocytes are effected by two distinct Ca^{2+} cycles (eFig. 102.0.10). In the extracellular cycle, Ca^{2+} enters and leaves the cytosol by crossing the plasma membrane from what is, in effect, an unlimited store of Ca^{2+} in the extracellular space. In the intracellular cycle, Ca^{2+} is pumped into and out of limited stores within the sarcoplasmic reticulum. Most of the Ca^{2+} that activates contraction by the adult human heart is derived from the sarcoplasmic reticulum (the intracellular cycle). Although Ca^{2+} derived from the extracellular space makes only a small contribution to the intracellular pool of activator Ca^{2+}, this Ca^{2+} flux plays a major role in triggering Ca^{2+} release from the sarcoplasmic reticulum and in determining the Ca^{2+} content of the internal stores. Both Ca^{2+} cycles are regulated by channels through which Ca^{2+} diffuses into the cytosol and by Ca^{2+} pumps and exchangers that actively transport this cation into the extracellular

space and lumen of the sarcoplasmic reticulum.



***e*FIGURE 102.0.10** Schematic diagram showing key structures **(A)** and Ca^{2+} fluxes **(B)** that control cardiac excitation-contraction coupling and relaxation. Ca^{2+} "pools" are in bold capital letters **(A)**. In **B**, the thickness of the arrows indicates the magnitude of the Ca^{2+} fluxes, whereas their vertical orientations describe their "energetics": downward arrows represent passive Ca^{2+} fluxes and upward arrows represent energy-dependent active Ca^{2+} transport. Most of the Ca^{2+} that enters the cell from the extracellular fluid via L-type Ca^{2+} channels (*arrow A*) triggers Ca^{2+} release from the sarcoplasmic reticulum; only a small portion directly activates the contractile proteins (*arrow A1*). Ca^{2+} is actively transported back into the extracellular fluid by the plasma membrane Ca^{2+} pump adenosine triphosphatase (PMCA; *arrow B1*) and the Na^+/ Ca^{2+} exchanger (*arrow B2*). The Na^+ that enters the cell in exchange for Ca^{2+} (*dashed line*) is pumped out of the cytosol by the Na^+ pump. Two Ca^{2+} fluxes are regulated by the sarcoplasmic reticulum: Ca^{2+} efflux from the subsarcolemmal cisternae via Ca^{2+} release channels (*arrow C*) and Ca^{2+} uptake into the sarcotubular network by the sarco(endo)plasmic reticulum Ca^{2+} pump adenosine triphosphatase (SERCA; *arrow D*). Ca^{2+} diffuses within the sarcoplasmic reticulum from the sarcotubular network to the subsarcolemmal cisternae (*arrow G*), where it is stored in a complex with calsequestrin and other Ca^{2+}-binding proteins. Ca^{2+} binding to (*arrow E*) and dissociation from (*arrow F*) high-affinity Ca^{2+}-binding sites of troponin C activate and inhibit the interactions of the contractile proteins. Ca^{2+} movements into and out of mitochondria (*arrow H*) buffer cytosolic Ca^{2+} concentration. The extracellular Ca^{2+} cycle consists of arrows A, B1, and B2, whereas the intracellular cycle involves arrows C, E, F, D, and G. (Modified from Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

The plasma membrane Ca^{2+} channels (extracellular Ca^{2+} cycle) and the sarcoplasmic reticulum Ca^{2+} release channels (intracellular Ca^{2+} cycle) are members of two distinct protein families (*e*Table 102.0.2), whereas the ATP-dependent Ca^{2+} pumps in the plasma membrane and sarcoplasmic reticulum belong to a single family of ATPases that also includes the Na^+ pump (Na^+-K^+ ATPase). The Na^+/Ca^{2+} exchanger, which transports Ca^{2+} uphill out of the cytosol in exchange for extracellular Na^+, belongs to a different class of membrane proteins.

***e*TABLE 102.0.2** STRUCTURE-FUNCTION RELATIONSHIPS IN EXCITATION-CONTRACTION COUPLING OF WORKING CARDIAC MYOCYTES

Structure	Role in systole	Role in diastole
Plasma membrane		
Sarcolemma		
Na^+ channel	Depolarization	
	Opening of Ca^{2+} channels	
Ca^{2+} channel	Action potential plateau	
	Ca^{2+}-triggered Ca^{2+} release	
Ca^{2+} pump (PMCA)		Ca^{2+} removal
Na^+/Ca^{2+} exchanger	Ca^{2+} entry	Ca^{2+} removal
Na^+ pump		Repolarization
		Na^+ gradient for Na^+/Ca^{2+} exchanger
Transverse tubule		
Na^+ channel	Action potential propagation	
Ca^{2+} channel	Ca^{2+}-triggered Ca^{2+} release	
Sarcoplasmic reticulum		
Subsarcolemmal cisternae		
Ca^{2+} release channel	Ca^{2+} release	
Sarcotubular network		
Ca^{2+} pump (SERCA)		Ca^{2+} removal
Myofilaments		
Actin and myosin	Contraction	
Troponin C	Ca^{2+} receptor	
Other proteins	Allosteric regulation	

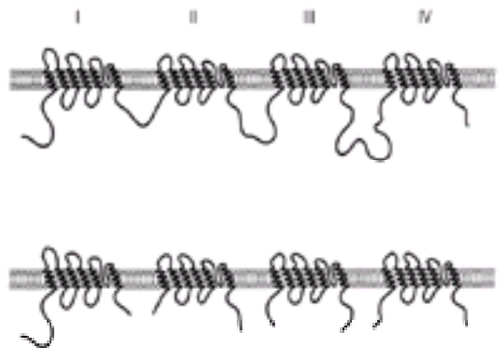
PMCA, plasma membrane Ca^{2+} pump adenosine triphosphatase; SERCA, sarco(endo)plasmic reticulum Ca^{2+} adenosine triphosphatase.

The functional link between plasma membrane depolarization (the action potential) and the opening of intracellular Ca^{2+} release channels in the heart is provided by L-type plasma membrane Ca^{2+} channels. When membrane depolarization opens the latter, a localized increase in cytosolic Ca^{2+} concentration, called a "Ca^{2+} spark" (16), opens nearby intracellular Ca^{2+} release channels. This causes a much greater Ca^{2+} release from the sarcoplasmic reticulum by a process that is often referred to as "Ca^{2+}-induced Ca^{2+} release" (17,18).

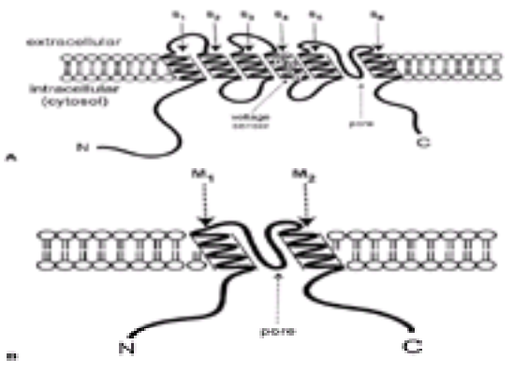
Structures Involved in Excitation-Contraction Coupling and Relaxation

Plasma Membrane Ion Channels

Plasma membrane channels, which are generally named for the ions that they carry (*e*Table 102.0.2), are oligomers that can contain as many as five subunits, called a_1, a_2, b, g, and d (for review, see references 1 and 8). Central to their physiologic function are large proteins (called a or a_1 in different channels) that make up and surround the channel pores, which determine ion specificity and which contain the activation and inactivation gates that open, close, and inactivate the channels. The a and a_1 subunits of Na^+ and Ca^{2+} channels, and outwardly rectifying K^+ channels, are tetramers (*e*Fig. 102.0.11), each of whose four domains contains six a-helical transmembrane segments (*e*Fig. 102.0.12). The S_4 transmembrane segment, which is rich in charged amino acids, provides the "voltage sensor" that mediates the voltage-dependent conformational changes that open (activate) the channel. Several of these channels are inactivated by the intracellular peptide chain that links domains III and IV. The "pore" region of the channel is made up of the S_5 and S_6 a-helical transmembrane segments and the intervening sequence of amino acids. The major subunits of inwardly rectifying K^+ channels, which are closed by depolarization, are smaller peptides that consist of only the pore region of the ancestral channel domain (19,20). The four domains of the a and a_1 subunits of most plasma membrane Na^+ and Ca^{2+} channels are linked covalently (*e*Fig. 102.0.11), whereas the K^+ channel domains are not covalently linked; as a result, K^+ channel domains can exchange among each other so as to generate a large number of channel subtypes (21,22 and 23).



***e*FIGURE 102.0.11** Schematic representation of two types of voltage-gated ion channels. **Top:** Na^+ and Ca^{2+} channels are covalently linked tetramers made up of four homologous domains (numbered I through IV), each of which contains six a-helical transmembrane segments. **Bottom:** The major class of K^+ channels is also made up of four homologous domains, except that unlike the channels shown at top, these domains are not linked covalently. (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

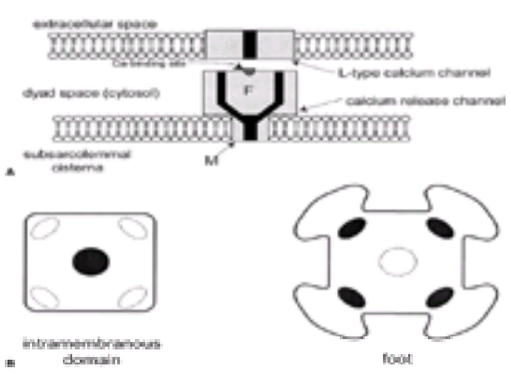


***e*FIGURE 102.0.12** Schematic representation of two types of ion channel domains. **A:** The domains in Na^+ and Ca^{2+} channels, and in the major class of K^+ channels, contain six transmembrane a-helices. The positively charged S_4 transmembrane segment in each of these domains provides the voltage sensor that responds to membrane depolarization by opening the channel. The "pore region" is made up of the S_5 and S_6 transmembrane segments and the intervening loop that "dips" into the membrane bilayer. **B:** Inward-rectifying K^+ channels are made of smaller domains that are homologous to the S_5 and S_6 transmembrane segments of the larger domain shown in **(A)**. This domain is largely a pore, composed of the M_1 and M_2 transmembrane segments along with the intervening loop. The absence of a charged transmembrane segment homologous to S_4 explains why the response of inward-rectifying channels to membrane depolarization differs from that of channels made up of the larger domains depicted in **(A)**. C, C terminus; N, N terminus. (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

Several classes of the plasma membrane Ca^{2+} channels are found (for review, see references 9, 24, and 25). In the heart, the most important members of this family are the L-type Ca^{2+} channels, which bind the familiar classes of Ca^{2+} channel blockers (*dihydropyridines* such as nifedipine, *phenylalkylamines* such as verapamil, and *benzothiazepines* such as diltiazem). These are sometimes called *dihydropyridine receptors* because of their high-affinity binding to this class of Ca^{2+} channel blockers. A second class, the T-type Ca^{2+} channels, opens only transiently and plays an important role in the sinoatrial node pacemaker; these channels may also participate in proliferative signaling.

Intracellular Ca^{2+} Release Channels

Intracellular Ca^{2+} release channels, whose structure differs considerably from that of the plasma membrane Ca^{2+} channels, include at least two classes of related proteins (for review, see references 26,27 and 28). The larger *ryanodine receptors*, so named because they bind to this plant alkaloid, mediate excitation-contraction coupling by releasing Ca^{2+} from the sarcoplasmic reticulum. A smaller class of Ca^{2+} channels, called *$InsP_3$ receptors*, are activated by inositol triphosphate ($InsP_3$). Both the ryanodine receptors and the $InsP_3$ receptors are tetrameric structures in which the four subunits surround a central pore through which Ca^{2+} is released when the channel is opened (*e*Fig. 102.0.13).

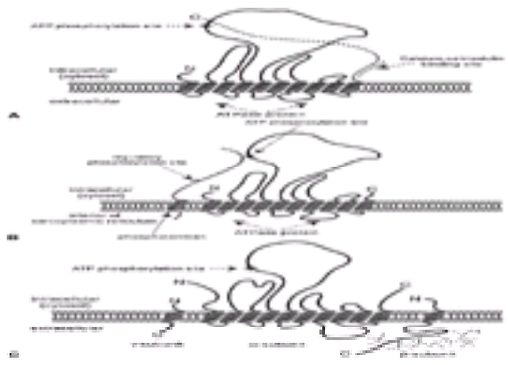


***e*FIGURE 102.0.13** Schematic representation of a single Ca^{2+} release channel (foot protein or ryanodine receptor) in a dyad. **A:** View through the plane of the bilayer showing the plasma membrane (*above*) and the subsarcolemmal cisterna (*below*). The former contains an L-type Ca^{2+} channel that delivers Ca^{2+} to a binding site on the sarcoplasmic reticulum Ca^{2+} release channel. Each of the latter is a tetrameric structure that contains an intramembranous domain (M) and a large foot (F). Opening of the sarcoplasmic reticulum channel opens pores (*dark areas*). **B:** Intracellular Ca^{2+} release channel viewed from within the lumen of the subsarcolemmal cisterna, which faces the intramembranous domain (*left*), and from the cytosolic space within the dyad, which faces the foot. The intramembranous domain contains a central channel, whereas four radial channels are found within the foot (*right*). (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

The explosive contractile responses of cardiac and skeletal muscle are initiated by the opening of the ryanodine receptors, whereas the smaller $InsP_3$ receptors initiate the slower contractile responses in smooth muscle (29). In the heart, slow Ca^{2+} release by the $InsP_3$ receptors may, like Ca^{2+} entry through T-type Ca^{2+} channels, regulate proliferative responses, such as cell growth, differentiation, and programmed cell death (apoptosis).

Ca^{2+} Pump Adenosine Triphosphatases

The Ca^{2+} pump ATPases are members of a family called *P-type ion pumps* that contains ten membrane-spanning a-helices and a large "head" that projects into the cytosol (*e*Fig. 102.0.14) (for review, see reference 30). All use a similar reaction mechanism to couple the hydrolysis of the high-energy phosphate bond of ATP to ion transport. The cardiac plasma membrane Ca^{2+} pump (31,32) is larger than that of the sarcoplasmic reticulum, called *SERCA* [sarco(endo)plasmic reticulum Ca^{2+} ATPase]; both share a similar reaction mechanism, but they are regulated differently.



***e*FIGURE 102.0.14** Molecular structure of three P-type adenosine triphosphatase pump proteins. The plasma membrane Ca^{2+} pump **(A)**, sarcoplasmic reticulum Ca^{2+} pump **(B)**, and major a-subunit of the Na^{+} pump **(C)** contain ten membrane-spanning a-helices within the plane of the membrane bilayer. In all three proteins, a large cytosolic loop between the fourth and fifth membrane-spanning helices contains the active site that is phosphorylated by adenosine triphosphate (ATP) to provide energy for active transport. In the plasma membrane Ca^{2+} pump **(A)**, a portion of the C-terminal peptide chain provides a regulatory site that binds the Ca^{2+}-calmodulin complex. Phospholamban, which regulates the sarcoplasmic reticulum Ca^{2+} pump **(B)**, has a sequence similar to the C-terminal portion of the plasma membrane Ca^{2+} pump. The Na^{+} pump has three subunits; the larger a-subunit contains the Na^{+}-, K^{+}-, ATP-, and cardiac glycoside–binding sites. The glycosylated b-subunit and small g-subunit regulate Na^{+} pump activity. C, C terminus; N, N terminus. (From Katz AM. *Physiology of the heart*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)

The sarcoplasmic reticulum Ca^{2+} pump is stimulated when cyclic AMP stimulates PK-A to catalyze the phosphorylation of phospholamban that, when phosphorylated, accelerates Ca^{2+} uptake by SERCA (for review, see reference 33). The result is accelerated relaxation and increased Ca^{2+} stores in the sarcoplasmic reticulum that contribute to the lusitropic and inotropic effects of beta-adrenergic stimulation (34). Phospholamban can also be phosphorylated by a Ca^{2+}-calmodulin–dependent protein kinase, which helps rid the cytosol of excess Ca^{2+}. The plasma membrane Ca^{2+} pump ATPase is stimulated when the Ca^{2+}-calmodulin complex binds to an inhibitory site located on the C-terminal domain of the molecule (31), which promotes Ca^{2+} efflux from Ca^{2+}-overloaded cells.

Na^{+}/Ca^{2+} Exchanger

A second mechanism that transports Ca^{2+} out of the cytosol is the Na^{+}/Ca^{2+} exchanger, which uses the osmotic energy of the Na^{+} gradient across the plasma membrane for the uphill transport of Ca^{2+} (for review, see references 35,36 and 37). The Na^{+}/Ca^{2+} exchanger is a large membrane protein that contains 12 a-helical transmembrane segments and so differs structurally from the Ca^{2+} pump ATPases.

Ca^{2+} efflux via the Na^{+}/Ca^{2+} exchanger occurs when one cytosolic Ca^{2+} ion is exchanged for three Na^{+} ions that enter the cytosol, so that Na^{+}/Ca^{2+} exchange generates a small ionic current. These currents are small, and probably contribute less than a few millivolts to membrane potential. The electrogenicity also allows membrane potential to influence ion exchange. In resting cells, the negative intracellular potential tends to pull Na^{+} into the cell, so that during diastole the exchanger favors Ca^{2+} efflux, whereas reversal of membrane potential during systole, when the cell interior becomes positively charged, has the opposite effect and favors Ca^{2+} influx. The ultimate energy source for Ca^{2+} transport out of the cell via the exchanger is the Na^{+} gradient established by the Na^{+}-K^{+} ATPase (Na^{+} pump).

Na^{+} Pump

The Na^{+} pump serves several functions in the myocardium (for review, see reference 38). Most important are to exchange the small amount of Na^{+} that enters the cell during each action potential for K^{+} lost during repolarization and to generate a Na^{+} gradient across the plasma membrane that can be coupled to the active transport of several molecules, notably Ca^{2+} (see earlier). Because three Na^{+} ions are exchanged for only two K^{+} ions, the Na^{+} pump is electrogenic, generating a small, repolarizing current.

Ca^{2+} Retention within the Sarcoplasmic Reticulum

Although some of the Ca^{2+} stored in the sarcoplasmic reticulum is free (ionized), much of this cation is associated with Ca^{2+}-binding proteins that include *calsequestrin*, *calreticulin,* and a *histidine-rich calcium-binding protein* (39). These Ca^{2+}-binding proteins, which are concentrated in the subsarcolemmal cisternae, store Ca^{2+} for release through the Ca^{2+} release channels.

Mitochondria

Mitochondria, although serving primarily to regenerate ATP, can also take up Ca^{2+}. Because of the low Ca^{2+} affinity of mitochondrial Ca^{2+} uptake, little mitochondrial Ca^{2+} transport occurs at physiologic cytosolic Ca^{2+} concentrations. For this reason, these energy-producing structures do not normally play a role in excitation-contraction coupling. Under conditions of Ca^{2+} overload, the mitochondria can “buffer” cytosolic Ca^{2+} and so protect the myocardium from the detrimental effects of excess Ca^{2+}.

SUMMARY

Contraction of the working cells of the myocardium involves interactions among six proteins: myosin of the thick filament, actin, tropomyosin, and the three components of troponin in the thin filament. These interactions are controlled by the downhill movement of Ca^{2+} into the cytosol (excitation-contraction coupling) and active Ca^{2+} transport out of the cytosol. All of these Ca^{2+} fluxes are highly regulated, which provides for the changes in cardiac muscle chemistry that give rise to changes in myocardial contractility.

THE FUTURE

As knowledge of the biochemistry of myocardial contraction, excitation-contraction coupling, and relaxation have become clarified, new questions as to molecular alterations in the contractile machinery have come into focus. Important advances can be expected in areas that relate alterations in the mechanical behavior of muscle to changes in the composition of the myocardial cell. Links between these aspects of functional signaling and the proliferative signal transduction pathways that control cell differentiation, growth, and death (apoptosis) should provide new insights into the mechanism—and treatment—of heart disease.

OVERVIEW

Heart development results from a complex but highly integrated series of interactions involving various cell types of diverse origins. These are carried out in a strictly regulated environment at both genetic and epigenetic levels. This chapter focuses on the molecular control of the sequential processes involved in heart development, from cardiac progenitors through the fully developed four-chambered heart. Recent advances in cardiomyogenesis, including commitment, differentiation, and modulation of cardiac muscle lineage, are described. The critical role of the neural crest to cardiac development and the genetic basis for cardiac malformations are also presented.

The heart is a unique organ. Its development begins shortly after the onset of embryogenesis, and it is functional long before other parts of the embryo are discernible. It comprises diversified cell types of different embryonic lineages, including myocyte of the myocardium, endothelial cells of the endocardium, and cells of the neural crest that participate in the formation of the outflow tract. Each cell type has distinct inherent potential for proliferation, growth, cell migration, and cell death. Accordingly, the process of heart development follows a complex series of events involving highly integrated and programmed morphogenetic interactions among the cells of various origins. To understand heart formation at the very early stages of development, it is imperative to analyze the basic cell biology of the constituent cells and identify the key factors that regulate their development. Recent advances in molecular biology, such as gene cloning, immunohistochemistry, *in situ* hybridization, and targeted mutagenesis, have introduced new insights. This chapter is divided into three main parts: (a) molecular changes during heart development, (b) regulation of cardiac myogenesis, and (c) current concepts on cardiac malformations.

MOLECULAR BASIS OF THE DEVELOPING HEART

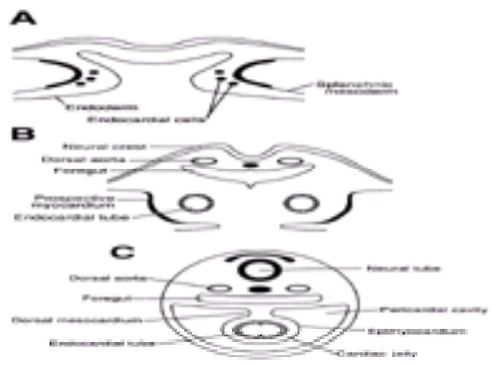
In this section, we briefly describe the molecular changes at various morphologic stages, starting from cardiac primordia through the fully developed four-chambered heart. *e*Table 103.0.1 summarizes the important genes and their functions in vertebrates.

***e*TABLE 103.0.1** ROLE OF DIFFERENT GENE PRODUCTS IN DIFFERENT STAGES OF HEART DEVELOPMENT

Morphologic changes/developmental stages	Genes	Gene function
Cardiac progenitors	Adhesion molecules (cadherins, catenins)	Show restricted expression in cell clusters that subsequently form splanchnic mesoderm.
	Bone morphogenic protein	Expressed in endoderm, induces expression of Nkx2-5 in the overlying cardiogenic mesoderm.
	GATA-6	Reduction in GATA-6 is required for cardiac progenitors to proceed in development.
Cardiac tube	Tinman/Nkx2-5/Csx	Essential for heart development.
	GATA-4, retinoic acid receptor signaling	Participates in ventromedial migration and eventual fusion of cardiac progenitors.
Cardiac looping	Signaling molecules (activin receptors, Shh, nodal, cSnR, Pitx-2)	Asymmetric expression along left-right axis is essential for looping.
	Gap junction protein connexin 43	Mutations are associated with left and right atrial isomerism.
Septae formation	Bone morphogenetic protein 4, transforming growth factor-b, Msx-1,2	Show regional expression in atrioventricular canal and conotruncus.
	N-CAM, tenascin	Involved in transformation of endocardial cells to mesenchymal cells.
Valves	Fibrillin, fibulin, transforming growth factor-b	Involved in remodeling of cushion to valvular tissue.
	NFATC, Sox 4	Transcription factors show restricted expression, mutations result in defective semilunar and possibly atrioventricular valves.
	Smad6	Gene disruption leads to hyperplasia of cardiac valves and outflow tract.
	Epidermal growth factor receptors (ErbB2, ErbB4)	Signaling between myocardial receptor and endocardial ligand is essential for trabeculae growth.
Trabeculation	Neuregulins	Ligand for ErbB2 and ErbB4 expressed in the endocardium, mutations in either receptors or ligand result in aborted trabeculations.
Conduction system	MSX-2	A homeobox gene expressed in the central portion of conduction system.

Cardiac Progenitors

In all vertebrates, the heart is derived from the splanchnic mesoderm and the endoderm situated in the anterior region of the developing embryo. Cardiac primordia appear as bilateral thickenings of the splanchnic mesoderm. In avians, heart specification occurs at about the time of Hamburger Hamilton (H-H) stages 3 to 4 (1); in humans, it occurs during the third week of embryogenesis, right after gastrulation when three germ layers are formed and simple diffusion alone is no longer adequate for the nutritional requirements of the embryo. These precardiac areas situated on either side of the embryonic midline contain splanchnic mesodermal cells, the preendocardial cells, and associated extracellular matrix (*e*Fig. 103.0.1). In chick embryos (H-H stages 5 to 9), expression of certain adhesion molecules such as N-cadherin and catenins is restricted to specific cell clusters that subsequently develop into cardiac splanchnic mesoderm, suggesting their important roles in early heart specification (2).



***e*FIGURE 103.0.1** Diagram illustrating paired cardiac primordia undergoing fusion to form a single heart tube. **A:** Endocardial cells appear between the endoderm and splanchnic mesoderm. The prospective myocardium is seen as bilateral thickenings of splanchnic mesoderm. **B:** The prospective myocardium is bending toward the embryonic midline enwrapping both endocardial tubes. **C:** The two endocardial tubes have undergone fusion, and the unfused mesodermal layer remains as dorsal mesocardium.

Studies in avians and amphibians have demonstrated that endodermal cells play an inductive role in cardiogenesis and in the subsequent beating of the primitive heart. In chick embryos, removal of the endodermal cells at H-H stage 4 prevented heart formation (3). A recent study involving cultured explants of chick embryo at H-H stage 6 further emphasized the role of endodermal cells (4). In this study, explants from anterior endoderm/mesoderm underwent terminal differentiation, whereas those from anterior ectoderm/mesoderm or posterior endoderm/mesoderm did not, suggesting the role of anterior endoderm in providing the inducers. One such molecule includes bone morphogenetic protein (BMP-2), which is expressed in the endoderm and is able to induce expression of transcription factor Csx/Nkx2-5 (*c*ardiac-*s*pecific homeob*x*/*n*eurenberg *k*im homeob*x*) in the overlying (cardiogenic) mesoderm (5). Nkx2-5 is a homologue of *Drosophila tinman* and shows conserved expression in many species including humans (6). Targeted disruption of *NKX-2.5* results in abnormal morphogenesis, growth retardation, and even embryonic death (7). These studies underscore the important role of homeobox genes in specifying heart mesoderm and during cardiogenesis.

Lineage-labeling studies suggest that mesoderm and endoderm cells arise from a common progenitor. The two germ layers of cardiac primordia retain certain properties in common, as for example, expression of certain key transcription factors belonging to NKX and GATA families of proteins. Some of these factors such as GATA-6 maintain heart cells in precursor state, and reduction in GATA-6 is required for the progenitors to proceed in development (8).

Formation of the Tubular Heart and Looping

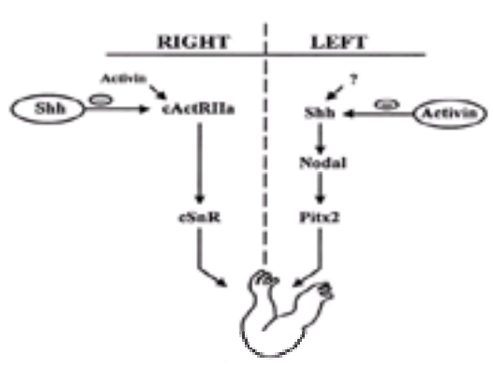
As development proceeds, after closure of the neural tube and subsequent folding of the embryo, the cardiogenic area is pulled forward and rotated approximately 180 degrees along a transverse axis. This results in the two lateral endothelial/mesodermal primordia approximating each other and eventually fusing to form the cardiac tube. Fusion of the mesodermal layers begins at the cephalic end and progresses toward the caudal end. Although the molecular events during these changes have not been fully characterized, several studies implicate the role of retinoic acid receptor signaling pathways. Treatment with retinoic acid in chicks inhibited embryonic folding, resulting in persistence of the cardiac progenitors at their posterior and medial positions and failure of primordial fusion at the midline (9). In addition, injection of antibodies against N-cadherins (to block the actions of cadherins) into cultured chick embryos (stages 5 to 12) blocked the fusion (10).

Transcription factor GATA-4 has also been emphasized to play a role in heart tube formation in two separate studies using gene targeting to produce GATA-deficient mice in which cardiac primordia failed to migrate ventrally (11,12). Because GATA-4 is expressed both in the endoderm as well as in the cardiogenic mesoderm, it is the endodermal expression that contributes to the heart development (13). More recently a cofactor of GATA (FOG-2) has been cloned (14) and shown to repress GATA-4–dependent transcription (15). FOG-2–deficient mice die of heart failure at E13 and show several septal defects (16).

After fusion of the paired primordia at the midline, a straight heart tube located inside the pericardial cavity shows an outer mesenchymal layer, or *myocardium*, and an inner endothelial layer, or *endocardium*. A gelatinous substance, the cardiac jelly, which is later invaded by cells derived from the endothelium, separates the two layers. Eventually, the wall of the heart tube consists of three layers: the endocardium, the myocardium, and the epicardium. At this stage, the cardiac tube can be divided into a bulboventricular portion located inside the pericardial cavity, an atrial portion, and a paired sinus venosus lying outside the pericardium. Subsequent development results in elongation and bending of the cardiac tube in such a manner that the cranial portion of the tube bends in a ventral and caudal direction to the right, whereas the caudal atrial portion shifts in a dorsocranial direction to the left.

Looping of the heart toward the right provides the first indication of programmed left-right asymmetry. The direction of looping is conserved within the vertebrate phyla, suggesting that it is an evolutionary conserved course of events (17). Asymmetric looping of the cardiac tube is essential for the proper spatial orientation of the future right and left cardiac chambers. Understanding the mechanisms for the dominant right-sided heart looping is crucial, because several syndromes display laterality defects, including a laterality mutation that was mapped to the X chromosome in humans (18).

Asymmetric expression of several signaling molecules mainly belonging to transforming growth factor-b (TGF-b) family is essential to cardiac looping. Experimental perturbation of their expression pattern results in randomized looping (19,20 and 21). These molecules include activin; activin receptor protein (cAct RIIa); Shh, a vertebrate homologue of *Drosophila melanogaster* hedgehog protein; and nodal. Analysis of these transcripts during and after gastrulation showed transient asymmetric expression along the left-right axis of the chick embryo just before the onset of cardiac looping (19,20 and 21). At H-H stage 4, the cAct RIIa is expressed in the ectodermal layer near the right side of Hensen's node. Shortly thereafter, Shh is expressed on the left side in the same germ layer, and in subsequent hours, nodal is expressed on the left side but in the mesodermal layer. These molecules regulate the expression of one another in a sequential pathway such that activin stimulates cAct RIIa and suppresses the expression of Shh along the right axis (eFig. 103.0.2). Absence of cAct RIIa allows Shh to be expressed and stimulates nodal gene expression along the left axis. Manipulation of the sidedness of these molecules by ectopically expressing either activin or Shh protein also results in randomized cardiac looping (20). A putative transcription factor encoded by a snail-related gene *cSnR* also is implicated in the process of cardiac looping (21). In the chick embryo, the mRNA for this gene was expressed in the right lateral plate mesoderm in a domain that roughly mirrored that of nodal on the left. Antisense disruption of this transcript before heart formation randomized cardiac looping (21). The expression of another transcription factor, Pitx2, is induced by nodal and Shh in the left lateral plate mesoderm and, subsequently, on the left side of the developing heart. Forced expression of Pitx2 on the right side of the developing embryo was sufficient to reverse cardiac looping and heart isomerisms (22). Thus, these studies collectively suggest that asymmetric expression of some of the signaling molecules and certain transcription factors is crucial for the normal cardiac looping to the right.



***e*FIGURE 103.0.2** Signaling molecules implicated in the process of cardiac looping. Activin molecule induces cAct RIIa and cSnR on right; Shh induces expression of nodal on the left side of the embryo. Signal for the induction of Shh's expression on left is not known (?). Ectopic expression of Shh on the right, or of activin on the left, randomizes asymmetric expression of these molecules as well as of cardiac looping. —, inhibitory effect on the expression of target protein.

Other embryologic manipulations, such as stimulation of the $alpha_1$-adrenergic receptor subtype in rat neurula-stage embryos, result in randomization of cardiac asymmetry (23). A gap junction protein, connexin 43, also plays an important role in defining left-right asymmetry. In a clinical study, patients with visceroatrial heterotaxia syndrome and complex cardiac malformations (including right or left atrial isomerism) showed mutations in the coding region of the connexin 43 gene (24).

In addition, transgenic mice embryos with homozygous mutation in the connexin 43 gene showed a laterality defect (25).

Chamber Formation

Septa and Valve Formation

The transformation of the developing heart from a simple tube to a four-chamber structure containing valves and septa is accomplished through highly integrated and sequential processes of cell proliferation and cell migration. The heart tube is subdivided into segments that give rise to the outflow tract (*conotruncus*), the ventricle, the atrioventricular (AV) canal, and the atrium. Segmentation of heart tube is accomplished by regionally restricted changes surrounding two regions: the AV canal site and the outflow tract. Endocardial cells in the two regions extend pseudopodia and filopodia and eventually migrate into the cardiac jelly, where they become mesenchymal cells. As cell density progressively increases, the previously acellular cardiac jelly becomes transformed into mesenchymal outgrowths known as *endocardial cushions*.

Why is transformation of endocardial cells to cushion-forming mesenchymal cells restricted regionally to the AV canal region and to the outflow tract? This process was studied extensively in chicks by Runyan et al. (26) and Eisenberg and Markwald (27). It has been suggested that a regional induction signal emanating from the myocardium acts on the endocardium to initiate this transformation. Regional specificity is provided by the ability of the myocardium to produce the inducer(s) and endocardial endothelial cells to respond. Alterations in the expression of several genes have been demonstrated during AV canal morphogenesis. In particular, members of the TGF-b family (BMP-4, TGF-b_1, and TGF-b_2), homeobox genes (*Msx*-1, *Mox*-1), and Es antigens (adherons) show restricted expressions in the AV canal and conotruncal regions. The cell adhesion molecule N-CAM, initially expressed throughout the endocardium, is greatly downregulated after transformation of endocardial to mesenchymal cells. On the other hand, the substrate adhesion molecule, tenascin, is upregulated in the transformed cells. Tenascin disrupts cell substrate adhesion, thus allowing cells to migrate more freely. Abnormalities or arrests in these processes may result in developmental abnormalities of the AV canal and conotruncal regions.

The interatrial septum originates as an invagination from the dorsocephalic wall of the atrium between the openings of the sinus venosus and pulmonary veins to form a thin myocardial partition between the atria. Formation of the interventricular septum is intimately related to myocardial trabeculation.

The primordia of the semilunar valves are three pairs of small tubercles of the cushion tissue, whereas the primordia of the AV valve leaflets consist of cushion as well as muscular tissues. In mammalian embryos, the muscular tissues are soon replaced by connective tissue, and only occasionally are muscle fibers found at the base of the leaflets in the mature heart. It is now clear that cushion mesenchymal cells differentiate into fibrous connective tissue of both the semilunar and AV valves and that this process correlates with the expression of two microfibrillar proteins, fibrillin and fibulin (28,29). Sulfated proteoglycans (another matrix protein) have also been implicated in this remodeling process (30). Furthermore, several regulatory molecules may participate in valvulogenesis, including TGF-b_1, which maintains high expression levels throughout valve formation (26). More recently, transcription factors NF-ATc and Sox 4 have been shown to play important roles in valve formation (31,32 and 33). In normal embryos, Sox 4 has specific expression in the endocardial cushion and ridges, and NF-ATc has restricted but transient expression in endocardial cushion, followed by outflow tract and developing valves (32,33). Targeted disruption of NF-ATc and Sox 4 gene products in mice has resulted in embryonic death before day 14.5 due to circulatory failure. These mutants showed defective development of the semilunar valves and ventricular septum; the mitral and tricuspid valves had normal development (32) or restricted development (31). Nuclear localization of NF-ATc involves Ca^{2+}/calicineurin–signaling pathway; however, the ligand and receptor involved, and their downstream targets, are not known. Smad6 involved in signaling of TGF-b family (activins and BMPs) shows restricted expression in the developing heart, and its disruption leads to hyperplasia of cardiac valves and outflow tract (34).

Myocardial Trabeculation

At the final stages of loop formation, the myocardium is a compact epithelial tissue layer formed exclusively of myocytes. In the ventricular region, wide intercellular spaces start appearing between the myocardial cells, separating the myocardium into two distinct zones: a compact outer layer and an inner spongy layer. Simultaneously, the endocardium evaginates at discrete points, forming outpocketing that is directed toward the myocardium. When the endocardial outpocketing establishes contact with the myocardial basal surface, the myocardial cells separate to form little gaps. Subsequently, the endocardium penetrates the myocardial wall through these gaps and expands laterally into the previously formed intercellular spaces, resulting in primitive trabecular formation, which later assumes a more complex pattern. Most of the primitive trabeculae eventually disappear, but some coalesce to form papillary muscles or trabecula carneae of the mature heart. Continued trabeculae formation has an important developmental impact. It prevents unrestricted myocyte growth during cardiogenesis and at the same time ensures potential chamber cavity preservation. The net result is a ventricular structure that is not solid or excessively thick-walled and, consequently, able to perform the fundamental pump function during all stages of cardiac development and thereafter.

Signaling events between the endocardium and the myocardium are important for ventricular growth. Recent studies have demonstrated that cell surface receptors ErbB2 and ErbB4, both members of the epidermal growth factor receptor family, are involved in ventricular trabeculae formation. Transcripts of these receptors have been detected in the myocardium but not in the endocardium of the developing heart (35). The endocardium expresses neuregulins, which are ligands for these receptors. Mice deficient in receptors or their ligands die during mid-embryogenesis and show aborted development of myocardial trabeculae in the ventricle (36).

Conduction System

Establishment of the cardiac conduction system represents another cellular diversification of the developing myocardium. It is not precisely known when this system develops; however, experiments suggest that the conduction system is already functional during the final stages of cardiac loop formation. The cells of the future conduction system are found mostly in the vicinity of arterioles and show distinct morphologic features such as higher glycogen content and lesser myofibrils. The cells of the conduction system probably have dual origin because both muscle- and neuron-specific genes are coexpressed in these cells (37).

Molecular signals that promote and regulate the development of the conduction system from specialized cardiomyocytes have not been identified. The homeobox gene *Msx-2* is expressed in central portions of the conduction system (38). The peripheral Purkinje fibers appear with the coronary arterial bed, suggesting participation of a blood-derived factor in the transformation of myocardial cells to Purkinje fibers (39).

Role of Neural Crest Cells

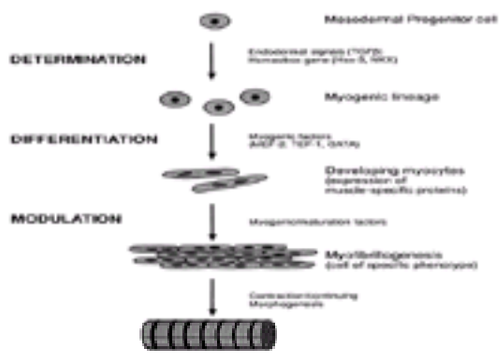
The neural crest exists only briefly during early embryonic development and constitutes a population of cells contained initially in the neural folds. As the neural plate closes to form the neural tube, neural crest cells are released from the neural folds. The neural crest is anatomically divided into two parts: a cranial region and a trunk region. A portion of the cranial region extending between midotic placodes and somite 3 is known as the *cardiac neural crest*. Cells of the cardiac neural crest play crucial roles in cardiac development. Ablation of the cardiac neural crest, either surgically or chemically, resulted in predictable cardiac malformations that include persistent truncus arteriosus and double-outlet right ventricle (reviewed in reference 40). More recently, neural crest cells, which contribute to the formation of the aorticopulmonary septum, have been directly visualized by specific cell-labeling techniques (41). The cardiac neural crest cells migrate to and populate pharyngeal arches 3, 4, and 6 to participate in the development of the major branches of the aortic arch.

Despite the critical role of the neural crest to cardiovascular development, little is known about its contribution at the molecular level. Suggested molecules include retinoic acid, vitamin A, endothelin-1, or endothelin-A receptor (42). Mice deficient in these molecules display similar cardiovascular abnormalities to those seen after neural crest ablation. Endothelin-3 has been shown to promote neural crest cell proliferation in a cell culture model (43). Candidate genes for neural crest origin belong to the homeodomain family of transcription factors such as Pax 3, Msx1, and Msx2 (reviewed in reference 44). Besides neural crest, these genes are also expressed in the outflow tract region and in the endocardial cushion of the developing heart. Transgenic mice deficient in one of these regulatory molecules display normal cardiovascular development, but double homozygous-deficient mice show cardiac defects (44), suggesting that these transcription factors may cooperate in the regulation of as yet unidentified target genes. Other genes of cardiac neural crest origin include the *bHLH* gene products dHAND and eHAND, which are expressed in crest-derived tissue structures (45).

MOLECULAR REGULATION OF CARDIAC MYOGENESIS

Myogenesis of cross-striated muscle consists of three basic developmental stages: (a) commitment (also known as *determination*), (b) differentiation, and (c) modulation (or *maturation*). During *commitment*, the mesodermal cell is specified to a muscle lineage such that the committed cell, unlike the noncommitted ones, will have restricted potential. *Differentiation* consists of expression of cardiac-specific proteins such as myosins, actins, troponins, tropomyosins, and channel proteins. Some investigators refer to “terminal differentiation” as either a state when a battery of cell-specific genes becomes turned on, resulting in the cells exhibiting morphologic and functional characteristics of their specific phenotype, or to a terminal pathway culminating in an irreversible phenotype. It has been argued, however, that terminal differentiation has little meaning because in many instances the differentiated state is not irreversible but requires continuous maintenance (46). *Modulation* is characterized by sequential changes in the pattern of gene expression whereby genes coding for some of muscle proteins are induced, whereas others become repressed. This stage of muscle maturation takes place during the fetal and neonatal periods when muscle cells begin to assume morphologic features

required for contractile function. The regulatory aspects of these various stages are summarized in *e*Figure 103.0.3.



***e*FIGURE 103.0.3** Schematic illustration of molecular events during cardiac myogenesis. Stages of myogenesis are represented by (1) determination, conversion of progenitor cells to myogenic lineage; (2) differentiation, conversion of lineage-specific cells to myocytes that now express muscle-specific proteins, and (3) modulation, the process of maturation resulting in a specific phenotype. Regulatory factors involved in different stages of myogenesis are shown. MEF-2, myocyte enhancer factor 2; TEF, transcription enhancer factor; TGFb, transforming growth factor-b.

Determination of Cardiogenic Muscle Lineage

Determination of lateral mesodermal cells to cardiac muscle lineage is an early event. In chick embryos, it occurs at the late primitive stage (47). The cardiogenic area shows regional differences along an anteroposterior axis such that the posteriorly positioned cardiac precursors express atrial-specific, but not ventricular-specific, myosin heavy chain (MHC). Thus, atrial and ventricular lineages are separately specified, and their determination is primarily based on the anteroposterior polarity of the heart progenitors in the very early embryo (reviewed in reference 48).

Our understanding regarding regulation of the determination stage of myogenesis is still fragmentary. Current theories predict two types of regulation. One consists of signals derived from neighboring endodermal cells because mesodermal cells cultured alone fail to express cardiac-specific muscle proteins. The role of endodermal inducers and other signaling mechanisms in lineage specification has been described above. The other type of regulation assumes an existing determination gene(s) coding for lineage-restricted factors that play an important role in commitment and differentiation of cardiogenic cells and are regulated by signals derived from the neighboring cells. These molecules fall into the category of transcription factors, which are DNA-binding proteins and regulate gene expression through interaction with regulatory elements in the target genes. Most of these regulators exist as multimember families, with each member sharing extensive sequence homology in their DNA binding domain, often providing redundancy to their function.

The well-described class of transcription factors that play important roles in cardiac muscle commitment and differentiation belong to homeobox proteins. Homeobox-containing genes were first defined in *Drosophila* to possess a 180–base pair conserved sequence motif that encodes a helix-turn-helix DNA-binding domain called a *homeodomain*. Mammalian homeobox genes may be divided into two classes: hox-class genes and non–hox-class genes. Hox-class genes exist in four clusters in the mammalian genome and appear to convey positional information rather than specification of cell type. Members of hox-class genes, such as *Mox-1* and *Mox-2*, are expressed in the posterior mesoderm during early mouse embryogenesis before extensive mesoderm patterning is apparent. Other members, such as *Hox-7*, *Hox-3.1*, and *Hox-1.5*, display different but overlapping patterns of expression. The interplay of these proteins is considered to have major roles in both early and late embryonic and fetal heart development (reviewed in reference 49). The importance of non-hox proteins (Nkx family) in cardiac lineage (progenitors) specification has been described. There are at least six different Nkx-2 genes, but the expression pattern of only a few genes has been characterized (50). In Nkx2-5 knockout mice, the expression of several cardiac muscle genes was not affected, most likely due to genetic redundancy of Nkx-2 loci during cardiogenesis (50).

Differentiation and Activation of Cardiac Genes

Once committed, the precursor myogenic cells have the potential to express muscle genes through the process of differentiation, resulting in a cardiac-specific phenotype. Differentiation proceeds in a highly ordered anterior-to-posterior manner within the cardiogenic mesoderm. MHC mRNA has been detected in the cardiac primordia, suggesting that differentiation of lineage-specific cells occurs much before the primitive heart tube is formed. In the newly formed cardiac tube, the expression of different contractile proteins varies along the antero-posterior axis (51). In the developing heart, all cardiac myoblasts undergo differentiation, and further increase in number occurs strictly through mitosis of differentiated myocytes. Mitotic potential is lost once cardiomyocytes attain their adult phenotype during development. Regulation of muscle cell differentiation is provided by transcription factors that belong to the basic helix-loop-helix (bHLH) proteins, transcription enhancer factor 1 (TEF-1) proteins, and myocyte enhancer factor 2 (MEF-2) and GATA family of factors. A list of these factors, target genes, and their role in muscle gene regulation is provided in *e*Table 103.0.2.

***e*TABLE 103.0.2** IMPORTANT FACTORS INVOLVED IN CARDIAC MUSCLE GENE TRANSCRIPTION

Transcription factor	Target sequence	Name	Gene regulation
MEF-2	CT (A/T)(A/T) AAATAG	AT-rich	Expressed in cardiac precursors; regulate cardiac and skeletal muscle genes
TEF-1	CATTCCT	M-CAT	Muscle-specific expression of cardiac troponin-T and a- and b-MHC genes; protein kinase C–induced expression of b-MHC gene
Myc family	CANNTG	E-box	Cardiac-specific expression of a-MHC
GATA family	GATA	GATA	Expressed in cardiac precursors; involved in cardiac tube formation
TEF-1 and MAX	CACGTGGAATG	EM	Cyclic adenosine monophosphate– and contractility-induced regulation of a-MHC
T_3 receptor (c-erbA)	C (T/A) GGAGG (T/A)	TRE	T_3-induced expression of a-MHC

EM, E-box/M-CAT element; M-CAT, muscle CAT element; MEF-2, myocyte enhancer factor 2; MHC, myosin heavy chain; TEF-1, transcription enhancer factor 1; TRE, thyroid response element; T_3, thyroid hormone.

Basic Helix-Loop-Helix Proteins

Many, but not all, sarcomeric proteins are expressed in cardiac as well as in skeletal muscle cells, suggesting that overlapping as well as divergent regulatory pathways must be involved in their expression. Of the known factors in skeletal muscle gene transcription, members of the *MyoD family* (MyoD, Myf-5, myogenin, and MRF-4) are the best understood. They share a high degree of homology in their DNA-binding domain, referred to as *bHLH domain*. Proteins of the bHLH class mediate their effects by forming heterodimers with other ubiquitously expressed proteins known as *E-proteins* (52). The MyoD family of bHLH proteins has not been detected in cardiac myocytes, and double-mutant (Myf-$5^{-/-}$MyoD$^{-/-}$) mice develop normally functioning hearts (52,53). However, the MyoD inhibitor Id is present in cardiac cells and, similar to skeletal muscle, is regulated by alpha-adrenergic agonists and by serum (54). In addition, forced expression of Id downregulates transcription from both skeletal and cardiac actin promoter constructs in neonatal cardiac myocytes (55). These findings suggest that the cardiac cell context is permissive to the E-box–dependent pathway and must involve a separate class of transcription factors for the regulation of cardiac-specific genes. Recently, such a role has been assigned to the bHLH-LZ class (myc family) of factors, which mediate their effects through E-box (56). Transgenic studies involving knockouts of the N-*myc* gene resulted in embryonic death around embryonic day 11, accompanied by multiple developmental defects of the myocardium and interventricular septum and consequent pump failure. N-myc, like other myc proteins, is able to transactivate target genes by binding to specific DNA sequences as a heterodimer with another protein, Max. Nevertheless, the downstream target genes in cardiomyocytes are not known (reviewed in reference 57).

Transcription Enhancer Factor 1 Proteins

Another class of factors necessary for muscle-specific gene expression in both the cardiac and skeletal muscle cell context binds to the muscle CAT (M-CAT) (CATTCCT) element originally identified in the regulation of cardiac troponin-T gene. The factor binding to the M-CAT element is related to TEF-1 (58), which belongs to a family of factors having TEA/ATTS DNA-binding domain. Transcripts of TEF-1 family members are abundant in many tissues, and cardiac- and neuronal cell–specific isoforms have recently been reported. Knockout experiments of TEF-1 resulted in fetal death from cardiac malformation, including thinning of the ventricular wall (59). One interesting feature in many TEF-1–regulated muscle genes relates to the TEF-1 binding site, M-CAT, located at an overlapping site or in close

proximity to a canonical E-box binding consensus. Such a hybrid motif located immediately upstream to the TATA box sequence was identified in the rat cardiac a-*MHC* gene responsible for muscle-specific as well as contraction-induced gene expression in cultured cardiac myocytes (60,61). Similar motifs have been described in the human b-*MHC* gene and in the avian cardiac troponin-T genes, where both the E-box and M-CAT elements are functionally important in determining promoter specificity of the gene (61). Two factors, Max and TEF-1, bind this hybrid motif in the rat cardiac a-*MHC* gene. These two factors physically interact with each other both *in vitro* and *in vivo,* and transactivate the a-*MHC*/*CAT* gene. Thus, a cooperative synergism exists between TEF-1 and Max for cardiac muscle gene regulation (56). Recently TEF-1 has been shown to be a substrate for protein kinase A–dependent phosphorylation, which enhances the activation potential of TEF-1 for a-*MHC* gene transcription (62).

MCM1, Agamous, Deficiens, and Serum Response Factor Proteins

The MADS [name derived from four of the originally identified members: *M*CM1, *a*gamous, *d*eficiens, and *s*erum response factor (SRF)] family of transcription factors share a conserved DNA-binding domain (MADS-box). The majority of MADS-box proteins binds to consensus sequence $CC(A/T)_6GG$ and recruits other transcription factors into multicomponent regulatory complexes with subtly different DNA-binding specificities (63 and references therein). Until recently, SRF has been considered as a ubiquitous transcription factor involved in regulation of growth factor–responsive genes; however, preferential expression of SRF has been demonstrated in chick myogenic lineages, in adult murine skeletal and cardiac muscle, and in the embryonic heart. SRF promoter activity is also higher in muscle cell background (64). Further, SRF physically interacts with Nkx-2.5 and results in strong transcriptional activation of the cardiac alpha-actin promoter via serum response element (65). Additionally, effect of SRF is enhanced by TEF-1 for the activation of rat a-skeletal actin promoter (66). Thus, through cooperative interaction, SRF controls muscle gene expression. Recent gene knockout studies have shown an obligatory role of SRF in mesoderm differentiation (67).

MEF-2, another member of MADS proteins, comprises a subfamily of transcription factors that also participate in muscle gene regulation. Four MEF-2 isoforms (MEF-2A through D) are expressed in the precursors of cardiac muscle lineage, have the ability to physically interact with the MyoD family of factors, and together can activate muscle gene promoters. Mutations in the MEF-2 gene in *Drosophila* blocked differentiation of all muscle cell types in the embryo (68 and references therein). This family of transcription factors is regulated by non–hox-class determination factors, as the MEF-2D gene has recently been shown to be a target for Nkx activation (69). A homozygous mouse with null mutation of MEF-2C has shown failure of the cardiac tube to undergo looping and nonexpression of muscle genes (70), demonstrating the importance of these factors in cardiogenesis.

GATA Proteins

The GATA family of transcription factors binds to GATA-rich sequences in various cardiac gene promoters. Expression of GATA-4 and GATA-5 has been detected in the splanchnic mesoderm and subsequently in endocardial and myocardial layers of the developing heart. These factors were originally thought to play roles in cardiac muscle cell differentiation. However, studies in transgenic mice deficient in GATA-4 have demonstrated normal development of splanchnic mesoderm, its differentiation into primitive cardiomyocytes, and normal expression of contractile proteins. Thus, in spite of their crucial role in early morphogenesis, GATA proteins are not essential for the induction of the cardiac myogenic program (11,12).

Modulation of Gene Transcription by Extrinsic Factors

Differentiation, as described previously, is due to the activation of muscle gene transcription, followed by sequential changes in gene expression, resulting in replacement of some isoforms by others. In some cases, this diversity is generated at the transcriptional level (e.g., MHCs); in others it is achieved by alternative splicing of gene transcripts as seen in tropomyosin or troponin T. From a pool of various isoforms, only a subset is expressed at any given time. Some of these changes follow an intrinsic program, whereas others require hormonal input.

Among the isoform families, the MHCs have been studied most extensively. In rodents, the two isoforms of MHC (a and b) are already coexpressed in the newly formed cardiac tube. As trabeculation begins, selective downregulation of a-MHC expression occurs in the ventricle; however, a-MHC expression in the atria remains unchanged. After a-MHC mRNA has decreased to the lowest level in the developing ventricular myocardium, it begins to increase just before birth and ultimately replaces all b-MHC mRNA postnatally (71). The well-described hormonal signals involved in this transition are thyroid hormones (THs) and catecholamines. This dynamic state of muscle phenotypes (also known as *phenotypic plasticity*) is noticeable not only during embryonic and fetal development but also postnatally, and even in adult animals.

Thyroid Hormone

TH exerts a variety of effects on gene transcription of several muscle genes. Its role in modulating cardiac muscle gene transcription is complex because the same gene responds to the hormone differently in different chambers of the heart or in different cell backgrounds. For example, TH influences a-MHC expression in the ventricle but the atria remain unresponsive. Likewise, b-MHC is repressed by the TH in the ventricle but remains almost unaffected in slow-type skeletal muscle (72).

The molecular mechanism of the TH action is mediated through its binding to a TH receptor, which is a nuclear protein product of the *c-erbA* protooncogene (73). These receptors are hormone-dependent transcription factors and exert their effects by binding to a hormone-responsive DNA element thyroid response element (TRE) in the target gene. The TH effect on a-*MHC* gene expression is mediated by TRE present in the 5' promoter region of both the human and rat a-*MHC* genes. This TRE is responsive to TH even on a heterologous promoter, suggesting that TRE of the a-*MHC* gene acts as an enhancer element (73). The mechanism for the TH-dependent repression of b-*MHC* gene expression is not yet fully understood.

Adrenergic System

In recent years, several studies have documented the importance of alpha- and beta-adrenergic receptor pathways in the regulation of cardiac MHC gene transcription. These studies suggest that $alpha_1$-adrenergic receptor agonists activate b-*MHC* gene transcription through protein kinase C, whereas beta-adrenergic receptor agonists activate a-*MHC* gene transcription via protein kinase A–dependent pathway (reviewed in reference 74). In each case, the hormone-responsive sequence is identified in the promoter region of the respective genes. The protein kinase A pathway involves E-box/M-CAT hybrid motif in the a-*MHC* gene promoter that interacts with TEF-1. The protein kinase C mediates its effect via the M-CAT element of b-*MHC* gene promoter, which also recognizes TEF-1 (75). Thus, these observations implicate that TEF-1 binding is a functional end point for both alpha- and beta-adrenergic–regulated expression of cardiac *MHC* genes. The precise mechanism on how phosphorylation of TEF-1 by two different signaling pathways regulates expression of a- and b-*MHC* genes remains to be defined.

Recent studies have demonstrated the presence of cell clusters capable of synthesizing and releasing catecholamines in the atrial and ventricular chambers of the fetal heart at a developmental stage before the onset of sympathetic innervation (76). In addition, targeted disruption of enzyme genes of catecholamine synthesis (77) and of the beta-adrenergic receptor kinase (78) resulted in embryonic death and severe anomalies of the heart. These observations indicate an important contributory role of the adrenergic pathway to the development and maintenance of the cardiac muscle phenotype.

GENETIC BASIS OF CONGENITAL HEART DEFECTS

Recent advances in cardiac molecular biology provide noteworthy insights into our understanding of congenital heart disease. Despite these advances, our knowledge remains fragmentary. In most cases, the abnormalities are linked to a specific locus, and only in a few cases have the gene abnormalities been identified. The role of a single gene product in the overall pathogenesis of the cardiac abnormality remains to be established. In this section, we briefly review the relevant literature pertaining to the genetic basis for congenital heart disease (summarized in *e*Table 103.0.3).

***e*TABLE 103.0.3** MOLECULAR BASIS OF HERITABLE CONGENITAL MALFORMATIONS

Disorder	Mode of inheritance	Chromosome location	Gene	Cardiovascular manifestation
Marfan syndrome	Autosomal dominant	15q21.1	Fibrillin-1	Aortic root dilation, elongated chordae, atrioventricular prolapse plus regurgitation, aortic dissection
Supravalvular aortic stenosis	Autosomal dominant	7q11.23	Elastin	Discrete or diffuse narrowing of ascending aorta
Williams syndrome	Sporadic	7q11.23	Elastin	Same as above plus other symptoms
Duchenne’s muscular dystrophy	X-linked	Xp21	Dystrophin	Dilated cardiomyopathy
CATCH 22 (DiGeorge, velocardiofacial syndrome, conotruncal heart defects)	Sporadic	22q11 deletion	Contiguous gene disorder	Interrupted aortic arch, truncus arteriosus, tetralogy of Fallot, double-outlet right ventricle
Long QT syndrome	Autosomal dominant	11p15.5	Na and K channel	Ventricular arrhythmias

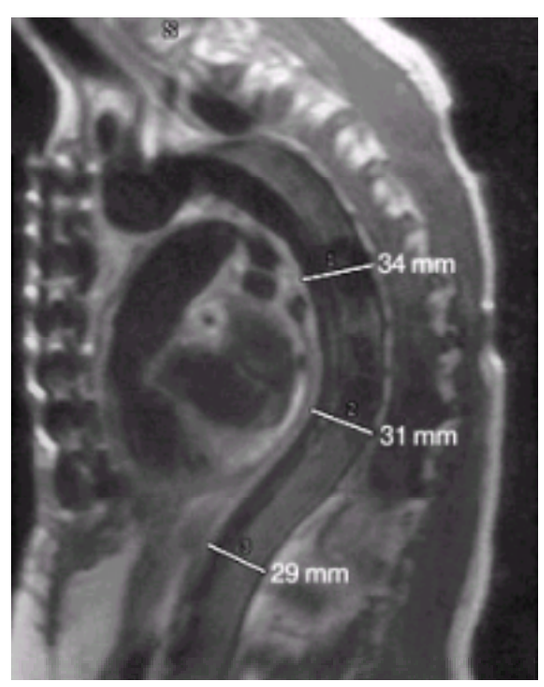
Holt-Oram syndrome	Autosomal dominant	12q2	TBX5	Atrial septal defects
Down syndrome	Autosomal dominant	21q22 (trisomy)	?	Atrioventricular canal defects
Familial hypertrophic cardiomyopathy	Autosomal dominant	14q11,15q21q3,11p13–q13, 7q3	b-MHC, cTnT, a-tropomyosin	Asymmetric cardiac hypertrophy and subaortic stenosis

Marfan Syndrome

Marfan syndrome is a pleiotropic, autosomal dominant, connective tissue disorder with prominent manifestations in the cardiovascular, skeletal, and ocular systems. The molecular genetic defect is linked to abnormalities in the *FBN1* gene, which is located on chromosome 15 and codes for fibrillin-1 protein. It is a microfibrillar protein that is a part of a multiprotein complex involving elastin and other extracellular matrix proteins. This protein has several epidermal growth factor-like repeats, suggesting an important role of these domains in its function. There are at least 30 different mutations described in the fibrillin gene in association with Marfan syndrome. These mutations result in truncated protein or affect its functional properties (reviewed in references 79 and 80). The mechanism by which abnormal fibrillin produces the Marfan syndrome phenotype is not known.

Ectopia lentis. This lens dislocation is associated with Marfan syndrome.

Arachnodactylia in Marfan syndrome. The ratio of finger length to hand size is markedly increased.



Magnetic resonance scan of the thoracic aorta in Marfan syndrome. There is dilation of the descending aorta with an average diameter of approximately 3 cm.

Supravalvular Aortic Stenosis

Supravalvular aortic stenosis (SVAS) is a congenital localized or diffuse narrowing of the ascending aorta that may occur sporadically, as a familial defect, or in relation with Williams syndrome (WS). WS is a contiguous gene syndrome associated with neurodevelopmental and multisystemic manifestation caused by hemizygous microdeletion of 1.4 MB at chromosomal 7q11.23. Genetic linkage analysis showed that alteration in elastin, an extracellular matrix component, may result in SVAS. The first evidence that elastin is defective in SVAS was provided by mapping studies on the long arm of chromosome 7 (81). Using positional cloning, three genes were identified at this locus, namely, collagen 1A2, laminin B1, and elastin. A truncated elastin protein was demonstrated in a family due to translocation of part of chromosome 6 to the elastin locus of chromosome 7 on one allele (82).

Monosomy at the elastin locus (7q11.23) has been demonstrated in many patients with WS and also may harbor mutations in nearby genes located near elastin (83). These additional mutations may account for the psychological and behavioral abnormalities associated with WS. More recently, six novel point mutations were identified in the elastin gene in patients with nonsyndromic SVAS from a total of eight unrelated families. These mutations resulted in selective elimination of the mutant

transcript and an overall decrease of the steady-state levels of elastin mRNA (84).

Duchenne's Muscular Dystrophy

Duchenne's muscular dystrophy is a common X-linked heritable form of muscle disease and is one of the most severe forms of muscular dystrophy, causing progressive muscle wasting and death in adolescence or early adulthood. Cardiac dysrhythmias and dilated cardiomyopathy are common features at the late stages of the disease. An X-linked dilated cardiomyopathy linkage has been provided to the locus of the dystrophin gene at Xp21 (85). Mutations in the dystrophin gene have been described as the genetic basis of Duchenne's muscular dystrophy. The gene codes for a cytoskeletal protein anchoring membrane proteins and may be involved in maintaining intracellular calcium levels. This protein is present widely, and multiple isoforms of dystrophin RNA are identified in the brain and skeletal and cardiac muscle. These isoforms show developmentally regulated expression in different tissues (86).

DiGeorge Syndrome

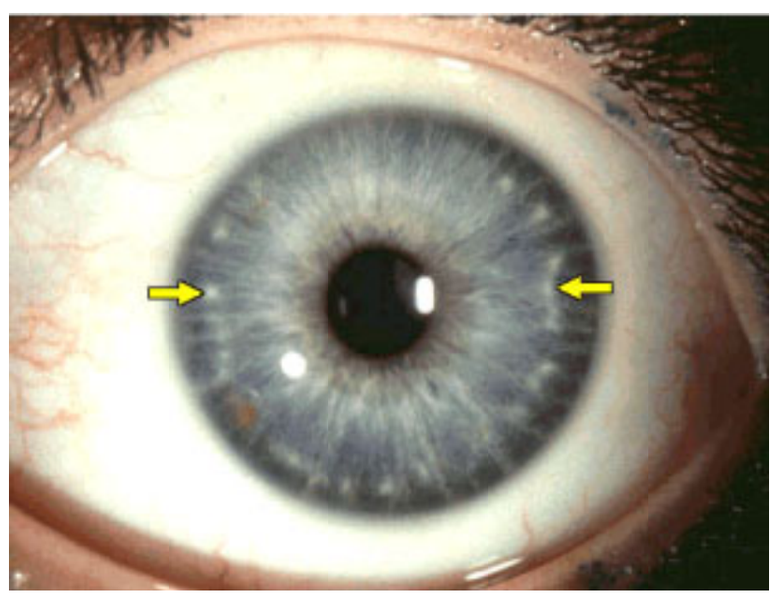
Both microdeletions and rearrangements in chromosome 22 are linked to DiGeorge syndrome. This condition, along with conotruncal face anomaly syndrome and Shprintzen syndrome, displays a group of cardiovascular defects that have several etiologic bases and are known collectively as CATCH 22 (for *c*ardiac, *a*bnormal facies, *t*hymic hypoplasia, *c*left palate, *h*ypocalcemia, and chromosome *22*). Velocardiofacial syndrome also shares some of these abnormalities, namely, cleft palate and cardiac and cognitive defects. Cardiovascular defects in these syndromes include persistent truncus arteriosus, tetralogy of Fallot, double-outlet right ventricle, interrupted aortic arch, and ventricular septal defect. A variable percentage of patients with one of these defects or syndromes have deletion in the long arm of one of the chromosomes 22 close to the centromere, resulting in a 22q11.2 monosomy that is either through a large interstitial deletion or through an unbalanced translocation in a 500-kb region (87). Extensive analysis of this region led to the cloning of the translocation breakpoint and isolation of several candidate genes. Some of these genes are transcribed as nontranslatable RNA (88) or as translatable RNA such as a cDNA (IDD) encoding a transmembrane protein, mapped within 10 kb of the break-point (89). A human analog of *Drosophila* segment-polarity gene (*dsh*) was cloned and its deletion was reported in DiGeorge syndrome (90). How these genes fit into the pathogenesis of DiGeorge syndrome remains to be clarified.

Long QT Syndrome

Long QT syndrome is an autosomal inheritance disorder characterized by syncope, seizures, and sudden death resulting from episodic ventricular dysrhythmia. Linkage analyses indicate that this syndrome is genetically heterogeneous, involving at least three distinct loci in different families: LQT1 on chromosome 11p15.5, LQT2 on 7q35–36, LQT3 on 3p21–24, LQT5, and LQT6. Mutations in a putative potassium channel are identified in LQT2, whereas mutations in the cardiac sodium channel gene are linked to LQT3 (for a recent review, see reference 91).

Down Syndrome

Down syndrome, which is caused by trisomy of chromosome 21, is associated with congenital heart disease in approximately 50% of patients, most often with AV canal defects. Although the defect has not been mapped to a specific gene, candidate genes include a tetratricopeptide repeat sequence located within the Down syndrome region on chromosome 21 (92). Similarly, *CAF1P60* gene, also located on chromosome 21, is overexpressed in this syndrome (93). Other candidate genes include a transcription factor, GABPA, belonging to the E26 transformation–specific family of DNA-binding proteins (94). The role of these factors in the pathogenesis of Down syndrome remains to be identified.



Brush field spots in association with Down syndrome. The yellow arrows indicate grayish-white spots in the iris, which are associated with trisomy 21.

Holt-Oram Syndrome

Holt-Oram syndrome is a prototypical heart-hand disorder characterized by atrial septal defect and radial ray limb deformity with autosomal dominance. Genetic mapping studies in two large families revealed the linkage on the long arm of chromosome 12 at 12q2 (95) and suggest it to be a genetically heterogeneous disorder (96).

Recent studies have implicated many different mutations in a transcription factor TBX5 to be responsible for this syndrome (97). Introduction of specific missense mutations in the TBX5 gene in mice resulted in either heart or skeletal abnormalities that resembled the clinical phenotype of Holt-Oram syndrome (98). Expression studies also suggest an essential role for TBX5 in early heart development and chamber-specific gene expression (99).

Familial Hypertrophic Cardiomyopathy

Familial hypertrophic cardiomyopathy is an autosomal dominant disorder manifesting as primary cardiac hypertrophy. It is phenotypically and genotypically a heterogeneous disease. So far, hypertrophic cardiomyopathy has been mapped to five different loci, of which three genes have been identified to be mutated. All three genes encode contractile proteins of the thick and thin filaments of the sarcomere: the b-*MHC* gene on chromosome 14q11, the a-tropomyosin gene on chromosome 15q2, and the cardiac troponin-T gene on chromosome 1q3. Other disease loci have been mapped to chromosome 11p13–q13 and 7q3, but the candidate genes at these two additional loci have not been identified. A number of missense mutations have been found in each of the three genes coding for sarcomere proteins. These mutations result in alteration of the peptide structure, causing abnormal myofibrillar formation and alignment, which in turn impair cross-bridge cycling and contractile function of the myocardium. Identification of the mutations in these genes is extremely useful for screening or preclinical diagnosis in high-risk patients (i.e., with a family history of hypertrophic cardiomyopathy). In addition, specific mutations are associated with increased disease severity and shortened life span, providing prognostic information not available from clinical assessment (100).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Future investigations will complete our information on the molecular regulatory mechanisms involved in normal cardiogenesis. Genetic screening of many types of heart defects will be available. With the development of effective delivery systems, gene therapy *in utero* will be possible for certain types of cardiac anomalies, such as hypoplastic right or left ventricle complexes, ventricular septal defects, and AV canal defects.

THE FUTURE

Rapid advances in molecular biology continue to enhance our understanding of normal heart development and to provide insights into fundamental mechanisms that may lead to cardiac malformations. Molecular regulatory mechanisms involved in normal cardiogenesis have been identified, but important informational gaps still must be clarified in future investigations. The critical role of the neural crest to cardiovascular development, specifically, the outflow tract and great vessels of the developing heart, is well recognized; nevertheless, its embryogenetic contributions at the molecular level still need to be defined. A few candidate genes have been suggested, but more definitive investigations are needed to characterize gene expression by the neural crest cells and their interactions with other regulatory factors. Identification of these genes will allow us to screen families of children with certain types of heart defects and will help to identify alterations in human genomes that may be responsible for the neural crest–related cardiac defects.

The study of regulatory mechanisms that maintain cardiac cells in terminally differentiated states and the ability to manipulate muscle gene transcription will greatly facilitate efforts to regenerate heart muscle in patients with myocardial cell loss. There is a need for more studies in this field to expand current knowledge and discover new ones to pave the way for future therapeutic interventions, such as gene therapy *in utero* for certain types of cardiac anomalies that are currently diagnosed by fetal echocardiography. Potential therapy includes direct delivery of genes into the myocardium or introduction of genetically altered cells into the heart, but effective delivery systems must be developed. This potential for genetic manipulation in congenital heart disease, as is the case for many other cardiovascular disorders, remains a distant possibility. The combined advances in molecular biology, genetics, and gene therapy will not only improve our basic understanding of cardiovascular disease processes but also create new diagnostic and therapeutic programs.

ACKNOWLEDGMENT

This work was supported in part by a grant from The Heart Institute for Children Research and Education Foundation and from the American Heart Association.

INTRODUCTION

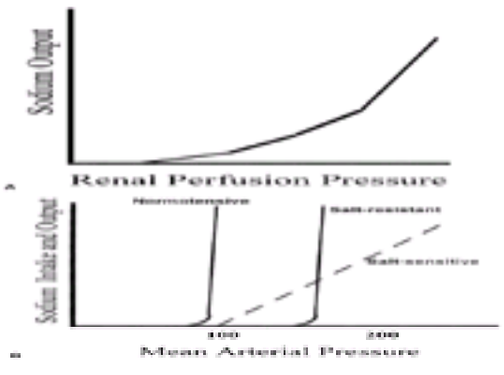
Although the clinical problem of hypertension is relatively well defined, its etiologic basis remains an enigma. A century has passed since the discovery of renin by Tigerstedt and Bergman, and more than 60 years have elapsed since the first animal model of hypertension was created by Harry Goldblatt (1). During the intervening period, students of hypertension have attempted to elucidate the causes of hypertension by characterizing the factors that regulate blood pressure and creating animal models that simulate the human disease. This chapter reviews our current understanding of the pathobiologic basis of hypertension in the hope that these principles will further advance the treatment of this disorder.

BLOOD PRESSURE AND THE KIDNEY

Any attempt to define the etiologic basis of human hypertension must begin by understanding the normal homeostatic regulatory mechanisms that control blood pressure. Moreover, a distinction must be made between short-term regulatory systems that buffer changes in blood pressure *around* a set point and long-term regulatory systems that *establish* the blood pressure set point. Short-term blood pressure buffering systems such as arterial baroreceptors are important homeostatic mechanisms in contexts such as acute hemorrhage but play relatively minor roles as long-term determinants of blood pressure. In an elegant series of experimental studies using integrative physiology as well as computer modeling, Guyton and his colleagues systematically characterized the relative contributions of various regulatory systems as long-term determinants of blood pressure (2,3). These analytical models based on extensive experimental studies have clearly established that the kidney plays an overarching role as the dominant long-term determinant of blood pressure.

An Intrinsic Antihypertensive Mechanism: Pressure-Natriuresis

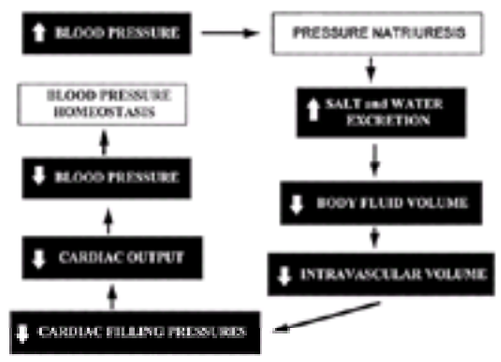
Perhaps one of the earliest clues about the pathogenesis of hypertension was derived from the observation that it is actually difficult to create an animal model of the disease. The normal function of the kidney serves as an intrinsic antihypertensive mechanism. The phenomenon of pressure-natriuresis, illustrated schematically in *e*Figure 104.0.1A, functions to prevent a chronic hypertensive state (3,4 and 5). This response creates a strict and intimate relationship between blood pressure and a control mechanism that governs the body fluid volume.



***e*FIGURE 104.0.1 A:** Pressure-natriuresis curve. The relationship between renal perfusion pressure and kidney sodium output observed in an isolated kidney preparation is illustrated. **B:** The renal function curve. The curve illustrates the maintenance of the normotensive state by the kidney at the equilibrium set point over a wide range of sodium intakes. The hypertensive state is characterized by a rightward shift in the equilibrium set point pressure. The salt sensitivity of the hypertensive state is a function of the slope of the renal function curve.

Although the mechanistic basis of the pressure-natriuresis phenomenon is not entirely clear, it is postulated that hemodynamic and humoral changes within the renal medullary circulation are involved (4,5). Although controversial, this working hypothesis predicts that factors that induce an increase in vascular resistance within the renal medullary bed and/or the afferent arteriole will modify the pressure-natriuresis curve and thereby promote a hypertensive state. The relative balance of factors such as nitric oxide (NO), reactive oxygen species, angiotensin II (Ang II), and arachidonic acid metabolites appear to play an important role in defining the pressure-natriuresis curve and thereby exert a long-term influence on systemic blood pressure (4,5 and 6).

Implicit in the renal function curve is an intrinsic antihypertensive mechanism that maintains the blood pressure at a certain set point (*e*Fig. 104.0.1B). At this set point, or equilibrium blood pressure, the net intake of salt and water equals the urinary fluid output. When the systemic pressure rises above a certain set point, a sequence of antihypertensive processes is activated: The kidney increases its excretion of salt and water in proportion to the elevation of the blood pressure such that the loss of salt and water promotes a decline in cardiac output and a decrease in blood pressure (*e*Fig. 104.0.2). Thus, the kidney is strategically poised to regulate blood pressure by mediating the pressure-natriuresis phenomenon and regulating body fluid volume in accordance with the renal function curve.



***e*FIGURE 104.0.2** The body fluid volume–blood pressure homeostatic mechanism. The sequential steps linking pressure natriuresis with the maintenance of blood pressure homeostasis at the equilibrium set point are illustrated.

Body Fluid Volume–Blood Pressure Relationship

The clinical observation that primary hypertension is characterized by an increase total peripheral resistance raises the question: How does an initial increase in body fluid volume result in a chronic increase in peripheral resistance?

Experimental studies have established that volume expansion results in an increase in cardiac output and therefore blood pressure. Over the course of time, the etiology of the blood pressure elevation shifts from a high cardiac output hypertension to a high total peripheral resistance form of hypertension. This shift in the hemodynamics of hypertension occurs as a result of a phenomenon described as *whole body autoregulation* (2,3,7). The delivery of excess oxygen and/or the enhanced removal of vasodilatory metabolic end products (e.g., adenosine) combined with the intrinsic myogenic properties of the vasculature cause the blood vessels to constrict in response to the increase in flow and pressure. This autoregulatory increase in vascular resistance effectively maintains the hypertensive state as cardiac output returns toward normal.

Causes of Hypertension: Insights from the Renal Function Curve

The fundamental thesis of the guytonian model is that all causes of chronic hypertension must modify the relationship between blood pressure and salt–water balance defined by the renal function curve. In general, the shape of the renal function curve can be modified by three basic mechanisms: (a) an alteration in the transmission of systemic pressure to the glomerulus, (b) a change in the ultrafiltration properties of the glomerulus, and (c) modifications in the sodium absorptive capacity of the tubules. This conceptual framework suggests a list of potential causes of hypertension (*e*Table 104.0.1).

***e*TABLE 104.0.1** SHIFTING THE RENAL FUNCTION CURVE: MECHANISMS OF HYPERTENSION
I. Renal resistance
Renal artery stenosis
Increased preglomerular vascular tone (increased vasoconstrictors/decreased vasodilators)
Increased preglomerular vascular reactivity (alterations in vasoactive receptor expression)
Increased vasoconstrictive ion fluxes (changes in ion channel expression/sensitivity)
Structural decrease in lumen dimensions (vascular remodeling)
II. Glomerular filtration
Alteration in glomerular ultrafiltration characteristics (glomerulosclerosis)
Decreased glomerular number
III. Tubular reabsorption
Increased sodium reabsorption (increased sodium channel activity/sensitivity)
Increased antinatriuretic factors (aldosterone)
Increased mineralocorticoid receptor activity (11b-hydroxylase)
Decreased natriuretic factors (atrial natriuretic peptide)
Dysfunctional natriuretic factor receptor pathways

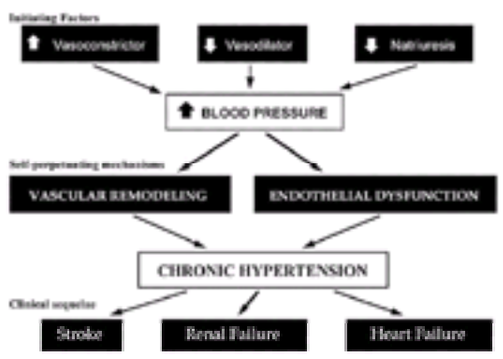
As we seek to understand the interaction between genetic and environmental factors that cause hypertension, it is readily apparent that this may involve a dynamic interplay between several variables that influence vascular tone and body fluid homeostasis. Moreover, this model predicts that hypertensives will be a heterogeneous population in which the relative mediator role of each of these factors will vary. Furthermore, it predicts that the hypertensive phenotype will include relatively simple etiologies such as single gene defects of sodium reabsorption (e.g., Liddle's syndrome) as well as more complex multifactorial forms of hypertension. Similarly, the model accommodates either congenital or genetic developmental determinants such as nephron number as well as age-related changes such as nephron loss (8). This guytonian model provides a unifying paradigm in which a large body of experimental evidence derived from a wide variety of model systems can be integrated into a powerful working hypothesis. It is anticipated that characterizing the molecular basis of shifts in the renal function curve will provide new insights into the fundamental causes of hypertension.

Clinical Implications of the Renal Function Curve

In addition to providing a framework for using a reductionist approach to characterize the etiology of hypertension, the guytonian model is also a useful paradigm in the clinical context. For example, the renal function curves defined in human hypertensives are strikingly similar to those characterized in genetically hypertensive rats (9,10). In some cases, analyses have documented that this shift is related to an increase in renal vascular resistance (*e*Fig. 104.0.1B). Clinical studies have documented that "salt-sensitive" hypertensive patients also exhibit the reduced slope of the renal function curve observed in animal models. Moreover, it is this patient subset that appears to have the greatest clinical response to diuretic treatment. Furthermore, it is apparent that many of the effective pharmacologic interventions used to treat hypertension modulate the renal function curve. For example, angiotensin-converting enzyme inhibitors and calcium channel blockers appear to be particularly effective in altering the pressure-natriuresis relationship (9,10,11 and 12). Finally, the pivotal role of the kidney as the critical determinant of the hypertensive state is most definitively demonstrated by studies in humans that have established that implanting a kidney from a normotensive donor into a hypertensive individual can induce the remission of hypertension (13,14,15 and 16). Thus, a substantial body of evidence has confirmed that the guytonian model is equally applicable to the clinical problem of primary hypertension.

CHRONIC HYPERTENSION: MALADAPTIVE SELF-PERPETUATING MECHANISMS

It is clear that a myriad of factors may initiate the pathogenesis of hypertension. It is important to recognize, however, that the development of chronic hypertension involves a complex cascade of pathobiologic processes. The set of factors that initiates the hypertensive state may be quite distinct from the factors that perpetuate the elevation of blood pressure. This postulate is illustrated schematically in *e*Figure 104.0.3. These intermediate processes appear to function as a common pathogenic pathway observed in a variety of animal models as well as in human hypertension.



***e*FIGURE 104.0.3** The pathogenic cascade of chronic hypertension. The sequence of pathophysiologic events linking initiating factors and self-perpetuating

mechanisms with the clinical course of hypertensive vascular disease.

It is important to recognize that the vasculature is itself a complex, integrated organ capable of modulating its tone and structure in accordance to its microenvironment. The chronic nature of the hypertensive state is dependent in part on self-perpetuating mechanisms that involve these intrinsic properties of the vasculature. During the pathogenesis of hypertensive vascular disease, these self-perpetuating mechanisms become maladaptive and appear to predispose to the common clinical sequelae of hypertension: stroke, myocardial infarction, and renal failure.

Vascular Remodeling: A Final Common Pathway

The intrinsic capacity of the vasculature to modify its geometry has been described as vascular remodeling. The experimental basis for the concept of vascular remodeling in hypertension has been established over many years (17,18,19 and 20). *Vascular remodeling* can be broadly defined as an alteration in vessel architecture that includes changes in overall vessel dimensions, the outer circumference, lumen dimensions, or the wall thickness–lumen ratio. Morphometric studies of hypertensive vessels in various animal models as well as in humans have documented several forms of vascular remodeling including (a) medial layer hypertrophy due to an increase in cellular mass, (b) medial layer hypertrophy due to expansion or alteration of the extracellular matrix without changes in cellular mass, (c) decreased vessel or lumen diameter (shrinkage remodeling), and (d) vessel rarefaction (microvessel occlusion).

In many cases of hypertension, vascular remodeling involves a structural decrease in lumen diameter that promotes a chronic increase in vascular resistance. These changes in vessel architecture reduce the overall vasodilatory capacity of the hypertensive vessel. Moreover, the structural increase in the wall–lumen ratio confers an increase in vascular reactivity that amplifies the effect of vasoconstrictors on vessel tone (17). Thus, structural changes in vessel lumen size and vascular reactivity may explain why relatively normal levels of circulating neurohumoral vasoconstrictors may be associated with a chronic increase in peripheral resistance and target organs are predisposed to tissue ischemia.

Another important form of vascular remodeling characterized in all species involves the process of rarefaction in which the number of microvessels becomes reduced by an occlusive process. This reduction in the arborization network of the microcirculation appears to be potentiated by a high salt diet (21) and is an important component of the overall increase in systemic resistance in hypertension (22). Bioengineering models suggest that this process of microvessel occlusion serves as an adaptive response to maintain the autoregulation of tissue blood flow in the setting of increased arterial pressure while normalizing wall stress (23).

These structural responses of the vasculature to chronic elevations in blood pressure, blood flow, or salt intake provide a long-term mechanism for the process of whole body autoregulation described previously. The guytonian model predicts that maladaptive remodeling (i.e., medial hypertrophy, shrinkage remodeling, or rarefaction) involving the afferent arteriole of the kidney, the renal medullary bed, or the glomerulus will be sufficient to alter the renal function curve. Thus vascular remodeling appears to be a common, self-perpetuating mechanism that resets the renal function curve and thereby contributes to maintaining the chronic hypertensive state (24,25).

Vascular Remodeling: Mechanisms and Mediators

The process of vascular remodeling involves the modification of four basic cellular functions within the blood vessel: cell growth, programmed cell death (apoptosis), migration, and extracellular matrix modification. Several studies have documented that the balance between cell proliferation and apoptosis accompanies the process of vascular remodeling in hypertension (25,26 and 27). Similarly, the architecture of the vessel is critically dependent on the scaffolding provided by the extracellular matrix. The matrix that is fashioned by a homeostatic balance of synthesis, cross-linking, reshaping, and degradation. The activation of metalloproteinases appears to play an important role in the process of vascular remodeling in response to hemodynamic stimuli (28).

The signaling pathways and factors that mediate the process of vascular remodeling during the pathogenesis of hypertension have not been fully characterized. It is clear that hemodynamic stimuli play an important role in promoting changes in vessel architecture. *In vitro* model systems that simulate the hypertensive state by imposing biomechanical forces such as mechanical strain and shear stress on vascular cells have documented alterations in ion channel activity, G-protein coupling, redox state, and signaling cascades of tyrosine kinase activation in response to mechanical stress (29,30). Recent studies incorporating DNA microarray technology have shown that mechanical stress activates signaling cascades that are coordinately coupled to subsets of genes (e.g., growth factors and matrix proteins) that can mediate changes in vessel structure (31,32). This pathobiologic insight may explain why simply lowering blood pressure is effective in reversing maladaptive changes in vessel structure and preventing the clinical sequelae of hypertensive vascular disease.

In addition to the effects of hemodynamic stimuli, it is clear that vasoactive factors produced locally within the vessel wall may play a critical role in the remodeling process. Many vasoactive substances (e.g., Ang II) that were originally defined as regulators of vessel tone are now recognized as pleiotropic factors capable of modulating vascular cell growth, cell death, migration, and extracellular matrix composition. Ang II serves as a useful archetype of a vasoactive substance that can modulate the cellular processes of vascular remodeling. Experimental studies have documented that blockade of Ang II effectively reverses the changes in vascular structure associated with hypertension in both animal models as well as in patients with hypertension (33,34). Stimulation of the Ang II type I receptor activates signaling molecules such as c-Src and mitogen-activated protein kinase in a manner similar to classic mitogens such as platelet-derived growth factor. Recent studies indicate that Ang II–induced vascular cell growth is mediated in part by reactive oxygen species generated by the NADPH oxidase (35). Ang II also induces the expression of growth factors such as platelet-derived growth factor and transforming growth factor-b_1 by vascular cells (35,36). These studies indicate that activation of a local paracrine systems such as the vascular angiotensin system (37,38) can induce the vascular remodeling characteristic of hypertensive vessels independent of changes in systemic hemodynamics.

Ang II may also mediate remodeling by altering extracellular matrix composition via its effect on thrombospondin, collagen, fibronectin, osteopontin, tenascin, and plasminogen activator activity (25,35,37,39,40 and 41). Similarly, there is a growing body of evidence that Ang II is a proinflammatory and procoagulant factor that promotes the generation of mediators such vascular cell adhesion molecule-1, monocyte chemoattractant protein-1, tumor necrosis factor-a, and tissue factor that may predispose to atherogenesis and acute thrombotic syndromes (37,42,43 and 44). Finally, there is emerging evidence that the Ang II–mediated stimulation of aldosterone production is not simply a mechanism to promote sodium retention. In addition to its effects on the adrenal gland, Ang II also stimulates local aldosterone production within the heart and vasculature. Moreover, aldosterone activates a transcription factor that is coupled to the expression of genes regulating vascular cell growth and tissue fibrosis (45,46 and 47).

Thus, Ang II is a pleiotropic local mediator capable of modulating cell growth, apoptosis, migration, inflammation, hemostasis, and matrix modulation—all of the biologic mechanisms of vascular remodeling and acute vascular complications. Although Ang II serves as a useful example, similar pleiotropic effects on vascular smooth muscle cell behavior have been described for other vasoconstrictors such as norepinephrine and endothelin-1 (48,49). These mechanisms are consistent with the recent clinical findings of the Heart Outcomes Prevention Evaluation trial demonstrating that blockade of Ang II generation is associated with the prevention of vascular complications in high-risk patients either with or without hypertension (50).

Endothelial Dysfunction: An Imbalance in Reactive Nitrogen and Oxygen Species

The endothelium is a multifunctional determinant of tissue function based on its capacity to regulate vessel tone, thrombosis, inflammation, and structure. A large body of evidence indicates that the normal endothelium functions as an intrinsic mechanism that prevents vascular disease. However, an impairment of endothelial function manifested as abnormal endothelium-dependent vasorelaxation has been documented in a wide variety of vascular diseases, including hypertension (51). In fact, this perturbation has been described in normotensive subjects who merely have a positive family history of hypertension (52). In most cases, this reflects a decrease in the bioactivity of endothelium-derived NO due to catabolism by reactive oxygen species. Studies involving pharmacologic blockade of NO generation in normotensive humans have documented that NO inactivation is sufficient to induce marked increases in vascular resistance (53). Moreover, the demonstration that mutant mice that lack the endothelial cell–type NO synthase gene are spontaneously hypertensive indicates that NO is an important long-term determinant of blood pressure (54). Thus, endothelial dysfunction manifested as a deficiency in NO bioactivity may represent a self-perpetuating mechanism that promotes the progression of hypertensive vascular disease.

Endogenous vasodilators such as NO and natriuretic peptides appear to have a countervailing influence on vascular architecture relative to vasoconstrictors. In general, the vasodilators inhibit vascular smooth muscle cell growth (55,56). Moreover, NO appears to counteract the process of shrinkage remodeling that characterizes the hypertensive vasculopathy (57). Thus, impairment of endothelial NO generation may predispose to vascular complications. Recent evidence suggests that the mechanism of the decreased NO bioactivity is related to increased generation of reactive oxygen species by the NADPH oxidase in response to vasoconstrictors such as Ang II as well as the mechanical stress imposed by elevations in blood pressure (58,59).

Overall, these data indicate that an imbalance between vasoconstrictors versus vasodilators and the alteration in the vascular redox state can initiate the hypertensive

state by increasing vessel tone and perpetuate the elevation in blood pressure by inducing long-term changes in vessel structure.

Vascular Remodeling and Lesion Formation: Clinical Implications

Microvascular Disease

One pathologic role of vascular remodeling involves its participation in the vicious cycle of events that promote the clinical complications of hypertension. Studies of animal models have documented that hypertensive states associated with impaired NO generation develop occlusive coronary microvascular disease that promotes myocardial ischemia or glomerulosclerosis that results in renal failure (12,42,60). Similarly, analyses of the stroke-prone spontaneously hypertensive rat have documented that stroke susceptibility is related to alterations in cerebral microvascular structure that can be reversed by antihypertensive treatment (60). In the clinical context, arteriovenous nicking due to arteriolar hypertrophy is a clinical manifestation of remodeling in the brain microvasculature that correlates with progressive hypertension and its complications (61). This remodeled cerebral microvasculature may be the mechanistic basis for the clinical associations between hypertension, subcortical white matter disease, lacunar infarction, and vascular dementia (62,63). In accord with this postulate, recent clinical trials have documented that blockade of angiotensin generation is associated with the amelioration of vascular lesions and the prevention of microvascular complications such as renal failure and stroke (64,65).

Insulin Resistance

The coincidence of obesity, insulin resistance, and hypertension is a common clinical scenario. There is evidence to suggest that endothelial dysfunction and hypertension-induced vessel rarefaction in skeletal muscle beds may promote the phenomenon of insulin resistance in hypertension by compromising the delivery of insulin and glucose to skeletal muscle (54). The provocative observation that blockade of angiotensin may be associated with retarding the onset of diabetes is of interest in this regard (50). An exciting recent study in human genetics has provided evidence that a transcription factor, peroxisome proliferator–activated receptor-g, is a molecular link between hypertension and insulin resistance (66). In the clinical context, it is noteworthy that glycemic control with peroxisome proliferator–activated receptor-g agonists (e.g., the thiazolidinediones) is associated with improvements in vascular function and a regression of hypertensive vascular remodeling (67).

Vascular Compliance

The capacity for the conduit vasculature to absorb each ejected stroke volume diminishes as a function of age, and this decline is accelerated by hypertension. An imbalance between vasoconstrictors versus vasodilators coupled with a structural decrease in the elastin–collagen ratio promotes this decline in vascular compliance. This increase in vascular “stiffness” predisposes to an increase in systolic blood pressure and a widened pulse pressure common among the elderly. Indeed, epidemiologic studies suggest that the increase in vascular stiffness and the widened pulse pressure may be more sensitive indices of a poor prognosis than the mean arterial pressure alone (68,69). This decrease in vascular compliance promotes an increased afterload that predisposes to left ventricular hypertrophy, maladaptive remodeling, and worsening heart failure (69,70). Thus, many of the clinical sequelae of hypertension (i.e., heart failure, stroke, and renal failure) may result from vascular remodeling within conduit vessels as well as the microcirculation.

ANIMAL MODELS OF GENETIC HYPERTENSION: WHAT CAN WE LEARN?

Innumerable studies have been performed over the years comparing the physiologic, hormonal, biochemical, and morphometric differences between genetically hypertensive animals and normotensive animals. However, it remains to be demonstrated how closely the characterization of the genetic basis of hypertension in these animal models will mirror the characterization of the genetic basis of primary hypertension or intermediate phenotypes (e.g., salt sensitivity) in humans (71,72 and 73).

Well-defined models of genetic hypertension include the spontaneously hypertensive rat (SHR); Dahl salt-sensitive strains; the Fawn-hooded model; and rat strains derived in Lyon, Milan, and New Zealand as well as the spontaneously hypertensive BPH mouse. The detailed characteristics of various genetic models of hypertension have been previously reviewed (71,72 and 73). A host of experimental studies have documented a myriad of differences between the hypertensive and normal animals as well as distinctions between the various strains of hypertensive models. Perhaps what is most remarkable are the *similarities* between the models derived from various founder strains and breeding regimens. For example, it is remarkable that many of the models recapitulate the common clinical complications observed in human hypertension—left ventricular hypertrophy, stroke, and nephrosclerosis. Moreover, nearly all of the models studied exhibit the self-perpetuating mechanisms of hypertension—vascular remodeling, endothelial dysfunction, and vascular stiffness. All of these pathogenic processes participate in the maintenance of hypertension as well as the vascular complications such as stroke, heart failure, and renal failure. Thus, the pathobiologic principles that have emerged from these studies reemphasize the pivotal importance of the kidney in hypertension and the ubiquity of critical self-perpetuating mechanisms.

Despite this understanding of broad pathobiologic principles, we lack a fundamental understanding of the molecular basis of hypertension and its complications. The fact that blood pressure is a continuous variable probably reflects the integrated effects of alleles at multiple genetic loci that have either positive or negative effects on blood pressure. It is a complex matter to dissect out the links between the multiple genes that promote hypertension, the cellular processes controlled by these genes, as well as the integrative physiology induced by these cellular processes that eventuates in the hypertension phenotype.

The characterization of quantitative trait loci by genomic scanning coupled with the creation of congenic and consomic animals has begun to enable investigators to narrow down the regions within the genome that contribute to the hypertensive phenotype. Although there are many pitfalls in this rather daunting task, the power and usefulness of this approach are already evidenced in recent studies (74,77). This experimental strategy will not only identify genes that may initiate hypertension but also genes that predispose to the clinical complications of the disease. For example, morphometric studies of the Fawn-hooded strain have noted a particularly high incidence of nephrosclerosis and renal dysfunction in this particular model of genetic hypertension. Genomic scanning studies have begun to identify loci that predispose to renal dysfunction yet are distinct from genetic loci that promote the hypertensive state per se (74). Similarly, there appear to be discrete genetic loci that increase the susceptibility to complications such as left ventricular hypertrophy (75) and stroke (76) that are distinct from the loci that determine blood pressure in genetically hypertensive rats. Conversely, this approach can also lead to the identification of genes that may be protective against salt-sensitive elevations in blood pressure and the development of target organ injury such as proteinuria (77). Eventually, it is hoped that the genes that predispose or prevent the clinical complications of hypertension can be identified and cloned as a novel approach to drug target discovery.

One emerging technology that may enhance the identification of hypertension susceptibility genes is the use of gene expression profiling techniques such as DNA microarrays and serial analysis of gene expression (78). A recent series of experiments has provided an exciting demonstration of the usefulness of this strategy and has provided new insights into the mechanistic links between hypertension and insulin resistance (79). The use of DNA microarrays enabled investigators to rapidly assay thousands of transcripts and define the subset of genes that were differentially expressed in the tissues of spontaneously hypertensive rats compared with normotensive controls. These experiments established that the hypertensive, insulin-resistant phenotype observed in SHR was associated with a decreased expression of CD36, a membrane fatty acid transporter. To further establish a causal relationship between genotype and phenotype, these investigators generated SHR transgenic rats with upregulated expression of CD36 and documented changes in fatty acid metabolism and amelioration of the insulin resistance (80). Thus, this combination of genomic strategies that includes systematic mapping of genetic loci associated with disease phenotypes, the incorporation of gene expression profiling, and the creation of novel congenic or transgenic models has great potential for identifying factors that cause hypertension and predispose to its complications. To the extent that these animal models simulate human hypertension, the characterization of these susceptibility loci may also accelerate the identification of genes involved in human hypertensive vascular disease.

PHYSIOLOGIC GENOMICS OF BLOOD PRESSURE: NEW INSIGHTS INTO AN OLD PROBLEM

One of the challenges to defining the molecular basis of human hypertension is to recreate the state of chronic hypertension that simulates what is observed in the clinical context. The revolution in molecular genetics and genomic technologies has made it possible to create animal models by genetic engineering and analyzing changes in gene expression profiles of thousands of genes at a given time point. The creation of new models has proceeded at such a fast rate that any list that includes published descriptions of models becomes out of date within months (*e*Table 104.0.2). In general, the predictions of the guytonian model based on physiologic principles have been validated by the use of genetic engineering approaches.

***e*TABLE 104.0.2** GENETIC ENGINEERING OF BLOOD PRESSURE

Gene knockout	Phenotype
Angiotensinogen	Hypotension, abnormal kidney
Angiotensin-converting enzyme	Hypotension, abnormal kidney
Angiotensin type I receptor	Hypotension
Angiotensin type II receptor	Normotensive
Endothelin-1	Normotensive, craniofacial abnormalities
Endothelial cell–type nitric oxide synthase	Hypertension
Large conductance K^+ channel	Hypertension

Atrial natriuretic peptide	Hypertension, salt-sensitive
Brain natriuretic peptide	Normotensive, cardiac fibrosis
b-Adducin	Hypertension
Glomerular epithelial protein phosphatase	Hypertension, abnormal glomerulus, decreased renal ultrafiltration

Despite all of the compensatory and countervailing mechanisms that determine blood pressure, it is noteworthy that the ablation of a single gene encoding a component of the renin-angiotensin system has profound long-term effects on blood pressure. Smithies and colleagues conducted a series of elegant studies using homologous recombination techniques to ablate the expression of the substrate angiotensinogen, angiotensin-converting enzyme, and the Ang II type I receptor (81,82 and 83). In the studies involving angiotensinogen, a gene duplication construct was created such that mice exhibited a range of zero to four copies of the angiotensinogen gene. There was a linear relationship between angiotensinogen gene copy number, plasma angiotensinogen levels, and blood pressure increases of approximately 8 mm Hg per gene copy. The homozygous null mutants that lacked angiotensinogen, angiotensin-converting enzyme, or the angiotensin-type IA receptor exhibited a substantial decrease in blood pressure that could not be compensated for by alternative homeostatic mechanisms. Taken together, this series of observations suggests that inactivation of the renin-angiotensin-aldosterone system resets the renal function curve and exerts long-term influences on blood pressure.

The use of genetic engineering techniques has also shed light on the mechanisms by which the renin-angiotensin-aldosterone system regulates cardiovascular function and structure. For example, an ongoing controversy relates to the relative roles of the circulating versus tissue renin-angiotensin-aldosterone systems as determinants of cardiovascular homeostasis. To address this issue, Bernstein and colleagues generated genetically engineered mice with two different forms of the angiotensin-converting enzyme such that animals had relatively normal levels of circulating plasma angiotensin-converting enzyme but were deficient in tissue angiotensin-converting enzyme (84). Of note, the animals deficient in tissue angiotensin-converting enzyme exhibited a hypotensive phenotype similar to those in which the entire angiotensin-converting enzyme gene was deleted (84). These findings are consistent with the concept that local generation of angiotensin within tissues may be as important as the circulating system as a long-term determinant of blood pressure. Another clinical controversy relates to the fact that enzymes such as chymase are capable of generating Ang II but are not inhibited by conventional angiotensin-converting enzyme inhibitors. Although the physiologic significance of chymase remains to be further defined, it is noteworthy that vascular-selective, conditional overexpression of chymase is sufficient to promote hypertension in transgenic mice (85). These animal model studies may have implications for achieving effective blockade of Ang II in the clinical context.

It could be argued that the results of gene deletion experiments targeted at the renin-angiotensin system were predictable given the potency of Ang II as a vasoactive agent. However, it is interesting that gene knockout experiments involving endothelin and its receptors failed to document significant effects of gene ablation on blood pressure despite the fact that it is a more potent vasoconstrictor than Ang II (86). It is also noteworthy that several models have documented that hypertension is readily induced by the deletion of certain vasodilators such as NO, natriuretic peptides, prostaglandin E_2, dopamine, and calcitonin gene-related peptide (54,87,88,89,90 and 91). In addition to receptor-mediated vasodilation, recent studies have also shown that disruption of large-conductance potassium channels modulates calcium metabolism, promotes increased vasoconstriction, and results in sustained hypertension (92). Overall, these findings are consistent with the postulate that the balance of vasoconstrictors versus vasodilators is an important determinant of the renal function curve and thereby exerts long-term influences on blood pressure homeostasis.

It is also noteworthy that the generation of gene ablation models can provide insights into less obvious candidate genes for hypertension susceptibility. For example, disruption of the glomerular epithelial protein, a receptor tyrosine phosphatase, is associated with a hypertensive phenotype. In retrospect, this finding is consistent with the guytonian model because ablating the gene perturbs glomerular podocyte structure such that ultrafiltration is compromised and the renal function curve is altered (93). Similarly, the adducin gene became a candidate susceptibility gene for hypertension based on genome scanning in the Milan hypertensive rat model (94). Genetic association studies of human hypertensives have yielded suggestive but equivocal results (95). However, the mechanism by which a cytoskeletal protein such as adducin is coupled to long-term control of blood pressure was not readily apparent. Recent experimental findings have provided a mechanistic basis for these associations and linkage studies by documenting a causal relationship between ablation of the b-adducin gene and a hypertensive phenotype (96). Thus, genome scanning may generate hypotheses about novel mediators of hypertension that can be tested by the creation of genetically modified animals.

Finally, it is anticipated that the use of genetically engineered models will provide important clinical insights into the molecular basis of hypertensive complications or the potential usefulness of certain therapeutic options. For example, studies involving mice that lack the brain natriuretic peptide have documented substantial cardiac fibrosis despite the fact that the animals are normotensive at baseline (97). These studies in knockout mice indicate that brain natriuretic peptide (BNP) not only serves as a marker of ventricular dysfunction but may also be a key mediator in the process of ventricular remodeling. The clinical implications of this observation have become more profound with the advent of a new class of drugs, the vasopeptidase inhibitors, that block both angiotensin-converting enzyme and a neutral endopeptidase that degrades peptides such as BNP. It is conceivable that pharmacologic interventions that prevent BNP degradation may not only promote vasodilation and natriuresis but may also have direct salutary effects on cardiovascular structure. However, a cautionary approach is suggested by the observation that genetic ablation of the neutral endopeptidase is associated with a phenotype in which the mutant mice exhibit increased microvascular permeability and tissue edema (98). It remains to be determined whether clinical trials will document whether the beneficial effects of vasodilation and natriuresis induced by pharmacologic inhibitors of the neutral endopeptidase counterbalance a potentially adverse effect on microvascular permeability.

In summary, the capacity to target, mutate, ablate, or conditionally regulate a gene that is transmitted through the germline has become a powerful tool for elucidating the fundamental basis of pathophysiologic processes such as hypertension (99). The studies performed to date are consistent with the pathobiologic principles that emphasize the role of the kidney as a critical long-term determinant of the blood pressure. In addition, they have proved to be useful in defining the molecular basis of hypertensive vascular complications as well as characterizing the mechanisms of effective therapeutic interventions. Finally, these models have provided a very important link between the molecular genetics that identify susceptibility genes and physiologic experiments that establish causality.

CONTROVERSIES AND PERSONAL PERSPECTIVES

As detailed above, a great deal has been learned about the pathobiology of hypertension during the past century. The advent of powerful new experimental technologies continues to reinforce the time-tested concept that the kidney is the predominant long-term determinant of blood pressure and that neurohumoral systems such as the renin-angiotensin system and the sympathetic nervous system are major modulators of this function.

It is anticipated that advances in rodent molecular genetics, genetically engineered model systems, microarray technology, and human molecular genetics will begin to provide important new insights into the factors that predispose individuals to elevations in blood pressure. In addition to defining these etiologic factors, the incorporation of genomic technologies into molecular cardiology holds promise for elucidating the variances in the susceptibility to complications such as stroke, renal failure, or heart failure among hypertensive patients.

THE FUTURE

With the completion of the Human Genome Project, we stand on the threshold of an unprecedented opportunity to discover the molecular basis of hypertension and its clinical complications. The capacity for large-scale assays of RNA and protein levels by genomic and proteomic technologies should provide a means for investigators to characterize the molecular basis of the physiologic phenomena defined in the guytonian models. It promises to be an exciting second century of discovery in which we embrace the challenge of translating new pathobiologic insights into ameliorating the course of the disease.

ACKNOWLEDGMENTS

The author is deeply indebted to the many investigators who have contributed to our current understanding of hypertension summarized herein. In particular, I am thankful for the inspiration, mentorship, and support of Drs. A. Clifford Barger and Victor Dzau. The support of the American Heart Association and the National Institutes of Health is also appreciated.

OVERVIEW

Neointimal thickening, also referred to as *neointimal hyperplasia*, occurs in response to experimental arterial injury with a balloon catheter. This process, which is mainly the consequence of a growth response of the smooth muscle cells (SMCs), is maximal 1 to 4 weeks after the initial injury. It occurs in different vascular beds (coronary arteries, peripheral arteries) and in various animal species, including rats, rabbits, and pigs. A marked hyperplastic response can be observed after a single injury performed in normal vessels but also in animal models in which a first injury combined with a hypercholesterolemic diet has induced a stenosis that can then be dilated with an angioplasty balloon catheter. Neointimal formation involves the activation, proliferation, and migration of SMCs, and the production of extracellular matrix (ECM).

The factors that control neointimal thickening include growth factors, hormonal factors, and mechanical factors. Growth factors released at the site of injury play a major role in the response of SMCs to balloon injury and include platelet-derived growth factor (PDGF), basic fibroblastic growth factor (bFGF), transforming growth factor-b (TGF-b), and insulin-like growth factor-1 (IGF-1). Hormonal factors include angiotensin II, serotonin, and endothelin. Mechanical factors include trauma related to interventional devices and the mechanical events that comprise plaque rupture.

Experimental evidence is increasing that neointimal hyperplasia is not the sole mechanism leading to lumen renarrowing after angioplasty, namely, that arterial remodeling also plays a major role in this process. Studies performed in animals and human subjects have established the potential for "constrictive remodeling" to reduce vessel wall area after angioplasty, which indirectly narrows the vessel lumen and thus contributes to restenosis.

Delinquent reendothelialization has been shown to have a permissive, if not facilitatory, impact on SMC proliferation. This inverse relationship has been attributed to certain functions of the endothelium, including barrier regulation of permeability, thrombogenicity, and leukocyte adherence, as well as to growth-inhibitory molecules. More recent studies have confirmed this notion by demonstrating that administration of endothelial cell mitogens may facilitate endothelial cell regeneration, reduce neointimal thickening, and promote recovery of endothelial dysfunction after balloon injury.

Histologic findings after stent deployment in animal models and analyses of specimens retrieved from patients with in-stent restenosis have established that this complication of endovascular stents is due to intimal hyperplasia. Application of endothelial cell mitogens to promote endothelialization of the stent struts seems to reduce the thickness of the stent neointima in animal models.

Studies have also shown that endovascular brachytherapy might interfere with the various mechanisms involved in the restenosis process, and this new approach is currently under investigation in humans to treat or to prevent restenosis.

INTRODUCTION

Percutaneous transluminal coronary angioplasty (PTCA) has become a well-established technique for myocardial revascularization of patients with coronary artery disease (1,2 and 3). The use of PTCA remains limited by restenosis, however, which occurs in 30% to 60% of patients despite performance of a successful procedure (4,5,6,7,8 and 9). If one assumes that 500,000 PTCA procedures are performed per year in the United States (10), then more than 150,000 patients develop restenosis every year.

During the last decade, numerous agents have been used in an attempt to prevent restenosis (5,11,12 and 13). Despite positive results in animal models, no pharmacologic therapy has been found to significantly decrease the risk of restenosis in humans. These apparent discrepancies between animal models and the clinical situation were probably related mainly to an incomplete understanding of the mechanisms of restenosis in humans as well as in animal models. During the last few years, important experimental and clinical studies have allowed a better understanding of the various processes that occur after PTCA and that may lead to restenosis. The purpose of this chapter is to review the available information relevant to the response of the vascular wall to injury. The focus is on four major processes: neointimal hyperplasia, vessel remodeling, thrombosis, and endothelial regeneration. The mechanisms of these processes, as well as their relative contributions to lumen renarrowing in animals and humans, are reviewed in an attempt to reconcile results for animal models of restenosis with the clinical situation.

NEOINTIMAL HYPERPLASIA

Neointimal Hyperplasia after Experimental Arterial Injury

During the past 10 to 15 years, multiple studies have described the process of neointimal thickening—also known as *neointimal hyperplasia*—that occurs in response to experimental arterial injury with a balloon catheter (6,14,15,16,17,18,19,20,21 and 22) (Fig. 105.1). This process is due largely to growth of the SMCs and is maximal 1 to 4 weeks after the initial injury (Fig. 105.2). Neointimal thickening occurs both in coronary arteries and in peripheral arteries and is found in various animal species, including rats, rabbits, and pigs (14,22,23,24,25 and 26). A single injury performed in a normal vessel can produce a marked hyperplastic response (14,22,27). Neointimal hyperplasia is also observed in animal models fed a hypercholesterolemic diet after a first injury to induce a stenosis that can then be dilated with an angioplasty balloon catheter (double-injury model) (17,18). Neointimal formation involves several steps: SMC activation, proliferation, and migration, and the production of ECM.

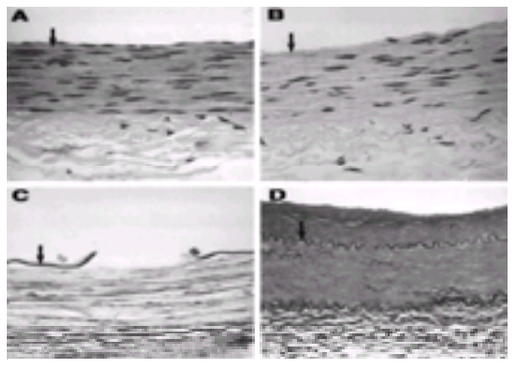

FIGURE 105.1 Experimental balloon denudation of rabbit aorta. **A:** Noninjured artery. **B:** Immediately after balloon denudation, complete deendothelialization is apparent. **C:** Immediately after balloon denudation, a break is also seen in the internal elastic membrane. **D:** Twenty-eight days after balloon denudation, neointimal thickening is observed. Arrow indicates the internal elastic lamina.

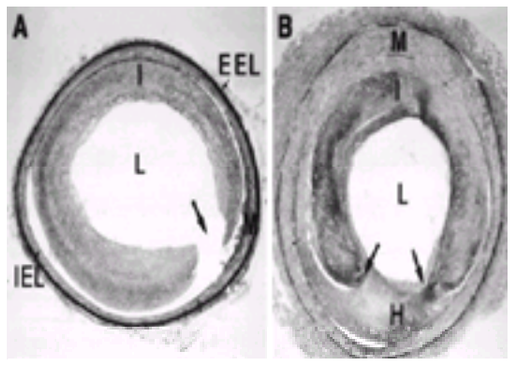

FIGURE 105.2 Experimental balloon angioplasty of an iliac artery in the hypercholesterolemic rabbit model. **A:** Immediately after balloon angioplasty, rupture (*arrow*) of the atherosclerotic lesion is seen. **B:** Twenty-eight days after balloon angioplasty, site of plaque rupture is "grouted in" by neointimal hyperplasia (H), maximal at the site of plaque rupture (elastic tissue stain). EEL, external elastic lamina; I, intima; IEL, internal elastic lamina; L, lumen; M, media.

The Early Phase: Smooth Muscle Cell Activation

Immediately after experimental arterial injury with a balloon catheter, multiple factors (see later) lead to the activation of SMCs. Early markers of SMC activation, such as expression of nuclear oncogenes, are detectable as soon as 30 minutes after injury (22,28,29,30 and 31). Induction of c-*fos*, c-*jun*, and c-*myc* protooncogenes is one of the earliest transcriptional events associated with growth factor stimulation (32), and the increased expression of these genes is a transient response to mitogenic stimulation persisting at most for a few hours after exposure to growth factors (33). The distribution of c-*fos* and c-*jun* products after arterial injury is concentrated in SMC nuclei (28). The corresponding oncoproteins bind to specific DNA sequence of target genes to stimulate their transcription and are involved in the G_1 phase of the cell cycle (32). Experiments involving cell culture models have shown that the use of antibodies or antisense RNA against nuclear oncogenes prevents cell entry into the S phase and the subsequent synthesis of DNA (34,35). That this expression of nuclear oncogenes in the hours after angioplasty is associated with the early G_1 events preceding DNA synthesis in SMCs is therefore plausible. The use of antisense oligonucleotides against nuclear oncogenes was shown to inhibit neointimal thickening *in vivo* in various animal models (36,37); these results suggest that the inhibition of this early phase can significantly affect the cascade of events leading to neointimal hyperplasia a few weeks later.

Interestingly, some genes expressed early after vascular injury may also be downregulated during the process of SMC activation. One of these genes is the homeobox transcription factor gax, which has now been cloned. Gax is unique among homeobox factors in that it is expressed in quiescent SMCs but rapidly downregulated when the SMCs are stimulated to proliferate (38). *In vivo*, gax expression is rapidly reduced in rat aorta after balloon denudation. Furthermore, an adenoviral vector expressing gax was shown to efficiently inhibit SMC growth by blocking the cell cycle in the G_0 phase (39).

The activation of SMCs is thus a very early response after experimental balloon denudation. Changes in gene expression can be detected very soon after arterial injury; some genes are switched on whereas others are downregulated. These early events are likely to be of major importance for the occurrence of the next steps of the vascular wall response.

Proliferation and Migration of Smooth Muscle Cells

Activation of SMCs is associated with a shift from a contractile to a synthetic phenotype (40,41 and 42) and leads to proliferation, migration, and synthesis of ECM. Proliferation of medial SMCs is evident 24 hours after experimental balloon injury and continues for at least 2 weeks (16). At least 20% to 40% of medial SMCs are activated and enter the cell cycle between 24 hours and 3 days after balloon denudation (43). *In vivo* animal studies have demonstrated the extent to which cell-cycle events are temporally coordinated after balloon injury (44). These cells then migrate to the intima through breaks in the internal elastic membrane. SMCs are observed on the luminal side of the internal elastic lamina 4 days after injury to rat arteries (14). Many of these neointimal cells continue to proliferate for several cycles, but nearly half of the migrating cells do not synthesize DNA (43). Proliferation and migration should thus be considered as two distinct mechanisms leading to neointimal thickening; as discussed later, some factors may affect SMC migration but have no effect on SMC proliferation, and vice versa (15).

Synthesis of Extracellular Matrix

In animal models, the degree of intimal thickening is maximal after 3 months (14). The additional volume that accumulates after 2 to 4 weeks reflects the adjunctive synthesis of ECM by synthetic SMCs. Experimental balloon denudation is followed by a marked increase in expression of the genes that code for ECM proteins such as collagen and elastin in the arterial wall (45). Similarly, the reexpression of embryonic forms of fibronectin occurs in the media and adventitia of rabbit arteries 24 to 48 hours after injury. Two weeks after balloon denudation, when the neointima is formed, fibronectin messenger RNAs (mRNAs) as well as the fibronectin protein accumulate in the luminal layers of the neointima (46). Fibronectin, as well as other matrix constituents characterized by the presence of an RGD amino acid sequence such as osteopontin (47) and vitronectin, is likely to facilitate SMC migration by interaction with certain integrins expressed by activated SMCs (48). As pointed out by Schwartz et al. (49), cellular components constitute only approximately 11% of neointimal volume, and the remainder is ECM. After 2 to 3 months, SMCs return to a contractile phenotype, and no further significant increase in intimal thickening occurs (50).

Potential Regulators of Neointimal Formation

Although the process of neointimal formation has been relatively well described, the factors that control it are still under intense investigation. The candidates for this regulation include growth factors, hormonal factors, and mechanical factors.

Growth Factors

Growth factors released at the site of injury play a major role in the response of SMCs to balloon injury. Platelets are an important source of PDGF, but endothelial cells, macrophages, and SMCs may themselves secrete PDGF after arterial injury (40,51,52 and 53). PDGF may be critical for SMC migration from media to intima; however, its absence does not limit SMC proliferation (23,54). Indeed, using an antibody to PDGF, Ferns et al. (54) were able to reduce neointimal SMC accumulation after experimental angioplasty without affecting mitogenic activity.

Basic fibroblast growth factor, an *in vivo* angiogenic factor (55) that is mitogenic for SMCs as well as endothelial cells through specific receptors (56,57), may also play a role in restenosis. SMCs within the tunica media, when damaged by an oversized balloon, may release bFGF due to stretch or crush injury. The liberated bFGF can

then mediate the initial wave of cell division within this layer of the blood vessel. Infusion of an antibody that neutralizes bFGF reduces the first cycle of SMC replication by up to 80% in the arterial media after balloon denudation but has no effect on the resulting neointimal thickening (58).

Additional growth factors that have been implicated in the development of restenosis include TGF-b and IGF-1. TGF-b mRNA is increased in SMCs after arterial wall injury and reaches a maximum before the phase of ECM synthesis (59,60). TGF-b is known to modulate fibronectin expression (61) and may be important in the control of ECM synthesis (62,63). TGF-b is produced by SMCs, platelets, and endothelial cells (51,64). The main source of IGF-1 is SMCs, and its mRNA expression undergoes a tenfold increase in the weeks after balloon denudation (65).

Hormonal Factors

Work by Dzau and colleagues has suggested a role for the renin-angiotensin-aldosterone axis in the pathogenesis of restenosis (66,67,68 and 69). Angiotensin II may modulate SMC growth *in vitro* (70,71); *in vivo* studies have demonstrated that angiotensin II infusion in rats is followed by marked SMC proliferation in the intima (72). Rakugi et al. (67) have reported that after balloon injury the rat abdominal aorta expresses increased levels of angiotensin-converting enzyme (ACE) activity as well as increased immunoreactivity for ACE in the neointima. Powell et al. (73) and others (74) have reported that inhibitors of ACE suppress myointimal proliferation after vascular injury. Intimal thickening can also be prevented by angiotensin II type 1 receptor antagonists (75). The actions of ACE inhibitors are probably not related solely to an effect on angiotensin II levels, however, but may in part be due to an effect on bradykinin metabolism (76,77). Farhy et al. (77) have reported that *N*(*G*)-monomethyl-L-arginine (L-NMMA), a blocker of nitric oxide (NO) generation, can partially counteract the suppressive effect of the ACE inhibitor ramipril on neointimal thickening after balloon injury in rat arteries. As bradykinin is a potent stimulator of NO production and is itself normally degraded by ACE, they speculated that the decrease in neointimal thickening observed with ACE inhibitors may be a result of elevation in the level of bradykinin. Similarly, in a rabbit model of balloon denudation the reduction in neointimal thickening observed with the ACE inhibitor perindopril erbumine was reversed by cotreatment with *N*(*G*)-nitro-L-arginine methyl ester (76).

Serotonin and other vasoactive hormones (catecholamines, vasopressin) released at the angioplasty site are also able to induce SMC proliferation (78,79,80 and 81). Considerable interest has been focused on endothelin, a potent vasoconstrictor peptide produced by vascular endothelial cells (82). Endothelin binds specifically to human SMCs in culture and can induce nuclear oncogene expression (83,84). Endothelin has been shown to have mitogenic activity for rat aortic SMCs (85), and use of endothelin antagonists reduces neointimal thickening after vascular injury *in vivo* (86,87).

Mechanical Factors

Mechanical factors may also play a role in determining the magnitude of the restenotic lesion generated in experimental models. Large areas of endothelial denudation without trauma to the media lead to mild neointimal thickening despite late endothelial regeneration (88). In contrast, focal endothelial denudation with substantial medial trauma, including rupture of the internal elastic lamina, is associated with marked neointimal proliferation, despite prompt endothelial regeneration (89). These results suggest that endothelial denudation alone is not sufficient to produce major neointimal thickening and that direct stimulation of SMCs is also an important factor. Direct injury of SMCs may induce a greater neointimal response by (a) increasing the local release of growth factors from necrotic SMCs and (b) activating intracellular pathways leading to proliferation of residual viable SMCs (90,91).

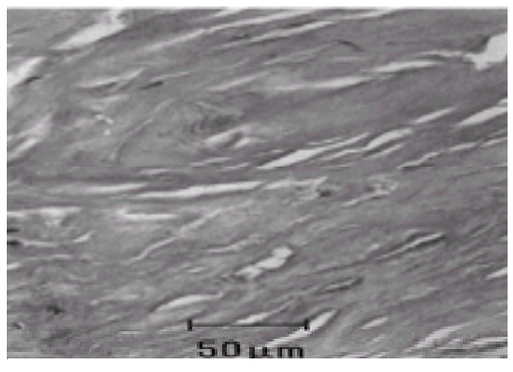
Besides acute mechanical factors, chronic mechanical factors may also play a role. Blood flow in the injured vessel may be a determinant of subsequent restenosis. Experimental studies by Kohler et al. (92,93) have demonstrated greater neointimal hyperplasia when blood flow is reduced after angioplasty.

Neointimal Formation after Percutaneous Transluminal Coronary Angioplasty in Humans

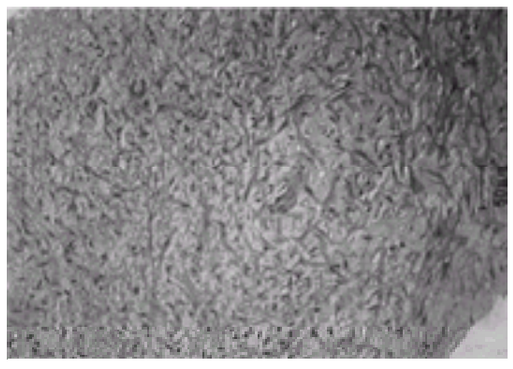
An important issue is to determine whether evidence for certain pathophysiologic mechanisms of restenosis demonstrated in experimental models can be supported by clinical observations in humans. Although angiographic studies have exhaustively detailed the incidence and time course of restenosis after PTCA, the arterial wall response in humans has been less well documented than responses in experimental animal models. Nevertheless, necropsy studies and contemporary diagnostic tools of invasive cardiology such as directional atherectomy, intravascular ultrasonography (IVUS), and angioscopy have allowed a better description and understanding of neointimal formation after PTCA in humans.

Proliferation and Restenosis

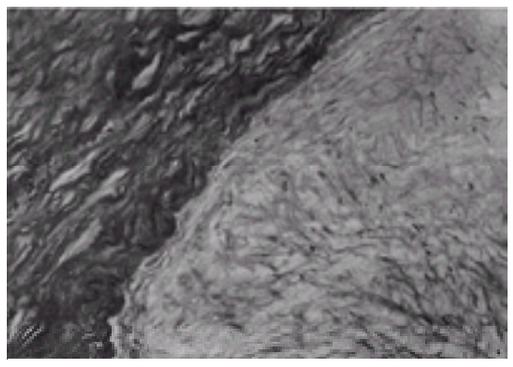
Light-microscopic features of atherectomy specimens retrieved from coronary arteries of patients undergoing percutaneous revascularization (94,95 and 96) have confirmed observations made in smaller numbers of patients at necropsy (97,98). Primary and restenotic lesions can often be distinguished from each other on the basis of certain light-microscopic findings (99). Primary lesions (*e*Fig. 105.2.1) appear typically hypocellular, consisting predominantly of well-organized collagen and ground substance. In contrast, restenotic lesions (*e*Fig. 105.2.2) typically include a focus of hypercellularity. Cells within these foci have phenotypic characteristics of proliferative SMCs, and the ECM surrounding these cells has a distinctive hue and less compact appearance than does the ECM of primary plaque (*e*Fig. 105.2.3).



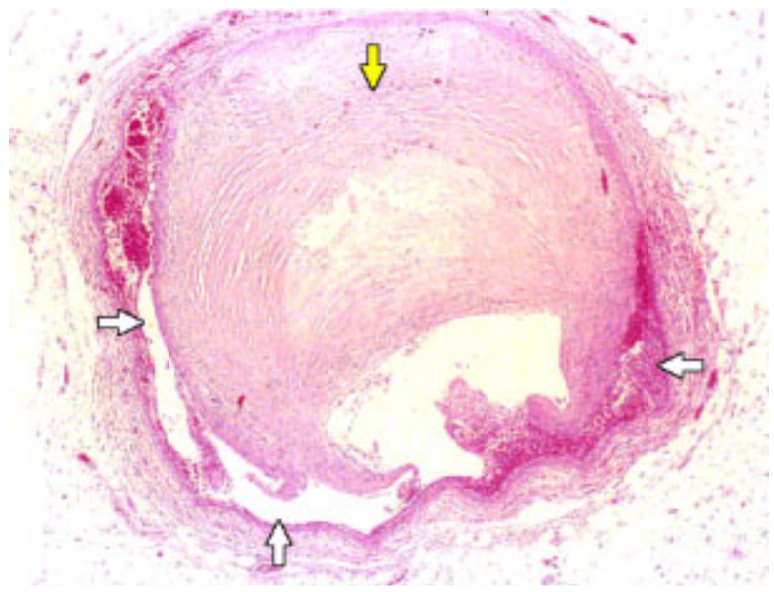
***e*FIGURE 105.2.1** Typical histologic appearance of primary atherosclerotic lesion. The specimen consists principally of collagenous extracellular matrix with a paucity of cellular elements (hematoxylin and eosin stain).



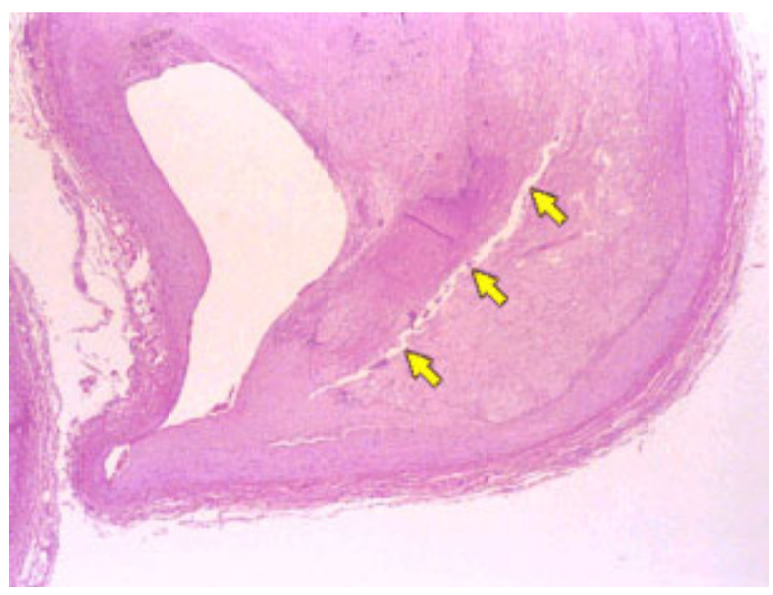
***e*FIGURE 105.2.2** Classic hyperplastic response in a human restenotic lesion comprised of smooth muscle cells with “activated” phenotypic appearance (hematoxylin and eosin stain).



***e*FIGURE 105.2.3** Bilayer appearance illustrating contrasting features of primary lesion and superimposed restenosis aspect. Primary lesion is hypocellular, and extracellular matrix has a blue-green hue. Restenosis component is hypercellular, including cells with phenotypic features of “activated” smooth muscle cells, embedded in loose, less compact matrix with a distinctive, light-staining hue (elastic tissue stain).

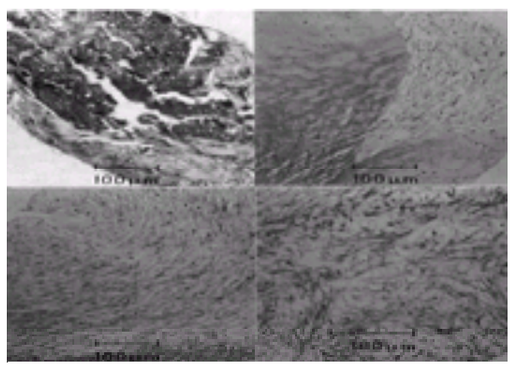


Linear, circumferential dissection 2 days after balloon angioplasty of a restenotic lesion. Note the extensive neointimal proliferation (*yellow arrow*) and dissection (*white arrows*).



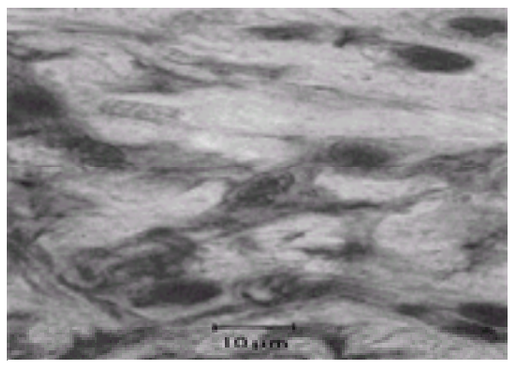
Restenotic lesion. Residual tear in atherosclerotic plaque (*yellow arrows*) and large amount of neointimal proliferation 76 days after balloon angioplasty.

These contrasting findings between primary and restenotic lesions are perhaps best illustrated in a group of 18 patients studied in the authors’ laboratory (100), in whom directional atherectomy had been performed both as the primary intervention and again at the time that the patient returned with restenosis (*e*Fig. 105.2.4). These 18 patients thus offered a unique opportunity to study the same lesion site in the same artery of the same patient at two different times. Light-microscopic examination documented distinctive features, including hypercellular foci consisting of proliferative vascular SMCs surrounded by a loose neomatrix, in 13 (72%) of 18 cases. In five patients, neither the primary nor the restenotic specimen demonstrated such a “restenotic focus.” A similar restenotic focus has been observed in 165 (65%) of 253 restenotic specimens retrieved by directional atherectomy in the authors’ laboratory. Acknowledgment must be made, however, that the hypercellular lesion is not altogether specific for restenosis: In *de novo* directional atherectomy specimens, a similar lesion was observed in 7% of primary specimens (99).



***e*FIGURE 105.2.4** Sequential specimens retrieved by directional atherectomy from same patient. **Top left:** Thrombotic primary lesion. **Top right:** Restenotic lesion no. 1, demonstrating bilayer appearance with hypocellular primary component and hypercellular restenosis portion. **Bottom left:** Restenotic lesion no. 2. **Bottom right:** Restenotic lesion no. 3.

Pathologic analyses of specimens retrieved from restenotic lesions by directional atherectomy have been performed to determine the extent of ongoing cellular proliferation (101). Pickering et al. (101) have analyzed the expression of the proliferating-cell nuclear antigen (PCNA) (restenosis) (*e*Fig. 105.2.5) and found that the proliferative index (percentage of PCNA-positive cells) was higher in restenotic than in primary lesions. Proliferating cells were detected by *in situ* hybridization and immunohistochemistry in 15% to 20% of cells of specimens retrieved from restenotic lesions. These findings thus indicate that, among patients referred for percutaneous revascularization, SMC proliferative activity is still ongoing at the time the patient presents with symptoms requiring interventional therapy. One must underscore, however, that based on animal studies (102) in which the histopathology of restenosis could be systematically examined at a number of arbitrary—including early—time points, peak proliferative activity occurs soon after the initial injury; thus, the proliferative activity seen at the time of intervention represents a fraction of the proliferative activity responsible for generating hyperplastic lesions typical of restenosis.



***e*FIGURE 105.2.5** Restenotic lesion double immunostained with antibody to proliferating-cell nuclear antigen (red nuclear reaction product) and a-actin (yellow-brown cytoplasmic stain).

Apoptosis and Restenosis

Previous studies have suggested that development of restenosis represents the net outcome of SMC proliferation and programmed cell death, or apoptosis (103,104,105 and 105a), and that cellular proliferation is associated with apoptosis rates that are higher than those observed in primary lesions; this is true for coronary as well as peripheral vascular sites (104) (Fig. 105.3).

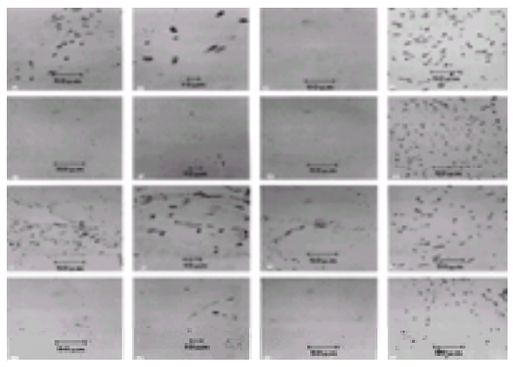


FIGURE 105.3 Apoptosis in human vascular lesions retrieved by directional atherectomy and identified by immunostaining of primary atherosclerosis. This composite photograph illustrates the use of terminal deoxytransferase (TdT)–mediated deoxyuridine 5-triphosphate–biotin nick end labeling to immunostain sections from specimens representative of the four groups of lesions studied: peripheral restenosis **(A–D)**, peripheral primary **(E–H)**, coronary restenosis **(I–L)**, and coronary primary **(M–P)**. Negative control was incubated in the absence of the TdT enzyme. One section of each tissue was processed as a positive control by pretreatment with deoxyribonuclease.

The possibility, if not the likelihood, exists that proliferation and apoptosis are temporally dissociated. Specifically, the contribution of SMC proliferation to the genesis of the restenotic lesion may peak relatively early after angioplasty, as has been repeatedly demonstrated in various animal models (106,107,108,109,110,111 and 112) studied at early time points seldom sampled in human subjects. Apoptosis, in contrast, may become more frequently recognizable at a later time. This latter concept is in fact consistent with previous animal studies reported by Clowes et al. (113) in the balloon-injured rat carotid artery. They found that proliferative activity of vascular SMCs, as determined by use of tritiated thymidine, persisted at relatively high levels (3.8%) for up to 12 weeks after balloon injury. Total arterial SMC content at 12 weeks, however, was unchanged from that measured at 2 weeks. In the absence of cell death, Clowes et al. calculated that this level of ongoing proliferation should have led to a 36% increase in cell number. Because this increase was not observed, they made the clairvoyant deduction that “cell death must account for our finding.”

Extracellular Matrix and Restenosis

Although vascular SMC proliferation and the resulting hypercellular nature of the fibroproliferative tissue have been the focus of most studies of restenosis, it is the ECM that in fact accounts for the bulk volume of these lesions (Fig. 105.4). Together with activated SMCs, ECM having a distinctively lighter hue on histochemical staining comprises the classic restenotic focus (114). Various collagen subtypes and proteoglycans have been demonstrated to comprise the ECM of atherectomy specimens (115), and certain constituents, particularly collagen, are derived from adventitial fibroblasts (116). The contribution of two proteoglycans in particular, biglycan and decorin (Fig. 105.5), known to be differentially modulated during ECM elaboration and differentially regulated by TGF-b_1 (Fig. 105.6), have been found to be differentially distributed in primary versus restenotic lesions (115). Extracellular deposits of biglycan were found to be characteristic of the loose, rich ECM typical of restenosis, whereas staining for decorin was limited to weak staining intensity in the more compact transition zone between loose ECM and dense connective tissue typical of advanced lesions composed of hypocellular fibrous plaque. More recently, the glycosaminoglycan hyaluronic acid (Fig. 105.7) has been shown to be a characteristic constituent of the loose myxoid ECM of human restenotic arteries (117). The presence of hyaluronic acid may be a marker for an initial phase of the ECM remodeling that occurs during the development of a fibroproliferative lesion and could facilitate biologic processes such as cell migration. Furthermore, because hyaluronic acid is heavily hydrated, the proposal has been made that (a) this hydrated feature of restenotic lesions may be responsible for the distinctive hue of the restenotic lesion; and (b) gradual loss of water or replacement of hyaluronan by collagen, or both, converts the restenotic lesion into a compact scar, with the resulting cicatrization then pulling in the arterial wall, which leads to constrictive remodeling (Fig. 105.8).

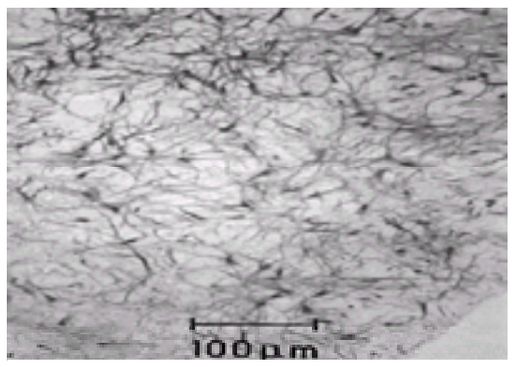

FIGURE 105.4 Restenosis specimen with abundant extracellular matrix. Note characteristic light-hued area in which are embedded stellate-shaped, synthetic smooth muscle cells (elastic tissue stain).

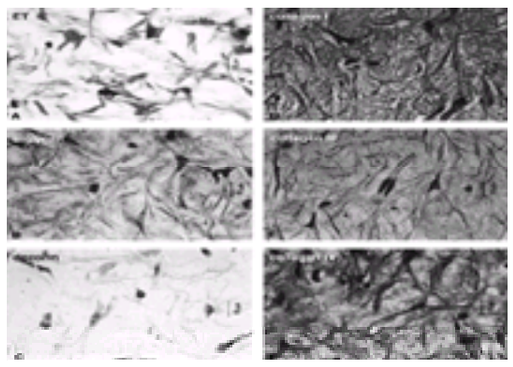

FIGURE 105.5 High-magnification photomicrographs taken from serial sections of a restenotic lesion (6 months after angioplasty) showing a fibroproliferative focus. Stellate-shaped a-actin–positive smooth muscle cells (not shown) are embedded in a loose extracellular matrix (elastic tissue trichrome stain) **(A)**. Immunostaining shows disseminated biglycan deposits **(B)**, no decorin **(C)**, and a loose network of collagen type I **(D)** and type III **(E)**. Staining for collagen type IV **(F)**, although also present in an interstitial distribution, is most intense around the perimeter of the cells.

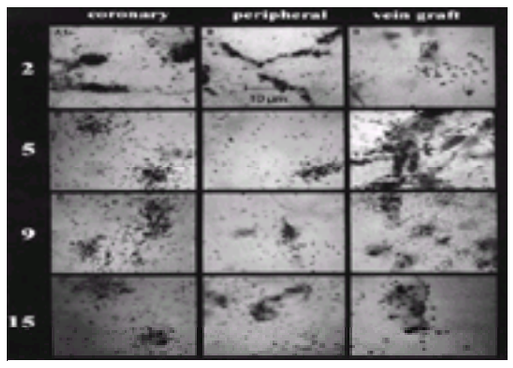

FIGURE 105.6 *In situ* hybridization performed on specimens retrieved by directional atherectomy from restenotic lesions in coronary and peripheral arteries and vein grafts. Numbers on the left refer to the time interval (months) between previous intervention and atherectomy procedure. Dark black silver grains overlying smooth muscle cells denote messenger RNA for transforming growth factor-b.

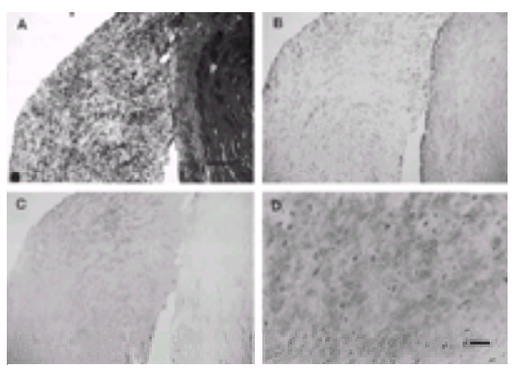

FIGURE 105.7 A: Low magnification of the elastic tissue trichrome staining of a restenotic lesion retrieved 7 months after angioplasty. A large restenotic focus (fibroproliferative tissue, FPT) is clearly demarcated from dense, compact matrix typical of primary plaque (*P*) (bar = 10 µm). **B:** In this adjacent section, the restenotic focus shows patchy staining for collagen type III, whereas collagen staining in areas of primary plaque is much more homogeneous. **C:** Staining for hyaluronic acid (HA) is inversely related to that for collagen, with dense, homogeneous staining for HA in the restenotic regions and only focal deposits of HA in primary plaque. **D:** High-power view of restenotic portion of previous specimen, double-stained for HA and proliferating-cell nuclear antigen (PCNA). The numerous PCNA-positive smooth muscle cells in this tissue are surrounded by an HA-rich matrix (bar = 10 µm).

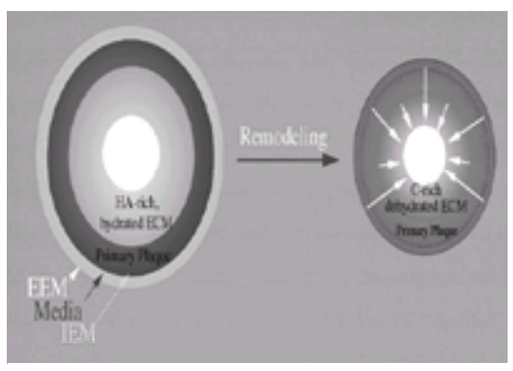

FIGURE 105.8 As hyaluronic acid (HA), heavily hydrated, is replaced by collagen (C), resulting dehydration of the extracellular matrix (ECM) may exert a cicatrizing effect on the arterial wall, retracting the dimensions of the artery wall, much as a contracting scar pulls in skin. This process is proposed to contribute to constrictive remodeling of the vessel wall. EEM, external elastic membrane; IEM, internal elastic membrane.

Angioscopic Findings

Evidence for neointimal formation after PTCA in humans can also be obtained from angioscopic studies (118,119) (Fig. 105.9). Although the angioscopic appearance of a primary lesion is extremely variable in terms of color, shape, and presence of superimposed thrombus, the angioscopic appearance of a lesion that was dilated a few months earlier is almost unvaryingly that of a stable smooth white plaque without thrombus (119). These differences reflect the magnitude of the changes occurring at the lesion site during the months after PTCA. The smooth concentric white aspect of the plaque is likely to be a consequence of neointimal hyperplasia that leads to a remodeling of the inner part of the vessel. Interestingly, this angioscopic aspect is not limited to restenotic lesions (greater than 50% stenosis by angiography) but is also observed in vessels that are widely patent at 6-month angiographic follow-up. This suggests that a significant healing process of the inner part of the vessel (probably related to neointimal hyperplasia) may occur without deleterious effects in terms of lumen size.

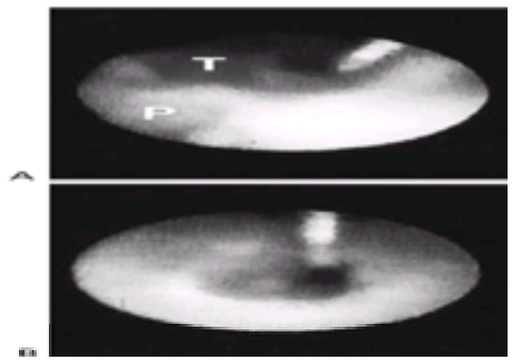

FIGURE 105.9 Serial images before angioplasty and 6 months after angioplasty. **A:** Angioscopic appearance of a lesion before angioplasty in a patient with unstable angina discloses a yellow plaque (*P*) with a superimposed red thrombus (*T*). **B:** Angioscopy of the same lesion 6 months after successful angioplasty; angioscopy now discloses a white, smooth, concentric lesion without thrombus.

Rotational atherectomy to treat in-stent restenosis. Diffuse restenosis within a previously placed Palmaz-Schatz stent (A, *arrows*) is treated with rotational atherectomy (B), followed by adjunctive stent placement (C). The postintervention result is shown in D.

Vessel Remodeling

Experimental evidence is increasing that neointimal hyperplasia is not the sole mechanism leading to lumen renarrowing after angioplasty, namely, that arterial remodeling also plays a major role in this process (17,18,120,121 and 122). Arterial remodeling is a well-recognized feature of *de novo* atherosclerosis. Glagov et al. (123) observed that human coronary arteries undergo adaptive enlargement in response to progressive plaque expansion and maintain the lumen area until the plaque occupies 40% of the area circumscribed by the internal elastic lamina. *In vivo* confirmation of the "Glagov hypothesis" was reported by Losordo et al. (124). This compensatory enlargement may thus obviate the effect of plaque development on lumen narrowing.

Studies involving animals and human subjects have established the potential for an alternative form of remodeling, constrictive remodeling. In contrast to the compensatory dilatation described by Glagov et al., constrictive remodeling after angioplasty results in reduced vessel wall diameter, indirectly narrowing the vessel lumen and thus contributing to restenosis.

Post et al. (120) observed a consistent deficit between the magnitude of late lumen loss measured by serial quantitative angiography and the diameter reduction that could be attributed to histologically identifiable intimal thickening. They concluded that "the deficit appeared to be due predominantly to reduction in the area circumscribed by the internal elastic membrane." Because the internal elastic membrane demarcates the native arterial lumen, any reduction in lumen area unassociated with plaque growth must, by default, be due to "constriction" of the lumen by a "shrinking" arterial wall. Post et al. estimated that remodeling accounted for 52% to 89% of the late loss in their *in vivo* experiments. Conversely, neointimal proliferation seemed to be responsible for an insignificant fraction of the late lumen loss in most cases.

Subsequently, double-injury models (i.e., models in which a first injury has been combined with a hypercholesterolemic diet to induce a stenosis that can be dilated with an angioplasty balloon) were used to study the impact of neointimal formation on lumen size a few weeks after angioplasty. Using this model, Kakuta et al. (18) showed that compensatory enlargement of the vessel (increase in internal elastic lamina area) occurs in the weeks after experimental angioplasty. This process seemed to compensate for nearly 60% of neointimal thickening in response to balloon injury and to prevent lumen narrowing. In this model, restenosis is not related to neointimal thickening but to a lack of compensatory enlargement or some degree of vessel constriction or both. The vessel size (area circumscribed by the internal elastic lamina) increased with increases in intimal area. In restenotic arteries, the slope of this correlation was less than one, which showed inadequate compensatory enlargement for neointimal formation. In nonrestenotic arteries, the slope was greater than one, which indicates limited effects of neointimal formation on luminal narrowing. Vascular remodeling thus acts to offset the effect of neointimal formation on chronic luminal narrowing, and differences in vascular remodeling seem to constitute a key element leading to restenosis in this model.

Mintz et al. (125) analyzed the contribution of neointimal formation to restenosis in human subjects studied by serial IVUS imaging after successful coronary angioplasty and again at the time of late angiographic follow-up. They observed that the change in lumen area between post-PTCA and late angiographic follow-up were more strongly correlated with the change in vessel size (area circumscribed by the external elastic lamina) than with the change in plaque plus media area (125,126). In the study by Mintz et al. (125), the changes in vessel size were bidirectional: Some lesions showed an increase in vessel size (enlargement), whereas others showed a decrease in vessel size (constriction). Lesions that exhibited an increase in vessel size had no change in lumen area (–0.1 ± 3.3 mm^2 versus a decrease in lumen area of 3.6 ± 2.3 mm^2 for lesions with a decrease in vessel size; p <.0001). Seventy-three percent of the late lumen loss was explained by the decrease in vessel size. They concluded that restenosis was determined primarily by the direction and magnitude of the vessel wall remodeling (change in external elastic lamina). An increase in the area circumscribed by the external elastic lamina is adaptive, whereas a decrease contributes to restenosis.

The precise mechanisms responsible for arterial remodeling after balloon injury remain uncertain. Proposed mechanisms for compensatory enlargement in *de novo* arteriosclerosis include increased flow with concomitant increase in shear stress and modulation of the ECM support structure with protrusion of the lesion outside the original contour of the artery (123). After balloon angioplasty, compensatory enlargement in response to neointimal growth may occur as a result of high flow velocity or as a consequence of ECM degradation (18). Chronic constriction, on the other hand, may be related to collagen deposition and reorganization of a hyaluronan-rich matrix (127). This is accentuated by low flow and may be secondary to stimulation of PDGF and TGF-b expression by low shear (127a,127b).

Studies have also suggested a role for the adventitia in the remodeling process (128,129). In the porcine model, injury leads to sequential changes in the adventitial layer, including cell proliferation, myofibroblast formation, and fibrosis (128). Associated significant focal adventitial thickening may play a role in the remodeling process.

THROMBOSIS

Immediately after experimental balloon injury, endothelial denudation induces platelet adhesion and aggregation, which results in release of the constituents of their alpha granules within a few minutes (6,23). Numerous mitogenic substances, including PDGF, are thus released at the site of injury and may be involved in the process of SMC activation (130). Experiments performed in thrombocytopenic animals have demonstrated the fundamental role of platelets in determining the extent of neointimal thickening after arterial injury (131). Experiments involving a canine model of endothelial injury have demonstrated that the intensity of cyclic flow variations related to platelet accumulation constitutes a major determinant of neointimal thickening (132). Thrombocytopenia has been shown to inhibit migration of activated SMCs from the media to the intima but to have no effect on the initial cycle of cell proliferation (23). Coagulation proteins such as thrombin may also be implicated in the response of SMCs (133). Thrombin has mitogenic properties for SMCs (134) and has been demonstrated to induce multiple growth-related signals in SMCs, including the expression of the c-*fos* protooncogenes (135). Finally, the volume of thrombus at the PTCA site may also play a role in the subsequent restenosis process; Schwartz et al. (49), based on observations made in the porcine coronary injury model, proposed that the volume of intracoronary thrombus resulting from PTCA may serve as a scaffold that determines the subsequent volume of neointima.

Clinical studies have suggested that thrombus formation may play a role in restenosis after PTCA in humans. The contribution of thrombosis to lumen renarrowing may be especially marked when PTCA is indicated for an unstable coronary syndrome. High restenosis rates have been observed, for example, in patients in whom angioplasty was performed at an infarct-related lesion (136,137) or in patients with severe unstable angina (138,139). The impact of local versus systemic factors on restenosis after PTCA of patients with unstable angina was studied (139). To assess these factors, a group of patients was identified who had unstable angina with a clearly defined culprit lesion and who underwent successful double-vessel angioplasty during a single catheterization session. Using quantitative angiography, the incidence of restenosis at culprit and nonculprit lesions was compared. The late loss at culprit lesions (0.87 ± 0.75 mm) was significantly greater than the equivalent value for nonculprit lesions (0.33 ± 0.69 mm; p <.01). Restenosis occurred at 67% of culprit lesions and at 32% of nonculprit lesions (p <.01). These results suggest that the increased rate of restenosis in patients with unstable angina predominantly reflects the influence of local lesion-related factors.

Because the pathophysiology of unstable angina or acute myocardial infarction, or both, involves episodes of plaque rupture associated with platelet aggregation and thrombus formation (140,141 and 142), studies have been designed to examine the relationship between thrombus and restenosis (118,143). Coronary angioscopy is

to date the reference technique for the detection of intracoronary thrombus in humans. More than 50% of the thrombi detected by angioscopy are not detected by angiography (144,145). Ninety-nine consecutively treated patients who underwent coronary angioscopy before and immediately after a successful PTCA procedure and who had angiographic follow-up 6 months later were studied (118). To assess the role of an angioscopically visible thrombus at the PTCA site on the risk of restenosis, patients were classified into three groups: no thrombus, lining thrombus, and protruding thrombus. An angioscopic protruding thrombus at the PTCA site was associated with significantly greater loss in luminal diameter (late loss: no thrombus, 0.47 ± 0.52 mm; lining thrombus, 0.59 ± 0.67 mm; protruding thrombus, 1.07 ± 0.77 mm; p <.05). The restenosis rate (greater than 50% stenosis at follow-up) was also higher in the case of an angioscopic protruding thrombus (no thrombus, 38%; lining thrombus, 47%; protruding thrombus, 65%).

The mechanisms by which an intraluminal thrombus may increase the risk of restenosis after PTCA are not known specifically, but at least two hypotheses may be invoked. First, as discussed earlier, thrombosis may stimulate neointimal formation (49,131,132). However, a significant proportion of the restenoses observed after PTCA of lesions with superimposed thrombus are in fact due to total occlusion of the vessel at follow-up (118,143). These occlusions may occur as a final step in severely restenotic lesions but also may be the consequence of a thrombotic event occurring early after PTCA.

ENDOTHELIAL REGENERATION

Endothelial Regeneration after Experimental Arterial Injury

Endothelial Regrowth

In the hours after experimental angioplasty, endothelial cells rapidly enter the replication cycle to restore endothelial continuity. Proliferation and migration can be initiated either by loss of contact inhibition, stretch, or growth factors secreted by endothelial cells, SMCs, and circulating cells (15,56). Endothelial regeneration starts from the leading edge of the denuded area and from the ostia of collateral or branch arteries or both (146). Reendothelialization begins within the first 24 hours of arterial denudation and ceases 6 or 10 weeks later, depending on animal species (19). The rate and extent of endothelial regrowth are related to animal models and experimental conditions, but the most important factor seems to be the severity of the initial injury. Indeed, although complete reendothelialization can be achieved after small denuding injuries (147,148), endothelial cells have been found to be incapable of sustained regrowth after widespread denudation (19,20,149). Even if complete reendothelialization occurs, the regenerated endothelium often displays abnormal morphologic characteristics. In contrast to normal endothelial cells, regenerating endothelial cells grow as a sheet with close cell-to-cell contacts, no longer aligned with blood flow, and are both polygonal in shape and irregular in size, with cytoplasm bulging toward the lumen (19,146,148,149 and 150).

Studies have emphasized the important role of endothelial cell growth factors in the reendothelialization process. Lindner et al. (56) have shown that systemic administration of bFGF (120 µg over an 8-hour period) after balloon catheter denudation of the rat carotid artery induces a highly significant increase in the replication rate of endothelial cells at the leading edge of the regrowth process. In this study, when bFGF was given over a longer period of time (12 µg daily for 12 days), a significant increase in the extent of endothelial outgrowth onto the denuded surface was observed. A study of the effect of much lower dosages of bFGF (systemic administration of 2.5 µg twice a week for 2 weeks) on the extent of endothelial regrowth after balloon denudation of rabbit iliac arteries found that animals in the bFGF group had a significantly greater degree of reendothelialization than did controls (151). Similar results have been observed with the use of acidic fibroblast growth factor in the same model (152). Stimulation of endothelial regrowth can also be achieved with vascular endothelial growth factor (VEGF). Asahara et al. (153) have demonstrated that a single local administration of VEGF (100 µg) immediately after balloon injury of the rat carotid artery is sufficient to significantly increase carotid artery reendothelialization at 2 and 4 weeks after injury. More recently, gene transfer of a plasmid encoding VEGF was associated with accelerated endothelial regrowth in a rabbit model (154) (Fig. 105.10). Taken together, these results demonstrate that both bFGF and VEGF are powerful stimuli of endothelial regrowth *in vivo* and suggest that they may participate in the spontaneous reendothelialization that occurs after injury.

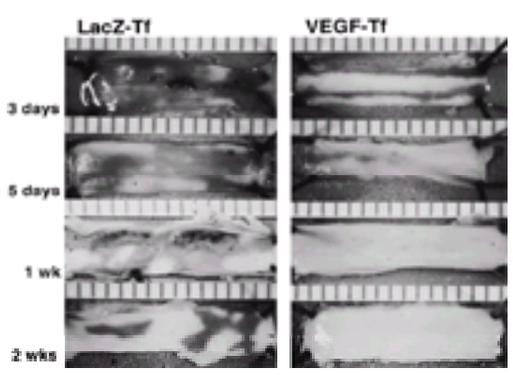

FIGURE 105.10 Representative macroscopic appearance of intimal surface of balloon-injured arteries transfected with control gene encoding b-galactosidase (LacZ-Tf) and gene encoding vascular endothelial growth factor (VEGF-Tf) at 3 days, 5 days, 1 week, and 2 weeks after gene transfer. Animals received systemic injection of Evans blue dye before sacrifice. Stained areas denote absent endothelium; reendothelialized areas, not stained by dye, appear white. Reendothelialization is accelerated in animals given VEGF-Tf.

Role of Progenitor Endothelial Cells in Reendothelialization

Work by Asahara et al. (155) has established that circulating mononuclear cells isolated from peripheral blood using antibodies to CD34 or Flk-1 can differentiate into endothelial cells *in vitro*. *In vivo*, such circulating endothelial cell progenitor cells were shown to incorporate into sites of angiogenesis, and more recent studies have indicated that such cells may contribute to reendothelialization at sites where balloon angioplasty has resulted in endothelial denudation. These findings thus suggest the need to reevaluate the conventional paradigm in which endothelial cells responsible for reendothelialization are considered to proliferate and migrate from intact endothelium at the proximal and distal boundaries of the balloon-injured segment, or from branch vessels. Some as-yet-undefined proportion of these endothelial cells may in fact be derived from circulating endothelial cell progenitor cells. Still to be determined is whether primary alterations in the proteoglycan “landing pad” that constitutes the denuded segment—for example, expression of osteopontin or fibronectin beginning at the wound edges and progressing to the center of the denuded segment—determine the sequence in which such circulating progenitor cells may attach, differentiate, migrate, and proliferate.

Endothelial Dysfunction

The functional properties of regenerated endothelium have also been shown to be abnormal (27,148,156). After vascular injury, endothelium-dependent relaxation to vasodilator agonists is depressed in arteries with regenerated endothelium at a time when the ability of underlying vascular SMCs to relax or contract is unchanged. The severity of the endothelial dysfunction seems to be dependent on the nature of the initial injury. In a rabbit iliac artery model of angioplasty, impaired endothelium-dependent relaxation was found 4 weeks after the procedure only if animals experienced severe injury (148). Similarly, studies performed after coronary angioplasty in humans have demonstrated abnormal responses of previously dilated sites to endothelium-dependent agonists such as serotonin (157) and acetylcholine (158).

Endothelial dysfunction may be related to a reduction in the ability of endothelial cells to produce endothelium-derived relaxing factors (159,160 and 161). Indeed, enhancing the production and release of NO may reverse endothelial dysfunction. In a rabbit model of balloon-injured iliac arteries, L-arginine, given in animal drinking water, restored acetylcholine-induced relaxations 4 weeks after vascular injury when these responses were depressed in the control group (27). This finding is in agreement with a reported study in which a constant intravenous infusion of the NO donor SPM-5185 significantly accelerated the functional recovery of the regenerating endothelium (162).

Importantly, the function of the endothelium that regenerates in response to exogenous administration of bFGF or VEGF seems to be normal (151,154). This demonstrates that endothelial cell growth factors are not only associated with a beneficial anatomic effect but also with an improvement in endothelial cell function. Similar results have been reported in other models of endothelial dysfunction. For example, the administration of angiogenic growth factors has been demonstrated to restore endothelium-dependent responses in arterial beds perfused via collaterals (163,164 and 165) and in hypercholesterolemic rabbits (166,167).

Impact of Endothelial Regeneration on Restenosis

Effects on Neointimal Hyperplasia

Previous investigations have underscored the principle of cross talk between endothelial cells and SMCs (149,168,169 and 170). Neointimal thickness is closely related to the presence of a regenerated endothelium. Indeed, intimal areas that are rapidly covered by continuous endothelium are protected from the accumulation of intimal SMCs, whereas typical intimal hyperplasia occurs in areas where reendothelialization is delayed.

Endothelium, in addition to its well-known role in regulating vessel tone and platelet aggregation, seems to modulate proliferative activity of the underlying SMCs. *In vitro* studies have emphasized a possible role for NO in controlling SMC growth (171,172). NO donors inhibit DNA synthesis in cultured SMCs, and similar effects achieved by administration of the analog 8-bromo-cyclic-guanosine monophosphate implicate the cyclic guanosine monophosphate pathway, physiologically activated by NO, in SMC growth regulation. Endothelial cells may maintain SMC quiescence through the growth-inhibitory effect of NO (172). Dysfunctional regenerating endothelium in which NO production is compromised may thus contribute to the development of a thickened intima due to reduced inhibition of platelet aggregation as well as SMC proliferation. Intriguingly, animal experiments have in fact documented that endothelial cell recovery is slower over damaged media than over normal media (173). On the basis that NO synthase catalyzes the synthesis of NO after oxidation of terminal guanidine-nitrogen atoms of L-arginine (174,175), several authors have administered this precursor locally or systemically and confirmed *in vivo* the efficacy of NO in preventing intimal hyperplasia (21,176,177).

Investigational experience with endothelial cell mitogens has yielded similar results. As discussed earlier, Asahara et al. demonstrated that a single local application of the endothelial cell–specific mitogen VEGF, either as a recombinant protein (153) or as naked DNA (154) (Fig. 105.10), is sufficient to facilitate endothelial repair after balloon injury (153). In these studies neointimal thickening was correspondingly attenuated to a statistically significant degree in VEGF-treated animals (Fig. 105.11). Somewhat different results have been observed in the case of FGF-induced reendothelialization. Lindner et al. (55), using high dosages of bFGF (12 µg daily for 12 days in a rat model), found a significant increase in neointimal thickening. By contrast, Bjornsson et al. (152), using low dosages of acidic FGF [a mitogen for SMCs *in vitro* (178)] in the same model, observed an inhibition of neointimal thickening. The present authors found that administration of 2.5 µg of bFGF twice a week for 2 weeks in a rabbit model was associated with a very significant increase in endothelial regrowth but with no change in neointimal thickening (151). As bFGF is also a growth factor for SMCs, its final effect on neointimal thickening may be the consequence of a balance between stimulatory and inhibitory mechanisms on SMC growth. Factors such as the dosage used, the duration of the treatment, and the animal model studied may explain discrepancies between studies. On the other hand, the results obtained with VEGF are probably mainly the consequence of reendothelialization, without detrimental effect on SMC—that is, proliferation—because VEGF high-affinity binding sites are limited to endothelial cells.

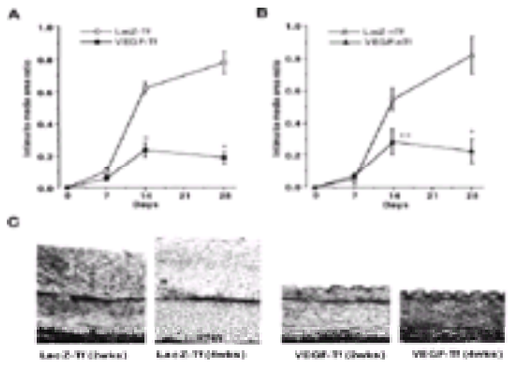

FIGURE 105.11 A: Arteries transfected with control gene encoding b-galactosidase (LacZ-Tf) showed progressive neointimal thickening through 4 weeks. Significantly less intimal thickening was observed among arteries transfected with gene encoding vascular endothelial growth factor (VEGF-Tf), including regression of intimal thickening between 2 and 4 weeks (*, p <.01 vs. LacZ-Tf). **B:** Contralateral balloon-injured, nontransfected arteries in VEGF group (VEGF-nTf) developed less intimal thickening and displayed no progression during weeks 2 to 4 compared with those in LacZ-nTf group (*, p <.01 vs. LacZ-nTf; **, p <.05). **C:** Representative effect of transfection on intimal thickening for LacZ-Tf and VEGF-Tf at 2 and 4 weeks posttransfection.

Effects on Vessel Remodeling

Several studies have also suggested a potential role for the endothelium in modifying the remodeling process. Previous studies have shown that adaptive enlargement, that is, increase in the lumen area of the vessel, occurs in response to a long-term increase in flow velocity (179). Conversely, a structural decrease in the lumen diameter is associated with a long-term decrease in blood flow. A functional endothelium seems to be essential for the compensatory arterial response to long-term changes in luminal flow rates (180). Thus, the absence of endothelium or the presence of a regenerated dysfunctional endothelium after arterial injury may impair the shear stress–induced remodeling response and may be an important factor in restenosis (181).

Antithrombotic Effects

In addition to the effects on the vascular wall described earlier, endothelial regeneration may also exert beneficial antithrombotic effects. Endothelium-derived relaxing factors such as NO and prostacyclin act synergistically to inhibit platelet aggregation and leukocyte adhesion (182,183). Aggregating platelets can initiate the coagulation cascade with the production of thrombin.

IMPACT OF ENDOVASCULAR STENTS ON THE BIOLOGY OF RESTENOSIS

Coronary stenting is emerging as an effective treatment for patients with coronary artery disease (184,185 and 186). Changes in antithrombotic regimens and in the technique of implantation have allowed coronary stenting to be performed with excellent immediate outcome (187,188 and 189). As a result, the proportion of patients receiving a stent as an adjunct to conventional balloon angioplasty is increasing exponentially. Studies have shown that implantation of permanent metal prosthetic stents results in significantly lower rates of clinically and angiographically determined recurrence than with conventional balloon angioplasty (190,191). Even if restenosis is less frequent, however, it remains a significant problem after coronary stenting. Rates of angiographically identified restenosis varying between 13% and 32% have been reported after successful coronary stenting (190,191 and 192). Importantly, the mechanisms of restenosis within coronary stents differ very significantly from those of restenosis after conventional balloon angioplasty.

Stent and Vessel Remodeling

Serial intravascular ultrasonographic studies have indicated that stents do not recoil over the long term (193,194). Implantation of an intracoronary stent seems to eliminate any component of arterial remodeling, either enlargement or constriction. As vessel remodeling is the major mechanism of restenosis after conventional balloon angioplasty (125), its elimination is probably the main explanation for the decrease in restenosis rate after coronary stenting.

In-Stent Restenosis

Because stents are considered to neutralize geometric effects, including remodeling (121), development of restenosis after stent implantation has been attributed principally to SMC proliferation. Successful application of intravascular radiation to limit thickening of stent neointima in a variety of animal models (195,196 and 197), on the premise that proliferating cells display enhanced sensitivity to ionizing radiation, constitutes indirect support for this notion. Likewise, accelerated endothelialization of stents after catheter delivery of the gene encoding VEGF has been shown to markedly reduce SMC proliferation and thereby reduce luminal narrowing due to thickening of the stent neointima (198).

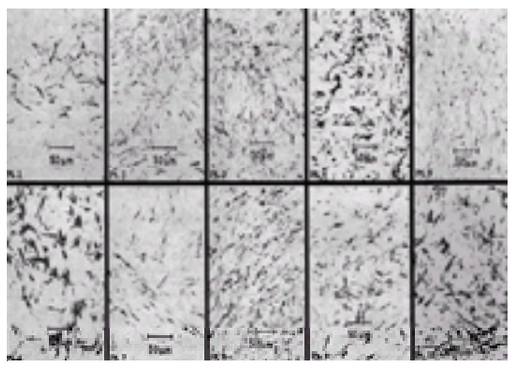
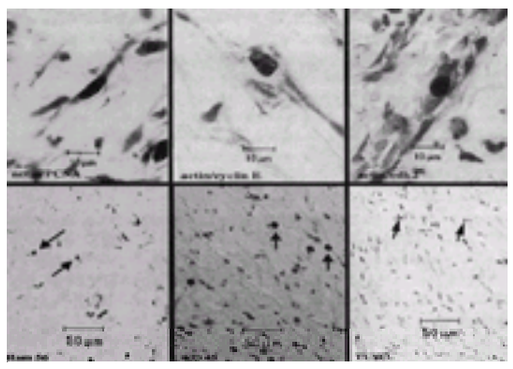
Histologic findings reported for a limited number of patients have suggested that in-stent restenosis is characterized by SMC hyperplasia. Pathologic analysis of graft segments surgically retrieved from two patients described by Anderson et al. (199) revealed "smooth muscle cells with abundant eosinophilic cytoplasm and minimal interstitial tissue" in the tissue overlying the stent wires. Among four patients with in-stent restenosis described by van Beusekom et al. (200), "tissue that narrowed the vessels always consisted of SMCs (often with a 'dendritic' appearance) within an extensive extracellular matrix." The extent of residual proliferative activity among these hypercellular foci was not specifically investigated in either series of patients.

Strauss et al. (201) identified foci of intimal hyperplasia, defined as a proliferative cellular response associated with a matrix of loose connective tissue, in eight of ten specimens retrieved from sites of in-stent restenosis. SMCs were identified as the principal cell type within the lesion by the presence of alpha-actin. In none of the seven cases, however, did they observe positive staining for PCNA. Unfortunately, all of the specimens studied by Strauss et al. had been fixed in 10% buffered formalin, a preservative that has been shown to attenuate or eliminate positive staining for PCNA (96,202).

Kearney et al. (203) analyzed a series of ten atherectomy specimens retrieved from stents deployed in patients undergoing lower-extremity percutaneous revascularization. Each of the ten specimens contained extensive foci of hypercellularity, predominantly SMCs (eFig. 105.11.1). Moreover, when these tissues were preserved in fixative specifically intended to preserve the antigenicity of three different cell-cycle regulatory proteins, immunostaining performed with the corresponding monoclonal (PCNA) or polyclonal (cyclin 2, cdk2) antibodies (204) disclosed that proliferative activity was abundant in all such specimens (eFig. 105.11.2). Double immunostaining with cell-specific markers confirmed that SMCs accounted for most proliferative activity. These findings thus constitute direct evidence that SMC proliferation contributes to in-stent restenosis in human subjects and implies a potential role for adjunctive therapies intended to reduce in-stent restenosis by inhibiting SMC proliferation.



***e*FIGURE 105.11.1** Photomicrographs showing representative hypercellular foci in tissue retrieved from sites of in-stent restenosis in ten patients. Low-power photomicrographs of a-actin–immunostained sections show abundant cells with phenotypic characteristics of activated smooth muscle cells. In methanol-preserved specimens (patients 1, 4, 6, 7, 8, 9, and 10), immunostaining for proliferating-cell nuclear antigen disclosed evidence of abundant proliferative activity.



***e*FIGURE 105.11.2** Cell-specific, cell-cycle, and apoptotic immunostaining. Hematoxylin and eosin staining shows typical hypercellular focus. Three top photomicrographs illustrate proliferating smooth muscle cells, double-immunostained for a-actin and either proliferating-cell nuclear antigen (PCNA), cyclin E, or cdk2. Bottom left two panels show sparsely distributed macrophages [human alveolar macrophage 56 (HAM 56)] and leukocytes (CD45). Terminal deoxytransferase–mediated deoxyuridine 5-triphosphate–biotin nick end labeling (TUNEL) stain applied to eight specimens preserved in paraformaldehyde-identified evidence of abundant apoptosis in all eight cases. Arrows identify representative positive staining.

Foci of apoptosis were relatively abundant among these ten cases of in-stent restenosis, a finding that is consistent with observations made in restenosis specimens retrieved from native vessels (204). Cardiovascular and noncardiovascular studies have typically disclosed a relationship between cellular proliferation and apoptosis, a finding that is consistent with the proliferative activity demonstrated in the restenosis specimens.

Inflammatory cells, including foreign body granulomata formation, have been described in at least one previous animal study of endovascular stents (205). Although neither giant cells nor granulomata were observed in these specimens, occasional inflammatory cells were identified by CD45 immunostaining. A relatively small human alveolar macrophage-56 population was identified as well, but the contribution of both cell types to restenosis in these ten cases seems limited.

The role of thrombus in restenosis, including in-stent restenosis, is unclear. Schwartz et al. (206) have suggested that mural thrombus may constitute the primordial infrastructure that is subsequently colonized by activated SMCs. Thrombus was in fact observed in 60% of ten specimens in the cohort described and thus cannot be excluded as a factor contributing to the genesis of in-stent restenosis.

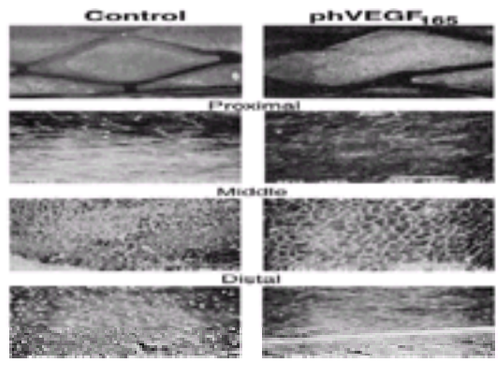
Stents and Thrombosis

As discussed earlier, thrombosis may contribute to restenosis. Stent implantation per se may increase the thrombotic response of the vessel wall. Thrombosis, however, may be significantly reduced by new antithrombotic regimens (189) and the use of heparin-coated stents (192).

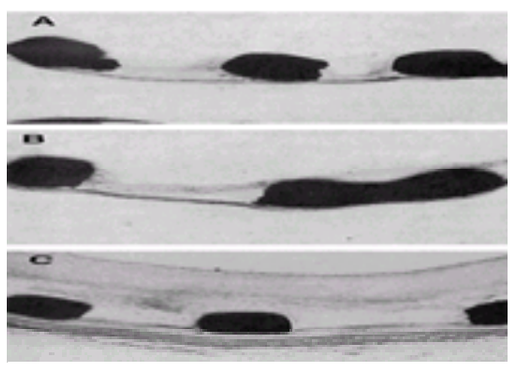
Stent Reendothelialization

Discordant results have been published regarding the process of stent reendothelialization. In rabbit aorta the process has been described as "completed" after 1 week (207); for rabbit iliac arteries, arteries were observed to "begin to endothelialize" after 1 week (195); and in dog and pig coronary models endothelialization was evaluated as "incomplete" (208) or "advanced" (209) after 1 week. In a series in which stents were implanted in human venous bypass grafts, no significant endothelialization was observed in three specimens retrieved within 14 days of implantation (200). In the only published series of human coronary stents examined at necropsy, endothelialization was observed in one of three specimens retrieved 3 weeks after implantation (199).

Reendothelialization was studied after Palmaz-Schatz stent implantation in iliac arteries of New Zealand White rabbits (210). Planimetric time-course analysis disclosed less than 20% stent endothelialization at 4 days, less than 40% at 7 days, and near-complete endothelialization at 28 days. When VEGF (100 µg) was delivered from a local catheter after stent implant, however, stent endothelialization was nearly complete by day 7 (92 ± 4%; p <.001 vs. no local delivery). In addition, a dramatic reduction in mural thrombus on the luminal surface of stents treated with VEGF was observed. Similar results were achieved with arterial gene transfer of naked plasmid DNA encoding for VEGF ($phVEGF_{165}$) (211) (eFig. 105.11.3 and eFig. 105.11.4). These findings may ultimately have important implications for preservation of stent patency.



***e*FIGURE 105.11.3** Representative examples of spontaneous stent endothelialization at day 7 (*left*) or after site-specific gene transfer of $phVEGF_{165}$ (*right*). Top left panel shows a macrophotograph of the silver-stained surface of the middle portion of the stent (×8.5). Stent endothelialization is incomplete (*bottom*), and mural thrombus is visible at the stent struts. Scanning electron photomicrographs from the proximal (×500), middle (×300), and distal portions (×300) of the stent confirm incomplete stent endothelialization of the proximal and distal portions of the stent with blood cell deposition in areas of nonconfluent endothelial cells (*Distal*), as well as thrombus along a nonendothelialized strut segment (*Middle*). Top right panel shows a macrophotograph of the silver-stained surface of the middle portion of the stent (×8.5). Stent endothelialization is virtually complete; no mural thrombus is visible. Scanning electron photomicrographs from the proximal (×300), middle (×300), and distal portions (×300) of the stent confirm that a confluent endothelial cell monolayer completely covers the stent (see *Distal*). The endothelial cells appear arranged in the direction of the flow in the proximal part of the stent. No foci of blood cells are visible.



***e*FIGURE 105.11.4** Effect of $phVEGF_{165}$ on intimal hyperplasia. **A,B:** Cross sections of transfected arteries 2 and 4 weeks, respectively, after stent implantation and site-specific delivery of 800 µg of $phVEGF_{165}$. Note limited intimal hyperplasia. **C:** Cross section of artery transfected with pCMV-luciferase (control) at 4 weeks posttransfection.

IMPACT OF ENDOVASCULAR BRACHYTHERAPY ON THE BIOLOGY OF RESTENOSIS

Endovascular brachytherapy is currently under investigation in humans to treat or prevent coronary restenosis after standard balloon angioplasty or coronary stenting. Although preliminary results are encouraging and suggest that this strategy may be effective in reducing restenosis rates at 6 months in selected patients (212,213), several issues are still unresolved. For example, the optimal dosage, the nature of the source (beta vs. gamma), and the ideal mode of administration (external irradiation vs. catheter-based irradiation, stent-based vs. wire-based delivery) are unknown. In addition, although long-term results of radiation are still uncertain, the suggestion has been made that endovascular brachytherapy may be harmful and may increase the rate of restenosis at the edge of stents (214) or increase the rate of thrombotic events (215,216). The effects of radiation on the restenotic process and on the cellular components involved in vascular healing are discussed in the following sections.

Brachytherapy and Vessel Remodeling

Animal and IVUS studies have shown that brachytherapy may alter vessel remodeling. In porcine coronary arteries (217,218), administration of intravascular irradiation at the time of balloon injury was associated with a larger external diameter of coronary vessels at 14 days than in animals receiving balloon injury alone. Consistent with this observation, a serial IVUS study (219) involving patients treated with balloon angioplasty and receiving beta irradiation found that 16 of 22 patients (76%) had vessel enlargement at 6 months. Similarly, Condado et al. (220) reported a negative late loss by angiography at 6 months in 10 of 22 patients (45%) treated with gamma radiation. This effect seems to be related to inhibition of adventitial fibrosis as suggested by the decrease in the number of adventitial cells expressing alpha-actin immunostaining after intravascular irradiation (218,221).

One must also point out, however, that animal experiments using external beam radiation have shown that irradiation may induce vessel constriction rather than vessel enlargement at 4 weeks (217). These effects were related to fibroblast proliferation and inflammation in the myocardium and to an increase in interstitial and perivascular fibrosis.

Brachytherapy and Intimal Hyperplasia

Studies have shown that intravascular radiation using a beta or gamma source may reduce intimal hyperplasia after balloon angioplasty at 14 days and 6 months in pigs (222,223 and 224) and at 6 weeks in rabbits (225). Similar results were found in animal models using beta-emitting stents (226,227 and 228). Results of preliminary trials showing that intravascular irradiation associated with stent implantation may reduce restenosis at 6 months suggest that this is also the case in humans (212). IVUS studies performed in humans are also consistent with a reduction of intimal hyperplasia at 6 months (229). Whether these results may last over the long term is not clear, however. Indeed, endovascular irradiation has also been associated with delayed arterial wound healing, including delayed endothelialization and persistent fibrin deposition in the intima 3 months after the implantation of beta-emitting stents in rabbits (230). In addition, smooth muscle cells with a synthetic rather than contractile phenotype produced large amounts of collagen 6 months after endovascular radiotherapy (217). Reports showing that intimal hyperplasia may continue to increase beyond the 6-month point in patients treated by endovascular brachytherapy are also consistent with these observations (231,232). Finally, some reports suggest that radiation may increase, rather than decrease, intimal hyperplasia. This has been observed with beta-emitting stents in animal models (233,234 and 235) as well as in humans at the stent edges (214).

Radiation inhibits proliferation and migration of endothelial and vascular smooth muscle cells and inhibits proliferation of myofibroblasts as demonstrated *in vitro* and *in vivo* (218,236,237). *In vitro*, the effects of radiation on endothelial cells and vascular SMCs relate to induction of G_0/G_1 arrest, without evidence of cell viability alteration, apoptosis, or ultrastructural changes (237,238). The absence of an effect of radiation on apoptosis was confirmed *in vivo* (218).

The apparently contradictory results observed in animal models and in humans seem to depend on the dosage, the method of delivery, and the timing of follow-up. The increase in intimal hyperplasia is thought to be secondary to insufficient direct inhibitory effect of radiation on proliferation and migration of vascular SMCs associated with stimulation of the production of collagen (6), a key component of ECM and intimal hyperplasia. The lack of the endothelial barrier may also indirectly stimulate the

growth of vascular SMCs (239).

Brachytherapy and Reendothelialization

Balloon angioplasty and stent implantation induce disruption of the endothelial lining. Radiation, by inhibiting endothelial cell proliferation and migration (236), may delay the reendothelialization process. Endothelialization remains incomplete 2 to 3 months after implantation of beta-emitting stents in animals (230), and analysis of human coronary artery specimens also shows limited endothelialization at 2 months (230). Delayed reendothelialization may have some impact on endothelial function and may explain the impaired endothelium-dependent relaxation observed at 6 weeks after endovascular brachytherapy and balloon injury in animals (240). Endothelial function seems to have returned to normal at 6 months, however, as observed in patients treated with endovascular brachytherapy (241). Delayed endothelialization may also partly explain some of the side effects that have been reported in some circumstances with endovascular brachytherapy, such as increased thrombus formation (242,243) and increased intimal hyperplasia (243,244 and 245). A study showing that the combination of agents able to stimulate reendothelialization may reduce thrombus formation after endovascular brachytherapy provides additional support to this hypothesis (244).

Brachytherapy and Thrombosis

A high rate (approximately 9%) of late total occlusion 1 to 6 months after endovascular gamma or beta radiotherapy was reported in the early experience of endovascular brachytherapy. This was more frequently observed in patients receiving a new stent (14.6%) than in patients receiving radiation but no new stenting (3.8%). This complication is usually observed after the first month and the discontinuation of ticlopidine hydrochloride or clopidogrel bisulfate (245).

As discussed earlier, delayed healing of the intima and lack of endothelial coverage for several months (242,243) are probably key factors leading to coronary thrombosis after endovascular brachytherapy combined with stent implantation.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Certain issues pertaining to the biology of restenosis have generated some controversy. Four, in particular, merit comment. The first issue is the extent to which SMC proliferation contributes to restenosis. All animal studies, without exception, have shown that when tissue sampling can be performed at arbitrary, including early, times, evidence of SMC proliferation is abundant. Most, indeed nearly all, human studies of tissues obtained at necropsy or surgery (including atherectomy) have shown evidence of SMC hyperplasia. The controversy has been generated largely because of one study in which proliferative activity was observed (using PCNA staining) in 15% to 20% of atherectomy specimens, whereas in a subsequent study PCNA staining was infrequent. The difference between these two studies may be explained largely by differences in methodology: In the latter study, a PCNA stain was identified as positive only if the staining intensity corresponded to that of control tissues colabeled for PCNA and the S-phase–specific marker bromodeoxyuridine. Such an analysis tests SMCs in S phase, as opposed to proliferating SMCs stained by PCNA in G_1 and G_2 as well. Because proportionately far more cells are in G_1 and G_2 at any given time, this methodology severely underestimates proliferative activity. Furthermore, because animal studies indicate that peak proliferative activity occurs soon after the initial injury, the extent of cellular proliferation seen at the time of intervention represents a fraction of the proliferative activity responsible for generating hyperplastic lesions typical of restenosis.

A second issue is the role of constrictive remodeling in the pathogenesis of restenosis. No controversy exists that constrictive remodeling, first demonstrated by the laboratory of Cornelius Borst, contributes to restenosis. This has been inferentially confirmed by the clinical experience with endovascular stents, in which the reduction of restenosis is assumed to represent successful inhibition of remodeling. What is controversial is the extent to which remodeling contributes to restenosis in general. Clinical studies performed using high-resolution IVUS to follow patients treated by angioplasty without stents may clarify this issue; the authors' own personal perspective, however, is that remodeling accounts for proportionately fewer cases of restenosis than does SMC proliferation. Parenthetically, published data regarding stenosis that develops within a stent has unequivocally indicated that SMC proliferation is the culprit.

A third issue also relates to the pathogenesis of restenosis, namely, the role of postangioplasty mural thrombus. Some have held the view that such mural thrombus forms the infrastructure of the restenotic lesion; indeed, good data are available from animal models of stent restenosis to support this interpretation. Others have questioned this view, based on patients studied by angiography and particularly angioscopy postangioplasty, in whom evidence of such mural thrombus has been difficult to identify. Suffice it to say that even if mural thrombus does not itself comprise a precursor scaffold for neointimal thickening, the possibility remains that elements derived from transient thrombus formation—for example, thrombin—contribute to neointimal thickening via their mitogenic effect on SMCs.

Finally, what is perhaps the most controversial issue of all relates not to restenosis per se but instead to one principal means used to study its pathogenesis: the use of animal models. Species that have been used for this purpose include mouse, rat, rabbit, pig, and primate. Although certain of these models have gained favored status at one time or another, none has been shown to be uniquely predictive of what happens when a certain intervention is performed in human species. Each has certain advantages and liabilities. No basis exists, however, for considering any one, two, or combination of these to be uniquely valid in a scientific sense. At best, each offers only the opportunity to establish proof of concept, and when considered in such context, each may be instructive.

SUMMARY

Restenosis is clearly a multifactorial entity. SMC proliferation, elaboration of ECM, thrombosis, and vascular remodeling all contribute to its pathogenesis. The contribution of these individual elements does not seem to be consistently proportional from one patient to another, or even from one lesion to another in the same patient. Similarly, the mechanisms of restenosis after coronary stent implantation are different from those of restenosis after conventional balloon angioplasty.

In the absence of a single therapy that effectively addresses all of these pathogenic elements, the capability to routinely preempt restenosis will likely require accurate clinical identification and understanding of the principal factor governing the biology of a given restenotic lesion.

THE FUTURE

Subsequent studies may further disclose the extent to which SMC proliferation, vessel remodeling, and thrombosis proportionately contribute to restenosis. Much of this may come with investigation of stented arteries, because the remodeling component should be minimal and SMC is currently considered to represent the key pathogenetic mechanism of in-stent restenosis.

Current studies focusing on the interaction of key integrins and their respective ligands may also clarify the extent to which upregulation of specific integrins in SMCs contributes to restenosis and, correspondingly, whether this represents a suitable target for antirestenosis strategies.

The role played by progenitor endothelial cells in passivating the site of balloon injury should be clarified by ongoing studies. Resolution of this issue will determine the extent to which conventional concepts regarding the source of endothelial cells responsible for reendothelialization need to be modified. These studies may also offer insights into the potential for such precursor cells, with or without administration of endothelial cell mitogens, to constitute a novel therapy for expediting reendothelialization and thereby inhibiting restenosis.

Identification of genotypes that predispose to restenosis will receive increasing attention. Successful execution of such investigations will not only assist in management decisions regarding percutaneous revascularization but may also provide clues to restenosis prevention.

OVERVIEW

The development of blood vessels can be considered in several contexts. Vasculogenesis and angiogenesis are the processes that are responsible for the development of the circulatory system, the first functional unit in the developing embryo (1). Therapeutic angiogenesis includes the development of collateral blood vessels that supply ischemic tissues, either endogenously or in response to administered growth factors. Pathologic angiogenesis includes the role of postnatal neovascularization in the pathogenesis of arthritis, diabetic retinopathy, and, most notably, tumor growth and metastasis (2).

Because recapitulation of the embryonic paradigm forms the basis for therapeutic, as well as pathologic, angiogenesis, this chapter addresses selected aspects of embryonic blood vessel development. Therapeutic angiogenesis represents a natural response to myocardial ischemia in particular and tissue ischemia in general, and, along with novel strategies that have been devised to augment this response, is discussed in detail. Although pathologic angiogenesis is beyond the scope of the current chapter, certain principles that have emerged from studies of pathologic neovascularization are considered for the implications that they may have for cardiovascular disease.

VASCULOGENESIS AND ANGIOGENESIS

Vasculogenesis refers to the *in situ* formation of blood vessels from progenitor endothelial cells (ECs), or angioblasts (3). It is necessary to distinguish between vascular development that takes place in the yolk sac of the embryo from that which occurs in the embryo proper. Extraembryonic vasculogenesis begins as a cluster formation, or blood island (Fig. 106.1). Growth and fusion of multiple blood islands in the yolk sac of the embryo ultimately give rise to the yolk sac capillary network (4); after the onset of blood circulation, this network differentiates into an arteriovenous vascular system (5). The integral relationship between the elements that circulate in the vascular system—the blood cells—and the cells that are principally responsible for the vessels themselves—ECs—is implied by the composition of the embryonic blood islands. The cells that are destined to generate hematopoietic cells are situated in the center of the blood island and are termed *hematopoietic stem cells* (*HSCs*). Endothelial progenitor cells (EPCs), or angioblasts, are located at the periphery of the blood islands. In addition to this spatial association, HSCs and angioblasts share certain antigenic determinants, including Flk-1, Tie-2, and CD34. These progenitor cells have consequently been considered to derive from a common precursor, putatively termed a *hemangioblast* (6, 7 and 8).

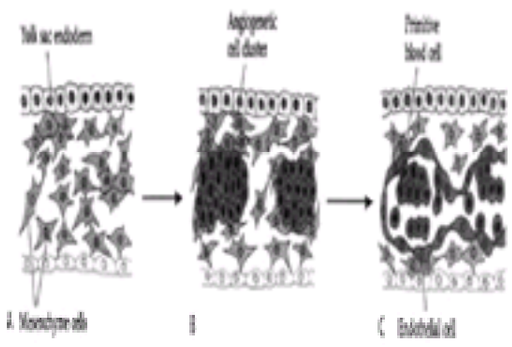

FIGURE 106.1 Blood islands. Blood vessel formation is first seen in the wall of the yolk sac, where **(A)** undifferentiated mesenchyme condenses to form **(B)** angiogenic cell clusters. **C:** The centers of these clusters form the blood cells, and the outside of the clusters develop into blood vessel endothelial cells. (From Gilbert SF. *Developmental biology*, 4th ed. Sunderland, MA: Sinauer Associates, 1997:342, with permission.)

Vasculogenesis that occurs within the embryo proper is currently considered to involve differentiation of so-called solitary angioblasts—that is, angioblasts that are not intimately associated with concomitantly differentiating HSCs (3). The sole exception to this is a small region in the aorta, termed *paraaortic clusters*. *In situ* differentiation of such solitary angioblasts occurs primarily from mesodermal cells in contact with endoderm. These angioblasts may migrate and fuse with other angioblasts and capillaries or form vessels *in situ*. Blood elements that circulate within the blood vessels of the embryo proper are believed to derive from the yolk sac

or paraaortic clusters.

In contrast to *in situ* differentiation of progenitor cells that are required to establish the primordial vascular network, extension of the primitive vasculature involves angiogenesis—that is, sprouting of new capillaries from the preexisting network; by definition, this implicates differentiated ECs as the responsible cellular element. Full development of the circulatory system involves recurrent remodeling, as some vessels regress, presumably by apoptosis, and others branch or are invested with a multilayer architecture characteristic of medium to large arteries and veins, or both. The extensive EC proliferative activity, which constitutes the basis for angiogenesis in the embryo, contrasts with extraordinary EC quiescence in the adult, in whom the interval for EC turnover is estimated to be more than 1,000 days (9).

Classic Paradigm for Angiogenesis

Until recently, vasculogenesis was considered to be restricted to the embryo, and new blood vessel formation in adult species was inferred to be the exclusive consequence of angiogenesis. The full paradigm for angiogenesis has been suggested to begin with “activation” of ECs within a parent vessel, followed by disruption of the basement membrane and subsequent migration of ECs into the interstitial space, possibly in the direction of an ischemic stimulus (10) (Fig. 106.2). Concomitant and/or subsequent EC proliferation, intracellular-vacuolar lumen formation, pericyte “capping,” and production of a basement membrane complete the developmental sequence.

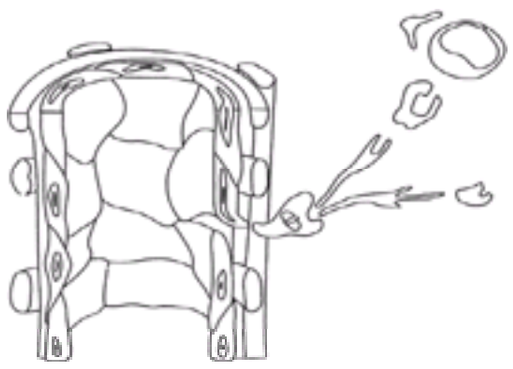

FIGURE 106.2 Classic paradigm for angiogenesis. Endothelial cells break free from their basement membrane and surrounding extracellular matrix, migrate, proliferate, and remodel (i.e., form a lumen), thus generating new blood vessels or “sprouts” from the parent vessel. (From D’Amore PA, Thompson RW. Mechanisms of angiogenesis. *Annu Rev Physiol* 1987;49:453–464, with permission.)

During angiogenesis, migration always precedes proliferation by approximately 24 hours (11). This principle was best demonstrated in classic experiments performed by Sholley et al. (12). Using a model of inflammation-induced angiogenesis of the rat cornea, initiation of vascular sprouting was shown to occur in the absence of EC proliferation. EC proliferation in this model was suppressed by X-irradiation with 2,000 or 8,000 rads before application of the inflammatory stimulus. In irradiated corneas displaying no cellular proliferation, vascular sprouting at 2 days was similar to that seen in contralateral shielded corneas. Although neovascular growth was subsequently blunted and ultimately ceased by 4 to 7 days, these experiments documented the critical if not exclusive roles of migration and redistribution of preexisting ECs in the commencement of neovascularization. Similar implications resulted from work by Nicosia et al. (13): Fibronectin was shown to promote, in a dose-dependent fashion, the elongation of microvessels that sprout from explants of rat aorta placed in serum-free collagen gel—despite the fact that neither deoxyribonucleic acid (DNA) synthesis nor mitotic activity was increased in comparison to fibronectin-negative gels. Fibronectin was therefore inferred to promote angiogenesis *in vitro* by migratory recruitment of preexisting ECs. Subsequent studies have established the critical role played by plasmin and other proteases in promoting migration through preexisting matrix (14,15).

In contrast to these *in vivo* inflammatory and *in vitro* organ culture models, angiogenesis that develops in response to experimental vascular obstruction, that is, collateral vessel development, has been shown by several previous investigators to involve proliferation of not only ECs but smooth muscle cells (SMCs) as well. Several important principles were elucidated by these studies.

First, evidence of EC proliferation is nearly absent in normal arteries (16,17), a finding that is consistent with an estimated EC turnover time of “thousands of days” in quiescent microvasculature (9). Even a relatively low percentage of EC proliferation observed in response to arterial occlusion or exogenous growth factors may therefore represent considerable enhancement of EC proliferative activity and, when considered in relation to a denominator of thousands of ECs, is clearly sufficient to provide the basis for new blood vessel formation. Second, peak EC proliferation that contributes to naturally occurring collateral development in the setting of vascular occlusion varies from 2.6% to 3.5% in the canine coronary circulation (16,18), from 5% to 6% in the rodent renal vasculature (19), and less than 1% in swine coronaries (20). The contrasting rates of EC proliferation between the canine and swine coronary circulations are indeed representative of the contrasting propensity for natural collateral artery development in these two species. Third, proliferation of SMCs, the additional requisite cell type for the formation of larger blood vessels, is an implicit component of angiogenesis, regardless of animal species or circulatory site. In fact, Schaper et al. (21) speculated more than 30 years ago that “it is tempting to assume that EC proliferation not only serves the purpose of forming the endothelium of a finally larger artery but rather actively participates in the development of the tunica media.” Fourth, proliferative activity—for SMCs as well as ECs—is highest at the level of the smallest-diameter collateral vessels, the so-called midzone collateral segments (16,18,22,23). Fifth, although evidence of EC and SMC proliferation alone does not necessarily distinguish new vessel development from an increase in the size of preexisting vessels, adjunctive data regarding increased capillary density (24,25) support the notion that proliferative activity does in fact reflect true angiogenesis.

Ligand-Receptor Systems Modulate Vasculogenesis and Angiogenesis

A series of gene-targeting studies has elucidated the role of certain ligands or their receptors, or both, in vasculogenesis and angiogenesis. The phenotypic characteristics of these “knockout” mice are relevant to adult cardiovascular disease because of the implications they may have for the role played by these same ligand-receptor systems in promoting postnatal angiogenesis.

As indicated previously, KDR (the murine equivalent is known as *Flk-1* or *VEGFR-2*), the principal receptor for vascular endothelial growth factor (VEGF), is expressed by angioblasts and HSCs. It is perhaps not surprising, therefore, that mice deficient in this gene die *in utero* between 8.5 and 9.5 days postcoitum as the result of an early defect in the development of hematopoietic cells and ECs. Yolk sac blood islands were absent at 7.5 days, organized blood vessels could not be observed in the embryo and yolk sac at any stage, and hematopoietic progenitors were severely reduced (26). Markers of early endothelial precursors, such as Flt-1, Flt-4, and Tie-2, were expressed, but a marker of later endothelial development, Tie-2, could not be detected, indicating a deficiency of mature ECs (26). Expression of CD34, a marker of HSCs, was greatly reduced as well. The absence of blood islands and blood vessels in these mice established that the Flk-1 signaling pathway is required very early in the development of endothelial lineage and may be important for blood cell development as well.

Findings in the Flk-1 knockout mouse predicted what was to be found when the ligand, VEGF, was deficient. Mice that were deficient in even one of two VEGF alleles died *in utero* between days 10.5 and 12. Blood island formation (vasculogenesis) and vascular sprouting from preexisting vessels (angiogenesis) were again impaired (27,28). The failure of blood vessel ingrowth was accompanied by apoptosis and disorganization of neuroepithelial cells. The heterozygous lethal phenotype was interpreted as evidence for tight dose-dependent regulation of embryonic vessel development by VEGF. Parenthetically, the aortas of VEGF-deficient mice have been noted to be hypoplastic, similar to those observed in mice deficient in endothelial nitric oxide (NO) synthase (P. Huang, *personal communication*, 2001). It is interesting to speculate that this may reflect the role of NO in VEGF-modulation of EC function.

The tyrosine kinase Flt-1 receptor (VEGF-R1) constitutes a second high-affinity binding receptor for VEGF. Mouse embryos that are homozygous for a targeted mutation in the Flt-1 locus formed fully differentiated ECs in embryonic and extraembryonic regions but assembled these cells into abnormal vascular channels and died *in utero* (29). Blood islands, for example, were disorganized, consisting of intermixed angioblasts and HSCs. In the head mesenchyme, instead of progressive development of individual small vessels, large fused vessels were seen that contained internally localized groups of ECs. These findings were interpreted as evidence that the Flt-1 signaling pathway may regulate normal EC cell-cell or cell-matrix interactions during vascular development.

Tie-1 and Tie-2 (30) comprise a second family of receptor tyrosine kinases, other than the VEGF family, in which expression is nearly specific for ECs. Mice embryos that are deficient in Tie-1 fail to establish structural integrity of otherwise differentiated ECs (31); consequently, erythrocytes extravasate through the blood-vessel EC (but not between ECs), leading to death immediately after birth with widespread hemorrhage. Embryos that are homozygous mutant for Tie-2 die earlier (day 10.5 *in utero*), with dilated vessels lacking distinction between small and large vessels; absence of ordered branching has been inferred as evidence of disordered

angiogenesis. Vasculogenesis *per se* was not disrupted.

Successful disruption of the ligand for Tie-2, angiopoietin-1 (32,33), resulted in embryonic lethality by day 12.5, with defects similar to those seen in the Tie-2 receptor knockout. These included defects in organized branching, so that vessels remained dilated and almost syncytial. No change occurred in the total number of ECs, however.

The critical roles played by VEGF and its receptors in governing vasculogenesis and angiogenesis, and the Tie receptor/ligand family in maturation of the vascular network, have implications for the roles of these EC mitogens in promoting angiogenesis under circumstances of tissue ischemia in adults. In contrast to the lethal consequences of VEGF and Tie deficiencies, it is interesting to note that mice in which gene targeting has been used to disrupt the gene for basic fibroblast growth factor (bFGF) survive to maturity with no apparent phenotypic abnormalities of either the vascular or hematopoietic systems (G. Dorn and T. Deutschman, *personal communication*, 2001).

Remodeling

Remodeling in angiogenesis refers to the formation of a vascular lumen. Whereas multiple cell types, including ECs, grown *in vitro* on a collagen-matrix gel form cords, the presence of a lumen distinguishes vessels, or tubes, from solid cords. The presence of a lumen is clearly fundamental to the function of the circulatory system; however, the mechanisms that are responsible for tube formation are perhaps the least well understood aspect of angiogenesis (34). As Risau has pointed out, because isolated ECs may combine to form a lumen *in vitro* (35), lumen formation must represent an intrinsic feature or differentiation program of these cells (3). Mechanisms that have been discussed include the joining of polarized ends of capillary ECs in a ring-like fashion or, alternatively, simple deletion of a portion of the cell (vacuole formation) (36). Adding further to the complexity is the requirement to form qualitatively differing luminal and abluminal surfaces. Finally, it is inferred that remodeling comprises a coordinated process of lumen formation and vessel extension, with fusion of individual cells and their lumina via cell-cell adhesion molecules. The specific molecules that are responsible for vessel extension remain ambiguous. It is presumed that this aspect of vessel formation is subject to the regulatory factors that are responsible for vascular development in the embryo, as discussed above. In this respect, it is interesting to note that VEGF, for example, upregulates gap junction expression (specifically connexin 43) in ECs (37).

Nascent Vessels

Capillary growth rates (i.e., the velocity of neovascularization) range from 0.23 to 0.80 mm per day, depending on the experimental system used or the type of tumor, or both (38). The light microscopic features of newly formed vessels have been distinguished from those of native vessels (39). Whereas a histologic section of a capillary blood vessel in the normal brain reveals one or two ECs per lumen, in a brain tumor such as a glioblastoma, five to ten ECs may occupy one lumen. Tumor-induced vessels often appear dilated and saccular. Moreover, tumors may contain giant capillaries and arteriovenous shunts without intervening capillaries, so that blood may even flow from one venule to another.

Ultrastructural analysis of newly formed vessels has focused on features that are potentially responsible for augmented permeability. Dvorak et al. (40,41), for example, found that vascular leakage could not be attributed to passage of molecules through inter-EC junctions or injured tumor endothelium but instead involved transendothelial transport via a novel cytoplasmic organelle that they termed the *vesicular-vacuolar organelle*. Others (42) have reported VEGF-induced ultrastructural features that are consistent with endothelial fenestration.

Matrix-Integrin Interactions

Activated or proliferative ECs have been shown to express high levels of anb_3 (43,44). In nonhuman primates that were subjected to focal cerebral ischemia, for example, microvascular expression of anb_3 was noted in ischemic, but not nonischemic, tissues (45). Ligation of anb_3 on proliferating ECs promotes a critical adhesion-dependent cell survival signal, leading to inhibition of p53 activity, decreased expression of $p21^{WAF1/CIP1}$, and suppression of the bax cell death pathway (46). The intracellular molecular conflict that results from blocking anb_3 thus leads to unscheduled apoptosis and the abrogation of angiogenesis (44,46,47). Failure to ligate anb_3 may therefore inhibit the ability of actively cycling cells to ligate extracellular matrix proteins, including fibronectin, vitronectin, fibrinogen, and osteopontin, thereby influencing adhesion, migration, and, ultimately, survival of these cells (48).

Consistent with this notion, the integrin anb_3 has been shown to be required for angiogenesis *in vivo* (43), and antagonists of this integrin have been shown to inhibit angiogenesis by inducing apoptosis (44). Basic FGF, which has been shown to protect ECs from apoptosis (49), is known to modulate integrin expression by ECs (50,51 and 52). VEGF, by upregulation of the b_3 integrin and fibronectin, may similarly inhibit apoptosis by enhancing EC adhesion to matrix proteins (53). This notion is thus consistent with the concept that VEGF may exert a survival effect on ECs (43,44,54,55 and 56). These findings suggest that the net increase in EC viability after VEGF administration is not limited to the mitogenic effects of VEGF on ECs but is supplemented by the potential for VEGF to inhibit apoptosis.

Vasculogenesis in the Adult

Postnatal neovascularization was previously considered to result exclusively from the proliferation, migration, and remodeling of fully differentiated ECs derived from preexisting blood vessels, that is, angiogenesis (3,9,16). The formation of blood vessels from EC progenitors, or angioblasts (i.e., vasculogenesis), has been considered to be restricted to embryogenesis (5,57). However, the use of HSCs derived from peripheral blood in lieu of bone marrow to provide sustained hematopoietic recovery can be reasoned to constitute inferential evidence for circulating stem cells (58). Given the common ancestry of HSCs and angioblasts, the hypothesis that stem cells circulating in peripheral blood might under selected circumstances differentiate into ECs was investigated (59,60). Flk-1 and a second antigen, CD34, shared by angioblasts and HSCs (26,61,62,63,64,65,66,67,68,69,70 and 71), were used to isolate putative angioblasts from the leukocyte fraction of peripheral blood. *In vitro*, these cells differentiated into ECs (Fig. 106.3). In animal models of ischemia, heterologous, homologous, and autologous EC progenitors are incorporated into sites of active angiogenesis (Fig. 106.4). These findings thus suggest that circulating EC progenitors may contribute to neoangiogenesis in adult species, consistent with vasculogenesis.

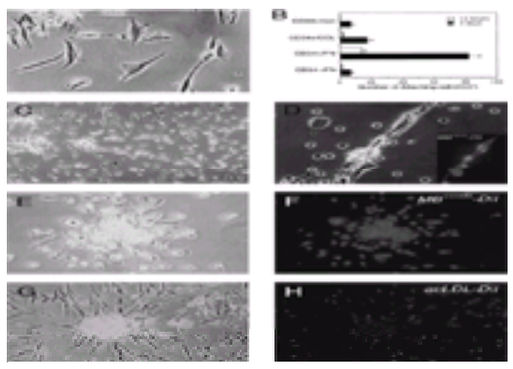

FIGURE 106.3 Attachment, cluster formation, and capillary network development by progenitor endothelial cells *in vitro*. **A:** Spindle-shaped attaching cells (AT^{CD34+}) 7 days after plating CD34+ mononuclear peripheral blood cells (MB^{CD34+}) (5 × 10 per mm^2) on fibronectin with standard medium. **B:** Number of AT^{CD34+} 12 hours and 3 days after single culture of MB^{CD34+} on plastic alone (CD34+/non), collagen coating (CD34+/COL), or fibronectin (CD34+/FN) and MB^{CD34-} on fibronectin (CD34–/FN). AT^{CD34+} yielded a significantly higher number of cells at 12 hours and 3 days when plated on fibronectin. Network formation **(C)** and cord-like structures **(D)** were observed 48 hours after plating coculture of MB^{CD34+}, labeled with DiI fluorescent dye, and unlabeled MB^{CD34-} (ratio of 1:100) on fibronectin-coated dish. These cords consisted principally of DiI-labeled MB^{CD34+}-derived cells (AT^{CD34+}). Beginning 12 hours after coculture, MB^{CD34+}-derived cells demonstrated multiple foci of cluster formation **(E,F)**. AT^{CD34+} sprout from the periphery, whereas round cells remain in the center and detach from the cluster several days later. After 5 days, uptake of DiI-labeled acLDL was seen in AT^{CD34+} at the periphery but not the center of the cluster **(G,H)**. (From Asahara T, Murohara T, Sullivan A, et al. Isolation of putative progenitor endothelial cells for angiogenesis. *Science* 1997;275:964–967, with permission.)

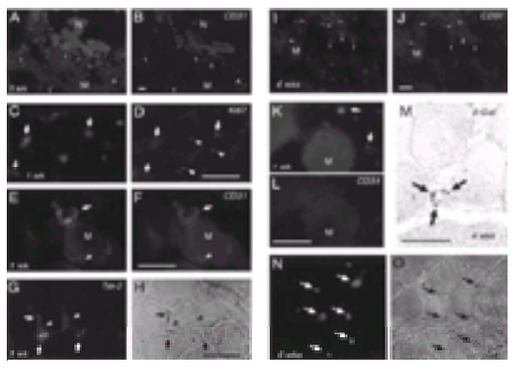

FIGURE 106.4 Heterologous **(A–L)**, homologous **(M)**, or autologous **(N and O)** endothelial cell (EC) progenitors incorporate into sites of angiogenesis *in vivo*. **A,B:** CD34+ mononuclear peripheral blood cells (MB^{CD34+}; *arrows*), labeled with the fluorescent dye DiI, between skeletal myocytes **(M)**, including necrotic **(N)** myocytes 1 week after injection; most are colabeled with CD31 (*arrows*). Note preexisting artery (a), identified as CD31 positive but DiI negative. **C,D:** Evidence of proliferative activity among several DiI-labeled MB^{CD34+}-derived cells (*arrows*), indicated by coimmunostaining for Ki^{67} antibody. Proliferative activity is also seen among DiI-negative, Ki^{67}-positive capillary ECs (*arrowheads*); both cell types comprise neovasculature. **E:** DiI and CD31 in capillary ECs (*arrows*) between skeletal myocytes, photographed through double filter 1 week after DiI-labeled MB^{CD34+} injection. **F:** Single green filter shows CD31 expression in DiI-labeled capillary ECs, integrated into capillary with native (DiI-negative, CD31-positive) ECs (*arrowheads*). **G:** Immunostaining 1 week after MB^{CD34+} injection showing capillaries comprised of DiI-labeled MB^{CD34+}-derived cells expressing Tie-2 receptor. Several MB^{CD34+}-derived cells (*arrows*) are Tie-2 positive and are integrated with some Tie-2–positive host capillary cells (*arrowheads*) identified by the absence of red fluorescence. **H:** Phase-contrast photomicrograph of same tissue section shown in **G** indicates corresponding DiI-labeled (*arrows*) and -unlabeled (*arrowheads*) capillary ECs. **I,J:** Six weeks after administration, MB^{CD34+}-derived cells colabel for CD31 in capillaries between preserved skeletal myocytes. **K,L:** One week after injection of MB^{CD34-}, isolated MB^{CD34-} derived cells (*arrows*) are observed between myocytes but do not express CD31. **M:** Immunostaining of b-galactosidase (b-gal) in tissue section harvested from ischemic muscle of B6,129 mice 4 weeks after administration of MB^{Flk-1+} isolated from transgenic mice constitutively expressing b-gal. (Flk-1 cell isolation was used for selection of EC progenitors due to lack of a suitable antimouse CD34 antibody.) Cells overexpressing b-gal (*arrows*) have been incorporated into capillaries and small arteries; these cells were identified as ECs by anti-CD31 and anti-BS-1 lectin. **N,O:** Sections of muscles harvested from rabbit ischemic hindlimb 4 weeks after administration of autologous MB^{CD34+}. Red fluorescence indicates localization of MB^{CD34+}-derived cells in capillaries, seen (*arrows*) in phase-contrast photomicrograph **(O)**. Each scale bar indicates 50 mm. (From Asahara T, Murohara T, Sullivan A, et al. Isolation of putative progenitor endothelial cells for angiogenesis. *Science* 1997;275:964–967, with permission.)

Parenthetically, these findings may have implications for augmenting collateral vessel growth to ischemic tissues (see Therapeutic Angiogenesis) and for delivery of anti- or proangiogenic agents, respectively, to sites of pathologic or utilitarian angiogenesis. A potentially limiting factor in strategies designed to promote neovascularization of ischemic tissues (72) is the resident population of ECs that is competent to respond to administered angiogenic cytokines (73). This issue can be successfully addressed with autologous EC transplants (74,75 and 76) (Fig. 106.5). The fact that progenitor ECs are home to foci of angiogenesis suggests potential utility as autologous vectors for gene therapy. For antineoplastic therapies, CD34+ mononuclear peripheral blood cells (MB^{CD34+}) could be transfected with or coupled to antitumor drugs or angiogenesis inhibitors. For treatment of regional ischemia, angiogenesis could be amplified by transfection of MB^{CD34+} to achieve constitutive expression of angiogenic cytokines or provisional matrix proteins, or both (77).

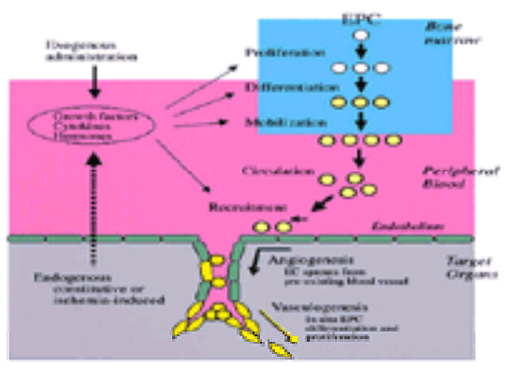

FIGURE 106.5 Neovascularization encompasses angiogenesis and vasculogenesis. Angiogenesis represents the classic paradigm for new vessel growth, as mature, differentiated endothelial cells (ECs) break free from their basement membrane and migrate as well as proliferate to form sprouts from parental vessels. Vasculogenesis involves participation of bone marrow–derived endothelial progenitor cells (EPCs), which circulate to sites of neovascularization, where they differentiate *in situ* into mature ECs. Growth factors, cytokines, or hormones released endogenously in response to tissue ischemia, or administered exogenously for therapeutic neovascularization, act to promote EPC proliferation, differentiation, and mobilization from bone marrow, via the peripheral circulation, to neovascular foci.

Angiogenesis within Blood Vessels: the Special Case of the Vasa Vasorum

The vasa vasorum consist of blood vessels that vary in size from vessels with single or multiple SMC layers to simple endothelial channels (78). In all but large or atherosclerotic vessels, the vasa vasorum are confined essentially to the adventitia of the blood vessel wall (79). This microcirculatory system presumably exists for the purpose of nourishing large and medium-sized blood vessels, including the aorta and epicardial coronary arteries. The vasa vasorum constitute a reservoir for postnatal angiogenesis that has been studied for its potential contribution to the growth and development of neointimal thickening.

Examination of human atherosclerotic specimens obtained by directional atherectomy (80,81 and 82) or at necropsy (83), together with studies performed in a variety of animal models (84,85,86 and 87), has clearly documented that extension of the vasa vasorum typically accompanies plaque growth and by inference “nourishes” the developing vascular lesion (Fig. 106.6). The ultimate extension of this principle is evidence suggesting that balloon injury to the arterial wall stimulates proliferation of vasa vasorum in conjunction with intimal thickening (88).

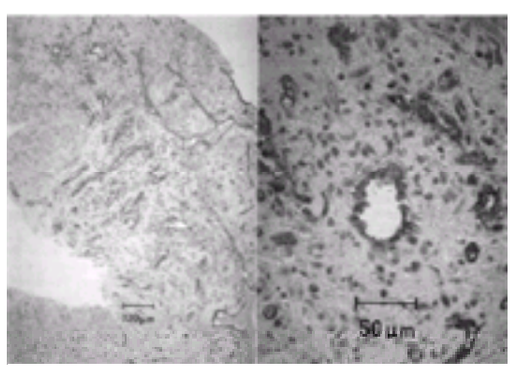

FIGURE 106.6 Identification of vasa vasorum in low-power (*left*) and higher-power (*right*) photomicrographs of atherosclerotic specimen obtained by directional atherectomy. Yellow-brown reaction product of Ulex immunostain identifies the endothelium of the vasa vasorum.

Experiments performed by Shweiki et al. (89) have identified hypoxia and glucose deprivation as the elements that are responsible for stimulating microangiogenesis in underperfused tissues. As indicated previously, EC mitogens, including VEGF (89), bFGF (90,91 and 92), and acidic fibroblast growth factor (aFGF) (93), have been

implicated in mediating such neovascularization. In the case of aFGF, Nabel et al. (94) have reported that arterial gene transfer of complementary DNA encoding aFGF to the arterial wall may result in neointimal microangiogenesis. It is thus intriguing to consider the developing primary or restenotic lesion as relatively underperfused and, as is the model for tumor development (95), dependent for continued growth on triggering augmented vascularization. Given the established association between diabetes and restenosis, it is further intriguing to consider that neointimal or medial cells, or both, that are relatively deprived of intracellular glucose and capable of elaborating angiogenic cytokines may facilitate combinatorial growth of vessel and plaque.

These findings have begun to undergo reevaluation for possible implications that they may have in designing novel treatment strategies for atherosclerosis and restenosis. Conceptually, this is not unrealistic. More than two decades of research aimed at elucidating the role of angiogenesis in tumor growth and metastases have led to the identification of several classes of agents that are capable of interfering with angiogenesis (95). From the standpoint of drug delivery, even if the agent were not preferentially targeted to the neovessels of the plaque or wall, or both, a variety of interventional devices (96) are now clinically available to execute local delivery to selected segments of the human vasculature.

With regard to primary atherosclerosis, there are at least two potential applications to consider. The first is restriction, including inhibition as well as regression, of plaque mass. As primary prevention, an inhibitory strategy targeted specifically at the vasa vasorum assumes that retardation of microangiogenesis secondarily inhibits plaque growth. Although it is true that wall (including plaque) thickness is a critical determinant of growth of the vasa (97), the extent of microvascular perfusion that is required to permit continued plaque expansion is uncertain. In the case of tumor growth, angiogenesis is regarded as “necessary but not sufficient” (95); in the case of plaque, whether angiogenesis is even necessary remains to be shown.

As secondary prevention, the ability to reduce established plaque mass medically represents the holy grail of preventive cardiology. It is encouraging to note that work performed by Brooks et al. (44) has demonstrated that antibodies targeted to adhesion integrins expressed by activated ECs can cause EC apoptosis, regression of tumor vasculature, and associated reduction in tumor mass. It is similarly provocative to note that studies performed in primates have documented a reduction in vasa vasorum *pari passu* with regression of atherosclerotic plaque (97). Whether any significant reduction in plaque mass could be achieved consequent to antiangiogenic therapy, however, remains to be demonstrated.

Acute stabilization of the so-called vulnerable lesion (98) constitutes a second potential application of therapies targeted at the vasa vasorum. Rupture of the vasa vasorum has been previously proposed (99) as the basis for plaque rupture and hemorrhage, the pathologic substrate that is considered to underlie most cases of acute myocardial infarction. Whether because of the lack of an animal model of plaque rupture or the complexities of establishing with certainty specific microvessels as the source of specific sites of intraplaque hemorrhage identified at necropsy, this proposed relationship remains currently intuitive. Nevertheless, given the limited options that are available for passivating destabilized lesions in patients with preinfarction angina, the logic of choking the putative microvascular source of intraplaque instability is appealing.

Studies of the vasa vasorum of the arterial wall also have therapeutic implications for local drug delivery *per se*. The network of transmural neovasculature may well be responsible for transport of agents from the intimal site of local delivery to the neointimal, medial, and adventitial layers of the arterial wall (96).

Although the catalogue of existing observations thus supports a number of logical strategies for targeting the vasa vasorum to develop novel therapeutic paradigms, the complexity of these proposals should not be underestimated. First, timing—when to initiate and how long to treat—is a difficult issue generic to any preventive therapy. More problematic, however, are certain inherent paradoxes that are peculiar to vasa vasorum and their presumed growth stimulus. For example, previous studies have demonstrated that adventitial injury may stimulate neointimal thickening; intimal ischemia resulting from injury to the vasa vasorum has been implicated in the development of such lesions. Similar consequences have been reported after thrombosis of the vasa (100). These observations suggest that interfering with the blood supply to the neointima to stabilize a vulnerable lesion or prevent further intimal thickening, or both, may constitute a “catch 22.” Moreover, experimental applications of bFGF (101), aFGF (102), and VEGF (103) to the injured arterial wall have all been shown to expedite reendothelialization and thus reduce intimal thickening; in the case of VEGF, no evidence of plaque neovascularity was observed (103). These findings are noteworthy, given the results of animal studies in which angiogenesis inhibitors have been shown to promote modest degrees of atherosclerosis in the ascending aorta in apoprotein $E^{-/-}$ mice (104). The consequences of exposure to an EC mitogen are thus likely to vary depending on the duration of cytokine expression and the circumstances of arterial wall pathology. Again, the “necessary but not sufficient” analogy to the tumor paradigm appears to apply to plaque angiogenesis as well.

ANGIOGENIC CYTOKINES

Beginning a little over a decade ago (105), a series of polypeptide growth factors (Table 106.1) was purified, sequenced, and demonstrated to be responsible for natural as well as pathologic angiogenesis. These angiogenic cytokines all share in common the ability to act as mitogens for ECs.

Cytokine	Protein	Gene Ph	Gene Ad	EC specific	Pleiotropic	Secretory sequence
$VEGF_{165}$	✓	✓		✓		✓
$VEGF_{121}$			✓	✓		✓
VEGF-2 (VEGF-C)		✓		✓		✓
HIF-1a			✓			
FGF-1 (aFGF)	✓				✓	
FGF-1 modified		✓			✓	✓
FGF-2 (bFGF)	✓				✓	
FGF-4			✓		✓	✓

a, acidic; Ad, adenoviral vector; b, basic; EC, endothelial cell; FGF, fibroblast growth factor; HIF, hypoxia inducible factor; Ph, plasmid human; VEGF, vascular endothelial growth factor.

TABLE 106.1 ANGIOGENIC CYTOKINES AND GENES USED IN CLINICAL ANGIOGENESIS TRIALS

Among the various growth factors that have been shown to promote angiogenesis, VEGF (106), also known as *vascular permeability factor* (107) and *vasculotropin* (108), is an EC-specific mitogen. Moreover, a plethora of studies have documented upregulation of VEGF in various cell types after exposure to other angiogenic cytokines. VEGF can thus be considered a prototypical angiogenic cytokine and for this reason is discussed here in further detail. Specific aspects of the remaining angiogenic cytokines in Table 106.1 can be found in the accompanying lists of citations.

At least five VEGF genes have now been identified: VEGF-1 (or VEGF-A), VEGF-2 (or VEGF-C), VEGF-3 (or VEGF-B), VEGF-D, and VEGF-E. In turn, four homodimeric species of VEGF-1 have been identified, with each monomer having 121, 165, 189, or 206 amino acids, respectively (109). The secretion pattern of the four isoforms differs markedly. $VEGF_{121}$ is a weakly acidic polypeptide that does not bind to heparin and is freely soluble in the conditioned medium of transfected cells. The heparin-binding capabilities of the remaining three isoforms are progressively augmented as the result of a stepwise enrichment in basic residues. Thus, $VEGF_{165}$, the predominant form secreted by a variety of normal and transformed cells (40), is a basic heparin-binding glycoprotein with an isoelectric point of 8.5; while secreted, a significant portion remains bound to the cell surface or extracellular matrix. The $VEGF_{189}$ isoform includes 24 additional amino acids and has been shown not to be freely secreted but instead remains nearly completely bound to the cell surface or extracellular matrix, or both (110). $VEGF_{206}$ is a rare isoform that has so far been identified only in a human fetal liver complementary DNA library.

The teleologic basis for the 121, 165, and 189 isoforms that result from alternative splicing of the VEGF-1 transcript has remained enigmatic. It has been proposed (111) that the heparin-binding feature of angiogenic growth factors such as VEGF may explain in part their protracted efficacy due to binding of the growth factor by heparan sulfate proteoglycans present on the luminal surface of the vascular endothelium or within the extracellular matrix, or both. Although $VEGF_{121}$ lacks heparin-binding ability, all three isoforms bind to the Flk-1 receptor, which transduces the mitogenic signal (112), including $VEGF_{121}$, which binds exclusively to Flk-1 (113). Plate et al. (114) speculated that the three principal isoforms might mediate distinct EC functions. We considered that angiogenesis induced by VEGF may be differentially dependent on the extent to which each particular isoform used is freely secreted and soluble. The magnitude of freely secreted $VEGF_{121}$ isoform that reaches the ischemic focus from the site of synthesis, for example, might be superior to that achieved with the $VEGF_{165}$ isoform; alternatively, avid binding of the $VEGF_{189}$ isoform to the basement membrane or extracellular matrix, or both (115), might result in more protracted bioavailability and thereby yield an outcome superior to that of $VEGF_{165}$.

Because it has proved difficult to express affinity-purified recombinant $VEGF_{189}$ protein from mammalian and bacterial systems, we investigated the possibility of

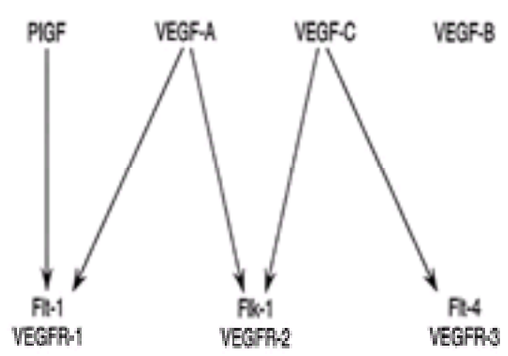
hierarchical efficacy among these three isoforms by performing arterial gene transfer of plasmid human (ph) $VEGF_{121}$, $phVEGF_{165}$, and $phVEGF_{189}$ in the rabbit ischemic hindlimb model (116). Remarkably, no differences with regard to anatomic or physiologic evidence of angiogenesis could be demonstrated, although all three isoforms yielded statistically significant improvement in every parameter measured compared to the LacZ controls. Moreover, separate experiments performed using 100, 200, and 400 µg of each plasmid failed to disclose a differential dose-response curve among the three isoforms with respect to angiographic score, calf blood pressure ratio, resting/maximum flow, or capillary-myocyte ratio (Y. Tsurumi, *unpublished data*, 2001).

These findings suggested biologic equivalency among the three principal VEGF-1 isoforms for *in vivo* angiogenesis in adult species and can be interpreted to support the observation made previously by Houck et al. (110) regarding the proteolytically clipped VEGF-1 species that result from the action of plasmin on the 165 and 189 isoforms. The size of the resulting monomers, which in each case are mitogenic for ECs and enhance vascular permeability in a Miles assay (117), is similar to the size of the intact 121 isoform. It is therefore possible that the proteolytic cascade of plasminogen activation, a key step during angiogenesis (14), cleaves the longer forms of VEGF-1, releasing a soluble $VEGF_{121}$-like species that is the final common mediator of angiogenesis *in vivo*. Although future experiments using conditional knockout genetically engineered mice will clarify the issue of isoform-dependent function, there is evidence that, at least during embryonic development, deletion of the 165 and 189 isoforms—but not the 121 isoform—results in ischemic cardiomyopathy (118).

Although the three principal VEGF-1 isoforms differ markedly with regard to heparin avidity, all include the secretory signal sequence. This contrasts with other angiogenic cytokines such as aFGF and bFGF, which lack such a signal peptide and thus are not typically secreted from intact cells. This feature has been critical to the use of naked DNA for gene therapy (116,119).

VEGF-2 or VEGF-C (120) and VEGF-3 or VEGF-B have been shown to be particularly abundant in heart and skeletal muscle (121). VEGF-C has now been demonstrated to promote angiogenesis *in vivo*, in experimental animal models (122,123), and in human subjects with ischemic heart disease (124). VEGF-C also promotes lymphangiogenesis. In contrast to the widespread distribution of these VEGFs, placenta growth factor (PlGF) (125), another VEGF family member, appears to be restricted *in vivo* to placenta and certain tumors (126,127). All four proteins share structural homology among themselves as well as with the platelet-derived growth factor A and B polypeptides (PDGF-A and -B), in particular a conserved motif, including eight cysteine residues in the putative receptor-binding domain (115). Similar to the A and B chains of PDGF, VEGF-1/VEGF-A and PlGF can form heterodimers with biologic activity (128,129 and 130). VEGF-3/VEGF-B is also able to heterodimerize with VEGF-1/VEGF-A in cells that express both factors (121). Although not shown thus far, it seems reasonable to assume that VEGF-2/VEGF-C, by virtue of its shared homology to the other members of the VEGF family, can form heterodimers in a similar manner, therefore adding another level of complexity to processes that are related to angiogenesis.

Whereas VEGF-1/VEGF-A is a high-affinity ligand for the receptors Flt-1 and KDR/Flk-1, VEGF-2/VEGF-C was shown to bind to another endothelial-specific receptor tyrosine kinase, Flt-4, as well as to Flk-1/KDR, but not to Flt-1 (120,131) (*e*Fig. 106.6.1). PlGF was shown to bind with high affinity to Flt-1, but not to Flk-1/KDR (129) or Flt-4 (132). The receptor(s) for VEGF-3/VEGF-B (121) have not yet been characterized. The constitutive coexpression of multiple VEGF types in many adult tissues (120,121,133) suggests an interactive or at least redundant capacity of the VEGF members to regulate angiogenesis and modulate EC function.



***e*FIGURE 106.6.1** Ligand-receptor relationships for placental growth factor (PlGF) and proteins encoded for by the three vascular endothelial growth factor (VEGF) genes (alternative receptor nomenclature is shown directly above). Autocrine Loop as a Feature of Angiogenic Cytokines

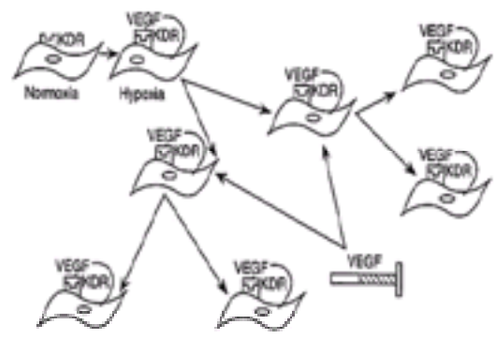
Certain angiogenic cytokines, notably aFGF and bFGF, lack a secretory signal sequence (134,135). This prompted previous investigators to study the possibility that these cytokines act via an alternative pathway. Several groups established evidence to support the notion that aFGF and bFGF can indeed modulate EC behavior via an autocrine pathway (136,137,138 and 139).

Evidence for a similar autocrine pathway in the case of VEGF was established by Namiki et al. (140). Under quiescent conditions, VEGF messenger ribonucleic acid (mRNA) was not detected in either human umbilical vein endothelial cells (HUVECs) or human microvascular ECs. In contrast, hypoxia provoked VEGF expression in HUVECs and human microvascular ECs. The response of human ECs to hypoxia was not limited to expression of VEGF mRNA but involved production of VEGF protein as well. Immunoreactive VEGF was distributed abundantly in the cytosol of hypoxic ECs. Because the VEGF antibody used recognizes all alternatively spliced VEGF isoforms (141,142), the specific VEGF species produced by HUVECs in response to hypoxia remain uncertain. The fact that media conditioned by hypoxic HUVECs augmented uptake of tritiated thymidine, however, implies a freely or relatively freely secreted (121 or 165) VEGF isoform.

Previous studies have indicated a variable requirement for new protein synthesis before hypoxic induction of erythropoietin and VEGF mRNA (143,144,145 and 146). We observed that cycloheximide pretreatment augmented VEGF expression induced by hypoxia as well as Co^{2+}, suggesting that a factor induced by hypoxia may modulate stability of VEGF mRNA, in part by inhibition of translation of ribonucleases responsible for degradation of mRNA. Similar regulatory influences have been previously demonstrated for other growth factors (147) and oncoproteins (148).

These findings thus establish that macrovascular and microvascular ECs, under hypoxic conditions, are capable of expressing VEGF mRNA and protein. Furthermore, thymidine incorporation was increased in ECs after application of media conditioned by hypoxic HUVECs, indicating that the magnitude of protein secreted is sufficient to drive mitogenesis. Because ECs also express the high-affinity VEGF receptors, Flt-1 and KDR, these cells in humans appear to include the requisite elements for an autocrine pathway. The finding that hypoxia induces activation of KDR in HUVECs is consistent with an external autocrine pathway (149), given that all VEGF isoforms include a secretory signal sequence.

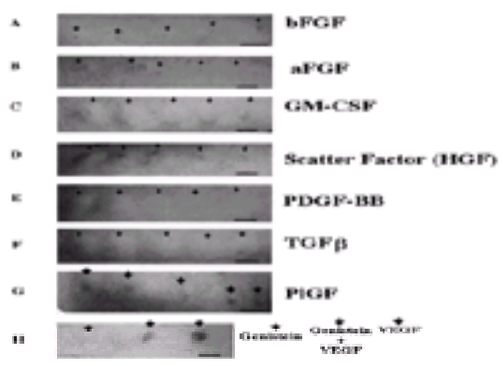
The extent to which such an autocrine pathway may complement endogenous production of VEGF from SMCs, macrophages, and tumor cells or facilitate the response to exogenous administration of VEGF remains to be determined. With regard to the latter, it has been recognized that single-bolus administration of VEGF may stimulate development of new collateral vessels over a period of several days, despite the fact that the circulating half-life of VEGF is less than 3 minutes. One explanation for this observation is that, as VEGF is rapidly cleared from the circulation, it binds avidly to heparan sulfate proteoglycans that are present on the luminal surface of the vascular endothelium. Experimental evidence to support this concept in the case of bFGF has been reported by Fuks et al. (49). Alternatively, an autocrine loop, activated under hypoxic conditions that are known to stimulate angiogenesis, might also serve to amplify and thereby protract the response in ECs stimulated by exogenously administered VEGF (*e*Fig. 106.6.2). Such autocrine amplification may in fact represent a common motif shared by angiogenic cytokines in general.



***e*FIGURE 106.6.2** Under conditions of hypoxia, endothelial cells upregulate vascular endothelial growth factor (VEGF), which, once secreted, may then interact with its receptor. Such an autocrine loop provides the basis for amplification of any given VEGF secreted or administered into an ischemic territory. Endothelial cells stimulated to proliferate in response to VEGF may then serve as additional sources of VEGF synthesis, thus amplifying the effect of the initial dose of VEGF.

Angiogenic Cytokines and Vascular Permeability

Vascular permeability often precedes and/or accompanies angiogenesis, particularly tumor-associated angiogenesis (40,77,150,151). As suggested by the designation *vascular permeability factor* (107), VEGF increases vascular permeability when assessed by the Miles assay (*e*Fig. 106.6.3). Angiogenic cytokines other than VEGF, including bFGF, aFGF, scatter factor (hepatocyte growth factor), granulocyte-macrophage colony-stimulating factor, transforming growth factor-b (TGF-b), PlGF, and PDGF-BB all fail to increase permeability in the Miles assay (117) (*e*Fig. 106.6.3).



***e*FIGURE 106.6.3 A–G:** Angiogenic cytokines other than vascular endothelial growth factor (VEGF)/vascular permeability factor failed to increase vascular permeability. aFGF, acidic fibroblast growth factor; bFGF, basic fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HGF, hepatocyte growth factor/scatter factor; PDGF-BB, platelet-derived growth factor-BB; PlGF, placenta growth factor (all 8, 16, 32, 64, and 128 ng in 0.1 mL saline); TGF-b, transforming growth factor-b. **H:** VEGF/vascular permeability factor (128 ng)–induced vascular permeability was reduced by previous intradermal injection of the tyrosine kinase inhibitor genistein (100 mM). Scale bar = 10 mm.

These findings have several possible interpretations. First, most of these angiogenic cytokines have been shown to increase VEGF expression (152,153,154,155,156 and 157). The failure of other angiogenic cytokines to result in a positive Miles assay might then be interpreted to indicate not that angiogenesis and permeability are disassociated but that other angiogenic cytokines stimulate permeability indirectly via VEGF. Because this depends on protein synthesis, however, the required time course (hours) is insufficient to explain the acute (minutes) response that is characteristic of the Miles assay. Second, VEGF, identified initially as a tumor-secreted protein (158), has been more tightly linked with tumor angiogenesis than other angiogenic cytokines (2). Perhaps, then, increased vascular permeability is more particularly a function of tumor-associated angiogenesis. Third, increased vascular permeability may not in fact be a common feature of angiogenesis that is mediated by growth factors but rather may be most specifically associated with VEGF-induced angiogenesis.

The mechanism of action by which VEGF augments permeability has remained enigmatic. NO has been previously implicated as a factor in regulating vascular permeability (159,160 and 161). Nguyen et al. (160) demonstrated that substance P, a potent endothelium-dependent vasodilator, increases microvascular permeability via NO-dependent pathways. More recent findings suggest that NO-mediated alteration of vascular permeability may depend on its local concentration (161).

Prostaglandins have similarly been suggested to regulate angiogenesis and vascular permeability (162,163). Yamamoto's group (162) reported that a stable prostacyclin analog, SM-10902, accelerated wound healing in a murine model of diabetic skin ulcers. Fujii et al. (163) have demonstrated that lipopolysaccharide-induced vascular permeability is significantly attenuated by either an NO synthase inhibitor or indomethacin. These results collectively support the notion that prostaglandins that are produced from arachidonic acid via cyclooxygenase can regulate vascular permeability.

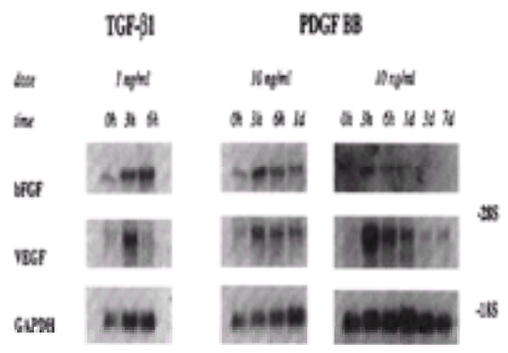
The author's group used the Miles assay to study the putative mediators of VEGF-induced permeability. VEGF (8 to 128 ng) and positive controls (platelet-activating factor and bradykinin) increased vascular permeability. Prior administration of the tyrosine kinase inhibitor, genistein, prevented VEGF-induced permeability. PlGF, which binds to Flt-1/VEGF-R1 but not Flk-1/KDR/VEGF-R2 receptor tyrosine kinase, failed to increase permeability. VEGF-induced permeability was significantly attenuated by the NO synthase inhibitors N^{w}-nitro-L-arginine (10 mg per kg) or N^{w}-nitro-L-arginine methyl ester (20 mg per kg) or the cyclooxygenase inhibitor indomethacin (5 mg per kg). *In vitro* studies confirmed that VEGF stimulates synthesis of NO (164) and prostaglandin metabolites in microvascular ECs. NO donors and the prostacyclin analog taprostene administered together, but not alone, reproduced the increase in permeability that was observed with VEGF. These results implicate NO and prostaglandin(s) produced via the interaction of VEGF with its Flk-1/KDR/VEGF-R2 receptor as mediators of VEGF-induced vascular permeability. Moreover, this property appears unique to VEGF among angiogenic cytokines. Given the conceptual link between permeability and angiogenesis, these findings can be interpreted to suggest a role for NO in VEGF-induced angiogenesis.

Direct versus Indirect Cytokines

Certain stimuli that are capable of inducing the development of neovessels *in vivo*, specifically certain cytokines (165,166,167 and 168) and hypoxia, fail to stimulate EC proliferation *in vitro*, suggesting a role for additional mediators or cell types, or both. The author's group considered whether these so-called indirect angiogenic growth factors might stimulate vascular SMCs to express genes that encode direct EC mitogens. Such a sequential cascade would provide a mechanism by which growth factors that are otherwise nonmitogenic or frankly inhibitory for EC proliferation *in vitro* could instead stimulate angiogenesis *in vivo*.

Although PDGF-BB, for example, can directly stimulate proliferation of selected populations of microvascular ECs *in vitro* (169,170 and 171), ECs from most vascular districts do not respond to treatment with PDGF-BB (172). Nonetheless, *in vivo* PDGF-BB has been clearly demonstrated to induce supportive angiogenesis in a wound-healing model (167) and chorioallantoic membrane assay (168). Furthermore, microvascular ECs that are isolated from rat epididymal fat pads and not directly responsive to PDGF-BB stimulation, when cocultured with myofibroblasts from the same tissue source, form capillary chords in the presence of PDGF-BB (166). The angiogenic action of PDGF-BB documented in this way was attributed to production of soluble EC mitogen(s) by myofibroblasts in response to stimulation with PDGF-BB.

PDGF-BB treatment of human vascular SMCs was demonstrated to induce VEGF and bFGF mRNA species concurrently (152) (*e*Fig. 106.6.4). This finding indicates that PDGF-BB, a known mitogen for SMCs, could also stimulate SMCs to produce direct angiogenic factors and thereby promote angiogenesis.



***e*FIGURE 106.6.4** Transforming growth factor-b1 (TGF-b1) and platelet-derived growth factor-BB (PDGF-BB) induce vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) gene expression in vascular smooth muscle cells (SMCs). Northern analysis of SMCs treated with TGF-b1 (0.1 or 1 ng per mL) or PDGF-BB (10 ng per mL) in serum-free medium to detect VEGF (3.7- and 4.2-kb bands) and bFGF (7.0-kb band) mRNA. Unstimulated SMCs contained low basal levels of VEGF or bFGF mRNA species. Levels of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA demonstrate similar loading of lanes. TGF-b1 stimulation of SMCs induced VEGF and bFGF mRNA. Accumulation of VEGF transcripts is evident at 3 hours and increase of bFGF mRNA at 8 hours of treatment. The dose of 1 ng per mL was the most effective for inducing VEGF and bFGF gene expression. PDGF-BB stimulation induced VEGF and bFGF mRNA species, with simultaneous peak at 3 hours. VEGF mRNA transcripts are still evident at 7 days of treatment. (From Brogi E, Wu T, Namiki A, et al. Indirect angiogenic cytokines upregulate VEGF and bFGF expression in vascular smooth muscle cells, while hypoxia upregulates VEGF expression only. *Circulation* 1994;90:649–652, with permission.)

Likewise, the plurality of mechanisms that contribute to the angiogenic activity of TGF-b1 (173) has been the subject of controversy. Although clearly inhibiting growth and migration of subconfluent ECs *in vitro* (174), TGF-b1 facilitates capillary formation *in vivo* (173). Furthermore, TGF-b1 modulates the composition of the extracellular matrix (175) and may therefore act in part by locally creating a proangiogenic environment. Although TGF-b1 directly inhibits EC proliferation (174), it may nevertheless direct organization of ECs into tube-like structures, depending on the conditions of culture tested (176). TGF-b1 in high concentrations was found to inhibit the formation of capillary-like structures in an *in vitro* model of angiogenesis, whereas low doses were observed to potentiate VEGF- or bFGF-induced neovessel formation in the same assay system (174). This phenomenon was interpreted by Pepper et al. (174) as an example of “contextual” angiogenesis to indicate that the angiogenic response to a given cytokine is dependent on the presence and concentration of other mediators in the pericellular environment of the target ECs. Winkles et al. (177) have also observed that TGF-b1 stimulates bFGF expression by SMCs, thus supporting the notion that direct angiogenic mediators might contribute in part to TGF-b1–induced angiogenesis. The finding (152) that TGF-b1 stimulation induces VEGF as well as bFGF gene expression, in concert with the above-described mechanisms, suggests that both EC mitogens are likely instrumental for mediating the indirect angiogenic effects of TGF-b1 *in vivo*. More recently, the notion of indirect angiogenic growth factors has been shown to extend to morphogens, such as sonic hedgehog, inducing angiogenesis via upregulated expression of VEGF as well as angiopoietin and possibly scatter factor from fibroblasts (178).

Subsequently, this same motif has been demonstrated for insulin-like growth factor (157), bFGF (153), and scatter factor (hepatocyte growth factor) (156). bFGF and scatter factor, however, are further distinguished by the fact that they exert a direct effect on EC proliferation and migration, in addition to upregulating VEGF synthesis in vascular SMCs.

In the context of factors that upregulate VEGF expression, it is important to emphasize the critical role played by hypoxia, because this explains at least in part the clinical observation that tissue ischemia is a fundamental stimulus for angiogenesis. Increased expression of VEGF has been documented at the periphery of necrotic foci of certain neoplasms, as well as hypoxia-stimulated induction of VEGF in cultured cells from glial tumor and rat skeletal muscle (144). Low oxygen tension has been shown to selectively modulate VEGF but not bFGF in vascular SMCs (152). This observation is intriguing in light of homology between a sequence in the VEGF promoter (109) and a nucleotide sequence in the erythropoietin promoter identified as a binding site for a hypoxia-specific transcription factor (179). It is now clear that, although transcriptional as well as posttranslational (146,180,181 and 182) upregulation of VEGF occurs in response to hypoxia and is mediated via hypoxia-specific growth factor-1 (183), VEGF expression may be upregulated by non–hypoxia-inducing mechanisms (184,185) as well.

Synergism of Angiogenic Cytokines

Studies from several groups have disclosed evidence for a synergistic effect of growth factors on angiogenesis *in vitro*. Pepper et al. (174) demonstrated that, whereas EC migration and capillary lumen formation were inhibited by TGF-b1 alone, a lower concentration of TGF-b1 potentiated the effect of bFGF- and VEGF-induced migration. Furthermore, these same authors (186) showed that adding VEGF or bFGF to microvascular ECs grown on the surface of three-dimensional collagen gels induced the cells to invade the underlying matrix and form capillary-like tubules. When these same two mitogens were added simultaneously, however, they induced an angiogenic response that was far greater than additive and occurred with greater rapidity than the response to either cytokine alone. Goto et al. (187) measured the combined effect of VEGF and bFGF on the proliferative and morphologic changes exhibited by bovine capillary ECs cultured in a gel of type I collagen; when the two factors were added simultaneously, the number of cells and the number of cord-like structures were greater than the sum of those that were stimulated with either growth factor alone. Results of *in vivo* studies performed in the author’s laboratory (188) are in agreement with these previous *in vitro* experiments. Necropsy examination documented an increase in vascularity at the capillary level, consistent with the classic definition of angiogenesis that was formulated by Klagsbrun and Folkman (189). Moreover, the angiographic luminal diameter of the stem artery was significantly greater in the group treated with VEGF + bFGF than VEGF or bFGF alone.

The potential therapeutic benefit of stimulating formation of larger, more “mature” collaterals is suggested by the physiologic evidence of increased downstream perfusion that was documented on serial measurements of the lower limb blood pressure ratio. The dramatic increase in blood pressure ratio in rabbits treated with VEGF + bFGF between day 0 and day 10 compared with that seen after administration of either growth factor alone is likely to be a consequence of better arterial reconstitution in the combined therapy group. This conclusion is further supported by findings in the author’s laboratory in which the combination of VEGF and bFGF was found to have a synergistic effect on maximum flow reserve in this same animal model, compared to bFGF or VEGF alone (C. Bauters, *unpublished observations*, 2001).

The fundamental basis for the synergistic effect of VEGF and bFGF *in vivo* remains to be elucidated. Although VEGF is EC specific, bFGF is also a potent mitogen for a variety of other cell types, including SMCs. Direct stimulation of SMCs by bFGF might be responsible for certain of the *in vivo* effects that have been observed, such as the increase in the angiographic luminal diameter of the stem artery.

Conversely, the increase in capillary density and capillary-muscle fiber ratio in the ischemic muscles is more likely to be a consequence of a synergistic effect on ECs similar to that observed in the previously cited *in vitro* experiments. It is important in this regard to underscore the independent receptor systems that are responsible for signaling the mitogenic effects of VEGF and bFGF in ECs (67,190,191). Thus, amplification of the endothelial response to these mitogens is feasible based on their independent receptor systems alone.

Park et al. (129) proposed another possible basis for synergism among angiogenic growth factors. They demonstrated that the 152–amino acid isoform of PlGF potentiates the action of low, marginally efficacious concentrations of VEGF on EC growth *in vitro* and *in vivo* potentiates Evans blue dye extravasation observed in a Miles assay. Although PlGF binds with high affinity to Flt-1, it does not bind to the KDR receptor. The latter receptor appears to account for most of the bioactivity induced by VEGF. These authors thus suggested that potentiation in this case might be the result of the Flt-1 receptor behaving as a “decoy,” that is, binding either ligand but having little or no transducing activity. PlGF might therefore act to release VEGF from Flt-1 and increase its availability to the more relevant KDR receptor. Because PlGF failed to potentiate low doses of bFGF, these findings were interpreted to be specific for VEGF. Whether an as-yet-unidentified high-affinity receptor for VEGF/bFGF could similarly contribute to the synergism we observed remains to be investigated.

Site-Specific Effects of Angiogenic Cytokines

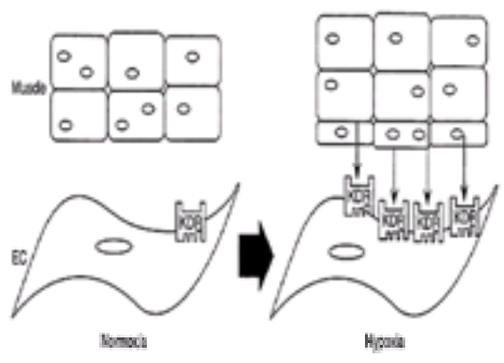
From a teleologic perspective, it appears critical that EC mitogens not promote angiogenesis in an indiscriminate fashion; it is clearly preferable for the survival of the organism that angiogenesis be limited to sites of wound healing and tissue ischemia, where it may have facilitatory effects. In fact, there is evidence to indicate that this is the case. Studies in a variety of animal models using aFGF (192), bFGF (188,193), VEGF (25,194,195), and scatter factor (156) have shown that systemic administration of angiogenic cytokines selectively produces neovascularization in the ischemic limb (196); neither in the contralateral normal limb nor in any other organs were foci of neovascularization observed. In fact, when recombinant human vascular endothelial growth factor (rhVEGF) was injected into the normal or ischemic limb of rabbits with unilateral hindlimb ischemia, angiogenesis was observed only in the ischemic limb.

Furthermore, although patients with peripheral vascular disease have been shown to have detectable levels of circulating bFGF (197), evidence of angiogenesis appeared limited in these individuals to collateral vessel development in the ischemic lower extremities. More recently, after intramuscular injection of the gene that encodes VEGF, circulating levels of VEGF have been documented (198); nevertheless, again, evidence of angiogenesis was limited to the ischemic limb.

Evidence suggests that regional ischemia is the principal factor that is responsible for localization of angiogenesis. For example, in rabbits treated with rhVEGF, the magnitude of augmented collateral development is inversely related to the extent of hindlimb collateral arteries seen before rhVEGF therapy (25). The same is true for blood flow in the ischemic limb (199). Thus, if a paucity of angiographically visible collaterals and reduced blood flow is indicative of limb ischemia, it appears that the extent to which angiogenesis is enhanced is related to the severity of ischemia.

Experiments performed on ECs *in vitro* suggest that the basis for localized bioactivity of angiogenic cytokines such as VEGF is due to upregulation of the VEGF receptor in response to hypoxia. In certain types of ECs, notably bovine retinal ECs, this may occur as a direct response to hypoxia (200); in our experience, direct upregulation of receptor expression does not occur in HUVECs or microvascular ECs. The difference in these observations may be due to the fact that bovine retinal ECs possess threefold more VEGF receptors (200).

In the case of HUVECs and microvascular ECs, receptor upregulation appears to occur indirectly in response to hypoxia (eFig. 106.6.5). Specifically, we observed an increase in KDR mRNA levels in HUVECs that were treated for 3 hours with conditioned medium from hypoxic myoblasts, as compared to KDR mRNA levels of HUVECs treated for the same time with conditioned medium from normoxic myoblasts (201). Such increase suggests new receptor synthesis, in conjunction with mobilization of preformed receptors from the cellular pool. Scatchard analysis of iodine-125 VEGF binding indicated no substantial change in affinity of the KDR receptor in HUVECs that were treated with myoblast medium conditioned either in normoxia or hypoxia. Thus, increased binding observed using hypoxia-CM was due to a 13-fold increase in the number of KDR receptors. These data suggest that a “factor” secreted from hypoxic myocytes in ischemic tissues upregulates VEGF receptor expression on adjacent ECs; consequently, the ECs in these ischemic tissues act as a magnet for circulating VEGF.



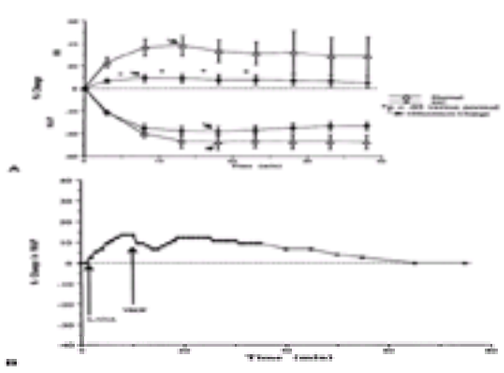
***e*FIGURE 106.6.5** Factors secreted by hypoxic myocytes upregulate vascular endothelial growth factor receptor expression on endothelial cells (ECs) within the hypoxic milieu. Such localized receptor expression may explain the finding that angiogenesis does not occur indiscriminately but rather at sites of tissue ischemia.

Role of Nitric Oxide in Mediating Effects of Angiogenic Growth Factors

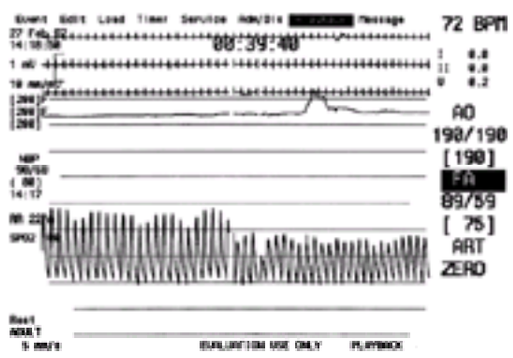
To elucidate the mechanisms by which VEGF may modulate EC biology, Brock et al. (202) used Fura-2, a Ca^{2+}-sensitive fluorescent dye, to monitor changes in $[Ca^{2+}]_i$ in suspensions of human ECs. They observed a three- to fourfold increase in $[Ca^{2+}]_i$ associated with an increase in inositol triphosphate in response to VEGF. Although an influx of extracellular Ca^{2+} appeared to constitute the predominant source of $[Ca^{2+}]_i$, a blunted but reproducible increase in $[Ca^{2+}]_i$ was obtained even in the absence of extracellular Ca^{2+}, suggesting that the VEGF-induced $[Ca^{2+}]_i$ increase was due to release of Ca^{2+} from internal as well as extracellular pools.

Evidence that the VEGF-induced increase in $[Ca^{2+}]_i$ was sufficient to stimulate production of NO was subsequently published by Ku et al. (203). They observed that VEGF-induced dose-dependent relaxation of isolated canine coronary arteries could be abolished by prior endothelium disruption or pretreatment with N^G-monomethyl-L-arginine, or both. The findings of Brock and of Ku suggest that VEGF-receptor binding is associated with tyrosine kinase–mediated phosphorylation of phospholipase C-g-1, release of inositol triphosphate from phosphoinositide, a consequent increase in $[Ca^{2+}]_i$, and ultimately increased EC production of NO. More recently, measurements performed in the author’s own laboratory have confirmed that application of VEGF to freshly excised arterial segments with intact endothelium results in a dose-dependent increase in the production or release, or both, of NO (164).

Cuevas et al. (22) successfully dissociated the mitogenic and hypotensive effects of aFGF, using a truncated form of the protein, mitogenically inactive due to loss of the nuclear translocation sequence but nevertheless capable of producing hypotension equivalent to that observed with the full-length wild type. Work from the author’s own laboratory has documented endothelium-dependent hypotension following intracoronary and intravenous administration of rhVEGF (eFig. 106.6.6 and eFig. 106.6.7). Leibovich et al. (204) found that the angiogenic activity of monocytes stimulated with lipopolysaccharide was L-arginine dependent and inhibited by inhibitors of NO synthase. Similarly, we have shown that dietary supplements of L-arginine enhance angiogenesis in the rabbit model of hindlimb ischemia and that genetically engineered mice lacking the eNOS gene fail to develop mature collaterals after iatrogenic ischemic injury (205), consistent with a role for NO in promoting angiogenesis *in vivo*.



***e*FIGURE 106.6.6 A:** Administration of recombinant human vascular endothelial growth factor (VEGF) to normal and hypercholesterolemic (HC) rabbits leads to prompt reduction in mean arterial pressure (MAP), with compensatory increase in heart rate (HR). The magnitude and duration (40 minutes) of hypotension are not significantly different in HC versus normal rabbits. **B:** MAP does not drop below baseline when administration of VEGF is preceded by administration of an inhibitor of nitric oxide synthase (L-NNA).



***e*FIGURE 106.6.7** Mild reduction in systemic blood pressure after injection of recombinant human vascular endothelial growth factor into saphenous vein graft of patient receiving recombinant protein therapy for myocardial angiogenesis.

THERAPEUTIC ANGIOGENESIS

The therapeutic implications of angiogenic growth factors were identified by the pioneering work of Folkman and colleagues more than two decades ago (206). Their work documented the extent to which tumor development was dependent on neovascularization and suggested that this relationship might involve angiogenic growth factors that were specific for neoplasms.

More recent investigations have established the feasibility of using recombinant formulations of such angiogenic growth factors to expedite and/or augment collateral artery development in animal models of myocardial and hindlimb ischemia. This novel strategy for the treatment of vascular insufficiency has been termed *therapeutic angiogenesis* (25).

Rationale for Therapeutic Angiogenesis in Patients with Occlusive Vascular Disease

Although ischemia from vascular occlusion upregulates expression of angiogenic growth factors, the fact that certain patients present with disabling angina indicates that such natural compensatory processes are not always sufficient. This can be explained in two possible ways: Either the production of angiogenic cytokines is inadequate or patients' response to them is attenuated. It has been shown that angiogenesis is impaired in older versus younger animals (207), secondary to reduced VEGF expression. Similar reductions in VEGF expression were observed in nonobese diabetic mice (208) and in hypercholesterolemic mice (209). These limitations in VEGF expression can be overcome in part by VEGF supplementation (208,209). Patients with advanced coronary disease are often older and may have diabetes, hypercholesterolemia, or other undetermined characteristics, limiting their capacity to upregulate angiogenic cytokines in response to ischemia, but may nevertheless respond to exogenous angiogenic cytokines. Significantly higher VEGF production in response to hypoxia was demonstrated in monocytes harvested from patients with angiographically visible collaterals, compared to those with reduced collaterals, suggesting that individual differences in cytokine expression may constitute yet another basis for variations in the magnitude of collateral development (210).

Reduced expression of angiogenic cytokines is not the only factor that contributes to the heterogeneous response to collateral vessel development. Marked genetic heterogeneity in the response to growth factor–stimulated angiogenesis has been observed in different strains of inbred mice (211). Age-related reduction in EC viability has also been demonstrated (207). Endothelial dysfunction accompanies many of the known coronary risk factors and may reduce endothelial responsiveness to angiogenic growth factors. Also, the responsiveness of EPCs to hypoxic stimuli may well be deficient and potentially limit therapeutic angiogenesis. Strategies to increase EC responsiveness and to enhance EPC production or availability are therefore reasonable targets for therapeutic angiogenesis (212,213 and 214).

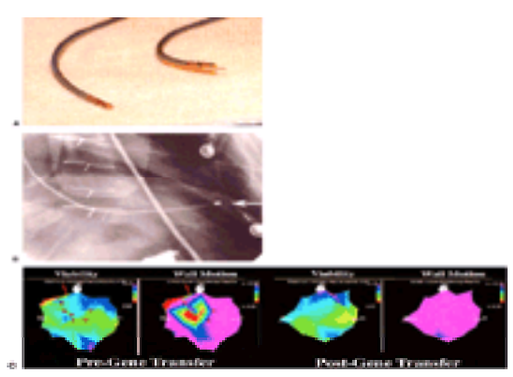
Angiogenic Protein versus Gene Therapy

Angiogenic cytokines can be administered as the natural recombinant human protein or by gene transfer. Recombinant protein is a more conventional approach and typically displays a more precise dose-response relationship than gene transfer. Recombinant protein is usually administered systemically and is therefore limited by potential adverse effects of the high plasma concentrations that are required to achieve adequate myocardial uptake. These include hypotension and edema with VEGF (215,216) and anemia, thrombocytopenia, and renal toxicity for FGF (217,218). Data regarding the kinetics of recombinant protein circulation suggest that intravenous delivery is unlikely to result in sufficient myocardial uptake or residence time to achieve important biologic effects; intracoronary delivery constitutes an alternative route of parenteral administration (219).

The ideal regimen for therapeutic angiogenesis is a single administration that provides a sustained but transient (2–3 weeks) increase in local angiogenic protein concentration at foci of myocardial ischemia. A limited rise in systemic VEGF levels would be expected to reduce the potential for distant unwanted side effects. Currently available gene therapy strategies approach this ideal. Naked DNA and adenoviral vectors produce only transient transfection, ideal for the time scale that is required for angiogenesis. The principal challenge is that optimal transfection in the case of naked DNA is best achieved by intramyocardial injection, although intracoronary administration may be sufficient for adenoviral gene transfer (220). Unlike viral vectors, plasmid DNA does not induce inflammation. Although naked DNA gene transfer is less efficient than viral-mediated transduction, uptake of naked DNA is augmented in muscle (221), particularly ischemic or inflamed muscle (119,222).

Routes of Administration

Angiogenic cytokines and genes have been administered via a wide variety of routes. Injection sites include intravenous, selective pulmonary artery, left atrium, intracoronary, selective intracoronary, transepicardial intramyocardial at time of bypass surgery or via thoracotomy, transendocardial intramyocardial by electromechanical catheter, periadventitial at time of bypass surgery or by thoracotomy, and intrapericardial. Because local delivery of recombinant protein or gene can be considered ideal (223), trials in patients have favored the intracoronary (adenovirus) or intramyocardial (naked DNA or adenovirus) route. Although not an issue if performed as a part of a coronary bypass procedure, the attendant risk of surgery is otherwise a limitation of the transepicardial route; in the future, this may be averted by the catheter-based transendocardial approach (*e*Fig. 106.6.8).



***e*FIGURE 106.6.8** Composite illustration of gene transfer of vascular endothelial growth factor-2 (VEGF-2). **A:** Catheter on the left, with the 27-gauge needle advanced on the right. **B:** Position of the catheter tip (*arrow*) in the left ventricle. A combination of electromechanical mapping and fluoroscopy is used to guide catheter positioning within the ventricle. **C:** Four electromechanical maps: two before and two after VEGF-2 gene transfer. Pregene transfer, the left map ("viability"), comprises the maximum unipolar voltage electrical endocardial map, with viable areas color coded from green through blue to purple, indicating that hypocontractile areas were viable. The points chosen for gene transfer are marked in brown. The next panel ("wall motion") shows the linear local shortening map before gene transfer, with an area of hypocontractility, indicated by the red, yellow, green, and blue colors in the anterolateral wall. Surrounding areas have normal contractility color-coded purple. Hypocontractile areas were inferred to be either ischemic or hibernating. The follow-up maps in this patient, on the right, performed at 12 weeks after gene transfer, show no change in the unipolar voltage map (viability unchanged); the far right panel of linear local shortening shows complete normalization of contraction in the previously hypocontractile area as indicated by the uniform purple color after gene transfer. LV, left ventricular.

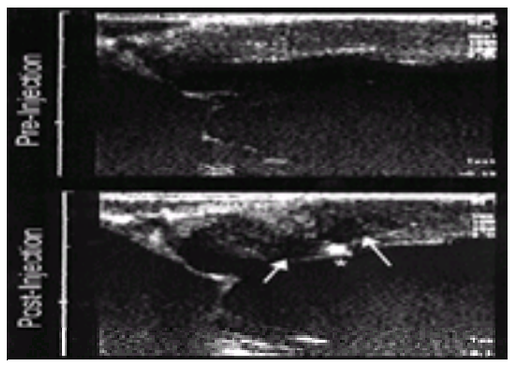
Experimental Studies in Animal Models of Myocardial Ischemia

The most widely studied animal model of focal myocardial ischemia involves application of an ameroid constrictor to produce gradual occlusion of the left circumflex coronary artery over 10 to 20 days. The choice of animal is important, as species differ from one another and from humans in the number of preexisting arteriolar connections: Pigs and rabbits have few, whereas dogs have many. Acute coronary ligation produces transmural infarction in the pig, compared to smaller nontransmural infarcts in dogs (224). In these models, angiogenic proteins or encoding genes have been administered successfully via a wide variety of routes. The effectiveness of angiogenesis has been documented by histologic assessment of capillary or vessel number and size, quantitation of EC markers, measures of resting or vasodilated coronary blood flow, angiography, and measures of left ventricular function at rest or during stress.

Most, but not all, of the studies have demonstrated evidence of enhanced angiogenesis after the intervention. FGF-2 increased collateral flow in the dog when given by the intracoronary route for 2, 7, or 28 days (225,226,227 and 228), with effects that were measurable for up to 5 weeks, but not at 6 months (229). Central venous administration in the same model was ineffective (228), presumably due to lung sequestration (219). Beneficial effects on collateral flow and left ventricular function were also seen with FGF-2 in the pig after single doses administered perivascularly or into the pericardium (230,231 and 232). FGF-1 recombinant protein was ineffective in the dog (233,234), probably because of rapid inactivation of this protein, which can be prevented by altering its structure (235). Experience with FGF gene transfer is more limited. Single-dose intramuscular injection of naked DNA encoding FGF-1 and intracoronary adenoviral transfer of the FGF-5 gene have each been shown to improve flow in the rabbit hindlimb (236) and porcine myocardium (220), respectively.

The effect of $VEGF_{165}$ protein has been studied in dog and in porcine models. Single intracoronary doses were effective in the pig (215,237), as was a series of two local injections via a balloon catheter, 3- or 4-week periadventitial infusions via minipump (237,238), and intramyocardial injection (239). Collateral perfusion improved after VEGF, and endocardial-epicardial flow ratios were improved. Intravenous administration, however, was ineffective (239). In the dog, $VEGF_{165}$ protein injected by the intracoronary route over 28 days was reported to improve collateral flow (240).

Genes that encode $VEGF_{165}$ and $VEGF_{121}$ as well as VEGF-2 have been transfected in a number of animal studies using either naked plasmid DNA or adenoviral vectors. Intramyocardial injection of plasmid DNA encoding $VEGF_{165}$ (241,242) (eFig. 106.6.9), VEGF-2 (243), or adenovirus encoding $VEGF_{121}$ (244,245) via thoracotomy in a pig ameroid model improved collateral perfusion and function. Intracoronary adenoviral gene delivery produced much lower gene and VEGF levels in the myocardium with poor localization, which would favor the intramyocardial route (245). Pericardial delivery of adenovirus encoding $VEGF_{165}$ in a dog model did not increase collateral flow (246). Intramyocardial injection of the entire dose of plasmid $VEGF_{165}$ at a single site in a rat model of myocardial infarction induced angiogenesis with angioma formation at the injection site, without enhancing regional blood flow (247); subsequent studies suggested that this was a dose-related event, in that a 50% reduction in dose of plasmid DNA did not induce angiomas (R. A. Kloner, *personal communication*, 2001). Similar results were observed with local massive overexpression of VEGF achieved with transformed myoblasts (248).



***e*FIGURE 106.6.9** Transepicardial two-dimensional echocardiogram demonstrating distribution of vascular endothelial growth factor DNA solution injected directly into ischemic porcine myocardium. **Top:** Anterolateral free wall is shown superiorly, with the mitral valve plane at the left of the image. **Bottom:** Bright needle artifact (*asterisk*) is seen in the anterolateral wall near two echolucent zones (*arrows*); the echolucency is the result of injected fluid containing the plasmid vascular endothelial growth factor DNA.

Studies have suggested that catheter-based intramyocardial injection of plasmid $VEGF_{165}$ is effective in the pig (242). This less invasive approach to intramyocardial gene transfer has been shown to achieve suitable gene expression (242,249,250 and 251) and is currently being investigated in a double-blind, randomized, prospective placebo-controlled trial of VEGF-2 gene transfer (124) (eFig. 106.6.8).

Translation of Therapeutic Myocardial Angiogenesis from Bench to Bedside

The species differences in myocardial collateralization and the relatively small area of ischemia that is produced in the pig model underscore the difficulty in taking the results from animal models of myocardial ischemia directly to the clinical arena for myocardial angiogenesis. In addition, the heart is a difficult organ to access directly for either vascular or intramyocardial administration of angiogenic factors, and assessment of neovascularization and blood flow is not trivial. Consequently, to investigate therapeutic angiogenesis in human subjects, a strategy was adopted of first studying patients with peripheral artery disease, specifically critical limb ischemia. The rationale for this included consideration of two issues. First, in patients with critical limb ischemia, the risk (limb loss)-benefit (limb salvage) ratio is appropriate for a novel therapeutic, due to the absence of any effective medical therapy (252). Second, access to ischemic skeletal muscle is straightforward, requiring only a superficial, nearly painless injection with a 27-gauge needle.

The effects of VEGF gene transfer were initially studied in patients with critical limb ischemia by delivering the gene to a patent arterial site in the ischemic limb upstream from the site of occlusion (72,253). Subsequently, however, this approach was replaced by direct intramuscular injection (198,254). Clinical benefit, including abolition of rest pain, limb salvage, and healing of ischemic ulcers, was associated with objective findings of improved perfusion (Fig. 106.7, Fig. 106.8, Fig. 106.9, and Fig. 106.10), including increase in ankle-brachial index, angiographic evidence of new collaterals, and improved leg blood flow on magnetic resonance angiography. Having established proof of the concept for therapeutic angiogenesis in human subjects, extrapolation of these findings to patients with myocardial ischemia were sought (255).

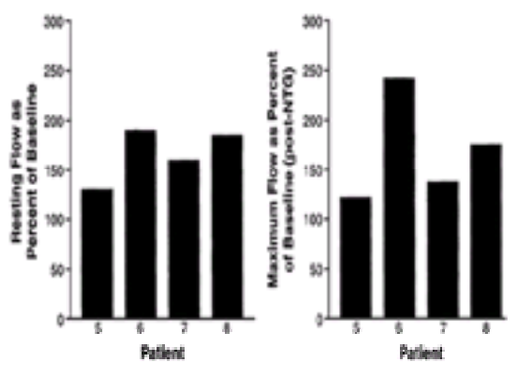


FIGURE 106.7 Resting flow (*left*) and maximum flow stimulated by intraarterial administration of nitroglycerin (NTG) (*right*) are augmented by 100% to 250% above baseline measurements in four patients undergoing gene therapy with 1,000 µg (patients 5, 6, 7) or 2,000 µg (patient 8) naked DNA encoding vascular endothelial growth factor. Blood flow was measured with intraarterial Doppler wire (FloMap, Cardiometrics).

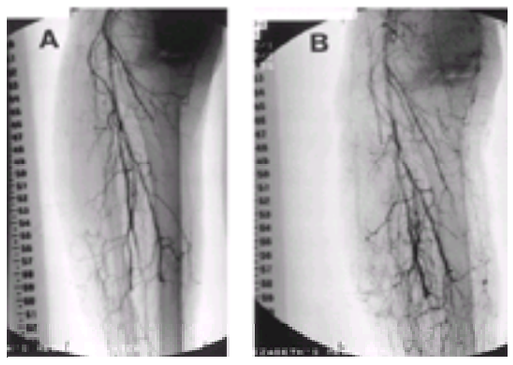

FIGURE 106.8 Selective digital subtraction angiograms performed in patient with critical limb ischemia due to occlusion of all three infrapopliteal vessels at midcalf level. Immediately before **(A)** and 1 month after gene therapy with 2,000 µg naked DNA encoding vascular endothelial growth factor **(B)**. The latter angiogram disclosed a plethora of new collateral vessels in the ischemic limb.

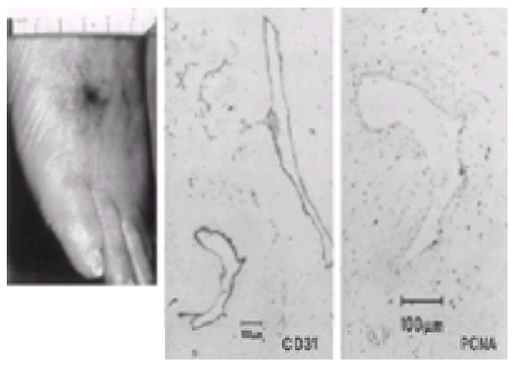

FIGURE 106.9 One of three spider angiomas that developed approximately 1 week after gene therapy in the distal portion of the ischemic limb of a patient whose angiograms are shown in Figure 106.8. Photomicrographs of tissue sections immunostained with antibody to endothelial antigen CD31 indicate the vascularity of the lesion, and immunostain of the adjacent section for proliferating cell nuclear antigen (PCNA) indicates the extent of proliferative activity among endothelial cells in the lesion.

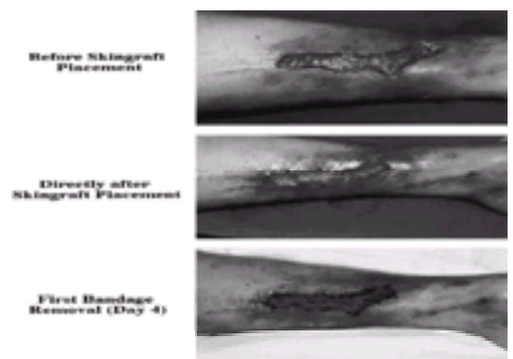

FIGURE 106.10 Successful placement of split-thickness skin graft in first patient treated with intramuscular administration of naked DNA encoding plasmid human vascular endothelial growth factor (phVEGF$_{165}$). After two intramuscular injections of 2,000 µg phVEGF$_{165}$, the patient's ankle-brachial index increased from 0.28 to 0.55, angiography disclosed new collateral vessels in the ischemic limb, and a 9 × 3–cm wound at the site of vein harvest in the medial calf healed sufficiently to permit successful grafting.

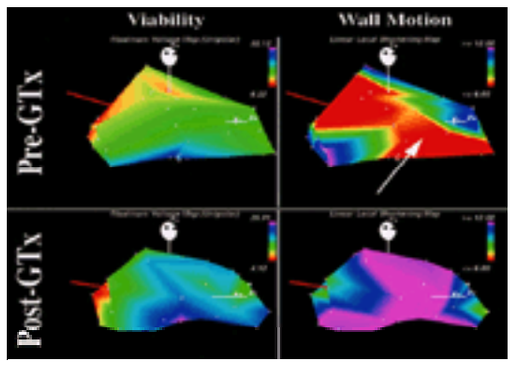
Evaluating Clinical Results of Myocardial Angiogenesis

No consensus has been reached regarding how best to evaluate the efficacy of therapeutic angiogenesis in patients with coronary heart disease. Most clinical studies have focused on the clinical end points that were used historically to evaluate new antianginal drugs, namely, angina class, exercise time, and quality of life. Each of these, however, is potentially subject to placebo and training effects, which cannot be eliminated in phase I trials and may limit the power of smaller phase II studies to detect a meaningful difference. Although these parameters may ultimately prove useful for establishing efficacy in larger phase II/III trials, additional objective evaluations may help to establish evidence of biologic effects that are attributable to therapeutic angiogenesis.

Rest and stress single-photon emission computed tomography (SPECT) perfusion imaging with thallium-201 or technetium-99m sestamibi provide objective estimates of relative myocardial blood flow and are used widely and routinely in clinical practice. As such, evidence of improved relative myocardial perfusion on images recorded before and after gene transfer may constitute inferential evidence of angiogenesis.

Percutaneous catheter-based electromechanical mapping (256,257) is a novel technique that provides concurrent imaging of myocardial viability and endocardial wall motion (*e*Fig. 106.6.8 and *e*Fig. 106.10.1); analysis of the two resulting maps can be used to identify foci of hibernating myocardium, which can be serially evaluated before and after gene transfer (258).



***e*FIGURE 106.10.1** NOGA (Biosense Webster) left ventricular (LV) electromechanical mapping performed in a 48-year-old man. NOGA images in the right anterior oblique projection before gene transfer (GTx) show the unipolar voltage map **(upper left panel)**, with normal voltages suggestive of viable myocardium (*purple/pink/blue/green*) and the linear local shortening (LLS) map **(upper right panel)** with a large zone of abnormal wall motion (*red, arrow*) representing electromechanical uncoupling that suggests ischemic or hibernating myocardium predominantly involving the septum. Unipolar voltage and LLS maps in the right anterior oblique projection 60 days after GTx (**lower left and right panels**, respectively) demonstrate almost complete resolution of the ischemic zone (ischemic area 9.57 cm^2 pre-GTx vs. 0.39 cm^2 post-GTx). Changes in LLS correspond to changes observed on single-photon emission computed tomographic scan (Fig. 106.6). Red line represents long axis through the apex.

Positron emission tomography using $^{13}NH_3$ or $H_2{}^{15}O$ can quantify regional coronary blood flow at rest and during vasodilation and has been used to demonstrate increased flow after a variety of interventions (259), but the technique is not widely available. Novel modifications of magnetic resonance perfusion imaging to detect foci of neovascularization (260,261) may prove useful for evaluation of angiogenesis after confirmation of reproducibility, sensitivity, and specificity by other centers.

Serial measures of left ventricular function have not proved consistently useful in animal or clinical studies to date. Angiographic studies have likewise failed to depict consistently reproducible evidence of neovascularization, even in animal or clinical studies with evidence of improved myocardial perfusion. This is likely due to the fact that the diameter of most collaterals formed in response to arterial occlusion or therapeutic angiogenesis, or both, is less than 200 µm (20)—that is, beyond the resolution of conventional angiography and certainly beyond the spatial resolution of magnetic resonance angiography. Consistent with this notion is the fact that the increased resolution achieved by synchrotron radiation imaging has disclosed new collateral vessels in preclinical studies that could not be identified by conventional angiographic techniques (262).

Initial Results of Therapeutic Myocardial Angiogenesis in Patients with Coronary Disease

Table 106.2 and Table 106.3 list completed and ongoing clinical trials of recombinant proteins and genes used for therapeutic angiogenesis, although data regarding the major end points have been published in only five, with two currently in press. Patients in these trials generally have severe angina that is unresponsive to medical therapy and are unsuitable for conventional revascularization. Many of the studies have been small phase I trials without control groups, designed primarily to establish safety or to evaluate dose-related effects, or both. Nevertheless, almost all have reported encouraging reductions in angina and nitroglycerin consumption and, in certain cases, improvement in exercise time and/or improvement in objective measures of left ventricular perfusion or function, or both.

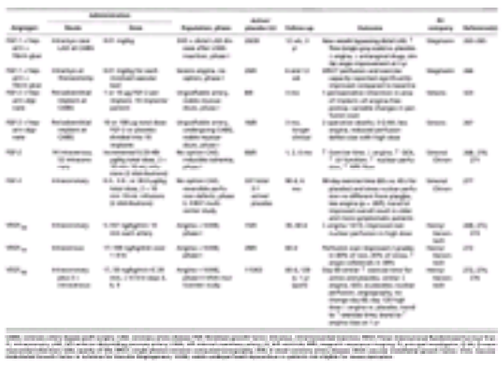


TABLE 106.2 CLINICAL STUDIES OF RECOMBINANT PROTEINS FOR MYOCARDIAL ANGIOGENESIS—COMPLETED AND IN PROGRESS

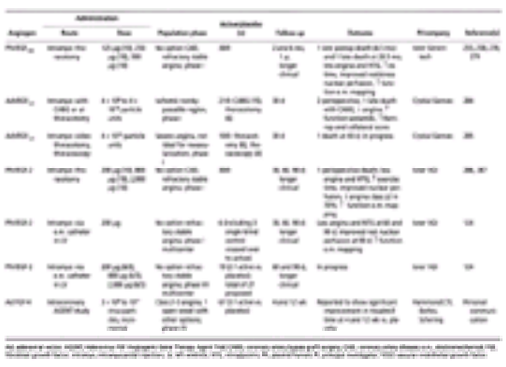

TABLE 106.3 CLINICAL STUDIES OF GENE TRANSFER FOR MYOCARDIAL ANGIOGENESIS—COMPLETED AND IN PROGRESS

Clinical Studies Using Recombinant Proteins

The first clinical study of recombinant protein for myocardial ischemia used intramyocardial injections of FGF-1 (aFGF) with heparin in patients who were undergoing left internal mammary bypass of the left anterior descending coronary artery (263,264) (Table 106.2). Twenty patients received active drug, and 20 received heat-denatured protein as placebo. The authors used a novel form of imaging to suggest improved collateralization of the distal left anterior descending coronary artery in comparison to placebo. This effect was maintained at 3-year follow-up (265). At 3 years, 16 of 17 patients who were given FGF were in Canadian functional class I compared to 12 of 16 control subjects, and only 1 of 17 given FGF required nitrates compared to 12 of 16 controls (p <.01). In addition, fewer patients given FGF were on calcium channel blockers (1 of 17 vs. 10 of 16) or beta-blockers (5 of 17 vs. 10 of 16). The same group completed an uncontrolled study of FGF-1 injected transepicardially via minithoracotomy in patients with severe angina that was unsuitable for conventional revascularization (266). Compared to baseline preoperative values, SPECT perfusion and exercise capacity were reported to be improved at 6 and at 12 weeks.

Periadventitial implantation of FGF-2 (bFGF) administered intraoperatively in heparin alginate beads at the site of a nonbypassable artery has been evaluated in a placebo-controlled trial of patients who were undergoing concomitant bypass surgery (267). Despite a relatively high perioperative mortality and morbidity attributed to the advanced nature of coronary artery disease in the patient cohort, the investigators reported less angina in the active treatment group. Trends to less severe stress nuclear perfusion defects and less evidence of ischemia by magnetic resonance imaging were noted as well in the high-dose FGF-2 group.

Three uncontrolled phase I studies of intravenous or intracoronary FGF-2 or VEGF recombinant protein have been completed (Table 106.2). These studies overall reported less angina and improved exercise time and improvements in either nuclear or magnetic resonance imaging perfusion or left ventricular function (268,269,270,271,272 and 273).

Results of phase I studies, designed by definition to assess safety, must be interpreted with caution. Typically, the number of patients who are enrolled in such trials is relatively small, and for those lacking a control group, a placebo effect cannot be excluded. For studies in which recombinant protein or gene is administered in conjunction with conventional revascularization, it may be difficult to determine the relative contributions of the angiogenic agent versus bypass surgery to the symptomatic response.

Two larger placebo-controlled phase II studies of intracoronary ± intravenous recombinant protein have been completed. The Vascular Endothelial Growth Factor in Ischemia for Vascular Angiogenesis (VIVA) study compared two doses of VEGF-1 protein to placebo in 178 patients who were given a single intracoronary infusion followed by three separate intravenous infusions (274,275 and 276). The primary end point of exercise duration was not different from placebo in the VIVA study; in each of the three groups, the increase in exercise time at 60 days, approximately 45 seconds, was similar. At 120 days, the high-dose group maintained the improvement, with an increase of 47 seconds over baseline, whereas the placebo group showed only a 14-second improvement. Although this difference was not significant, given the relatively small numbers and the large placebo effect, the possibility of a type II error cannot be excluded. No significant differences from placebo were found in angina grade or quality-of-life measures at 60 days, although there was a significant reduction in angina grade at 120 days in the high-dose group. Angiographic and nuclear perfusion studies were interpreted to show no differences between active therapy and placebo at 60 days.

Perhaps the most striking finding in the VIVA trial was that, in spite of exclusion of patients with evidence of a malignancy, three patients were diagnosed and one died of cancer within the 120-day follow-up period, and worsening retinopathy developed in one patient. Remarkably, all of these individuals had been fortuitously randomized to the placebo group.

The Flolan International Randomized Survival Trial (FIRST) compared a single intracoronary dose of FGF-2 (bFGF) with placebo in 337 patients. The 90-day results (277) failed to show significant differences from placebo in the primary end point of exercise time (65 vs. 45 seconds' improvement, p = .64) or in rest or stress nuclear

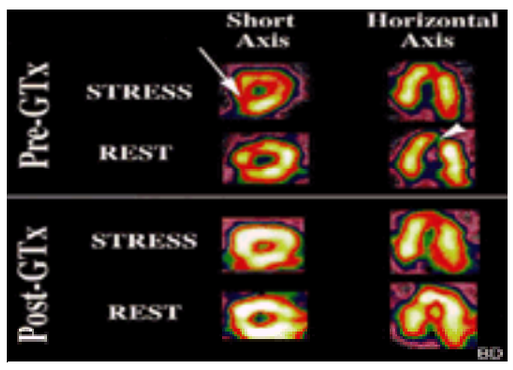
perfusion. Angina frequency determined by the Seattle Angina Questionnaire was less in the FGF group, although this did not achieve statistical significance. In a *post hoc* analysis, a significant improvement in exercise time was seen in patients who were older than 63 years (80 vs. 40 seconds, $p = .03$). The otherwise negative primary endpoint results of the VIVA and FIRST studies using intracoronary ± intravenous protein administration underscore the concern that the pharmacokinetics of recombinant protein administered into the vascular space may lead to inadequate local delivery of angiogenic growth factor within the ischemic myocardium, as suggested by studies reported previously using labeled ligand (219,223).

Clinical Studies Using Gene Transfer

Published studies of gene transfer for therapeutic angiogenesis in human subjects have thus far been limited to phase I dose-escalating, nonrandomized trials (Table 106.3). The largest of these trials with the longest follow-up to date involved 30 patients with refractory angina that was unsuitable for conventional revascularization, in whom naked DNA encoding the 165 isoform of the VEGF-1 gene as sole therapy was administered intraoperatively by direct intramyocardial injection via a minithoracotomy (255,258,278,279). A technical aspect of the procedure worthy of note was the use of intraoperative multiplane transesophageal echocardiography with test injections of agitated saline to ensure that the DNA injectate was not delivered into the left ventricular cavity (280). Intracavitary microbubbles that necessitated needle repositioning were seen in 20% of needle placements, underscoring this aspect of transepicardial gene transfer.

The patients experienced a remarkable reduction in angina frequency, with weekly nitroglycerin consumption falling from an average of 60 per week to 3.5 per week at 90 days. Exercise time for the group at 90 days improved by an average of 47 seconds, and exercise time to angina improved by almost 2 minutes; the improvements in symptoms were maintained at 1 year, and there was further improvement in exercise time (increase of 98 seconds over baseline) and time to angina (increase of 2.5 minutes). Two late deaths [4.5 (278) and 28.5 months] occurred, and one patient underwent a cardiac transplant at 13 months.

An important objective evaluation in the final 13 consecutive patients was the use of electromechanical endocardial maps of left ventricular shortening before and 60 days after gene transfer (258). Foci of electromechanical uncoupling (reduced endocardial shortening with persistent evidence of electrical viability) were identified preoperatively in all patients, with significant improvement in these endocardial wall motion abnormalities in the repeat study at 60 days (*e*Fig. 106.6.8 and *e*Fig. 106.10.1). These findings corresponded to improved perfusion scores calculated from SPECT-sestamibi myocardial perfusion scans recorded at rest and with pharmacologic stress. Perfusion defects on the SPECT rest images were associated with ischemic characteristics on the endocardial maps. Sequential SPECT scans (*e*Fig. 106.10.2) recorded before and after gene transfer demonstrated partial or complete resolution of fixed defects in four (33%) and five (43%) patients, respectively, in whom defects were present on the initial rest images. Partial or complete resolution of these rest defects after gene transfer is consistent with the notion that these preexisting defects constitute foci of hibernating viable myocardium (281,282 and 283), which have resumed or improved contractile activity as a result of therapeutic neovascularization.



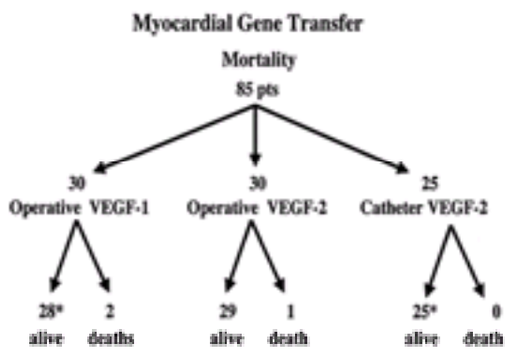
***e*FIGURE 106.10.2** Persantine single-photon emission computed tomographic–sestamibi myocardial perfusion scanning. Selected short and horizontal axis stress and rest images taken before and after plasmid human vascular endothelial growth factor165–gene transfer (GTx) in the same patient as shown in *e*Figure 106.10.1. White/yellow color depicts maximal uptake of radionuclide, and red depicts impaired uptake. Pre-GTx scans **(upper panel)** show a fixed anteroapical defect (*arrowhead*) and a partially reversible inferoseptal defect (*arrow*). Post-GTx scans **(lower panel)** show complete normalization of resting perfusion with a small, persistent, reversible anteroapical defect after pharmacologic stress.

A second phase I study of intramyocardial gene transfer was reported by Rosengart et al. (284). In that study, a first-generation adenoviral vector was used to deliver the 121 isoform of the VEGF-1 gene to 15 patients who were undergoing bypass graft surgery and as sole therapy to 6 patients via minithoracotomy. Symptoms improved in bypass surgery and in sole-therapy groups, although stress-induced nuclear perfusion images remained unchanged. The same group has since injected adenoviral $VEGF_{121}$ transepicardially, using video-assisted thoracotomy or thoracoscopy in ten patients (285), with one late death. Symptomatic outcomes in these latter patients have not yet been reported.

Our initial experience with intramyocardial naked DNA gene transfer was subsequently reproduced in a multicenter, consecutive series, dose-escalating study of transepicardial VEGF-2 gene transfer in 30 patients with class 3 or 4 angina. Once again, angina frequency and nitroglycerin consumption were reduced, and exercise time was increased by more than 2 minutes (*unpublished data*); improvement in nuclear perfusion studies and NOGA maps (Biosense Webster) similar to those described for naked DNA gene transfer of VEGF-1 (286,287) were documented as well. Among the 30-patient cohort, 29 are alive at a minimum of 12 months' follow-up, and none has undergone cardiac transplantation. A single postoperative death occurred 20 hours after gene transfer.

More recently, the first clinical study of percutaneous, catheter-based myocardial gene transfer was completed (124). This single-blind pilot study, designed to establish the safety and feasibility of nonsurgical needle injection, involved a total of six patients who were randomized to gene transfer or a mock procedure; each of the three patients assigned to the mock group ultimately required crossover to gene transfer for persistent symptoms. The number of anginal episodes fell similarly in the active and control groups over the first 30 days after gene transfer, suggesting an initial placebo effect (33 ± 5 to 14 ± 5 episodes per week for active therapy vs. 40 ± 5 to 15 ± 5 episodes per week for control, p = not significant). Longer follow-up, however, disclosed that angina continued to decrease at 90 days only in the active group, whereas patients in the mock group regressed toward their initial symptomatic status (3 ± 6 episodes per week vs. 22 ± 4, $p = .002$), suggesting that the late reduction in angina was not a placebo effect. The symptomatic improvement was again accompanied by noninvasive evidence of improved myocardial perfusion and electromechanical evidence of improved myocardial function (124). This study served as the basis for a multicenter, randomized, double-blind, placebo-controlled trial of catheter-based VEGF-2 gene transfer that has thus far enrolled 19 patients. No complications have been associated with a total of 150 injections among the 25 patients who were given either VEGF-2 or placebo in these two studies.

With specific regard to mortality, it should be noted that the cumulative mortality for the 85 patients with class 3 or 4 angina, all of whom were refused for conventional revascularization, undergoing operative or percutaneous naked DNA gene transfer of VEGF-1 or VEGF-2, has been 3 of 85, or 3.5%, at up to 33 months' follow-up (*e*Fig. 106.10.3). This compares favorably with an average 11% to 13% 1-year mortality for a similar group of almost 1,000 patients who received laser myocardial revascularization (see Transmyocardial Laser Revascularization) or continued medical therapy in five contemporary controlled studies (288,289,290,291 and 292).



***e*FIGURE 106.10.3** Mortality outcome data for all clinical trials using plasmid human (naked DNA) vascular endothelial growth factor (VEGF)-1 or VEGF-2 gene transfer in patients with disabling angina and severe coronary artery disease that was unsuitable for revascularization. Cumulative overall mortality in all 85 patients in the combined studies, with follow-up ranging from 10 to 33 months, was 3.5%, with 1 patient requiring cardiac transplantation at 13 months for symptoms (*asterisk*). No

mortality has occurred in the catheter-based gene transfer studies.

Potential Risks of Inducing Angiogenesis

The risks associated with therapeutic angiogenesis include those that are specific to the growth factor *per se* and those generic to strategies of promoting angiogenesis. With regard to the former, risks thus far recognized clinically in association with VEGF depend on the mode of administration. Administration of recombinant protein can lead to hypotension (215,293), because VEGF upregulates NO synthesis (164,205); this complication, however, has never been described after gene transfer in either animals or humans. Although experiments performed in transgenic mice that were engineered to overexpress VEGF ± angiopoietin have been interpreted to suggest lethal permeability-enhancing effects of VEGF (294), evidence of enhanced permeability in humans has been limited to transient lower extremity edema (Fig. 106.11) in patients with critical limb ischemia following VEGF gene transfer (216). A third issue concerns the development of angiomas in mice (295) or rats (247) that were treated with transduced myoblasts or supraphysiologic doses of plasmid DNA, respectively. Importantly, in the latter study, no angiomas were observed when the dose of administered plasmid DNA was reduced by 50% (R. A. Kloner et al., *unpublished data*, 2001). Except for these studies, no other preclinical or clinical reports, including those that used adenoviral vectors, have described this complication. With bFGF, hypotension may also result from the use of recombinant protein—again mediated via augmented NO release—but has not been described after gene transfer. Use of recombinant protein has also been associated with proteinuria (218).

FIGURE 106.11 Representative examples of lower extremity edema (*asterisk*) according to clinical grade in four patients after intramuscular plasmid human vascular endothelial growth factor$_{165}$ gene transfer. **A:** Grade 1. **B:** Grade 2. **C:** Grade 3. **D:** Grade 4.

More generic safety issues concern the potential to stimulate tumor vascularity and growth in the case of occult neoplasms, as well as the potential to exacerbate proliferative or hemorrhagic retinopathy, or both, in patients with diabetes, in view of the high VEGF levels that are demonstrated in the ocular fluid of patients with active proliferative retinopathy (296). With regard to carcinogenesis, there are neither *in vitro* nor *in vivo* data to date to suggest that VEGF increases the risk of neoplastic growth or metastases, or both, although longer-term follow-up will be required to address this issue in clinical trials. With regard to retinopathy, more than 100 patients who received VEGF-1 or -2 have now been treated at the author's institution and undergone serial funduscopic examinations before and after gene transfer by an independent group of retinal specialists; none to date (up to 4 years follow-up) has shown evidence of new retinopathy, despite the fact that nearly one-third had a history of diabetes or remote retinopathy, or both (297).

Another concern stems from the demonstration that inhibitors of angiogenesis tested in an apolipoprotein E–deficient mouse model of atherosclerosis inhibited plaque growth and intimal neovascularization (104). It is important to underscore the fact that these experiments were designed to test the hypothesis that inhibition of plaque angiogenesis would reduce the growth of atherosclerotic lesions; the experiments were not designed to test the hypothesis that administration of agents that promote angiogenesis would enhance atherosclerosis. To this end, several animal studies (103,298,299 and 300) and clinical studies of human subjects (301,302) (Table 106.4) fail to support the notion that accelerated atherosclerosis is a likely consequence of administering angiogenic cytokines; the outcome, in fact, is quite the opposite, in that administration of VEGF led to a statistically significant reduction in intimal thickening due to accelerated reendothelialization. The data available to date thus do not support the notion that acceleration of atherosclerosis is a consequence of VEGF-induced stimulation of angiogenesis.

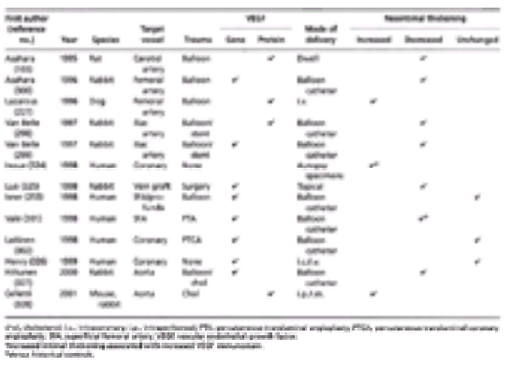


TABLE 106.4 STUDIES REGARDING VASCULAR ENDOTHELIAL GROWTH FACTOR AND NEOINTIMAL THICKENING

Transmyocardial Laser Revascularization

Transmyocardial laser revascularization (TMR) was investigated initially by Mirhoseini in 1982 (303) as a means of augmenting blood flow to the myocardium by creating sinusoidal tracts that are typical of amphibian ventricles. The past decade has witnessed renewed interest in this strategy, particularly for patients who are not suitable candidates for conventional revascularization. Indeed, the U.S. Food and Drug Administration approved two systems for commercial use, and the costs of TMR are now coded for reimbursement by the Health Care Financing Administration. As interest in TMR was renewed during the past decade, it was suggested that putative benefit from the procedure might be the result of angiogenesis (304,305 and 306), as multiple pathologic studies failed to show evidence that the lased channels remained patent (307,308 and 309). This issue remains unresolved because of the difficulty in distinguishing neovascularization that is associated with wound healing in response to laser injury from nutrient angiogenesis (310,311).

Mechanisms aside, TMR as sole therapy has now been compared to maximum medical therapy for severe angina in just under 1,000 patients with coronary artery disease that is not amenable to standard revascularization in five randomized trials (288,289,290,291 and 292). One-year mortality was high in this patient group (11.5% for laser and 12.7% for medical controls). The trials were concordant in showing reduced angina compared to control subjects, but quite variable in comparisons of treadmill time. No consistent pattern of change in SPECT nuclear perfusion was found, with three of four studies showing no improvement in reversible SPECT defects. In two uncontrolled studies in which perfusion was determined by positron emission tomography (312,313), no increase in regional blood flow was observed in the laser-irradiated regions. These findings have been interpreted by some to suggest that reduction in angina may result from either denervation or the placebo effect of thoracotomy. Denervation as a mechanism of symptom relief is supported by the predominance of silent ischemia in the perioperative period (314) and by evidence of denervation in canine models of TMR (315,316), as well as in patients who showed reduced hydroxyephedrine uptake with positron tomography (313).

More recently, several trials have tested the potential to perform TMR percutaneously using catheter-based fiberoptic delivery of laser light to multiple left ventricular endocardial sites. The first of these trials (317) showed a significant improvement in exercise capacity and reduction in anginal symptoms at 6 months, but thallium perfusion scintigraphy was unchanged. The Direct Myocardial Revascularization In Regeneration of Endomyocardial Channels Trial (DIRECT), a stringent multicenter, double-blind, placebo-controlled study in which patients received either holmium:YAG (yttrium-aluminum-garnet) or mock laser irradiation, failed to show improvement in anginal symptoms or exercise time compared to placebo; at 6 months, the treated and control groups reported an almost identical reduction in angina symptoms and

a similar improvement in exercise time (27- and 35-second increases in high- and low-dose laser, respectively, vs. 31 seconds in placebo) (318).

CONCLUSIONS

The immediate goal of clinical research in therapeutic myocardial angiogenesis with either protein administration or gene transfer is to demonstrate efficacy in larger-scale, placebo-controlled trials. To be sure, the rate at which regulatory agencies have permitted clinical trials of gene therapy, as opposed to recombinant protein or TMR, to progress has delayed achieving this objective. In addition, it should be acknowledged that clinical evaluation of therapies designed to promote collateral development would benefit from improvements in imaging capabilities that permit routine, high-resolution imaging of vessels less than 200 µm in diameter, typical of synchrotron radiation (262) but not possible with current angiographic imaging suites. Given the goal of optimizing tissue exposure to growth factor, it remains to be demonstrated that this can be achieved with single or even multiple injections of recombinant protein; recognizing this, certain groups are currently investigating sustained-release formulations of recombinant protein (N. Ferrara, *personal communication*, 2001). In contrast, sustained release is an inherent feature of gene transfer, at least over a period of 2 to 4 weeks in the case of naked plasmid or adenoviral gene transfer (119,319), and thus constitutes a potential advantage for gene therapy. Subsequent studies will be required to confirm preliminary suggestions that the levels and duration of gene expression achieved with naked plasmid DNA are of sufficient magnitude to achieve therapeutic angiogenesis while avoiding adverse effects and to optimize the choice, dose, and route of administration of angiogenic growth factor. Similarly, clinical trials will ultimately be required to test combinations of growth factors (188,320) in an attempt to reproduce the cascade evolved by nature to elaborate vascular networks.

Finally, complementary strategies that are not limited to supplying the growth factor, but instead enrich the cellular population capable of responding to the ligand, may be required for optimally robust vascularity. A number of studies (207,208 and 209,212,214,321,322) have suggested that the viable population of ECs capable of responding to angiogenic cytokine replacement may represent a limiting factor in trials of angiogenesis. Preliminary attempts to address this by a strategy of “supply side” angiogenesis, administering expanded populations of endothelial progenitors harvested from the patient’s own circulating blood volume, have successfully augmented hindlimb (74) and myocardial (75) angiogenesis. Clinical implementation of such a strategy will require further research into techniques for harvesting and separating cells and stimulation of their growth *ex vivo* before reinfusion at the time of cytokine stimulation. Implicit in this approach is the development of paradigms capable of identifying which patients are likely to have inadequate cytokine (21) or cellular responses to ischemia, so that therapy can be tailored and therapeutic angiogenesis targeted appropriately.

CONTROVERSIES AND PERSONAL PERSPECTIVES

The most daunting controversy in the clinical field of therapeutic angiogenesis is the task of executing a definitive clinical trial with regard to efficacy of either recombinant protein or gene transfer. Federal regulatory agencies have thus far been more permissive with regard to the more conventional of these two options, namely, recombinant protein. Unfortunately, the short half-life and greater difficulty of establishing site-preferential delivery have constituted recognized liabilities of this approach, and, not surprisingly, clinical trials to date have established limited evidence that recombinant proteins are efficacious for therapeutic angiogenesis.

Clinical trials of gene therapy for therapeutic angiogenesis have come under far greater scrutiny by federal regulatory agencies, and, thus, available clinical data regarding the efficacy of this delivery strategy to date are less robust than those for recombinant protein. The ability to extend the half-life of the angiogenic agent considerably as well as optimize local concentrations while minimizing systemic exposure is an inherent advantage of gene transfer; evidence of efficacy in the limited clinical investigations carried out thus far indeed suggests that these conceptual features translate into clinical advantages for therapeutic angiogenesis.

It is hoped that the clinical evidence to date that gene transfer for therapeutic angiogenesis is safe and well tolerated will now permit larger-scale, appropriately randomized trials to be performed at the more accelerated pace necessary to establish definitive evidence of therapeutic utility. In particular, it is noteworthy that many of the potential toxicities raised by experiments involving a variety of genetically engineered mice have not been borne out in clinical trials of either protein or gene therapy performed to date. Specifically, clinical trials to date do not suggest that the use of angiogenic cytokines accelerates atherosclerosis; indeed, the preclinical and more limited clinical data now available suggest that certain angiogenic cytokines, such as VEGF, may have utility for preventing restenosis; this strategy is parenthetically being tested clinically (using gene transfer) for patients with lower extremity vascular disease and will soon begin for patients with coronary artery disease, as catheter and as stent delivery of the transgene.

Finally, the potential to use cell therapy as an adjunct or even independent mode of therapeutic angiogenesis has now been established in preclinical studies and is about to be tested in human subjects. This therapeutic approach has great appeal, as it constitutes a “supply side” approach to replacing senescent ECs with robust precursors that may integrate into neovascular foci and at the same time delivers with each cell a “payload” of angiogenic cytokines that may facilitate neovascularization. It is likely that this approach will emerge as an effective option for promoting lower extremity and myocardial revascularization.

THE FUTURE

The identification of angiogenic growth factors has generated the opportunity for novel therapies in the treatment of a variety of diseases. This includes pathologic angiogenesis, such as diabetic retinopathy, rheumatoid arthritis, and cancer. In these cases, antibodies or naturally occurring angiogenesis inhibitors, or both, are being investigated clinically to antagonize key angiogenic factors. The strategy is designed to eliminate the vascular infrastructure and thereby minimize the extent of pathologic consequences to the patient.

A complementary strategy is now emerging for the treatment of cardiovascular diseases. Clinical trials of therapeutic angiogenesis have already been initiated in patients with myocardial ischemia and peripheral vascular disease and are imminent for patients with heart failure. These include trials of recombinant protein therapy as well as gene transfer. Protein and gene transfer have thus far been shown to be safe in human subjects. Preliminary trials of recombinant protein have shown limited evidence of efficacy. Preliminary applications of gene therapy have established proof of concept that angiogenic growth factors can augment myocardial perfusion. Subsequent clinical trials will determine the relative advantages of protein versus gene therapy, in terms of bioactivity and cost and safety; the maximum extent of clinical improvement that can be expected; and how the therapeutic outcome may be affected by certain features of the host.

It is also likely that future investigations may clarify the impact on established risk factors for vascular disease, such as lipid dyscrasias and diabetes, on native angiogenesis; thus, risk factor modifications may be useful for indirectly aiding natural angiogenesis in ischemic territories. It is intriguing to consider the possibility that one may be able to identify certain genotypic characteristics that may indicate why some patients form robust collateral networks whereas others fail to do so.

The role of EC progenitors in natural as well as therapeutic angiogenesis will be clarified by future studies. Recent studies have forced us to modify the classic concept that collateral development occurs solely by migration of fully differentiated ECs. It is now clear that circulating stem or progenitor cells, or both, contribute to such neovascularization. What remains to be determined is the proportion of new vessel growth that results from circulating stem cells versus parent vessel ECs. Finally, clinical trials will soon investigate the possibility that EC progenitors may be used in strategies of “supply side” therapeutic angiogenesis, specifically, whether administration of enriched or mixed populations of EC or less lineage-defined progenitors, including cells that are engineered to secrete proangiogenic agents, complement the impact of angiogenic cytokines on collateral vessel growth.

OVERVIEW

Perturbations in pulmonary vascular development *in utero* associated with lesions such as pulmonary atresia and ventricular septal defect (VSD), absence of the pulmonary valve, or diaphragmatic hernia lead to major difficulties in clinical management. Understanding cellular and molecular mechanisms governing early endothelial and smooth muscle cell differentiation, hypertrophy, and proliferation will affect our ability to reverse and overcome the hemodynamic consequences of these aberrations.

The mechanisms that lead to the severe structural remodeling observed in pulmonary arteries have many common features at the cellular and molecular levels regardless of the initiating cause. Experimental *in vivo* and *in vitro* studies suggest that this is due to induction of elastase activity and the consequent sequelae, including the release of growth factors, smooth muscle cell proliferation, induction of fibronectin, and smooth muscle cell migration.

In the setting of patients with congenital heart defects, pulmonary artery medial hypertrophy will cause increased vasoreactivity, particularly in the early postoperative period, which will likely be responsive to dilators such as nitric oxide (NO) phosphodiesterase inhibitors or endothelin receptor blockers. The more advanced changes of neointimal formation, combined with the patient's age at intracardiac repair (older than 8 months), will be the major determinants of hemodynamic reversibility.

Increased production of endothelin and altered potassium channel activation appear to be responsible for hypoxia-induced pulmonary vasoconstriction. The development of chronic hypoxia-induced pulmonary vascular abnormalities is characterized by dense accumulation of connective tissue proteins. Return to normoxia or improvement in the parenchymal lung disease results in regression of hemodynamic and structural abnormalities.

Immune/inflammatory mechanisms are likely responsible for the pulmonary vascular disease that accompanies autoimmune disorders, and therapy targeted at altering lymphocyte-endothelial interaction and activation will likely prove useful. The discovery of mutations in the bone morphogenetic protein receptor underlying unexplained or primary pulmonary hypertension will allow for new approaches to diagnosis and treatment. Currently, introduction of chronic intravenous prostacyclin or NO therapy and a variety of analogs including oral prostaglandin is proving of benefit in inducing regression in some patients and in retarding the progression of the changes in others.

INTRODUCTION

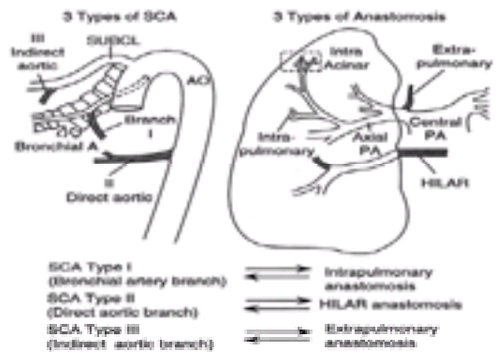
This chapter addresses the structural basis and functional sequelae of diseases of the pulmonary vasculature. The embryology of the pulmonary arterial tree is presented and the etiologic basis of developmental and genetic aberrations discussed. The structural changes associated with the altered pulmonary hemodynamics observed in congenital heart defects and alveolar hypoxia are described, as is the pulmonary vascular pathophysiology associated with thromboembolic disease, portal hypertension, and immune/inflammatory states. Unexplained (primary) pulmonary hypertension and associated vascular lesions also are considered, and recent genetic studies are discussed. Experimental studies addressing mechanisms leading to the structural lesions that cause pulmonary hypertension are discussed. Particular emphasis is placed on the degradation and synthesis of connective tissue proteins and the impact this has on vascular cell–extracellular matrix interactions, leading to cellular differentiation, hyperplasia, hypertrophy, and migration and culminating in occlusive neointimal formation. Current thinking is presented with regard to the roles of growth factors and their receptors and inflammatory and vasoactive mediator pathways. Treatments that are currently being instituted to control pulmonary vascular disease and future therapies aimed at preventing progression and inducing regression are discussed.

DEVELOPMENTAL BIOLOGY OF THE PULMONARY VASCULATURE

Macroscopic Features

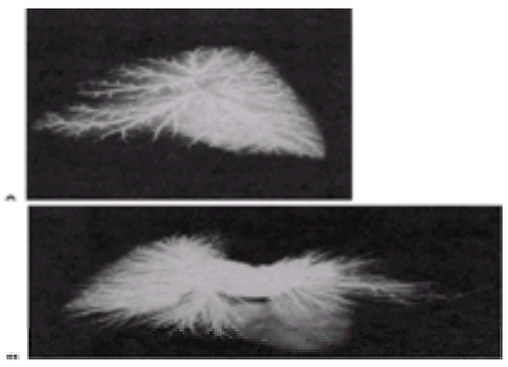
In the fifth-week human embryo, primitive pulmonary vessels from the sixth aortic arch supply the upper "poles" of the right and left lung, whereas the lower poles are supplied by a pair of intersegmental arteries arising from the dorsal aorta and penetrating upward through the diaphragm. The developing lung parenchymal blood vessels are largely localized to the interlobular septae. Between the fifth and eighth weeks of gestation, numerous paired dorsal intersegmental arteries supply the emerging blood vessels that are developing alongside the branching bronchi in the lung parenchyma. As the true central pulmonary arteries form from the aortopulmonary trunk and anastomose with the intrapulmonary arteries, the primitive pulmonary arteries arising from the aorta, as well as the primitive intersegmental arteries, involute. Formation of the bronchial system occurs only at the ninth week of gestation. With each airway generation, there is an accompanying artery in addition to numerous supernumerary arteries. By the sixteenth week of gestation, the number of preacinar airways and accompanying arteries is complete. Thereafter, as the acini (terminal bronchioli, respiratory bronchioli, alveolar ducts, and alveoli) develop, so do the accompanying and supernumerary arteries (reviewed in references 1 and 2).

Abnormal maturation or maturational arrest in pulmonary arterial development is reflected in functional derangement, which can present in the newborn period. Persistent pulmonary hypertension of the newborn has been reported in association with pulmonary arterial maturational arrest at the fifth week of gestation (3). Infants with pulmonary atresia and VSD frequently have persistence of the intersegmental arteries (aortopulmonary collaterals) (*e*Fig. 107.0.1) (4). These vessels can serve as the sole source of blood supply to a lobe or lobar segment; alternatively, they can form a dual circulation with intersegmental arteries anastomosing to arteries that can be traced back to a central pulmonary artery origin. There also can be multiple "indirect" aortopulmonary collaterals arising from aortic branches (e.g., from subclavian, intercostals, coronary arteries) and observed in the absence of direct collaterals, suggesting that they develop as a consequence of pulmonary atresia when it occurs later in development. Finally, in some cases of pulmonary atresia, there is supply by anastomotic vessels that arise from true bronchial arteries.



***e*FIGURE 107.0.1** The collateral anatomy in ventricular septal defect with pulmonary atresia. The three types of systemic collateral arteries (SCA) and the three types of anastomoses with the pulmonary artery (PA) are generally observed. The characteristic pattern of anastomosis for each type of SCA is given. AO, aorta; SUBCL, subclavian. (Reproduced from Rabinovitch M, Herrera-DeLeon V, Castaneda AR, Reid L. Growth and development of the pulmonary vascular bed in patients with tetralogy of Fallot with or without pulmonary atresia. *Circulation* 1981;64:1234–1249, with permission.)

A striking pulmonary vascular abnormality is observed with absence of the pulmonary valve (5). In patients who present with severe respiratory problems from birth, we have observed abnormal branching morphogenesis. Tufts of intersegmental pulmonary arteries are seen arising in “weeping willow” or “squid-like” fashion, encircling and compressing the intrapulmonary airways (*e*Fig. 107.0.2).

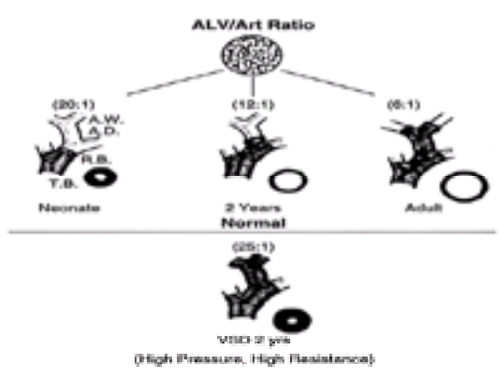


***e*FIGURE 107.0.2** Postmortem arteriograms. **A:** Arteriogram from a 4-day-old healthy infant. **B:** From a 4-day-old patient with absent pulmonary valve syndrome associated with a ventricular septal defect and D-transposition of the great arteries (*right*) showing tufts of vessels in both lungs. (Reproduced from Rabinovitch M, Grady S, David I, et al. Compression of intrapulmonary bronchi by abnormally branching pulmonary arteries associated with absent pulmonary valves. *Am J Cardiol* 1982;50:804–813, with permission.)

Microscopic Features

In the fetus, the preacinar arteries and those at the terminal bronchiolus level are muscular, whereas the intraacinar arteries (i.e., those accompanying respiratory bronchioli) are partially muscular (surrounded by a spiral of muscle) or nonmuscular. Arteries at alveolar duct and wall levels are nonmuscular. The preacinar arteries are thick-walled, and wall thickness changes little relative to external diameter throughout the fetal period. Experimental studies (6) suggest that the immediate postnatal period is characterized by rapid recruitment of small alveolar duct and wall vessels, which appear to be functionally and structurally closed in the prenatal period. Progressive dilatation of muscular arteries also occurs—that is, the smallest muscular arteries (less than 250 µm) dilate, and their walls thin to adult levels within a few days, and by the age of 4 months, this process has included the largest pulmonary arteries at the hilum. As the external diameter of the intraacinar arteries at the various airway levels increases with age, muscle appears to extend peripherally in that it is observed in arteries located more distally within the acinus. Nonmuscular arteries become partially muscular and later fully muscularized. For example, in infancy, vessels at the alveolar duct level are still largely nonmuscular, but in childhood they become partially muscularized and in the adult are fully muscularized (7). Alveolar wall arteries remain largely nonmuscular even in the adult. The muscularization of these peripheral pulmonary arteries may be related to the differentiation of pericytes as well as to the recruitment of fibroblasts (8,9).

Arteries proliferate through the neonatal period and early infancy, accompanying the proliferation of alveoli; the ratio of alveoli to arteries can therefore be used as a measure of numerical arterial growth. The ratio of alveoli to arteries actually decreases from the newborn value of 20:1 to the value of 6:1 to 8:1, which is achieved first in early childhood and persists (*e*Fig. 107.0.3). The growth and development of the pulmonary circulation are also likely influenced by the trophic effects of neuropeptides (10) released from nerve endings as well as from neuroendocrine bodies (11) associated with accompanying airways.



***e*FIGURE 107.0.3** Schema showing peripheral pulmonary arterial development through morphometric changes: extension of muscle into peripheral arteries, percent wall thickness, and artery number (alveolar-arterial ratio), as they relate to age. **Upper panel:** Normal development. **Lower panel:** Abnormalities in all three features in a 2-year-old child with a hypertensive ventricular septal defect (VSD). A.D., artery accompanying an alveolar duct; A.W., artery accompanying an alveolar wall; ALV/Art, alveolar-arterial ratio; R.B., artery accompanying a respiratory bronchiolus; T.B., artery accompanying a terminal bronchiolus. (Reproduced from Rabinovitch M, Haworth SG, Castaneda AR, et al. Lung biopsy in congenital heart disease: a morphometric approach to pulmonary vascular disease. *Circulation* 1978;58:1107–1122, with permission.)

Experimental studies indicate that the normal adaptation to postnatal life is regulated by remodeling of the smooth muscle cell actin cytoskeleton (12) changes in the production and distribution of connective tissue, especially elastin and collagen (13,14) and by consequent cellular rearrangement (15). It also has been shown experimentally that there are smooth muscle cells with differing proliferative potential (16,17). For example, metavinculin-positive smooth muscle cells are relatively resistant to proliferation, and the variability in proliferative potential is reflective of differences in activation of protein kinase C intracellular signaling pathways (18).

Cellular Mechanisms of Vascular Development

Current studies by several groups (reviewed in reference 19) are addressing specific cellular and molecular mechanisms that might regulate fetal growth and development of the pulmonary vasculature. These mechanisms include expression of cell adhesion molecules, such as vascular cell adhesion molecule 1 (20) and platelet endothelial cell adhesion molecule (21), in addition to the b_1 (22) and, more recently, the b_3 family of integrin receptors, especially $a_v b_3$ (23). The b_1 family of integrins binds fibronectin, and the b_3 family also binds fibronectin, as well as a host of matrix molecules, but especially tenascin, osteopontin, and vitronectin, some of

which have been shown to govern vascular cell migration (e.g., fibronectin) (24,25,26 and 27) or proliferation (e.g., tenascin) (28). Because these molecules mediate direct interactions between vascular cells and the extracellular matrix, perturbations can be expected to lead to malformation of the pulmonary and systemic arteries. A variety of growth factors, including vascular endothelial growth factor (29) and acidic and basic fibroblast growth factor (FGF-1 and FGF-2) (30), are also responsible for the orderly growth and branching morphogenesis of blood vessels. These factors are regulated through their interaction with specific cell-surface tyrosine kinase receptors, such as flt-1 and flk-1, tek, and tie (31,32 and 33). The balance between proteases and antiproteinases also controls growth factor interaction with cell-surface molecules. Plasmin, thrombin (34,35), and elastases, including leukocyte and endogenous vascular elastase (36), release growth factors from storage sites in the extracellular matrix in an active form. In addition, a variety of endogenously expressed inhibitors of proteinases and elastases, such as plasminogen activator inhibitor (37) and elafin (38), likely control growth and development. Other classes of molecules are known to control angiogenesis, such as angiostatin, a molecule that appears to be derived from plasminogen (39) and endostatin (40). Production of matrix proteins, specifically elastin and collagen, in blood vessels, is regulated by insulin-like growth factor I (41) and transforming growth factor-b (TGF-b) (42).

Vasoactive peptides also regulate pulmonary vascular development—for example, endothelin production is associated with cell proliferation and NO with the suppression of cell growth (reviewed in references 43 and 44). Transcription factors are being identified that control vascular smooth muscle cell differentiation (45,46) and the programming of constellations of genes involved in pulmonary vascular morphogenesis.

Abnormal Pulmonary Vascular Development *In Utero*

Underdevelopment of the lung parenchyma and associated pulmonary vasculature (reviewed in reference 1) is associated with congenital diaphragmatic hernia (47), hypoplastic or dysplastic lungs, scimitar syndrome, and oligohydramnios secondary to renal agenesis and dysplasia. Pulmonary hypoplasia is also a feature of prematurity, the absence of the phrenic nerve, asphyxiating thoracic dystrophy, rhesus isoimmunization, and, experimentally, amniocentesis (48) and smoking (49).

Reversible or irreversible pulmonary artery hypertension and right-to-left shunting from birth can be a direct result of derangement or hypoplasia of the pulmonary vascular bed. Heightened pulmonary vascular resistance can be attributed to the impaired gas exchange (hypoxia, hypercapnia) in addition to the structural changes in the vessels. In infants with congenital diaphragmatic hernia, reversal of the pulmonary hypertension was achieved by using vasodilators (50), extracorporeal membrane oxygenation (or high-frequency oscillation) (51), and NO alone or in combination with phosphodiesterase inhibitors (52). Some infants with hypoplastic lungs who had been refractory to NO before extracorporeal membrane oxygenation demonstrated a beneficial effect of NO after extracorporeal membrane oxygenation. The expectation is that the reduction in pulmonary artery resistance will stimulate regression of vascular changes and maturation in growth of the pulmonary arteries. In our studies of infants who died after an attempt at repair of congenital diaphragmatic hernia, a striking decrease in the number of alveoli and associated arteries (47) was the major determinant of mortality, explaining why attempts to reverse severe pulmonary hypertension with NO have been less successful in this group of patients. Dysplasias of the lung associated with persistent pulmonary hypertension of the newborn [e.g., alveolar capillary dysplasia (*e*Fig. 107.0.4) (53)] are currently so refractory to treatment that a biopsy should probably be done to guide clinical management.

***e*FIGURE 107.0.4 A–C:** Lung micrographs from an infant with alveolar capillary dysplasia. Barium distends the lumen of a preacinar artery (A) but does not enter the anomalous vein to the left of the artery. Intraacinar arterial branches that contain barium are identified, but intraacinar veins and venules are distended with red cells, presumably forced ahead of the barium by the postmortem angiogram. Air spaces are lined by cuboidal epithelium, and no luminal capillaries are seen; all vessels lie centrally in the air-space walls (hematoxylin and eosin, ×90). **B:** Intraacinar pulmonary arteries show medial muscular thickening that forms a continuous layer even in the smallest branch, which is 20 µm in external diameter. Media is demarcated by external and internal elastic laminae, stained black in this elastic stain. A bronchiole is identified (B). Elastin–van Gieson, ×220. (Reproduced from Cullinane C, Cox PN, Silver MM. Persistent pulmonary hypertension of the newborn due to alveolar capillary dysplasia. *Pediatr Pathol Lab Med* 1992;12:499–514, with permission.)

Structural studies of the lung at postmortem in fatal cases of meconium aspiration suggest that antecedent pulmonary vascular abnormalities exacerbated the postnatal pulmonary hypertension (54). The most striking feature is the presence of muscle in arteries that are small and peripheral in location and normally nonmuscular. The muscle cells are surrounded by darkly stained elastic laminae, suggesting that they formed several weeks before death and therefore *in utero*. Clinical studies suggest in some cases a relationship between maternal ingestion of prostaglandin synthetase inhibitors and subsequent persistent pulmonary hypertension (55). Chronic hypoxia in pregnant rats will produce structural changes in the pulmonary vascular bed of the newborn (56). In lambs, the clinical syndrome was produced by administration of a cytokine associated with inflammation (i.e., tumor necrosis factor- a) (57). Relatively short periods of hypoxia in the fetal lamb will result in sustained elevation of pulmonary artery pressure and structural changes in the pulmonary arteries. *In utero* closure or constriction of the ductus arteriosus simulates the structural changes and the initial hemodynamic profile of persistent pulmonary hypertension (58,59). Pulmonary hypertension can be created *in utero* by prolonged endothelin receptor blockade (60) and by chronic lung injury (61). The sequelae of experimental pulmonary hypertension that is established *in utero* include decreased potassium channel gene expression (62), which could contribute to heightened vasoreactivity and impaired endothelium-dependent relaxation (63), reduced cyclic guanosine monophosphate, and reduced soluble guanylate cyclase (64).

Recent experimental studies carried out in newborn lambs and rabbits showed that heparin can stimulate remodeling of the pulmonary circulation. Accelerated maturation of the pulmonary circulation was achieved by inducing an increase in he number of peripheral pulmonary arteries relative to alveoli (unpublished), and clinical studies have supported this strategy (65). Therapy with phosphodiesterase inhibitors (66) as well as with estradiol (67) has been shown to positively influence vascular remodeling associated with pulmonary hypertension. There is experimental evidence that NO therapy impairs the endogenous production of NO synthase in lambs with pulmonary hypertension induced *in utero* (68), which is in keeping with clinical data that show profound rebound effects in some patients on withdrawal of therapy. A positive feedback mechanism was, however, observed in cultured endothelial cells, suggesting that there may be other contributing factors (69). One study suggests that brief *in utero* exposure to hypoxia may aggravate the response to pulmonary hypertension–producing stimuli later in life (70).

Perinatal stress (e.g., hemorrhage, hypoglycemia, aspiration, hypoxia) may result in failure of dilatation of normally muscular vessels and left ventricular dysfunction, both of which contribute to persistent pulmonary hypertension. The use of inhaled NO in clinical studies (71,72), the use of L-arginine in experimental studies (73), and strategies to maximize dilator effects with phosphodiesterase inhibitors (66,74) proved effective in lowering pulmonary artery pressure. Because increased production of endothelin may underlie the pathophysiology (75,76), the use of endothelin receptor blockade or endothelial-converting enzyme inhibition (77,78) may prove beneficial, especially if specificity could be controlled to maximize dilatory activity.

ALTERED POSTNATAL PULMONARY VASCULAR DEVELOPMENT

Alterations in pulmonary blood flow associated with congenital heart defects, hypoxia, hyperoxia or toxins also affect the postnatal structural development of the pulmonary vascular bed in infancy and childhood.

Congenital Heart Defects and Pulmonary Vascular Disease

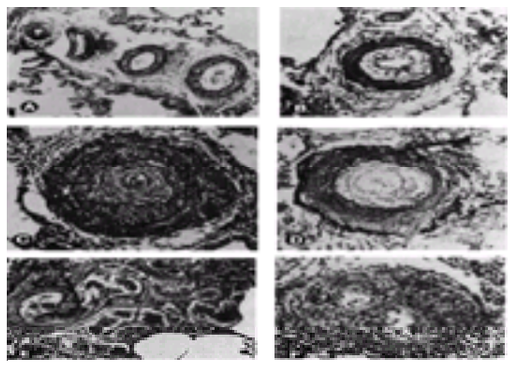
High Flow and Pressure and Structural Abnormalities

In clinical studies, it has been shown that high flow and pressure induce increasing pulmonary hypertension related to progressive vascular abnormalities (79) associated with impaired growth of the pulmonary arteries as assessed morphometrically. The first abnormality detected is extension of muscle into peripheral normally nonmuscular arteries (morphometric grade A) (*e*Fig. 107.0.3). Meyrick and Reid (8) showed from ultrastructural studies of lung biopsy tissue that this change is due to precocious differentiation of precursor cells (i.e., the pericyte in the nonmuscular region of the artery and the intermediate cell in the partially muscular region) to mature smooth muscle cells. Because arteries become more muscular as they increase in size, it is tempting to speculate that, in the altered hemodynamic setting of chronic

high flow and high pressure, “stretch” is the stimulus for smooth muscle cell differentiation from precursor cells.

With grade B, as in grade A, there is increased extension of muscle, but in addition, there is more severe medial hypertrophy of normally muscular arteries. When medial wall thickness is greater than 1.5 but less than 2 times normal (mild grade B), pulmonary hypertension is usually present; when medial wall thickness is more than twice normal (severe grade B), pulmonary hypertension is invariably present and usually has a pressure value greater than half that of the systemic level. The medial thickness is due to hypertrophy as well as hyperplasia of preexisting smooth muscle cells and also to an increase in the intercellular connective tissue proteins.

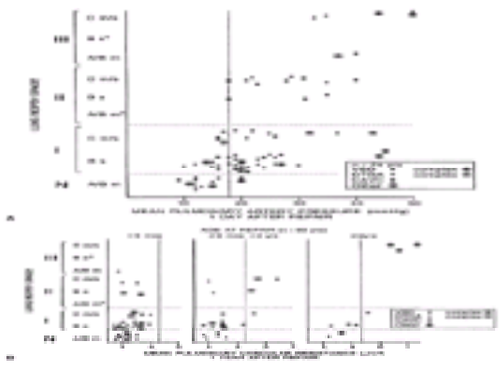
With grade C, in addition to the findings of “severe grade B,” arterial concentration and, usually, artery size are reduced. Patients with these changes usually have a pulmonary vascular resistance of greater than 3.5 U•m^2. When the artery number is less than half of normal (severe grade C), pulmonary vascular resistance values are often greater than 6 U•m^2. The basis for grade C is likely the failure of new vessels to grow normally, although some loss of arteries also may occur. Morphometric grades A and B are refinements of Heath-Edwards grade I (medial hypertrophy) (eFig. 107.0.5). Grade C may be found with Heath-Edwards grade I, is common with grade II (cellular neointimal formation), and is invariable with grade III (occlusive neointimal formation with fibrosis). In fact, when grade III is seen, arterial concentration is generally half of normal or less. In general, features of grade III C or more severe abnormalities such as Heath-Edwards grade IV (dilatation complexes), grade V angiomata formation, or grade VI (fibrinoid necrosis) correlate with severe elevation in pulmonary vascular resistance of greater than 8 U•m^2, which is refractory to vasodilators such as oxygen, prostacyclin, or NO.



***e*FIGURE 107.0.5** Heath-Edwards classification of pulmonary vascular changes. **A:** Grade I: medial hypertrophy. Elastin–van Gieson stain (EVG), ×150. **B:** Grade II: cellular intimal proliferation in an abnormally muscular artery. EVG, ×250. **C:** Grade III: occlusive changes. Medium is thickened due to fasciculi of longitudinal muscle, and vessel is all but occluded by fibroelastic tissue. EVG, ×150. **D:** Grade IV: dilatation. Vessel is dilated, and muscular media is abnormally thin. Lumen is occluded by fibrous tissue. EVG, ×150. **E:** Grade V: plexiform lesion. There is cellular intimal proliferation; clustered around are numerous thin-walled vessels that terminate as capillaries in the alveolar wall. EVG, ×95. **F:** Grade VI: acute necrotizing arteritis. A severe reactive inflammatory exudate is seen through all layers of the vessel. Hematoxylin and eosin stain, ×250. (Reproduced from Wagenvoort CA, Health D, Edwards JE. *The pathology of the pulmonary vasculature*. Springfield, IL: Charles C Thomas, 1964, with permission.)

We correlated the quantitative features of abnormal growth and remodeling of the pulmonary arteries and the qualitative changes described by Heath and Edwards with the hemodynamic behavior of the pulmonary circulation in the immediate postoperative period in the intensive care unit, 1 day after repair, and at the time of routine cardiac catheter study (i.e., 1 year later). Patients with grade A or mild grade B changes have normal pulmonary artery pressures in the early postoperative period or only a minimal degree of elevation. Most patients with more severe medial hypertrophy (i.e., severe grade B and Heath-Edwards grade I) have elevated values (8). The observed pulmonary hypertension is frequently labile and almost always can be controlled, and the mechanism and treatment are discussed in the next section. Both the presence and the severity of pulmonary hypertension in the early postoperative period are increasingly predictable when there are more advanced changes on lung biopsy (i.e., reduced artery number, grade C) and intimal hyperplasia (Heath-Edwards grades II and III).

One year after repair, however, patients operated on within the first 8 months of life tend to have normal pulmonary hemodynamics regardless of the severity of vascular changes on lung biopsy, as do all patients with severe grade B (Heath-Edwards grade I) abnormalities, regardless of their age at repair. Patients surgically corrected between 9 months and 2 years of life with grade C and Heath-Edwards grades II or III structural changes may have persistent elevation in pulmonary vascular resistance; this appears inevitable in those operated after 2 years of life (eFig. 107.0.6) (80).



***e*FIGURE 107.0.6 A:** Lung biopsy grade is correlated with mean pulmonary arterial pressure recorded the day after surgical repair. Dashed vertical lines separate normal from abnormally elevated pressure values, and the dotted horizontal lines separate the biopsy grades. Note that with the more severe Heath-Edwards changes on lung biopsy tissue, there is a trend toward a greater proportion of patients with elevated pulmonary arterial pressures and higher values. **B:** Graph correlating lung biopsy grade with pulmonary vascular resistance 1 year after cardiac repair. Patients who underwent repair within the first 8 months of life, but not those operated on later, had normal pulmonary vascular resistance regardless of the severity of their structural changes. *, no patients in this group; A, B, and C, morphometric grades; CAVC, complete atrioventricular canal; complex, associated abnormality; DTGA, D-transposition of the great arteries; m, mild; N, I, II, III, Heath-Edwards grades; n, normal; s, severe; VSD, ventricular septal defect. (Reproduced from Rabinovitch M, Keane JF, Norwood WI, et al. Vascular structure in lung tissue obtained at biopsy correlated with pulmonary hemodynamic findings after repair of congenital heart defects. *Circulation* 1984;69:655–667, with permission.)

A variety of physiologic factors appears to contribute to the severity and rate at which vascular disease develops in patients with congenital heart defects (eTable 107.0.1). It is recognized that certain lesions, such as transposition of the great arteries with intact septum (81) but especially with a large VSD (82) or a patent ductus arteriosus (83), are at high risk. Curiously, there have been reports of the progression of pulmonary vascular disease in infants with transposition of the great arteries, even after successful surgical correction (84). Infants with a large VSD (85), and especially an atrioventricular septal defect (86,87), also develop pulmonary vascular disease in early infancy, and in the latter, there are advanced changes observed even within the first 6 months of life. Patients with cyanotic heart defects who have large surgically created systemic-to-pulmonary artery shunts are also at risk for pulmonary vascular disease (88).

Application of Wedge Angiography

Techniques of wedge angiography have been developed to assess preoperatively the structural state of the pulmonary vascular bed. Changes that can be evaluated quantitatively (i.e., sparsity of arborization of the pulmonary tree, abrupt termination, tortuosity and narrowing of small arteries, reduced background capillary filling) generally reflect advanced changes in the preacinar arteries of at least Heath-Edwards grade III severity (89). A technique has been described that allows quantitative assessment of abnormalities in a pulmonary wedge angiogram (90). A balloon catheter is directed to the origin of the axial artery of the posterior basal segment of the right lower lobe; contrast material is injected, and the injection is filmed on biplane cine. The rate of tapering of the arteries is assessed by measuring the length of a segment over which the lumen diameter narrows between 2.5 mm and 1.5 mm. More abrupt arterial tapering is suggestive of more severe changes in the intraacinar arteries, assessed both morphometrically and by the Heath-Edwards classification (*e*Table 107.0.2 and *e*Fig. 107.0.7).

***e*TABLE 107.0.2** CORRELATION OF THE PATHOLOGY, PHYSIOLOGY, AND ANGIOGRAM IN PULMONARY VASCULAR DISEASE

		Physiology			
Grade	**Pathology**	**Q_P**	**P_{PA}**	**R_P**	**Wedge angiogram**

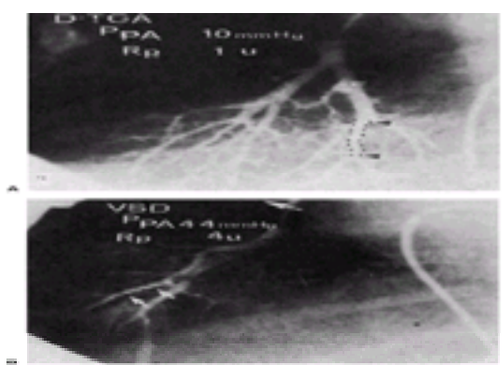
C	B and reduced artery, number, and size	±	↑	↑	Very abrupt tapering

↑, increased; ±, may or may not be increased; N, normal; P_{PA}, mean pulmonary artery pressure; Q_P, pulmonary blood flow; R_P, pulmonary vascular resistance.



***e*FIGURE 107.0.7 A:** A wedge angiogram shows slow tapering of the axial artery in a child with D-transposition of the great arteries (D-TGA) and normal pulmonary artery pressure (P_{PA}) and resistance (R_P). Approximate segment length between 2.5- and 1.5-mm internal diameter is marked off (*arrows*). **B:** A wedge angiogram in a child with a ventricular septal defect (VSD) shows rapid tapering of the artery when there is increased pulmonary artery pressure and resistance. An approximate segment length of 2.5- to 1.5-mm internal diameter is marked off (*arrows*). Large arrow denotes takeoff to the right pulmonary artery. (Reproduced from Rabinovitch M. Quantitative structural analysis of the pulmonary vascular bed in congenital heart defects. In: Engle MA, ed. *Pediatric cardiovascular disease.* Philadelphia: FA Davis, 1981:149–169, with permission.)

There are, however, pitfalls and limitations in the interpretation of the pulmonary wedge angiogram. Pulmonary stenosis or previous placement of a pulmonary artery band, owing to poststenotic dilatation, will give the impression of rapid tapering. With advanced vascular disease, there is sometimes such extensive intimal hyperplasia that the vessel appears narrowed all the way from the hilum so that abrupt tapering is no longer apparent. In that situation, however, the background haze is absent, and the pulmonary circulation time usually is prolonged. Technical abnormalities also can result in difficulties in interpretation. If the injection of contrast fails to fill the vessels all the way out to the pleura, the background will appear dark, and if the balloon does not completely occlude the vessel, the false impression of a dense background will be created, owing to filling of capillaries and veins. The circulation-time assessment depends on exclusion of pulmonary vein stenosis and intrapulmonary shunting.

When pulmonary vascular-resistance calculations (based on measured oxygen consumption) are elevated (>8 U•m^2 and nonreactive) and wedge angiography supports extensive structural abnormalities, lung biopsy evaluation has not, in our experience, provided other than confirmatory evidence of severe pulmonary vascular disease. If, however, discrepancies are found or if the patient is in the first 2 years of life, the analysis of lung biopsy tissue, even prepared by frozen section, will help decide on a corrective procedure (91). The ability to predict from biopsy tissue whether even mild elevation in pulmonary vascular resistance will be present postoperatively is also of increasing importance, particularly in the consideration of patients who require a Fontan procedure (92). Patients with tricuspid atresia who have had previous systemic-to-pulmonary artery shunts and those with single ventricle and previous pulmonary artery bands are a particular problem. We currently consider a biopsy showing severe grade C (less than one-half the normal number of arteries) and grade III or greater changes in 20% of vessels to indicate severe vascular disease that is unlikely to regress postoperatively and may preclude a successful result from closure of a VSD; severe grade B, medial wall thickness greater than twice normal, and grade II changes in any vessels may preclude a favorable result from a Fontan procedure. Further studies showed that even minor vascular changes on lung biopsy tissue (mild grade B) are associated with increased morbidity after Fontan procedure, as gauged by prolonged hospitalization because of the need for increased ventilator support and drainage from chest tubes (our unpublished data).

Intravascular ultrasound may hold new promise for estimating the severity of pulmonary vascular disease (93). Noninvasive methods may help estimate the level of pulmonary artery pressure, in addition to pulsed Doppler echocardiography (94), high-resolution computed tomography (95), magnetic resonance imaging (96), and fractal analysis (97).

Postoperative Increased Pulmonary Vascular Reactivity

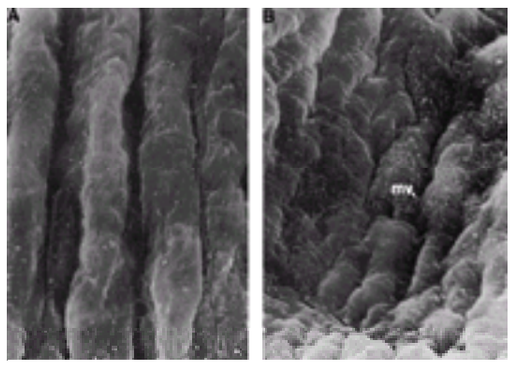
Various methods of managing postoperative increased pulmonary vascular reactivity have been proposed, including prolonged anesthesia with fentanyl (98) and vasodilators such as prostacyclin or, more recently, atrial natriuretic peptide or inhaled NO, which has proven to be particularly useful (99,100 and 101). Infusion of L-arginine also may hold promise (102), as do endothelin receptor antagonists (77,103,104). Adenosine (105,106) and amrinone (107) also have been used effectively to dilate the pulmonary vascular bed. Recent studies have shown beneficial effects with inhaled NO (108) or aerosolized prostacyclin (iloprost) (109). In our own unit, we have benefited from continuous monitoring of pulmonary artery and left atrial pressure. To maintain the pulmonary artery pressure at less than or equal to half systemic level, we institute hyperventilation (carbon dioxide tension 25 to 30 mm Hg) for the first 24 hours. We are currently assessing whether weaning from the ventilator can be accomplished more effectively using NO or phenoxybenzamine. Usually, the use of the extracorporeal membrane oxygenator (110) or ventricular assist devices is necessary only when there is severe ventricular dysfunction. Experimentally, cardiomyoplasty has been successful in providing hemodynamic support during acute pulmonary hypertension (111). Experimental studies with left-to-right shunts have related the pulmonary hypertension to increased production of endothelin, reduced “dilator” endothelin B receptors (112), and impaired endothelial-dependent relaxation (113,114). In addition, NO can suppress the pulmonary vascular remodeling associated with pulmonary hypertension (115). There is experimental evidence that reduction in pulmonary artery pressure per se will induce regression of even advanced pulmonary vascular disease induced by high flow and endothelial injury (116).

A few patients, however, maintain a high level of pulmonary vascular resistance and are refractory to vasodilator therapy despite what appear to be mild vascular

changes on light microscopy (medial hypertrophy), and there are other patients who develop rapidly progressive pulmonary vascular disease despite early diagnosis and timely intervention. For these patients, the prognosis may not be much better than those with unexplained pulmonary hypertension (117). Therapies for the patient with Eisenmenger's have included chronic oxygen (118), anticoagulants (119), and palliative surgical procedures, including atrial septal defect creation (120,121), and intravenous (122), aerosolized (123), or oral prostacyclin (124), although the results from nonintravenously administered prostacyclin are less encouraging. Generally, these measures are taken to gain time in anticipation of a heart-lung transplantation, a heterotopic heart transplantation, or surgical correction along with single-or double-lung transplantation (125,126,127 and 128).

Mechanisms Underlying the Reactive Pulmonary Circulation

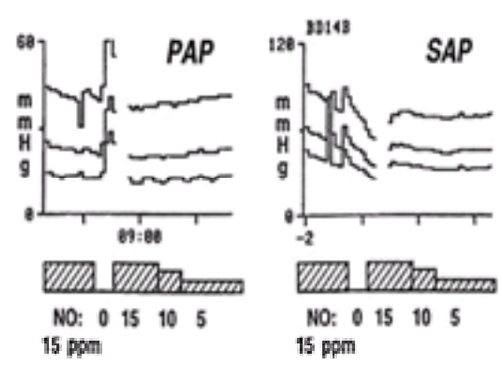
Many factors could contribute to the hyperreactive pulmonary circulation. We observed endothelial changes on scanning and transmission electron microscopy, suggesting a potential for altered function, as well as increased interaction with circulating blood elements, such as platelets and leukocytes (*e*Fig. 107.0.8) (129,130,131,132 and 133), through the release of thromboxanes (131) and other vasoactive mediators such as angiotensin II. In fact, angiotensin II elevation is attributed to an elevation in both angiotensin-converting enzyme (134) as well as mast cell chymase, which can also produce endothelin-1 (135). In addition, alterations in the subendothelium reflected in fragmentation of elastin suggest that an elastolytic enzyme might be stimulating the remodeling process as well as altering the functional response of the vessel. On scanning electron microscopy, the endothelial surface of normal thin-walled pulmonary arteries has a "corduroy-like" appearance in that the cells form narrow, even ridges. In contrast, the endothelial surface of hypertensive thick-walled pulmonary arteries has a "cable-like" texture in that the cells form deep, twisted ridges. In patients with advanced pulmonary vascular changes, the endothelial surface exhibits a chenille pattern in which high ridges alternate with narrow, twisted, misshapen ones. If this abnormally contoured endothelium is more likely to interact with marginating blood cells (platelets and leukocytes), the result might be the release of pulmonary vasoconstrictor substances, such as thromboxanes and smooth muscle mitogens. Platelet-activating factor also may be important, although its effect is likely local, as an increase in circulating levels of this agent has not been documented in patients after repair of a congenital heart defect (133). On transmission electron microscopy, an increased density of microfilament bundles and rough endoplasmic reticulum are seen. The former suggests an altered cytoskeleton, which may affect endothelial permeability, and the latter is associated with increased protein synthesis and metabolic activity.



***e*FIGURE 107.0.8** Scanning electron photomicrographs of pulmonary artery endothelial surfaces. **A:** Normal pulmonary artery shows "corduroy" pattern, closely aligned ridges. **B:** Hypertensive pulmonary artery shows "cable" pattern, deep knotted ridges, and numerous microvilli (mv). ×810. (Reproduced from Rabinovitch M, Bothwell T, Hayakawa BN, et al. Pulmonary artery endothelial abnormalities in patients with congenital heart defects and pulmonary hypertension: a correlation of light with scanning electron microscopy and transmission electron microscopy. *Lab Invest* 1986;55:632–653, with permission.)

We showed by immunohistochemistry that hypertensive endothelial cells produce increased von Willebrand factor (factor VIII). The factor VIII:Ag levels were significantly higher in patients with congenital heart defects and elevated pulmonary artery pressure than in those with normal pressure, but the molecule being secreted was lacking in biologic activity. Under conditions that aggravate the endothelial dysfunction (e.g., cardiopulmonary bypass), von Willebrand factor biologic activity is markedly increased (132), which could account for the development of platelet fibrin microthrombi in the postoperative period and for the abnormal release of vasoactive compounds, causing increased vascular reactivity. In recent studies, an increased density of neuroepithelial bodies has been observed in the airways of patients at risk for this complication as well as an elevation in vasoconstrictor neuropeptide-containing nerves (10). The neuroendocrine cells, which are also oxygen sensors (11), contain bombesin and serotonin, agents known to be potent vasoconstrictors. Because most of the pulmonary hypertensive crises occur on weaning from the ventilator, it is tempting to speculate that "swings" in airway pressure might lead to degranulation of the neuroepithelial cells and release of the vasoconstrictor substances. To support this, we observed a striking decrease in lung compliance accompanying the pulmonary hypertensive crisis (136).

There is now very convincing evidence that endothelial-dependent relaxing factor, or NO, is lacking in hypertensive pulmonary arteries of patients with Eisenmenger's syndrome and the production of endothelial-dependent relaxing factor is impaired beginning at an early time in patients with congenital heart defects (137,138,139 and 140). Injury to the endothelium after cardiopulmonary bypass likely explains the further decrease in endothelial-dependent relaxing factor production, which has prompted the successful use of NO in the postoperative patient (*e*Fig. 107.0.9). There is also evidence that production of the vasoconstrictor endothelin might be increased in patients with pulmonary hypertension and congenital heart defects (141,142). Because endothelin is proproliferative as well as vasoconstrictive, it is tempting to speculate that mechanical factors may mediate the increase in DNA associated with cell proliferation (143) through release of endothelin. Receptors for growth factors such as platelet-derived growth factor are increased in response to mechanical forces as well (144).



***e*FIGURE 107.0.9** Systemic (SAP) and pulmonary (PAP) artery recordings from the bedside monitor in a 1-day-old patient immediately after repair of obstructed total anomalous pulmonary venous connection. Systolic, mean, and diastolic pressures are recorded each minute. Stable SAP and PAP are noted on 15 ppm of nitric oxide (NO). When the NO is transiently stopped, there is a prompt increase in PAP and decrease in SAP. With reinstitution of NO, recovery occurs. (Reproduced from Adatia I, Wessel DL. Diagnostic and therapeutic uses of inhaled nitric oxide in congenital heart disease. Nature of the Vascular Lesions

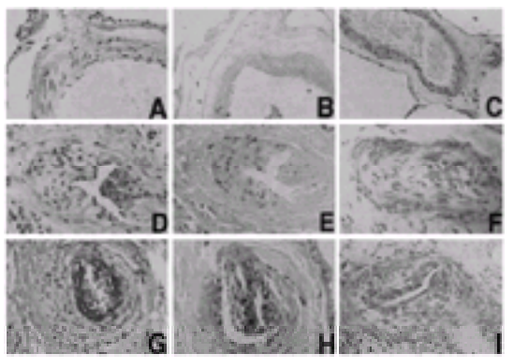
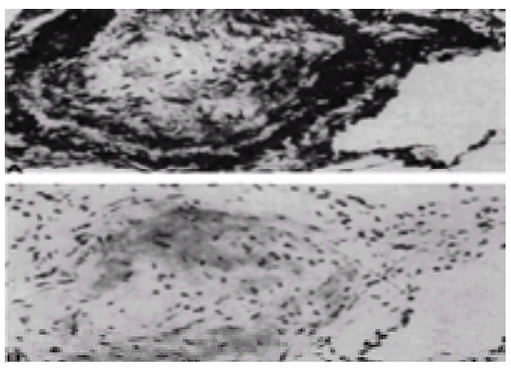
Our recent immunohistochemical studies carried out in lung biopsy tissue from patients with congenital heart defects showed that the deposition of tenascin and fibronectin in the media and neointima increases progressively with the severity of the lesion (*e*Fig. 107.0.10) (145). We related increased expression of tenascin to vascular smooth muscle cell proliferation (146) in cultured smooth muscle cells, and in fact, there is colocalization of tenascin with proliferating smooth muscle cells, as judged by the proliferating cell nuclear antigen and with expression of growth factors such as epidermal growth factor in human lung tissue. We also related fibronectin to increased smooth muscle cell migration in the context of neointimal formation (147). Studies by other investigators found evidence that the neointimal lesions in the context of primary pulmonary hypertension are associated with increased expression of TGF-b (148) and procollagen (*e*Fig. 107.0.11) (149) in addition to fibronectin (150). It is also proposed that endothelial cell proliferation and a form of angiogenesis are observed with plexiform lesions (151).



***e*FIGURE 107.0.10** Representative photomicrographs showing immunoperoxidase staining for tenascin-C (TN) **(A,D,G)**, proliferating cell nuclear antigen (PCNA) **(B,E,H)**, and epidermal growth factor (EGF) **(C,F,I)** in graded lung biopsy tissue sections. **A–C:** Vessel showing a typical grade I^A lesion. **D–F:** Vessel showing a typical grade I^C lesion. **G–I:** Vessel showing a typical grade III^C lesion. In low-grade lesions **(A)**, modest TN immunostaining was evident in the adventitia. With medial hypertrophy, TN immunoreactivity became more prominent in the periendothelium **(D)**, with the most intense immunostaining being apparent within the neointima of high-grade lesions showing occlusive neointimal formation **(G)**. In the lowest grade of lesion, PCNA was negative **(B)**, despite foci of EGF in the media. With medial hypertrophy, PCNA was expressed in the media **(E)**, together with foci of EGF **(F)**. With the development of higher grade occlusive lesions, TN **(G)**, PCNA **(H)**, and EGF **(I)** colocalized to the neointimal cell layers. Note that TN and PCNA staining was performed on serial sections, whereas EGF detection was carried out on similar vessels within the same biopsy. ×40. (Reproduced from Jones PL, Cowan KN, Rabinovitch M. Progressive pulmonary vascular disease is characterized by a proliferative response related to deposition of tenascin-C and is preceded by subendothelial accumulation of fibronectin. *Am J Pathol* 1997;150:1349–1360, with permission.)



***e*FIGURE 107.0.11** Immunohistochemistry was performed on formalin-fixed, paraffin-embedded parenchyma obtained from patients with severe primary pulmonary hypertension at the time of single-lung transplantation. Tissue sections then were stained with antibodies to the aminoterminal end of the procollagen type 1 propeptide **(B)**. This antibody identifies newly synthesized a-I(I) procollagen before cleavage of the aminoterminal propeptide after secretion and therefore can identify sites of active collagen deposition. An elastin–van Gieson stain demonstrates vascular structures **(A)**. Procollagen immunoreactivity **(B)** is present only within the neointima of this occluded artery. ×10. Experimental Studies

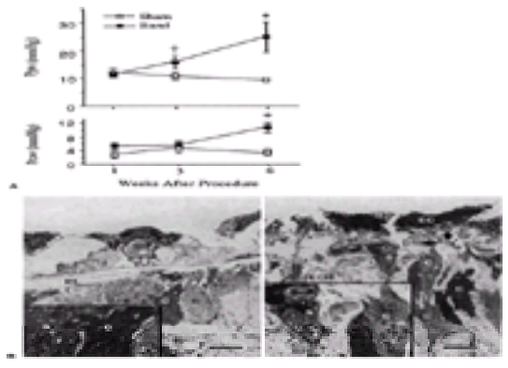
In experimental studies, high pulmonary blood flow alone produced by pneumonectomy (152), single pulmonary artery banding, or ligation (153,154 and 155) results in minimal, if any, elevation in pulmonary artery pressure and structural changes in the vessels. Slight elevation in pulmonary artery pressure is accompanied by extension of muscle into peripheral arteries. Aortopulmonary shunts surgically created in growing piglets are associated with a progressive increase in pulmonary artery pressure and with the development of structural changes, specifically, extension of muscle into peripheral arteries, medial hypertrophy of muscular arteries, and reduced arterial number (155). Takedown of the shunts during the period of rapid lung growth results in regression of the structural changes and of pulmonary hypertension (156). However, even reduction in pressure in adult animals results in regression of vascular disease (116). Creation of large aortopulmonary shunts in dogs, particularly into a single pulmonary artery, results in rapidly progressive pulmonary vascular changes (157,158). Several additional experimental models of high-flow congenital heart defects have been created, including lambs with a VSD (159) or placement of an aortopulmonary shunt in fetal lambs *in utero* (104), in sheep (158), or in calves (160). In addition to abnormalities in endothelial-dependent relaxation and in the production of vasoconstrictors previously discussed, many common features link the cellular and molecular pathophysiology of pulmonary vascular disease regardless of etiology; this subject is discussed at the end of the chapter.

High Pulmonary Venous Pressure–Pulmonary Vascular Disease

Advanced pulmonary vascular disease is unlikely to occur rapidly in patients with congenital heart defects related to increased pulmonary venous pressure. Collins-Nakai et al. (161), however, reported changes greater than Heath-Edwards grade III in most older children with congenital mitral stenosis in their series. In patients with total anomalous pulmonary venous connection, abnormal muscularization of the small arteries and veins has been observed from birth, and more severe structural changes (i.e., Heath-Edwards grade III) have been described in infants as young as 1 month (162). In infants with hypoplastic left heart syndrome, medial hypertrophy of the small arteries and veins from birth is so severe that it must have developed *in utero* (163,164). The presence of pulmonary vascular changes in defects and the capacity for these abnormalities to regress with improvement in hemodynamics may be of relevance because the Norwood staged surgical procedure for the treatment of hypoplastic left heart syndrome ultimately depends on the success of a bidirectional cavopulmonary shunt and a right atrial-to-pulmonary artery anastomosis or tunnel. Recent studies showed that manipulation of oxygen and carbon dioxide can successfully control pulmonary blood flow and resistance in managing infants with hypoplastic left-sided heart syndrome preoperatively and postoperatively (165). In both adults and children with rheumatic mitral stenosis, Wagenvoort and Wagenvoort (166) observed increased medial wall thickness of the pulmonary arteries; in children, this is due to hyperplasia of smooth muscle cells, but in adults, only hypertrophy is present.

Experimental Studies

Pulmonary venous hypertension has been reproduced experimentally by banding the pulmonary veins (167,168), by elevating left atrial pressure (169), or by creating coarctation of the aorta *in utero* in fetal lambs (170). In studies from our laboratory, LaBourene et al. (168) banded the pulmonary veins in newborn piglets and observed a striking decrease in compliance of the pulmonary veins after 1 week but no change in pulmonary hemodynamics. By 3 weeks, there was pulmonary arterial hypertension without elevation in pulmonary venous pressure; by 6 weeks, further progression of pulmonary hypertension was associated with elevated pulmonary venous pressure (*e*Fig. 07.0.12). Ultrastructural changes in the veins were seen at 1 week, consisting of fragmentation of elastin and a phenotypic switch in medial smooth muscle cells in which they appeared to be more synthetic and to be migrating toward the subendothelium (*e*Fig. 107.0.12). By 3 weeks, there was already evidence of intimal proliferation; by 6 weeks, collagen had increased in the walls of the pulmonary veins. This study suggests that pulmonary hypertension may be the first sign of pulmonary venous obstruction and that elevation of pulmonary venous pressure is associated with considerable structural remodeling. This may explain the frequent failure of surgical therapy in correcting pulmonary vein stenoses and suggests that it should be undertaken at the earliest suggestion of this disease and with a novel approach minimizing suture lines (171).



***e*FIGURE 107.0.12 A:** Pulmonary artery pressure (Ppa) (*upper panel*) and pulmonary capillary wedge pressure (Pcw) (*lower panel*) in banded and sham-operated piglets 1, 3, and 6 weeks after banding. Values are averages of mean ± SEM (n = 6 piglets per group at each time point). At 1 week, there was no change. At 3 weeks, there was a significant increase in P_{pa}, which preceded the rise in P_{cw} at 6 weeks and a further increase in P_{pa} (**p* <.01; †*p* <.05). **B:** Transmission electron photomicrographs of representative pulmonary veins (PVs) from banded (*right panel*) and sham-operated (*left panel*) piglets at 3 weeks after banding (×14,131) (inset, ×28,263). Both pulmonary veins show apparent injury and lifting of endothelial cells and subendothelial spaces due to poor preservation during handling. Sham-operated PV displays on intact internal elastic lamina (IEL) and predominantly contractile-appearing smooth muscle cells (C) in media. In contrast, PV from banded piglet depicts complete breakdown of IEL into elastin fragments (Efg), a thickened subendothelium composed of collagen, extracellular matrix (ECM), and smooth muscle cells that appear to have migrated in from the media, many of which have a synthetic-appearing phenotype (S) exemplified by a large amount of endoplasmic reticulum and a corresponding paucity of contractile filaments. C and S smooth muscle cells are better appreciated in insets. Bar = 1 µm. (Reproduced from LaBourene JI, Coles JG, Johnson DJ, et al. Alterations in elastin and collagen related to the mechanism of progressive pulmonary venous obstruction in a piglet model: a hemodynamic, ultrastructural, and biochemical study. *Circ Res* 1990;66:438–456, with permission.)

Decreased Pulmonary Blood Flow

In patients with congenital heart defects causing low pulmonary blood flow, hypoplasia of the pulmonary arterial musculature is observed; in those in whom the hematocrit is particularly elevated, thromboembolic changes occur (172,173,174,175,176,177 and 178). The creation of systemic to pulmonary artery shunts may improve the hypoplasia, but secondary to abnormally high flow and pressure, medial hypertrophy and intimal hyperplasia soon occur. Recent studies suggest that the potential for growth of the central pulmonary arteries is correlated with the proportion of elastin in the media, and the same may be true for the intrapulmonary vessels (178).

On the postmortem arteriograms in patients with decreased pulmonary blood flow, the axial arteries are abnormally narrow in lumen diameter (4). On microscopic examination of the lung, the intraacinar pulmonary arteries are abnormally thin-walled, small, and few. Alveolar development is impaired in patients with decreased pulmonary blood flow. Patients with tetralogy of Fallot and associated pulmonary atresia form a special subgroup in which the relative distribution of central pulmonary arteries and aortopulmonary collaterals determines peripheral pulmonary vascular structure (4,176).

Experimental Studies

Levin et al. (179) also created low pulmonary blood flow by banding the main pulmonary artery of fetal lambs. The changes in the lung resembled those seen clinically in that there was diffuse hypoplasia of the musculature of the peripheral pulmonary vessels. Haworth et al. (180) ligated the left pulmonary artery in newborn piglets and demonstrated normal development of the intraacinar arteries owing to extensive anastomoses with bronchial arteries and occlusive fibrosis in the preacinar vessels.

CHRONIC HYPOXIA-INDUCED PULMONARY VASCULAR DISEASE

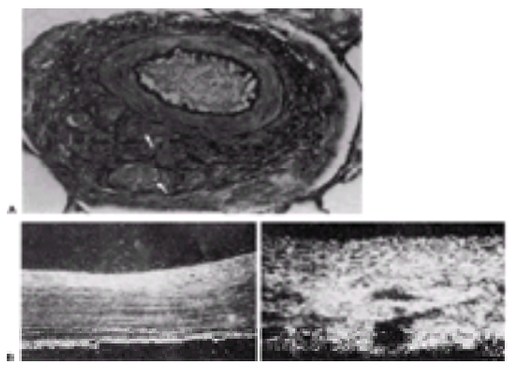
High-Altitude Hypoxia

In those living at high altitude, there is chronic elevation of pulmonary artery pressure present, only a small portion of which is reversible with administration of oxygen (181,182). The peripheral arteries are more muscular than normal and have a decreased lumen diameter. The severity of pulmonary hypertension is variable and almost always improves on return to sea level, at least at rest. In response to exercise, it may increase markedly, suggesting limited functional reserve, owing to persistent structural abnormalities (183).

Experimental Studies

The degree of reactivity to hypoxia or the level of pulmonary hypertension with chronic hypoxia may be a function of the amount of smooth muscle in the pulmonary vascular bed, the llama having the least muscle and being the least reactive (184). In the rat, the development of structural changes and sustained pulmonary hypertension appears to occur after 3 days of chronic hypoxia (air at half atmospheric pressure, oxygen partial pressure = approximately 40 mm Hg). Over the ensuing 2 weeks, pulmonary artery pressure progressively doubles and is associated with progressive extension of muscle into peripheral normally nonmuscular arteries, medial hypertrophy of normally muscular arteries, and reduction in arterial number, and right ventricular hypertrophy is evident. The hemodynamic and structural responses progress slowly thereafter. The structural changes induced by hypoxia appear to be less severe in mature female experimental animals, and those of both sexes exposed to hypoxia through the period of development may show less potential for regression (185,186). Regression of smooth muscle hypertrophy may be accompanied by a relative increase in the amount of elastin and collagen (187), so the vessel, although less muscular, nonetheless may be abnormally noncompliant (188). Collagen increases in hypertensive pulmonary arteries, and stretch may be the stimulus (189,190 and 191); inhibition of collagen synthesis decreases chronic hypoxic pulmonary hypertension and vascular changes (192). Recent work suggests that increased activity of metalloproteinases may be evident in the regression of vascular disease (193), but inhibition of metalloproteinases appears to aggravate experimental pulmonary hypertension in rats (194). Loss of small arteries may not, however, be recoverable, explaining why the pulmonary vascular bed may have limited functional reserve.

Stenmark et al. (195) took newborn calves to a simulated high altitude of 4,300 m and observed severe pulmonary hypertension with right-to-left shunting owing to the rapid development of suprasystemic levels of pulmonary artery pressure. There was striking medial hypertrophy and remarkable proliferation of a dense adventitial sheath that, in large vessels, was sometimes seen to exhibit neovascularization (eFig. 107.0.13). Hypoxia-induced adventitial fibroblast proliferation has been related to protein kinase C (zeta isoform) (196). Further studies have shown striking synthesis of elastin in the pulmonary arteries of these neonatal calves (eFig. 107.0.13) (13,14). There may be a role for insulin-like growth factor I, as increased expression of this growth factor stimulates elastin synthesis in cultured vascular cells (197), as does TGF-b (198). Studies in the piglet by Allen and Haworth (199) showed that when the animal is subjected to hypoxia from birth, the fetal medial musculature does not regress, but connective tissue synthesis is not stimulated. When hypoxic exposure begins at 3 days of age, however—that is, after the fall in pulmonary vascular resistance and the regression of the fetal musculature—neosynthesis of elastin is apparent.



***e*FIGURE 107.0.13 A:** An artery from the lung of a 2-week-old calf raised at a simulated altitude of 4,300 m from birth. Pulmonary artery systolic pressure was 100 mm Hg. There is marked medial hypertrophy and adventitial thickening with neovascularization (*arrows*). Elastin tissue stain, ×400. (Reproduced from Rabinovitch M. Pathophysiology of pulmonary hypertension. In: Emmanouilides GC, Allen HD, Thomas AR, Howard PG, eds. *Moss and Adams heart disease in infants, children, and adolescents including the fetus and young adult*, 5th ed. Baltimore: Williams & Wilkins, 1995:1659–1695, with permission.) **B:** *In situ* hybridization localization of

tropoelastin messenger RNA (mRNA) in control and hypertensive vessels from neonatal calves. White staining over areas indicates tropoelastin mRNA labeling. In normotensive vessels (*left*), labeled cells (^{35}S-labeled T66-T7) were confined to the inner media. Minimal signal is noted in the outer vessel wall. In vessels from hypertensive animals (14 days of hypoxia) (*right*), intense autoradiographic signal was observed throughout the media, albeit in a patchy distribution. (Reproduced from Prosser IW, Stenmark KR, Suthar M, et al. Regional heterogeneity of elastin and collagen gene expression in intralobar arteries in response to hypoxic pulmonary hypertension as demonstrated by in situ hybridization. *Am J Pathol* 1989;135:1073–1088, with permission.)

A variety of studies attempted to show how acute vasoconstriction or a direct hypoxic "injury" initiates the structural changes observed in the pulmonary arteries. Angiotensin II appears to be unimportant as a hypoxic vasoconstrictor but nonetheless is critical to the mechanism responsible for inducing vascular disease because of its biologic properties in stimulating vascular smooth muscle cell hypertrophy and proliferation (200). Chronic hypoxia is also associated with an increase in angiotensin I and II receptors (201). On the other hand, we showed that chronic infusion of angiotensin II by releasing prostacyclin is actually protective of the pulmonary hypertension and vascular changes that develop during exposure to chronic hypoxia (202). Fetal and neonatal lamb pulmonary artery smooth muscle cells in culture show a decrease in the production of prostacyclin in response to acute hypoxic exposure (203), as do bovine endothelial cells (204). Although a variety of vasoactive blockers will lower pressure, endothelin receptor blockade appears to be most promising as a selective strategy in reversing acute hypoxia-induced pulmonary vasoconstriction as well as the remodeling associated with chronic exposure. These studies have provided convincing evidence that the high endothelin levels observed are causally related to hypoxic vasoconstriction (205,206). In addition, hypoxia inhibits endothelin receptor B–mediated NO synthesis (207). Impaired NO synthesis and vasodilatation in chronic hypoxia are also associated with impaired cyclic guanosine monophosphate–dependent mechanisms (208). Agents also shown to be effective in the treatment of chronic hypoxic pulmonary hypertension in rats include inhibitors of 5-lipoxygenase activating protein (209) as well as of cyclic 3',5' guanosinemonophosphate-specific phosphodiesterase (210) and continuous inhalation of NO (211). Additional strategies are aimed at preventing acute hypoxic vasoconstriction by blocking potassium channels (212,213). Recent studies in transgenic mice suggest that genetic factors might modulate the response to chronic hypoxia. For example, in the absence of hemoxygenase 1, there is reduced production of CO and its associated vasodilatory effects (214). Prostacyclin synthetase overexpression is protective against the hemodynamic and vascular changes of pulmonary hypertension (215). Serotonin has been implicated in the increased vasoreactivity of the fawn-hooded rat (216), and there is attenuated severity of pulmonary vascular disease in mice lacking the serotonin transporter gene (217). We also showed that endogenous or exogenous (unpublished) serine elastase inhibitors will effectively reduce chronic hypoxia-induced pulmonary hypertension (218).

In addition, experimental studies of Thompson et al. (219) and Benitz et al. *in vitro* (220) suggest that vascular smooth muscle growth inhibitors may be useful in preventing vascular disease. Heparin infusion will decrease the severity of hypoxia-induced vascular changes, presumably by decreasing smooth muscle hyperplasia. The influence of the Na/H antiporter in the mechanism of heparin-induced inhibition of smooth muscle cell growth is currently being addressed (221). Recent studies have also shown that calcitonin gene–related peptide administered by gene transfer not only attenuated hypoxia-induced vasoconstriction and remodeling but also enhanced the effects of phosphodiesterase inhibitors (222).

Lung Disease

Clinically, lung disease is the most common cause of hypoxia-induced pulmonary vascular disease. The pulmonary hypertension may be the result of hypoxic vasoconstriction-induced abnormalities described above, compounded by the adverse effects of long-standing polycythemia (microthrombi) and elevated pulmonary venous pressure secondary to dysfunction of the hypoxemic left ventricle. Treatment of the lung disease will decrease the level of pulmonary artery pressure and hence allow some regression of the structural changes. It is of interest that the severity of the vascular lesions and associated elevation in pulmonary vascular resistance, even with extensive lung disease, is usually so much more manageable than that observed with congenital heart disease. Cor pulmonale is discussed in detail in Chapter 27. Pulmonary vascular disease is rare with obstructive lung disorders, such as asthma (223), and more common with parenchymal disorders associated with loss of tissue, such as cystic fibrosis (224), in which it is more likely a late complication. Restrictive lung disease also may be associated with pulmonary hypertension. Restrictive lung disorders include diffuse interstitial fibrosis (Hamman-Rich) (225), radiation fibrosis and chemotherapy toxicity (226), and infiltrative lung tumors (227). Neuromuscular disorders affecting the chest wall [e.g., Duchenne's muscular dystrophy (228) and Werdnig-Hoffmann disease] also can cause pulmonary hypertension, as can diseases affecting the vertebrae and rib cage, such as severe scoliosis (229,230).

Upper Airway Obstruction

Severe upper airway obstruction from a variety of causes may be complicated by the development of pulmonary hypertension. Obstructive sleep apnea may be associated with the pickwickian syndrome (231,232). Obesity, through the increased work of breathing and carbon dioxide production, stresses the respiratory control system, and depending on its inherent sensitivity, hypoventilation may result, causing further carbon dioxide retention and hypoxia, which contribute to the lethargy and cor pulmonale. Damage to the respiratory center is rarely a primary disorder (Ondine's curse) or secondary to trauma or other neurologic disease. Although removal of the airway obstruction often results in a prompt return to normal pulmonary artery pressure and resolution of the heart failure, these symptoms can persist for some time due to slow regression of hypoxia-induced structural changes in the pulmonary vascular bed or persistent impairment of ventilatory drive.

THROMBOEMBOLIC DISEASES

Diagnosing thromboemboli as a cause of pulmonary hypertension requires a high index of suspicion in patients who have disorders in which the former are likely to occur. Deep vein thrombosis (233), right-sided endocarditis, and right atrial myxoma also may be sources of emboli (234). Patients with sickle cell anemia may develop pulmonary thromboses and infarctions (235), and thromboemboli occur in children with ventriculoatrial shunts for hydrocephalus (236). In endogenous areas, ova emboli resulting from schistosomiasis have been described (237), and fatal emboli may occur secondary to trauma or in association with collagen vascular disease (238). Tumor emboli may carry metastatic disease from the kidneys or other abdominal organs or may be present in association with infiltrative carcinomatous disease of the lung (239), and thromboembolic pulmonary hypertension is associated with tumor chemotherapy as well as steroids (240). There is little direct evidence that oral contraceptives alone will cause the development of pulmonary vascular disease in women; these compounds probably should be avoided, however, particularly in susceptible women, such as those with congenital heart defects and pulmonary hypertension. Diagnosis of the nature and severity of embolic phenomena may be established by chest radiographs and lung scans, although occasionally angiography is necessary. Recent advances have been made in treatment by thromboendarterectomy (241).

The pulmonary hypertension of thromboembolic disease is likely related to both the structural damage and occlusion as well as to the concomitant release of vasoactive substances from degenerating platelets. The microscopic features of thromboembolic disease reflect both the patchy nature of the abnormalities and the eccentricity of the fibrotic lesions (242)—that is, some vessels show evidence of having been completely occluded and later recanalized, but in other areas, vessels are increased both in size and concentration, suggesting compensatory dilatation and recruitment.

PORTAL HYPERTENSION

Intrahepatic portal hypertension resulting from severe liver disease causing cirrhosis and extrahepatic portal hypertension due to portal vein thrombosis have been associated with pulmonary hypertension (243,244,245,246 and 247). The pulmonary vascular changes include medial hypertrophy, occlusive cellular intimal hyperplasia, plexiform lesions, and dilatation complexes (246,247). It has been postulated that the "toxic liver" is unable to degrade a certain vasoconstrictor or toxin that circulates through the lung in high concentration, inducing structural changes in the vessels. In some patients with liver disease, however, there is generalized vasodilatation of the vessels in the lung (247), and there are also cases in which large vascular fistulae between pulmonary and hepatic arteries are observed, suggesting abnormal production of a different metabolite or a different end-organ response. Severe pulmonary hypertension should not, however, be considered a contraindication to liver transplantation, because regression of the hemodynamic abnormalities has been described (248).

GRANULOMATOUS AND COLLAGEN VASCULAR DISEASE

Pulmonary hypertension may occur with sarcoidosis as a result of the presence of obstructive granulomas within the pulmonary arteries (249). It is also a complication of certain collagen vascular diseases (e.g., commonly scleroderma); the CREST syndrome (*c*alcinosis cutis, *R*aynaud's phenomenon, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasias) (250,251); and, more rarely, systemic lupus erythematosus (252,253), rheumatoid arthritis (254,255), Takayasu's arteritis (256), polymyositis (257), and dermatomyositis (258). Most recently, severe pulmonary hypertension has been associated with acquired immunodeficiency syndrome, even in the absence of lung parenchymal disease (259,260), and has been reproduced experimentally (261). Moreover, the development of pulmonary hypertension in the subset of patients with human immunodeficiency virus infection may be a function of the immunogenetic background (i.e., human leukocyte antigen class II alleles) (262).

The structural basis for the pulmonary hypertension of collagen vascular disease is usually a vasculitis believed to be immune/inflammatory in origin and usually observed in the absence of or with minimal evidence of parenchymal lung disease. Thromboembolic phenomena also have been described, particularly in association with the antiphospholipid syndrome (263). There is also high circulating endothelin-1 described in subsets of patients with systemic sclerosis (264). There may be many

pathophysiologic similarities between the immune/inflammatory–mediated postcardiac transplant coronary artery disease, which we and others have studied, and collagen vascular disease–associated pulmonary hypertension. We showed experimentally that the neointimal formation seen in the coronary arteries is mediated by an increase in serine elastase activity (265), which together with an increase in cytokine release (266) induces the production or release of gene products, such as vascular cell adhesion molecule 1, inflammatory cell adhesion molecule 1, and fibronectin (267,268). These molecules are associated with neointimal formation related to smooth muscle cell proliferation and migration. In our studies, cytokine blockade with the tumor necrosis factor-a–soluble receptor (269), the VLA-4 integrin inhibitor CS-1 (270), which prevents interaction between fibronectin and T cells, and the elastase inhibitor elafin (271) all can serve to reduce markedly the incidence and severity of coronary artery neointimal lesions in rabbits after heterotopic transplant. These same strategies might be relevant to the treatment of pulmonary vasculitis–associated pulmonary hypertension. Recent studies have shown good results from intravenous epoprostenol in the treatment of pulmonary hypertension associated with immune inflammatory diseases such as lupus (272).

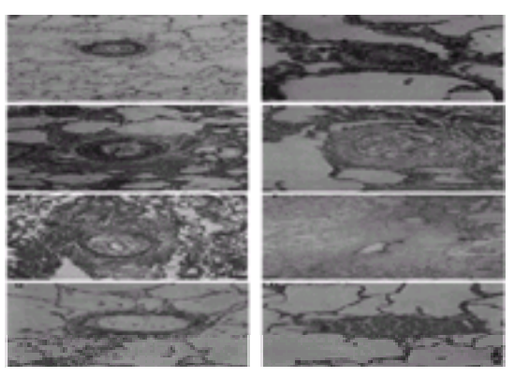
DRUGS

The ingestion of various substances is known to be associated with pulmonary hypertension (273). These substances include aminorex, which resembles epinephrine in its chemical structure, suppresses appetite, and causes symptoms of right-sided heart failure in 10% of patients within 6 to 12 months of initial administration (274), and the fenfluramine compounds, most recently, dexfenfluramine, a serotonin antagonist (275). The mechanism whereby these compounds induce progressive pulmonary hypertension is uncertain, but there is no evidence that they are vasoconstrictors (276), although they can be responsible for the release of intracellular calcium (277). Pathophysiologic studies have also suggested that there are similarities to primary pulmonary hypertension in terms of monoclonal expansion of endothelial cell populations (278). The toxic oils, such as rapeseed oil, also have been implicated in the development of malignant pulmonary hypertension (279). Ingestion of pyrrolizidine alkaloids, such as bush tea, causes hepatic venoocclusive disease, and a similar compound, monocrotaline, when ingested by animals, causes pulmonary vascular disease (280). In many cases, there has been regression on termination of the treatment, but in other cases, the disease presumably was detected at a very advanced stage or persisted in a malignant course. Microscopic changes in the lung were similar to those in patients with end-stage pulmonary vascular disease, regardless of etiology (i.e., medial hypertrophy and intimal fibroelastosis), including the presence of plexiform and dilatation lesions (279).

UNEXPLAINED PULMONARY HYPERTENSION

After all known causes of pulmonary hypertension have been ruled out, the diagnosis becomes that of idiopathic pulmonary hypertension. This unexplained disease, in which a structural abnormality is always found either in the arteries or in the veins, occurs both in children and adults and sometimes with a familial tendency (281,282,283,284,285 and 286). Recently a breakthrough has been made in the discovery of the locus and more recently the mutation in the gene associated with 40% of familial cases of pulmonary hypertension (282,283,284,285 and 286). The mutation discovered was in the gene for bone morphogenetic protein receptor II (285,286), a receptor for growth factors of the TGF-b receptor family. More recently, mutations in this pathway have been described in sporadic cases of primary pulmonary hypertension (287,288). Many studies are currently addressing the pathophysiologic mechanism involved, but bone morphogenetic protein receptor II signaling might suppress intracellular mechanisms responsible for the proliferative response associated with pulmonary hypertension. Other studies using cDNA array technology have suggested that there might be mutations in the genes for TGF-b receptor II, *Bax* (antiapoptosis) (289), and a homeobox gene *HOXA5* (290).

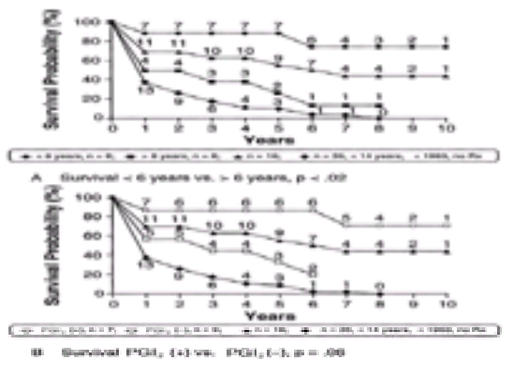
By the time the patient becomes symptomatic, the disease is usually advanced. In the absence of treatment, it is usually rapidly progressive and invariably fatal, although rare cases of spontaneous regression have been reported (291,292). The preponderance of affected females ranges in some studies from a ratio of 4:1 to 2:1 (117). In general, there is an inverse relationship between the age of onset of symptoms and the duration of illness until death. In young children, the pathobiology suggests failure of the neonatal vasculature to open and a striking reduction in arterial number (293). In older children, intimal hyperplasia and occlusive changes are found in the pulmonary arteries as well as plexiform lesions. In adults, in addition to the latter changes, “ghost” arteries also have been reported. An electron microscopic study by Meyrick et al. (294), performed on a lung biopsy of an adult patient, showed severe endothelial injury, which they speculated to be the initial site of damage. In some patients, defective von Willebrand factor (295) and fibrinolysis (296) have been described. Additional features most recently described include thickening of the pulmonary adventitia and venous hypertrophy as well as endothelial cell hyperplasia (*e*Fig. 107.0.14) (297). Immunohistochemical changes have been described and include increased expression of TGF-b matrix proteins and macrophages (298).



***e*FIGURE 107.0.14** Micrographs of pulmonary arteries from patients with primary pulmonary hypertension. **A:** Concentric intimal thickening with whorls of cells with elastin and collagen deposition in an artery, approximately 180-µm diameter. The thickness of the medial wall also is increased ×100. **B:** Obliteration of lumen of artery, approximately 80 µm in diameter. ×260. **C:** Eccentric intimal thickening (*arrow*), approximately 220-µm diameter. The medial and adventitial layers are also thickened. ×130. **D:** Recanalization of an artery, approximately 120 µm in diameter. **E:** Note the numerous small vessels containing red blood cells in the thickened intima. The adventitial and medial coats also are thickened. ×120. **F:** A plexiform lesion (*arrow*) associated with a muscular pulmonary artery. Note the absence of elastic laminae in the wall of the artery where the plexiform lesion arises. ×110. **G:** Pulmonary vein, approximately 100 µm in diameter, from a patient with primary pulmonary hypertension showing a thickened intimal and adventitial layer. ×210. **H:** Control vein, approximately 100 µm in diameter. ×210. Sections were stained with Verhoeff’s elastin stain followed by van Gieson’s stain. (Reproduced from Chazova I, Loyd JE, Zhdanov VS, et al. Pulmonary artery adventitial changes and venous involvement in primary pulmonary hypertension. *Am J Pathol* 1995;146:389–397, with permission.)

In the venous form of unexplained pulmonary hypertension (299), the clinical presentation differs somewhat from the arterial in that orthopnea is a characteristic feature and changes suggesting pulmonary edema are apparent on the chest radiograph despite a normal pulmonary wedge pressure. Structural abnormalities in the lung are most striking in both large and small veins and consist of loose fibrous intimal hyperplasia with dilated lymphatics. There are secondary changes in the arteries of mild medial hypertrophy and intimal hyperplasia. There is evidence that pulmonary venous occlusive disease might also occur *in utero* (299).

Studies of the National Registry of Primary Pulmonary Hypertension (300) showed some relationship between advanced disease and outcome. An intimal area of 18% had an 85% predictive value for patients who did poorly during the first 3 years of follow-up. Some studies (301) suggest that the acute response to vasodilators may have some predictive value in assessing the long-term response, but this is not a uniform finding (302). Intravenous prostacyclin has been given, even without evidence of a favorable acute hemodynamic effect (303,304). In many patients, stabilization of their clinical condition has allowed time for lung transplantation. In other patients, particularly in children, the beneficial effects have so improved their clinical condition and hemodynamics that they have been removed from the transplant list (*e*Fig. 107.0.15), and some patients have been successfully weaned from this therapy onto calcium channel blockers (unpublished).



***e*FIGURE 107.0.15 A:** Prolonged vasodilator therapy improved long-term survival in children with primary pulmonary hypertension (n = 16) compared with historical controls (n = 35) who never received vasodilator treatment (5-year survival 55 vs. 9%, respectively; *p* <.005). Long-term survival was further increased in the children

diagnosed early in life. Five-year survival for the younger children was 88% compared with 25% for patients diagnosed at 6 years of age or older (p <.02). **B:** Improved long-term survival in children with primary pulmonary hypertension who had a positive response to acute prostacyclin (PGI_2) testing. Five-year survival for children with a positive response to acute prostacyclin testing was 86% compared with 33% for patients who did not respond favorably to such testing (p = .06). (Reproduced from Barst RJ. Primary pulmonary hypertension in children. In: Rubin LJ, Rich S, eds. *Primary pulmonary hypertension*. New York: Marcel Dekker, 1997:179–225, with permission.)

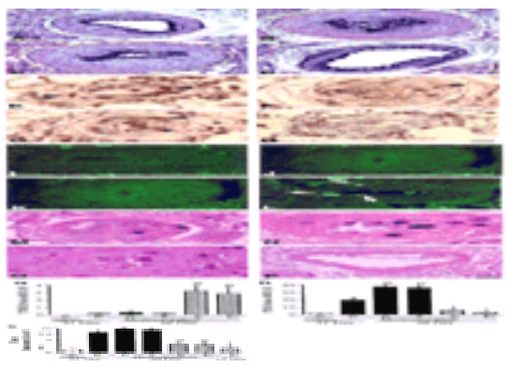
The use of chronic aerosolized or oral prostaglandin agents may, of course, prove more convenient than the constant intravenous infusion but may also be less efficacious (305). In addition to its vasodilating properties (306), the lack of expression of NO synthase (307) coupled with increased expression of endothelin (308) in the vessels of patients with unexplained pulmonary hypertension suggests that treatment with NO, L-arginine, phosphodiesterase inhibitors such as sildenafil (309), or endothelin receptor blockers (310) may be beneficial. Because inflammatory mediators are elevated (311), it could be suggested that cytokine blockade may also be beneficial. Although a variety of treatments have been tried (see reference 312), the calcium channel blocker diltiazem and oxygen therapy remain mainstays of initial therapy. Studies aimed at the identification of coagulation disturbances (313) also have suggested that anticoagulants could be of benefit, and clinical trials indicate that this treatment may rarely induce regression of disease.

Review of the literature reveals that approximately one-third of patients with unexplained pulmonary hypertension will show a decrease in pulmonary artery pressure or resistance with vasodilators. In approximately a third of those, the response will be sustained, however temporarily, although the data are more encouraging in the pediatric population. Whereas blade septostomy has been used in isolated cases (314), most patients will ultimately require a lung transplant (315,316,317 and 318). Our approaches to the diagnosis of pulmonary hypertension might be feasible because pulmonary artery pressure is elevated in carriers of the primary pulmonary hypertension gene (319). Studies addressing endothelial cell phenotype on biopsy tissue (320) or altered potassium channel function in isolated smooth muscle cells might prove useful (321), as might detection of antifibrillin 1 antibodies (322). Experimental studies indicate that exposure to dexamethasone in neonatal rats correlated with lung hypoplasia and increased pulmonary hypertension in adults (323). The studies using long-term prostacyclin suggest that this agent may have direct effects in suppressing smooth muscle cell proliferation (324), and studies suggest that interfering with smooth muscle cell contractility may provide new therapeutic possibilities (325). Particularly promising are experimental studies with elastase inhibitors to be described, which have shown reversibility of advanced disease in rats (326).

Experimental Models

Rats that ingest the toxin monocrotaline develop pulmonary arterial changes that can be correlated with hemodynamic evidence of progressive pulmonary hypertension and increased pulmonary vascular resistance (327,328,329,330,331 and 332). Initially, there is an increase in cardiac output associated with extension of muscle into peripheral arteries that are normally nonmuscular. After a few weeks, when there is an increase in pulmonary artery pressure, medial hypertrophy of normally muscular arteries is apparent. After 3 weeks, when an increase in pulmonary vascular resistance occurs secondary to both a further rise in pulmonary artery pressure and a drop in cardiac output, there is a reduction in the number of peripheral pulmonary arteries, and “ghost,” or disappearing, vessels can be seen. Ultrastructural studies have shown injury to the vascular endothelium within several hours of monocrotaline injection; inflammatory cells and edema are apparent after 1 week. Studies carried out in our laboratory comparing the response to monocrotaline in neonatal, infant, and adult rats suggested that, in the neonate, transient inflammation causes a severe decrease in alveolar number. The development of vascular changes is similar in the three groups. In the infant rat, however, the abnormalities regress between 2 and 4 weeks after injection, whereas in the adult animal, they progress (327). Our studies showed that increased elastase activity not only initiated but also contributed to the progression of the vascular changes (330). Similar to pulmonary hypertension secondary to chronic hypoxia, there is an early increase in enzymatic activity only 2 days after injection of the toxin, but there is also a further increase in elastase activity observed with malignant progression of the disease in adult rats.

Furthermore, we demonstrated that elastase inhibitors are effective in reducing the pulmonary hypertension and vascular changes (330) in association with decreasing the elastase activity in the pulmonary arteries. Even when infusion of elastase inhibitors is delayed, they are still effective in retarding the progression of the hypertensive process. The pulmonary artery endogenous vascular elastase was localized to the smooth muscle cells of the arterial wall and appeared to be related to the serine proteinase adipsin (331). The mechanism of induction of vascular disease is likely related to the endothelial injury (332), and perhaps parenchymal lung injury as well (333), and is reflected in Na/K adenosine triphosphatase activity (334), metabolism of ornithine decarboxylase (335), and expression of growth factors (336) and interleukin receptors (337). In addition, there is evidence that cytokine blockade may prevent monocrotaline-induced pulmonary vascular changes (337), as might L-arginine (338) or endothelin receptor A–selective and nonselective endothelin A/B receptor antagonists (339). Expression of growth factors, such as (basic) FGF-2, has been implicated in the pathophysiology of monocrotaline-induced pulmonary vascular disease (336), and we have shown that elastase will induce release of (basic) FGF-2 in a mitogenically active form from the extracellular matrix (340). Other strategies to prevent monocrotaline-induced pulmonary hypertension have included inhaled NO (341) as well as cell-based delivery of NO synthase (342). In addition, reduction in monocrotaline-induced pulmonary vascular disease has been achieved with serotonin receptor antagonists (343) as well as with a Chinese herbal medicine called *triptolide* (344), which has been used in inflammatory conditions. As alluded to previously, we have shown that elastase inhibitors will not only retard progression of pulmonary vascular disease but will also induce regression by blocking b_3 integrin–mediated signal transduction and inducing programmed cell death, or apoptosis, of vascular smooth muscle cells (*e*Fig. 107.0.16) (345).



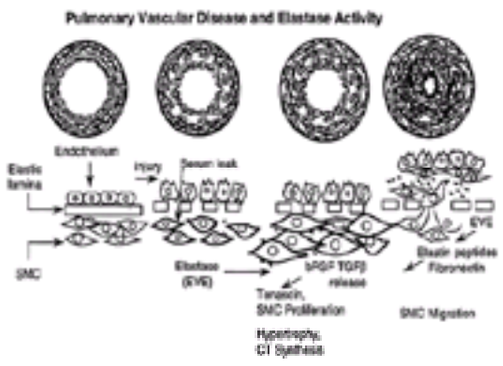
***e*FIGURE 107.0.16** Cellular mechanism responsible for reversal of pulmonary artery muscularity. Elastase inhibition arrests tenascin-C accumulation and proliferation and induces apoptosis and loss of extracellular matrix (such as elastin). **A–P:** Days refer to time after injection of monocrotaline: **A,E,I,M**, day 21; **B,F,J,N**, day 28; **C,G,K,O**, day 28; **D,H,L,P**, day 28. **A–D:** Saline-perfused pulmonary arteries stained with Movat pentachrome stain. **E–H:** Pulmonary arteries after tenascin-C immunohistochemistry. Arrows indicate positive brown peroxidase staining. **I–L:** *In situ* TUNEL assays identifying apoptosis. Arrows indicate TUNEL-positive vascular cells. **M–P:** Proliferating vascular cells, shown by immunohistochemistry for proliferating cell nuclear antigen (PCNA); dark nuclei are PCNA-positive cells. **Q, R:** Percent of smooth muscles cells (SMCs) that are TUNEL-positive **(Q)** or PCNA-positive **(R)**. **S:** Densitometric quantification of elastin. I, inhibitor-treated (I^Z, ZD0892; I^M M249314); TUNEL, *in situ* DNA nick end labeling; u, untreated; v, vehicle-treated. Graphed data represent mean + standard error of the mean of n = 4; scale bars represent 5 µm; *, p <.05, compared with †, p <.05, compared with results on day 21 in rats treated with monocrotaline.

Our studies showed that with progressive pulmonary vascular disease, there is increased expression of the matrix glycoprotein tenascin, where there is also increased cellular proliferation, as judged by expression of proliferating cell nuclear antigen (146). Growth factors such as FGF-2 (released by elastases) can stimulate the production of tenascin, and elastin peptides released by elastase can induce fibronectin synthesis (346,347). Based on our previous studies, increased fibronectin in the subendothelium appears to form a favorable environment for smooth muscle cell migration, and increased tenascin has been shown in our pulmonary artery smooth muscle cell culture systems to be a prerequisite for epidermal growth factor–dependent proliferation and to enhance FGF-2–induced proliferation (146). The mechanism involves the clustering of $a_v b_3$ integrins, the subsequent alteration in the actin cytoskeleton, clustering of epidermal growth factor receptors, and their subsequent rapid phosphorylation and nuclear signal on ligation with epidermal growth factor (28).

Other models of chronic inflammation, such as repeated injections of endotoxin (348) and tumor necrosis factor (349), also have been associated with the development of pulmonary vascular changes. Whereas in these models there is at least a transient inflammatory response, in models of chronic air embolization (350) and thoracic irradiation (351) in which pulmonary hypertension and vascular changes are produced, endothelial injury is the common observation, as it is in the monocrotaline model. Increased elastin peptides also are observed in lung lymph early after induction of chronic air embolism, suggesting increased elastolytic activity in this model of pulmonary hypertension (350). Serine leukoproteinase inhibitor proved beneficial in alleviating the pulmonary hypertension (352). Increased expression of TGF-b has been described but not specifically targeted therapeutically to determine its pathophysiologic significance (353,354). It also was shown that repeated injections of indomethacin will induce pulmonary hypertension and structural changes (355).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Based on experimental and clinical observations, we propose the following hypothesis with regard to the pathophysiology of pulmonary hypertension (eFig. 107.0.17). A mechanical stimulus such as the high flow and pressure of a congenital heart defect with a left-to-right shunt, hypoxic vasoconstriction, or a toxin will injure the pulmonary vascular bed, and the first casualty will be the endothelial cell. We propose that endothelial perturbation results in a “serum leak” owing to loss of barrier function. In cell culture studies, we showed that both serum and endothelial factors increase smooth muscle cell elastase activity and that elastase releases biologically active mitogens by degrading extracellular matrix proteoglycans that “store” these growth factors in an inactive form. We showed that serum-induced smooth muscle cell elastase activity releases FGF-2, whereas others have shown that TGF-b also can be released from proteoglycan storage sites by proteolytic enzymes, including elastases. These growth factors will induce smooth muscle cell hypertrophy and proliferation and stimulate connective tissue protein synthesis, leading to hypertrophy of the arterial wall. Breakdown products of elastin and collagen, as well as TGF-b, stimulate neosynthesis of collagen elastin and fibronectin. The increase in elastin and collagen synthesis observed with pulmonary hypertension also may be related directly to the increase in pressure. Continued release of elastase will lead to smooth muscle cell migration by inducing further changes in matrix that signal the smooth muscle cells to produce a new constellation of gene products, including fibronectin, that change their shape and confer on them the properties of motility.



***e*FIGURE 107.0.17** We speculated as to how a stimulus could induce activity of an elastolytic enzyme and how this might stimulate the remodeling process. The process of progressive pulmonary hypertension involves a series of switches in the smooth muscle cell (SMC) phenotype (i.e., differentiation of muscle from nonmuscle precursor cells, SMC hypertrophy and proliferation accounting for medial hypertrophy, and SMC migration resulting in neointimal formation). In response to a stimulus, such as high flow and pressure, the first “casualty” is the endothelial cell. As a result of structural and functional alterations in endothelial cells, some of the barrier function would be lost, allowing a leak into the subendothelium of a serum factor normally excluded from this region. The serum factor could induce activity of an endogenous vascular elastase (EVE). This enzyme released from precursor or mature SMCs would activate growth factors normally stored in the extracellular matrix in an inactive form, such as basic fibroblast growth factor (bFGF) and transforming growth factor-b (TGF-b), which are known to induce smooth muscle hypertrophy and proliferation and increases in connective tissue (CT) protein (e.g., collagen and elastin) synthesis. bFGF also induces tenascin, a matrix glycoprotein that amplifies the proliferative response as described in the text. This also results in the differentiation of precursor cells to mature smooth muscle related to the muscularization of normally nonmuscular small peripheral arteries. In the muscular arteries, the release of growth factors would also result in hypertrophy of the vessel wall. Continued elastase activity would cause migration of SMCs in several ways. The elastin peptides or degradation products of elastin can stimulate fibronectin, a glycoprotein that is pivotal in altering smooth muscle cell shape and in switching them from the contractile to motile phenotype. [Reproduced from Rabinovitch M. It all begins with EVE (endogenous vascular elastase). *Isr J Med Sci* 1996;32:803–808, with permission.]

The mechanism of induction of elastase by serum factors involves engagement of integrins, binding of elastin to smooth muscle cell surfaces, tyrosine kinase activity, and phosphorylation of focal adhesion kinase and extracellular-related kinase 1 and extracellular-related kinase 2 of the mitogen-activated protein kinase family, culminating in transactivation of the transcription factor for elastase, AML-1 (338).

THE FUTURE

We are making progress in understanding critical gene products involved in the development of the pulmonary vasculature and in the initiation of abnormalities as a result of injurious stimuli. Many more gene products remain to be discovered that are likely also to be key players in the mechanisms causing pulmonary vascular disease. With advanced microsequencing capability, more sophisticated understanding, and application of candidate gene approaches, we will determine the predisposing profile of the patient who develops pulmonary vascular disease or in whom the course is rapidly progressive. The future is aimed not only at retarding progression but also at preventing the development of vascular disease and inducing regression of advanced structural abnormalities. We have made important inroads in this regard with elastase inhibitors and with b_3 integrin blockers, but a continuous armamentarium will be necessary given the varied etiologies and pathogeneses of this condition. The development of highly targeted approaches aimed at introducing genes or gene products in a tissue- and time-specific manner will allow the future development of “biologic interventional cardiology” to address the pulmonary vascular complications and abnormalities associated with congenital and acquired heart disease.

OVERVIEW

Increased awareness of the clinical features of acquired diseases of the thoracic and abdominal aorta and familiarity with currently available diagnostic techniques are basic to their effective treatment. Acute dissection of the thoracic aorta, one of the most common fatal aortic conditions that is encountered clinically, is commonly misdiagnosed and has a markedly increased mortality during the first 48 hours after the onset of symptoms. Aortic dissection should always be included in the differential diagnosis of a patient with unexplained syncope, stroke, congestive heart failure, acute arterial occlusion, or an abnormal aortic contour on chest radiography, even in the absence of chest pain. In suspected acute aortic dissection, institution of beta-adrenergic blockade followed by rapid diagnosis with transesophageal echocardiography (TEE) is indicated. If ascending aortic dissection is present, emergent surgical therapy is indicated. Indications for surgical resection of a thoracic aortic aneurysm include symptomatic aneurysm and an aneurysm diameter of 6 cm or greater (>5.0 cm in diameter in patients with Marfan syndrome). Unless there are contraindications, elective surgical resection of thoracic aortic aneurysm that results from trauma, even when asymptomatic, is indicated because of the unpredictability of these aneurysms and the low risk of elective surgical repair. Surgical repair of an abdominal aortic aneurysm (AAA) is indicated when aneurysm diameter reaches 5 cm. In good-risk patients, selective repair of an AAA is indicated when the diameter reaches 4.5 cm. Surgical resection is the treatment of choice in patients with an inflammatory AAA, regardless of diameter. All patients with Marfan syndrome should be placed on a beta-adrenergic blocking agent if no contraindications exist. When an uncommon type of aortic disease is suspected (i.e., Takayasu's disease or giant-cell aortitis), invasive diagnosis should be pursued (angiography and/or arterial biopsy).

INTRODUCTION

Acquired diseases of the thoracic and abdominal aorta are encountered frequently in cardiologic practice. Their clinical presentation is highly variable, ranging from occult disease to classic clinical presentations. Numerous etiologic factors, acting singly and in combination, have been identified (Table 108.1). Diagnosis is possible by noninvasive means in most patients, but some types of aortic diseases require a high index of suspicion and invasive angiographic study or arterial biopsy. Awareness of the clinical features of acquired diseases of the thoracic and abdominal aorta and familiarity with currently available diagnostic techniques are basic to their effective treatment.

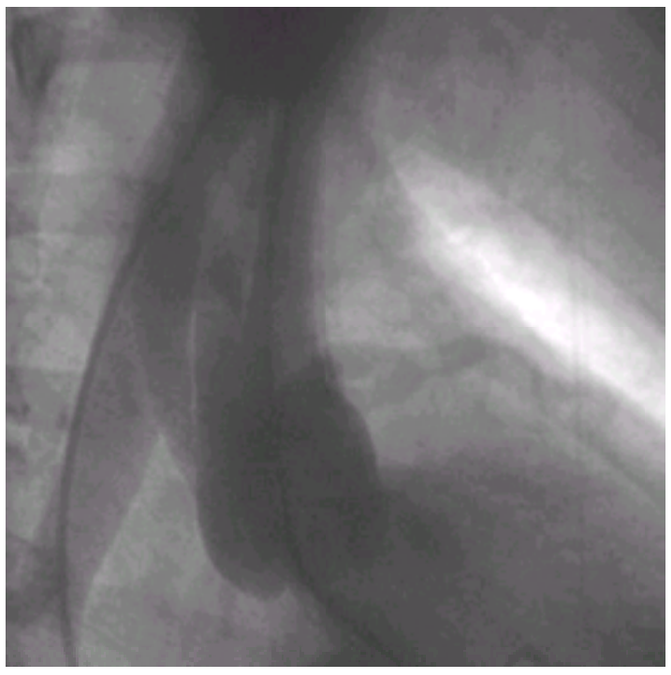
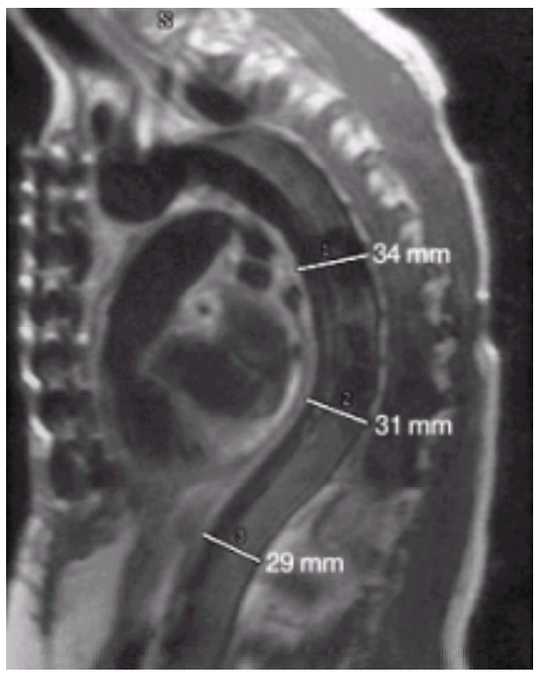
AORTIC DISSECTION

Acute dissection of the thoracic aorta is one of the most common catastrophic aortic conditions that is encountered in clinical practice. Its incidence has been reported to be approximately 2.9 in 100,000 per year (1). The variable manifestations of aortic dissection, in combination with a mortality in untreated cases of as high as 1% per hour during the first 48 hours after the onset of symptoms, underscore the importance of a high index of suspicion and prompt diagnosis and therapy (2,3 and 4). Noninvasive testing [TEE, computed tomography (CT), or magnetic resonance imaging (MRI)] allows an accurate diagnosis to be made in the majority of patients (5). Effective treatment exists, so that future improvements in initial and long-term survival in acute aortic dissection depend on increased clinical awareness, rapid noninvasive diagnosis, and the early institution of appropriate medical or surgical therapy, or both.



A 77-year-old male patient presented to the emergency department with severe chest pain and hypertension. Aortogram revealed type A aortic dissection.

Ascending aortic dissection extending into the left main. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)



Magnetic resonance scan of the thoracic aorta in Marfan syndrome. There is dilation of the descending aorta with an average diameter of approximately 3 cm.

Pathogenesis

Aortic dissection originates at the site of an intimal tear in more than 95% of patients (2,6). Whether the intimal tear or rupture of the vasa vasorum with secondary intramural hematoma producing the intimal tear is the initial event is controversial. Nevertheless, the resultant intimal tear exposes the media to pulsatile aortic flow, creating a second or “false” aortic lumen that then dissects in the outer layer of aortic media, propagating distally and, occasionally, proximally. One feature differentiating proximal and distal aortic dissection is the greater frequency of hypertension in patients with distal dissection, a possible factor in pathogenesis (7).

The primary intimal tear is located, in decreasing order of frequency, in the ascending aorta 1 to 5 cm above the right or left Valsalva’s sinus (65%), in the proximal descending thoracic aorta just beyond the left subclavian artery origin (20%), in the transverse aortic arch (10%), and more distally in the thoracic aorta or abdominal aorta (5%) (2,6). Once initiated, the dissection usually extends distally and, occasionally, proximally for a variable distance. As the dissecting process encounters branches of the aorta, it may pass around their origins, extend into their walls, or occlude them (2,6). Reentry of the dissection through a second, more distal intimal tear may occur, usually in one of the iliac arteries. External rupture of the dissecting process into the pericardial space is the most common cause of death in aortic dissection; congestive heart failure, usually due to aortic regurgitation, is the second most common cause of death.

Predisposing Factors

Multiple risk factors for aortic dissection have been identified, the most common being advanced age, systemic hypertension, congenital abnormalities of the aortic valve, and heritable disorders of connective tissue. Aortic dissection most frequently affects patients in the fifth to seventh decades of life and is more common in men (male-female ratio, 3:1). In patients younger than 40 years, the incidence between men and women is equal due to the occurrence of aortic dissection in women during pregnancy, with approximately 50% of all aortic dissections occurring during the third trimester of pregnancy (8).

Systemic hypertension is the most frequently encountered predisposing factor for aortic dissection, being present in more than 75% of patients (2,3,9,10 and 11). Hypertension may play a role in initiating the intramural hematoma, as well as having a direct weakening effect on the aortic media (6,11). The causative role of systemic hypertension is further supported by the finding that coarctation of the aorta predisposes to aortic dissection (12). Other major risk factors for aortic dissection, especially proximal aortic dissection, are congenitally bicuspid or unicommissural aortic valves (9,11) and the congenital disorders of connective tissue such as Marfan syndrome (13) and Ehlers-Danlos syndrome.

VIDEO

Video 108.1 Coarctation of aorta (oblique). A signal-void jet is visible in the proximal descending aorta due to a short-segment narrowing representing a coarctation. Left ventricular hypertrophy is also present. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

HEART SOUNDS

Audio 108.2 Coarctation of the aorta. Auscultation performed in a 54-year-old female patient with coarctation of the aorta, status post Dacron graft replacement of the proximal descending aorta and persistent severe graft stenosis. The mid-systolic ejection murmur is a result of residual high-grade coarctation. Left upper sternal border. (The heart sounds were digitally acquired courtesy of equipment from Welch Allyn/Meditron and Cardionics Inc.) *This video must be viewed with QuickTime. VIDEO

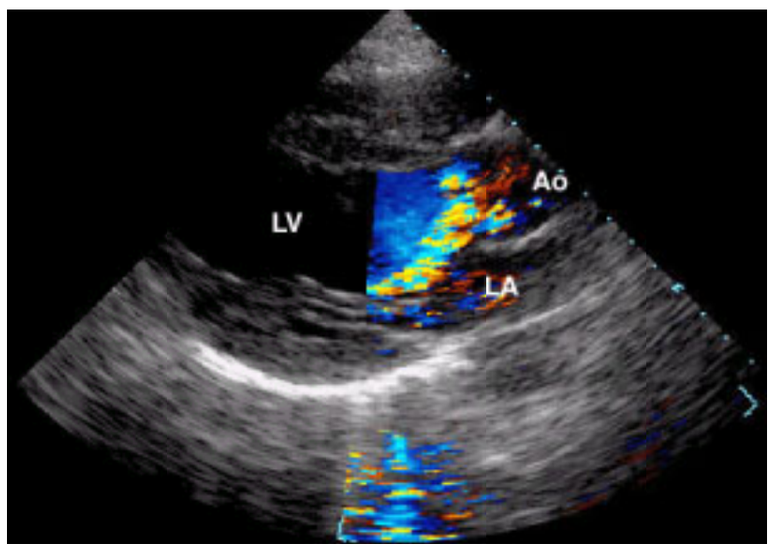
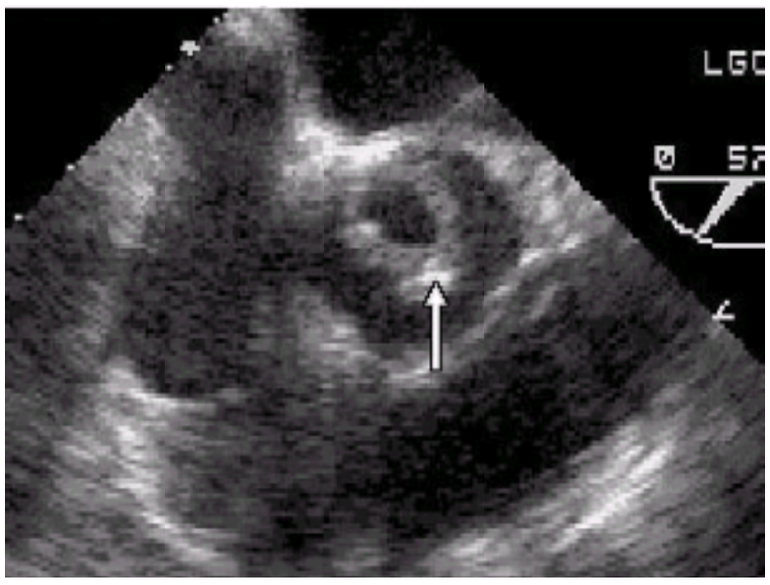
Video 108.6 A 49-year-old male patient with bicuspid aortic valve and severe aortic regurgitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Parasternal long-axis view (transthoracic echo) with color Doppler demonstrating the posteriorly directed aortic insufficiency caused by prolapse of the

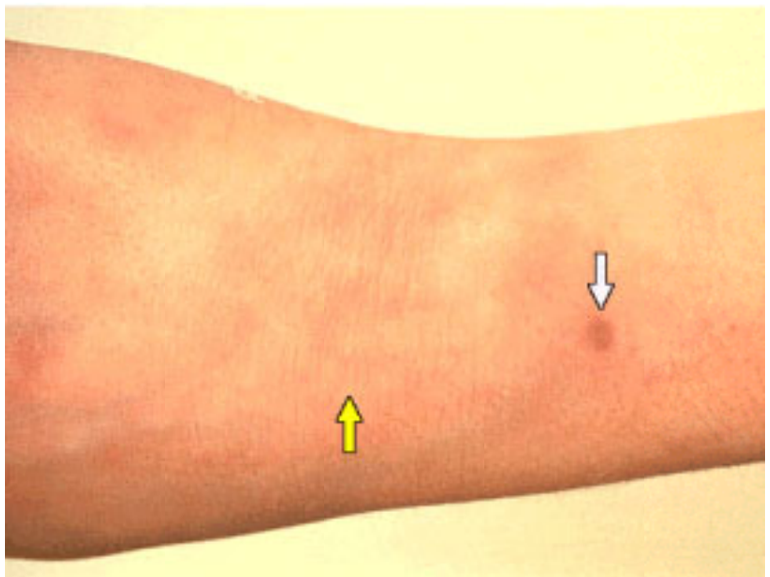
anterior leaflet of a bicuspid aortic valve. Note that the jet hits the anterior mitral leaflet.



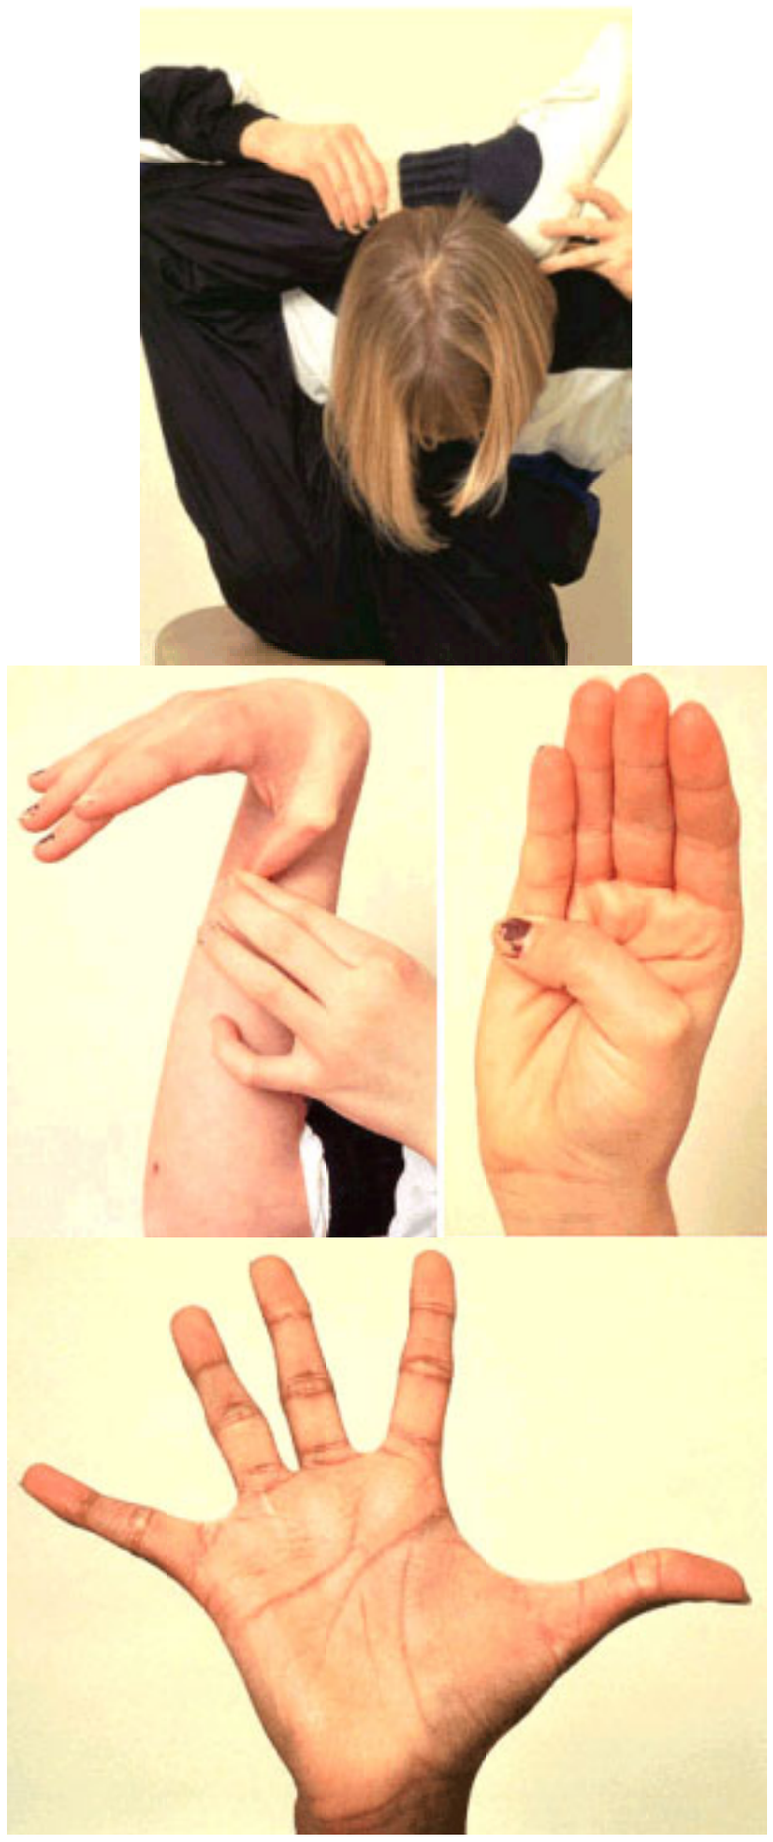
Short axis transesophageal view of a unicuspid aortic valve with aortic stenosis. The arrow designates the single commissure present in this aortic valve. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.)

Ectopia lentis. This lens dislocation is associated with Marfan syndrome.

Arachnodactylia in Marfan syndrome. The ratio of finger length to hand size is markedly increased.



Skin changes of Ehlers-Danlos syndrome. There is thin, velvety appearance of the skin (*yellow arrow*), as well as easy bruisability (*white arrow*).



Ehlers-Danlos syndrome. There is severe joint laxity and hypermobility that may produce joint dislocations (A–C).

Iatrogenic aortic dissection is an uncommon but potentially serious complication of invasive angiographic procedures and cardiac surgery. Angiographic procedures such as coronary angiography, percutaneous transluminal coronary angioplasty, intraaortic balloon insertion, and translumbar aortography have been complicated by aortic dissection (11,14,15,16). Catheter-induced dissection can originate at any location, and it is most common in Valsalva's sinus, brachiocephalic arteries, the descending thoracic aorta, the abdominal aorta, and iliac or femoral arteries. The majority of catheter-induced dissections is retrograde and tends to decrease in size over time as a result of thrombosis of the false lumen, whereas anterograde dissections tend to persist on follow-up. Nearly all iatrogenic aortic dissection can be treated medically, with serial clinical examinations and noninvasive testing used to identify those who are in need of surgical therapy (15).

Cardiac surgical procedures complicated by aortic dissection include those that require cross-clamp or cannulation of the ascending aorta, such as aortic valve replacement (11,17,18) or coronary artery bypass grafting (11,19), or both. Dissection can arise at the site of ascending aortic cannulation, aortosaphenous vein anastomosis, or aortic cross-clamp or as a result of direct arterial injury. Dissection in association with these procedures usually occurs intraoperatively and is promptly diagnosed and treated, but chronic dissection in the postoperative period has been reported (18). Aortic dissection has also been found in association with giant-cell aortitis (11,20), systemic lupus erythematosus (21), Noonan's syndrome (22), Turner's syndrome (23), fibromuscular dysplasia (10), annuloaortic ectasia (10), cocaine use (24,25), methamphetamine use, polycystic kidney disease (26), polyarteritis nodosa (27), and trauma (28).

Video 108.8 Coronary ectasia. These angiograms were obtained in a 40-year-old patient with Noonan's syndrome and no coronary risk factors. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Classification

The most widely used classification system for acute aortic dissection is that of DeBakey and associates (29), which recognizes three types of dissections (Fig. 108.1). Type I dissection arises in the ascending aorta and extends distally, type II dissection is limited to the ascending aorta, and type III dissection arises at or just distal to the origin of the left subclavian artery and extends distally or, rarely, retrogradely into the arch of the ascending aorta.

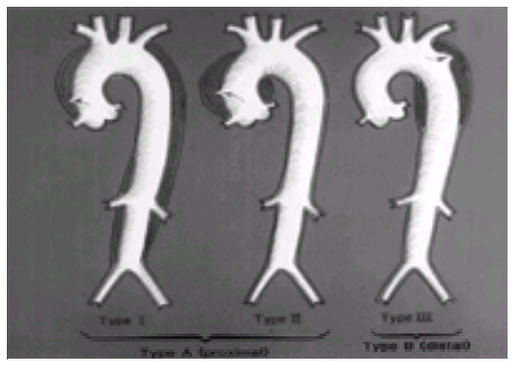


FIGURE 108.1 Classification of aortic dissection. Type I: primary tear in ascending aorta and dissection involving aortic arch and distal aorta for a variable distance. Type II: dissection involving only ascending aorta. Type III: primary tear distal to subclavian artery origin, extending distally for a variable distance. (Modified from DeBakey ME, Henly WS, Cooley DA, et al. Surgical management of dissecting aneurysms of the aorta. *J Thorac Cardiovasc Surg* 1965;49:130–149.)

For clinical purposes, because types I and II have a similar prognosis, aortic dissection can be broadly divided into those with the tear in the ascending aorta and those with the tear in the descending aorta, also called *proximal* and *distal*, respectively (30). A similar classification system, proposed by Daily and associates (31), designates all dissections that involve the ascending aorta as type A, regardless of the site of the primary intimal tear. All other dissections are designated type B.

VIDEO

Video 108.9 Aortic dissection (left anterior oblique). Type A dissection of the aorta is manifested on the cine image loop by a mobile intimal flap extending from the mid-ascending aorta to the descending thoracic aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 108.10 Aortic dissection (left anterior oblique). Type B dissection of the aorta extending distally from the isthmus, just after the left subclavian artery, to the abdominal aorta. A communication between the true and false lumen is seen in the proximal portion of the descending aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

An important aspect of classification is the duration of the dissection at the time of first presentation. Dissections are categorized as “acute” if the presentation occurs within 2 weeks of onset and as “chronic” if more than 2 weeks have elapsed. The distinction is important due to the fact that approximately 65% to 75% of patients with untreated aortic dissection die in the first 2 weeks after the onset of symptoms (2).

Clinical Features

Due to variable involvement of the aorta and its branches by the dissecting process, the patient with acute aortic dissection may have clinical manifestations of ischemia of various organ systems, singly or in combination, as well as symptoms and signs of cardiac disease. The diverse presentations of aortic dissection can provide for difficult diagnosis, and misdiagnosis commonly occurs (2,11). Despite major advances in the noninvasive diagnosis of aortic dissection and in medical and surgical therapy, up to 55% of patients in reported series die without a correct antemortem diagnosis (1,2,11,32,33). Therefore, a high index of clinical suspicion in any likely setting is imperative.

The classic presentation of a patient with acute aortic dissection, occurring in up to 94% of patients, is the sudden onset of severe pain, usually beginning in the anterior chest, radiating to the back, and moving distally as the dissection progresses (1,30). The pain is most commonly described as sudden in onset with a “ripping,” “tearing,” or “stabbing” quality; this is in contrast to the crescendo nature of the discomfort of acute myocardial infarction. Patients with acute aortic dissection often appear to be in shock, although blood pressure is elevated in one-half to two-thirds of cases, especially those with distal dissection. Hypotension in aortic dissection is usually attributable to rupture of the dissection into the pericardial space or, less commonly, the pleural space or mediastinum and is more common with proximal dissection.

Although definitive diagnosis requires further noninvasive testing (see Diagnosis), the location of initial pain can help predict the site of the intimal tear (11,30,33) (*e*Table 108.1.1). It should be remembered, however, that painless dissection occurs in 14% to 21% of patients (2,11).

***e*TABLE 108.1.1** CLINICAL CLUES TO PROXIMAL VERSUS DISTAL AORTIC DISSECTION

Proximal	Distal
Initial pain in the anterior chest	Interscapular pain
Aortic diastolic murmur	Hypertension
Pericardial friction rub	Left pleural effusion
Decreased or absent blood pressure or pulses in right arm	
Decreased right carotid artery pulsation	
Evidence of myocardial ischemia or infarction on electrocardiogram	
Marfan syndrome	
Congenital abnormality of the aortic valve	

A cardiac murmur may be present, usually at the cardiac base, and may be systolic, diastolic, or both. A diastolic murmur of aortic regurgitation indicates involvement of the ascending aorta and is heard in up to 50% of patients with type I aortic dissection. Congestive heart failure, when present in association with proximal aortic dissection, is most often due to severe aortic regurgitation (9,30), but cases of congestive heart failure due to rupture of the dissecting process into the right or left atrium or right ventricle have also been reported (34,35 and 36). Myocardial infarction occurs in 1% to 2% of patients and is due to compromise of the coronary ostium by the hematoma or intimal flap. Peripheral pulse deficits are noted in approximately 40% of patients (3,30), more commonly with proximal aortic dissection. Pulse deficits may be transitory due to oscillation of the intimal flap or distal reentry of the hematoma into the true lumen. Acute lower-extremity ischemia, with or without chest pain, as a result of dissection extending into the iliac arteries occurs in 6% to 12% of patients (3,37,38) and may provide an important clue to the diagnosis (37). Other cardiovascular findings include a difference in blood pressure between the arms, tachycardia, friction rubs, bruits, pulsus paradoxus, and cardiac tamponade.

HEART SOUNDS

Apical continuous-wave Doppler spectrum of aortic valve disease. Note high forward velocities in systole (V_{max} 4.5 m/sec) and early peak of aortic stenosis. At the bottom, wrapped-around diastolic flow velocities from aortic regurgitation are seen.

Syncope in a patient with aortic dissection is an important event, as it usually results from rupture of the dissecting process into the pericardial space producing cardiac tamponade (11,30). Less commonly, rupture occurs into the left pleural space producing left hemothorax (11). Neurologic deficits, including cerebrovascular accident, disturbances of consciousness, ischemic paraparesis, and ischemic peripheral neuropathy, occur in more than 40% of patients, more commonly with proximal aortic dissection (1,39). Other, less-frequent findings include Horner's syndrome, a pulsatile sternoclavicular joint (40), vocal cord paralysis, hemoptysis (41), superior vena cava syndrome (42), upper airway obstruction (43), hematemesis (44), pleural effusion, unilateral pulmonary edema (45), signs of mesenteric or renal infarction, fever (46), and deep venous thrombosis (11).

Pericardial tamponade. Low QRS voltage and electrical alternans are characteristic findings of tamponade.

VIDEO

Video 108.15 Apical four-chamber view demonstrating a large pericardial effusion causing tamponade. Note the inability of the right side to fill. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

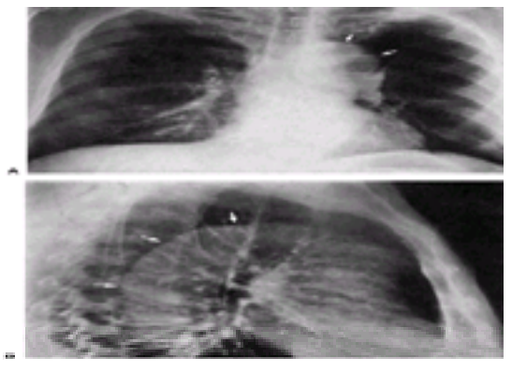
As a general rule, aortic dissection should always be considered in the differential diagnosis of a patient with unexplained syncope, stroke, congestive heart failure, acute arterial occlusion, or an abnormal aortic contour on chest radiography, even in the absence of chest pain.

Diagnosis

Routine laboratory studies are nonspecific in acute aortic dissection. A mild to moderate leukocytosis occurs in two-thirds of patients, and anemia may occur as a result of leakage of the dissection or from sequestration of blood in the false lumen. Serum lactate dehydrogenase and bilirubin levels are sometimes increased because of blood sequestered within the false lumen, but serum glutamic oxaloacetic transaminase and creatine phosphokinase are usually normal (30). Hematologic studies consistent with disseminated intravascular coagulation can also occur.

The most common electrocardiographic abnormality in patients with aortic dissection is left ventricular hypertrophy from chronic systemic hypertension (3). Acute electrocardiographic changes occur in up to 55% of patients and include ST-segment depression, T-wave changes, and ST-segment elevation, in decreasing order of frequency (47). Acute ischemic changes can occur when one or more coronary ostia becomes obstructed, either by the intimal flap or from external compression by the dissecting hematoma. The electrocardiographic changes of acute pericarditis can be seen if there has been leakage of blood into the pericardial space. Heart block resulting from proximal extension of the hematoma into the area of the atrioventricular node has also been reported (48). The chief value of the electrocardiogram is in distinguishing aortic dissection from acute myocardial infarction, especially with the current widespread use of early intravenous (i.v.) thrombolytic therapy for the latter disorder.

Chest radiography is helpful in suggesting the diagnosis of aortic dissection in more than 85% of patients, with abnormalities of the aortic silhouette being the most common finding (49,50). Additional findings include pleural effusion, mediastinal widening, displacement of intimal calcification greater than 6 mm inside the outer edge of the aortic shadow, and the radiographic findings of congestive heart failure (*e*Fig. 108.1.1). Nonetheless, it is important to remember that normal chest radiographic findings do not exclude the diagnosis of aortic dissection.



***e*FIGURE 108.1.1** Chest radiograph in a patient with type III (distal) aortic dissection. **A:** Posteroanterior view demonstrates a dilated transverse aortic arch and descending thoracic aorta (*arrows*). **B:** Lateral view demonstrates dilation of the thoracic aorta (*arrows*).

Currently available noninvasive imaging modalities that are accurate in the diagnosis of acute aortic dissection include echocardiography [combined transthoracic echocardiography (TTE) and TEE], CT, and MRI. The choice of test depends on which imaging modality is most readily available at a particular institution and the hemodynamic stability of the patient.

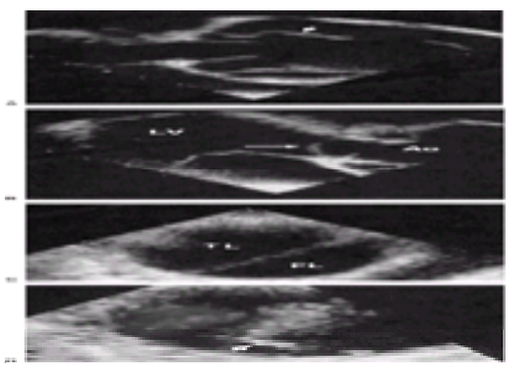
Video 108.16 Intraoperative transesophageal echo with color Doppler of an ascending aortic dissection. Note the mobile flap with the color flow separation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 108.17 Short-axis transesophageal echo view of a type I aortic dissection. Note the flap originating within the noncoronary cusp (leaflet upper left screen) and extending towards the ostium of the left main trunk. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 108.18 Intraoperative 120-degree transesophageal echo of an ascending aortic dissection. Note the large, complex flap in the ascending aorta seen originating near the origin of the right coronary artery. There is a small amount of aortic insufficiency. Flow is seen in the true lumen (*left*) whereas no flow is seen in the false lumen (*right*). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

TTE can be very useful in some patients with suspected aortic dissection. When the findings of a dilated aortic root (end diastolic diameter >42 mm), widening of the aortic walls (16–20 mm for the anterior wall and 10–13 mm for the posterior wall), and a linear undulating echo representing the intimal flap are present, the positive predictive value for TTE is 100% (51,52 and 53). Advantages of TTE are its portability; rapid “online” diagnosis; ability to identify associated aortic regurgitation and other valvular disease; and ability to assess left ventricular function, regional wall motion abnormalities, pericardial effusion, and cardiac tamponade. The diagnosis of cardiac tamponade in a patient who is suspected of having aortic dissection deserves special mention. Echocardiographically guided pericardiocentesis should be avoided in this setting because the rapid withdrawal of pericardial fluid can result in a prompt improvement in left ventricular systolic function, change in left ventricular pressure over time (dP/dT), and systolic blood pressure, producing aortic rupture (54). The patient with aortic dissection complicated by cardiac tamponade should be taken emergently to surgery for institution of cardiopulmonary bypass followed by evacuation of blood from the pericardial space. Disadvantages of TTE include difficulty in adequately visualizing the descending thoracic aorta (5) in patients with suboptimal echocardiographic “windows” due to obesity or chronic obstructive pulmonary disease.

TEE (biplane or multiplane), in combination with TTE, has a sensitivity of 99% and a specificity of 98% in the diagnosis of aortic dissection (55) and is currently the initial diagnostic test of choice in suspected acute aortic dissection. TEE is rapid, portable, and minimally invasive and can accurately determine the type and extent of dissection safely in an emergent setting, allowing effective triage of patients to either surgical or medical therapy (56,57). Color-flow Doppler imaging significantly improves the sensitivity of TEE by allowing visualization of the dissection entry site, the true and false lumina, the presence of thrombus, and associated aortic regurgitation (57) (*e*Fig. 108.1.2). The overall sensitivity of TEE is comparable with that of CT (58), MRI (5,59,60), and aortography (61) in the diagnosis of aortic dissection. Current multiplane TEE probes have largely overcome impediments in the ascending aorta that are present with monoplane and biplane transducers, although artifacts in this region continue to be a diagnostic challenge.

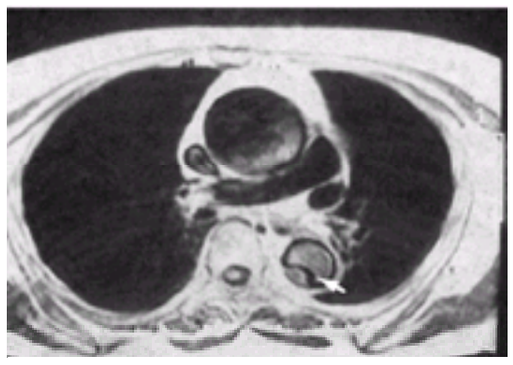


***e*FIGURE 108.1.2** Transesophageal echocardiogram in a patient with type I (proximal) aortic dissection. **A:** Longitudinal view of the ascending aorta (Ao) demonstrates

an intimal flap (*arrow*) originating in the right coronary sinus. **B:** Intimal flap prolapses through the aortic valve during diastole (*arrow*). **C:** Transverse views of the descending thoracic aorta demonstrate an intimal flap. **D:** A communication point (*arrow*) in the mid-descending thoracic aorta is readily identified with color-flow Doppler imaging. FL, false lumen; LV, left ventricle; TL, true lumen.

CT with i.v. contrast enhancement is also an accurate noninvasive screening test in patients with suspected aortic dissection (62). CT can reliably demonstrate the intimal flap, pericardial and pleural effusion, associated mediastinal hemorrhage, and involvement of the abdominal aorta; however, it often fails to demonstrate the site of entry or reentry, associated aortic regurgitation, or involvement of branches of the aorta (5). Additional disadvantages of CT include the need for contrast exposure and nonportability, limiting its use in patients with significant renal insufficiency and in hemodynamically unstable patients, respectively.

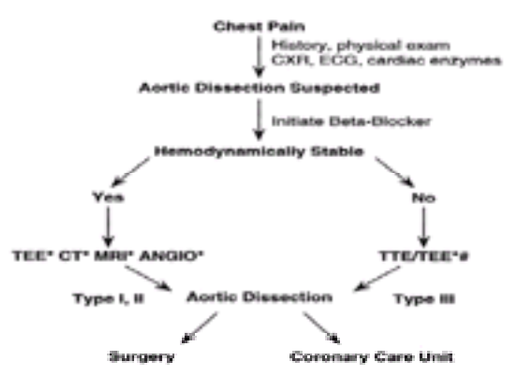
MRI is an excellent noninvasive method for diagnosing aortic dissection (63) (eFig. 108.1.3). It is superior to TEE and CT in detecting arch vessel involvement and in identifying the anastomosis in patients who are managed with surgical therapy, and it may facilitate comparison of serial studies (5,59,64). Gated spin-echo MRI accurately demonstrates the entry site and intimal flap (65) and may be the optimal method for demonstrating thrombus formation and entry site location within all segments of the aorta (66). The ability to obtain oblique and longitudinal planes of section makes MRI especially valuable in demonstrating dissection without intimal tear (5,60,67). Disadvantages of MRI include cost, examination time, reduced availability, and standard contraindications to MRI. The most important limitation of MRI in acute aortic dissection is its nonportability, limiting its use in hemodynamically unstable patients.



***e*FIGURE 108.1.3** Magnetic resonance images demonstrate type III (distal) aortic dissection. An intimal flap is present in the descending thoracic aorta (*arrow*). An ascending aortic aneurysm is also identified.

Aortography, the traditional definitive diagnostic method in aortic dissection, is able to localize the site of origin of the dissection and delineate the extent of the dissection, as well as the circulation to vital organs. Diagnostic aortographic features include opacification of the false lumen, deformity of the true lumen by the false lumen, widening of the aorta, narrowing or occlusion of branches of the aorta, and the presence of an intimal flap (68). Disadvantages of aortography include nonportability, invasive technique, exposure to ionizing radiation, the use of i.v. contrast agents, and an inherent delay in diagnosis. False-negative aortogram results can occur if there is simultaneous and equal opacification of the true and false lumina or if the false channel is very faintly opacified (69). Intravascular ultrasound, in combination with standard aortographic technique, greatly improves the accuracy of aortography, can be performed rapidly and safely, and could serve as an accessory diagnostic procedure in selected patients with suspected aortic dissection (70,71).

In view of the increased early mortality of untreated acute aortic dissection, the screening test chosen depends on which test is most readily available at a particular institution and the patient's hemodynamic status (eFig. 108.1.4). Noninvasive diagnosis of acute dissection by TEE, MRI, or CT, if readily available, is preferred, as it avoids the risks and delays that are inherent in invasive angiography (72).



***e*FIGURE 108.1.4** Initial management of suspected acute aortic dissection. ANGIO, aortography; CT, computed tomography; CXR, chest x-ray; ECG, electrocardiogram; MRI, magnetic resonance imaging; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography; #, aortogram or computed tomography if transesophageal echocardiography is not available, or rapid transfer to a tertiary facility.

Management

The initial treatment objectives in suspected aortic dissection are to control pain, reduce systemic blood pressure, and lower dP/dT to the lowest level that is compatible with maintenance of adequate visceral, renal, and cerebral perfusion (73). In hypertensive patients, treatment consists of an i.v. beta-adrenergic blocking agent, most commonly propranolol, in combination with i.v. sodium nitroprusside (eTable 108.1.2). Alternatives to propranolol include i.v. esmolol, metoprolol, or atenolol. Beta-blockade before nitroprusside therapy is essential because the latter increases the velocity of left ventricular ejection and promotes propagation of the dissection (74). Intravenous labetalol in place of a beta-blocker and sodium nitroprusside is an alternative, but it has the potential for hepatotoxicity with long-term therapy (75). In normotensive patients, propranolol, metoprolol, atenolol, or esmolol can be used alone. To assist in monitoring blood pressure and renal perfusion, an intraarterial cannula and indwelling bladder catheter are advisable.

***e*TABLE 108.1.2** PHARMACOLOGIC THERAPY OF ACUTE AORTIC DISSECTION

Hypertensive patients

Sodium nitroprusside i.v. (2.5–5.0 mg/kg/min)
with
Propranolol i.v. (1 mg q4–6h)
Goal is systolic blood pressure in the range of 110 mm Hg (or the lowest level to maintain a urine output of 25–30 mL/h) until oral medication is started
or i.v. esmolol, metoprolol, or atenolol (in place of propranolol)
or i.v. labetalol (in place of sodium nitroprusside and a beta-blocker)

Normotensive patients

Propranolol, 1 mg i.v. q4–6h or 20–40 mg orally q6h (metoprolol, atenolol, or labetalol can be used in place of propranolol)

It is generally accepted that patients with type I and II aortic dissection should undergo emergent surgical repair (76,77). Coronary angiography before surgery is not indicated, as it does not improve survival (78). Resection of the ascending aorta and replacement with Dacron represent the usual procedure in type I or type II aortic dissection (76,77). The objectives of surgery include excision of the intimal tear, obliteration of the entrance into the false lumen, repair of aortic regurgitation (if present), and restoration of patency to any major arteries that are occluded by the dissection. With associated aortic regurgitation, resuspension of the valve, if possible, is preferred. Intraoperative TEE can define the severity and mechanisms of aortic regurgitation and can assist the surgeon in identifying patients in whom valve repair is likely to be successful (79). If there is associated annuloaortic ectasia or destruction of the aortic wall, a valved conduit can be used. The coronary

arteries are reimplanted, or if they are involved by the dissection, they are reattached using vein bypass grafts anastomosed proximally to the aortic graft and distally to the uninvolved coronary arteries (77,80,81). If compromise of a branch of the aorta that supplies a vital organ is present and is not relieved by closing the false channel, direct repair or surgical replacement of that branch is indicated. Aortic fenestration may be indicated in patients with severe organ or limb ischemia complicating either acute or chronic aortic dissection. Fenestration, either surgical or percutaneous techniques, can effectively relieve the ischemia and can be performed safely in chronic aortic dissection (82,83). Inhospital mortality is approximately 14%, with patients in cardiogenic shock and those who require concomitant coronary artery bypass grafting being the highest-risk subgroup (84).

Aortic thrombus in a patient with lupus anticoagulant. A probe is placed behind the thrombus within the lumen of the aorta (*yellow arrow*).

With acute type III aortic dissection, surgery is indicated for rupture, acute expansion or impending rupture, or vascular occlusion (85). The best therapy for uncomplicated type III aortic dissection is less well defined (86). Long-term medical therapy focuses on control of blood pressure, using a beta-blocker if possible and periodic evaluation for evidence of any progression of dissection, patency of the false lumen, progression of aortic diameter to greater than 5 cm, or development of saccular aneurysm (87,88 and 89). An alternate approach is 2 to 3 weeks of pharmacologic therapy followed by surgical repair if the dissection becomes stable and the patient's general condition does not contraindicate surgery (90,91). Transluminal placement of an endovascular stent-graft device in type III aortic dissection has been successfully performed and may provide an alternative to surgery in highly selected patients in the future (92,93).

Postoperatively, continuation of beta-blockade, if possible, is essential, as hypertension and left ventricular ejection velocity play an important role in the recurrence of aortic dissection. Postoperative management includes maintenance of adequate blood pressure and serial clinical evaluations. Noninvasive testing is performed at periodic intervals to detect the development of anastomotic aneurysm or saccular aneurysm, extension of the dissection, patency of the false lumen, or progressive aortic dilation (94,95).

PENETRATING AORTIC ULCER

Penetrating aortic ulcer shares several clinical features with aortic dissection, especially type III aortic dissection, but the absence of certain clinical signs favors a diagnosis of penetrating aortic ulcer. Results of noninvasive imaging studies are usually distinctive, allowing differentiation of penetrating aortic ulcer from typical aortic dissection (96,97). Differentiation between the two disorders is important in view of the fact that the natural history of penetrating aortic ulcer is less well defined; therefore, treatment may differ from that currently used for classic aortic dissection (96,97).

Pathogenesis

Penetrating aortic ulcer refers to an atherosclerotic lesion of the thoracic aorta that undergoes ulceration that penetrates the internal elastic lamina of the thoracic aorta, resulting in formation of one of the following: intramural hematoma within the media of the aortic wall, a true saccular aneurysm, a pseudoaneurysm, or transmural aortic rupture (98) (Fig. 108.2).

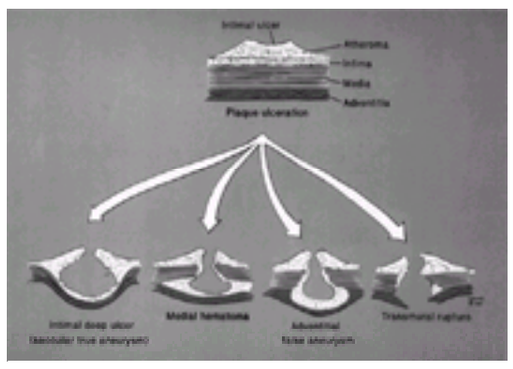


FIGURE 108.2 Pathologic consequences of penetrating atherosclerotic ulcer of the aorta. Atheromatous ulceration that burrows deeply into an atheroma can result in one of four potential outcomes (*from left to right*): a true saccular aneurysm, a medial hematoma, an adventitial false aneurysm, or transmural rupture. An intramural (medial) hematoma is the most commonly observed fate of a penetrating aortic ulcer.

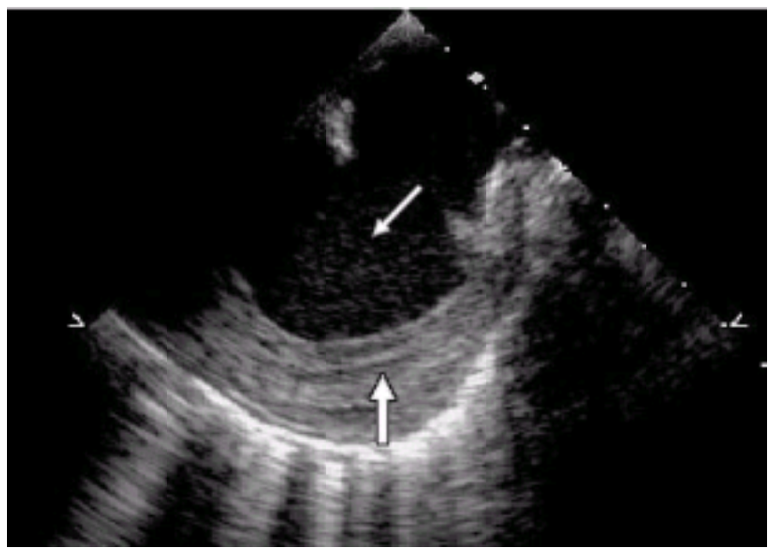


Transesophageal view of the aortic arch demonstrating an arch aneurysm (*thin arrow*) with layering of thrombus inferiorly (*thick arrow*).

Penetrating aortic ulcer was first described as a rare cause of aortic dissection by Shennan in 1934 (99). Subsequently, Willius and Cragg (100) noted that some primary aortic intimal ruptures involved the more distal thoracic aorta and were associated with "ulcerating atheromatous abscesses." Multiple other case reports and small series have subsequently been published, with the majority focusing on the imaging characteristics and surgical treatment of penetrating aortic ulcer (101,102,103 and 104).

Risk Factors

Risk factors for penetrating aortic ulcer are similar to those for aortic dissection, the most common being advanced age, chronic systemic hypertension, and evidence of atherosclerotic disease (105). In contrast to aortic dissection, men and women are equally affected. Long-standing hypertension is present in the majority of patients and likely contributes to the advanced atherosclerotic disease that is universally evident. More than one-half of the patients with penetrating aortic ulcer have advanced atherosclerotic disease in other locations, including coronary artery disease, peripheral arterial occlusive disease, and cerebrovascular disease. An increased association of penetrating aortic ulcer and AAA, as well as aneurysms in other locations, has also been reported (98,101).

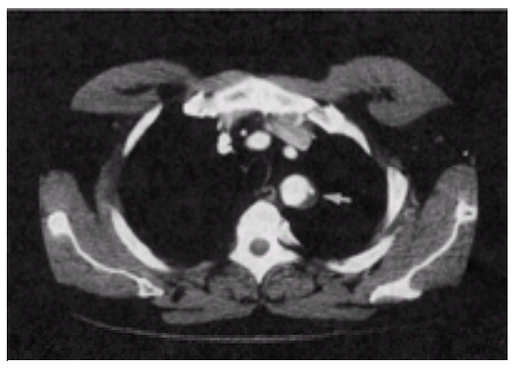
Clinical Features

The clinical presentations of penetrating aortic ulcer and acute aortic dissection are similar, the most common being an elderly patient with systemic hypertension and the acute onset of severe pain in the chest, back, and, less commonly, epigastrium. Unlike aortic dissection, the pain is rarely migratory. Because the most common site of penetrating aortic ulcer is in the descending thoracic aorta, a murmur of aortic regurgitation, pericardial friction rub, and peripheral pulse deficits are not seen. In addition, visceral vessel involvement has not been reported. Neurologic deficits are very rare, but acute lower-extremity paraplegia has been reported (98). In a patient with a history that is compatible with aortic dissection, the *absence* of physical findings suggests the diagnosis of penetrating aortic ulcer. Asymptomatic penetrating aortic ulcer does occur and is usually incidentally discovered as enlargement of the descending thoracic aorta or a hilar mass on routine chest radiography (98,101).

Laboratory Findings

Routine laboratory studies are nonspecific with penetrating aortic ulcer. The chest radiograph is the most helpful of the routine laboratory tests because it is often abnormal. It may demonstrate mediastinal widening, focal or diffuse enlargement of the descending thoracic aorta, a hilar mass, left apical mass, bilateral pleural effusion, or isolated left pleural effusion (96,97). However, normal chest radiographic findings do not exclude penetrating aortic ulcer. The most common electrocardiographic abnormality is left ventricular hypertrophy from chronic systemic hypertension.

The findings on CT, MRI, TEE, and aortography in patients with penetrating aortic ulcer are characteristic, allowing differentiation of penetrating aortic ulcer from classic aortic dissection (eFig. 108.2.1).



***e*FIGURE 108.2.1** Computed tomographic scan in a patient with penetrating atherosclerotic ulcer of the proximal descending thoracic aorta (*arrow*). Note small dimple of contrast material extending from the aortic lumen into an area of hematoma formation (the ulcer penetration site).

Management

Treatment is individualized, as the natural history of penetrating aortic ulcer and indications for surgery are not well defined. The natural history of an intramural hematoma has been shown by serial noninvasive imaging studies to follow a course of resorption of the hematoma and aortic dilation in the region of the involved aorta (97,98). Patients with an intramural hematoma should be treated medically, with special emphasis placed on control of blood pressure, preferably with a beta-adrenergic blocking agent. Ascending aortic involvement, progressive aortic dilation, persistent symptoms, or difficult-to-control hypertension is an indication for surgery. When saccular aneurysm or pseudoaneurysm is the result of a penetrating atherosclerotic ulcer of the aorta, surgery is recommended.

ANEURYSMAL DISEASE

An aneurysm can be defined as a permanent localized dilation of an artery. Because atherosclerosis is the most common cause of arterial aneurysm, aneurysmal disease and its complications are frequent clinical problems. Once initiated, an aneurysm tends to enlarge progressively. Although most aneurysms enlarge in an occult fashion, pressure of the aneurysm on surrounding structures or eventual rupture may occur. Furthermore, nonlaminar flow within the aneurysm leads to the formation of laminated thrombus, which may lead to distal embolization. Despite advances in noninvasive imaging and surgical techniques, the diverse presentations of aortic aneurysm can challenge the best of clinicians at times, making the aphorism of Sir William Osler, “There is no disease more conducive to clinical humility than aneurysm of the aorta,” (106) appropriate even today.

Thoracic Aortic Aneurysm

Atherosclerosis is the most common cause of aneurysmal disease of the aorta; thus, aneurysms are more common in men than in women (5:1) and are rare in patients who are younger than 50 years of age. Less common causes include congenital defects of the arterial wall, hypertension, tobacco use, familial tendency, inherited disorders of connective tissue, infections, arteritis, sudden deceleration, entrapment, and trauma. Perhaps less appreciated is the condition termed *annuloaortic ectasia* by Ellis et al. (107), a disorder that is more common in men and characterized by dilatation of the aortic root without other features of Marfan syndrome. These patients typically have aortic regurgitation and are prone to aortic dissection and sudden death (108). Dilatation of the aortic root causing severe aortic regurgitation can also result from poorly controlled systemic hypertension (109). Aortitis secondary to inflammatory disorders of the aorta—for example, giant-cell and Takayasu’s arteritis—can cause dilatation of the aorta, usually in the root and ascending portion, which results at times in associated aortic valve regurgitation (110). The aorta is also the most common site of infectious arteritis and mycotic aneurysm (111).

Whatever the underlying cause, the development of an aneurysm is related to weakening of the media of the artery. Once dilation begins, enlargement tends to be progressive, because lateral pressure increases with widening of the aortic lumen (Bernoulli theorem). Furthermore, wall tension at constant arterial pressure increases with increasing diameter (Laplace’s law) (112). Systemic hypertension also accelerates aneurysm expansion (113). Subtle defects in collagen and elastin, combined with an accelerated breakdown of these molecules by an increase in proteolytic enzyme activity or a decrease in the levels of protease inhibitors (or both), play a significant role in the development of aortic aneurysm (114).

Most aneurysms of the thoracic aorta are asymptomatic, being incidentally discovered on chest radiography (115,116). When symptoms develop, the aneurysm is usually large enough to encroach on surrounding structures and cause chest pain, back pain, dyspnea, dysphagia, cough, hoarseness, or stridor. When there is venous compression (eFig. 108.2.2), compression of other structures (e.g., fixation of a vocal cord), or encroachment on the chest wall, corresponding findings may be noted. The symptoms and signs of congestive heart failure may predominate when there is significant aortic regurgitation. Atheroembolism is not an infrequent clinical presentation of aortic aneurysm. As a result of slowing of flow in the peripheral portions of the aneurysm, laminated mural thrombus develops and may subsequently embolize to the distal arterial circulation (68).

On a plain radiograph, an aneurysm appears as a rounded or smooth density in the central portion of the chest if it is not obscured by other structures (Fig. 108.3). Unless there is calcification in its wall, the aneurysm may be difficult to differentiate from intrathoracic tumor in the central chest or from simple elongation and torsion of the aorta. Aortography has been the classic method to diagnose thoracic aortic aneurysm, but CT, particularly with i.v. contrast enhancement; MRI; and combined TTE and TEE have become the noninvasive diagnostic tests of choice (117,118,119,120 and 121).

The dilation is confined to the ascending aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The prognosis of untreated thoracic aortic aneurysm is poor, with 3-year survival rates as low as 25% (122). Factors that seem to worsen the prognosis are female gender, diastolic hypertension, size greater than 6 cm, traumatic aneurysm, and associated coronary and cerebrovascular disease. The cumulative risk of rupture is 20% after 5 years (123). The 5-year risk of rupture as a function of aneurysm size at recognition is 0% for aneurysms less than 4 cm in diameter, 16% for those 4.0 to 5.9 cm, and 31% for aneurysms of 6 cm or more (123). Because of the poor prognosis for the untreated patient with a thoracic aortic aneurysm, surgical treatment is justified unless comorbid medical conditions contraindicate an operation. Based on previous natural history studies (115,116,123), the following seem to be reasonable indications for surgical treatment: (a) an aneurysm that is symptomatic, (b) an aneurysm with a diameter of 6 cm or greater, (c) an aneurysm that enlarges under

observation, and (d) an aneurysm in a person with poorly controlled systemic hypertension.

Unless there are contraindications, elective surgical resection of thoracic aortic aneurysms that result from trauma, even when asymptomatic, is indicated because of the inability to predict rupture (124,125). Prophylactic surgical treatment of aortic root dilation greater than 5.0 cm in diameter in the person with Marfan syndrome is advisable to prevent the complications of aortic dissection and rupture (126,127).

The surgical approach to repair of an aortic aneurysm depends on its location and extent. Special problems attend operations on the thoracic aorta, in contrast to infrarenal aortic procedures. Neither the ascending nor the arch portion of the aorta should be cross-clamped for repair of an aneurysm without the use of heart-lung bypass, adjunctive hypothermia, and myocardial protection. Cross-clamping the aorta at a point just distal to the left subclavian artery involves a substantial risk (4% to 18%) of inducing severe ischemia of the spinal cord with resultant paraplegia. Risk factors for spinal cord ischemia or infarction include female gender and intraoperative hypotension (mean arterial pressure <55 mm Hg) (128). Attempts to reduce spinal cord ischemia with systemic hypothermia, rapid repair, temporary aortic shunt bypass, femoral-femoral extracorporeal circulation, intrathecal papaverine, and left atrial-to-distal arterial aortic bypass have all been used with limited success.

In general, fusiform aneurysms are opened and stripped clean of thrombus and atherosclerotic intima, after which an aortic vascular prosthesis is sutured to the luminal aspect of the proximal and distal uninvolved aorta. The less common saccular aneurysm is usually transected at its neck, and aortic integrity is reconstituted by direct suturing or by a patch of vascular graft material. If aortic annular dilatation results from proximal extension of the aortic aneurysm, thus causing aortic valvular regurgitation, repair is effected by replacing the valve and ascending aorta separately, the narrow rim of aortic root from which the coronary arteries arise being allowed to remain. Alternatively, a composite graft can be attached proximally at the annulus, after resection of the natural valve, and distally just beyond the aneurysm (129,130). The composite graft consists of a replacement aortic valve that is inserted into the proximal end of a tubular aortic vascular crimped-fabric graft. In the use of such a composite graft, buttons of the aortic wall containing the coronary ostia must be implanted into the proximal portion of the aortic graft. With technical improvements, the perioperative risk for these procedures is between 3% and 10% depending on the size and location of the aneurysm and the general condition of the patient.

Abdominal Aortic Aneurysm

Approximately three-fourths of all atherosclerotic aneurysms involve the abdominal aorta. Men are affected more frequently than women (9:1), and the majority of patients are older than 50 years. Hypertension often coexists and further contributes to aneurysm formation (7). Current smoking also increases the risk of aneurysm rupture and reduces long-term survival (131). A familial tendency for development of AAA is well established, with sex-linked and autosomal patterns of inheritance involved (132,133). First-degree male relatives of patients with AAA have a 12-fold increased risk of developing an aneurysm compared with control subjects (132). Most AAAs are infrarenal in location. Two percent to 5% are suprarenal, usually the result of distal extension of a thoracic aneurysm (thoracoabdominal aneurysm).

Video 108.30 Transesophageal echo in a patient with severe left ventricular dysfunction and a descending aortic aneurysm with severe spontaneous echo contrast within the aorta (seen in short axis). Note the significant layering of thrombus along the wall of the aneurysm (*right*). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Infectious (mycotic) aneurysms frequently involve the abdominal aorta and tend to occur at regions of diseased tissue, such as areas of atherosclerosis (134). Arterial trauma caused by accidents, surgical manipulation, i.v. drug abuse, or invasive diagnostic procedures has surpassed endocarditis as the most frequent cause of mycotic aneurysm, accounting for up to 42% of cases (134). *Salmonella* species and *Staphylococcus aureus* are the most common organisms isolated, accounting for 50% and 30% of cases, respectively (134). A less common cause of AAA that frequently goes unrecognized is trauma, usually blunt (i.e., seat belt injury), which can result in the formation of true aneurysm and pseudoaneurysm of the abdominal aorta in persons of any age.

The majority of patients with AAA are asymptomatic, emphasizing the importance of increased clinical awareness for the condition, especially when risk factors for aneurysmal disease are present. The most frequent and important physical finding in AAA is the presence of a pulsatile abdominal mass. The sensitivity of abdominal palpation for the detection of AAA is 43% overall (57% for aneurysms >4.0 cm in diameter, 29% for aneurysms <4.0 cm in diameter) (135). Previous pathologic studies have suggested that an AAA must be 4.5 cm in diameter before it can be diagnosed with any degree of accuracy on physical examination (136). In clinical practice, with time and experience, AAAs of smaller size can be palpated in most nonobese patients. A tortuous abdominal aorta, transmitted pulsation from an abdominal mass, or a horseshoe kidney anteriorly displacing the abdominal aorta are conditions that can mimic AAA on physical examination.

Miniaturized ultrasonographic machines (2.5-MHz curved array transducer connected to a compact 2.6-kg console), termed personal ultrasound imagers, now enable detection of occult AAA with a sensitivity and specificity of 91% and 96%, respectively (137,138). Ultrasound screening programs for asymptomatic AAA result in a significant reduction in mortality from all aneurysm causes (139).

When an AAA is symptomatic without rupture, the most common complaint is abdominal pain, intermittent or constant, over the preceding days or weeks. Recent-onset low back pain can occur and may be due to dissection within the aneurysm or retroperitoneal hematoma. Abdominal pain that radiates to the flank, groin, or testes may be a dominant or associated complaint. If atheroembolism from AAA has occurred, painful blue toes, livedo reticularis, hypertension, and renal insufficiency develop (eFig. 108.3.1). Less commonly, intermittent claudication from embolization of the muscular branches of the lower extremity arteries can occur.

***e*FIGURE 108.3.1** After intravenous thrombolytic therapy for acute myocardial infarction in a man with an abdominal aortic aneurysm, atheroembolism to both lower extremities occurred, causing multiple blue toes bilaterally.

Livedo reticularis. Mottled reddish discoloration of the lower extremities with accompanying multiple ulcerations associated with atheroemboli.

Atheroemboli. Embolization of cholesterol, fibrin, and platelet debris results in digital necrosis and gangrene (*yellow arrow*), as well as localized skin necrosis and livedo reticularis (*white arrows*).

Atheroemboli. Embolization of cholesterol, fibrin, and platelet debris results in digital necrosis and gangrene, as well as localized skin necrosis and livedo reticularis (*white arrows*).

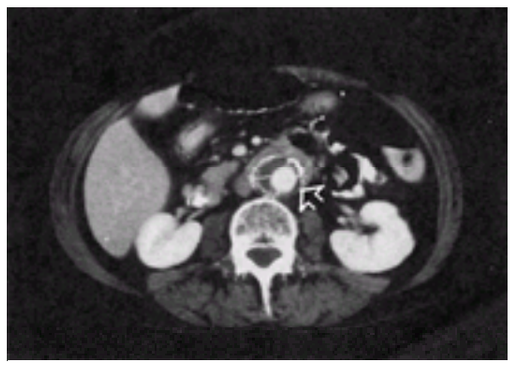
Atheroemboli. Digital necrosis resulting from severe atheroemboli.

Cholesterol emboli. Purpura secondary to cholesterol emboli are shown (*yellow arrows*).

The most frequent complication of AAA is rupture, which occurs most often when aortic diameter exceeds 5 cm (140). Rupture of an AAA is characterized by the triad of severe pain, hypotension, and a tender abdominal mass. The pain is acute in onset, constant, and severe, most commonly located in the lumbar area or diffusely throughout the abdomen with radiation into the flanks, genitals, or legs. The abdominal aorta is usually tender to palpation, and there may be peritoneal signs if free rupture into the peritoneal cavity has occurred. Findings suggestive of a ruptured AAA or contained rupture represent a true surgical emergency, and prompt diagnosis and surgical therapy are crucial to improve survival.

Less common presentations of AAA include obstructive uropathy due to ureteral compression, gastrointestinal hemorrhage when the aneurysm ruptures into the intestinal tract, high-output congestive heart failure due to an aortocaval fistula, and disseminated intravascular coagulation.

Inflammatory AAAs comprise approximately 2% to 14% of all AAAs. Patients with an inflammatory AAA classically present with abdominal or back pain, malaise, weight loss, and an elevated sedimentation rate (141,142 and 143). Obstructive uropathy is an additional presentation. Preliminary evidence suggests that inflammatory AAAs may have a familial component and that current smoking may play a role in the inflammatory process (143). The diagnosis can be established by CT or MRI (eFig. 108.3.2). Treatment is surgical grafting. The role of corticosteroid therapy is less well defined. Preliminary case reports suggest that corticosteroid therapy may facilitate surgery when severe inflammation or ureteral involvement is present and reduce inflammation after surgical resection of an inflammatory AAA (144).



***e*FIGURE 108.3.2** Computed tomographic scan of typical thick wall of inflammatory abdominal aortic aneurysm (*arrow*).

Aneurysmal disease in other locations is important to keep in mind when examining patients with AAA. Up to 30% of persons with AAA have aneurysms of other arteries, most often the iliac, femoral, and popliteal arteries. Coronary artery disease, carotid occlusive disease, and peripheral arterial occlusive disease are frequently present in patients with AAA, an important point to remember during the clinical evaluation and preoperative assessment of these patients (145). In individuals who are

selected for AAA repair, careful clinical and noninvasive assessment of associated coronary and carotid artery disease is indicated to stratify the patient's perioperative cardiac risk. The identification and surgical treatment of significant correctable coronary artery disease and carotid occlusive disease before elective resection of AAA have been shown to reduce the incidence of postoperative myocardial infarction and mortality (145).

AAA can be accurately diagnosed with ultrasonography, CT, or MRI and magnetic resonance angiography (MRA) (Fig. 108.4). Angiography is not needed to diagnose AAA, but it is useful when a juxtarenal aneurysm is suspected or when delineation of associated peripheral, renal, or visceral arterial occlusive disease is indicated before surgical repair.

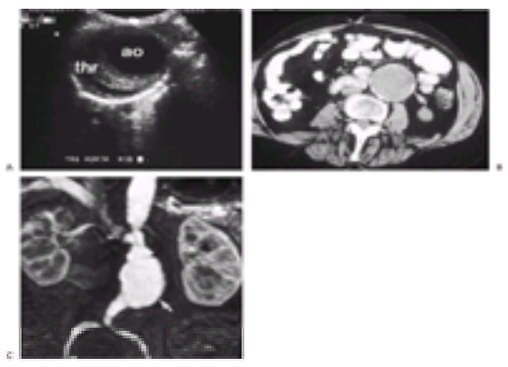


FIGURE 108.4 Noninvasive imaging in the diagnosis of abdominal aortic aneurysm. **A:** Ultrasound examination demonstrates large abdominal aortic aneurysm with large amount of laminated thrombus (thr). ao, aortic lumen. **B:** Computed tomographic study demonstrates large abdominal aortic aneurysm with calcification of the aortic wall (*arrow*). **C:** Magnetic resonance angiography demonstrates infrarenal abdominal aortic aneurysm (*arrow*).

Natural history studies of AAAs demonstrate an increase in risk of rupture when aneurysm diameter exceeds 5 cm (140,146). Elective resection and graft replacement have a surgical mortality of less than 5%, but emergent surgical treatment after the aneurysm has ruptured has a much higher mortality (145).

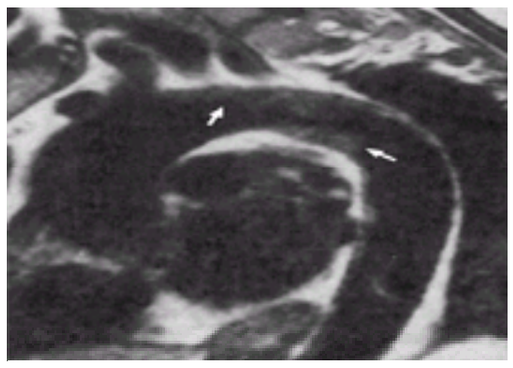
In the poor-risk patient with an aneurysm of less than 5 cm in diameter, observation of the aneurysm with serial ultrasound examinations every 3 to 6 months is appropriate. Some evidence has been found that long-term beta-adrenergic blockade may decrease the rate of expansion of AAA (147).

Endovascular repair of AAA, first reported in 1991 (148), is being used with increasing success (149,150 and 151). Advances in technology over the past 10 years and more well-defined indications have established endovascular repair of AAA as a safe and effective procedure in selected patients (151,152 and 153). With second-generation devices, the procedure is initially successful in greater than 95% of patients, with 2-year success rates that are comparable to those of standard surgical repair (151,152). Specific computed tomographic and angiographic criteria are used to determine if endovascular repair is feasible, the most common primary reasons for ineligibility being related to morphology of the aneurysm neck or abnormalities of the iliac arteries, or both. Despite the minimally invasive nature of endovascular aneurysm repair, a variety of complications occur with considerable frequency (153). Complications are more often encountered in patients with large aneurysms, advanced age, and if adjuvant procedures are required (153). Evidence of blood flow in the aneurysm sac (endoleak) occurs in up to 50% of patients but does not appear to predict patient survival or aneurysm rupture rate (152,154).

OCCLUSIVE DISEASE

Etiology

Occlusive disease of the aorta is most commonly due to advanced atherosclerosis. Additional causes include giant-cell arteritis and Takayasu's disease. Rarely, primary intimal sarcoma of the aorta can cause occlusive or embolic symptoms, or both (*e*Fig. 108.4.1).



***e*FIGURE 108.4.1** Magnetic resonance imaging demonstrates large mass (*arrows*) nearly occluding the lumen of the transverse aortic arch in a patient with cerebral, upper and lower extremity, and visceral emboli. Postmortem examination demonstrates the mass to be a primary intimal sarcoma of the aortic arch.

Severe calcific atherosclerosis of aorta. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Transesophageal echo view of the descending aorta in short axis demonstrating significant atheromatous plaque.

Atherosclerosis

Atherosclerosis in the thoracic aorta usually involves the origin of the brachiocephalic arteries, principally the left subclavian and occasionally the innominate artery. Although atherosclerotic disease of the aortic arch branches is usually asymptomatic, stenosis of the origin of the left or right subclavian artery may cause intermittent claudication of the arm of sufficient degree to warrant surgical treatment. With complete occlusion of the origin of either subclavian artery, collateral blood flow to the arm may be derived principally from the cerebral circulation via reversed flow through the ipsilateral vertebral artery, so-called subclavian steal. This results in episodes of transient cerebral ischemia, especially when the ipsilateral arm is exercised. A similar situation may occur on the right side if the obstruction occurs at the origin of the innominate artery, in which case flow in the right vertebral artery can “reverse” to enter the right subclavian artery. In addition to the symptoms of transient cerebral ischemia, physical signs of this condition include reduced arm and wrist pulses and reduced blood pressure on the affected side. Furthermore, a coronary-subclavian steal phenomenon can occur in patients who have undergone prior coronary artery bypass surgery using the internal mammary artery (IMA). When a hemodynamically significant subclavian artery stenosis is present ipsilateral to the IMA graft, flow through the IMA may reverse or “steal” during upper extremity exercise. Coronary and graft angiography demonstrate retrograde flow in the involved IMA during injection of the grafted coronary artery. The astute examiner, when palpating both radial pulses simultaneously, may also detect a delay in pulsation on the affected side (155).

Acquired coarctation of the thoracic aorta due to focally obstructive calcific atherosclerotic disease is rare but has been reported (156). Symptomatic patients present with upper extremity hypertension and reduced blood pressure in the lower extremities, with or without intermittent claudication.

Micro- or macroemboli from atherosclerotic plaque and thrombus in the thoracic aorta are important causes of stroke and peripheral embolization. Aortic atheromas occur with a prevalence of approximately 27% in patients with previous embolic events, and aortic atheromas are also strong predictors of coronary artery disease (157,158). Assessment of thoracic aortic atherosclerotic plaque is most accurately obtained with TEE. Plaque thickness of greater than 4 mm and mobile thrombus (of any size) are associated with an increased risk of embolism (158). Embolism can occur spontaneously, in relation to invasive angiographic procedures, secondary to warfarin or thrombolytic therapy, and secondary to cardiac surgical procedures that require cardiopulmonary bypass. Treatment is surgical resection if a focal source of embolism is present and the patient’s general medical condition permits. Preliminary research suggests that warfarin may be beneficial in reducing subsequent embolic events, but further randomized trials are required (157).

Giant-Cell Arteritis

The cause of giant-cell arteritis (formerly called *temporal arteritis* or *cranial arteritis*) is unknown. The dominant clinical symptom is usually headache; the most frequent and dreaded complication is blindness. The classic physical finding is prominent, inflamed, or tender temporal arteries. Significant involvement of the aorta and large arteries is being recognized with increasing frequency.

Giant-cell arteritis is a subacute and chronic inflammatory process with local and systemic manifestations. It is generally seen in persons older than 55 years, and it is twice as common in women as in men. Involvement of the thoracic aorta and its branches may be minimal and asymptomatic, but when it is more extensive it can result in occlusion of one or more branches of the aortic arch (159), dilatation or saccular aneurysm of the aorta (160), or even aortic dissection (160).

Giant cell myocarditis. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

The diagnosis is typically established by biopsy of the superficial temporal artery. However, MRI/MRA or standard contrast angiography is required to confirm the diagnosis of aortic and branch vessel involvement and to differentiate this disorder from atherosclerotic occlusion. The ascending aorta can be dilated, and there may be thickening of its wall; involvement of branches of the arch, when present, is often bilateral, with segmental areas of smooth, tapered arterial stenosis or occlusion, or both, in the absence of atherosclerotic changes.

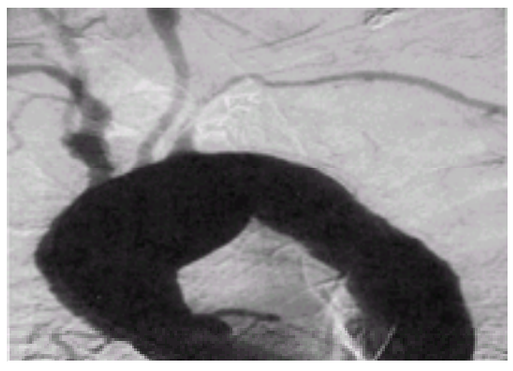
Management of the patient with aortic or large-artery involvement by giant-cell arteritis is principally by administration of corticosteroids in adequate doses (beginning with 45–60 mg prednisone daily), often in combination with methotrexate (161). Arterial changes are reversible with adequate therapy, but when pharmacologic therapy has been insufficient to suppress the arteritis, there may be progressive involvement of the aorta and resultant dissection or rupture.

Takayasu's Disease

This disorder, also called *pulseless disease* and *idiopathic medial aortopathy and arteriopathy*, is another syndrome of arteritis that involves the aorta and its branches. In contrast to patients with giant-cell arteritis, most individuals with Takayasu's disease are younger than 40 years; it also occurs more commonly in women (>80% of cases).

The early subacute phase of fever, anorexia, malaise, weight loss, night sweats, and fatigue often go unrecognized, with the diagnosis first being suspected when symptoms and signs of the occlusive phase develop. The clinical manifestations of occlusion may include cerebrovascular insufficiency, arterial insufficiency of the upper or lower extremities, or mesenteric insufficiency, depending on the location of the aortitis and arteritis. Hypertension is very common; it occurs as a result of acquired aortic coarctation or involvement of the renal arteries by the arteritis.

MRA or standard contrast aortography is of great value in the diagnosis of Takayasu's disease. Segmental narrowing of a variable length of descending or abdominal aorta or narrowing of the origin of major branches of the aorta occurs as a result of thickening of the aorta or arterial wall (*e*Fig. 108.4.2). This usually allows distinction of Takayasu's disease from other causes of the aortic arch syndrome (162). Although aneurysmal dilatation of the thoracic aorta can occur in Takayasu's disease (163), it is not common or distinctive in this disorder.



***e*FIGURE 108.4.2** Aortogram in a patient with Takayasu's disease demonstrates large ascending aortic aneurysm and long tapered stenoses of the proximal left common carotid artery (*arrowheads*) and left subclavian artery *(open arrowheads)*.

Therapy with corticosteroids, sometimes combined with anticoagulant therapy, is effective for patients in the early phase of the disease in controlling systemic symptoms and allowing return of pulses. For the patient in the later occlusive phase, surgical treatment to bypass the obstruction may be indicated to relieve hypertension caused by the acquired coarctation or renal artery stenosis (164). Similarly, other occlusive arterial lesions may require surgical treatment for relief of ischemic manifestations.

TRAUMATIC RUPTURE OF THE THORACIC AORTA

Pathogenesis

Trauma to the thoracic aorta may result from crushing injury and deceleration, as well as from penetrating injuries, or it may be iatrogenic from intraaortic procedures. Aortic rupture from sudden deceleration is the most common traumatic condition of the thoracic aorta that is encountered clinically. Rupture of the thoracic aorta as a result of sudden deceleration may vary in degree from incomplete laceration to complete transection. The injury occurs most often as a result of an automobile accident but may also occur in falls from heights or compression by heavy objects (165). With horizontal deceleration, as in automobile accidents, 80% of the aortic ruptures occur at the isthmus of the thoracic aorta just distal to the origin of the left subclavian artery and near the attachment of the ligamentum arteriosum, the point of aortic

fixation where the shearing stress is maximal (166).

Clinical Features

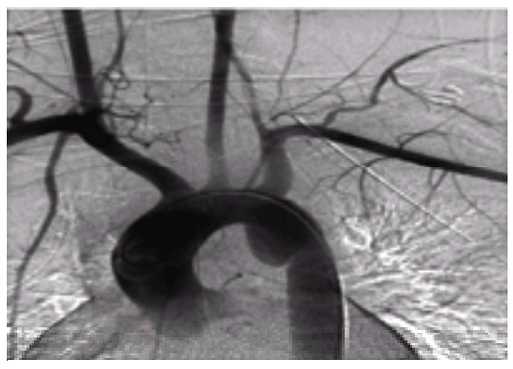
Traumatic aortic rupture should be suspected whenever an injury involves sudden deceleration or chest trauma, either blunt or penetrating. The presence of chest contusions or penetrating wounds, rib or sternal fractures (167), hypertension in the arms (168), decreased or absent pulses in the legs (169), or evidence of fluid in the left side of the chest (170) is a clue to the possibility of aortic rupture.

Radiologic Features

The only finding on radiography of the chest may be widening of the mediastinum (170). The presence of left pleural fluid in association with mediastinal widening is an even stronger clue (170). Associated rib, clavicle, or sternal fractures may also be seen.

Diagnosis

In a patient with suspected traumatic rupture of the thoracic aorta, TEE, CT, or aortography should be performed emergently to confirm the diagnosis and localize the site of aortic rupture (171,172 and 173) (*e*Fig. 108.4.3). TEE is the initial test of choice, as it permits rapid diagnosis and effective triage of patients (173). The echocardiographic signs of aortic injury are complex and may be confined to a short section of the aorta. Therefore, examination by a physician who is highly trained in echocardiography is necessary in such cases.



***e*FIGURE 108.4.3** Aortogram in a patient with traumatic rupture of the thoracic aorta demonstrates a pseudoaneurysm just distal to the left subclavian artery.

Prognosis

Most patients with traumatic aortic rupture die before they reach a hospital, but as many as 20% may survive long enough to permit diagnosis and treatment (165). Some patients survive the aortic laceration and later present with so-called chronic traumatic thoracic aortic aneurysm; approximately half of these lesions become unstable and enlarge at some time in their course, but there are no criteria to predict which will do so (124).

Treatment

In the acute setting, extreme alertness, prompt diagnosis, and immediate surgical repair are necessary. Ordinarily, end-to-end anastomosis is not feasible, and therefore a prosthetic graft is interposed after resection of the lacerated area (174).

For chronic traumatic thoracic aortic aneurysm, we and others (124,125) favor surgical treatment, even though some of these patients may survive without surgery for long periods, because of the unpredictable course of this lesion and the low morbidity and mortality of elective surgical repair.

AORTITIS

Aortitis refers to a group of disorders with diverse etiologies. Although not a particularly common primary problem, aortitis, because of its role in aortic regurgitation, aortic dissection, and aneurysmal disease, is an important disorder of the thoracic and abdominal aorta.

Video 108.31 Aortography in a patient with giant cell aortitis, a severely dilated aorta, and aortic regurgitation. After contrast injection, approximately 1+ aortic regurgitations are evident. The ascending and descending aorta are significantly enlarged (left anterior oblique view). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Etiology

Inflammatory change can occur in the wall of the aorta in response to any type of injury. One way of classifying aortitis that involves a systematic approach to diagnosis is shown in *e*Table 108.1.3. Giant-cell arteritis and Takayasu's disease have already received attention in this chapter in the discussion of the arteritides in the section Occlusive Disease.

***e*TABLE 108.1.3** CLASSIFICATION OF AORTITIS

Nonstenosing aortitis
Infectious
Syphilitic aortitis
Infectious aortitis
Rheumatic fever
Noninfectious
Giant-cell arteritis

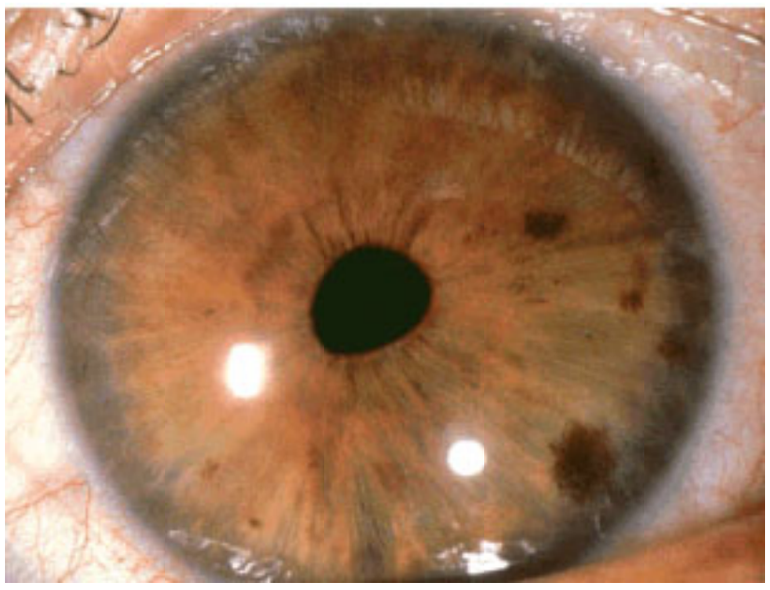
Rheumatoid arthritis
Ankylosing spondylitis
Psoriatic arthritis
Enteropathic arthropathies
Relapsing polychondritis
Rheumatic fever
Reiter's syndrome
Stenosing aortitis
Takayasu's disease

Pathogenesis

Syphilitic aortitis affects the ascending aorta most commonly, the arch next, and the descending thoracic aorta least frequently. With the initial infection, the spirochetes travel to the aorta, where they produce inflammation in the media, adventitia, and vasa vasorum. Fibrosis replaces the degenerative muscle fibers; this weakens the arterial wall and produces the characteristic wrinkling of the intima as a late manifestation some 10 to 30 years after the initial infection.



Argyll-Robertson pupil.

Infections other than syphilis may cause an infectious aortitis and produce an aneurysm or involve an existing aneurysm. In the case of infectious aortitis, the primary lesion seems to be in the vasa vasorum, leading to an abscess in the arterial wall. Fusiform, saccular, or false aneurysms result. The aorta is the artery most often involved with mycotic aneurysm (175,176). The natural history of mycotic aneurysm is one of progressive expansion, thinning of the aneurysm wall, and eventual rupture.

The cause of noninfectious aortitis remains obscure. In most types, however, the aortic involvement seems to be an expression of the systemic nature of the underlying illness and vasculitis. The basic lesions involve primarily the media, and to some extent the adventitia, and are often focal, except in rheumatic fever and rheumatoid arthritis, in which intimal involvement also occurs, producing a panaortitis (177). Aortitis involving predominantly the ascending aorta has been documented in patients with rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, Reiter's syndrome, relapsing polychondritis, and enteropathic arthropathies. Aortic regurgitation may result from dilatation of the aortic annulus in all forms of aortitis that affect the ascending aorta. Takayasu's aortitis differs from other types in that in some patients it can produce aortic narrowing ("acquired" coarctation) involving the descending thoracic or abdominal aorta, or both.

Clinical Features

Syphilitic aortitis, unless complicated, is usually asymptomatic. Other manifestations of tertiary lues may be seen in 10% to 30% of patients. With aneurysm formation, usually saccular in type, there may be signs of compression of other mediastinal structures; rarely, bony erosion occurs. When significant aortic regurgitation develops, a diastolic murmur and signs of a widened pulse pressure are noted.

In other types of infectious aortitis ("mycotic" aneurysm), the findings are those of infectious endocarditis. Usually no specific signs of mycotic aneurysm are seen unless it encroaches on a surrounding structure or it ruptures. With other types of aortitis, the clinical signs are those of the underlying disease.

Radiographic Features

The diagnosis of aortitis is often first suspected from the findings on a chest radiograph (dilation of the ascending aorta or aneurysm). Linear calcification of the ascending aorta and not the arch is most suggestive of syphilitic aortitis. Calcification can also be seen with other types of aortitis and in atherosclerotic disease, but it does not usually involve the ascending aorta alone.

TEE, CT, MRI, and aortography are all accurate in demonstrating the extent of aortic dilatation and any aneurysmal change. Aortography or MRA is generally required to define any branch artery occlusion that may be present.

Diagnosis

The diagnosis of aortitis is usually inferred from any related clinical or chest radiographic findings, or both. Aortography can also demonstrate coronary ostial involvement in patients with syphilitic aortitis and Takayasu's disease. Further differentiation of the type of aortitis depends on associated findings of syphilis (serologic findings and characteristic calcification) or an associated systemic illness.

Prognosis

The prognosis for patients with syphilitic aortitis is about the same as that for the general population (178), and death from its complications, other than aneurysm, is unusual. The prognosis for syphilitic aortic aneurysm, on the other hand, is poor, particularly when it is large enough to cause symptoms (179).

Aortic rupture or dissection is a potential complication of giant-cell arteritis. Otherwise, the prognosis of aortitis is generally that of the underlying systemic disorder.

Treatment

The preventive value of adequate therapy of early syphilis is the most important therapeutic aspect of syphilitic aortitis. Therapy of other types of aortitis is basically that of the underlying disorder. Management of any aneurysm, aortic regurgitation, or arterial occlusive disease is the same as that for such a lesion when it is due to other causes.

MARFAN SYNDROME

Marfan syndrome is a generalized disorder of connective tissue and is relatively common, with an incidence of 1 per 20,000. The incidence of Marfan syndrome does not differ according to gender, race, or ethnicity. It is an autosomal dominant disorder with extremely variable expression (180,181 and 182). Sporadic mutations account for approximately 25% of cases. The cause of Marfan syndrome has been found to be a defect in fibrillin; the gene that encodes fibrillin is on chromosome 15q15–21 (183,184).

Clinical diagnostic criteria for Marfan syndrome depend on manifestations in the skeletal, cardiovascular, and ocular systems and the family history (185). A "marfanoid" body habitus is not diagnostic of Marfan syndrome in the absence of other characteristic features or a well-documented family history of Marfan syndrome.

The ocular abnormalities associated with Marfan syndrome include subluxation of the lenses, myopia, and retinal detachment. Ectopia lentis is the most helpful ocular finding in making a diagnosis of Marfan syndrome.

Skeletal abnormalities associated with Marfan syndrome are frequent and include tall stature, a low upper/lower segment ratio, scoliosis or kyphosis, pectus deformities, and arachnodactyly (eFig. 108.4.4). Increased joint laxity and hyperextensibility are common. The face may be long and thin, and the palate may be narrow and highly arched.

***e*FIGURE 108.4.4** Thumb sign in patient with Marfan syndrome. Note that the thumb extends beyond the fifth digit with the hand clenched in a fist.

Cardiovascular abnormalities are clinically apparent in 40% to 60% of patients with Marfan syndrome, whereas 80% to 95% of patients have cardiovascular findings by echocardiography or pathologic examination. The most common cardiovascular abnormalities are mitral valve prolapse with or without mitral regurgitation and dilation of the ascending aorta, which may result in aortic regurgitation, aortic dissection, or aortic rupture (180,185,186,187,188 and 189). Less commonly reported abnormalities are tricuspid valve prolapse and dilation of the main pulmonary artery. Cardiovascular complications, especially aortic root dilation with dissection or rupture, account for most of the early mortality in patients with Marfan syndrome. Before effective surgical techniques, most patients with Marfan syndrome died in the fourth and fifth decades of life (186,190).

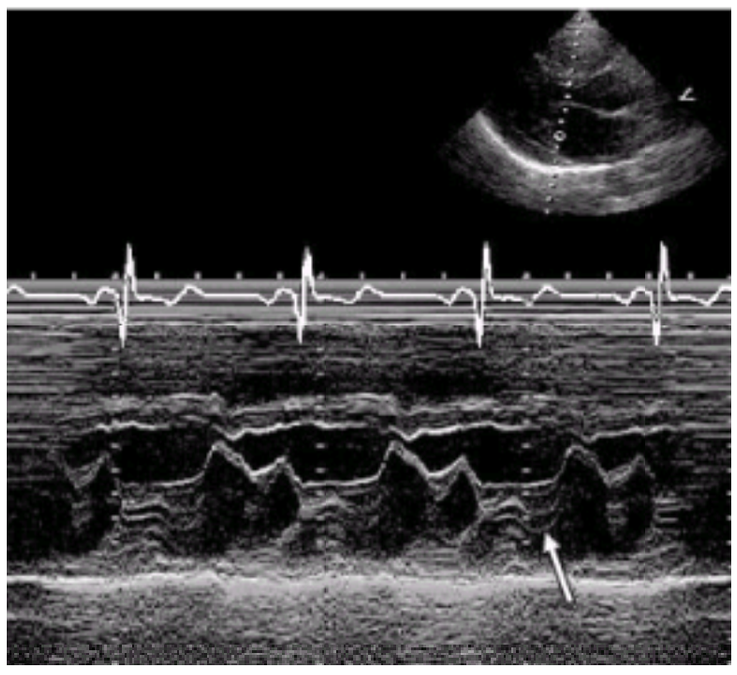
VIDEO

Video 108.32 Aortic insufficiency associated with annuloaortic ectasia of aortic root (oblique-coronal). An “onion-bulb” dilatation of the proximal ascending aorta and the sinuses of Valsalva is observed. A signal-void jet of aortic insufficiency is seen extending from the aortic valve into the left ventricular cavity during diastole. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Aortic abnormalities are found in 60% to 90% of patients (191). The prevalence of aortic root enlargement is greater in males than in females (192). Throughout life, the diameter of the aortic root is usually abnormal in proportion to body surface area in patients with Marfan syndrome; there is symmetric involvement of the sinuses of Valsalva and sinotubular ridge. Aortic dilation is usually progressive, likely due to abnormalities in aortic wall elastic properties such as increased wall stiffness (193,194). Aortic dilation may be limited to the sinuses of Valsalva or may involve the proximal and mid-ascending aorta. Generalized aortic dilation in patients with Marfan syndrome is a marker for increased risk of subsequent aortic complications (195). Dilation of the aorta is often accompanied by aortic regurgitation, and these patients often have a diastolic aortic regurgitation murmur (192). Aortic valve prolapse associated with a myxomatous aortic valve may also cause aortic regurgitation in patients without significant aortic dilation.

Aortic dissection in patients with Marfan syndrome is associated with aortic root dilatation (>6 cm) and a family history of dissection (196). Increased wall stress (Laplace’s law) in the dilated aorta may contribute to the pathogenesis of aortic dissection in these patients. Dissection most commonly involves the ascending aorta, although isolated distal dissection may also occur. Pregnancy in patients with Marfan syndrome is associated with an increased risk of aortic dissection, especially during the third trimester, parturition, and the first month postpartum (197,198).

Mitral valve prolapse and mitral regurgitation cause significant morbidity and mortality in patients with Marfan syndrome (199). Mitral regurgitation may be chronic and progressive or appear acutely if chordal rupture occurs. The finding of mitral valve prolapse in a patient with a marfanoid body habitus does not justify a diagnosis of Marfan syndrome in the absence of a positive family history or other characteristic features.



M-mode tracing of posterior leaflet mitral valve prolapse. Note the posterior displacement of the posterior mitral leaflet after the leaflets close in systole.

you may download it here.

The initial evaluation of patients who are suspected of having Marfan syndrome should include a chest radiograph, ophthalmologic examination (including slit lamp examination of the lenses), and echocardiography. Echocardiography is ideal in the initial evaluation of patients who are suspected of having Marfan syndrome. For the ability to accurately diagnose mitral valve prolapse and associated mitral regurgitation, aortic root dilation, aortic dissection, and aortic regurgitation, echocardiography is the test of choice in patients who are suspected of having Marfan syndrome. Echocardiography is essential for prognosis and management because no other phenotypic features predict a poor outcome (195). MRI and CT are also accurate in diagnosing aortic aneurysm and aortic dissection.

Treatment

Beta-adrenergic blockade to reduce the rate of dilation of the ascending aorta in Marfan syndrome has been shown to be beneficial (200,201,202 and 203). Progressive aortic root dilation occurs throughout life in patients with Marfan syndrome, the rate of dilation being greatest during early childhood and adolescent years. Although aortic root diameter increases over time in all patients, the rate of increase is significantly less in patients who are treated with beta-adrenergic blockade (202). Furthermore, beta-adrenergic blockade seems to improve survival without congestive heart failure, aortic regurgitation, aortic dissection, and aortic surgery (202). Therefore, patients with Marfan syndrome should begin beta-blockade therapy at the earliest age possible, and the dose should be adjusted to the largest dose that is tolerable. Atenolol has become the drug of choice for many physicians because of its relative cardioselectivity and the less frequent occurrence of adverse effects compared with lipid-soluble agents. Although no other drugs have been subjected to formal testing, verapamil, because of its negative inotropic action, is preferred in patients who cannot tolerate beta-adrenergic blocking agents (201).

Patients with aortic diameters greater than 5.0 cm have an increased risk of aortic dissection and should undergo prophylactic surgery (126). Patients with Marfan syndrome and ascending aortic aneurysm can undergo elective surgery with a low operative risk and excellent long-term survival with low morbidity. Aortic diameters less than 4 cm can be followed annually by echocardiography. Patients with aortic diameters between 4 and 5 cm should be observed more closely (every 6 to 12 months), especially if they have generalized aortic dilation and aortic regurgitation.

Video 108.36 A 120-degree postpump intraoperative transesophageal echo after placement of an aortic valve replacement conduit. The St. Jude aortic valve replacement is toward the left of the screen, and the aortic graft can be seen in the center of the screen. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 108.37 Postpump intraoperative echo after placement of an aortic valve homograft. Notice that the leaflets look like a native valve. The only clue that it is a homograft is the thickening at the annulus and the proximal ascending aorta due to the double thickness of the graft cuff with the native aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

CONTROVERSIES AND PERSONAL PERSPECTIVES

Long-term management of type III aortic dissection continues to be an area of debate. Currently, most patients with type III aortic dissection are initially treated medically, with a beta-adrenergic blocking agent and adequate control of hypertension, and followed with noninvasive testing for the development of progressive aortic dilation and aneurysm formation, findings that might indicate the need for surgical intervention. Opinions differ about the indications for and timing of any surgical intervention in patients with “uncomplicated” type III aortic dissection. We and others currently advocate surgical therapy for patients with type III dissection after 2 to 3 weeks of pharmacologic therapy, if the patient’s general condition does not contraindicate this approach (90,91). If pharmacologic therapy does not relieve pain and stabilize the dissection, prompt surgical therapy is also indicated. Transluminal placement of an endovascular stent-graft device in type III aortic dissection has been successfully performed and may provide an alternative to surgery in highly selected patients in the future (92,204).

Debate is ongoing regarding the best noninvasive test in suspected aortic dissection. CT, MRI, and TEE, using current-generation technology, all have an exceedingly high sensitivity and specificity (>95%) in the diagnosis of aortic dissection. Currently, the diagnostic test of choice in suspected acute aortic dissection is TEE because of its rapid availability, portability, ability to provide a comprehensive cardiovascular assessment, and intraoperative applications. If TEE is not immediately available and the patient is stable hemodynamically, CT and MRI can be used as a substitute for TEE. Coronary angiography is not required in patients with acute proximal aortic dissection due to the high early mortality that is associated with this disease and inherent delays that are present with angiography (78). MRI is the preferred test in patients with chronic aortic dissection.

Equally as controversial is the treatment of patients with certain types of penetrating aortic ulcers. Although the natural history of an intramural hematoma is generally benign (i.e., resorption of the hematoma and compensatory dilation of the involved aorta) (101), the natural history of saccular aneurysm and pseudoaneurysm (due to penetrating aortic ulcer) is presently not known. Further study in this area is needed. Equally important are improved surgical techniques to decrease the risk of perioperative spinal cord ischemia and resultant paraplegia in patients undergoing thoracic aortic surgery.

The utility of beta-adrenergic blockade therapy in patients who have aneurysmal disease but not Marfan syndrome is poorly understood. The rare reports of the utility of beta-adrenergic blockade in these patients show benefit in decreasing aneurysm expansion rate, but the number of studies and patients involved are exceedingly small. Presently, our practice has been to institute a beta-blocking agent in all patients with aneurysmal disease if no contraindications to such therapy exist. Furthermore, most of these patients have concomitant coronary artery disease and systemic hypertension, which are well-established indications for beta-adrenergic blockade therapy.

Another highly controversial topic in aortic disease, especially in view of the current emphasis on cost containment in medicine, is screening for AAA. Screening programs for the general population have not been clinically or economically effective. It has been demonstrated, however, that screening certain populations who are at risk for development of an AAA (i.e., older than 70 years, hypertension, tobacco use, family history of AAA, etc.) identifies a group of patients with a significantly increased incidence of AAA compared with the general population. Targeting “high-risk” patients in future aneurysm screening programs will be more clinically meaningful and cost effective (205).

THE FUTURE

With regard to aortic dissection, continued efforts at earlier clinical recognition, allowing for more rapid diagnosis and treatment, are needed. Inclusion of aortic dissection in the differential diagnosis of patients presenting with acute chest pain is important, especially in view of the current widespread use of early i.v. thrombolytic therapy in patients with suspected acute myocardial infarction. Biochemical techniques will be integrated into the initial evaluation of patients with suspected aortic dissection. For example, elevated levels of smooth muscle myosin heavy-chain protein have been demonstrated to have a sensitivity and specificity of 91% and 98%, respectively, in patients with acute aortic dissection (206).

Based on the current size boundaries, the timing of surgical resection of aneurysms is less than perfect. For example, in patients with Marfan syndrome, an ascending aortic diameter of greater than 5 cm is associated with a small, although real, risk of rupture, and the risk increases significantly when aortic diameter exceeds 6 cm. Currently, surgery is indicated for patients with Marfan syndrome who have an ascending aortic diameter of greater than 5.5 cm, although surgery is less complicated and has less morbidity and mortality in patients with smaller aneurysms. The timing of surgical repair of AAA, in relation to aneurysm size, also requires further study. Currently, patients who are in otherwise good general health with an AAA diameter of greater than 4.5 cm are considered for *selective* surgical treatment. In the future, it is hoped that more emphasis will be placed on accurately determining aneurysm expansion rate to identify those patients with more rapid expansion rates who are at increased risk of rupture.

Increased efforts in identifying populations at risk for AAA are also clearly needed to allow more effective screening programs and identification of patients in the earlier stages of disease. Identification of less advanced aneurysmal disease may allow for earlier institution of pharmacologic therapy (i.e., beta-adrenergic blockade) and may lead to favorable alterations in the natural history of disease (i.e., decreased aneurysm expansion rate). Therapeutic agents that are targeted at the cellular level, for example, matrix metalloproteinases, may limit the growth of small AAAs. Personal ultrasound imagers will likely find increased utility in screening for aneurysmal disease and become an integral portion of the physical examination in patients who are at increased risk for development of an AAA. Earlier detection of AAA at a smaller size and careful clinical follow-up may also allow for more appropriate timing of surgical intervention and a decrease in mortality from ruptured AAA. Furthermore, the role of medical therapy (i.e., corticosteroids) in inflammatory AAA, in addition to or in place of surgical therapy, warrants further study.

Clearly, the most exciting and promising advance in the treatment of aortic disease will involve the use of percutaneous endovascular techniques to place stents, bypass grafts, and other therapeutic agents. Percutaneous placement of an endovascular stent to treat AAA, as well as thoracic aortic aneurysm, and aortic dissection may become the optimal method of treatment in the future. Furthermore, percutaneous stent or stented graft placement may allow treatment of diffuse atherosclerotic disease of the aorta in patients with atheroembolic disease who would otherwise not tolerate extensive aortic reconstructive surgery. Indications for endovascular stent placement will clearly increase in patients who cannot tolerate aortic surgery but otherwise have an acceptable prognosis. With further improvements in catheter and stent technology and, therefore, fewer initial and long-term complications, endovascular stent therapy will certainly find increasing indications.

Future improvements in imaging techniques, in particular MRA and three-dimensional TEE, will allow for more accurate diagnosis and improved preoperative planning. The ability to provide the most accurate three-dimensional information about aortic intimal flaps, aneurysm anatomy, and atherosclerotic disease will be crucial to future advancements in medical and surgical treatment of these disorders.

Improvements in imaging techniques, in particular MRA and three-dimensional TEE, will allow for more accurate and earlier diagnosis of aortic aneurysms with an associated improvement in the timing of surgical treatment. Further improvements in percutaneous endovascular techniques to place stents and bypass grafts will lead to increasing indications. In addition, therapeutic agents will be developed to effectively retard the growth rate of AAAs.

OVERVIEW

This chapter reviews the application of the currently available indirect and direct methods of noninvasive testing that have been shown to be of value in the evaluation of peripheral vascular disease. The diseases considered include those most commonly seen in the practice of the cardiovascular specialist. The reader can determine which testing procedure(s) will best fit the patient population that he or she is addressing. It should also be evident how useful these testing procedures can be for evaluating the results of interventional therapy as well as the natural history of peripheral vascular disease without any form of intervention.

HISTORICAL PERSPECTIVE

Vascular diseases are broadly defined as afflictions of the arterial and venous system, the lymphatics, and the microcirculation. For the purpose of this chapter, those that involve the large- and medium-sized arteries are reviewed. The objective evaluation of peripheral vascular disease is finally reaching a mature stage. Although indirect and direct noninvasive methods were slow to be accepted, they have now become a daily part of our practice. As is noted in this chapter, there is increasing evidence that angiographic methods can be bypassed for diagnostic reasons and before surgical intervention. This is a remarkable change in practice and is one that will continue into the future. It is also evident that the natural history of vascular disease as well as the outcome following any form of intervention can be done by noninvasive means. It is no longer acceptable to document outcome based on physician interpretation alone without confirmatory studies, which are the topic of this chapter.

One of the first methods of objectively assessing arterial perfusion to the limbs was to assess the ankle systolic blood pressure and relate it to the arm systolic blood pressure [ankle/brachial index (ABI)] (1,2). This very simple determination was slow to become accepted until it was realized that it could provide an immediate indication of success or failure of arterial reconstructions. It is now a standard method to document outcome and monitor disease progression.

Before the development of ultrasonic methods, all of the approaches that were used to study the circulation were indirect. By the application of sensors to the limbs, one was able to derive physiologic information about the circulation at that site. Although the physiologic responses could be elicited, it was often difficult to relate those findings to the actual status of the disease. One example of how this information could often be misinterpreted is the instance in which a patient comes in with gangrene of the toes or forefoot but normal levels of calf blood flow. The skeptics failed to realize that blood flow levels at the calf could not be related to those found at the distal foot and toes.

Although the measurement of absolute blood flow levels has not found a very useful place in the clinical evaluation of patients, these studies have provided a valuable insight into the physiology of arterial obstruction. For example, the measurement of calf blood flow has shown how the blood flow patterns in patients with intermittent claudication are involved in the fall in ankle blood pressure and its delayed recovery with cessation of exercise (3). We now better understand the issue of postexercise hyperemia and how it relates to the severity of claudication.

Plethysmography

Plethysmography, which measures a volume change, is probably the oldest method that is used to evaluate circulation to the limbs. It comes in a variety of forms, ranging from those that completely encase the limb to the strain gauges that are applied to specific and limited segments. Historically, these were used to estimate the blood flow to a specific segment of the limb—usually the calf or forefoot (1,2,3 and 4). These measurements served as the basis for our understanding of the pathophysiology of blood flow as it is affected by arterial narrowing and occlusion. With each of these plethysmographic methods, it was possible to measure calf blood flow under a variety of circumstances. In addition, some of these methods served a dual purpose: assessment of flow and measurement of ankle and toe systolic blood

pressures (4,5).

The available plethysmographic systems were either of the volume type, in which the sensing unit would encompass the entire limb, or mercury Silastic strain gauges, which encompassed discrete circumferential segments of the limb, forefoot, or toe. The theory behind the use of such devices was verified by Whitney in 1953 (4). The Silastic strain gauge method is still in use for a variety of applications.

Ultrasound

The introduction of ultrasound undoubtedly had the greatest impact on the field of noninvasive assessment. The first development of major importance was the observation by Satomura (6) that ultrasound could be transmitted through the skin to detect frequency shifts in flowing blood. He showed that moving blood would shift the frequency of the transmitted ultrasound in a manner that could be detected and recorded. This was a remarkable observation that changed the entire picture with regard to the investigation of blood flow. Our group very quickly picked up on this method and developed the first device that could be used to detect arterial and venous blood flow from all levels of the limb (7,8). However, it had several major problems and drawbacks. It was nondirectional, and the observer could not always be sure which vessel was being interrogated by the method. However, one of its major advantages in its simplest format was that it could also be used to measure ankle systolic blood pressure. Even today, this is one of its most common applications.

One of the greatest concerns with the earliest systems was that the observer had to train his or her ear to interpret arterial and venous blood flow patterns. Although the normal and abnormal velocity patterns could be recognized, it was not possible to present the earliest systems in an understandable analog format that could be made from any desired recording site. This greatly hampered the rapid acceptance of the method.

Progress was rapid in this field, going from the simple continuous wave (CW) Doppler to the pulsed system (9), which permitted selective sampling from many depths along the path of the sound beam. In addition, it became possible to develop systems that would permit an accurate determination of the direction of blood flow (10). This innovation was quickly followed by the development of ultrasonic arteriography (11), which, by combining the pulsed Doppler with a position sensing arm, could be used to depict the anatomy of the flowing blood in any accessible arterial segment. This worked, but it was tedious to use and subject to numerous artifacts related to patient motion, depth, and anatomy of the underlying artery. It was quite clear that the best solution would be to combine the value of the ultrasonic B-mode image with a pulsed Doppler integrated into the system. This was accomplished in 1974 (12,13). Once this was done, the progress depended more on technology than anything else, and it was rapid. By the 1980s, the method was being widely applied to study disease in the large- and medium-sized vessels, wherever it was found. This was the most important development in this century, as it relates to the noninvasive study of diseases of the arterial and venous circulation. This fact will become evident as this chapter evolves.

INDIRECT NONINVASIVE TESTING

Beginning in the late 1960s, numerous indirect methods were introduced for the study of arterial and venous function (5,8,14,15,16 and 17). By definition, an indirect method is one that derives its value and information from physiologic sensors placed on a limb. These sensors can be used to obtain information on pressure and flow. From this information, it is possible to document important aspects of vascular function. All of these methods are used to measure systolic limb blood pressure, monitor digit/limb pulse volume changes, and assess (either qualitatively or quantitatively) limb blood flow.

Anatomic Considerations

Most of the observations made with the noninvasive tests to be described are useful for studying diseases of the medium-sized and large arteries and veins. By definition, these are vessels with proper names. Atherosclerosis, which is the most common of the vascular diseases that we deal with, affects vessels of this size. Structurally, the histology in general shows the same elements—an intima, media, and adventitia. Subunits such as the internal and external elastic lamina are not constant findings throughout the vascular system. In addition, the proportions of smooth muscle, elastin, and collagen also vary tremendously by location. It is these constituents that account for the varying viscoelastic properties of these vessels, be they arteries or veins. For most purposes, our studies do not include consideration of the viscoelastic elements of the circulation, but we must be aware of how important they are in the delivery aspects of blood flow to and from the various organs.

The distribution of atherosclerosis is different in diabetic patients. They have a lower incidence of aortoiliac disease but a much higher incidence below the knee as compared to the nondiabetic. The superficial femoral artery is the most common site of involvement in both groups of patients. A very important difference in diabetic patients is the high incidence of medial calcification in the tibial/peroneal arteries. This process bears no relationship to atherosclerosis but makes the measurement of ankle systolic pressures difficult if not impossible. For this reason, toe pressures should be measured in the diabetic patient (18).

One of the most important elements of the circulation that we need to appreciate is the resistance to flow offered by the various organs. The flow patterns observed are clearly dependent and different from one vascular bed to another. For example, there are three organ systems in the body that are normally low-resistance systems; that is, they require maximal blood flow at all times of the day to function properly. These are the liver, brain, and kidney. As is shown later in this chapter, these factors drastically affect the pattern of blood flow in health and in disease.

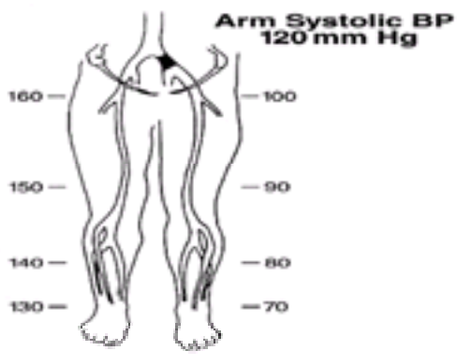
Plethysmography

For the three major types (air, mercury strain gauge, and impedance method), the principles behind each method varied, but the end point was the same (9,19,20,21 and 22). The methods were designed to measure a volume change of the limb at the point where the device was attached. The plethysmographs could be applied to any portion of the limb, including the digits. It should be noted that some plethysmographs can be used to quantitate limb blood flow at specific sites, such as the calf and the digits, but these types of data are of very little use for clinical applications. The information that is most useful is limb blood pressure (systolic), which can be obtained from the digits, ankles, below knee, above knee, and upper thigh level (5). These are often referred to as *segmental limb blood pressures*. It is also possible to use these methods to generate volume pulses from any part of the limb (20). The normal findings in a lower limb are as follows.

Systolic Blood Pressures

Systolic blood pressures are commonly expressed as absolute values or as a ratio to that recorded from the arm, often referred to as the *ABI* or *toe systolic/brachial index* (*TSPI*).

1. *Ankle.* Normally, the systolic pressure at the ankle is higher than that recorded from the arm. This gives an ABI of greater than 1.0. For clinical purposes the value that is normally taken to indicate that peripheral arterial occlusive disease (PAOD) is present is less than 0.90. The variability in the measurement is ±0.15% (23,24).
2. *Toe.* Toe measurements are most commonly taken in diabetics, in whom medial calcification of the tibial and peroneal arteries is common. When this occurs, the ABI is falsely high. The normal TSPI is greater than 0.60. The variability in measurement is ±0.17%.
3. *Segmental pressures.* It is possible to measure pressures at the ankle, calf, above knee, and upper thigh. This is done by cuffs that are placed in these locations with the sensor on the toe. The segmental pressures are used to define the level of occlusive involvement (eFig. 109.0.1). This method has been replaced by ultrasonic duplex scanning in most laboratories (5).



***e*FIGURE 109.0.1** In the presence of a left iliac artery occlusion, the left upper thigh systolic pressure is reduced. Normally, the pressure gradient between any two successive points should not exceed 20 mm Hg. BP, blood pressure.

4. *Absolute pressure levels.* It is important not only to assess the ABI and TSPI, but also to record the actual number, because it may have value from a clinical standpoint. For example, an absolute pressure of greater than 50 mm Hg is found with excellent collateral circulation. The absolute levels can also be useful in predicting when an open lesion might heal.

The ankle or toe pressures should also be measured from the arm using the same method. It is not advisable to use the stethoscopic measured arm pressure for calculation of either the ABI or the TSPI. It is now apparent that this simple measurement can be a good marker for atherosclerosis in other areas, such as the coronary/carotid artery.

Exercise Testing

The pressure recordings can be used to test the effect of exercise. Normally, the ankle systolic pressure does not decrease with moderate treadmill exercise. If occlusive disease and intermittent claudication occur, there is a drop in the ankle systolic pressure and a delayed recovery time (17,25,26 and 27). The time it takes for the ankle systolic pressure to recover is referred to as the *period of postexercise hyperemia*. It is not uncommon in cases of very severe claudication for the recovery to take more than 20 minutes.

Continuous Wave Doppler

With the development of Doppler systems, it became possible to generate information on the arterial and venous flow patterns in health and disease (8,14). The advantage of these simple systems is that they can be used at the bedside to measure ankle systolic blood pressure and assess the arterial flow patterns from the level of the tibial arteries to the external iliac artery in the leg and from the palmar circulation to the subclavian in the arm. The disadvantage of this method is that its use depends on a subjective interpretation of the audible velocity signals. However, the incorporation of this into imaging systems has produced a powerful diagnostic method that is now widely used.

TESTING PROCEDURES: ARTERIAL

Limb Blood Pressures

When a patient is first seen and suspected of having PAOD, it is necessary to measure the ABI, which provides confirmation of the presence of disease but also gives a rough index of its severity. Although presence or absence of peripheral pulses has been the major physical finding in documenting the presence of occlusive disease, this is not sufficiently sensitive or specific. That is why the simple measurement of ankle pressure and the ABI is so important. The criteria that are commonly used are as follows (28):

1. Abnormal levels are those less than 0.90.
2. An ABI of greater than 0.50 is most commonly seen with single-segment disease.
3. An ABI of less than 0.50 is commonly observed with multisegment disease.
4. For follow-up, a decrease of greater than 0.15 is consistent with disease progression. An ABI increase of greater than 0.15 is indicative of improvement in the collateral circulation.
5. If the ankle arteries are incompressible or the patient is a diabetic, the TSPI should be measured. As noted previously, this is normally greater than 0.60 (23).
6. In patients in whom it is not clear if the exercise-induced pain is due to arterial disease or some neurospinal cause, it is necessary to perform an exercise test (29). If an exercise test is performed, a normal ankle blood response is a drop of less than 20% from baseline, with recovery in less than 3 minutes. The treadmill walking time used is 2.0 mph on a 12% grade. For patients with suspected arterial disease, the maximal walking time used is 5 minutes, because this is sufficient to bring out any of the hemodynamic abnormalities. Most patients cannot walk this long even at this low workload. It is common practice to calculate the ABI after exercise, but this should not be done. The reason for this is that arm systolic pressure normally increases after exercise in proportion to the workload (17,25,26 and 27). Thus, it is only necessary to express the postexercise values in absolute units.

The most common error made by vascular laboratories is to calculate the ABI after exercise is completed. As has been noted, normally exercise induces an increase in arm systolic pressure, which, if used for the calculations, would lower the ABI, making the observer think that the testing is abnormal. After exercise, it is only necessary to measure the absolute levels of ankle systolic blood pressure.

Velocity Waveform Analysis

Because ultrasound can reach the major arteries of the upper and lower limbs, it is possible to use the CW Doppler to investigate the patterns at nearly all levels in which occlusive lesions are commonly found. Most use this method at the bedside and audibly interpret the back-scattered Doppler shift signals. It is also possible to obtain analog recordings that can provide hard copy verification. The most reliable method of analyzing the velocity patterns is by fast Fourier transform analysis. This method accurately presents the velocity information and the intensity of the back-scattered ultrasound. It is now the standard method used with Doppler ultrasound. The velocity patterns commonly observed follow.

Lower Limb

The normal velocity patterns exhibit a triphasic flow pattern from the level of the abdominal aorta to the tibial arteries at the ankle (Fig. 109.1). The three components are forward, reverse, and forward flow. If arterial occlusion is present, there will be no detectable signals from the site of involvement. Distal to the occlusion is damping of the arterial velocity patterns, with recordings showing a monophasic pattern (*e*Fig. 109.1.1). This is easily recognized by its audible characteristics.

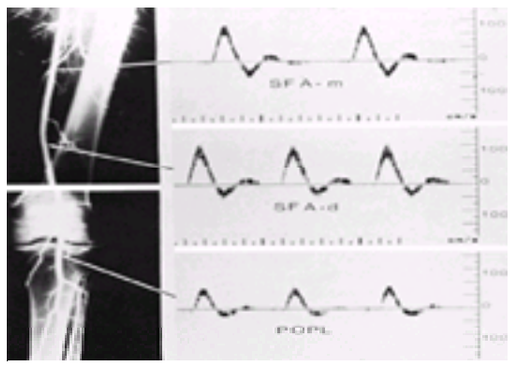


FIGURE 109.1 Hemodynamics of the normal arterial system. The normal arterial velocity patterns from the level of the abdominal aorta to the tibial arteries at the ankle are similar to those shown here. Flow is forward-reverse-forward, with a clear window beneath the systolic peak. POPL, popliteal artery; SFA-d, distal superficial femoral artery; SFA-m, medial superficial femoral artery. (From Strandness DE Jr. *Duplex scanning in vascular disorders*, 2nd ed. New York: Raven Press, 1993, with permission.)

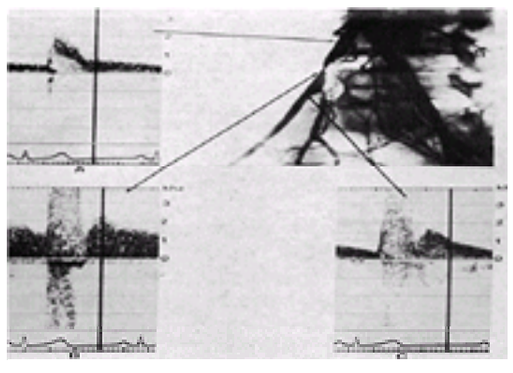


***e*FIGURE 109.1.1** At the site of the iliac artery stenosis is a marked increase in the velocity. As one moves away from the stenosis, the peak systolic velocity decreases, and the waveform becomes monophasic. **A:** Common iliac artery. **B:** Site of stenosis. **C:** External iliac artery. (From Strandness DE Jr. *Duplex scanning in vascular disorders*, 2nd ed. New York: Raven Press, 1993, with permission.)

Upper Limb

The only differences seen in the upper limb in normal subjects relate to the reverse flow component that is observed in the radial and ulnar arteries. Up to 50% of normal subjects do not have a reverse flow component at this level. The end diastolic velocity is above zero, and the waveform itself is biphasic. This is due to the fact that resistance to flow is lower than in those with the triphasic waveform. With arterial occlusion are monophasic flow patterns, as observed in the lower limb.

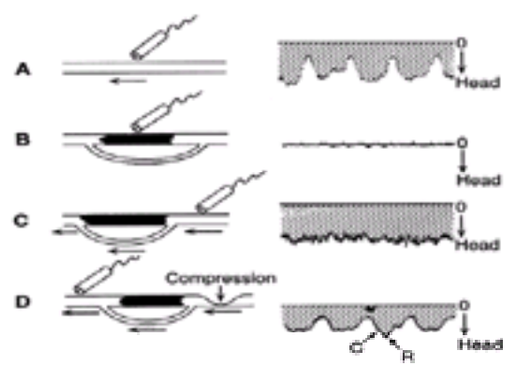
TESTING PROCEDURES: VENOUS

Acute Deep Vein Thrombosis

One of the most common vascular disorders is acute deep vein thrombosis (DVT). It affects all patient populations and is particularly common in the elderly and seriously ill patient. The major problem with DVT is the difficulty in making the diagnosis by the history and physical examination. It has been demonstrated that the bedside diagnosis is so poor that it must be established by objective means (30,31). It was to this end that indirect methods were developed to improve our recognition of this problem. The earliest methods used CW Doppler and impedance plethysmography. Their applications are as follows.

Continuous Wave Doppler

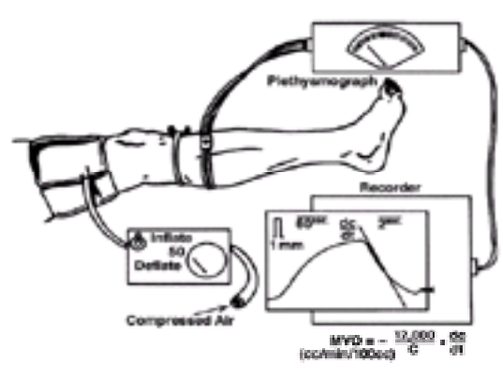
To test for acute DVT, the major deep veins (external iliac, common femoral, superficial femoral, popliteal, posterior tibial veins) are located by first identifying their companion artery. Velocity patterns in the major deep veins of the leg are phasic with respiration (30). Normally with inspiration, there is a decrease in venous flow that increases with expiration. The finding of a normal phasic flow pattern makes it very unlikely that there is an acute thrombus distal to the recording site. Of course, absence of a venous flow signal is a good sign that the vein at the site of interrogation is occluded. When listening distal to an acute occlusion, it is very common to hear continuous venous flow that no longer has a phasic flow component (32,33) (*e*Fig. 109.1.2). Its use is hampered by the subjective nature of the examination. For the experienced user, it has proved to be useful for detection of DVT of the roximal veins (popliteal to inferior vena cava). However, for calf vein thrombi, CW Doppler has a very high false-positive rate, making it unreliable in this area.



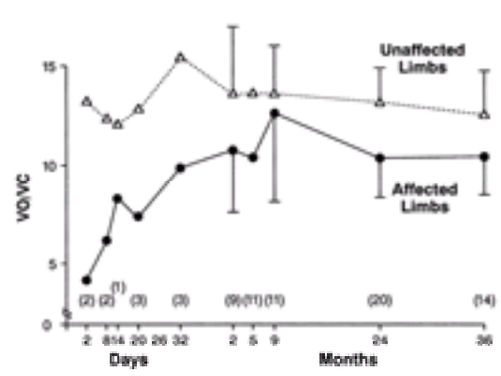
***e*FIGURE 109.1.2** Velocity patterns recorded from the normal deep veins and those affected by venous thrombosis. With the transducer over a normal vein **(A)**, flow is influenced by respiration. It decreases with inspiration and increases during expiration. With complete occlusion **(B)**, no flow is detected. With acute thrombosis and the probe placed proximal to the occlusion, flow is continuous **(C)**. With the velocity detector distal to the thrombus **(D)**, compression (C) augments flow, and release (R) results in a sudden decrease in venous flow. (From Sumner DS. Diagnosis of deep venous thrombosis. In: Rutherford RB, ed. *Vascular surgery*, 4th ed. Philadelphia: WB Saunders, 1995, with permission.)

Impedance Plethysmography

Impedance plethysmography, which has been widely tested and used as a screening test, depends on an assessment of venous outflow from the limb. This requires placing the sensor on the calf with a pneumatic cuff on the thigh (*e*Fig. 109.1.3). When the cuff is inflated to 50 mm Hg, venous volume increases. When the cuff is rapidly deflated, the rate of venous outflow can be recorded. In cases of proximal DVT, the rate of emptying is delayed (*e*Fig. 109.1.4). This method has been widely tested against venography, and it has been shown to be a useful screening test for acute DVT. The method is insensitive to venous thrombi in the calf region. In spite of its lack of sensitivity for calf vein thrombi, it has been shown that a negative impedance test is sufficient to withhold therapy.



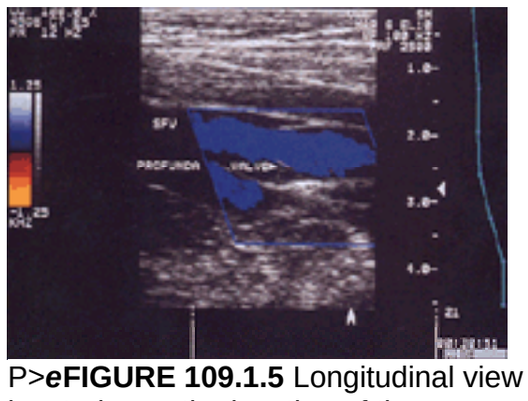
***e*FIGURE 109.1.3** Illustration of the use of a plethysmographic method to estimate the rate of venous outflow. With the thigh cuff inflated to 50 mm Hg, venous volume in the calf increases. Once it reaches a plateau, the cuff is suddenly deflated. The rate of venous outflow can be used to calculate the maximum venous outflow (MVO). In the presence of acute deep vein thrombosis, this decreases.



***e*FIGURE 109.1.4** To standardize the venous outflow data, it is useful to express the venous outflow (VO; cc per minute per 100 cc tissue) to the venous volume (VC; capacitance) at the time of cuff deflation. This is very low in patients with acute deep vein thrombosis. As thrombolysis proceeds and venous collaterals open, this tends to normalize. The numbers in parentheses reflect the numbers of patients studied at these time intervals.

Although these tests have been largely replaced by duplex scanning, they are still used in some centers and can be very helpful for the screening of patients with suspected DVT if used by personnel who understand their shortcomings.

Screening for DVT is now one of the most common examinations requested of a vascular laboratory. As the technology and study techniques have evolved, all deep veins of the lower leg can now be interrogated, including the soleal sinuses and the gastrocnemial veins. These developments provide a simple and direct way of ruling DVT in or out. The other value of this method is that it can be used to follow the progress of established DVT to monitor the rate of lysis, recanalization, and the presence of a recurrence when it occurs. In *e*Figure 109.1.5, a color Doppler longitudinal view of the junction of the common femoral/profunda femoris artery is seen. A venous valve is also visible.



P>***e*FIGURE 109.1.5** Longitudinal view of the common femoral/profunda femoris artery is shown by color Doppler. The veins are identified in blue. A valve is also seen, located near the junction of the common femoral/profunda femoris junction. SFV, superficial femoral vein.

DIRECT NONINVASIVE TESTING

Ultrasonic Duplex Scanning

The major advance in vascular testing was the development of ultrasonic duplex scanning (12,13,34,35). The method takes advantage of two ultrasonic methods, B-mode imaging and pulsed Doppler, by combining them into a single system. The major advantage of the method is that the imaging permits selective and accurate placement of the sample volume of the pulsed Doppler to sites of interest. The Doppler components of the system can now be expressed by color Doppler, power Doppler real-time fast Fourier transform spectral analysis that is used to document the velocity patterns at specific sites (36,37,38,39 and 40).

Magnetic Resonance Arteriography

Until the development of magnetic resonance arteriography (MRA), the only imaging method in common use was contrast arteriography. Because it is invasive, costly, and potentially dangerous, it is only natural that a method such as MRA would be developed. The technique that has the potential for use at all vascular beds is done with whole body imagers. Special coil designs and signal sequencing are needed and are still under evolution, but it is clear that the method will find increasing application as a potential replacement for contrast arteriography. It is possible to predict that, for certain applications, it will completely replace standard contrast studies.

Carotid Artery Screening

One of the more common problems that needs evaluation is extracranial atherosclerosis. Although there are exceptions, its most common site of involvement is the carotid bifurcation. At this site, the plaque takes its origin in the posterolateral aspect of the bulb. As it evolves, it gradually enlarges to encompass the entire bulb and undergoes degeneration to become the complicated plaque. In this form, the lesion increasingly narrows the artery, and there is frequent loss of surface covering (ulceration). At these sites, the plaque can rupture to release emboli or provide the nidus for thrombosis of the internal carotid artery to occur. Both of these events are common causes of transient ischemic attacks (TIAs) and strokes (41,42,43 and 44).

Several aspects of carotid bifurcation disease are of great interest to all cardiovascular specialists.

1. It is a common cause of stroke.
2. The results of four large, randomized clinical trials have demonstrated that carotid endarterectomy is superior to conventional medical therapy in the prevention of stroke (45,46,47,48 and 49).
3. Evidence has been found that the stroke rate following arteriography is comparable to that secondary to carotid endarterectomy.
4. The incidence of carotid disease is high in patients with coronary artery disease and peripheral artery disease.
5. Ultrasonic duplex scanning is the preferred method of screening.

RESULTS OF CLINICAL TRIALS

During the 1980s, there was considerable skepticism about the role of carotid endarterectomy in the prevention of stroke. Many prominent neurologists essentially asked for a moratorium on the operation until its efficacy had been tested by prospective clinical trials (49,50,51,52,53 and 54). As a result of this skepticism, four major trials were undertaken—two in symptomatic patients and two in asymptomatic patients. These trials are now finished; therefore, it is possible to review the results and place their conclusions in proper perspective. The major issue has now been resolved, which is that carotid endarterectomy is superior to conventional medical therapy for certain categories of lesions. However, some problems remain that affect our practice in this area. A brief summary of the results details the issues involved.

North American Symptomatic Carotid Endarterectomy Trial

The results of the North American Symptomatic Carotid Endarterectomy Trial (NASCET) were first reported in February 1991, when a stopping rule had been reached. It was clear that carotid endarterectomy was superior to medical therapy for the prevention of stroke. At 2 years, the cumulative stroke rate in the surgical group was 9%, as compared to 26% in the medical group. This was for patients with a greater than 70% diameter reducing stenosis of the internal carotid artery. Because the role of endarterectomy was uncertain for lesser degrees of stenosis, the trial was continued, and its final results were reported in 1998. The results have been modified based on longer follow-up and showed that even the 50% diameter reducing lesions had a better result with operation than conventional medical therapy (55).

European Carotid Surgery Trial

The European Carotid Surgery Trial (ECST) also included symptomatic patients, and they reported their results at nearly the same time as did NASCET. At 2 years, the stroke rate in the surgical arm of the trial was 10.3%, as compared to 16.9% in the medical arm of the study. This, as in NASCET, only applied to patients with a greater than 70% diameter reduction. This trial continued, as did NASCET, until all ranges of stenosis severity could be examined. The final report in 1999 showed that, much like NASCET, the degree of stroke risk and also the benefit from carotid endarterectomy were based on the degree of stenosis, with the very tight lesions (between 80% and 99%) benefiting most (56).

Critical Differences between These Trials

Several facts are not appreciated and must be taken into account when the results of these two trials are compared and one attempts to place them in context for

clinical practice. These factors are as follows:

1. In NASCET, randomization took place regardless of the viewpoint of the participating surgeon and neurologist (45). In the ECST study, patients were not randomized if, in the opinion of the surgeon and neurologist, the patient was best treated by operation (45).
2. The method of measuring the degree of stenosis in the two trials was entirely different (45,46). In NASCET, the distal internal carotid artery was used as the reference normal artery; in ECST, all measurements were made from the bulb itself.

A 50% diameter reduction in ECST would be a 0% stenosis in NASCET!

It has been estimated that more than 40% of the patients with a greater than 70% stenosis in ECST would be less than 70% in NASCET. What, then, should be the cutoff point for operation in this important group given the fact that both studies advocated operation for the greater than 70% lesion? This becomes even more important when the results of the asymptomatic trials are reviewed.

1. The Veterans Asymptomatic Trial (VAT) (47). This study concluded that for patients with a 50% diameter reducing lesion, the combined events (stroke, TIAs, and death) were reduced by the application of carotid endarterectomy. For stroke alone, the *p* value was .06. This trial was criticized for considering TIAs as events. They used the distal internal carotid artery as the normal reference artery when the arteriograms were read.
2. The National Institutes of Health–supported Asymptomatic Carotid Artery Surgery Trial (ACAS) (48). This trial supported the use of endarterectomy for asymptomatic patients with a greater than 60% diameter reducing stenosis. The stroke rate in the surgical arm of the trial was 2.7%. An important finding was that the risk of stroke with arteriography was 1.2%, which was only slightly less than that occurring from operation. The relative risk reduction for stroke was 55%. The morbidity from arteriography is an extremely important consideration, because it appears to carry nearly the same risk of stroke as operation. This fact cannot be dismissed lightly, even though there are studies that have shown lower complication rates. The centers that were chosen to participate in the ACAS trial were clearly good institutions with respectable records in all aspects of the trial performance. This fact should give us the impetus to consider more seriously the role of ultrasound alone or in combination with MRA before carotid endarterectomy. If this is done, the overall cost to the health system along with a reduction in morbid events could be expected.

Important differences in trial conduct and outcome need to be emphasized.

1. In the VAT trial, oculopneumoplethysmography was also performed as a part of the screening process.
2. Because of the limited numbers of patients in VAT, stratification by degree of narrowing was not possible. In NASCET, the risk of stroke went up with increasing degrees of narrowing. For example, a 90% to 99% stenosis placed the patient at greater risk than a 70% to 79% narrowing (45).
3. In ACAS, no arteriograms were performed in the medical arm of the trial. Thus, it was not possible to stratify risk of stroke by the degree of narrowing (49).
4. The cutoff point of 60% diameter reducing stenosis in ACAS was not arrived at when a compilation of events occurred. This was a predetermined cutoff point established at the outset of the trial. This degree of diameter reduction was that needed for the oculopneumoplethysmography to become positive (48).

Impact of Clinical Trials on Clinical Approach

Although the trials all suggest that endarterectomy is of benefit in the prevention of stroke, they have also created a great deal of confusion. The following questions have arisen.

1. Who should be screened? Some answers are known: (a) All patients who have symptoms that suggest carotid artery disease, (b) patients with bruits (57), and (c) individuals who are in a high-risk category for stroke should be screened. These include patients who are undergoing coronary artery bypass grafting, those with peripheral vascular disease, type 2 diabetics with a history of cardiovascular disease, and patients with renovascular hypertension (58,59). However, many questions also remain.

Considerable disagreement is found as to who should be screened. A consortium of Canadian neurologists addressed this issue and concluded that there was very little level 1 evidence to suggest screening even for patients who are normally considered to be at risk (60). This runs contrary to most specialists who deal with atherosclerotic disease in many different arterial circulations. It is clear that the presence of disease in one of the major vascular beds (coronary, peripheral, and carotid) is very likely to be associated with disease that is potentially serious in other areas. However, there is unlikely to be good evidence to suggest that screening of the general population is of value.

2. What screening procedure should be used? The NASCET investigators have suggested that ultrasound is not reliable enough to warrant its use. They maintain that contrast arteriography remains the best available method. Unfortunately, the ultrasound data from the NASCET study were seriously flawed, because there was no attempt at quality control (61).

3. When should arteriography be done? This is important because cerebral arteriography is not only costly but dangerous as well. In recent years, there has been a shift away from its routine use even in symptomatic patients, with more reliance on duplex ultrasound. In addition, there is growing evidence that carotid endarterectomy can be safely done on the basis of ultrasound alone when it is properly performed and interpreted (62,63,64 and 65).

4. Which cases demand that an arteriogram be done? This occurs in approximately 10% of cases (62): (a) unusual anatomy (coils and kinks) in which interpretation of the ultrasound studies is difficult, (b) cases in which the disease is not confined to the bulb, and (c) instances in which so much calcium is in the bulb that it is difficult to estimate the degree of stenosis.

5. What type of arteriogram should be done, and how should it be read? Selective arteriography is the most commonly done, but it provides only limited views of the bulb. Which artery should be taken as the normal reference artery? At present, most still use the distal internal carotid artery, but one must recognize that it greatly underestimates the degree of involvement. The European group has suggested that the common carotid artery now be used as the normal reference artery, but this has been rejected by the NASCET group (66,67).

6. How can one use the conflicting data on degree of diameter reduction from the clinical trials? For example, how can a 50% or 60% diameter reduction found in the VAT (47) and ACAS (48) trials be reconciled against the higher degree of stenosis found in NASCET (45) and ECST (45)? As noted previously, this is largely related to the methodology used in terms of the ultrasound and the arteriography that was used. A fact of great importance is the intra- and interobserver variability found with all of these studies. It is not possible to define with great precision the exact degree of stenosis by any of the present means at hand. For arteriography, this can be comfortably assumed to be in the ±20% range (68). In the case of ultrasound, it has been long recognized that classification of disease into rather broad categories of clinical relevance made sense. This has proved to be true.

7. What impact is MRA going to have on this field? One must remember that it is also an arteriogram in the sense that interpretation of the presented images is very similar. In addition, the signal dropout problem remains an important issue that cannot be disregarded. This can make the estimate of the true degree of diameter reduction a very difficult problem.

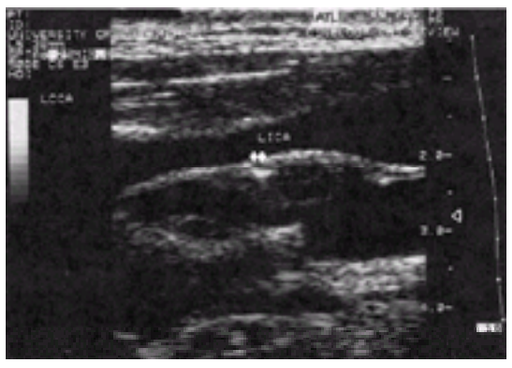
Current Clinical Approach

It is obvious that the cutoff points for each of the clinical trials is very confusing, because they seem to disagree in many respects. For example, why should a 50% or 60% diameter reduction of the carotid artery be of surgical importance in an asymptomatic patient but not apply to a symptomatic patient? This makes no sense, but that is what we are forced to live with, given the results of the randomized trials. Although calipers were used in the trials to estimate the degree of narrowing, this is not a common procedure in clinical practice.

When we introduced the use of duplex ultrasound for the evaluation of carotid artery disease, it was necessary to adapt the velocity criteria for varying degrees of stenosis (35,39,57,65). In addition, it became apparent that the method could not be used to determine precisely the degree of narrowing but could be usefully applied to determine categories of narrowing that might have relevance to clinical practice. We went through several validation trials that compared our results with cut-film selective carotid arteriograms that also included views of the aortic arch, three views of the bulb, the carotid siphon, and intracranial views (39,69,70). The categories finally arrived at (39) have been modified slightly to make them more useful clinically. The current classification scheme is as follows:

1. *Normal.* No evidence has been found on B-mode imaging of a lesion in the posterolateral aspect of the bulb. In addition, boundary layer separation has to be present.
2. *Less than 50% stenosis.* Plaque is present (with or without acoustical shadowing), but the peak systolic velocity does not exceed 125 cm per second at the site of narrowing.
3. *Narrowing of 50% to 79%.* For this category of disease, the peak systolic velocity at the site of greatest narrowing is greater than 125 cm per second, with an end

diastolic velocity of less than 140 cm per second (eFig. 109.1.6).



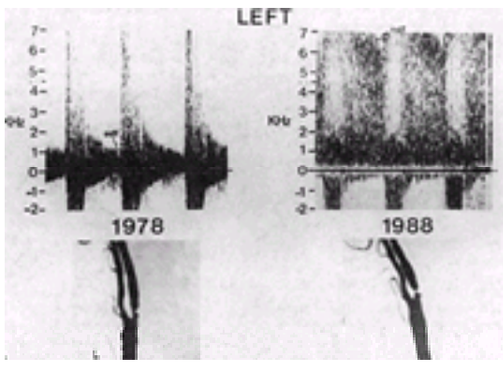
***e*FIGURE 109.1.6** This longitudinal scan of the carotid artery reveals a large heterogeneous plaque (*arrows*) in the bulb. LCCA, left common carotid artery; LICA, left internal carotid artery.

4. *Stenosis of 80% to 99%.* The end diastolic velocity exceeds 140 cm per second.
5. *Occlusion.* No detectable flow in the internal carotid artery.

How did duplex ultrasound using these criteria compare with arteriography? The best way of comparing two diagnostic tests is to calculate the kappa statistic. If there is perfect agreement, the kappa value is 1.0. If there is random distribution of values, the kappa value is 0.0. For one neuroradiologist reading the films a second time, the kappa statistic is 0.711 ± 0.054. For two neuroradiologists reading the same films, the kappa statistic is 0.568 ± 0.058. For duplex scanning and one radiologist, the kappa statistic is 0.769 ± 0.039. For most diagnostic tests used in medicine, kappa values in the range of 0.5 to 0.8 are considered to be satisfactory.

How should the data be used clinically? After several years of experience, we came to the following conclusions based on natural history studies (57,71,72,73 and 74):

1. The less than 50% diameter reducing lesions are generally of little clinical relevance and can be followed by an annual examination to document progression versus stability.
2. The 50% to 79% stenosis in an asymptomatic patient is also a relatively benign lesion, but it warrants closer follow-up. We recommend that these patients have a study performed every 6 months to assess stability of the lesion. If it progresses, the patient should be considered for endarterectomy (eFig. 109.1.7).



***e*FIGURE 109.1.7** The patient shown had his first screening examination in 1978. At that time, his carotid artery was narrowed by 50% to 79%, according to the criteria outlined. He was observed every 6 months until 1988. In the 6 months before this test, his lesion had progressed to an 80% to 99% stenosis. A carotid endarterectomy was performed at that time. (From Strandness DE Jr. *Duplex scanning in vascular disorders*, 2nd ed. New York: Raven Press, 1993, with permission.)

3. The 80% to 99% lesions are particularly dangerous and, in our view, should be considered candidates for operation.
4. The total occlusions cannot be opened surgically. However, even with an asymptomatic occlusion, the annual stroke rate on the side of the occlusion is in the range of 2% per year.

The clinical trials have posed new problems in terms of classification by ultrasound. However, it is possible to estimate the degree of stenosis defined by the trials without a major change in how the study is done. The method simply requires that the user divide the peak systolic velocity at the site of the stenosis by that found in the common carotid artery. Using this method, it has been possible to determine the 60% and 70% cutoff points defined by ACAS and NASCET.

Although one can use different cutoff points for the 60% cutoff, the author favors using a value of 3.2. This gives a positive predictive value of 85%, with a negative predictive value of 93% and overall accuracy of 89% (75).

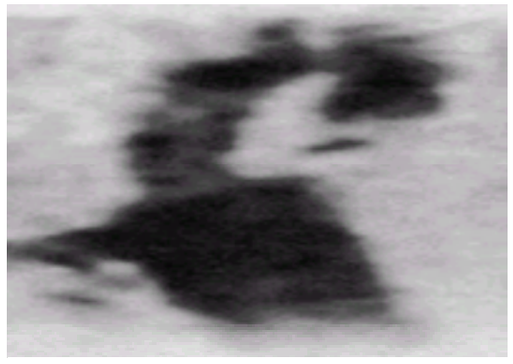
For greater than 70% stenosis, the ratio is 4.0. This provides a positive predictive value of 76%, with a negative predictive value of 96% and overall accuracy of 88% (76).

It is obvious by using receiver operator curves that different ratios can be used depending on one's personal approach to patients who might be candidates for operation. With symptomatic patients, one would not want to miss the appropriate patient. In asymptomatic patients, it is important to limit the number of invasive studies whenever possible or reasonable (75,76).

What about plaque morphology as determined by ultrasound and arteriography (42,77,78,79 and 80)? Can this be used as a surrogate finding to tell the physician which direction to go (eFig. 109.1.8)? Although it is agreed that loss of surface covering (ulceration) is a common cause for the accumulation of thrombotic debris and embolization, none of the current imaging methods is sufficiently sensitive to make them accurate enough to make this determination. Thus, one is forced at the present time to use the degree of narrowing as the sole determinant of when one should proceed with operation. Another common concept is that intraplaque hemorrhage precedes the sudden increase in size of a lesion rendering the patient symptomatic (81,82). This has also been discounted. Our own studies suggest that the most important factor to determine outcome of a stenotic lesion is the fibrous cap (83,84,85,86,87 and 88). If it remains intact, one has little to worry about. On the other hand, if it disrupts, the outcome depends on the material that is forced into the cerebral circulation. This could be thrombus, necrotic debris with cholesterol crystals, or lipid. The challenge over the next decade is to develop methods of studying the fibrous cap *in vivo*.

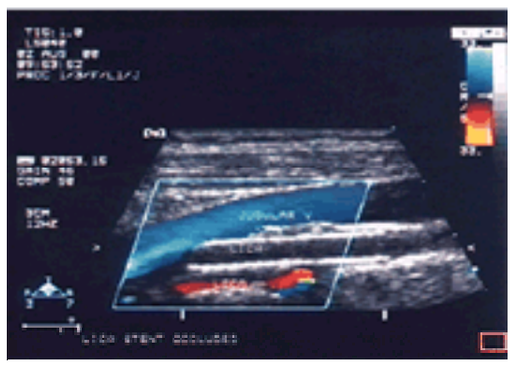
***e*FIGURE 109.1.8** A cross-sectional view of the common carotid artery. On the anterior wall is a large uniform plaque. This is a fibrous lesion that is benign. Contrast the appearance of this lesion with that shown in eFigure 109.1.6.

MRA is the latest method that is available for visualization of the carotid bifurcation. It is attractive because it is totally noninvasive and offers the opportunity of replacing conventional arteriography that will totally eliminate the risk and also lower the cost. The problem, however, is as shown in *e*Figure 109.1.9. As the degree of stenosis increases, there is often signal dropout, making it impossible to estimate the degree of diameter reduction.



***e*FIGURE 109.1.9** This magnetic resonance arteriogram (MRA) of the carotid bulb and internal carotid artery demonstrates the signal dropout commonly seen with MRA studies of stenoses. This makes it difficult to determine the degree of narrowing at that site.

Since the first edition of this book, there have been some dramatic changes in how carotid bifurcation disease might be treated. Interest in the use of stents to treat carotid bifurcation disease has increased. The procedure involves angioplasty that incorporates the stent to hold the artery in its newly distended position. Claims as to safety and efficacy vary widely, with some suggesting that this procedure will be as safe as endarterectomy and others providing a different picture. Another compounding problem is the realization that a retrieval device should be used distal to the carotid bifurcation to collect the debris that might be released when the lesion is dilated. These are all under testing. Most important, a National Institutes of Health–supported trial has been mounted to evaluate this procedure in symptomatic patients [Carotid Revascularization Endarterectomy vs. Stent Trial (CREST)]. The trial is randomized, and it is hoped that it will provide an answer to this problem. In *e*Figure 109.1.10, a color duplex study is shown visualizing the jugular vein, an internal carotid artery with a stent that is occluded (no flow seen within the stent), and a patent external carotid artery.



***e*FIGURE 109.1.10** Longitudinal view of the carotid artery with a stent in place in the internal carotid artery. The color flow shows that the left internal carotid artery (LICA) with the stent in place is occluded. The flow in the left external carotid artery (LECA) and the jugular vein is noted.

UPPER AND LOWER EXTREMITY ARTERIAL DISEASE

Arm

At the outset, it can be stated with certainty that the upper extremity is largely spared the ravages of atherosclerosis, except for the involvement of the subclavian artery at its origin. Even when the subclavian artery is totally occluded, it is unusual for this to lead to any symptoms at all. Surprisingly, arm claudication is rare, probably due to the fact that the vertebral artery, which serves as an excellent collateral source of blood to the arm, is sufficient to maintain the arm pain free even with exercise. If there is an anomalous origin of the vertebral artery from the arch of the aorta, claudication is commonly seen. However, this is rare (89).

What about the role of reverse flow in the vertebral artery and its place in the development of vertebrobasilar insufficiency? Again, although reverse flow is common in the vertebral artery with subclavian artery disease, it is rarely the cause of posterior circulation symptoms.

How does one recognize or suspect the presence of a subclavian artery stenosis or occlusion? Several clues may be found, some of which are as follows:

1. The presence of a supraclavicular bruit.
2. A differential in arm systolic pressure of 15 mm Hg or greater on the side of the disease.
3. A monophasic brachial artery velocity pattern.
4. The demonstration of a stenosis or occlusion by duplex scanning. With this method, it is also possible to document the direction of blood flow in the ipsilateral vertebral artery.

Leg

PAOD is very common in the Western world. The atherosclerosis that is responsible affects specific arteries more frequently than others and is magnified in the presence of diabetes. Although specific problems are associated with this disease, it must be recognized that it can be present without producing any symptoms at all. When it is a clinical problem, it presents in one or two ways, or both. The most common is pain with walking (intermittent claudication) or with critical ischemia (90,91). The latter is simply described as ischemia that is sufficient to warrant an amputation unless more blood can be brought to the limb.

It is important to emphasize the differences in the disease patterns between diabetics and nondiabetics. These are as follows:

1. A peripheral neuropathy is seen in up to 40% of patients with diabetes mellitus who also have PAOD (92).
2. In diabetics, there is a much higher incidence of medial calcification of the tibial and peroneal arteries (23).
3. The presence of medial calcification and the occlusive lesions of atherosclerosis are not related.
4. The occlusive lesions are much more common in the tibial and peroneal arteries of diabetics, with similar extent of involvement of the superficial femoral artery. Interestingly, less occlusive disease is found in the aorto-iliac segments in diabetic patients (92,93).

These factors are important to understand when considering the need for, or the understanding of, the noninvasive tests that are to be performed. It is necessary to realize that the indirect and direct testing procedures are of value here. It should be understood that patients with acute ischemia (due to emboli or thrombosis) demand immediate attention when compared to those with the chronic form of the disease.

Acute Limb Ischemia

When a patient has acute limb ischemia, the physician has to provide immediate action, because delays lead to progressive ischemia and tissue loss. In the past, the

majority of cases of acute ischemia were secondary to emboli from the heart. Although this still occurs, acute thrombosis in the setting of atherosclerosis or from emboli that arise from an ulcerated plaque is much more common. The common complaints in this setting are pain, paresthesias, paralysis plus pallor, and pulselessness. If the acute ischemia is critical, the physician must realize that progressive tissue death will begin within the 4- to 6-hour time frame. It is also important to realize that the muscles begin to die first, with the skin coming later.

The CW Doppler is particularly important in assessing the location of the occlusion and the extent of the available collateral circulation. As noted earlier, the normal ABI is 1.0 or greater. With acute ischemia, the following guidelines are useful:

1. An absolute systolic pressure of 50 mm Hg or greater at the ankle is reassuring evidence that the collateral circulation is adequate for tissue viability.
2. Ankle systolic pressures of less than 50 mm Hg. It is important to realize that the collateral circulation is marginal.
3. The absence of flow signals from the dorsalis pedis, posterior tibial, and peroneal arteries at the ankle is worrisome. This indicates either occlusion of these three arteries or marked compromise of the collateral inflow to the limb.
4. If the ABI of the uninvolved limb is normal, this suggests that the cause of the occlusion in the symptomatic limb may be due to emboli.
5. A survey of the major arteries (common femoral, superficial femoral, popliteal, and tibial) provides information on the most proximal level of involvement.
6. In some cases, it is helpful to carry out an ultrasonic duplex scan to document further the site of occlusion.

One of the major considerations with acute arterial occlusions relates to when and how one should intervene. Should the patient have an arteriogram and when? If the limb is severely ischemic, any delays before flow is restored can have a disastrous outcome. The physical examination of pulse level and a survey with the CW Doppler inform the physician concerning the segment(s) that are most likely occluded. Immediate operation with a confirmatory intraoperative arteriogram is a very satisfactory approach to rapid restoration of blood flow.

Chronic Limb Ischemia

Patients who present with either intermittent claudication or critical ischemia are first evaluated by the standard clinical evaluation and measurement of the ABI. If some form of intervention is going to be required, it has become a standard practice to carry out an ultrasonic duplex scan (94,95,96,97 and 98). With improvement in the technology and availability of a wide variety of transmitting frequencies and scan heads, it is now possible to assess the arterial flow from the level of the abdominal aorta to the tibial arteries at the ankle. From a clinical standpoint, the lesions that are of interest are total occlusions and stenoses that narrow the artery by more than 50% in terms of diameter reduction. The scans are done with the following guidelines in mind (94):

1. Isolated stenoses/short occlusions of the aorta/common iliac arteries are best treated by angioplasty.
2. Long occlusions of the aorto-iliac system are best treated by operative means.
3. Lesions that are distal to the inguinal ligament are best treated by surgical means.
4. Combined disease of the aorto-iliac and femoropopliteal segment can best be treated by angioplasty for the proximal lesions and bypass grafting for the below–inguinal ligament lesions.

The screening procedure used relies primarily on the following parameters for making a determination of the degree of involvement:

1. A triphasic velocity waveform is good evidence of a normal arterial system proximal to the recording site (89).
2. The degree of stenosis is estimated by noting the following changes.
3. For the stenoses that are less than 50% in terms of diameter reduction, the velocity pattern at the site of narrowing shows an increase of 30% to 100% in the peak systolic velocity with preservation of the reverse flow component (94,95,97).
4. For greater than 50% stenosis, the peak systolic velocity increases by more than 100% with loss of the reverse flow component (94,99) (Fig. 109.2).

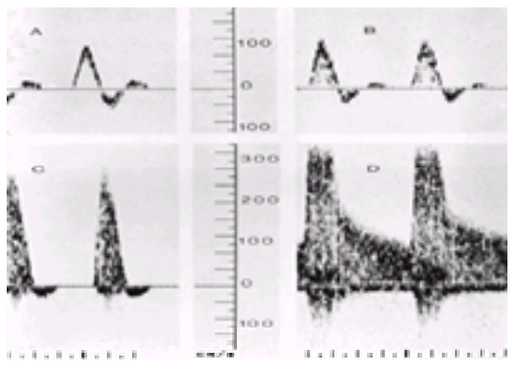


FIGURE 109.2 Velocity patterns recorded from peripheral arteries. In **A**, a normal triphasic waveform is shown. With a 1% to 19% narrowing **(B)**, the only change observed is some slight spectral broadening. When the stenosis is in the 16% to 49% diameter reducing range **(C)**, there is a peak systolic velocity change between 30% and 100% from the immediately adjacent proximal artery. Flow reversal is often preserved, but spectral broadening will be noted. With a greater than 50% stenosis **(D)**, the peak systolic velocity increases by an amount greater than 100% from the adjacent proximal artery. The reverse flow is now gone, and there is marked spectral broadening. (From Strandness DE Jr. *Duplex scanning in vascular disorders*, 2nd ed. New York: Raven Press, 1993, with permission.)

5. With total occlusion, no flow is detected.

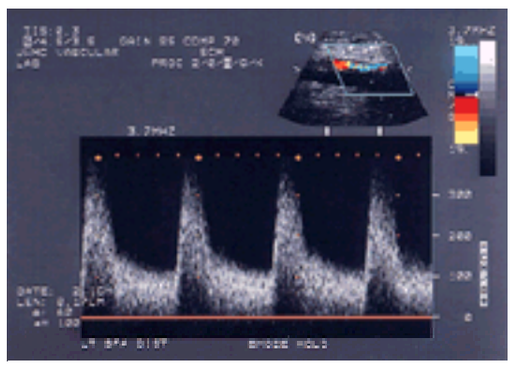
The prospective studies that have been done comparing the results with arteriography have given the results shown in Table 109.1. This scanning procedure has been useful not only in identifying the procedure that is most likely to succeed but in providing the necessary baseline data to assess the long-term outcome. Another major advantage of duplex scanning is that it is possible to carry out saphenous vein mapping. The most satisfactory method of treating lesions distal to the inguinal ligament is to use the saphenous vein. However, it is not possible to assess its suitability in terms of diameter and length without some imaging method. Duplex is ideal because it can provide both bits of information along with marking their course on the skin (100). In instances in which the leg veins may be inadequate, or if they had been previously stripped or used for other bypass procedures, it is also possible to scan the arms for suitable conduits. This procedure also is being used by cardiac surgeons, who may need to know the status of available veins for coronary bypass grafting.

Arterial segment	Sensitivity (%)	Specificity (%)	Positive predictive value (%)	Negative predictive value (%)
Iliac	94	95	94	95
Common femoral	96	100	100	91
Profunda	33	91	40	88
Superficial femoral–proximal	95	100	100	93
Superficial femoral–mid	100	94	82	100
Superficial femoral–distal	91	85	78	94
Popliteal	91	85	78	94
All segments	87	94	88	93

TABLE 109.1 COMPARISON BETWEEN ULTRASONIC DUPLEX SCANNING AND ARTERIOGRAPHY IN DETECTING A LESS THAN OR GREATER THAN 50% DIAMETER REDUCING STENOSIS

Progress in this area is also moving rapidly, with more frequent attempts to bypass preoperative arteriography and proceed directly to the operating room for direct repair with or without concomitant use of an endovascular procedure. This approach has several advantages, which include a marked reduction in cost to the patient and health-care system as well as avoidance of the potential risks. However, this approach requires expert duplex scanning to be done that can accurately document the site(s) of involvement. This approach is clearly feasible in some situations now, and these relate to the presence of single-segment occlusive disease without significant inflow or outflow problems. In *e*Figure 109.2.1, a color Doppler view of the superficial femoral artery is shown that was taken at the site of the

narrowing. The admixture of colors plus the finding of a peak systolic velocity exceeding 300 cm per second indicate that this is a pressure- or flow-reducing lesion.



***e*FIGURE 109.2.1** Color duplex study shows the narrowing in the superficial femoral artery. The admixture of colors distal to the stenosis is consistent with a stenosis. The peak systolic velocity at the site of the stenosis is approximately 300 cm per second, which is also consistent with a hemodynamically significant stenosis.

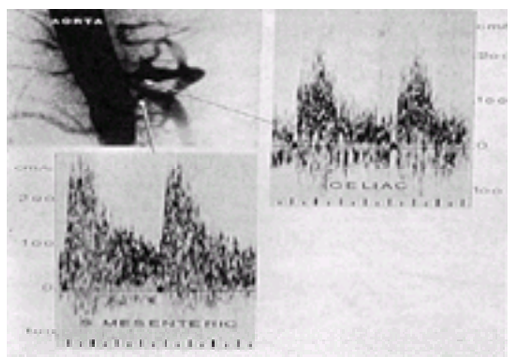
VISCERAL ARTERIAL STUDIES

The two common areas in the abdomen that are frequently the sites of atherosclerotic narrowing and occlusion are the mesenteric arteries and the renal arteries.

Mesenteric Arteries

Involvement of the mesenteric arteries (celiac, superior, and inferior mesenteric arteries) is responsible for two major clinical problems: acute mesenteric ischemia and chronic mesenteric angina (fear of food syndrome) (101,102,103,104,105 and 106). Although involvement of these arteries is common, the clinical syndromes are uncommon due to the excellent collateral circulation that exists between the major inputs to the gut. In fact, it is now well appreciated that one must have involvement of all three major vessels for intestinal angina to occur. Acute mesenteric ischemia is most often secondary to embolic occlusion and results in a dramatic clinical presentation that demands immediate attention. The urgency of this situation does not lend itself to noninvasive studies.

Chronic mesenteric angina is represented by the fear of food syndrome. Patients find that cramping abdominal pain and diarrhea develop when they eat. This results in dramatic weight loss. Although the diagnosis may be quite clear in some instances, in many cases symptoms develop that suggest the diagnosis and some independent method of evaluation is demanded. The only established method of making this diagnosis is to perform lateral aortography with visualization of the origins and the first few centimeters of the celiac and superior mesenteric arteries (eFig. 109.2.2). The advantage of duplex scanning is that the same arteries can be interrogated to assess their status. In the author's experience, if the syndrome is present, there must be very-high-grade stenoses or occlusions of both of these vessels (101,102,103,104,105 and 106). Recently, it has also been possible to assess the inferior mesenteric artery.



***e*FIGURE 109.2.2** Lateral aortogram shows high-grade lesions of the celiac and the superior mesenteric arteries. The corresponding velocity signals show marked increases in the peak systolic velocities with associated spectral broadening.

Renal Arteries

Although patients with renovascular hypertension constitute approximately 5% of the total population with hypertension, detection by noninvasive means has traditionally been difficult (107). In fact, it is agreed that the most certain method of establishing disease of the renal arteries has been arteriography. Most screening tests have not been very useful because of their poor predictive value. With the availability of lower-frequency scan heads (2.0 to 3.5 MHz) and color Doppler, it is not only possible to reach the renal arteries but to assess the presence of disease and its contribution to the parenchyma. The guidelines that have been worked out for detecting and grading the degree of stenosis are as follows:

1. The normal peak systolic velocity in the abdominal aorta at the level of the renal arteries is in the range of 100 cm per second. The variability is rather broad (±20%), making the absolute values less useful for quantitating the degree of stenosis.
2. To avoid unnecessary false-positive tests that might lead to arteriography, we elected to use a peak systolic velocity of 180 cm per second as the cutoff point for detecting narrowing. This value is 2.5 standard deviations above normal. If, at any point along the length of the renal artery, a value greater than 180 cm per second is found, the patient is classified as having renal artery stenosis (108) (Table 109.2).

Duplex	Normal	Disease	Total
Velocity <180 cm/s	9	4	13
Velocity >180 cm/s	1	60	61
Total	10	64	74

[a]Sensitivity: 94%; specificity: 90%; accuracy: 93%.

TABLE 109.2 RESULTS OF USING 180-CM-PER-SECOND PEAK SYSTOLIC VELOCITY FOR THE CUTOFF POINT OF DETECTING A RENAL ARTERY STENOSIS[a]

3. Because the development of hypertension depends on the presence of a high-grade stenosis (greater than 60% diameter reduction), it is important to have criteria for detecting this degree of narrowing. It has been found that if the ratio of the peak systolic velocity at the site of the stenosis divided by that recorded from the aorta at the level of the renal artery (the renal-aortic ratio) exceeds 3.5, the stenosis is classified as being greater than 60% in terms of diameter reduction (Table 109.3, Fig. 109.3).

Duplex	<60% diameter reduction	>60% diameter reduction	Occluded	Total
RAR <3.5	15	3	1	19
RAR >3.5	11	45	0	55
Occluded	0	0	10	10
Total	26	48	11	85

RAR, renal-aortic ratio.
[a]Sensitivity: 92%; specificity: 98%; accuracy: 91%.

TABLE 109.3 COMPARISON OF DUPLEX SCANNING VERSUS ARTERIOGRAPHY FOR DETECTION OF A GREATER THAN 60% DIAMETER REDUCING STENOSIS[a]

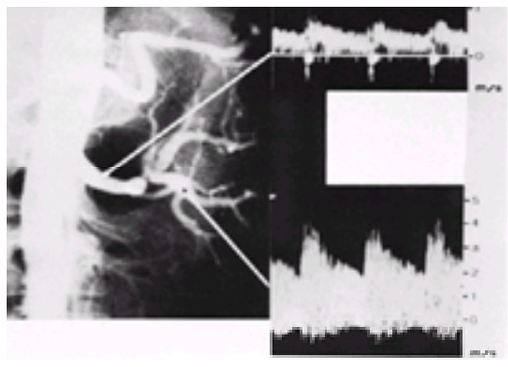


FIGURE 109.3 Velocity patterns recorded at the level of the renal hilus show a dramatic increase in peak systolic velocity (renal-aortic ratio less than 3.5). This is a case of fibromuscular hyperplasia (see text). (From Strandness DE Jr. *Duplex scanning in vascular disorders*, 2nd ed. New York: Raven Press; 1993, with permission.)

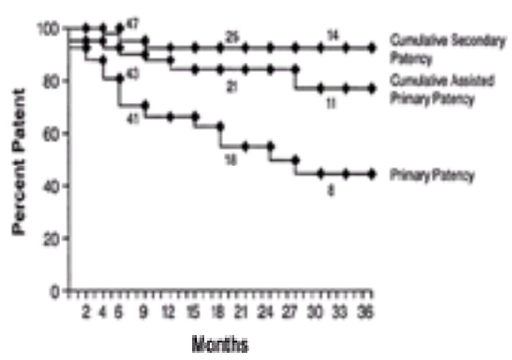
4. The inability to detect flow from the renal artery and finding a kidney less than 9.0 cm in length are taken as evidence of renal artery occlusion.
5. It is also important to measure the end diastolic ratio, which is the peak systolic velocity divided by the end diastolic velocity. The normal value is 0.34. This should be recorded from the distal renal artery and the parenchyma of the kidney itself. It reflects the parenchymal renal resistance and may be useful in predicting the response to revascularization. In patients with fibromuscular dysplasia, the end diastolic ratio is always normal, whereas in patients with renal atherosclerosis, it is often low.
6. For all follow-up studies, it is important to assess renal length. It has been shown that with greater than 60% diameter reducing lesions, there is often a loss of renal mass. This fact may well indicate the need for earlier intervention to preserve renal function (109).

Considerable progress has been made in identifying lesions in the renal artery and in predicting the long-term outcome without intervention. It is clear that the high-grade lesions not only are very prone to progress but are frequently followed by loss of renal mass (110,111). We have also come to realize the effect of parenchymal disease on the entire process and the results of intervention, be it surgical or interventional. Patients with atherosclerotic renal artery disease very commonly have arteriolar nephrosclerosis as a complicating feature. This makes the outcome of any form of intervention unpredictable. In contrast, patients with fibromuscular hyperplasia have an entirely different course. Although high-grade lesions and hypertension develop, parenchymal disease does not occur, and patients usually receive an excellent result from renal angioplasty. In addition, individuals with fibromuscular dysplasia do not progress to renal artery occlusion and do not end up in renal failure.

As with the carotid artery, there is increasing interest in the use of stents in the renal artery as the first form of intervention to be used. Several trials approved by the U.S. Food and Drug Administration are currently under way to document the role of this approach. In these trials, ultrasonic duplex scanning has become an important method of screening before intervention and a method of follow-up. Although there is general agreement that surgical repairs of the renal artery are very effective, the procedure itself carries a significant morbidity and mortality. For this reason, angioplasty and stenting deserve careful examination. If restenosis with persistence of hypertension remains a problem, this area needs to be reexamined.

Vein Graft Surveillance

It has been found that the longevity of saphenous vein grafts that are used to bypass occlusions in the leg can be increased by frequent duplex ultrasound surveillance, particularly during the first year (112,113,114 and 115). It has also been shown that up to 80% of vein grafts develop a lesion within the first 6 months. Not all of these fibromuscular lesions go on to narrow the graft progressively and lead to thrombosis, but by correcting the higher-grade lesions, the assisted secondary patency at 3 years will be in the range of 90% (eFig. 109.3.1). The criteria used to define the degree of stenosis depend on the ratio of the peak systolic velocity just proximal to a lesion divided into that found at the site of the lesion. We have found that a ratio of 3:5 is predictive of a high-grade (greater than 75% diameter reduction) stenosis that should be corrected by either transluminal angioplasty or direct surgical repair.



***e*FIGURE 109.3.1** Life table analysis of primary, cumulative assisted primary, and cumulative secondary patency rates for 61 grafts followed by ultrasonic duplex scanning to detect the development of fibromuscular dysplastic lesions (see text). COMMONLY PERFORMED PROCEDURES: VENOUS

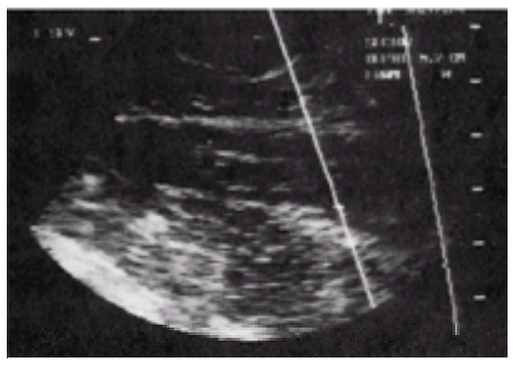
Screening for Acute Deep Vein Thrombosis

The introduction of duplex ultrasound with color Doppler has revolutionized our diagnostic approach to this very important area of vascular disease (116,117). This method has, in fact, eliminated the need for contrast venography, which is a real advance in this field. To be successfully applied, the method takes advantage of two modalities, the B-mode image and the flow patterns. The criteria for each segment of the venous circulation are as follows:

1. Thrombus visualization. In 50% of cases of acute DVT, the thrombus itself can be visualized (eFig. 109.3.2). Although it is tempting to try to age the thrombus on the basis of its echogenic characteristics, this must be done with care. It appears that the earlier thrombi are more uniformly echogenic, but this does not indicate the age

of the thrombus or when it may have started.



***e*FIGURE 109.3.2** Longitudinal B-mode image of the superficial femoral vein shows the presence of a large nonocclusive thrombus. (From Strandness DE Jr. *Duplex scanning in vascular disorders*, 2nd ed. New York: Raven Press; 1993, with permission.)

2. Because not all thrombi can be seen on the image, the second maneuver that is carried out is to test the compressibility of the visualized segment. If the two walls of the vein can be completely coapted, it is assumed that no thrombi are present. In some areas, compression is not feasible. These include the superficial femoral vein in the adductor canal and the iliac veins and the inferior vena cava. One must depend on thrombus visualization and the flow patterns to establish the status of these segments.

3. As noted in the section Continuous Wave Doppler, the venous flow patterns are also very useful in establishing the presence of acute DVT (118). These, as noted, are related to the spontaneity of the flow and its relationship to respiration. The one area where flow cannot be used effectively is for the deep veins of the calf. Here, flow under resting conditions is so low that spontaneous venous flow signals may not be seen even in normal subjects. The criteria for occlusion depend on compressibility and the appearance of flow with augmentation that is performed by compressing the limb distal to the site of probe placement.

4. One area of concern at the time of the original appearance of this text was the problems related to studying the veins of the calf. These are small paired veins, and with imaging alone they are often difficult to visualize. However, with the availability of color Doppler, it is now feasible to study this area as well. It is also possible to document the status of the soleal sinuses and the gastrocnemial veins.

With the availability of this testing procedure, physicians are more willing to request the test. In our early experience with this method, the positive yield for the procedure was in the range of 25% (119). The overall accuracy of the method for the detection of acute venous thrombosis is shown in Table 109.4.

	Contrast venography	Sensitivity (%)	Specificity (%)	Positive predictive value (%)	Negative predictive value (%)
Thrombus visualization	n = 38	1938 (5)	1772 (85)	1938 (95)	1128 (57)
Incompressibility	n = 38	3038 (75)	872 (87)	3038 (98)	616 (50)

TABLE 109.4 ACCURACY OF THROMBUS VISUALIZATION AND INCOMPRESSIBILITY IN DETECTING ACUTE DEEP VEIN THROMBOSIS

This is another area that is moving rapidly, in large part due to the availability of low-molecular-weight heparin, which permits some patients with DVT to be treated as outpatients. The sensitivity of the testing has led to the question of how to deal with isolated calf vein thrombosis. Is it necessary to treat and for how long? Opinion is divided on this subject due to the fact that thrombi below the knee rarely lead to serious and fatal pulmonary embolism. What is not known relates to the role of the veins in this location to the development of the postthrombotic syndrome. This question will be answered in the years to come.

Chronic Venous Disease

Patients who require some form of evaluation represent three major categories: those with primary varicose veins, those with secondary varicose veins, and those with the postthrombotic syndrome. Distinct ultrasonic features assist in proper classification of these patients. For each of these categories, it is necessary to establish the integrity of the venous valves at all levels of the limb (superficial and deep) (120). To do this, a variety of maneuvers can be used to establish valve competency. These are as follows:

Venous stasis eczema. Stasis dermatitis as a result of chronic edema and venous incompetence. There is erythema, scaling, pigmentation, crusting, and exudation.

1. Reflux with performance of Valsalva's maneuver. By suddenly increasing intraabdominal pressure, it is possible to detect reversal of flow in veins with incompetent valves. The problem with this maneuver is that one competent valve in the iliac veins may prevent the detection of incompetence in valves in the common femoral and superficial femoral vein. It is only reliable for the common and superficial femoral veins. This method does not permit quantification of the degree of reflux.

2. For the popliteal and distal vein valves, forceful limb compression is used. The principle is the same as for Valsalva's maneuver. The sudden creation of a reverse pressure gradient promotes reflux if the valves are unable to coapt completely.

3. To provide a quantitative method, a cuff method was developed that was performed in the upright position. The procedure is as follows (121,122): (a) Cuffs are placed at the thigh, below the knee, at the ankle, and on the foot, and (b) with the patient upright and the limb to be tested non-weight bearing, the cuffs are rapidly inflated to different pressures. For example, the 24-cm thigh cuff is inflated to 80 mm Hg, the 12-cm calf and ankle cuff to 100 mm Hg, and the 7-cm foot cuff to 120 mm Hg. The key is rapid inflation and deflation. The inflation time is 3 seconds, with deflation taking only 0.3 second.

4. To document reflux, the duplex transducer is placed proximal to the cuff itself. With cuff deflation, there is a reversal of the pressure gradient, with reversal of flow attempting to replace the volume displaced by cuff inflation.

When this procedure was used on 30 normal legs, 95% of the times taken for venous valve closure were less than 0.5 second. The veins tested were the common femoral, superficial femoral, profunda femoris, popliteal, and posterior tibial at the calf and ankle level. This method has the advantage of examining the entire venous system segment by segment from the groin to the ankle. The greater and lesser saphenous veins can also be evaluated

These methods of study are used for the evaluation of the location and extent of valvular incompetence. This is particularly helpful for documenting the changes that occur with acute DVT, the effects of spontaneous thrombolysis, and the long-term sequelae of acute DVT (123,124 and 125).

Given the availability of duplex ultrasound for the sequential study of acute DVT, it became possible to follow patients on a regular basis from the time of the event to document the long-term outcome. One of the first things to be discovered was that spontaneous thrombolysis was much more common than was previously suspected and could have a dramatic effect on long-term outcome. Killewich et al. (123) found that among 21 patients followed sequentially, recanalization developed by 7 days in 44% and in 100% by 90 days. The percentage of initially involved segments that remained occluded decreased to a mean of 44% by 30 days and 14% by 90 days. This finding may well explain what Browse et al. had observed in 1981 (126). They noted that there did not appear to be any relationship between the extent of the original thrombosis and long-term outcome, namely, the development of the postthrombotic syndrome. Spontaneous lysis must play a large role in the long-term outcome.

In addition, repeat duplex ultrasound studies have permitted a look at venous valve function and its relationship to the timing of recanalization and the rate of spontaneous lysis. Markel et al. (127) and Meissner et al. (128) have clearly shown a relationship between the rate of thrombus lysis and retention of venous valve competence. Van Ramshorst et al. (124) noted a similar decrease in thrombus load in the first 6 months after the acute DVT. Recanalization with reestablishment of flow occurred in 87% of the 23 completely occluded segments.

Johnson et al. (125) examined the relationship between the dynamic changes that occur and the long-term outcome in 78 patients (83 legs) followed by sequential studies for a median of 3 years. At the time of the last visit, 49 limbs (59%) were free of symptoms. Interestingly, 12% of the previously occluded limbs had no ultrasound evidence of chronic venous disease—they were entirely normal. The 41% of limbs that had evidence of the postthrombotic syndrome had more than three times the odds of having combined reflux and residual obstruction.

These studies clearly point out the need not only for the initial screening examination, but also for a repeat study at the time of completion of therapy. It is only then that one will be able to predict the long-term outcome and advise the patient as to the lifetime outcome. These studies are also important in those patients who may come back with recurrent symptoms that are suggestive of recurrent venous thrombosis. This occurs in up to 10% of patients who are given conventional anticoagulant therapy.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Is Noninvasive Testing Necessary?

When noninvasive testing for peripheral vascular disease was introduced, there was an enormous amount of resistance to this whole effort. This was largely due to the fact that the medical community had come to depend on a careful history and physical examination followed by angiography to establish the diagnosis. This became the only accepted method for planning therapy, for all vascular beds on the arterial and venous side of the circulation. The ideas and techniques for documenting the role of noninvasive testing gradually took hold and, with the introduction of ultrasonic duplex scanning, the progress and its acceptance became accelerated, and this process is continuing even today. It is my view that now, with the widespread availability of these newer devices along with trained people to use them, they are and will become even more important fixtures in our armamentarium. I do not believe that I could practice high-quality medicine without these devices and techniques.

Noninvasive Testing Alone before Surgical Intervention

We are beginning to see a revolution in the area of noninvasive testing alone before surgical intervention. It is now clear that increasing numbers of centers are starting to perform procedures such as carotid endarterectomy without the benefit of arteriography. Even a few years ago, this would have been considered heresy, and today many critics of this approach are still to be found. Why has the scene begun to change and what might be its impact? Studies have shown that contrast arteriograms are unduly costly and potentially dangerous, a fact that we all knew but were willing to accept because there was little else available (62,63). Now, it is common in centers with good quality control to perform carotid endarterectomy without the benefit of arteriography. This is going to continue into the future and will be extended to other vascular beds as well. Another striking change is the acceptance of duplex imaging alone for patients in clinical trials randomized to the surgical arm of the trial. This represents a major change.

Role of the Technologist

One of the major problems with ultrasound methods is that they are very operator dependent. The outcome of any study is entirely dependent on the skill of the examiner. Traditionally, tests performed by technologists have been finally interpreted by a physician, who either reviews the study directly or reviews hard copy output from key parts of the study. For example, for most radiologic examinations, the technologist performs the x-ray in a standard method and then gives it to the radiologist for review. This is entirely different with vascular ultrasound.

The entire examination is performed by the technologist, who follows certain guidelines, but these must be used and often modified in the context of what is being observed. In addition, the technologist must have a good grasp of regional anatomy and physiology in health and disease. At the end of each examination, the technologist has to formulate an impression based on the findings. Although this information is given to the physician for final review and approval, it is rare for the physician to change the impression of the examining technologist. This level of responsibility has caused considerable concern, particularly on the part of the radiology community members, who feel very uncomfortable from a diagnostic standpoint with the inroads made by these non-MDs. It is this level of responsibility that makes these technologists so important. They recognize their duty and level of responsibility. They generally do it very well and form the backbone of every good vascular diagnostic laboratory.

A very important step in improving quality control in this area was the establishment of the Intersocietal Commission for the Voluntary Accreditation of Vascular Laboratories. This independent reviewing body has representatives of all of the major specialty groups on its board. Certification is a very difficult job, requiring a great deal of work on the part of the laboratory that is requesting certification. Certification is for 3 years only. This program is moving forward very rapidly and will, in my view, create a ripple effect in the medical community concerning standards of performance for diagnostic methods of this type.

Role of Long-Term Studies

In cardiovascular disease, the era of treating and then discharging a patient without objective evaluation of the results must become a thing of the past. Patients who have these chronic illnesses must be under constant surveillance, and repeat studies must be performed whenever necessary to document outcome. Much of the confusion over certain forms of therapy has occurred because of the lack of objective follow-up. It now appears that we have made a major advance in attitude over the methods of follow-up. For example, in the stent trials that are currently under way, (carotid and renal) ultrasonic duplex scanning is accepted as the method. It is clear that one cannot resort to using blood pressure response alone as an index of technical and physiologic success.

The past 20 years have seen the rapid proliferation of diagnostic methods for the evaluation of vascular disease. The field has matured, and the poorer methods have been quickly replaced by more effective techniques such as ultrasonic duplex scanning. In addition, there has been a slow but deliberate movement to get away from the invasive angiographic approaches. This has been most successful in the field of acute DVT, for which venography is only rarely performed today in the United

States. As noted earlier, there are other areas, such as carotid bifurcation, in which contrast studies are being done less and less.

From a diagnostic standpoint, the only new methods that might alter the way we do business in the future revolve around intravascular ultrasound, spiral CT scanning, and magnetic resonance imaging (MRI) and angiography. These are all imaging methods that, at present, provide anatomic information alone. One fact that is not often remembered about such methods is the difficulty in quantitating the images themselves. Each of these methods has an application that can be of assistance for specific applications, some of which are as follows:

1. Intravascular ultrasound. Although currently in limited use, it appears to have found a place for the immediate evaluation of transluminal angioplasty with or without stenting. For example, after an iliac artery percutaneous transluminal angioplasty, visualization by the use of intravascular ultrasound may permit the detection of a dissection that can be corrected by the placement of a stent. Another very controversial area in which this has been recommended is for carotid artery angioplasty and stenting. Here, as in the iliac arteries, the ultrasound could be used to determine to what extent the stent has been properly placed and seated with regard to the walls of the arteries themselves. However, it is not clear even now whether this type of study is essential. It is apparent that endovascular grafting of all types is proceeding without the use of this method.

2. Spiral computed tomography (CT) can produce elegant three-dimensional displays of discrete anatomic areas such as the abdominal aorta. Here, this method was touted as being necessary as the primary diagnostic test to be done before placement of endoluminal aortic stent grafts. It provides information as to the size, location, and extent of the aneurysm itself. It can provide information as to the feasibility of placing a stent graft and its relationship to the renal arteries but as yet has not replaced conventional CT scanning. CT scanning can be used to detect paraprosthetic leaks after endovascular grafting. At the present time this constitutes one of the major problems that can occur with this form of treatment. It does have limitations that must be recognized. It requires between 100 and 200 mL contrast material and provides only limited areas of interrogation. For example, it would not be possible at the moment to extend the studies distal to the inguinal ligament, which is a disadvantage. It is also clear that color duplex imaging may be superior for the detection of endoleaks. This will be determined in the next few years.

3. It is most likely that the future will find ultrasound as the initial diagnostic study, to be followed by MRA-MRI when further diagnostic confirmation is needed. Considerable savings will still result, with absolutely no morbidity or mortality from the diagnostic studies themselves. This will be a major advance for our society.

Potential problems can be seen on the horizon that will limit the development and application of new technology. For example, the cost of new devices such as MRA will greatly limit their implementation. In addition, once they are in place within a hospital, the demand for their services will be such that it will be necessary to limit their use severely. Not enough systems will be available to satisfy the needs of the medical community. As one knows, this is all related to the availability of money and the costs of delivering health care. For example, it is very unlikely that many of the needed postoperative or postangioplasty studies will be paid for in the future. However, one would hope that those institutions that can carry out such studies will provide the necessary information to determine which categories of cases need such follow-up.

From a technological standpoint, what are some areas that badly need better data? One very important area is the morphology of the carotid bifurcation plaque. We have learned that the outcome with regard to such lesions is related to the degree of narrowing: the tighter the lesion, the more likely an adverse outcome. However, even given these facts, it is clear that most patients with similar degrees of narrowing do not have an ischemic event. The difference must lie in the morphology of the lesion. The current evidence, which appears to be consistent, is that the problem most likely lies within the fibrous cap. If it remains intact, there is little risk to the patient, but if fissuring occurs with rupture, an adverse outcome is more likely to occur. At present, there are no good methods of looking at the fibrous cap *in vivo*. Ultrasound can provide some information with regard to plaque morphology, but it is not specific enough to allow a detailed study of the fibrous cap. MRI may have some role here, but the work that needs to be done to prove its value will take a long time. The major problem will not only be a description of the lesion itself but its verification of the findings by *ex vivo* histologic confirmation. By necessity, this will have to be a method that allows three-dimensional reconstruction of the plaque.

THE FUTURE

The future will see a deliberate movement away from invasive angiographic approaches, which will be replaced by more effective methods, such as ultrasonic duplex scanning. Imaging methods such as intravascular ultrasound, spiral CT scanning, MRI, and MRA will evolve to provide more than basic anatomic function. However, cost may be an inhibiting factor in the development of these technologies.

OVERVIEW

The term *stroke* encompasses a heterogeneous group of cerebrovascular disorders, each with its own set of clinical presentations, etiologies, and management strategies. Hypertension is the single most important risk factor for stroke. Cerebral infarction accounts for 80% to 85% of all strokes, intracerebral hemorrhage for 10% to 15%, and subarachnoid hemorrhage for 5% to 6%. Of all cerebral infarctions, 20% to 30% are due to atherothrombosis or thromboembolism from the extracranial or intracranial vessels and can be managed by carotid revascularization or antithrombotic therapy. Lacunar infarcts make up another 20% to 25%, and their treatment focuses on risk-factor management. Cardioembolic sources account for 15% to 20% of cerebral infarctions; nearly half are associated with nonvalvular atrial fibrillation (NVAF), and many warrant anticoagulation. In at least 30% of cases of cerebral infarct, the cause remains unclear. Stroke prevention typically targets high-risk patients with a transient ischemic attack (TIA) or minor stroke and includes antithrombotic therapy with aspirin, clopidogrel bisulfate, ticlopidine hydrochloride, dipyridamole, or warfarin sodium. Intervention in acute ischemic stroke is modeled after therapeutic strategies in acute myocardial infarction (MI); however, the diversity of ischemic stroke mechanisms and the risk for brain hemorrhage have impeded the development of acute therapy protocols.

GLOSSARY

Angiographically occult: Vascular abnormality that is not delineated by cerebral angiography.

Complicated migraine (migraine stroke): A neurologic deficit that replicates the symptoms of prior migraine attacks but that is not transient, with other causes of stroke having been excluded.

Lacunar: Small, 3-mm to 2-cm infarcts of the deep subcortical structures resulting from vascular occlusion of penetrating branches of the larger cerebral arteries.

Penumbra: The border zone of ischemic, but not infarcted, tissue that surrounds the infarcted core of a cerebral infarct.

Stroke: A generic term for a group of cerebrovascular disorders in which part of the brain is transiently or permanently affected by ischemia or hemorrhage, or in which one or more blood vessels of the brain are primarily affected by a pathologic process, or both.

Transient ischemic attack: Sudden, focal, painless neurologic deficit of ischemic cause resolving within 24 hours but typically clearing within 15 minutes.

HISTORICAL PERSPECTIVE

Apoplexy and Other Early Concepts

Hippocrates' aphorism on apoplexy, written in approximately 400 BC, contains what is probably the first written description of stroke (1). The term *apoplexy* is derived from the Greek *apo* (from), *pleso* (thunderstruck), and *ia* (condition).

Willis (2) contributed the word *neurology* to medicine and was one of the first to recognize the clinical importance of the collateral flow afforded by the "circle" anastomosis at the base of the brain.

Wepfer (3), in 1658, was the first to recognize that apoplexy was due to cerebral hemorrhage; however, because his was an autopsy series, he did not recognize the role of cerebral infarction. Although atherosclerosis had been described by the 1500s, it was not linked to apoplexy until the late 1600s and was not recognized as a

cause of “softening of the brain,” or infarction, until Rostan’s work (4) in 1823. The clinical manifestations of TIAs were described by Heberden in 1802 and by Cheyne in 1820 and were related to carotid artery disease by many, including Kussmaul in 1872 and Gowers in 1875 (5). Gowers, in 1875, was the first to describe retinal and cerebral embolism due to mitral stenosis and “old clots . . . contained on the auricular appendices.” Ten years later, Gowers’ textbook (6) described the difference between embolism as “the result of a morbid process elsewhere in the vascular system, commonly in the heart” and thrombosis as “a local disease of the artery by which its caliber is narrowed and its inner surface is changed . . . usually the result of atheroma or of syphilitic disease.” Chiari (7) emphasized the carotid bifurcation as a frequent site of atherosclerosis and a source of cerebral embolic symptoms in 1905, and nine years later Hunt (8) described the syndrome of internal carotid artery occlusion.

Procedural Advances

Carotid arteriography was performed after surgical exposure of the artery by Moniz (9) in 1927 and after direct carotid puncture by Loman and Myerson (10) in 1936. By the late 1960s, direct puncture techniques were replaced by Seldinger’s techniques of femoral, subclavian, or axillary puncture (11). Computerized digital subtraction technology appeared in the 1970s, providing better-quality films with less contrast and lower risk to the patient (12).

In 1951, Fisher (13) emphasized that symptoms of cerebrovascular insufficiency and internal carotid artery thrombosis were much more frequent than previously suspected, correctly predicting that such thrombosis would prove to be a major cause of apoplexy and hoping that “some day vascular surgery will find a way to bypass the occluded portion of the internal carotid artery during the period of ominous fleeting symptoms.”

Therapeutic Trials

Carotid artery surgery had its roots in the 1950s and had to evolve through the initially high postsurgical mortality that was primarily cardiac in cause (14,15,16,17,18 and 19).

Although case series extolled the benefits of anticoagulation for ischemic stroke, subsequent clinical trials reported no reduction in recurrent stroke, a variable benefit in reduction of TIAs, and a significant increase in mortality due to brain hemorrhage (20,21,22,23 and 24). Most physicians were relieved when antiplatelet therapy became available (25,26 and 27), but despite multiple multicenter, randomized, controlled trials conducted since the 1970s, the optimum dosage of aspirin to prevent stroke remains controversial (28,29,30,31,32,33,34,35,36,37,38 and 39). Insights into the variable natural history of stroke as determined by etiology and other risk factors paved the way for clinical trials focusing on more homogeneous subsets of patients, such as those with carotid bifurcation atherosclerosis, intracranial atherosclerosis, or acute middle cerebral artery occlusion.

Neuroimaging

With the development in 1972 of Hounsfield’s concept of computerizing radiographic images, the computerized tomographic (CT) scan evolved. This technique revolutionized clinical-anatomic correlation, added to the understanding of the heterogeneity of cerebrovascular disorders, and advanced a pathophysiologic approach to evaluation and treatment that is far from the naïve concept of the “cerebrovascular accident” (40,41). Magnetic resonance imaging (MRI) provided improved imaging of posterior fossa structures, permitted noninvasive assessment of the cerebral venous system, and introduced angiographic-quality images of the cervical and intracranial arteries. Diffusion-weighted and perfusion images now pursue the elusive ischemic penumbra, or noninfarcted border zone, to improve patient selection for acute stroke therapies.

Evolution to Hyperacute Therapy

Reperfusion strategies for acute ischemic stroke are similar to those developed for acute MI. Implementation of treatments for stroke has been slow due to the painless nature of symptoms, ineffective health care delivery systems, heterogeneity of stroke, and risk of brain hemorrhage.

ANATOMIC CONSIDERATIONS

Heterogeneity of Cerebrovascular Disorders

Cerebrovascular disorders are a heterogeneous group of neurologic symptoms, signs, and mechanisms of injury. The first categorization relates to whether the injury is due to vascular occlusion or rupture and defines the main subsets of stroke: cerebral ischemia and infarction, cerebral hemorrhage, and subarachnoid hemorrhage (42). Cerebral infarction typically presents acutely as a painless, focal neurologic deficit with preserved consciousness. Cerebral hemorrhage also presents as an acute, focal neurologic deficit but subacutely progresses as the hematoma expands and is accompanied by headache and altered consciousness. Subarachnoid hemorrhage also presents acutely; however, as the hemorrhage is predominantly around the brain, headache is the major complaint, and the condition is accompanied by altered consciousness when severe. Subarachnoid hemorrhage is associated with early focal findings only when aneurysmal compression of cranial nerves or concomitant intracerebral hemorrhage is present.

Epidemiology and Risk Factors

Stroke is one of the three leading causes of death in the United States and developed nations. Cerebrovascular mortality rates have been declining since the 1920s. Before the 1950s, the decline in mortality from stroke reflected changes in death certificate coding due to the recognition that most sudden deaths were related to cardiac disease rather than stroke. The rate of decline in cerebrovascular mortality was 1% per year in the 1950s and accelerated to 5% per year in the mid-1970s. The decline in cerebrovascular mortality was greater than that in cardiovascular disease in general and has been linked to declining rates of incidence of infarction and intracerebral hemorrhage, as well as to a decreased case fatality rate (43). The decline in mortality from stroke may have plateaued, however (44). A recent increase in stroke fatality rates may reflect improved case ascertainment and aging of the population. As stroke typically follows cardiovascular events by 5 to 10 years, the stroke rate may increase as survival after cardiovascular events improves.

Stroke risk factors, defined in populations at risk, provide a framework for individual patient management (45,46 and 47) (Table 110.1). Primary prevention in asymptomatic and presymptomatic individuals is the ultimate goal.

Nonmodifiable
Advanced age
Gender
Race
Family history of stroke
Modifiable
Hypertension
Transient ischemic attacks or prior stroke
Cardiac disease
Nonvalvular atrial fibrillation
Acute myocardial infarction
Valvular heart disease
Impaired myocardial function
Asymptomatic carotid artery stenosis
Hyperlipidemia
Diabetes mellitus
Cigarette smoking
Alcohol abuse
Hypercoagulable states

TABLE 110.1 RISK FACTORS FOR STROKE

Hypertension

Hypertension is the single most important risk factor for both ischemic and hemorrhagic stroke. The risk of stroke is directly related to the magnitude of elevation of both the systolic and diastolic blood pressures for both genders and all age groups (48). Stroke risk is at least threefold higher in individuals with definite hypertension (higher than 160/95) and 1.5 times higher in those with borderline hypertension. Isolated systolic hypertension increases stroke risk two to four times, even after one

controls for age and diastolic blood pressure. Improvements in detecting and managing hypertension have been linked to the observed decline in stroke mortality.

Cardiac Disease

The presence of cardiac disease, including coronary artery disease (CAD), congestive heart failure (CHF), left ventricular hypertrophy, and cardiac arrhythmias, doubles the risk of stroke. This powerful relationship between stroke and cardiac disease is attributable to a number of mechanisms. Atherothrombotic stroke shares the same risk factors as CAD, and MI is the most frequent cause of death in patients with ischemic stroke (49). Cardiogenic embolism accounts for 15% to 20% of all ischemic strokes, of which half are due to atrial fibrillation (AF). The major causes of cardiogenic cerebral embolism are NVAF, acute MI, ventricular aneurysm, rheumatic heart disease, and prosthetic cardiac valves (Table 110.2). Potential cardioembolic sources of stroke include mitral valve prolapse, patent foramen ovale, atrial septal aneurysm, spontaneous echo contrast, left atrial enlargement, aortic arch atheromatous disease, and mitral annular calcification.

Risk factor	Increase in risk
Cardioembolic stroke	2%–4% recurrent stroke within 30 days
Atrial fibrillation	1%/yr: <65 yr, no risk factors 4.9%/yr: >65 yr, ≥1 risk factors 4.3%/yr: 65–75 yr, no risk factors 5.7%/yr: 65–75 yr, ≥1 risk factors 3.5%/yr: >75 yr, no risk factors 8.1%/yr: >75 yr, ≥1 risk factors
Acute MI	9%–11% all MI, 2%–4% anterior wall MI, 15% LV thrombus, clustered within 3 mo
LV hypertrophy on electrocardiogram	Twofold increase
Dilated cardiomyopathy	1%–3%/yr
Rheumatic mitral stenosis	5%/yr, 18-fold increase with AF, three- to sixfold increase without AF
Bioprosthetic aortic valve	0.2%–2.9%/yr stroke + systemic embolism
Bioprosthetic mitral valve	0.4%–1.9%/yr stroke + systemic embolism
Mechanical aortic valve	12.3%/yr stroke + systemic embolism
Mechanical aortic valve, anticoagulated	1.4%–3.9%/yr stroke + systemic embolism
Mechanical mitral valve	22.2%/yr stroke + systemic embolism
Mechanical mitral valve, anticoagulated	1.1%–6.5%/yr stroke + systemic embolism
Patent foramen ovale	0%–4%/yr
Cardiac morbidity for patients with rheumatic heart disease, stroke, or ischemia	5%/yr absolute

(AF, atrial fibrillation; LV, left ventricular; MI, myocardial infarction.)

Atrial Fibrillation

AF in patients with rheumatic mitral valve disease has long been recognized as a cause of stroke and systemic embolism. Epidemiologic studies identified the importance of chronic NVAF in the absence of rheumatic heart disease when stroke risk was increased fivefold after adjustment for other risk variables (50). The prevalence of NVAF increases with advancing age from 6.7% for those aged 50 to 59 years to 36.2% for those aged 80 to 89 years (51,52). More than one-third of ischemic strokes occurring in the elderly are in the setting of AF, and one-third of patients with AF will experience a stroke sometime during their lifetime. Clinically silent cerebral infarcts are also present on CT in more than one-third of patients with AF (53) (Fig. 110.1). The risk factors for stroke in patients with NVAF established by the Atrial Fibrillation investigators and Stroke Prevention and Atrial Fibrillation classification schemes have been combined into the $CHADS_2$ index to estimate stroke risk (54,55,56 and 57) (Table 110.3). This risk-stratification scheme assigns one point each for *C*ongestive heart failure, *H*ypertension, *A*dvanced age, and *D*iabetes and two points for prior *S*troke or TIA.

Left atrial enlargement
Thrombus or "smoke" in left atrium, left atrial appendage
Mitral annular calcification
Cigarette smoking

TABLE 110.3 RISK FACTORS FOR STROKE WITH ATRIAL FIBRILLATION

Atrial fibrillation. Narrow complex QRS with irregular RR intervals. Ventricular rate is controlled.

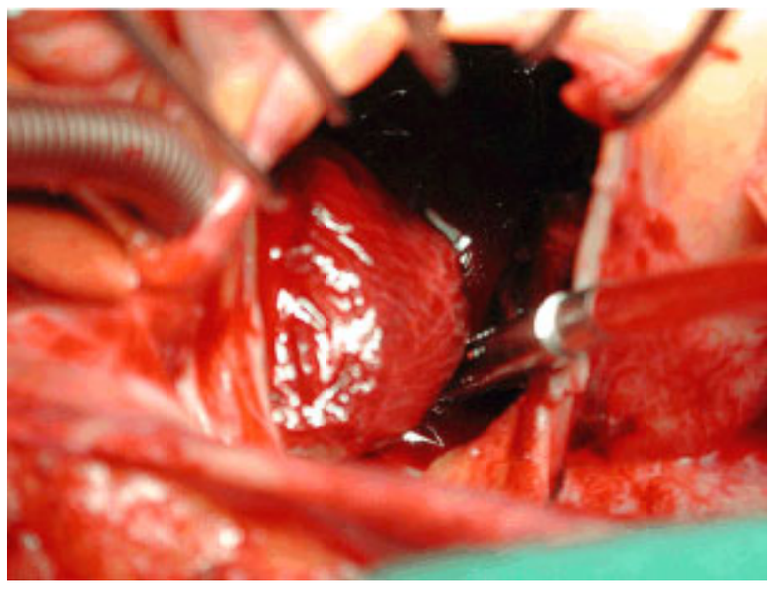
Myocardial Infarction

Before the advent of thrombolytic therapy, stroke complicated 0.8% to 5.5% of acute MIs (58,59 and 60). An embolic mechanism is supported by pathologic studies demonstrating left ventricular mural thrombi in 38% to 67% of cases, typically in the apex in patients with anteroapical infarctions (61,62). Transthoracic echocardiography (TTE) detects mural thrombi or severe wall motion abnormalities, which place patients at increased risk for embolic stroke, although embolization may occur even in the absence of detectable thrombus on echocardiography (63,64). The distribution of cerebral emboli reflects cerebral blood flow patterns, with the majority affecting the anterior circulation, particularly the middle cerebral artery. Although 90% of cerebral embolic events occur within the first 2 weeks after MI, risk for stroke continues for 4 to 6 months, with a minority of patients having a lifelong risk. Risk factors for stroke include older age, history of stroke, paroxysmal AF, anterior or apical location, impaired left ventricular function, and severity of MI as measured by levels of creatine phosphokinase, CHF, or advanced Killip class (65,66,67 and 68).

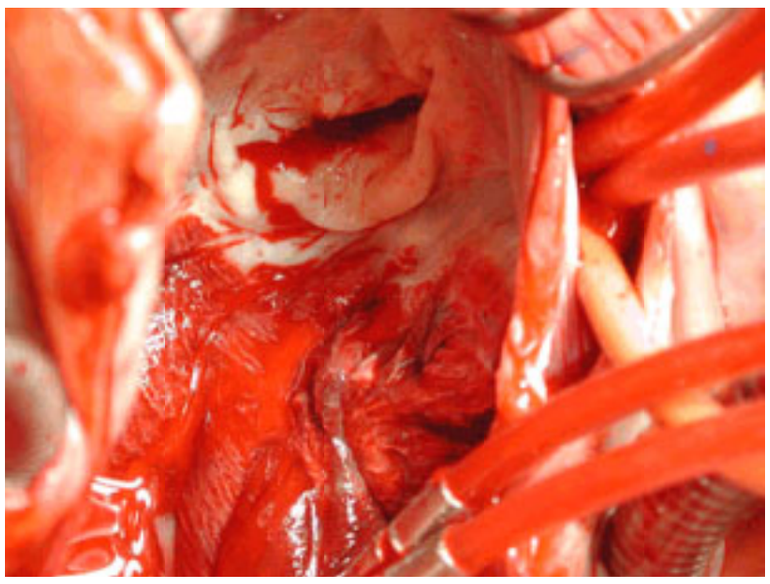
Valvular Heart Disease

Rheumatic mitral stenosis alone increases stroke risk by sixfold, and when it is associated with AF, stroke risk by increases 18-fold. Embolism occurs with all degrees of rheumatic mitral valve disease but is less frequently a complication of pure mitral regurgitation (69).

A 62-year-old female patient with mitral stenosis.



Intraoperative field looking into the left atrium of a patient with severe mitral stenosis who developed extensive clot within the left atrium. Notice the large mass in the center of the field, to the left of the opening within the left atrium. This is the largest portion of the left atrial thrombosis.



Intraoperative field looking into the left atrium after the large left atrial thrombus was resected demonstrating the rheumatic mitral valve at the top of the screen. Note the scarred, thickened, restricted mitral leaflets. This patient had severe mitral stenosis with a mean pressure gradient of 20 mm Hg across the valve and a mitral valve area of 0.7 cm^2.

VIDEO

Video 110.1 Parasternal long-axis view of a rheumatic mitral valve with thickened, restricted, doming leaflets. Severe mitral regurgitation is the primary functional problem with this valve with only mild mitral stenosis. The risk of prosthetic valve thromboembolism is higher for valves in the mitral than in the aortic position, higher for multiple prosthetic valves than for single, and higher for caged ball valves than for tilting disc or bileaflet valves. Additional risk factors for thromboembolism include prior thromboembolism, AF, CAD, an enlarged left atrium, and left atrial thrombus (70).

Impaired Myocardial Function

Clinical evidence of impaired cardiac function, including CAD and CHF, again doubles the risk for stroke. In heterogeneous groups of patients with cerebrovascular disease, 86% have angiographic evidence of CAD, which is severe in 40% as determined by noninvasive studies or cardiac catheterization (71). The neurologic presentation does not predict severity of CAD.

Transient Ischemic Attack

A TIA is a sudden, painless, focal neurologic dysfunction from a vascular cause resolving within 24 hours. This clinical definition predated CT scanning, and the median duration of a TIA is now known to be only 12 minutes. Twenty-five percent of those fulfilling the traditional criteria have evidence of cerebral infarction on CT or MRI (72). From aggregate data, TIA is associated with a 4% to 12% annual risk of stroke and a 10% to 17% annual risk of death, two-thirds of which are vascular deaths (73,74,75 and 76). The highest risk for stroke is in the first year after onset of TIA, especially in the first few months.

The North American Symptomatic Carotid Endarterectomy Trial (NASCET) reported nine risk factors associated with an increased risk of stroke in patients with atherosclerosis-related TIA (77,78). The 2-year risk of stroke ranged from 17% to nearly 40%, depending on the number of risk factors present (Table 110.4).

Stenosis (%)/no. of risk factors	Reduction in relative risk (%)
90–99	75
80–89	63
70–79	63
70–99	65
≥7 risk factors	78
6 risk factors	76
≤5 risk factors	38

NASCET, North American Symptomatic Carotid Endarterectomy Trial.
*Risk factors in NASCET: age >70 years; male gender; systolic blood pressure >160 mm Hg; diastolic blood pressure >90 mm Hg; symptoms within 31 days; history of stroke; stenosis >80%; plaque ulceration; history of smoking, hypertension, myocardial infarction, congestive heart failure, diabetes mellitus, claudication, or hyperlipidemia.

TABLE 110.4 REDUCTION IN RELATIVE RISK FOR IPSILATERAL STROKE AFTER ENDARTERECTOMY IN NASCET[a]

Asymptomatic Carotid Artery Stenosis

The frequency of cervical bruits increases with age and is 7% to 10% in those patients older than 65 years. Cervical bruits correlate poorly with the degree of underlying carotid artery stenosis, however, as only half of arteries with bruits harbor significant internal carotid artery stenosis and only half of the relevant stenoses produce an audible bruit. Carotid bruits and carotid plaque thickness as measured by ultrasonography are markers of systemic atherosclerosis and increased risk of vascular events, although they are not a good predictor of ipsilateral cerebral infarction. Stroke risk increases with the degree of carotid stenosis, from 1.3% per year for stenosis of less than 75% to 3.3% per year for stenosis greater than 75% (79,80). Even in the higher-risk group, however, the rate of ipsilateral cerebral infarction was only 2.5% per year, whereas the combined risk for myocardial ischemia and vascular death was 9.9% per year (81). Hence, asymptomatic carotid artery disease is a better indicator of MI and vascular death than stroke. The most important independent predictors of carotid artery stenosis are duration of cigarette smoking, hypertension, diabetes mellitus, and systolic blood pressure at the time of examination (82).

Lipid Level Abnormalities

Lipids and lipoprotein abnormalities have strong associations with coronary atherosclerosis, but their relationship to stroke is inconsistent and may be due to the heterogeneity of stroke pathogenesis. In individuals with hypertension, ischemic stroke is associated with hypercholesterolemia, but hemorrhagic stroke increases with very low cholesterol levels (83,84,85 and 86). Clinical trials carried out before the introduction of statins did not demonstrate stroke risk reduction with lipid-lowering strategies, and one trial demonstrated a paradoxical increase in hemorrhagic stroke. Trials using statin agents have demonstrated a reduction in stroke risk of from 19% to 31%, but only in high-risk patients with established cardiac disease.

The most convincing evidence that statins reduce stroke risk comes from trials of secondary prevention of heart disease in which stroke was prespecified as an end point. In the Cholesterol Reduction Prevents Ischemic Stroke trial, pravastatin sodium therapy reduced stroke incidence 31% from 3.8% to 2.6% (p = .03) without a strict relationship to cholesterol levels being noted (87). Although the Long-Term Intervention with Pravastatin in Ischemic Disease trial was prematurely terminated when mortality was significantly reduced by 23%, the 23% reduction in stroke was statistically significant (p <.022) (88). The primary prevention trials the West of Scotland Coronary Prevention Study and the Air Force/Texas Coronary Atherosclerosis Prevention Study had too few cerebrovascular end points to demonstrate any efficacy for statins in stroke prevention for middle-aged men or women with average cholesterol levels (89,90).

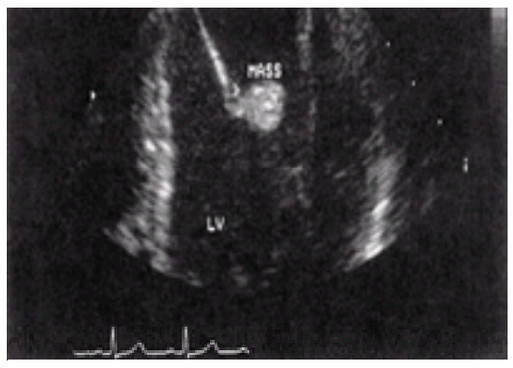
Diabetes Mellitus

Diabetes mellitus correlates strongly with hypertension, but it is an independent risk factor for cerebral infarction, especially in women, who have rates of intermittent claudication and cardiovascular complications similar to those for men. When adjusted for hypertension and diabetes, obesity is no longer an independent risk factor for stroke. The incidence of type 2 diabetes has increased dramatically, and it is a major contributor to small subcortical, or lacunar, strokes. Although aggressive treatment of hypertension among those with type 2 diabetes has been shown to reduce stroke risk, tight diabetic control has not (91). Hyperglycemia at the onset of cerebral infarction is a poor prognostic factor associated with increased infarct size (92).

Hypercoagulable States

A number of hematologic conditions collectively referred to as hypercoagulable states have been linked with an increased risk for stroke. These include elevated hematocrit, fibrinogen levels, and homocysteine levels, as well as activated protein C resistance related to the Leiden mutation and deficiencies in protein C, protein S, antithrombin III, and plasminogen.

The antiphospholipid syndrome is a heterogeneous syndrome of systemic venous and arterial thrombosis, thrombocytopenia, and recurrent fetal loss that is often, but not consistently, associated with lupus erythematosus. Rare cases of chronic, organized atrial thrombus mimicking an atrial myxoma have also been reported (*e*Fig. 110.1.1). Other manifestations include seizures, migraine, chorea, transverse myelitis, multiinfarct dementia, livedo reticularis skin patterns, and rheumatic symptoms (93,94). Laboratory test results employing phospholipid can be abnormal, including tests for anticardiolipin antibodies, antinuclear antibodies, a circulating or lupus anticoagulant, and thrombocytopenia; serologic tests for syphilis (rapid plasma reagin or VDRL) can be false-positive, and the activated partial thromboplastin time can be prolonged. Whether anticardiolipin antibodies, present in up to 8% to 15% of the elderly or in patients with other neurologic disease, interact with other risk factors to increase the risk for stroke is unknown (95).



***e*FIGURE 110.1.1** A left atrial mass mimicking an atrial myxoma in a young girl with antiphospholipid syndrome and an acute cerebral infarct. Pathologic diagnosis at resection was a chronic, organized thrombus. LV, left ventricle.

After four decades, the relationship between oral contraceptive use and stroke remains controversial. Although their use is best linked to subarachnoid hemorrhage in hypertensive women who smoke, the newer low-estrogen preparations have been associated with an increased relative risk of 1.9 for ischemic stroke. Oral contraceptive use probably acts as a risk factor only in concert with other factors, such as paradoxical embolism in women with interatrial septal abnormalities and the Leiden mutation who take oral contraceptives (96). Activated protein C resistance is acquired with oral contraceptive use and is known to increase the risk of deep venous thrombosis by three- to fourfold. Individuals who are heterozygous for the Leiden mutation have a four- to tenfold increased risk of deep venous thrombosis without oral contraceptive use and a 35-fold increased risk with oral contraceptive use. By comparison, homozygotes for the Leiden mutation have a 50- to 100-fold increased risk of deep venous thrombosis.

Genetic Factors

The familial effect of stroke predominantly reflects genetic influences of known risk factors for stroke such as hypertension, diabetes, and hyperlipidemia as well as learned behaviors of cigarette smoking, diet, and physical activity (97). However, more than 50 monogenetic disorders account for uncommon causes of stroke,

including amyloid angiopathy, coagulopathies, homocystinuria, familial cavernous malformations, saccular or berry aneurysms, and intracranial aneurysms associated with polycystic kidney disease, Ehlers-Danlos syndrome type IV, and Marfan syndrome.

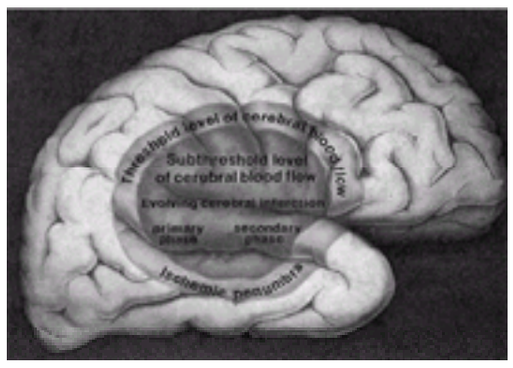
Alcohol and Tobacco Use

Consumption of modest amounts of alcohol (i.e., less than 2 oz daily) seems to reduce the risk for stroke, possibly through antiplatelet or lipid-lowering effects. High intake of alcohol increases the risk for stroke, especially for hemorrhagic stroke (98). However, hypertension, cigarette smoking, paroxysmal AF with alcoholic cardiomyopathy, and trauma are confounding factors that make the role of alcohol as an independent risk factor unclear.

Cigarette smoking increases the relative risk for both thromboembolic stroke and hemorrhagic stroke, specifically stroke from subarachnoid hemorrhage (99,100). A dose-response curve appears to exist, with risk for stroke increasing with the degree and frequency of cigarette smoking (101).

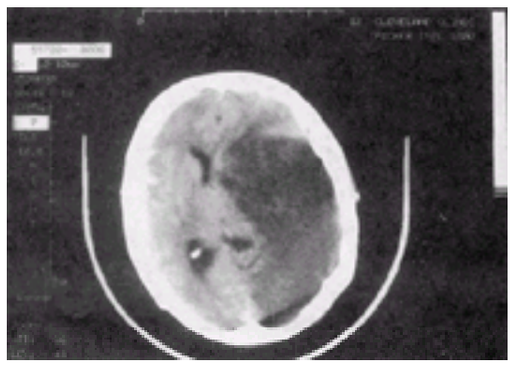
Pathophysiology of Brain Ischemia

Neuronal recovery from ischemia depends on the depth and duration of the ischemic insult, the collateral circulation, and the secondary effects of ischemic cerebral edema and metabolic derangements. In animal models, irreversible infarction occurs within 2 to 6 hours (102). Autoregulation, which maintains cerebral blood flow constant over a range of mean arterial pressures of 50 to 150 mm Hg, is disturbed in acute ischemia, and cerebral blood flow becomes passively dependent on mean arterial pressure. Aggressive management of hypertension in acute stroke, either preexisting or induced by the stroke itself, can cause extension of the infarct by lowering perfusion to the border zone (103,104) (*e*Fig. 110.1.2).



***e*FIGURE 110.1.2** Depiction of the infarcted core and the bordering “penumbra” in a middle cerebral artery distribution infarct.

The ischemic cascade consists of tissue acidosis, dysfunction of excitatory neurotransmitters (glutamate, aspartate), abnormalities of calcium homeostasis, free-radical production, cerebral edema, microcirculatory obstruction, and selective genetic expression (105). Membrane failure leads to cellular swelling from cytotoxic edema and, later, to vasogenic edema from fluid extravasation across a disrupted blood–brain barrier (*e*Fig. 110.1.3). Increased intracranial pressure (ICP) further impedes cerebral blood flow and impairs lactate clearance. Reduced microcirculatory flow results from swelling of cell processes and sludging of white and red blood cells within the arterioles and capillaries. The increase in viscosity further impairs oxygen delivery to the tissues.



***e*FIGURE 110.1.3** Cerebral edema and midline tissue shifts in a middle cerebral arterial distribution infarction.

CEREBRAL ISCHEMIA AND INFARCTION: CLINICAL PROFILE

The signs and symptoms of cerebral ischemia and infarction are related to the location and the volume of brain tissue injured as well as to the mechanism of injury. Symptoms of ischemia in the carotid territory include monocular blindness (amaurosis fugax), contralateral hemiparesis, and aphasia. These symptoms can be further divided into anterior cerebral and anterior/posterior or deep middle-cerebral artery territory symptoms (Table 110.5, Fig. 110.2, Fig. 110.3, and Fig. 110.4). Vertebrobasilar ischemia is characterized by bilateral neurologic symptoms (e.g., quadriplegia) that are frequently accompanied by vertigo, dysarthria, or diplopia (106,107 and 108). Infarction related to arteriolar or penetrator arterial occlusive disease produces several lacunar syndromes (109,110). The most common are pure motor hemiparesis, pure sensory syndrome, and ataxic hemiparesis (Table 110.6, *e*Fig. 110.4.1, *e*Fig. 110.4.2). A stereotyped pattern of symptoms suggests a focal stenosis, whereas variable symptoms referable to multiple vascular territories suggest a proximal source of embolism (e.g., heart) or a multifocal arteriopathy (e.g., vasculitis) (111).

Carotid occlusion	Manifestation
Ophthalmic artery	Amaurosis fugax (i.e., total or partial monocular blindness, usually altitudinal)
Anterior cerebral artery	Contralateral weakness involving leg more than proximal arm
Middle cerebral artery:	
Anterior branches	Contralateral motor and sensory loss, maximal for face, hand, and arm; if dominant hemisphere, nonfluent (Broca) aphasia
Posterior branches	Contralateral hemisensory loss and homonymous hemianopsia; if dominant hemisphere, fluent (Wernicke) aphasia
Deep perforating branches: lenticulostriate, anterior choroidal	Contralateral hemiparesis affecting face, arm, and leg about equally
Vertebrobasilar arterial occlusion	**Manifestation**
Bilateral symptoms	Binocular visual loss, quadriparesis, altered consciousness
Crossed symptoms	Ipsilateral cranial nerve/contralateral limbs
Combined symptoms	Dysarthria, diplopia, nausea, vomiting, vertigo, ataxia

CEREBRAL ISCHEMIA AND INFARCTION: MANAGEMENT PRINCIPLES

Primary Prevention of Stroke: Strategies for Targeting High-Risk Patients

For most patients, appropriate screening consists of a thorough history and physical examination guided by knowledge of predisposing risk factors. The examination may provide important clues such as the presence of retinal Hollenhorst plaques, cervical bruits, an irregular pulse, or a cardiac murmur.

Patients with Hypertension

The efficacy of hypertension management for stroke prevention has been confirmed by a series of controlled clinical trials performed over the past 30 years. From a metaanalysis of 14 trials, a 35% to 40% reduction in stroke risk was obtained with a 5- to 6-mm Hg reduction in diastolic blood pressure over 5 years (112). Population studies have been less convincing, however, which possibly reflects less strict blood pressure control in a community setting.

The efficacy of blood pressure reduction in preventing stroke was first demonstrated in patients with severe and moderately severe diastolic hypertension (115 to 130 mm Hg) in the 1960s (113). Subsequently, the efficacy of treating mild diastolic hypertension (90 to 109 mm Hg) was demonstrated in both placebo-controlled and treatment-versus-usual-care trials (114,115). The value of treating isolated systolic hypertension (systolic pressure higher than 160 mm Hg and diastolic less than 90 mm Hg) in persons older than 60 years was demonstrated in a randomized, double-blind, placebo-controlled trial (116). Fatal and nonfatal stroke, the primary end point, was reduced by 36%, which is consistent with the 42% reduction in stroke demonstrated by previous hypertension treatment trials. Moreover, because significant numbers of elderly patients were enrolled, this trial was the first to demonstrate a benefit for treating any form of hypertension in patients aged 80 years or older.

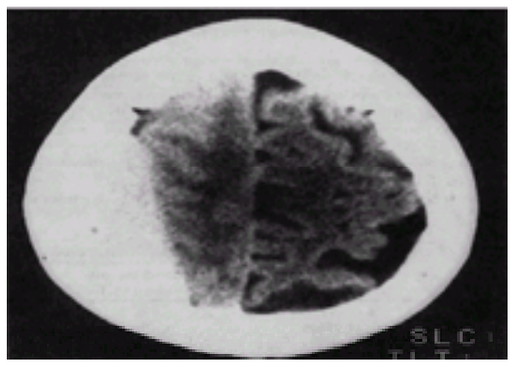
Patients with Nonvalvular Atrial Fibrillation

Oral anticoagulation had long been perceived to be such a hazardous therapy that its use was restricted to high-risk patients until pivotal clinical trials and the development and widespread adoption of the international normalized ratio (INR) method of anticoagulant monitoring established anticoagulation with warfarin as the standard of care for patients with NVAF. In the 1980s, a series of randomized clinical trials (level I evidence) addressed the prevention of cerebral and systemic embolism with long-term anticoagulant or antiplatelet therapy in patients with NVAF (117,118,119,120,121,122,123,124 and 125). A metaanalysis was conducted of data from five trials encompassing 2,461 patients followed up to 27 months. Treatment consisted of placebo, aspirin at dosages of 75 to 325 mg per day, and warfarin with an INR ranging from 1.2 to 4.5. Although the majority were in chronic fibrillation, approximately 15% of patients had paroxysmal AF. The primary end points included thromboembolic events of cerebral infarction and systemic embolism as well as hemorrhagic complications of intracranial hemorrhage (ICH), major hemorrhage (bleeding requiring hospitalization, transfusion, or surgery), and minor bleeding. Exclusion criteria typically entailed a significant bleeding history including ICH, predisposition to trauma, inability for adequate follow-up, uncontrolled hypertension, alcohol abuse, or a requirement for anticoagulant therapy.

Aggregate data from several trials including elderly patients with multiple comorbidities demonstrated a relative risk reduction of thromboembolic stroke with warfarin of 68% (range, 50% to 79%), which increased to 83% when target anticoagulation was achieved. Failure of anticoagulation to prevent stroke was associated with an INR close to 1.0 in 60% of patients. The relative risk reduction seen with aspirin, mostly at a dosage of 325 mg per day, ranges from 20% to 25%. The presence of concomitant CAD or CHF was shown to triple stroke risk, and additional clinical risk factors for stroke included prior TIA or stroke, hypertension, diabetes, and advanced age.

In the Copenhagen Atrial Fibrillation, Aspirin, and Anticoagulation (AFASAK) trial, one-third of the patients dropped out because of the inconvenience of monthly monitoring. The Boston Area Anticoagulation Trial for Atrial Fibrillation randomly assigned patients to receive anticoagulation or usual care in an unblinded fashion. The discretionary use of aspirin was carefully monitored, and 8 of 13 end points in the control group occurred in patients taking at least 325 mg of aspirin per day. The Stroke Prevention in Atrial Fibrillation (SPAF I) study consisted of patients (group I) randomly assigned to receive placebo, aspirin 325 mg per day, or warfarin, and patients (group II) who were warfarin ineligible but received aspirin or placebo. The study was prematurely interrupted when active treatment (aspirin or warfarin) was found significantly superior to placebo for group I patients, which left questions about the relative value of aspirin versus warfarin. SPAF II recruited additional patients and demonstrated that, although warfarin was superior to aspirin for the prevention of ischemic stroke at all ages, the benefit was nearly lost in the elderly. The 197 patients with a mean age of 80 years experienced a rate of ICH of 1.8% per year at an INR range of 2.0 to 4.0. SPAF III examined the use of low-intensity, fixed-dose warfarin therapy (INR, 1.2 to 1.5) plus aspirin 325 mg per day versus adjusted-dose warfarin (INR, 2.0 to 3.0) and was stopped prematurely when an interim analysis demonstrated that warfarin to maintain an INR of 2.0 to 3.0 was clearly superior.

Aggregate data on the complications of anticoagulant treatment showed intracerebral hemorrhage at an overall rate of 0.3% per year (eFig. 110.4.3). Major hemorrhage occurred in 1.5% per year regardless of treatment, but minor bleeding was three times more frequent in patients receiving anticoagulation therapy.



***e*FIGURE 110.4.3** This subdural hematoma occurred after a minor head injury in a patient who has received long-term anticoagulation therapy.

Recommendations for therapy from the American College of Chest Physicians Consensus Conference are based on these studies (eTable 110.6.1) and include the assessment of individual patient risk (125). The recommendations call for long-term anticoagulation with warfarin with ongoing monitoring and adjustment to achieve an INR in the range of 2.0 to 3.0, with a target of 2.5. Despite these recommendations, an estimated 75% of patients with AF are currently not receiving appropriate treatment. A more detailed discussion of AF as a risk factor for stroke can be found elsewhere in this textbook (see Chapter 64).

***e*TABLE 110.6.1** PREVENTION OF ISCHEMIC STROKE AND INCIDENCE OF HEMORRHAGIC COMPLICATIONS IN THE TREATMENT OF NONVALVULAR ATRIAL FIBRILLATION

Study (reference)	Control (%/yr)	Aspirin (%/yr) (reduction in risk, %)	Warfarin (%/yr) (reduction in risk, %)	Risk of ICH (%/yr)	Risk of major hemorrhage (%/yr)

Patients with Acute Myocardial Infarction

Three large randomized clinical trials (126,127 and 128) demonstrated that short-term anticoagulant therapy reduced stroke incidence from a rate of 2.3% to 5.0% to a rate of 0.8% to 1.7% after MI. Studies (129,130,131 and 132) assessing longer-term anticoagulant therapy after acute MI have demonstrated a reduction in embolic stroke that needs to be balanced by the increased risk for ICH. Such therapy is recommended for patients at increased risk for embolic stroke, such as those with AF, prior systemic embolism, CHF, two-dimensional echo evidence of mural thrombus, or persistent left ventricular dysfunction.

Patients with Valvular Heart Disease

Mitral Stenosis

The use of oral anticoagulation with warfarin at an INR range of 2.0 to 3.0 is recommended to prevent cerebral and systemic emboli in patients with rheumatic mitral valve disease and either chronic or paroxysmal AF or prior systemic embolism, based primarily on nonrandomized studies with historical controls (level IV evidence) (133). Even in the absence of AF, long-term anticoagulant therapy is recommended for certain subgroups, such as those with mitral stenosis associated with enlargement of the left atrium greater than 5.5 cm, those for whom left atrial spontaneous echo contrast is present, and those about to undergo balloon valvuloplasty (134).

Prosthetic Cardiac Valves

Antithrombotic therapies to prevent thromboembolic complications from prosthetic valves vary by the type of valve, valve position, and other comorbidities. For mechanical prosthetic cardiac valves, permanent anticoagulation is strongly recommended, and the relationship between efficacy and intensity of anticoagulation is often described by U-shaped curves (level III and V evidence) (135). Thromboembolic risk is higher for caged-ball and caged-disc valves than for bileaflet valves, higher for mitral valves than for aortic valves, and higher with AF or after failure of oral anticoagulant therapy alone.

Infectious Endocarditis

Although infectious endocarditis accounts for less than 1% of all embolic strokes, it requires emergent evaluation and initiation of appropriate antibiotic therapy. Neurologic complications, mostly stroke and encephalopathy, occur in 35% to 40% of patients with infectious endocarditis (136). Neuroimaging in the setting of an acute, focal neurologic deficit discloses a bland cerebral infarct in more than half, cerebral hemorrhage in 10%, and, less frequently, cerebritis or abscess. Neuroimaging in the setting of encephalopathy is typically unrevealing, but cases of bland or hemorrhagic infarction have been reported as well. The daily stroke risk before the institution of appropriate antibiotic therapy is estimated to be 6% per day; after establishment of appropriate therapy, stroke is rare (137).

The role of anticoagulation remains controversial, and data are limited to small retrospective studies (level V evidence). In the acute period, embolism is most effectively prevented by the prompt and appropriate administration of antibiotics. Anticoagulation does not appear to prevent embolism in the acute period of endocarditis affecting a native or bioprosthetic valve and increases the risk of hemorrhage. Because the subsequent risk of embolic stroke is threefold to fourfold higher in nonanticoagulated mechanical valves than in anticoagulated mechanical valves, however, the evidence favors continuation of anticoagulation for patients with mechanical valves despite an increased risk of ICH.

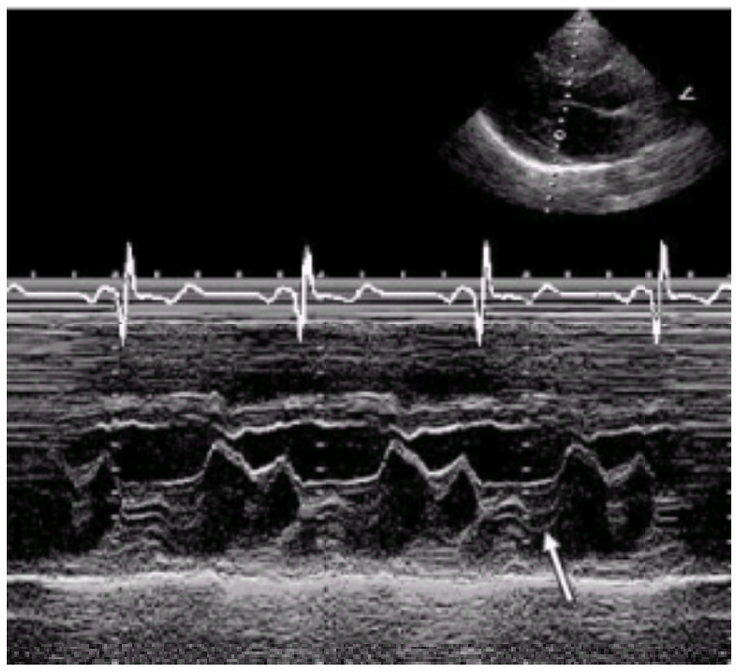
Noninfective Endocarditis

Nonbacterial thrombotic endocarditis or marantic endocarditis is a rare disorder complicating malignancies, typically mucin-producing carcinomas of the lung, colon, or pancreas. Most often diagnosed by autopsy, premorbid clinical clues include multiple organ dysfunction in the setting of arterial and venous thrombosis and ongoing disseminated intravascular coagulation. Although the treatment focuses on the underlying disease, the use of heparin sodium, but not warfarin, has been associated with benefit (level V evidence).

Libman-Sacks endocarditis is associated with inflammatory disorders such as systemic lupus erythematosus, particularly in the setting of the antiphospholipid antibody syndrome. The optimum therapy is unknown, although anticoagulation is often recommended.

Mitral Valve Prolapse

Mitral valve prolapse is identified in 1% to 10% of echocardiographic studies, with a slightly higher incidence in those with symptoms of cerebral ischemia than in controls (138). Although pathologic studies have identified platelet-fibrin aggregates on the valvular surface, mitral valve prolapse is more likely to be the cause of stroke when other risk factors are present, such as an associated atrial septal abnormality or hypercoagulable state (139). Antiplatelet therapy with aspirin, 160 to 325 mg per day, is recommended for secondary stroke prevention; anticoagulation therapy is reserved for those for whom antiplatelet therapy is ineffective (level V evidence).



M-mode tracing of posterior leaflet mitral valve prolapse. Note the posterior displacement of the posterior mitral leaflet after the leaflets close in systole.

Calcific Aortic Stenosis

Embolization of calcific debris can complicate valvuloplasty for calcific aortic stenosis (140). Although calcific emboli have been demonstrated, primarily in autopsy studies, the risk of stroke in the absence of AF remains uncertain. No evidence exists of any therapy that prevents embolization, but anticoagulation is not warranted (141).

Mitral Annular Calcification

Calcification of the mitral annulus can be identified in up to 30% of elderly patients with stroke, but it is also present in 20% of elderly patients without stroke and is associated with other risk factors such as hypertension, AF, CHF, and carotid stenosis. As with calcific aortic stenosis, its role as a cardioembolic cause of stroke and optimum therapy remains uncertain (142).

Patients with Asymptomatic Carotid Stenosis

Three early randomized trials of endarterectomy for asymptomatic carotid stenosis produced negative or inconclusive results (*e*Table 110.6.2). The Carotid Artery Stenosis with Asymptomatic Narrowing: Operation Versus Aspirin study (143) randomly assigned 410 patients with 50% to 90% asymptomatic internal carotid artery stenosis to receive either endarterectomy or aspirin therapy. Patients with recent MI or other severe medical diseases were excluded. No statistical difference was found in the number of neurologic deficits and deaths in the two groups. Because patients with greater than 90% stenosis were excluded, however, no conclusion could be offered about this subgroup. The Veterans Administration Asymptomatic Carotid Stenosis Trial (144) randomly assigned 444 patients with greater than 50% internal carotid artery stenosis to receive either optimal medical treatment (including aspirin) plus endarterectomy or optimal medical treatment alone. CAD was the prime determinant of operative mortality. A nonsignificant trend was seen toward a reduced incidence of ipsilateral stroke in the surgical group. The Mayo Asymptomatic Carotid Endarterectomy trial (145) was stopped early because of an excessive number of MIs in the placebo arm. Aspirin was not used in this trial.

***e*TABLE 110.6.2** TRIALS OF ENDARTERECTOMY FOR ASYMPTOMATIC CAROTID STENOSIS: OUTCOMES OF STROKE AND DEATH

Study (reference)	Carotid lesion studied (% stenosis)	Medical group events (%)	Surgical group events (%)	Reduction of relative risk (%)
ACAS (146)	>60	11	5.1	53
VAACST (144)	>50	44	41	NS
MACE (145)	>50	0	8	NS
CASANOVA (143)	50 to 90	28	29	NS

ACAS, Asymptomatic Carotid Atherosclerosis Study; CASANOVA, Carotid Artery Stenosis with Asymptomatic Narrowing: Operation Versus Aspirin; MACE, Mayo Asymptomatic Carotid Endarterectomy; NS, not significant; VAACST, Veterans Administration Asymptomatic Carotid Stenosis Trial.

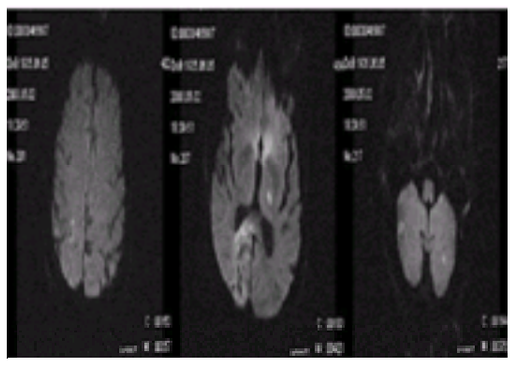
The Asymptomatic Carotid Atherosclerosis Study (ACAS) (146) randomly assigned 1,662 patients with greater than 60% internal carotid artery stenosis (determined by ultrasonography or angiography) to surgery or medical care only. Ultrasonography laboratories at participating sites underwent rigorous standardization and certification procedures to ensure the accuracy of noninvasive results (147). Despite such precautions, a 7% disagreement was seen between ultrasonography and angiography (ultrasonography positive predictive value, 93%) in ACAS. This is notable because of the increasing trend toward performing endarterectomy in asymptomatic patients based on noninvasive testing only (148,149).

ACAS was prematurely terminated after 2.7 median years of follow-up, with reported results based on Kaplan-Meier estimates of events at 5 years. The projected 5-year stroke rate in the medical group was 11.3% versus 5.6% in the surgical group. Despite the 5.7% absolute benefit demonstrated for surgery, ACAS has generated considerable controversy. Due to a higher angiographically determined complication rate in women, the benefits of surgery were seen only in men. Moreover, the rate of severe ipsilateral stroke was not reduced, and the relative efficacy of surgery by degree of stenosis (e.g., less than 90% or more than 90%) could not be determined. Concern also exists regarding the ability to replicate in the community setting the low surgical morbidity and mortality rate in ACAS (3%), which is essential for demonstrating overall efficacy (150,151,152,153 and 154).

Based on these trials, in asymptomatic patients, a conservative approach would be to recommend a prophylactic endarterectomy for those with a good 5-year life expectancy if the stenosis is greater than 80%, and the surgeon has a combined morbidity and mortality rate of less than 3%. For all others, the focus would be on medical treatment of risk factors, patient education about TIAs, and antiplatelet therapy (155,156).

Patients Undergoing Cardiovascular Procedures

Stroke complicates 2% to 5% of coronary revascularizations and up to 15% of operations that require opening of the cardiac chambers. Much of the risk is related to the cardiopulmonary bypass circuit, which can contribute to cerebral injury through a number of mechanisms, including hypoperfusion, embolization, and a provoking of a systemic inflammatory response. Additional factors include prolongation of the cardiopulmonary bypass time related to the complexity of the case, potential for embolism of valve debris, and embolism of air and particulates during mechanical de-airing of the heart. “Off-pump” coronary artery bypass surgery or the use of emboli capture devices may become the superior alternative for those at increased risk of stroke. Stroke is related to aortic arch emboli in 32%, cardiogenic emboli in 12%, hypoperfusion in 12%, and concomitant cerebrovascular disease in 11%. Stroke risk factors include atherosclerosis of the proximal aorta, hypertension, diabetes, prior cerebrovascular disease, history of neurologic disease, age older than 70 years, history of pulmonary disease, and postoperative AF (157,158 and 159). Clinically recognizable encephalopathy persisting to the fourth postoperative day occurs in 3% to 12%, although 80% of these patients recover to be able to perform normally on a simple mental status test by the time of discharge. Prospective investigations using extensive neuropsychological test batteries, however, have found that 35% to 75% of patients have impairments in cognitive function, which is severe in 20% of cases, within the first 7 to 10 days, and 10% to 30% have persistent significant deficits at 3 to 6 months. Neuroimaging studies using MRI techniques suggest that the presence of preoperative cerebral atrophy and postoperative ischemic changes manifesting as lesions on diffusion-weighted or T2-weighted MRI brain scans correlate with cognitive dysfunction, findings which support a theory of multifocal microembolism (*e*Fig. 110.4.4). Excessive alcohol consumption, postoperative AF, a history of peripheral vascular disease or prior coronary artery bypass graft, and cerebral atrophy by neuroimaging have also been reported as risk factors for cognitive decline. These identified risk factors for postoperative encephalopathy appear to reflect a patient’s “cerebral reserve” for withstanding a diffuse or multifocal ischemic insult.



***e*FIGURE 110.4.4** These diffusion-weighted magnetic resonance images demonstrate multiple acute infarcts in a patient with a prolonged encephalopathy after coronary artery bypass surgery.

Paraplegia from spinal cord infarction is a rare complication of intraaortic balloon counterpulsation support (160) (*e*Fig. 110.4.5).

***e*FIGURE 110.4.5** Magnetic resonance image depicting acute spinal cord infarction involving multiple thoracic segments.

Cerebral embolism complicates 0.1% to 1.0% of cardiac catheterizations and 0.2% to 0.3% of coronary interventions. Defects in the vertebrobasilar circulation account for 60% to 70% of cases presenting with combinations of confusional states, cortical blindness or hemianopic visual field defects, and intrinsic brainstem signs. The mechanism is generally felt to be embolic in nature, either from manipulation of the guidewire or during catheter flushing. Focal defects resolve within 48 hours in approximately half of patients; however, some strokes have been fatal. Rarely, a confusional state with headache and cortical blindness mimicking hypertensive encephalopathy or subarachnoid hemorrhage can occur. The cause is unknown, but the condition typically resolves within 48 hours with antihypertensive therapy (161,162 and 163) (*e*Fig. 110.4.6).

***e*FIGURE 110.4.6** Occipital contrast enhancement with transient cortical blindness after cardiac catheterization.

The risk of embolic stroke ranges from 1.4% to 11% for aortic valvuloplasty and 3.2% to 4.2% for mitral valvuloplasty. In the presence of an atrial thrombus, systemic embolism can result during mitral valvuloplasty, which prompted the recommendations for 3 months of anticoagulation therapy and transesophageal echocardiography before each procedure. Embolic events during aortic valvuloplasty are often highly focal, small neurologic deficits suggesting small calcific emboli (134).

The frequency of hypoxic-ischemic encephalopathy or stroke due to hypotension before insertion of a left ventricular assist device (LVAD) varies up to 25% in surgical series. Subsequent stroke from embolism of air or thrombus, or coagulopathy-related hemorrhage occurs in an additional 10% to 20% and is greater with longer durations of pump assist and during manipulation of the pump (164) ()*e*Fig. 110.4.7.

***e*FIGURE 110.4.7** Multifocal cerebral embolism after transient left ventricular assist device malfunction.

Secondary Prevention of Stroke: Prevention of Recurrent Ischemia in Patients Presenting with Transient Ischemic Attack or Major or Minor Cerebral Infarction

In patients with symptomatic retinal or cerebral ischemia, an evaluation is necessary to identify the underlying mechanism and to provide a rational basis for treatment. Depending on the clinical scenario, a complete history and physical and neurologic examination, some structural neuroimaging such as a CT scan of the brain, and basic systemic testing of blood as well as an electrocardiogram (ECG) may suffice; however, more typically, additional tests including noninvasive vascular studies, MRI, or TTE are performed (165). Additional levels of testing include cerebral angiography, transesophageal echocardiography, and assays of coagulation factors

(165a).

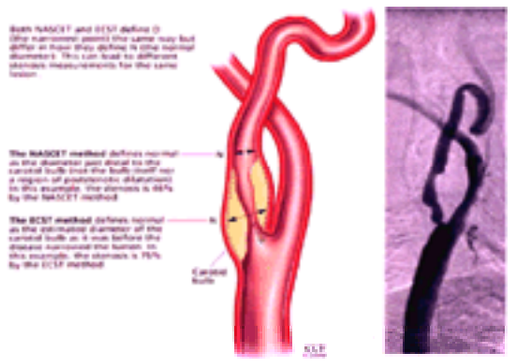
Checking for Occlusive Disease

Carotid artery screening is performed with duplex or Doppler ultrasonography. Duplex carotid ultrasonography combines b-mode anatomic imaging with a Doppler assessment of blood flow and is the preferred noninvasive study (85% sensitivity, 90% specificity). The surgical cutoff of more than 70% stenosis can be determined accurately in many laboratories. High-grade stenoses with low flow can be mistaken for occlusion and require angiographic confirmation. Doppler ultrasonography alone (70% sensitivity, 95% specificity) is an alternative screening modality at a reduced cost. Transcranial Doppler ultrasonography is used to evaluate the intracranial vasculature (166).

Magnetic resonance angiography (MRA) is noninvasive and provides a vascular image within minutes (eFig. 110.4.8). Its sensitivity and specificity are comparable to those of duplex carotid ultrasonography. MRA is also useful in evaluating intracranial circulation and the vertebrobasilar system. Besides cost, the major limitations of MRA include the fact that approximately 25% of patients are unable to tolerate the procedure because of claustrophobia and that its use is contraindicated in patients with implanted metal devices, including pacemakers, defibrillators, and certain aneurysm clips.

***e*FIGURE 110.4.8** Magnetic resonance angiography demonstrates normal intracranial cerebral circulation.

Carotid angiography is the reference diagnostic test for determining the degree of carotid artery stenosis based on NASCET and the European Carotid Surgery Trial (ECST) (eFig. 110.4.9). Serious complications occur in less than 1% to 3% of patients. Carotid angiography usually requires hospitalization, although intraarterial digital subtraction techniques and arterial closure devices allow outpatient scheduling.



***e*FIGURE 110.4.9** Measurement schemes for carotid stenosis. D, diameter of diseased narrowed lumen; ECST, European Carotid Surgery Trial; N, normal diameter; NASCET, North American Symptomatic Carotid Endarterectomy Trial.

Performing endarterectomy based on noninvasive testing alone remains controversial, as the outcomes-based studies have used angiography as the selection reference (167). In ACAS, in which strict quality control was conducted, almost a 6% false-positive error rate was seen with ultrasonography compared with angiography. However, when ultrasonography and MRA are in agreement and intracranial MRA has excluded significant intracranial lesions, the additional expense and risks associated with angiography are difficult to justify, especially in asymptomatic patients.

Checking for a Cardiac Source of Embolism

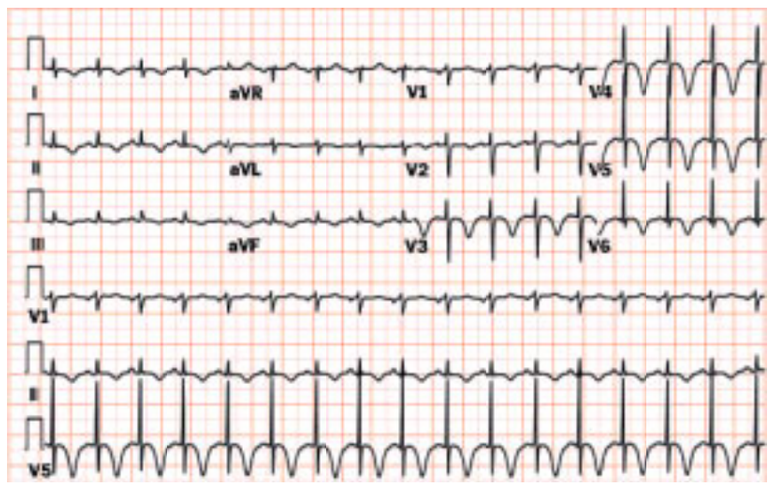
Some clinical features can clue the clinician to a proximal source of embolism, including (a) nonlacunar involvement of the cortex or cerebellum in multiple vascular territories; (b) evidence of systemic embolism, syncope, palpitations, seizures at onset, or rapid resolution of a neurologic deficit; or (c) stroke in a young patient without risk factors for premature atherosclerosis. Because emboli are more likely to lodge in the middle cerebral artery or the posterior cerebral artery, certain clinical syndromes are overrepresented, such as Wernicke aphasia, ideomotor apraxia, isolated hemianopia, or top-of-the-basilar syndrome (168). Also, because cerebral emboli spontaneously lyse in at least 30% of patients, which leads to reperfusion of the ischemic area, rapid recovery or hemorrhagic infarction also suggests an embolic mechanism. Several misconceptions about cardioembolic symptoms also warrant mention. Although repetitive ischemic symptoms referable to the same arterial territory make a proximal source less likely, cerebral emboli may travel repeatedly to the same artery, typically the middle cerebral artery. Retinal ischemia manifesting as transient monocular blindness may be the only clue to cardiac embolization. The prototypical onset is in an awake, active patient, but cardiac embolization can occur at any time of the day or night regardless of the level of activity. Although 90% of embolic strokes are maximal at onset, the remainder have a stuttering onset that reflects initial embolization with superimposed thrombus formation in a vessel with stagnant flow caused by a partially occluding embolus. A cardioembolic mechanism cannot always be inferred by the presence of a potential cardioembolic source, because an estimated 30% of patients with a cardioembolic source have concomitant cerebrovascular atherosclerosis that may also be the cause.

Echocardiography

TTE is indicated in young patients with unexplained cerebrovascular symptoms and in all patients with symptoms or signs of heart disease. In elderly patients with no evidence of heart disease, however, TTE is of limited use and is not cost effective (169,170). Transesophageal echocardiography can disclose potential cardioembolic sources of embolism, including the aortic arch, patent foramen ovale, atrial septal defects, and atrial septal aneurysms. As these conditions can be detected in up to 30% of selected populations, however, their etiologic role requires additional study (171,172,173,174 and 175).

Electrocardiographic Monitoring

ECG monitoring may reveal a variety of dysrhythmias, particularly in patients with subarachnoid hemorrhage or ICH, and should otherwise be reserved for patients with syncope or palpitations at onset, unexplained stroke, and other cardiac symptoms or signs (176,177,178 and 179).



Neurogenic T waves. These deep, symmetric T-wave inversions developed after intracranial hemorrhage.

Cerebral Angiography

The presence of branch occlusion or delayed perfusion of distal arterial branches in the absence of a more proximal arterial source of embolism suggests a more proximal source of embolism, such as the heart. Because of spontaneous clot lysis, however, angiography performed more than 24 hours after symptom onset frequently proves normal. Angiography has been useful in clinical trials investigating intraarterial delivery of thrombolytic agents after cerebral embolism.

Therapeutic Options for Patients with Transient Ischemic Attack and Stroke

Most clinical trials for stroke prevention have involved patients with TIA or minor stroke. Major treatments include antiplatelet therapy, anticoagulant therapy, and carotid endarterectomy.

Antiplatelet Therapy

Aspirin

Aspirin remains the standard preventive therapy for patients at risk for stroke. Its indications have grown from the initial U.S. Food and Drug Administration (FDA) approval in 1980, which specified its use in men with TIAs “due to fibrin platelet emboli” based on a trial in which 1,300 mg was taken daily. In a metaanalysis of 31 trials encompassing over 29,000 patients with cerebrovascular disease, the risk reduction for the combined end point of stroke, MI, or vascular death was 25%, but the major effect was from the 22% reduction in nonfatal stroke (33). Treatment was effective regardless of sex, middle or older age, or presence of hypertension or diabetes mellitus. Subgroup analyses (based on less than 400 events) in 25 trials showed no significant differences in reduction of vascular events for dosages of 75 to 150 mg (26%), 160 to 325 mg (28%), and 500 to 1,500 mg (21%), and documenting the optimum aspirin dosage would require a megatrial to avoid bias and random errors.

The United Kingdom Transient Ischemic Attack trial (34) directly compared aspirin dosages, randomly assigning patients to receive 300 mg daily or 600 mg twice daily. Although the combined end point of stroke, MI, and vascular death was reduced by 22%, the 7.7% reduction in disabling stroke and vascular death was not significant. No difference in outcomes was noted between the two dosage levels; however, the rate of gastrointestinal side effects was significantly lower in the low-dose group.

Very-low-dose aspirin was investigated in the Swedish Aspirin Low-Dose Trial, which found a statistically significant 17% relative risk reduction for the combined end point of stroke and vascular death among those taking aspirin 75 mg daily (37). The Dutch Transient Ischemic Attack Trial (36) could not demonstrate a difference in the frequency of stroke, MI, or vascular death between those taking aspirin in dosages of 30 mg per day and 283 mg per day, although major bleeding complications were slightly fewer in the lower-dosage group.

Metaanalyses provide no evidence that antiplatelet therapy reduces the risk of first stroke for “low-risk” individuals. The Physician’s Health Study addressed primary prevention of MI and stroke in a randomized trial in which asymptomatic men were treated with aspirin. The significant reduction in MI prompted premature termination of this study, unfortunately before sufficient cerebrovascular end points had occurred to allow for any meaningful statement about aspirin’s role in preventing first stroke (180).

Aspirin with Dipyridamole

Combination antiplatelet therapy with aspirin and dipyridamole was not demonstrated to be superior to treatment with aspirin alone in several trials and was largely abandoned for stroke prophylaxis until the European Stroke Prevention Study (ESPS) trials (31). ESPS I (35) followed 2,500 patients for 2 years, comparing aspirin 990 mg per day and dipyridamole 225 mg per day with placebo. The combination antiplatelet strategy achieved a 35% reduction in stroke and vascular death and a 38% reduction in fatal and nonfatal stroke over placebo but was not compared with aspirin alone. ESPS II (38) evaluated aspirin 50 mg and an extended-release formulation of dipyridamole 400 mg, either alone or in combination, versus placebo in a factorial design. The relative risk reduction for stroke was 18% for low-dose aspirin alone, 16% for dipyridamole alone, and 37% for the combination when compared with placebo. This study demonstrates the efficacy of very-low-dose aspirin and suggests that combination therapy has an additive effect, at least for stroke prevention. The combination was 23% better than low-dose aspirin alone in preventing stroke, with the predominant reduction in nonfatal stroke. None of the treatments was found to reduce the risk of MI or vascular death, but very few cardiovascular events occurred during the trial overall. The predominant side effects included gastrointestinal complaints with aspirin and headache with dipyridamole. Based on this study, the FDA approved this low-dose aspirin and high-dose extended-release dipyridamole formulation (Aggrenox) for stroke risk reduction, and the dosage of aspirin for stroke prevention in the American College of Chest Physicians guidelines was lowered to 50 mg.

Thienopyridines: Ticlopidine and Clopidogrel

Clopidogrel and ticlopidine are both thienopyridine derivatives that inhibit platelet aggregation by selectively and irreversibly inhibiting the adenosine diphosphate–dependent activation of fibrinogen binding via the glycoprotein IIb/IIIa complex. The Ticlopidine Aspirin Stroke Study (181) compared ticlopidine 250 mg twice daily with aspirin 650 mg twice daily in patients with TIAs or minor strokes. Ticlopidine reduced the overall risk for fatal or nonfatal stroke by 19% compared with aspirin, but in the first year of treatment the reduction in risk with ticlopidine proved 48% superior to that with aspirin. In the Canadian-American Ticlopidine Study (182), ticlopidine reduced recurrent stroke by 34% and reduced the combined risk for stroke, MI, or vascular death by 30% in patients with brain infarction. Ticlopidine proved effective in both men and women. Serious adverse events occurred in 2% of patients receiving both aspirin and ticlopidine, with gastrointestinal bleeding being the major side effect of aspirin. Significant neutropenia (i.e., absolute neutrophil count less than 450 per mm^3) occurred in less than 1% of ticlopidine-treated patients and almost exclusively within the first 3 months of therapy. Accordingly, a complete blood count with a differential count must be taken every 2 weeks for the first 3 months of ticlopidine therapy. Thrombotic thrombocytopenic purpura has been reported at an estimated rate of 200 to 625 cases per million ticlopidine-treated patients among those with cerebrovascular disease and after coronary interventions. As 80% of cases appeared within the first month of therapy, patients should be counseled to seek medical attention if fever, bruising, or neurologic symptoms develop (183). This safety and efficacy profile has limited the use of ticlopidine primarily to cases in which aspirin therapy has failed, although it remains under study in the African-American Antiplatelet Stroke Prevention Study.

A regimen of clopidogrel 75 mg once daily was compared to therapy with aspirin 325 mg daily in 19,185 patients with a recent stroke or MI or symptomatic peripheral vascular disease. The Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events study demonstrated a 9% relative risk reduction in the combined end point of stroke, MI, or vascular death for clopidogrel over aspirin (5.32% vs. 5.83%) (39). Although subset analyses were not powered to look at cerebrovascular patients separately, the major benefit was seen for patients with peripheral arterial disease, and results were not statistically significant for those patients who entered with cerebrovascular events. The 75-mg dosage of clopidogrel was selected to achieve bleeding times comparable to those with ticlopidine 250 mg twice a day. Side effects of rash and diarrhea were more frequent, but gastrointestinal symptoms and gastrointestinal bleeding were lower with clopidogrel. As the incidence of severe neutropenia was similar to that of aspirin (0.04% vs. 0.02%), hematologic monitoring is not warranted. In postmarket surveys, the risk of thrombotic thrombocytopenic purpura has been found to be 3.7 cases per million clopidogrel-treated patients against a background rate of four cases per million person-years in the general population (184,185). Given the efficacy data and superior safety profile, clopidogrel has essentially replaced ticlopidine as an aspirin alternative.

Anticoagulant Therapy

Although warfarin is used in many settings, the only clear indication for it is in the prevention of cardioembolic stroke, particularly that due to AF. A metaanalysis (186) was unable to find evidence for benefit in stroke prevention; however, the sample sizes were small, and a beneficial effect may have been missed due to a type II error.

The Warfarin-Aspirin Recurrent Stroke Study, which enrolled 2,206 patients, compared warfarin, adjusted to an INR range of 1.4 to 2.8, with aspirin 325 mg per day. The mechanism of the qualifying event was small vessel disease or lacunar stroke in 56%, cryptogenic mechanism in 26% (41% of whom had a patent foramen ovale), and large vessel stenosis or occlusion, including intracranial atherosclerosis, in 12% (186). No difference was seen in the 2-year rate of stroke and death, which reached 17.8% among those receiving warfarin and 16.0% among those given aspirin, and no differences were noted in safety, with overall low rates of major hemorrhage of 1.92% and 1.49%, respectively. Although patients who were on aspirin at the time of their qualifying event had a higher rate of recurrent events, no difference was found between those randomly assigned to receive aspirin and those assigned to receive warfarin. These data suggest that warfarin adjusted to an INR of 1.4 to 2.8 is safe but provides no additional benefit over aspirin for noncardioembolic, nonsurgical atherothrombotic causes of stroke, even in those patients for whom aspirin treatment has failed.

After a pilot retrospective case series of patients with symptomatic intracranial atherosclerosis suggested that warfarin-treated patients had lower event rates than those who received aspirin (187), the Warfarin-Aspirin Symptomatic Intracranial Disease trial was initiated to compare warfarin (INR range of 2 to 3) with aspirin 1,300 mg per day in patients with 50% or higher stenosis of the intracranial internal carotid, middle cerebral, basilar, or vertebral artery. Primarily on the basis of retrospective studies, warfarin has also been recommended for patients with the antiphospholipid syndrome who have TIA or stroke and who also have a cardiac source of stroke, recurrent deep venous thrombosis, or lupus erythematosus (188,189).

Carotid Endarterectomy for Symptomatic Carotid Stenosis

In the 1980s the Rand report (190) suggested that one-third of carotid endarterectomies were performed for inappropriate indications and that indications for another one-third were questionable. Several randomized trials (77,143,144,145 and 146,191,192 and 193) have subsequently evaluated the safety and efficacy of carotid endarterectomy (*e*Table 110.6.2, *e*Table 110.6.3, and *e*Table 110.6.4). The best indication for carotid endarterectomy is for the prevention of ipsilateral carotid territory ischemic stroke in patients with a recent TIA or minor ischemic stroke due to severe carotid bifurcation atherosclerosis. This position is supported by the results of the NASCET and ECST studies (194).

North American Symptomatic Carotid Endarterectomy Trial

Starting in 1987, NASCET randomly assigned patients who had carotid territory TIA or nondisabling ischemic stroke within the past 3 months and who had ipsilateral 30% to 99% internal carotid stenosis to receive best medical management (including antiplatelet therapy) alone or with surgery. The degree of stenosis was determined by comparing the angiographic residual lumen diameter at the narrowest point to the normal vessel diameter just distal to the carotid bulb (*e*Fig. 110.4.9). The "NASCET method" has become a standard for describing carotid stenosis and differs importantly from other methods. Carotid stenosis was stratified by angiographically defined severity as moderate (30% to 69%) or severe (70% to 99%).

Severe Symptomatic Carotid Stenosis (70% to 99%). The study of the subgroup of 659 patients with 70% to 99% stenosis was prematurely terminated and the results reported in 1991 after interim analyses demonstrated a statistically significant benefit in favor of surgery. Carotid endarterectomy for severe (70% to 99%) symptomatic carotid stenosis reduced the overall rate of ipsilateral stroke from 26% to 9% (17% absolute and 65% relative risk reduction) and reduced the rate of major or fatal ipsilateral stroke from 13.1% to 2.5% (81% relative risk reduction) at 2 years. As the severity of carotid stenosis increased, so did the risk of having a stroke; as stroke risk increased, so did the benefits of surgery. Ipsilateral ischemic stroke was reduced by 12% among those with 70% to 79% stenosis, by 18% among those with 80% to 89% stenosis, and by 26% among those with 90% to 99% stenosis. The overall risk of any stroke or death was also significantly reduced from 32.3% to 15.8% (51% relative risk reduction) at 2 years.

Nine prospectively selected risk factors identified those at high risk of stroke with medical therapy alone. Among those patients with more than six of these high-risk characteristics, 39% had an ipsilateral stroke within 2 years.

Moderate Symptomatic Carotid Stenosis (30% to 69%). In 1998, the results for the 2,226 patients with moderate symptomatic carotid stenosis (30% to 69%) were published along with the long-term follow-up on the patients with severe symptomatic carotid stenosis. The relationship between the degree of carotid stenosis, risk of stroke, and expected benefit from carotid endarterectomy continued to hold.

Carotid endarterectomy for high moderate (50% to 69%) symptomatic carotid stenosis also reduced the overall rate of ipsilateral stroke from 22.2% to 15.7% (6.5% absolute and 29% relative risk reduction) at 5 years, but the benefit was marginal (p = .045). Within this subgroup, characteristics that were associated with a greater benefit from surgery included male gender, a recent stroke (rather than a TIA), recent hemispheric symptoms (rather than retinal symptoms), and failure of therapy with aspirin at 650 mg or more daily.

Endarterectomy did not benefit those with low moderate (30% to 49%) symptomatic carotid stenosis, as the overall rate of ipsilateral stroke at 5 years was not

significantly different for those who had surgery (14.9%) for those given medical therapy alone (18.7%).

Perioperative Morbidity and Mortality in the North American Carotid Endarterectomy Trial. The perioperative stroke morbidity and mortality rate in all patients with severe carotid stenosis was 5.8%, which included a major stroke and death rate of 2% and a mortality rate of less than 1%. In comparison, during the 30-day perioperative period, stroke and death occurred in 3.3% of the group receiving medical treatment. The perioperative stroke morbidity and mortality rate in all patients with moderately severe carotid stenosis was 6.7%, which included a major stroke rate of 1.6% and a mortality rate of 1.2%. In comparison, stroke and death occurred in 2.4% of the group given medical treatment within 30 days. The net increase in 30-day risk with carotid endarterectomy for patients with moderate symptomatic stenosis was 4.3% for any stroke or death and 2% for disabling stroke or death. Characteristics that doubled the risk of perioperative stroke or death included contralateral carotid occlusion, evidence of an ipsilateral cerebral infarct on CT or MRI, left-sided carotid disease, diabetes, diastolic blood pressure above 90 mm Hg, absence of a history of MI or angina, and ingestion of less than 650 mg of aspirin per day, but not age or gender.

Among patients with symptomatic carotid stenosis of more than 50%, the risk of ipsilateral stroke was highest immediately after the initial ischemic event, declined gradually to 3% per year within 2 to 3 years with medical therapy alone, then dropped rapidly to 2% per year within 10 days of carotid endarterectomy. If patients with symptomatic carotid stenosis escaped recurrent symptoms for 2 or 3 years after the index ischemic event, they had little to gain from having subsequent surgery.

European Carotid Surgery Trial

The ECST began in 1981 and allowed individual physicians to randomly assign to treatment groups 2,518 patients who had had a TIA or nondisabling stroke within the past 3 months and for whom “substantial uncertainty” existed about which treatment they should receive. This unique and inexpensive enrollment method allowed for a heterogeneous group based on individual physician preference and stratified patients by severity of carotid stenosis: less than 30%, 30% to 69%, and 70% to 99%. Like NASCET, ECST determined the degree of carotid stenosis by angiography, but the method of measurement differed in that the residual lumen diameter at the narrowest point was compared to the estimated diameter of the carotid bulb before disease. This method overestimates the stenosis compared to the NASCET method, an important point to remember when the results of the clinical trials are compared.

Results from the subgroups with 70% to 99% stenosis and less than 30% stenosis were reported in 1991. Carotid endarterectomy was beneficial only for patients with severe (70% to 99%) symptomatic carotid stenosis. For those 778 patients, carotid endarterectomy reduced the overall rate of ipsilateral stroke or death from 16.8% to 10.3% (6.5% absolute and 39% relative risk reduction) at 3 years; the rate of disabling or fatal ipsilateral stroke was reduced from 11% to 6% (45% relative risk reduction) at 3 years. The perioperative stroke morbidity and mortality rate of 7.5% included a major stroke and death rate of 3.7%. The overall rate of ipsilateral stroke at 3 years for the 374 patients with mild (less than 30%) symptomatic carotid stenosis was so small that the surgical risk outweighed any potential benefit. The overall rate of ipsilateral stroke or death at 4 years was not significantly different among those 1,599 patients with moderate (30% to 69%) symptomatic carotid stenosis that had carotid endarterectomy (16.6%) and those that had medical therapy alone (12.7%). The ECST investigators concluded that carotid endarterectomy was indicated for carotid stenosis of greater than 80%, which corresponds to 60% stenosis by the NASCET method.

When Preventive Therapies Fail: Acute Ischemic Stroke Intervention

The American Heart Association (AHA) Stroke Council has published guidelines for the management of acute ischemic stroke, which have been updated for thrombolysis (195,196 and 197,270). A critical concept is time to treatment, because intravenous thrombolytic therapy must be initiated within 3 hours of stroke onset (Table 110.7).

Treatment goal	Time (min)
Door to doctor	10
Access to stroke expertise	15
Door to computed tomographic scan done	25
Door to computed tomographic scan read	45
Door to drug (intravenous t-PA)	60
Access to neurosurgical expertise	120
Door to monitored bed	180

NINDS, National Institute of Neurological Disorders and Stroke; t-PA, tissue-type plasminogen activator.
[a]NINDS Symposium on Rapid Identification and Treatment of Acute Stroke; December 1996; Arlington, VA.

TABLE 110.7 NINDS SYMPOSIUM: ACUTE STROKE TREATMENT GOALS[a]

Standard management includes respiratory support, aspiration precautions, and prevention of deep vein thrombosis. One of the most important issues in acute stroke is hemodynamic management (103,104). An algorithm for blood pressure management in patients with acute ischemic stroke has been published by the AHA (198). If the patient has a history of hypertension, blood pressure should be kept in the mildly elevated range; some patients require higher blood pressure elevations to maintain cerebral perfusion, although this may increase the risk for cerebral edema or hemorrhage. Sustained hypertension (higher than 185/110) must be strictly avoided in patients undergoing thrombolysis. Pharmacologic agents used to decrease blood pressure should allow for minute-to-minute titration. Intravenous labetalol hydrochloride 5 to 10 mg is initially recommended when blood pressure must be lowered after acute stroke. Intravenous sodium nitroprusside is rarely required; such patients are not eligible for thrombolysis.

Aggravation of tissue acidosis from excessive anaerobic metabolism of glucose may exacerbate ischemic damage. Intravenous solutions therefore should not contain glucose, and blood glucose levels should be kept to less than 180 mg per dL and carefully monitored (92). Cerebral edema is usually maximal 3 to 7 days after cerebral infarction. Cerebral edema is best treated in an intensive care unit with ICP monitoring, osmotic dehydration, and sometimes hemicraniectomy.

Thrombolytic Therapy

Based on the National Institute of Neurological Disorders and Stroke (NINDS) trial, the FDA approved the use of intravenous tissue-type plasminogen activator (t-PA) for ischemic stroke within 3 hours of symptom onset in June 1996 (198). Intravenous t-PA within 3 hours of onset remains the only FDA-approved treatment of acute ischemic stroke. Virtually no experience has been gained with newer thrombolytic agents in acute stroke. The approval of intravenous t-PA has resulted in a much more aggressive approach to acute stroke therapy in many ways analogous to treatment of acute coronary syndromes (199). Because of the narrow therapeutic window and the risk of hemorrhage, thrombolysis in acute stroke is one of the most controversial issues in neurology today (200,201,202,203,204 and 205).

Intravenous Thrombolysis

Intravenous administration has the important advantages of time, ease of administration, and widespread availability. Many small series investigating intravenous thrombolysis have been performed. A metaanalysis (206) of 12 thrombolytic trials performed since 1980 found an absolute increase in symptomatic hemorrhages of 7% [odds ratio (OR), 3.62; 95% confidence interval (CI), 2.73 to 4.80] and a 3.7% increase in death (OR, 1.36; 95% CI, 1.14 to 1.62). A significant 6.5% absolute reduction in poor outcome was seen, however; 61.5% of patients (798 of 1,297) randomly assigned to receive thrombolysis were dead or dependent compared with 65.0% (864 of 1,270) who did not receive thrombolysis (OR, 0.75; 95% CI, 0.63 to 0.88).

Seven multicenter trials of intravenous thrombolysis have been reported, four using t-PA (198,207) and three using streptokinase (208,209 and 210). The NINDS trial was a placebo-controlled, randomized trial of 0.9-mg-per-kg recombinant t-PA (rt-PA) given intravenously within 3 hours of symptom onset (eTable 110.7.1). The NINDS trial was a nonangiographic study involving 624 patients with all ischemic stroke subtypes of any degree of severity [median, National Institutes of Health Stroke Scale (NIHSS), 14]. Blood pressure was carefully controlled and maintained under 185/110 mm Hg. Patients meeting all entry criteria and treated with intravenous t-PA within 3 hours were at least 30% more likely to have minimal or no disability at 3 months than patients receiving placebo. The odds ratio of a favorable outcome with treatment was 1.7 (95% CI, 1.2 to 2.6; $p = .008$) (eFig. 110.4.10). This benefit was seen in all stroke subtypes. Post-hoc analysis failed to reveal any subgroup that did not benefit from thrombolysis, although the magnitude of improvement was less in elderly patients with severe stroke (211). Risk of symptomatic brain hemorrhage within the first 36 hours was increased tenfold: 6.4% in the group given rt-PA versus 0.6% in the group receiving placebo ($p <.001$). Although half of the brain hemorrhages were fatal, no difference was seen in overall mortality between the two treatment groups. Early CT changes and NIHSS score of greater than 20 were associated with an increased risk of symptomatic brain hemorrhage (212).

***e*TABLE 110.7.1** INCLUSION AND EXCLUSION CRITERIA FOR THE NINDS INTRAVENOUS T-PA ACUTE STROKE STUDY

Inclusion criteria
Ischemic stroke within 180 min of onset, with clearly defined time of onset
Neurologic deficit measurable on the NIH stroke scale
CT scan of the brain showing no evidence of ICH
Exclusion criteria
Stroke or serious head trauma within the preceding 3 mo
Major surgery within 14 d
History of ICH
Systolic BP >185 mm Hg or diastolic BP >110 mm Hg
Aggressive treatment required to reduce BP to the specified limits
Rapidly improving or minor neurologic symptoms
Symptoms suggestive of subarachnoid hemorrhage
GI or urinary tract hemorrhage within the previous 21 d
Arterial puncture at a noncompressible site within the previous 7 d
Seizure at the onset of stroke
Oral anticoagulation therapy
Prothrombin time >15 sec
Receipt of heparin within 48 h preceding onset of stroke, with an elevated partial thromboplastin time
Platelet count <100,000 mm^3
Glucose concentration <50 mg/dL (2.7 mmol/L) or >400 mg/dL (22.2 mmol/L)
Relative contraindications: from the FDA hearings
Severe neurologic deficit, with an NIH stroke scale score >22, especially in an elderly patient
Early signs of acute stroke on CT scan: evidence of large middle cerebral arterial involvement with hypodensity, blurring of the gray-white margins, or sulcal effacement in more than one-third of the middle cerebral artery territory

BP, blood pressure; CT, computerized tomography; FDA, U.S. Food and Drug Administration; GI, gastrointestinal; ICH, intracranial hemorrhage; NIH, National Institutes of Health; NINDS, National Institute of Neurological Disorders and Stroke; t-PA, tissue-type plasminogen activator.

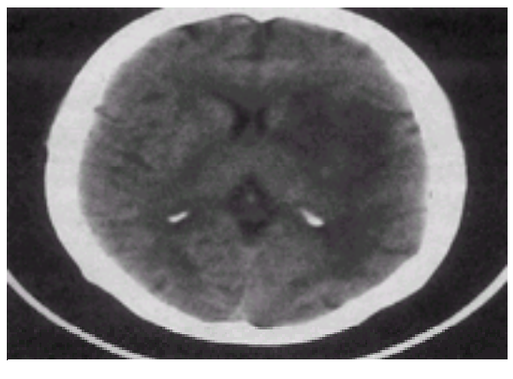
***e*FIGURE 110.4.10** Outcomes in the National Institute of Neurological Disorders and Stroke recombinant tissue plasminogen activator (t-PA) acute stroke study. NIHSS, National Institutes of Health Stroke Scale.

The European Cooperative Acute Stroke Study (ECASS) was a multicenter, controlled study of the use of intravenous t-PA for acute ischemic stroke conducted at 75 centers across Europe (207). A higher dose of t-PA, 1.1 mg per kg, and a longer time window of 6 hours were used in ECASS than in NINDS. No benefit was seen in the intent-to-treat population in the primary outcome measures: the Barthel index and modified Rankin Scale score at 3 months. Parenchymal hematomas occurred in 19.8% of the group given rt-PA group and 6.5% of the group given placebo (p <.001). Mortality was also significantly worse at 90 days in the t-PA–treated patients (p = .04). Outcome was especially poor for the protocol violators who received t-PA; 42% died.

Although the intent-to-treat analysis was negative, ECASS defined a “target” population by excluding protocol violators, mainly patients with extensive early infarct signs on CT (eFig. 110.4.11). In the target population, a significant improvement was seen in the 90-day Rankin score in t-PA–treated patients (p = .035). Also, when the NINDS statistical methodology is applied to the ECASS intent-to-treat data set, a significant increase in favorable outcome is seen in rt-PA–treated patients, similar in degree to that seen in the NINDS study (OR, 1.5; 95% CI, 1.1 to 2.0; p = .008) (213).



***e*FIGURE 110.4.11** Computed tomographic scan showing early signs of infarction: hypodensity involving most of the left middle cerebral artery territory (from a stroke of 6 hours’ duration).

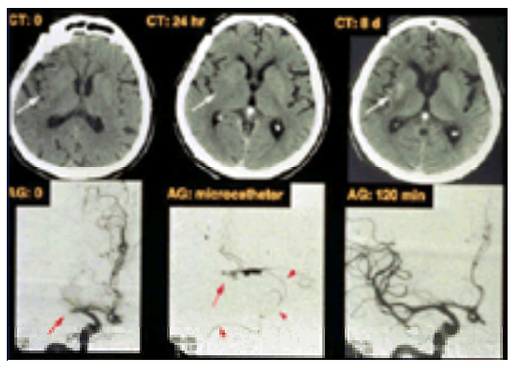
The ECASS II trial (214) again used a time window of 6 hours but reduced the intravenous t-PA dose to 0.9 mg per kg (as in the NINDS trial). Care was taken to ensure accurate CT interpretation by having all participating sites undergo CT training sessions. Blood pressure was also more tightly controlled. The parenchymal hemorrhage rate in patients receiving intravenous t-PA (11.8%) was lower than that seen in the initial trial, although it was four times higher than in placebo-treated patients (3.1%). Protocol deviations declined to 9%. The percentage of patients achieving the primary outcome measure of minimal or no disability (modified Rankin score of 0 or 1 at 90 days) was not significantly different for patients receiving t-PA (40.3%) and for controls (36.6%) (p = .277). A post-hoc analysis, however, did demonstrate a significant increase in the percentage of patients with slight to no disability (modified Rankin score of less than 2) for patients receiving t-PA.

The Alteplase Thrombolysis for Acute Noninterventional Therapy trial was designed to test whether the time window for intravenous t-PA administration could be extended to 3 to 5 hours from symptom onset (215). Inclusion and exclusion criteria for this multicenter randomized trial were very similar to those of the NINDS trial except for the time window and the exclusion of patients who had early infarct signs over one-third of the middle cerebral artery territory (a lesson from ECASS). This trial was halted prematurely after 63% of the planned patients were enrolled when an interim analysis indicated that treatment was unlikely to prove beneficial. Symptomatic ICH occurred in 7% of t-PA-treated patients versus 1.1% of those given placebo (p <.001). The Alteplase Thrombolysis for Acute Noninterventional Therapy trial, together with the ECASS I and ECASS II trials, suggest no or minimal beneficial effect of intravenous t-PA given beyond 3 hours to unselected patients with acute ischemic stroke.

The three streptokinase trials, Multicenter Acute Stroke Trial—Italy, Multicenter Acute Stroke Trial—Europe, and Australian Streptokinase Trial, were earlier trials that all used the cardiac dose of streptokinase, 1.5 million U. All three trials were prematurely halted due to the increased frequency of often fatal ICH in the streptokinase-treated patients and the lack of overall benefit.

Intraarterial Thrombolysis

The use of intraarterial thrombolysis has been reported in roughly 800 patients with acute stroke in contrast to the over 3,900 patients treated intravenously in randomized trials alone (206,214,215 and 216). Intraarterial thrombolysis requires interventional neuroradiology facilities that are not widely available and delays the time to initiation of the thrombolytic infusion. However, recanalization rates are 20% to 30% higher with local intraarterial infusion than with systemic intravenous infusion. The difference is most apparent in occlusions of larger vessels, such as the internal carotid artery or mainstem middle cerebral artery, which have larger thrombus loads. Because a lower thrombolytic dose is used, intraarterial thrombolysis may decrease systemic lytic effects. Intraarterial therapy also allows mechanical manipulation, which can speed clot lysis (eFig. 110.4.12).



***e*FIGURE 110.4.12** The initial angiogram (AG:0) reveals a proximal middle cerebral artery occlusion; there is no evidence of early infarction on the corresponding computed tomography (CT) scan. As the microcatheter is advanced into the middle cerebral artery, filling defects are appreciated. With intra-arterial thrombolysis, middle cerebral artery reperfusion is confirmed on the 2-hour AG. The follow-up CT scan at 24 hours demonstrates early infarction in the inferior striatum that undergoes asymptomatic hemorrhagic conversion by 8 days.

The Prolyse in Acute Cerebral Thromboembolism Trial (PROACT I) and PROACT II are the only randomized, controlled trials of intraarterial thrombolysis for acute ischemic stroke (216,217). The PROACT I trial was a phase I/II safety study that randomly assigned 46 patients with angiographically documented M1 or M2 segment middle cerebral artery occlusions to receive either 6 mg of recombinant prourokinase (rproUK) or placebo directly into the thrombus face within 6 hours of stroke onset. Recanalization was significantly higher in the rproUK-treated group, 57.7% versus 14.3%. Symptomatic brain hemorrhage within 24 hours occurred in 15.4% of the patients given rproUK and 7.1% of the patients receiving placebo. The brain hemorrhage rate was cut to 6.7% (similar to that with intravenous rt-PA) when the dose of concomitant heparin was reduced, but this also resulted in a lowered recanalization rate.

The follow-up phase III efficacy trial, PROACT II, used a 9-mg dose of rproUK and the reduced heparin regimen. A significant improvement was noted in the primary outcome, defined as modified Rankin score of 0 to 2 (slight or no neurologic disability) at 90 days. Symptomatic ICH occurred in 10% of patients receiving rproUK and 2% of control patients. Although the hemorrhage rate was higher than in the NINDS trial, PROACT II patients had a higher stroke severity (median NIHSS of 17 vs. 14) and a longer time before treatment (median of 5.3 vs. 1.5 hours) than in the NINDS trial. Recombinant prourokinase is not yet FDA approved.

A pilot study has explored combined intravenous and intraarterial thrombolytic therapy (218) in an attempt to optimize both time to treatment and recanalization rates. Although a combined approach resulted in more complete middle cerebral artery recanalizations, the risk of major hemorrhagic complications was increased. Further study is needed to determine the risks versus benefits of this approach.

Vertebrobasilar Thrombolysis

Because of a poor natural history (219,220), intraarterial thrombolysis has been preferred in patients with acute basilar artery occlusion. Basilar artery occlusions have a high incidence of residual atherostenosis, which often requires adjuvant therapies including angioplasty, stenting, and antithrombotic and antiplatelet therapy.

In a compilation of reported cases of vertebrobasilar thrombolysis, the mortality among patients for whom recanalization failed was 90% compared to 31% among patients achieving at least partial reperfusion. Good outcomes are strongly associated with recanalization after thrombolytic therapy. The majority of patients who successfully recanalized had outcomes of moderate disability or better, whereas less than 14% of patients whose vessels remained occluded achieved such outcomes. Recanalization depends on the location of the occlusion. Distal occlusions have higher recanalization rates than proximal occlusions. Emboli, which often lodge in the distal basilar artery, are easier to lyse than atherosclerosis-related thrombi, the usual cause of caudal basilar occlusions (221,222). Short-segment occlusions are easier to lyse than longer-segment occlusions (221). Patients who are younger have higher recanalization rates (223,224), probably due to the increased incidence of embolic occlusions seen in this setting.

The time window for thrombolysis may be longer in the posterior circulation. The presence of coma or tetraparesis for several hours portends poor prognosis, despite recanalization (220,221,224). These symptoms do not preclude survival, however, and recovery has been documented after successful recanalization in such patients (221,223,225,226).

The rates of hemorrhagic transformation after vertebrobasilar thrombolysis appear less than those after thrombolysis in the anterior circulation. The average rate of symptomatic brain hemorrhage is approximately 6.5% in such cases compared to 8.3% in cases involving the carotid circulation. The lower hemorrhagic transformation may be due to higher ischemic tolerance in the posterior circulation, improved collaterals, or an increased density of white matter tracts (227).

Risks of Hemorrhagic Transformation

Several series have found no relationship between recanalization and hemorrhage risk, although these series usually refer to early as opposed to delayed recanalization (220,226,228,229,230,231 and 232). The amount of ischemic damage is a key factor in the development of hemorrhage after thrombolysis. Early CT changes and severity of initial deficit, both indicators of the extent of ischemic damage, are currently some of the best predictors of hemorrhagic transformation (199,207,233).

Several factors have been associated with hemorrhage after thrombolysis for both stroke and MI, including thrombolytic dose (230,234), blood pressure (19,230,235,236 and 237), advanced age, and prior head injury (199,230,234,235,238,239). Age was the most important identifiable risk factor in one of the largest series investigating thrombolysis-related ICH (238). Because of the increased risk in elderly patients, an upper age limit was initially placed on patients being considered for coronary thrombolysis. These patients were found still to benefit from treatment, and the generally accepted age limit has increased. The strong relationship between advanced age and hemorrhage was demonstrated again in the NINDS and ECASS trials. At this time, no strict age cutoff exists for administering thrombolytics for stroke. Physicians need to take into account the increased risk of hemorrhage in patients aged 75 and older when making the decision to initiate thrombolysis.

Intracerebral hemorrhage after thrombolysis for stroke can occur at sites distant from the ischemic region (207,212,230). These hemorrhages may have similar pathogenesis to those occurring after coronary thrombolysis. Cerebral amyloid angiopathy has been reported as a causative factor for hemorrhages after thrombolysis for MI (240). This well-known cause of spontaneous hemorrhage in the elderly is associated with dementia of the Alzheimer's type, and elderly demented patients may have a particularly increased risk with thrombolytic therapy. Hemorrhage into an arteriovenous malformation and unsuspected ischemic infarction have also been reported as causes of postlysis ICH (240).

Thrombolysis in the Community Setting

Several phase IV series of t-PA use in experienced stroke centers have been published (241,242 and 243) that demonstrate similar rates of symptomatic ICH as seen in the NINDS trial. In the Cleveland metropolitan area, only 1.8% of all ischemic stroke patients admitted to hospitals and 10% arriving within 3 hours of symptom onset received intravenous t-PA (244). A systematic audit of t-PA use in Cleveland, performed in 1997 to 1998, found a higher symptomatic ICH rate (15.7%) (244), which suggests that the efficacy seen in clinical trials and experienced centers may not necessarily be replicated in communities. The presence of protocol deviations is

associated with higher rates of symptomatic ICH (243). Major early signs of infarction on CT portend a worse prognosis and increased hemorrhage risk; such patients probably should not receive intravenous rt-PA. These signs can be missed (207,217,245). In a study of the accuracy of interpretation of head CT scans by emergency physicians, only 43% correctly recognized a remote infarction as being old. Their ability to detect early CT changes was 0% for scans rated as “difficult” and 46% for scans rated as “intermediate” in difficulty (245).

Use of Ancrod

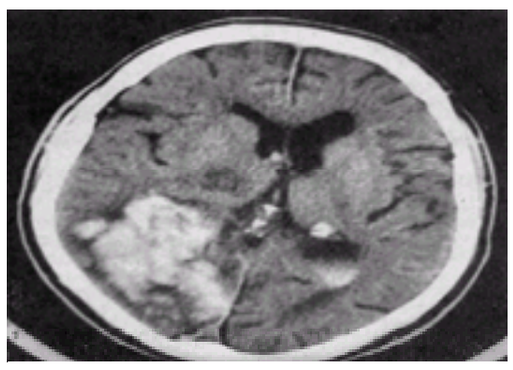
The defibrinogenating agent ancrod, derived from Malayan pit viper venom, has been studied in acute stroke (246). The positive results of the Stroke Treatment with Ancrod Trial were not replicated in a European study.

Anticoagulation and Antiplatelet Therapy

Heparin Therapy

Although many physicians believe that heparin may be useful in situations of acute ischemic stroke, data on its efficacy are insufficient or conflicting (247,248,249,250,251,252,253,254,255,256,257,258,259,260,261 and 262). Progressing stroke can be due to progression of occlusion, reembolization, reduced collateral perfusion, or reperfusion with hemorrhagic transformation (262a,263), as well as hemorrhagic transformation of the infarct, cerebral edema, or metabolic derangements (264,265 and 266). Once a fluctuating course is identified, further clinical worsening occurs in at least one-third of patients (267,268).

The risks of hemorrhagic transformation of a bland infarct (eFig. 110.4.13) and hemorrhage-related clinical worsening have been related to (a) advanced age, (b) hypertension, (c) embolic mechanism, (d) size of infarct on CT or clinical deficit, (e) early anticoagulant therapy for large infarcts, (f) use of a loading bolus, and (g) excessive prolongation of the activated partial thromboplastin time. Again, however, no consensus exists about the relative importance of these factors or their predictive value (263,269).



***e*FIGURE 110.4.13** Spontaneous hemorrhagic transformation of a cardioembolic infarction in the territory of the posterior cerebral artery.

The AHA guidelines (270) for managing acute ischemic stroke strongly recommend the prophylactic administration of heparin or low-molecular-weight heparins or heparinoids to prevent deep venous thrombosis in immobilized patients with acute stroke when no contraindication exists to the use of antithrombotic drugs. The guidelines could not offer any other recommendations for use of heparin, however, stating “until more data are available, the use of heparin remains a matter of preference of the treating physician. It should be understood that the use of heparin (or the lack of its administration) may not alter the outcome of a patient with acute ischemic stroke.”

In the first megatrial of stroke therapy and the largest study of early intervention in acute stroke, the International Stroke Trial (271) evaluated the risks and benefits of subcutaneous heparin (25,000 U per day or 10,000 U per day), with or without aspirin 300 mg per day, and placebo for 14 days in 19,436 patients with acute thrombotic or embolic stroke of less than 48 hours’ duration. Significantly fewer in-hospital deaths and recurrent strokes occurred among patients treated with aspirin. No early benefit was found for heparin, in part because the 0.9% reduction in recurrent ischemic stroke was offset by a 0.8% increase in symptomatic hemorrhagic stroke, mostly in those who received the higher heparin dosage. Taking CT scans before beginning heparin and monitoring coagulation were not required, however, which has sparked debate in the interpretation of the results. The Chinese Acute Stroke Trial studied the use of aspirin in 21,106 patients with acute ischemic stroke of less than 18 hours’ duration (272). Taken together, these megatrials found that administration of 160–300 mg of aspirin begun within 48 hours of acute ischemic stroke is significantly superior to placebo and reduces absolute early mortality by 0.5% to 0.6% and recurrent ischemic stroke by 0.5% to 1.1% while increasing the risk of symptomatic hemorrhagic stroke by a nonsignificant 0.1% to 0.2%.

With the present information, the prudent approach would be to begin aspirin therapy in all patients with acute ischemic stroke. Heparin may be used, but only in highly selected patients believed to be at risk for recurrent embolism or progressive thrombosis.

The use of heparin is contraindicated for 24 hours after delivery of intravenous t-PA for acute stroke. The risk of major hemorrhage, especially ICH, is increased when heparin is combined with thrombolytic agents, and the risk progressively increases as the activated partial thromboplastin time is prolonged beyond 80 seconds (273).

Use of Low-Molecular-Weight Heparin

Researchers have investigated the use of low-molecular-weight heparin in treating acute ischemic stroke (274). The Fraxiparine in Stroke Study (275) reported improved neurologic outcome at 6 months that was not present at 3 months in patients treated with low-molecular-weight heparin compared to those treated with placebo. Although this study has generated much interest, its methodologies have been criticized and its results must be interpreted with caution. The Trial of ORG 10172 in Acute Stroke Treatment (TOAST) evaluated the heparinoid Org 10172 in a randomized trial of the treatment of acute ischemic stroke. No overall benefit was found, and the rate of intracerebral hemorrhage in patients with more severe strokes was significant (NIHSS higher than 14). Subgroup analysis suggested a trend toward benefit for those patients with acute stroke due to large vessel atherosclerosis (276).

Glycoprotein IIb/IIIa Receptor Antagonism

The glycoprotein IIb/IIIa receptor is the final common pathway for platelet binding to fibrinogen and has demonstrated efficacy in prevention of thrombus formation in acute coronary syndromes and interventional procedures. In acute ischemic stroke, a dose-escalation study demonstrated that abciximab is safe when given as a 0.25-mg-per-kg bolus and 0.125-mg-per-kilogram-per-minute infusion (277). A phase II trial, Abciximab (ReoPro) in Acute Ischemic Stroke, is under way to test its use in treating acute ischemic stroke of less than 6 hours’ duration. The role of IIb/IIa agents in stroke prevention is less clear, as several prevention trials with oral IIb/IIIa agents have been stopped early due to increased mortality rates and lack of apparent efficacy.

Controversies and Personal Perspectives

Choice of Antithrombotic Therapy

The optimum dosage of aspirin for preventing stroke has become less controversial. Dosages from 50 mg to 325 mg have their advocates and a few trials still are using 650 mg to 1,300 mg. The FDA has approved aspirin in doses of 50 mg to 325 mg for the prevention of stroke and TIAs. A metaanalysis found no significant effect of aspirin dose on stroke risk reduction (278).

Treatment of patients who remain symptomatic on aspirin is still controversial. An increasing number of alternatives to aspirin are available. Despite the lack of definitive evidence that clopidogrel specifically reduces the risk of stroke, it has replaced ticlopidine for most cerebrovascular indications. Combinations of antiplatelet agents likely will soon supplant single-agent therapy. Although the 50-mg aspirin plus 400-mg extended-release dipyridamole formulation has significant benefit for stroke risk reduction, the lack of demonstrated cardiovascular risk reduction is problematic in patients with multisystem atherosclerosis. The Clopidogrel in Unstable Angina to Prevent Recurrent Ischemic Events (CURE) trial (279) suggests that the combination of clopidogrel and aspirin is safe and effective for coronary risk reduction, and this combination is being specifically studied in the Management of Atherothrombosis with Clopidogrel in High-Risk Patients with Recent Transient

Ischemic Attack or Ischemic Stroke (MATCH) trial. The Warfarin Aspirin Symptomatic Intracranial Disease study and the SPAF study demonstrated that antiplatelet or antithrombotic efficacy varies depending on the cause of the patient's cerebrovascular symptoms and on other poorly understood variables. These findings suggest that, in the future, therapy may well be determined by a number of selective factors.

Carotid Revascularization and Endovascular Therapies

Clinical trials have clarified the role of endarterectomy in symptomatic patients, but recommendations for asymptomatic patients remain controversial. The authors' conservative recommendations are based on (a) the particular cerebral event to be prevented (i.e., TIAs vs. all strokes vs. severe ipsilateral strokes), (b) the patient group in which such an event is to be prevented (e.g., men vs. women), and (c) the cost at which such prevention is to be achieved, both in terms of negative outcomes and economics. The lack of standard reporting of endarterectomy complication rates among surgeons and the performance of endarterectomy based on noninvasive testing alone are causes of concern. Carotid artery stenting has been proposed as an alternative to endarterectomy in cases of postradiation therapy carotid stenosis, restenosis after endarterectomy, and stenosis in high-risk patients with severe comorbidities, as well as in symptomatic, surgically inaccessible intracranial stenoses (280,281 and 282). Despite glowing case reports, however, the poor results with carotid angioplasty in the reported randomized trials should provoke a cautious advance of the technique, improved patient selection, then proof of equivalent efficacy in controlled clinical trials before it is widely embraced (283,284).

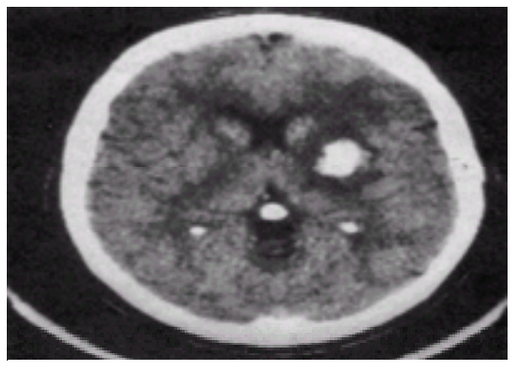
Endovascular techniques for aneurysm obliteration continue to carry substantial complication rates and uncertain longevity but are emerging as promising alternatives to aneurysm surgery ready for comparison in a clinical trial (285,286 and 287). Angioplasty is emerging as a promising treatment for vasospasm secondary to subarachnoid hemorrhage when standard medical therapy has failed (288,289,290 and 291).

CEREBRAL HEMORRHAGE: CLINICAL PROFILE

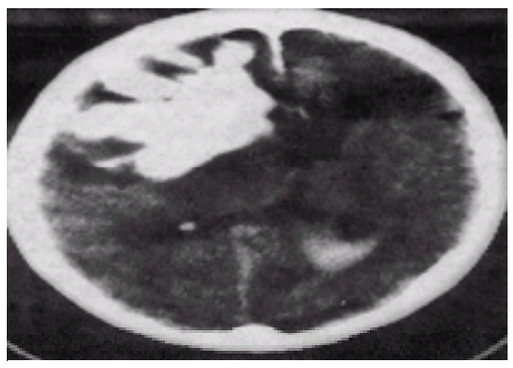
Nontraumatic ICHs are referred to as *primary* or *spontaneous* when no evidence is seen of an underlying cause, and as *secondary* when they occur because of a vascular malformation or aneurysm, coagulopathy, primary or metastatic tumor, or granuloma (292). Although time to diagnosis and overall mortality have improved with neuroimaging techniques and hypertension therapy, early mortality remains high at 30% to 40%.

The sites of bleeding are related to the cause. For primary ICH, 50% occur in the deep nuclei (putamen, 35%; thalamus, 10%; caudate nucleus, 5%), 30% occur in the lobar white matter, and 20% occur in the posterior fossa (cerebellum, 15%; brainstem, 5%) (293). Although ICHs related to coagulopathies are more frequently confluent, single, and lobar in location, tremendous variability can be found, with multiple hemorrhages and blood fluid levels within the hematomas (294,295).

Arterial hemorrhage into the brain parenchyma presents acutely with focal neurologic deficits that reflect the location and size of the hemorrhage and with generalized symptoms of headache, vomiting, and depressed consciousness that are related to an abrupt rise in ICP (296). Seizures occur in 10% to 40% of cases, most within 48 hours. Putamenal hemorrhage presents with a contralateral hemiparesis, relatively mild hemisensory loss, and forced head and eye deviation toward the side of the bleed (eFig. 110.4.14). Aphasia is associated with dominant hemisphere hemorrhage and a neglect syndrome with nondominant hemisphere involvement. Caudate nucleus hemorrhage is usually associated with memory disturbances, hemiparesis, and gaze deviation; however, small hemorrhages that decompress rapidly into the ventricular system may not produce any discernible focal neurologic deficits and can easily be mistaken for subarachnoid hemorrhages. Thalamic hemorrhage presents with prominent hemisensory loss, hemiparesis, forced downward deviation, paralysis of upgaze and convergence, retraction nystagmus, ptosis, and small unreactive pupils. Aphasia and neglect may be seen with larger hemorrhages. Hemorrhage into the frontal lobe produces hemiparesis and frontal headache (eFig. 110.4.15). Temporal hemorrhage produces superior quadrantic field defects, dysphasia or memory disturbance, and temporal or postauricular pain. Parietal hemorrhage produces hemisensory loss, behavioral disturbance, inferior quadrantic or hemianopic field defects, and temporal-parietal headache. Occipital hemorrhage produces a hemianopic visual field defect and an occipital or retroorbital headache (297). Cerebellar hemorrhage typically presents with generalized headache, nausea, and vomiting with truncal and gait ataxia that may be overlooked when violently ill patients are confined to a cart or bed. Nystagmus and appendicular ataxia may be associated findings. Decompression into the fourth ventricle is often associated with neck stiffness, but the danger of continued hemorrhage is the rapid development of brainstem compression heralded by irregular respirations, hemodynamic instability, and coma. Most brainstem hemorrhages occur within the pons. Large hemorrhages frequently manifest as locked-in syndrome, pinpoint reactive pupils, and coma. Small pontine hemorrhages may produce ataxic hemiparesis or sensorimotor stroke and more laterally located pontine hemorrhages usually manifest as abnormal extraocular movements such as ipsilateral gaze palsy, intranuclear ophthalmoplegia, and miosis.



***e*FIGURE 110.4.14** A hypertensive putamenal intracerebral hemorrhage.



***e*FIGURE 110.4.15** A massive intracerebral hemorrhage involving the frontal lobe.

Hypertension

Arterial hypertension is blamed for 70% to 90% of primary ICHs related to rupture of small perforating arteries damaged by lipohyalinosis and microaneurysm formation (298,299).

Amyloid Angiopathy

Beta-amyloid protein deposits within the media and adventitia of small meningeal and cortical vessels produce vascular fragility, which leads to lobar hemorrhages that tend to be multiple or recurrent. The most common cause of nonhypertensive hemorrhage in the elderly, amyloid angiopathy is also implicated in ICH complicating thrombolysis (300,301 and 302) (Fig. 110.5).

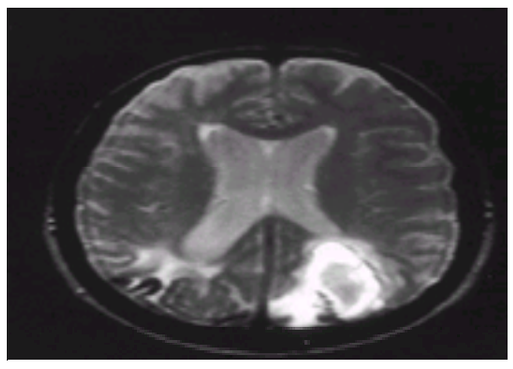


FIGURE 110.5 Residual hemosiderin in the right occipital lobe from a remote hemorrhage and subacute blood in the left occipital lobe in a patient with amyloid angiopathy.

Arteriovenous Malformation or Tumor

A history of seizures, headache, personality change, or subtle focal neurologic complaints suggests hemorrhage into a previously unrecognized vascular malformation or into a primary or metastatic brain tumor (303,304 and 305). Most ICHs are surrounded by an area of hypointensity on CT scanning that represents vasogenic edema; however, edema out of proportion to the size of the hematoma suggests hemorrhage into an underlying tumor such as glioblastoma multiforme or oligodendroglioma, or a metastatic adenocarcinoma, melanoma, choriocarcinoma, or hypernephroma. Abnormal vascular patterns on enhanced CT or MRI or areas of calcification suggest an underlying vascular malformation.

Coagulopathy-Induced Intracranial Hemorrhage

Anticoagulant-related ICHs account for 9% of all ICHs, and typically occur in patients on long-term or excessive oral anticoagulation. Other risk factors include increasing age, poorly controlled hypertension, and, probably, underlying cerebral amyloid angiopathy (306).

ICH is the most feared complication of thrombolytic therapy for acute ischemic stroke as well as a rare but serious complication of thrombolytic treatment of acute MI, peripheral vascular disease, and pulmonary embolism. Risk factors include advanced age, hypertension, low body weight, underlying hypertensive cerebrovascular disease, and amyloid angiopathy. Although hemorrhages are most commonly confluent, solitary, and lobar, the spectrum includes multiple, deep, or infratentorial hemorrhages, and associated subdural, intraventricular, and subarachnoid bleeding (235,238) (Fig. 110.6).

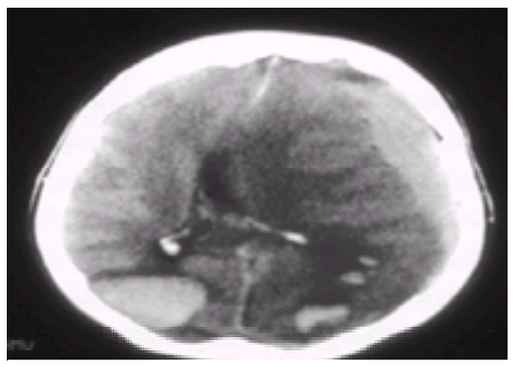

FIGURE 110.6 Complex multiple intracranial hemorrhages after coronary thrombolysis for acute myocardial infarction.

Drug-Related Intracranial Hemorrhage

Recreational drugs associated with ICH include the sympathomimetics, most commonly cocaine; amphetamines; and phencyclidine (307). Phenylpropanolamine has now been removed from appetite suppressants and cough and cold remedies, after it was associated with hemorrhagic stroke in women (308,309). An underlying structural cause, such as underlying arteriovenous malformation or aneurysm, is common, and rare cases of occlusive vasculopathy that mimics vasculitis have been described.

CEREBRAL HEMORRHAGE: MANAGEMENT PRINCIPLES

Stabilization of the Patient

The airway may be compromised by bulbar weakness in the setting of depressed consciousness. Acute hypertension is common in acute stroke but particularly dangerous in patients with intracranial bleeding and warrants aggressive treatment to limit hemorrhage extension (310). Target blood pressures for elderly or hypertensive patients (systolic pressure of 150 mm Hg) are more liberal than those for young or nonhypertensive patients (systolic pressure of less than 120 mm Hg) to limit the risk of cerebral hypoperfusion, which may occur with overzealous management in patients with impaired cerebral autoregulation (307). In patients with increased ICP, however, blood pressure management must be individualized to maintain cerebral perfusion pressure at levels above 45 to 50 mm Hg (311).

Blood should be drawn immediately for determination of coagulation parameters, including platelet count, prothrombin time, partial thromboplastin time, and bleeding time, and defects should be corrected rapidly as hemorrhage expansion can continue over the first 8 to 24 hours (312). If a focal neurologic deficit with altered mental status occurs within 24 hours of thrombolytic therapy, the event should be presumed to be an ICH until proven otherwise. Immediately stopping all thrombolytic, antithrombotic, and antiplatelet therapy while stabilizing the patient and obtaining laboratory coagulation testing should be the first consideration. Reversal of the coagulation disturbance should begin while emergency CT scanning is awaited to evaluate the neurologic event.

Medical complications are related to the severity of the hemorrhage and account for part of the morbidity. Cardiac arrhythmias, usually supraventricular tachyarrhythmias, and subendocardial ischemia may complicate ICH, especially in patients with subarachnoid bleeding (177,178 and 179). Continuous ECG monitoring and serial cardiac enzyme testing should be considered. Invasive cardiac monitoring with a Swan-Ganz catheter may be necessary if management of blood pressure and fluids is complicated by cardiac decompensation (313). If a seizure is suspected or documented, the patient should be rapidly loaded with anticonvulsants, although some clinicians recommend prophylactic anticonvulsant therapy in the acute period. Increased ICP may require more intensive monitoring by a transducer placed in either the subdural or epidural space, or, if obstructive hydrocephalus is present, by intraventricular catheter, which is diagnostic as well as therapeutic (314,315 and 316). The benefit of corticosteroid therapy in ICH has never been confirmed, and their use remains controversial (317,318).

Neuroimaging

Intracerebral bleeding should be confirmed by a noncontrast CT scan of the brain, which provides a highly accurate determination of hematoma size and location as well as other complicating factors, such as shift of intracranial structures relating to herniation and obstructive hydrocephalus (238,312). MRI is sensitive to small amounts of heme and may indicate a multifocal vasculopathy (amyloid, cavernous malformations) or underlying tumor. Lumbar puncture is rarely useful for diagnosis and is potentially hazardous in the presence of an intracranial mass lesion. Cerebral angiography is indicated when a vascular malformation, aneurysm, or vasculitis is suspected.

Surgical Evacuation for Intracranial Hemorrhage

Surgical evacuation for ICH should be considered before neurologic deterioration leads to coma and irreversible brainstem damage, although patient selection remains highly controversial. Symptomatic cerebellar ICHs are usually evacuated because of the unpredictable course and risk of rapid and progressive brainstem compression, producing respiratory arrest and death. Accessible subcortical ICHs, particularly those involving the nondominant hemisphere or noneloquent areas of the brain, are also amenable to surgical evacuation, and such evacuation should be considered in patients who present with relatively preserved neurologic function that subsequently begin to deteriorate (319). Surgical therapy does not improve outcome with ICHs affecting basal ganglia and the brainstem, and advanced age, large hematoma volume, and a depressed level of consciousness on evaluation are consistent predictors of poor neurologic outcome (320,321).

SUBARACHNOID HEMORRHAGE: CLINICAL PROFILE

Despite major advances in neurosurgical techniques over the past two decades, the acute mortality of approximately 10% continues to pose the major obstacle to treatment of subarachnoid hemorrhage. An additional 50% of patients die within 3 months, and of those who survive, more than half are left with a major neurologic or neurocognitive disability and a diminished quality of life (322,323).

The most common symptom of subarachnoid hemorrhage is a headache of noteworthy severity, ranging from the thunderclap prodromal headache with a minor leak to the sudden, severe, often exertional headache present in 45% of patients (324,325 and 326). Syncope at onset results from global cerebral hypoperfusion when the rupture causes a precipitous spike in ICP that approaches the mean arterial pressure and thus reduces cerebral perfusion pressure. Clinical grading of the patient based on headache and mental status is important in predicting prognosis and chance of recovery. The most commonly used scale is the Hunt and Hess classification scheme (*e*Table 110.7.2).

***e*TABLE 110.7.2** HUNT AND HESS CLASSIFICATION OF SUBARACHNOID HEMORRHAGE

Grade I:	Asymptomatic or minimal headache and slight nuchal rigidity
Grade II:	Moderate to severe headache, nuchal rigidity, no neurologic deficit other than cranial nerve palsy
Grade III:	Drowsiness, confusion, or mild focal deficit
Grade IV:	Stupor, moderate to severe hemiparesis, possible early decerebrate rigidity, and vegetative disturbance
Grade V:	Deep coma, decerebrate rigidity, moribund appearance

A CT scan of the brain without contrast performed within 24 hours shows positive findings in 92% but by 48 hours bears only a 75% chance of demonstrating cisternal or subarachnoid blood (Fig. 110.7). If no hemorrhage is seen, a lumbar puncture is recommended to establish the diagnosis. Selective intraarterial cerebral angiography remains the standard for diagnosis and planning of a therapeutic surgical or endovascular approach (327,328).

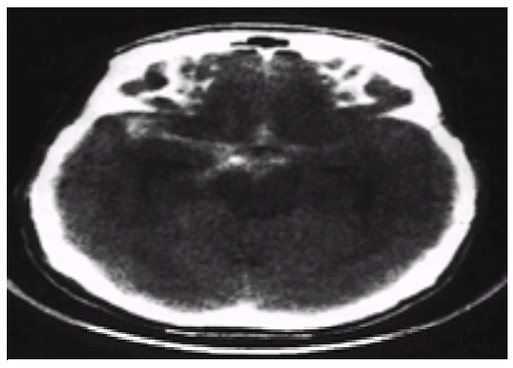

FIGURE 110.7 Computed tomographic scan showing cisternal blood in acute subarachnoid hemorrhage.

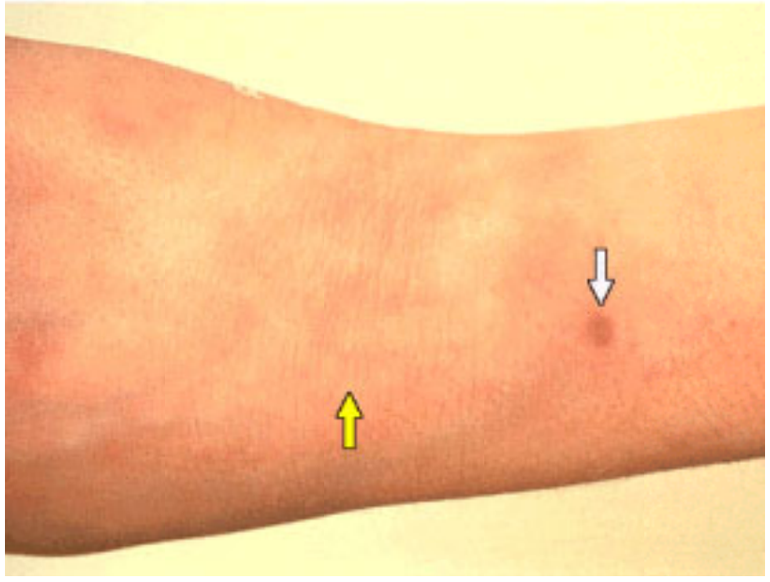
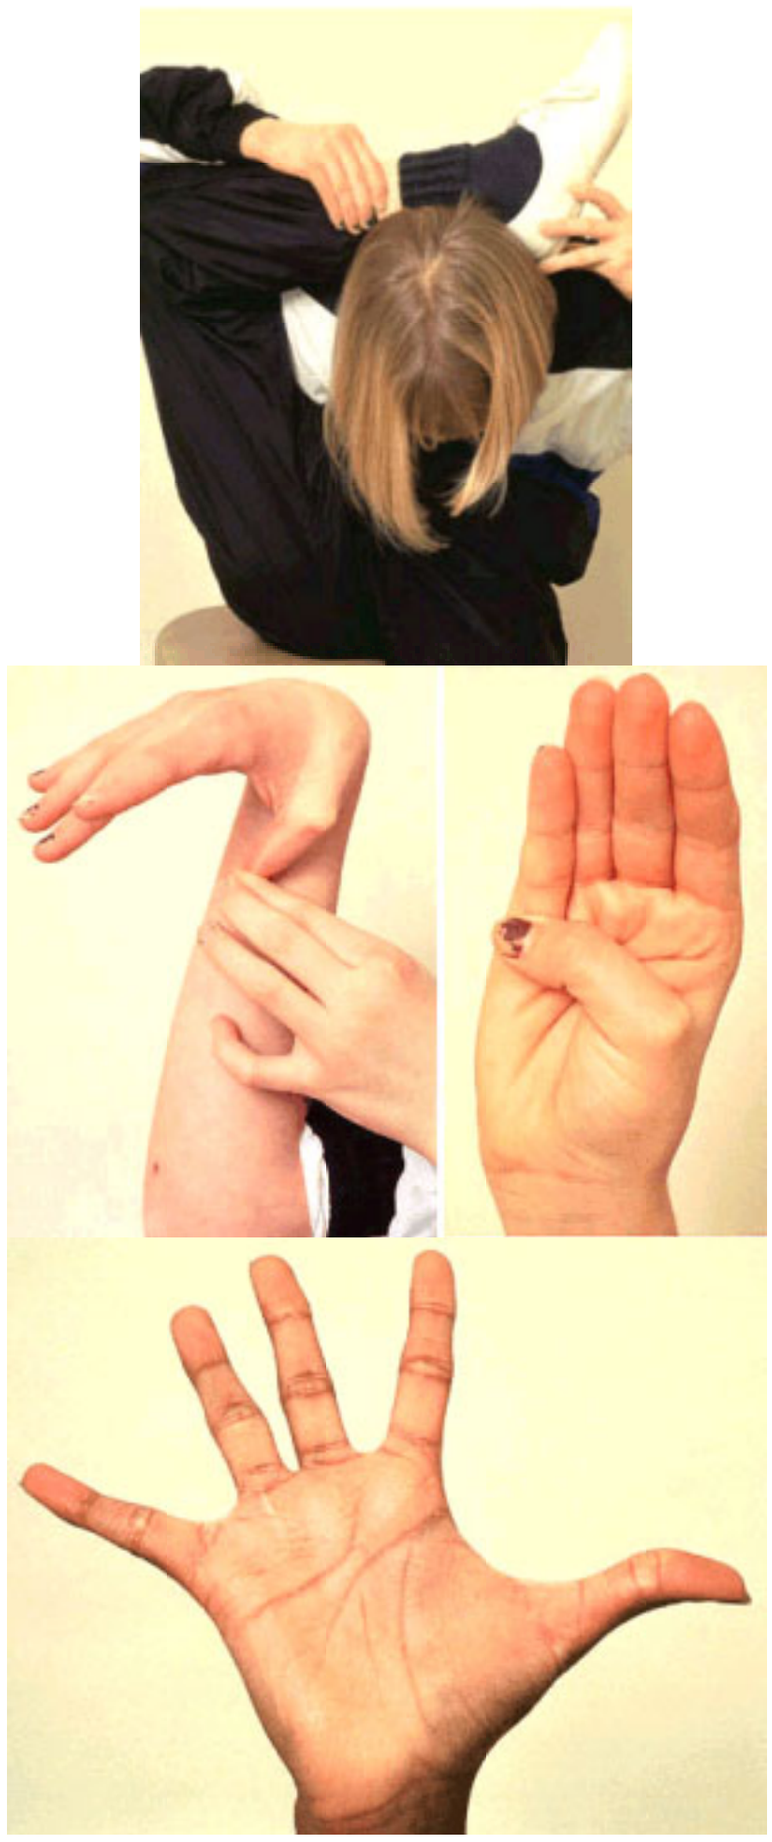
Aneurysms

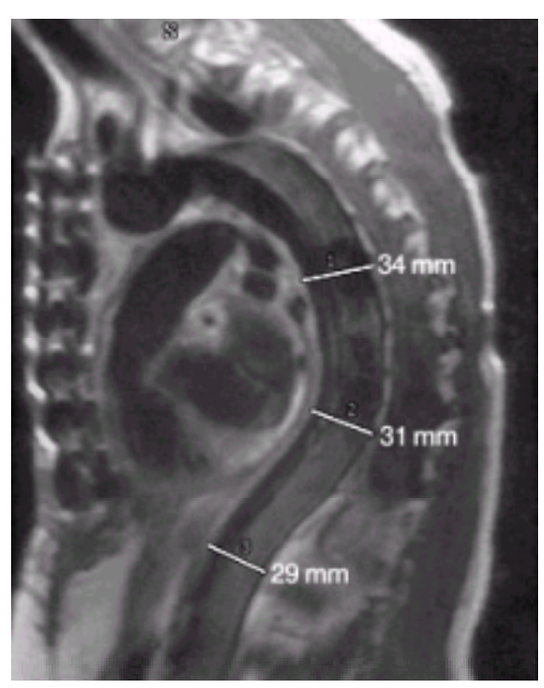
Most intracranial aneurysms are *saccular* and are believed to be outpouchings of the arterial wall as a result of a congenital defect in the muscular layer, a degenerative process in the internal elastic membrane, or a combination of both processes. They most frequently occur at bifurcations, branch and bending points within the arterial tree, with the majority at the base of the brain on the circle of Willis. They are associated with polycystic kidney disease, coarctation of the aorta, Ehlers-Danlos syndrome, neurofibromatosis, fibromuscular dysplasia, and arteriovenous malformations (329,330).



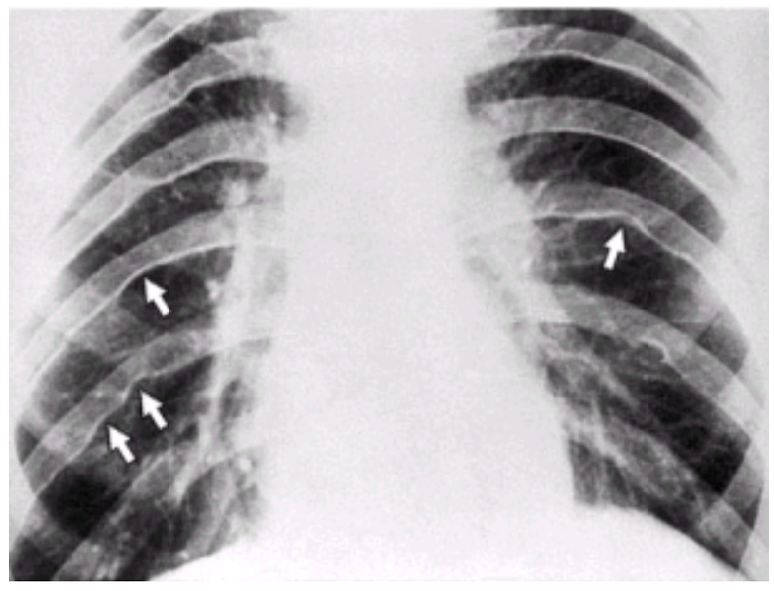
Skin changes of Ehlers-Danlos syndrome. There is thin, velvety appearance of the skin (*yellow arrow*), as well as easy bruisability (*white arrow*).



Ehlers-Danlos syndrome. There is severe joint laxity and hypermobility that may produce joint dislocations (A–C).

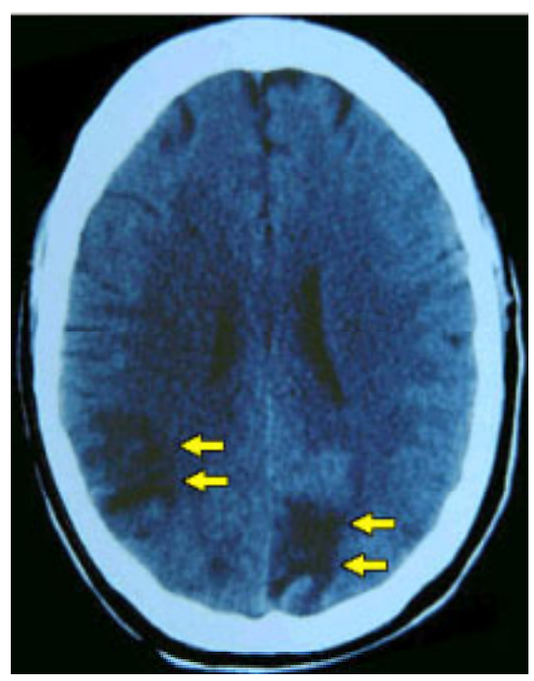


Magnetic resonance scan of the thoracic aorta in Marfan syndrome. There is dilation of the descending aorta with an average diameter of approximately 3 cm.

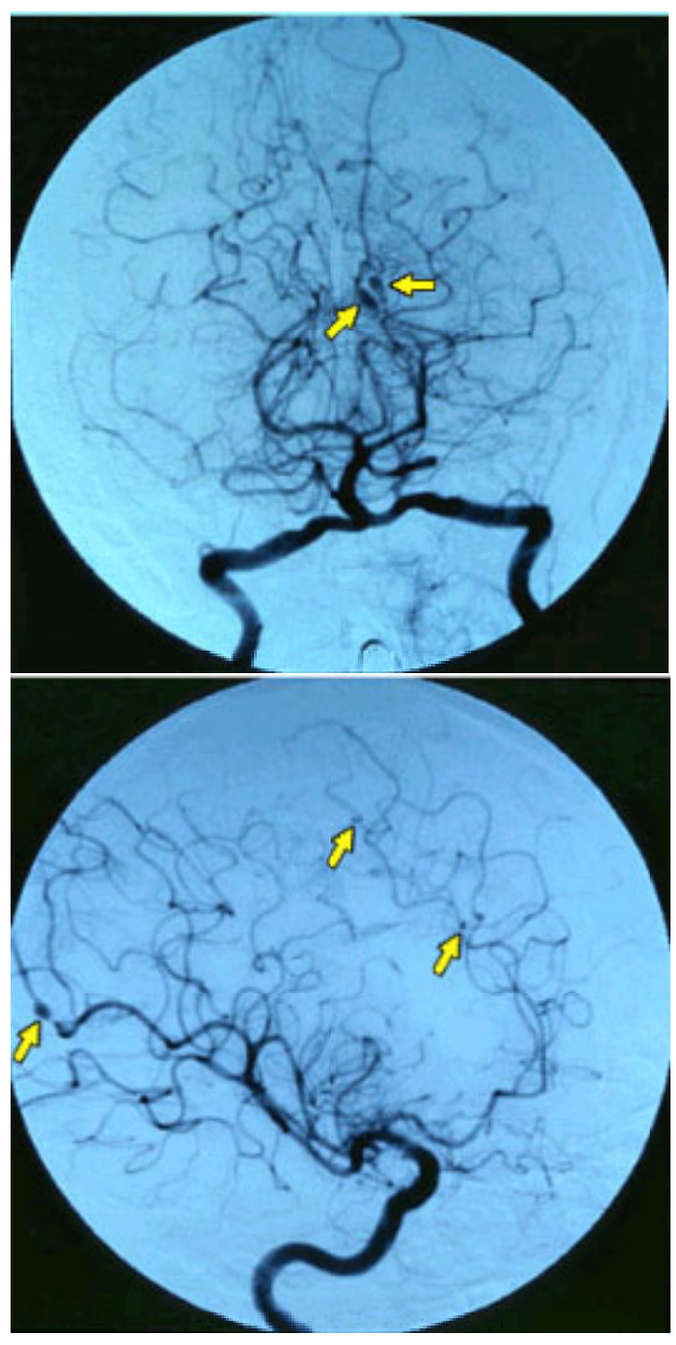


Chest x-ray in coarctation of the aorta. There is prominent rib notching (*white arrows*).

Mycotic aneurysms are a complication of subacute bacterial endocarditis in which an infective embolus produces a local arteritis and septic degeneration of the vessel wall. The true incidence of mycotic aneurysms is unknown and would require cerebral angiography in a large series of patients with subacute bacterial endocarditis to ascertain. The location of such aneurysms at peripheral cerebral branch sites and their small size defy adequate visualization by any currently available noninvasive neuroimaging technique, including MRA (327). The neurologic profile most suggestive of a possible mycotic aneurysm is a focal neurologic deficit consistent with cerebral embolism. In patients who have successfully completed their full course of appropriate antibiotic therapy, the risk for late mycotic aneurysm rupture is estimated to be less than 3% (136,137).



Ruptures mycotic aneurysms. Several areas of hypodensity representing ruptured mycotic aneurysms as a result of endocarditis (*arrows*).



Mycotic aneurysms from infective endocarditis. Localized aneurysmal dilatation of cerebral vessels as a result of endocarditis (*arrows*, A,B).

Atherosclerotic aneurysms are tortuous vessels that are most frequently located in the vertebrobasilar system; however, they can affect the major intracranial internal carotid branches. Symptoms are produced by mass effect, ischemia from branch artery occlusions, and obstructive hydrocephalus but rarely from rupture (Fig. 110.8).

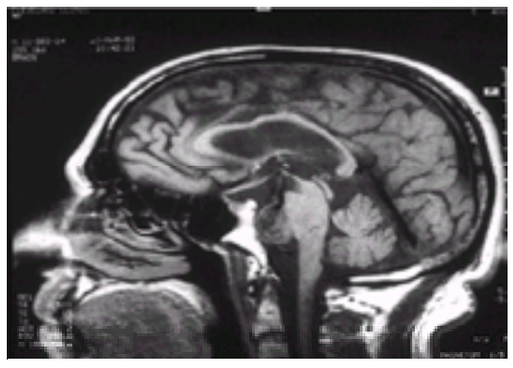


FIGURE 110.8 Magnetic resonance image demonstrating a large fusiform basilar arterial aneurysm producing brainstem compression and transient ischemic attacks.

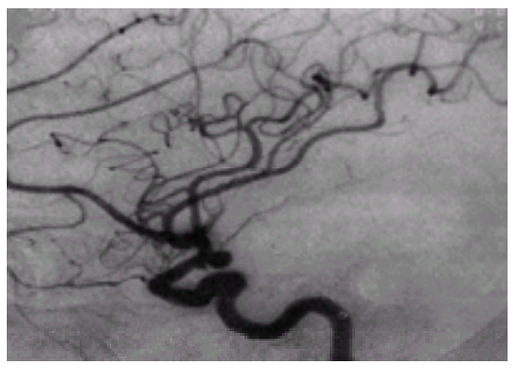
Unruptured Saccular Intracranial Aneurysms

The risk of rupture of incidental or symptomatic unruptured aneurysms is 1% to 2% per year (331,332 and 333). Factors that increase this risk include aneurysm size, multiplicity, location, and the patient's age. The median diameter of a ruptured aneurysm is 7 mm, with most being 5 to 10 mm. This translates into the common practice of considering surgery for any aneurysm larger than 5 mm (332,334,335 and 336) (eFig. 110.8.1).



***e*FIGURE 110.8.1** Lateral carotid arteriogram showing a posterior communicating arterial aneurysm.

Aneurysms rarely present with symptoms other than rupture with subarachnoid hemorrhage, but when they do, they can pose a diagnostic challenge. Enlargement and thrombosis can produce a mass effect, causing headache and focal neurologic signs appropriate to the structures involved. The most recognized syndromes include (a) a painful third nerve palsy with ptosis, mydriasis, and loss of pupillary light reflex with an expanding aneurysm at the origin of the posterior communicating artery; (b) a painful unilateral visual loss with diplopia due to an ophthalmic artery aneurysm; or (c) vertigo, brainstem signs, and hydrocephalus with an atherosclerotic fusiform vertebrobasilar aneurysm. Giant aneurysms also on rare occasions may embolize intraaneurysmal thrombotic material and may present as TIA or stroke.

SUBARACHNOID HEMORRHAGE: MANAGEMENT PRINCIPLES

Subarachnoid hemorrhage carries the highest mortality of all stroke and warrants highly specialized management (337,338 and 339). The introduction of microsurgical techniques has substantially reduced operative morbidity and mortality, but nonoperative complications of rebleeding, vasospasm, and hydrocephalus continue to contribute to the poor outcome in many patients (339,340,341 and 342).

Rebleeding occurs in 30% of patients, is highest in the first 3 weeks, and carries a much higher morbidity and mortality risk (343). Transient episodes of hypertension have often been observed to precede and to perhaps precipitate rebleeding, but antihypertensive treatment per se has not been shown to improve outcome (344). Nevertheless, precautions for patients with aneurysm include a combination of bed rest, analgesia, stool softeners, dim lighting, and strict visitor limitations; in short, avoidance of any stimulus that may cause agitation or excitement and result in a rise in blood pressure. The optimal blood pressure range in the post–subarachnoid hemorrhage period remains undefined but generally is within approximately 5% of the premorbid range.

Vasospasm

Vasospasm is clinically present in approximately 30% of patients, although angiographic evidence is present in approximately 70% (345,346). Symptoms of a focal neurologic deficit with a depression of consciousness usually begin between the third and fifth days after subarachnoid hemorrhage and peak between the fifth and fourteenth days, resolving over a period of weeks. Transcranial Doppler ultrasonography is useful in diagnosis and helps guide hypervolemic, hypertensive therapy (347,348). Hyponatremia often parallels the time course of vasospasm, is due to natriuresis or cerebral salt wasting and volume contraction mediated by atrial natriuretic factor, and is managed with intravascular administration of isotonic fluids (349,350). Oral nimodipine, 60 mg every 4 hours started within 4 days of the hemorrhage and continuing for 21 days, has been shown to reduce poor outcome due to vasospasm for patients of good neurologic condition after the ictus (i.e., Hunt and Hess grades I, II, and III) (351,352,353,354,355 and 356).

Medical Comorbidities

Subarachnoid hemorrhage is often accompanied by a massive rise in circulating levels of catecholamines that results in subendocardial ischemia, infarction, and arrhythmias. Premature ventricular complexes, bradyrhythmias, or supraventricular tachycardias occur in up to 90% of patients; however, potentially malignant arrhythmias such as atrioventricular dissociation, idioventricular arrhythmias, and ventricular tachycardia occur in 20% to 40% of patients. Arrhythmias are most frequent in the first 48 hours after subarachnoid hemorrhage, are often associated with QTc prolongation or hypokalemia, and may lead to sudden death.

Common pulmonary complications of subarachnoid hemorrhage include aspiration pneumonia and pulmonary edema. Pulmonary edema after subarachnoid hemorrhage may be due to elevated cardiac filling pressures or may be neurogenic, to which pulmonary capillary tight junction disruption is postulated as an important contributor.

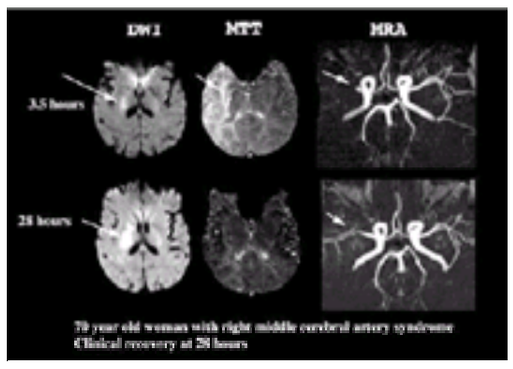
Hydrocephalus complicates 20% of cases and when acute and untreated, carries a grave prognosis. Hydrocephalus more frequently develops insidiously, resulting in impaired consciousness, lower limb spasticity, and increased ICP. Ventricular drainage is recommended for symptomatic patients; however, catheterization carries a risk for rebleeding and infection, and catheter patency may be difficult to maintain (357,358 and 358a).

Seizure-like events are more common at the ictus but may also occur in a delayed fashion and carry a potential risk for rebleeding. Use of prophylactic anticonvulsants in the early posthemorrhage period is recommended; however, long-term continuation is not necessary if the patient has been seizure free (359).

FUTURE DIRECTIONS

Advances in neuroimaging may refine patient selection for thrombolysis and other treatment strategies. Currently, a noncontrast CT scan is performed to exclude a hemorrhage or mass that can mimic stroke, as ischemic changes of sulcal effacement and blurring of the gray-white distinction are rarely seen before 3 hours after ictus. Diffusion-weighted MRI detects the random movements of water protons, which rapidly become restricted in ischemic tissue. Areas destined for infarction can be demonstrated on diffusion-weighted imaging sequences within several hours, expand to reflect ischemic edema, and then contract to correlate closely with T2-weighted images of the ultimate infarct volume. Perfusion MRI is a qualitative map of brain perfusion generated after a bolus of contrast. The demonstration of the penumbra of potentially salvageable tissue represented by the difference between the perfusion imaging and diffusion-weighted imaging regions is believed to have implications for

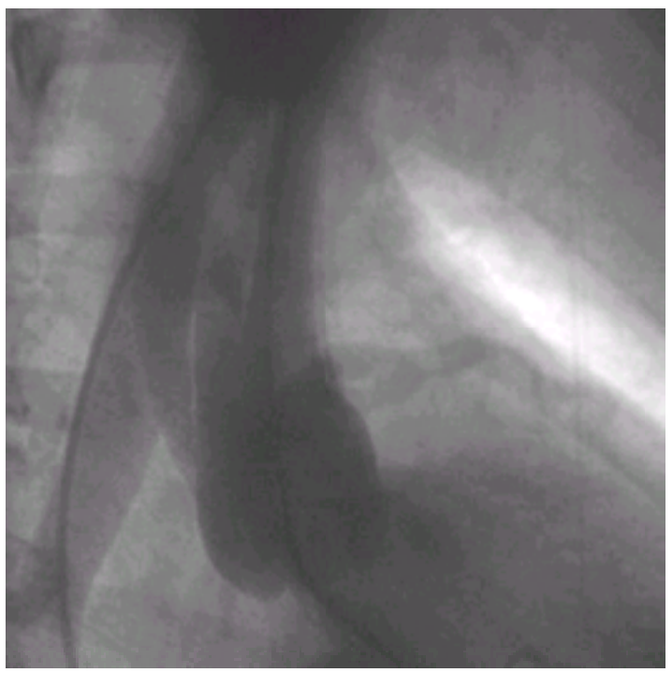
determining the true window of opportunity for reperfusion therapy (360,361). The addition of MRA of the extracranial and intracranial circulation would rapidly complete the assessment of vascular anatomy and collateral supply (*e*Fig. 110.8.2).



***e*FIGURE 110.8.2** Diffusion-weighted magnetic resonance image (DWI) depicting a small area in the basal ganglia of completed infarction with perfusion imaging sequences indicating a large area of middle cerebral artery distribution cortex at risk for infarction in the setting of a middle cerebral artery occlusion. Arterial recanalization with reperfusion of the middle cerebral artery occlusion reverses the perfusion abnormality. MRA, magnetic resonance angiogram; MTT, mean transit time.

Reperfusion will remain a core treatment strategy in acute ischemic stroke. Thrombolysis is in its infancy for treating cerebrovascular disease. New thrombolytic agents and delivery techniques that will improve reperfusion rates while limiting the risk of serious cerebral hemorrhage may well emerge. Thrombolytic agents with shorter half-lives and even more clot specificity are under development. Adjunctive agents such as platelet IIb/IIIa receptor antibodies may enhance recanalization; however, the risk of intracerebral hemorrhage limits their use to more than the coronary circulation.

Endovascular therapies provide many therapeutic opportunities. Advances in catheter design may permit recanalization of large vessel occlusions previously resistant even to direct intraarterial thrombolysis. A variety of mechanical strategies for clot removal in patients with acute stroke are under investigation. These range from lasers to high-pressure saline jet technology to simple snare devices. The theoretical advantages of these approaches include more rapid and complete clot removal and minimization of the use of thrombolytic agents.



A 77-year-old male patient presented to the emergency department with severe chest pain and hypertension. Aortogram revealed type A aortic dissection.

Numerous neuroprotective agents, many with dramatic effects in animal models, have made their way into clinical trials and onto a long list of efficacy failures for human stroke (362,363,364,365,366,367,368,369,370,371,372 and 373). Moderate to profound hypothermia, in use for decades as a means of protecting tissue during cardiovascular and neurovascular procedures, has been shown to decrease infarct volume and extend the time required for tissue damage to occur (therapeutic window). Complications include cardiac arrhythmias, pneumonia, and sepsis, and in patients with large hemispheric infarcts, the cerebral edema may just be delayed only to recur during rewarming. Two clinical trials are addressing hypothermia for cerebral protection. The Cooling for Acute Ischemic Brain Damage (COOL AID) trial focuses on moderate hypothermia in acute ischemic stroke of less than 12 hours' duration using an intravenous heat-exchange catheter that obviates the need for sedation, paralysis, and intubation (374). Intraoperative Hypothermia for Aneurysm Surgery Trial (IHAST) uses intraoperative surface cooling in patients with aneurysmal subarachnoid hemorrhage.

THE FUTURE

A better understanding of the risk factors specific for each stroke subtype will advance preventive strategies. Endovascular interventions will evolve and mature, combined with thrombolysis for acute ischemic stroke, as an alternative to surgery for aneurysms and vascular malformations and in the treatment of inaccessible occlusive disease. Stroke health care delivery systems will continue to evolve to allow better patient access to care.

Controversies and Personal Perspectives
When Is It Appropriate to Revascularize?
Who Should Decide on the Revascularization Strategy, and Who Should Perform Percutaneous Interventions?
Chapter References

OVERVIEW

Although their primary focus remains in the diagnosis and treatment of cardiac disorders, many cardiovascular specialists are no longer limiting themselves to treatment of coronary artery disease (CAD) but instead are adopting a "global vascular management" strategy for their patients. This approach has been promulgated by institutions setting up divisions of vascular medicine under two premises. First, the peripheral vasculature makes up the largest single "organ system" in the body—one that is complex and fascinating in its biology and dynamic in its function. The peripheral vessels hold many biologic secrets that, when unlocked, will open doors for new therapies for both noncoronary and coronary diseases. Second, both patients and medical science could benefit from the perspective and knowledge gained from a medical (as opposed to surgical) subspecialty whose sole focus encompasses the evaluation and management of vascular disease.

Cardiovascular specialists can no longer realistically limit their focus to the coronary vasculature. The coronary and noncoronary circulations are interdependent; they commonly coexist and may each cause disabling or life-threatening symptoms. Furthermore, they are affected by the same disease processes and often require similar treatment modalities. The approaches to treatment of one often depend on the other. For example, patients requiring vascular surgery generally have higher cardiac risk than those undergoing nonvascular surgery because of the increased prevalence of CAD in this group. Likewise, many patients under treatment for CAD are disabled by symptomatic peripheral arterial disease (PAD); post–myocardial infarction patients with claudication may not be able to be appropriately rehabilitated without treatment of their PAD.

Toward that end, the ensuing chapter is designed to provide a brief overview of the major disease states that occur in the peripheral arteries, as well as a synopsis of current treatment for each condition. The principal focus of the chapter, however, is on the management of *atherosclerotic* PAD. By far the most common disorder of lower extremities encountered by North American physicians, it afflicts more than 20% of men and women combined older than the age of 75 years (1). An aging population guarantees that the prevalence will continue to increase. Significant technological advances, especially in percutaneous therapies, over the past 10 years now enable safer and more efficacious treatment of atherosclerotic PAD. Knowledge about the range of therapeutic options available, and in which patients to apply them, is critical to the optimal management of these patients.

DISEASE STATES OF THE PERIPHERAL ARTERIES

Atherosclerosis

PAD, or arteriosclerosis obliterans, is the most common cause of symptomatic obstruction in the peripheral arterial tree. The pathophysiologic basis of PAD is identical to that of coronary artery atherosclerosis; the same risk factors are also associated, including tobacco smoking, diabetes mellitus, hypertension, hyperlipidemia, a positive family history, and advanced age. The estimated prevalence of PAD in people age 65 years or older is 20%; this estimate may, in fact, be conservative due to the presence of a large number of patients who have either asymptomatic disease or in whom the symptoms are not recognized as being due to arterial obstruction. The latter group, those in whom PVD symptoms are overlooked or falsely attributed to other etiologies (deconditioning, arthritis), make up an important subset who, if appropriately diagnosed, might benefit from available treatments.

The clinical presentation of patients with PAD is highly variable and depends on the involved vascular territory. Lower extremity symptoms range from mild discomfort during intense exercise to the presence of constant rest discomfort, painful ulceration, or frank gangrene. Claudication is described variably as pain, tightness, aching, soreness, hardness, or heaviness that occurs in the calf, buttocks, hips, or arch of the foot during ambulation and resolves with rest, similar to the pattern of exertional angina in CAD. Although intermittent claudication can be mild and nondisabling, it can become severely disabling. Pain at rest occurs if the impairment of blood flow is severe enough that oxygen and nutrient supply falls below the resting requirements of the distal tissue. Where the level of tissue ischemia is severe, cell injury and

death will occur, leading to tissue breakdown, clinically manifested as ulceration or gangrene. Neither of these is likely to resolve without restoration of nutrient (usually pulsatile) flow to the affected extremity. Similar symptoms occur in the hand or forearm of patients with severe atherosclerosis of vessels supplying the upper extremities.

As is the case in CAD, symptoms related to PAD rarely occur until the atherosclerotic process has narrowed the vessel diameter by at least 50%. However, the presence of one or more lesions with 50% or more narrowing does not imply that the patient will be symptomatic. Indeed, a large number of patients with PAD remain asymptomatic, even in the presence of severe and extensive disease. Patients with complete occlusion of the major blood supply to a limb or organ may have no symptoms if an ample collateral supply is present. Rutherford et al., by defining the signs and symptoms according to their intensity and combining these with noninvasive data, developed a series of categories to describe the severity of chronic limb ischemia (Table 111.1) (2). Such standardization has greatly enhanced the ability of investigators to perform meaningful comparative analyses of treatment strategies. Furthermore, it has facilitated decision making for clinicians regarding optimal therapy for a given level of limb ischemia.

Grade	Category	Clinical description	Objective criteria
0	0	Asymptomatic	Normal treadmill/stress test
	1	Mild claudication	Completes treadmill exercise,[a] ankle pressure after exercise <50 mm Hg but >25 mm Hg less than brachial
I	2	Moderate claudication	Between categories 1 and 3
	3	Severe claudication	Cannot complete treadmill exercise and ankle pressure after exercise <50 mm Hg
II	4	Ischemic rest pain	Resting ankle pressure <40 mm Hg; ankle or metatarsal pulse volume recording flat or barely pulsatile; toe pressure <40 mm Hg
	5	Minor tissue loss—nonhealing ulcer, focal gangrene with diffuse pedal ischemia	Resting ankle pressure <40 mm Hg; flat or barely pulsatile ankle or metatarsal pulse volume recording; toe pressure <30 mm Hg
III	6	Major tissue loss—extending above transmetatarsal level, functional foot no longer salvageable	Same as category 5

TABLE 111.1 CLINICAL CATEGORIES OF CHRONIC LIMB ISCHEMIA

Natural History of Peripheral Arterial Disease

An important consideration in any treatment strategy of patients with PAD is the natural history of both symptomatic and asymptomatic disease. The uninterrupted clinical course of lower extremity arterial disease is usually one of slow progression of symptoms over time (3). Approximately 70% of patients will remain unchanged or even less symptomatic after 5 to 10 years; less than 30% will progress to require intervention; and less than 10% will need amputation. Patients with diabetes mellitus, who comprise a large percentage of patients with PAD, are a unique subgroup in terms of prognosis and natural history of the disease. Diabetics have a higher likelihood of developing critical limb ischemia; indeed, their amputation rate is seven times greater than in nondiabetic patients with PAD.

Therapy for Atherosclerotic Peripheral Arterial Disease

The goals of therapy are to maintain functional status, reduce or eliminate ischemic symptoms, and prevent progression of disease. Insofar as PAD is a marker for systemic atherosclerosis, a secondary goal is to reduce the incidence of coronary and cerebrovascular events. Therapeutic options include conservative measures, percutaneous intervention, and surgery. With respect to noninvasive measures, risk factor modification (cessation of smoking is paramount) should thus be an important part of any treatment plan and may reduce progression of disease. Because limb ischemia may stimulate collateral growth, formal exercise training in a supervised setting may increase claudication-free walking distance by approximately twofold in patients with mild or moderate symptoms. Those with severe claudication, rest pain, or tissue loss (e.g., Rutherford category of 3 or more) are less likely to benefit from exercise.

Patients with PAD should receive drug treatment for coexisting disease (e.g., hypertension), risk factor modification (e.g., hyperlipidemia), and prophylaxis against thrombotic events associated with atherosclerosis (e.g., antiplatelet drugs), predominantly to reduce associated cardiac and cerebrovascular morbidity and mortality. No pharmacologic agent has proved efficacious enough to produce significant improvement in symptoms of PAD to gain widespread acceptance or use. Two established drugs, however, have gained U.S. Food and Drug Administration approval. Pentoxifylline (Trental), a rheolytic agent, has shown up to a 21% increase over placebo in walking distance; patients most likely to benefit were those with symptoms for longer than 1 year and an ankle-brachial index of less than 0.80. However, most investigators agree that Trental is of little overall value in the treatment of symptomatic PAD (4). Cilostazol (Pletal), a phosphodiesterase III inhibitor with vasodilator and antiplatelet activity, more recently gained approval and has demonstrated benefit in some patients. In randomized trials, cilostazol led to a 47% increase in walking distance compared with placebo (13%) and improved quality of life (5). Prostaglandins have been used in several studies of patients with critical limb ischemia with some success (6). A number of vasodilator (e.g., calcium channel blockers, alpha-adrenergic antagonists), antiplatelet (e.g., aspirin, ticlopidine, clopidogrel) (7), and metabolic agents (L-carnitine, L-arginine) (8) have been studied, but none has been conclusively demonstrated to improve symptoms related to PAD.

Another novel form of “medical” or “noninvasive” therapy currently under investigation in early phase I and II clinical trials is the use of growth factors to treat critical limb ischemia (9,10). The premise behind this treatment is that the obstructed main vessel may not require recanalization if flow can be augmented by the development of more collateral vessels, a process termed *therapeutic angiogenesis*. Angiogenic cytokines (e.g., vascular endothelial growth factor and basic fibroblast growth factor) can be administered as recombinant protein or as gene encoding for that protein, either by direct intravascular infusion or site-specific intramuscular injection.

Invasive therapy, including percutaneous revascularization and surgery, is the most effective therapy for immediate relief of symptoms related to PAD. Major advances in recent years have facilitated less invasive treatment modalities. The latter two-thirds of this chapter are devoted to the implementation of these new techniques and their results vis-à-vis surgical therapy.

Atheroembolism

Atheroembolism is a particularly malignant consequence of advanced atherosclerotic PAD. It is caused by embolization of micro- or macroscopic friable or ulcerated atherosclerotic plaque debris, liberated from the proximal arterial tree, either spontaneously or after provocation by direct surgical or catheter manipulation. Atheroembolism may result in ischemia or infarction of the tissue supplied by the small arteries and capillaries to which the debris travels. Atheroembolism to the lower extremities may be focal, in which one or more toes are involved (causing the so-called blue toe syndrome) or diffuse, causing bilateral livedo reticularis, cyanosis, and pain; ischemia may progress to painful ulceration and gangrene, depending on the embolic load and the status of the underlying vasculature. Involvement of the renovascular bed may result in deterioration of renal function.

Atheroemboli. Embolization of cholesterol, fibrin, and platelet debris results in digital necrosis and gangrene (*yellow arrow*), as well as localized skin

necrosis and livedo reticularis (*white arrows*).

Atheroemboli. Embolization of cholesterol, fibrin, and platelet debris results in digital necrosis and gangrene, as well as localized skin necrosis and livedo reticularis (*white arrows*).

Atheroemboli. Digital necrosis resulting from severe atheroemboli.

The treatment strategy for atheroembolism includes conservative local measures for the affected tissue and, importantly, appropriate steps to avoid future embolic events. These steps might include antiplatelet therapy and avoidance of future surgical and catheter manipulation near the presumed source of embolization, such as the abdominal aorta. Occasionally, especially in the case of recurrent atheroembolism, exclusion of the embolic source, either via percutaneous or surgical means, is recommended.

Other Disease States

Several other disease states involve the peripheral vessels; these include the vasculitic syndromes, thromboangiitis obliterans (TAO; Buerger's disease), vasospastic disorders, and the hypercoagulable states.

Vasculitis

The vasculitic syndromes (11) have in common the presence of vessel wall inflammation, but otherwise they are quite heterogeneous in their pathophysiology, clinical presentation, and consequences. The systemic necrotizing vasculitides (polyarteritis nodosa, Wegener's granulomatosis, essential cryoglobulinemia) and the hypersensitivity vasculitides can occasionally cause symptoms of claudication but more often are associated with cutaneous manifestations or signs and symptoms of organ involvement. In contrast, patients with Takayasu's disease not infrequently present during the chronic phase with upper and/or lower extremity claudication or with hypertension related to abdominal aortic coarctation and renal artery stenosis (RAS). Interventional treatment may sometimes alleviate the obstruction in these cases.

Thromboangiitis Obliterans (Buerger's Disease)

TAO is an aggressive form of inflammatory vasculitis, affecting predominantly the small- and medium-sized arteries and veins of the upper and lower extremities; it occurs in young (younger than 50 years old) predominantly male smokers and is associated with inflammatory thrombosis of extremity vessels (12). The etiology of TAO is poorly understood, but tobacco smoking clearly plays a central causative role. Patients typically present with an ischemic ulceration of one or more digits, which may progress to gangrene. They may have associated arch, foot, or calf claudication; cold sensitivity; and/or episodic superficial thrombophlebitis. The disease almost always involves two or more limbs; an abnormal Allen's test is present in two-thirds of patients. Proximal vessels in patients with TAO are normal, but angiography often demonstrates occlusion of small distal branches.

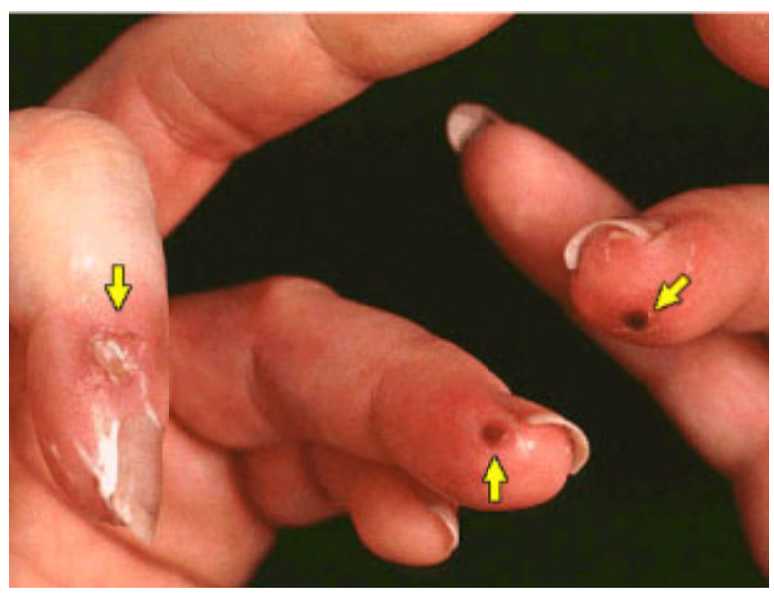
Buerger's disease (arteriosclerosis obliterans). Ulcers and gangrene from atherosclerosis involving the lower-extremity vasculature.

Buerger's disease (thromboangiitis obliterans). This inflammatory occlusive vascular disorder of small and medium-sized arteries and veins results in digital gangrene (*yellow arrows*), as well as skin ulceration (*white arrows*).

Several other diseases can mimic TAO, so excluding these other entities in the differential diagnosis is essential. Therapy for TAO consists primarily of (a) absolute cessation of smoking, (b) appropriate treatment of ulcers, including amputation if needed, and (c) palliation of symptoms. Judicious use of vasodilators, aspirin, anticoagulants, prostanoids, and sympathectomy may be appropriate in certain cases. Invasive treatment, both surgical and percutaneous, has little or no role in the treatment of TAO. The cornerstone of treatment is complete cessation of cigarette smoking, which generally leads to quiescence of the disease and eliminates need for repeated amputations (3). More recently, a strategy of intramuscular vascular endothelial growth factor gene transfer has been used successfully to eliminate rest pain and heal ischemic ulcers in patients with TAO (13).

Vasospastic Diseases

Vasospastic conditions, including Raynaud's phenomenon and others, can produce transient ischemic symptoms in the extremities, particularly involving digits. Most of these abnormalities are related to or exacerbated by cold exposure. Raynaud's may occur as an idiopathic phenomenon, in association with a number of collagen vascular, hypercoagulable, malignant, ischemic, drug-related, or metabolic syndromes (1).



Raynaud's disease. Ulcers and gangrene on the fingertips are shown (*arrows*) caused by vasospasm and abnormalities of digital vessels. Associated cardiac findings are coronary vasospasm and primary pulmonary hypertension.

Although most "attacks" are mild, patients with severe Raynaud's will occasionally present with ulceration or gangrene due to prolonged vasospasm. Treatment of Raynaud's and other vasospastic disorders is aimed at measures both local (e.g., warming the extremity) and pharmacologic that facilitate vasodilation.

Hypercoagulable States

A variety of hypercoagulable syndromes have been identified over the past two decades. Certain of these (e.g., hyperhomocysteinemia) are associated with premature onset of peripheral atherosclerosis and, secondarily, predisposition to thrombosis. Others, including the so-called primary hypercoagulable states (e.g., antithrombin III deficiency and protein C or S deficiency) and antiphospholipid syndrome, predispose patients to early thrombosis of arterial grafts and veins. The therapeutic approach to these patients includes early recognition of the abnormality and judicious use of anticoagulants and/or antiplatelet agents (14).

Acute Limb Ischemia

Acute limb ischemia most commonly occurs as a result of embolic arterial occlusion; the embolic source is cardiac in more than three-fourths of cases, and atrial fibrillation is responsible for the vast majority. *In situ* thrombosis of diseased native extremity vessels occurs less frequently; when spontaneous thrombosis does occur, especially in the absence of an underlying high-grade stenosis, the possibility of a previously unrecognized hypercoagulable state must be entertained. Bypass graft thrombosis with or without underlying impediment to flow is another frequent cause of acute limb ischemia.

Diagnosis

The clinical presentation of acute limb ischemia is typically dramatic, with acute onset of severe pain followed shortly thereafter by paresthesia and, ultimately, motor dysfunction (e.g., paralysis). On examination the extremity is cool, pale, and pulseless. Rutherford and colleagues described a series of clinical categories of acute limb ischemia (Table 111.2), with well-defined diagnostic criteria that help determine whether the affected limb is viable, in imminent jeopardy (e.g., "threatened"), or already irreversibly damaged (15). Whether a given patient will present with one category or another depends on many factors, including the duration of occlusion, the level and etiology of the occlusion, the status of the underlying vessels, and general factors (blood pressure, cardiac output, presence/absence of diabetes, oxygen saturation). Paradoxically, it is often the patient with less underlying PAD who develops the most severe ischemia—for example, the patient with atrial fibrillation and normal peripheral vessels who embolizes to the common femoral or popliteal arteries. The presence of better-developed collaterals in the patient with preexisting PAD can be protective.

Category	Description	Capillary return	Muscle weakness	Sensory loss	Doppler signals	
					Arterial	Venous
Viable	Not immediately threatened	Intact	None	None	Audible (ankle pressure >30 mm Hg)	Audible
Threatened	Salvageable if promptly treated	Intact, slow	Mild, partial	Mild, incomplete	Inaudible	Audible
Irreversible	Major tissue loss, amputation regardless of treatment	Absent (marbling)	Profound, paralysis	Profound, anesthetic	Inaudible	Inaudible

TABLE 111.2 CLINICAL CATEGORIES OF ACUTE LIMB ISCHEMIA

Therapy

Patients with acute limb ischemia, especially those with threatened limbs, require immediate attention and an accelerated effort to restore nutrient flow to the jeopardized limb. Treatment for each patient is individualized, as discussed later in this chapter. Options include surgical or catheter-based thrombectomy, bypass, thrombolytic therapy, or direct percutaneous recanalization.

CURRENT THERAPEUTIC APPROACH TO PERIPHERAL ARTERIAL DISEASE

Role of Catheter-Based Interventions

Since the pioneering work of Dotter, Judkins, Gruentzig, and others (16,17), technical innovations have resolved many of the limitations (large-profile balloons, stiff guidewires, and poor imaging equipment), and consequently reduced the hazards associated with the early years of percutaneous transluminal angioplasty (PTA). Catheter profiles have been streamlined, limiting complications related to vascular access. Novel materials for balloon and guidewire construction have facilitated passage through occluded vessels and permitted routine access to more remote vascular sites with less risk and greater efficacy. Directional and rotational atherectomy and laser irradiation now enable “debulking” of atheroma. Endovascular stents have dramatically improved both short-term and long-term outcomes of PTA (18,19,20 and 21). Foremost among improvements in imaging techniques has been the introduction of intravascular ultrasound (IVUS), digital enhancement of conventional contrast images, and magnetic resonance imaging.

Market forces and changes in population demographics have also made percutaneous revascularization increasingly attractive. Providers and insurers recognize that PTA, performed as a “same-day” procedure, is a potentially cost-saving approach. Patients favor using less-invasive techniques, even if the symptomatic improvement may not be as durable or the degree of revascularization not as complete; lower-risk partial revascularization by percutaneous means may suffice to treat symptoms and indeed may be preferable to higher-risk attempts at complete surgical revascularization. This philosophy is exemplified in the treatment of infrapopliteal disease in high-risk patients with limb-threatening ischemic ulceration, where even short-term restoration of antegrade flow by PTA can result in ulcer healing and the potential for long-term limb salvage, thereby providing a viable alternative to surgery in these patients (22). Finally, as the population ages, the prevalence of PAD is increasing, thus compelling health care providers to optimize treatment strategies. People older than age 65 years, the stage when vascular disease achieves its peak prevalence, now constitute nearly 15% of the population, a figure expected to double in the next 35 years. Judicious treatment of older patients disabled by PAD may enable them to experience the well-documented benefits of exercise and physical activity. In consideration of these goals, the availability of effective, “less invasive” percutaneous options for revascularization in this group of patients with a high-risk profile due to comorbid conditions has led to a reevaluation of the threshold for intervention.

The increasing popularity of percutaneous revascularization as first-line therapy for patients with PAD underscores the need for vascular specialists to have a comprehensive understanding of the mechanisms of angioplasty, indications for intervention, expected outcome, and potential complications of a given revascularization procedure.

Imaging in Percutaneous Angioplasty

Conventional contrast angiography remains the time-honored approach for lesion characterization. It is, however, limited by the fact that it depicts the vessel lumen only; plaque and vessel wall are viewed as a “negative imprint” on the contrast-filled lumen (23). Although this allows for characterization of lumen topography, irregularities within the vessel wall may only be inferred from the negative imprint. Furthermore, contrast angiography is limited to a single planar view per injection; as such, information regarding the circumferential nature of the plaque is not provided.

VIDEO

Video 111.1 Normal iliac-femoral run-off after distal aortography. In this example, cineangiography of a distal aortic injection is illustrated with brisk run-off in the iliac and femoral systems. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Pathologic evaluation of dilated vessels typically discloses plaque fractures and stretching of the arterial wall; the exact contribution of these, versus plaque compression and other factors that might augment lumen area, remains controversial. Most *in vivo* attempts to identify the mechanisms responsible for successful (or unsuccessful) PTA have been limited by the lack of ability to adequately assess the morphology and geometry of a lesion before and after treatment, and at the time of restenosis using standard angiographic imaging methods.

Intravascular Ultrasound

IVUS has become a very useful adjunctive imaging technique to contrast angiography by providing a cross-sectional view of the vessel similar to a histologic section, thereby addressing many of the angiographic limitations. IVUS is unequivocally superior to contrast angiography in its ability to demonstrate detailed characteristics at the interface of the lumen and vessel wall as well as within the plaque. Indeed, experimental and clinical experience indicates that IVUS images correlate remarkably well with histologic examination; IVUS is exquisitely sensitive in detecting details that are angiographically “silent” (Fig. 111.1 and Fig. 111.2) (24,25). For instance, angiographically normal sites that are adjacent to target lesions almost always demonstrate disease when imaged by IVUS. Similarly, calcified plaque, characterized by “acoustic shadowing,” is detected by IVUS in a majority of vessels undergoing angioplasty, a feature grossly underappreciated by angiography (26). Similarly, angiographically normal-appearing vessels are often found by IVUS to have diffuse plaque deposition, indicating a much more advanced stage of atherosclerosis than would have been presumed otherwise.

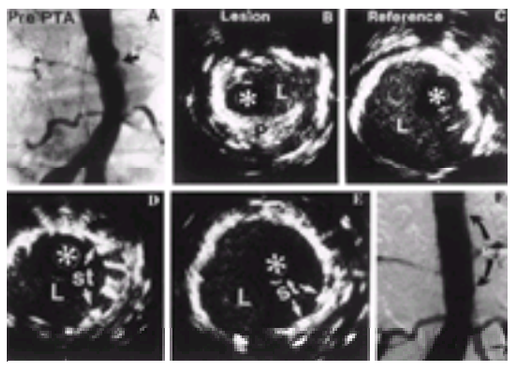

FIGURE 111.1 Superior imaging of eccentric aortic lesion by intravascular ultrasound (IVUS) compared with angiography. This 63-year-old woman presented with accelerated bilateral buttocks claudication, occurring at 1 to 2 blocks. **A:** Conventional anteroposterior angiography failed to disclose any significant stenosis; mild irregularity (*arrow*) was seen within the distal aorta. After discovering a large pressure gradient (see Fig. 111.4), IVUS examination was performed. **B:** IVUS image depicting focal eccentric plaque (P) narrowing the lumen (L) in distal aorta. **C:** IVUS from reference site distal to stenosis depicts normal lumen dimensions. **D:** Although lumen (L) is now enlarged compared with pre-percutaneous transluminal angioplasty (PTA), IVUS after 9-mm PTA/stent demonstrates stent underexpansion, with all struts (st) between 2 and 5 o'clock not in apposition to the arterial wall. **E:** IVUS after 12-mm PTA demonstrates complete expansion of stent, with all struts (st) now completely apposed to arterial wall and overall lumen (L) area further increased. **F:** Angiogram after 12-mm PTA shows slight decrease in luminal irregularity where stent has been redilated (*arrows*). *, IVUS catheter.

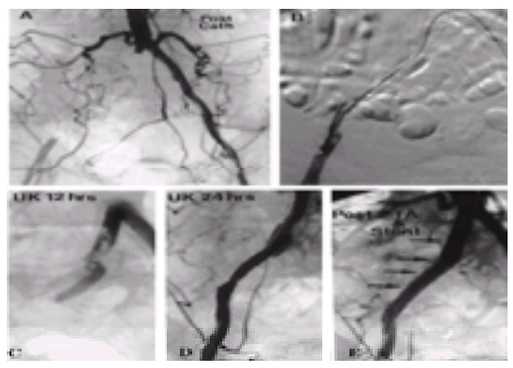

FIGURE 111.4 Thrombolysis, percutaneous transluminal angioplasty (PTA), and stent deployment in a patient with acute onset of right lower extremity ischemia after diagnostic cardiac catheterization (Cath). **A:** Baseline arteriogram demonstrates lengthy fresh occlusion of right common iliac artery, with reconstitution of common femoral artery by collaterals. **B:** Occlusion crossed in antegrade fashion from contralateral side and infusion of urokinase (UK) begun via Mewissen catheter and Katzen wire. **C:** After 12 hours of UK, common and external iliac arteries are now partially patent but have extensive dissection, residual thrombus, and blind cul-de-sac. Thrombolytic therapy therefore continued. **D:** After 24 hours of UK, vessel is now patent and thrombus resolved, but extensive dissection remains. **E:** After deployment of two Palmaz stents (*arrows*), the iliac artery is widely patent, with amelioration of dissection and elimination of the cul-de-sac. The patient remains asymptomatic 18 months later.

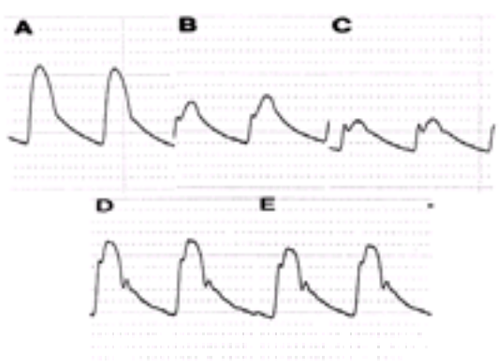

FIGURE 111.2 Intraarterial transstenotic pressure gradient before and after percutaneous transluminal angioplasty in the patient from Figure 111.3. **A:** Baseline blood pressure from aorta proximal to lesion. **B:** Pressure obtained simultaneously from aorta distal to lesion demonstrates 30-mm Hg peak gradient, which becomes exacerbated after administration of intraarterial nitroglycerin **(C)**. Proximal **(D)** and distal **(E)** aortic pressures after percutaneous transluminal angioplasty/stent are nearly identical, indicating hemodynamic improvement.

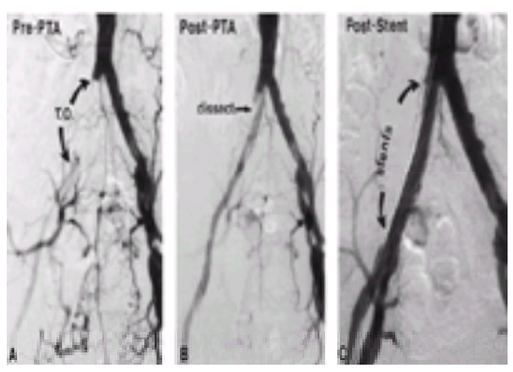

FIGURE 111.3 Percutaneous transluminal angioplasty (PTA) and stent deployment in chronically occluded right common iliac artery. **A:** Baseline angiogram demonstrates 5-cm total occlusion (T.O.) of right common iliac artery with reconstitution of external and internal iliac arteries. Occlusion was crossed using combination of angled and straight Glidewires, buttressed by a 4-Fr. catheter. **B:** Post-PTA angiogram demonstrating patent common iliac artery with extensive dissection (dissect.). **C:** Final angiogram after deployment of two Palmaz stents. Common iliac artery is widely patent. Baseline mean gradient of 37 mm Hg was reduced to 1 mm Hg. Patient is asymptomatic 4 years later.

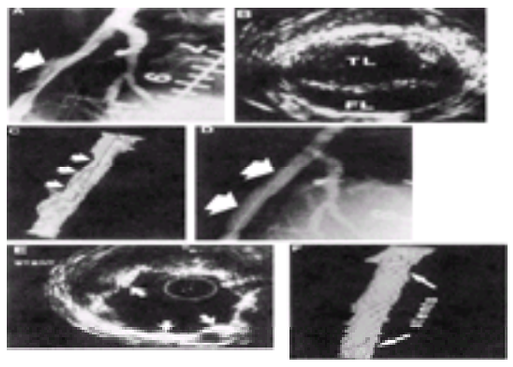
Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) has been increasingly used for assessment of the lower limb vasculature over the past decade. A metaanalysis of 34 MRA studies published in the past 8 years (27) showed that MRA was highly accurate for assessment of all lower extremity arteries, specifically for detection of stenoses greater than 50%, and three-dimensional gadolinium enhancement improved the diagnostic performance. Advancement in techniques has resulted in comparable accuracy of MRA to conventional arteriography or digital subtraction angiography for assessment of lower extremity arteries, particularly the infrapopliteal vessels. Nevertheless, until randomized trials are performed that compare outcomes of distal bypass surgery or infrapopliteal angioplasty based on arteriography and MRA, it will be unclear which modality is preferred.

Mechanisms of Angioplasty and Related Techniques

Plaque fracture, plaque compression, and stretching of arterial wall components all likely play a role in enhancing luminal dimensions. IVUS has provided new insight into the effects of angioplasty and other revascularization techniques (28). For example, observations from IVUS suggest that plaque fracture and/or dissection is associated with balloon dilation in the majority of angiographically and hemodynamically successful procedures (24). Vessels in which directional atherectomy (DA) is performed demonstrate less prominent plaque-arterial wall disruption; instead, the perimeter of the neolumen is typically smooth and uninterrupted, with discrete "bites" corresponding to individual passes of the cutting blade. Signs of arterial wall trauma, including severe disruption, are most completely ameliorated on IVUS images recorded after delivery of an endovascular stent (eFig. 111.2.1) (29).



***e*FIGURE 111.2.1** Amelioration of post–percutaneous transluminal angioplasty dissection of external iliac artery using stents. **A:** Post–percutaneous transluminal angioplasty angiogram demonstrates extensive dissection (*arrow*) in external iliac artery. **B:** Representative intravascular ultrasound frame shows extent of arterial wall trauma, with large dissection flap interposed between true lumen (TL) and false lumen (FL). **C:** Three-dimensional reconstruction of serial intravascular ultrasound images creates a "cast" of the vascular lumen, narrowed by dissection and encroaching false lumen (*arrows*). **D:** Angiogram after deployment of two Palmaz stents (*arrows*) shows improved patency, but the interface between stent and vessel wall is not delineated. **E:** Intravascular ultrasound image from stent site demonstrates amelioration of arterial wall pathology with effacement of dissection by expanded stent. Struts identified by arrows. **F:** Three-dimensional cast of stented iliac artery now depicts uniform dimensions throughout length of vessel, with resolution of luminal narrowing. Cobblestoned appearance of struts is evident.

ANATOMIC REGIONS OF INTEREST

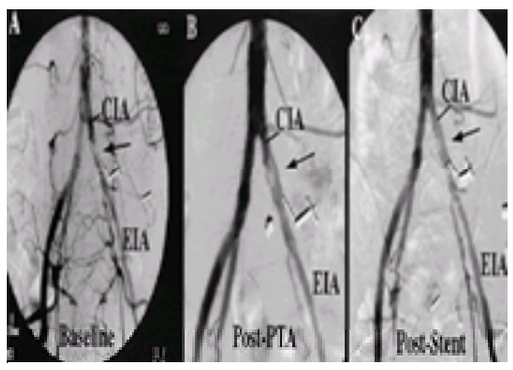
Therapy for certain sites within the peripheral circulation, particularly those previously considered to be inaccessible by the percutaneous approach, is evolving rapidly. Likelihood of success and chances for clinical improvement vary in degree according to the region of interest and extent of disease. However, because the management of an individual lesion in a particular patient depends on a number of factors, any classification or categorizing of recommendations is difficult (30). Weighted consideration of these individual issues is therefore required to determine, for any given combination of lesions, the appropriateness of nonsurgical revascularization (Table 111.3).

TABLE 111.3 REVASCULARIZATION STRATEGY FOR VARIOUS LOCATIONS (AS OF 2001)

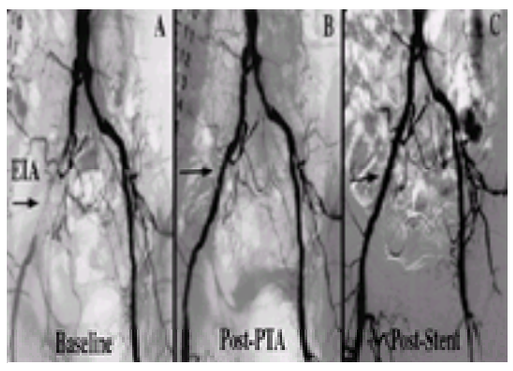
AORTOILIAC OBSTRUCTIVE DISEASE

Most stenotic disease in the infrarenal abdominal aorta and iliac arteries is atherosclerotic in origin. The excellent procedural and long-term results of aortoiliac PTA, enhanced by stenting, are so predictable that the physical finding of a diminished femoral pulse is a useful sign for identifying patients who are likely to derive benefit.

Aortoiliac revascularization is thus recommended for (a) relief of symptomatic lower extremity ischemia, including claudication, rest pain, ulceration or gangrene, or embolization causing blue toe syndrome (*e*Fig. 111.2.2) (31); (b) restoration and/or preservation of inflow to the lower extremity in the setting of preexisting or anticipated distal bypass (*e*Fig. 111.2.3) (32,33); (c) procurement of access to more proximal vascular beds for anticipated invasive procedures (e.g., cardiac catheterization/percutaneous transluminal coronary angioplasty, intraaortic balloon insertion) (34); and (d) rescue of flow-limiting dissection complicating access for other invasive procedures (*e*Fig. 111.2.4).

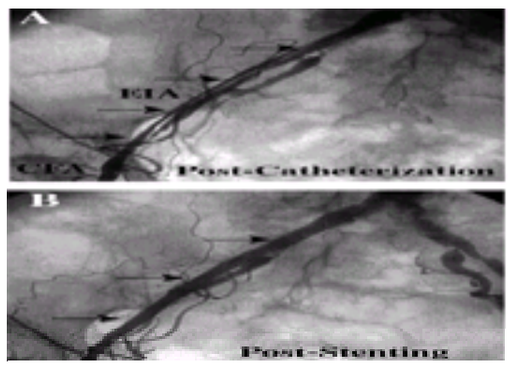


***e*FIGURE 111.2.2** Percutaneous transluminal angioplasty (PTA)/stent for iliac stenosis in a 54-year-old patient with Rutherford category 2 claudication and blue toe syndrome. **A:** Baseline angiogram demonstrates a focal stenosis in the left common iliac artery (CIA) resulting from a large, calcified, and ulcerated plaque (*arrow*) that was the likely source of the distal embolization. **B:** Persistence of the plaque (*arrow*) after balloon angioplasty; a suboptimal result despite some increase in luminal diameter. Rock-like calcium plaque remains a source of emboli. **C:** Exclusion of calcified plaque burden and restoration of full luminal patency after deployment of endovascular stent (*arrow*). EIA, external iliac artery.



***e*FIGURE 111.2.3** Percutaneous revascularization of external iliac artery (EIA) occlusion in a 75-year-old patient with distal disease and a nonhealing ulcer. Patient had significant coronary artery disease and previous abdominal surgery. Surgical risk of abdominal vascular reconstruction was therefore reduced by strategy of sequential percutaneous transluminal angioplasty (PTA)/stent and surgical distal bypass. **A:** Access obtained in the ipsilateral common femoral artery and the occlusion traversed

with a Glidewire. Angiography, in the left anterior oblique projection, demonstrates a lengthy (5 cm) occlusion of the right EIA (*arrow*), moderate disease of the contralateral common iliac artery, and right superficial femoral artery occlusion. **B:** Luminal patency was restored with balloon angioplasty (*arrow*). **C:** Final angiography after stent deployment demonstrates excellent result (*arrow*). Femoropopliteal bypass facilitated healing of the ulcer and resolution of symptoms.



***e*FIGURE 111.2.4** Eighty-four-year-old woman complaining of increasing right leg pain and coolness during cardiac catheterization. **A:** After cardiac catheterization, iliac angiogram demonstrates flow-limiting, lengthy spiral dissection (*arrows*). **B:** Flow was restored after treatment with percutaneous transluminal angioplasty and Wallstent (*arrow*). When encountering new symptoms of lower extremity ischemia during catheterization, angiographic delineation of the cause is preferable to removing the sheath and hoping for restoration of flow. EIA, external iliac artery.

Isolated Aortic Lesions

Isolated aortic lesions are relatively uncommon. Early reports of PTA for atherosclerotic aortic disease had been mostly limited to discrete, focal lesions of less than 2 cm in length (35). Successful dilation of these lesions was accomplished using either side-by-side simultaneously inflated balloons or a single large balloon, with favorable results in greater than 90% (36).

Aortoiliac Stenosis

Percutaneous therapy represents the first line of therapy for aortoiliac stenoses. Acute technical and clinical success of PTA alone for iliac stenoses exceeds 90%, and 1- and 5-year patency rates range from 75% to 95% and 55% to 85%, respectively (30,37). Stents have been shown to rescue the flow-limiting complications, reduce the acute recoil, and improve on the immediate hemodynamic results of PTA for aortoiliac stenoses, with acute technical success rates of 90% to 100% (eFig. 111.2.1 and Fig. 111.3) (30,38,39,40,41,42,43,44 and 45). Significant improvements in long-term patency have also been achieved in patients randomized to PTA and stent versus PTA alone: The angiographic patency (93%) in patients studied at 5-year follow-up rivals the best clinical patency reported at a similar time interval in patients undergoing operative revascularization (21,30).

Aortoiliac Occlusion

The approach to iliac occlusion is in evolution, moving from a predominantly surgically oriented therapy, to consideration of thrombolysis preceding PTA, and now toward a preference for primary PTA/stenting. There are two specific considerations in this regard. The first is the enhanced ability to traverse the segment of occluded artery (even chronic occlusions) by advancements in guidewire (e.g., hydrophilic) and catheter technologies (46) and novel technical approaches, such as the so-called pull-through technique (Fig. 111.3 and Fig. 111.4) (47), a combination that has yielded an extremely high procedural success rate, especially in lengthy occlusions. The second issue concerns the specter of acute limb-threatening ischemia resulting from distal embolization in direct (nonlytic) recanalization of iliac occlusions, previously reported to occur with alarming frequency (48). The current incidence of embolization in this setting is exceedingly low, especially if a strategy of initial underdilation followed by stent deployment is used; the stent provides a scaffold, which, in theory, affixes the thrombus/plaque to the vessel wall, thus reducing the likelihood of distal embolization. The exception is the case of documented recent thrombosis, where use of thrombolytic therapy is unequivocally indicated (Fig. 111.4) (49,50 and 51). The extent to which lytic therapy may further optimize the treatment of less acute iliac occlusions by exposing an underlying lesion and converting an occlusion to a stenosis remains to be defined.

PTA alone for aortoiliac occlusions has less favorable results than for stenoses; the technical success rate of PTA of segmental (external or common) iliac occlusions is 80% to 85% (37,52) and long-term patency rates are close to 80% at 1 year and 55% at 5 years (53). Consequently, stenting is the preferred primary therapy for aortoiliac occlusions (40,44,53); indeed, a strategy of primary stent deployment for aortoiliac disease has been adopted by many investigators (43,45,54). A metaanalysis (55) of more than 2,100 patients showed greater immediate success rate (96% vs. 91%) and higher 4-year patency rates (61% vs. 54%) for stents than for PTA alone; stents also reduced the relative risk of 4-year failure by nearly 39% over PTA alone. Disease severity and relative proximal locations also have a positive influence on the outcome of revascularization by stenting (42). In patients with only focal aortoiliac or common iliac lesions, the rates for complete relief of symptoms and 3-year persistent clinical benefit approach 90% and 95%, respectively, compared with 85% and 98% for patients with external iliac disease and 60% and 60% for patients with multilevel infrainguinal disease.

Use of Aortoiliac Percutaneous Transluminal Angioplasty/Stenting in Conjunction with Surgery

In some patients with claudication and in rare patients with limb ischemia, the iliac lesion typically coexists with more distal disease (56); in such cases, initial treatment of the iliac obstruction is based on the premise that improving inflow will secondarily improve outflow, either via the profunda in the case of an occluded superficial femoral artery (SFA) or by increasing the head of perfusion pressure to that segment of the infrapopliteal circulation that remains patent. Sometimes, this may obviate the need for reconstruction more distally. Implicit in this strategy are the lesser degree of technical difficulty, high incidence of procedural success, and low rate of restenosis associated with iliac PTA, compared with that for more distal segments.

A similar strategy underlies the preparatory role of iliac angioplasty in patients undergoing surgical revascularization for treatment of distal disease (eFig. 111.2.3) (56,57). Percutaneous revascularization of an iliac lesion may be required to facilitate patency of a downstream femoral-popliteal conduit designed to bypass an occluded SFA. Alternatively, in patients with coexistent coronary heart disease, the proximal anastomosis may be adjusted one level caudal, thereby reducing the risk associated with operative revascularization. For example, in the patient with a lengthy unilateral occlusion of one iliac artery and less extensive obstruction of the contralateral side, higher-risk aortofemoral bypass surgery may be obviated by percutaneous treatment of the less diseased iliac artery, followed by a cross-femoral graft to the contralateral femoral artery.

One additional issue regarding percutaneous treatment of aortoiliac disease deserves specific comment. This concerns the role of percutaneous revascularization in modifying the treatment of patients with cardiac disease, in whom abdominal-level surgery is associated with a marked increase in cardiac morbidity and mortality (58). Work from several groups (59,60 and 61) has demonstrated the feasibility of intraluminal insertion of stent-graft prostheses for the treatment of abdominal aortic aneurysms (AAAs).

Current Recommendations for the Treatment of Aortoiliac Disease

PTA is generally applied to more focal disease of the distal aorta, common iliac arteries, and external iliac arteries. The current consensus (30) is that stents are appropriate for use in aortoiliac disease in the following instances: for significant elastic recoil after PTA based on residual pressure gradient causing insufficient hemodynamic result; in flow-limiting dissection; for lengthy or complex lesions where balloon angioplasty has been shown to yield suboptimal results and for which primary stenting may give more satisfactory results; for restenotic aortoiliac lesion after previously performed PTA; in reconstruction of the aortoiliac bifurcation; for iliac artery ulceration associated with symptoms; for revascularization of “donor artery,” in preparation for more distal cross-femoral or femoral-to-distal bypass; and as primary therapy for aortoiliac chronic occlusion. Several issues, however, remain outstanding. First, the role of primary stent deployment for *uncomplicated* iliac lesions is yet to be defined. Many interventionalists believe this strategy is warranted, given the positive aspects and the absence of significant complications associated with stenting at this level. Second, the usefulness and cost-effectiveness of multiple stents also remain to be established.

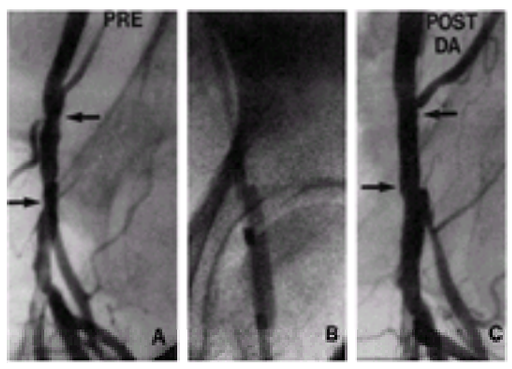
ABDOMINAL AORTIC ANEURYSM

Open surgical repair remains the current gold standard for treatment of AAAs. The operative mortality of resection is between 1.4% and 7.6% (59) and rises significantly for patients with symptomatic aneurysms. A substantial number of patients (15%) with AAA greater than or equal to 5 cm in diameter have comorbid conditions or unsuitable anatomy for repair. Such patients have a poor prognosis: a fivefold chance of rupture when the diameter exceeds 6 cm and a 5-year survival rate of 18% (62). Rapid advances have been made with endovascular devices, allowing high-risk patients with aneurysmal disease involving the abdominal aorta and other sites to benefit from the availability of less invasive therapy. Currently, more than 5,000 stent-graft procedures worldwide have been performed for AAA exclusion. The Guidant/EVT and Medtronic AVE AneuRx devices received U.S. Food and Drug Administration approval in 1999. Other devices include Boston Scientific Vanguard, Medtronic AVE Talent, Cook Zenith, Corvita Endograft, and Gore Prograft. D'Ayala and colleagues (61) reported a success rate of 74% to 100% in 767 patients, endoleaks in 14% (one-third sealed spontaneously), and 8% requiring conversion to open procedures; overall mortality was 4%. Two other studies report experience with the AneuRx stent-graft (60) and a combination of bifurcated Mintec and Boston Scientific Vanguard devices (59), achieving technical success in 80% to 90%, endoleaks in 10% to 20%, and morbidity rates of 10% to 15%. Current limitations include the obligatory sacrifice of one or both internal iliac arteries and the large-caliber device (12 Fr. to 28 Fr.), which requires access by femoral artery cutdown. Situations that may not be appropriate for stent-grafting include aneurysms with a short or absent proximal neck and severe angulation at the origin of the aneurysm. The use of stent-graft technology to treat iliac aneurysms has also been very successful (63).

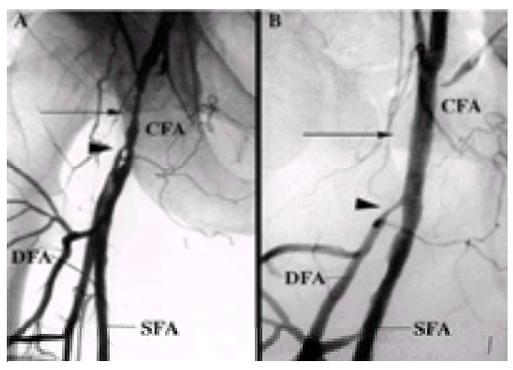
COMMON FEMORAL AND PROFUNDA FEMORIS ARTERIES

Revascularization of the common femoral artery (CFA) has long been considered to be exclusively surgical for several reasons. Access is easily achieved through a local incision and often under local anesthesia, the results of endarterectomy or patch angioplasty are outstanding, and this vessel has the propensity to demonstrate elastic recoil.

Lesions of the CFA may be accessed without great difficulty and results of PTA or DA can be quite favorable (*e*Fig. 111.4.1). Lesion characteristics play a significant role in determining the success of PTA (*e*Fig. 111.4.2). In general, the more calcification that is present, the less responsive is the CFA lesion to PTA, particularly lesions extending into the origins of the superficial femoral and profunda femoris arteries. However, the concern that PTA-induced plaque fractures could propagate into the common femoral bifurcation, leading to potential compromise of both the SFA and profunda, implicitly suggests that PTA of the CFA must be undertaken with considerable caution. The biggest impediments to successful long-term outcome after CFA revascularization are recoil and restenosis. There are no long-term studies, but the restenosis rate is widely accepted to be greater than 50%. The use of stents in the CFA is ill advised, as their placement may preclude future surgical procedures or compromise future attempts at percutaneous access.



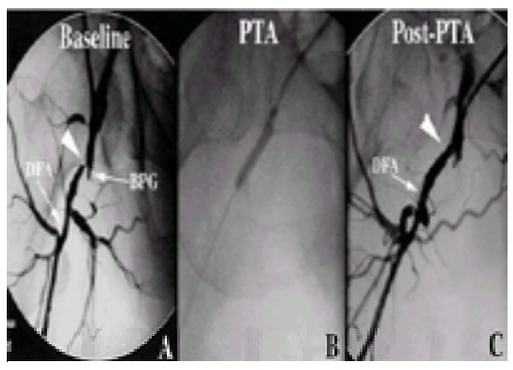
***e*FIGURE 111.4.1** Directional atherectomy (DA) of common femoral artery stenosis. **A:** Severe left common femoral artery stenosis *arrows*) in an elderly female with coronary artery disease. **B:** DA catheter placed via retrograde puncture. **C:** Angiogram post-DA demonstrating improved patency. Arrows indicate site of previous stenosis.



***e*FIGURE 111.4.2** Balloon angioplasty (percutaneous transluminal angioplasty) of common femoral artery in a patient with multiple previous right leg surgical interventions, resulting in severe scarring of right groin. **A:** High-grade, diffuse stenosis (*arrow*) in right common femoral artery (CFA) extending to the origins (*arrowhead*) of the profunda femoris (DFA) and superficial femoral artery (SFA). Revascularization with percutaneous transluminal angioplasty was performed via the contralateral approach. **B:** Final angiogram demonstrates excellent patency of the CFA and proximal SFA, with mild recoil at the origin of the DFA. Patient's claudication symptoms resolved, and he continues to be minimally symptomatic 4 years later. Arrow indicates previous site of stenosis; arrowhead indicates origin of the DFA.

The profunda femoris, or deep femoral, artery is the main source of collaterals to the lower extremity. In occlusion of the SFA the deep femoral artery alone becomes responsible for maintaining viability of the lower extremity (64). Traditionally, bypass surgery (endarterectomy and patch angioplasty) is performed for occlusive disease in the deep femoral artery, which almost always occurs in conjunction with ostial SFA disease. Technically satisfactory results of profunda PTA have been described (65). However, because of the potential for jeopardizing the limb, in the event that the vessel dissects or occludes, caution should be exercised when considering PTA in the profunda.

For the present, PTA is reserved for situations of severe ischemia (Rutherford category 4, 5, or 6) and for situations in which surgery is contraindicated (*e*Fig. 111.4.3). Stenting in the profunda is usually reserved for cases of true flow-limiting dissection after balloon angioplasty, wherein patency of the vessel and viability of the limb might be threatened without maintaining an open vessel.



***e*FIGURE 111.4.3** Balloon angioplasty [percutaneous transluminal angioplasty (PTA)] for profunda femoris disease in a 50-year-old patient with multiple previous

percutaneous interventions, including endovascular stenting, for recurrent femoropopliteal bypass graft occlusion (chronic superficial femoral artery occlusion). A below-knee amputation was ultimately required for critical limb ischemia. **A:** Critical stenosis (*arrow*) of the profunda femoris artery (DFA) causing stump ischemia and chronic occlusion of a femoropopliteal graft (BPG). **B:** Balloon angioplasty performed at low inflation pressure using the antegrade approach. **C:** Final angiographic image demonstrating restoration of luminal patency.

SUPERFICIAL FEMORAL AND POPLITEAL ARTERIES

Previous experience has failed to document any significant differences in either acute or long-term results for percutaneous revascularization of the SFA versus the popliteal artery; accordingly, both are herein considered together under the heading of SFA.

In contrast to aortoiliac disease, disease in the SFA/popliteal arteries typically occurs in older patients and is associated more closely with the presence of CAD (66), and symptoms are two or more times more frequent. Patients with SFA/popliteal disease usually present with calf claudication. Less frequently, the presenting sign is critical limb ischemia; proximal SFA occlusion alone may be associated with only mild claudication, and in some patients, no claudication at all in the presence of well-developed profunda collaterals.

Stenoses of the Superficial Femoral Artery or Popliteal Artery

The acute procedural success that may be currently achieved using conventional guidewires and standard PTA in SFA stenoses is similar to that reported for iliac stenoses, approaching 100%. Long-term patency in the SFA, however, is clearly inferior to that which may be expected in iliac stenoses; from pooled data among patients undergoing PTA of femoral-popliteal stenoses, primary patency rates at 1, 3, and 5 years were, on average, 60%, 50%, and 45%, respectively (67,68,69 and 70). Variability in long-term results is due in part to the multiple lengths and morphologies of SFA lesions selected for treatment, including a mixture of stenoses and occlusions. In one of the more comprehensive reports, using a prospective analysis of PTA of 208 lesions in 140 limbs, Matsi and colleagues reported an overall acute angiographic success rate of 88% and a successful immediate clinical outcome in 91% of SFA lesions (70). Systematic, prospective long-term follow-up of all study patients using ankle-brachial indices and clinical symptoms revealed 1-, 2-, and 3-year primary patency rates of 47%, 44%, and 43%, respectively. Secondary patency was 63% at 1 year and 59% at both 2 and 3 years.

Predictors of long-term patency after SFA/popliteal PTA include claudication as the presenting symptom, a more severe lesion at baseline, stenosis versus occlusion, concentric morphology, fewer stenoses, two- to three-vessel runoff, absence of residual stenosis after angioplasty, and restoration of an ankle-brachial index to greater than 0.9 at 24 hours postprocedure (67,70,71). Factors that negatively influence long-term patency include the presence of diabetes, threatened limb loss, or diffuse atherosclerotic vascular disease (71).

A variety of other technologies have been investigated as means of improving long-term patency and reducing restenosis in the SFA. DA has the unique capability of resecting intact atherosclerotic plaque, which can be used for a variety of laboratory analyses (72), including prospectively identifying those patients likely to develop restenosis (73). In patients with short, eccentric lesions, particularly those lesions resistant to balloon dilation, and for fibrotic lesions with significant recoil (e.g., graft anastomoses), DA (with or without adjunctive PTA) seems to offer satisfactory acute results, similar to those for PTA (74,75 and 76). Currently, however, there is no evidence to support the use of DA as a means of preventing restenosis (76).

Rotational atherectomy (77,78) has not thus far been demonstrated to have an advantage for SFA/popliteal revascularization, save for those rare patients in whom the extent of calcific deposits renders the lesion refractory to alternative techniques. In the smaller popliteal artery, it is possible that the debulking effect of rotational atherectomy may ultimately prove to offer some benefit over balloon angioplasty alone. The role of laser angioplasty in SFA/popliteal revascularization remains controversial and unproven. A variety of laser sources have been investigated for this application (79,80 and 81), but trials thus far have demonstrated no definitive benefit of this device at this level.

In contrast to the documented benefits achieved by use of endovascular stents for iliac PTA, experience thus far in the SFA has been less favorable. Although preliminary, nonrandomized studies using the Palmaz stent (82) and the Wallstent (83,84) demonstrated modest improvement in intermediate-term patency, primary 1-year and 3-year patency rates of 22% to 81% and 18% to 72%, respectively, have been reported (85,86 and 87); restenosis caused by intimal hyperplasia in the stented segment is quite common in the first 3 to 6 months (86). More recently, pooled data from 11 studies (585 patients) of stents in both femoropopliteal stenoses and occlusions revealed technical success, 1- and 3-year patency rates of 98%, 67%, and 58%, respectively (30). Furthermore, the use of stents in the SFA has been complicated by an unpredictable incidence of subacute thrombosis (85). However, there appears to be an acute hemodynamic benefit of femoropopliteal stenting for treatment of a flow-limiting dissection and for failed balloon angioplasty (30,86) despite a lack of encouraging long-term benefits. The descriptions of deformation or compression of stents placed within the adductor canal (88) suggest that balloon-expandable stents should be avoided in favor of self-expandable stents. Future studies will determine whether the newer Nitinol self-expanding stents offer any advantage over the previous stainless steel designs, as is widely believed to be the case.

Occlusion of the Superficial Femoral Artery or Popliteal Artery

Among patients studied angiographically for consideration of revascularization, occlusions are more prevalent than stenoses. Two technical advances have facilitated treatment of SFA occlusions, even lengthy (more than 10 cm) or chronically occluded segments. The first is the use of hydrophilic wires. At our institution, the Glidewire was used to attempt percutaneous revascularization of 109 SFA total occlusions and was successfully advanced across the occluded segment in 107 (98%); PTA alone or in combination with DA and/or laser angioplasty was then used to complete percutaneous revascularization in all 107 patients (46). Improvements in ankle-brachial index (from 0.48 pre- to 0.82 postrevascularization) and in Rutherford class (one grade or more) were observed in 94% at 1-month follow-up. This experience was noteworthy for two reasons in particular. First, 50 lesions measured 5 to 10 cm in length and 21 were more than 20 cm long; consequently, mean occlusion length (9.8 cm) exceeded that reported in most previous series. Second, IVUS examination during these procedures demonstrated a subintimal route of recanalization in approximately one-third of patients (89).

The second advance is the use of thrombolytic therapy (Fig. 111.5), which has been proven effective, even for some patients with chronic total occlusions, because occlusion of the lower extremity arteries is typically characterized by a lengthy, gelatin-like thrombus superimposed on a high-grade atherosclerotic lesion. In such cases, lytic therapy can be effective in converting a long occlusion to one that is either shorter or no longer occlusive and thereby more amenable to mechanical revascularization. The efficacy of this approach underwent systematic multicenter investigation in patients with lower extremity occlusions who were randomized to lytic versus operative therapy in the Surgery and Thrombolysis for Ischemia of the Lower Extremity (STILE) Trial (90). Data from the STILE Trial suggest that successful recanalization of *chronic* SFA occlusions using thrombolytic agents (tissue plasminogen activator or urokinase) is technically feasible and, in many instances, associated with an excellent outcome. However, reestablishing patency by this approach is less reliable for lengthy or “flush” total occlusions than surgical bypass, and for these lesions the outcomes of surgery are more durable. The use of thrombolytic therapy for “acute” occlusions (14 days’ duration or less) appears to be more favorable (Fig. 111.5 and eFig. 111.5.1). Both the STILE Trial and a similar randomized investigation executed by Ouriel and associates (91) demonstrated that, for acute or subacute occlusions, thrombolysis and surgery were equivalent in terms of restoration of patency and limb salvage. In addition, there was a significant reduction in the frequency of both in-hospital complications and 12-month mortality in patients receiving thrombolysis versus those treated surgically. Thus, there is compelling evidence to support a strategy of primary thrombolysis for acute occlusions of the SFA.

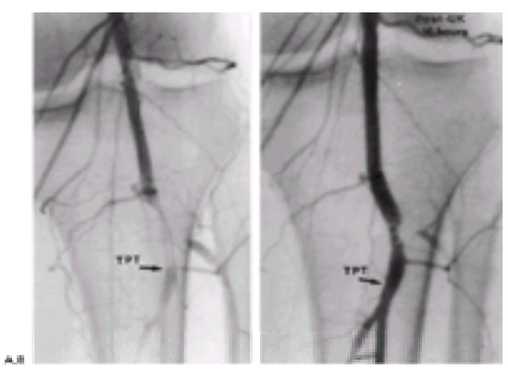


FIGURE 111.5 A: Acute embolic occlusion in an elderly woman with chronic atrial fibrillation. **B:** Rest pain resolved promptly after administration of urokinase (UK).

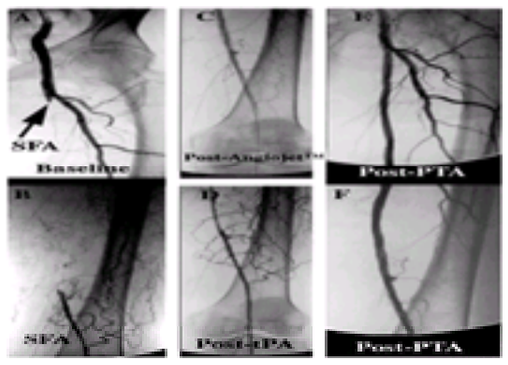
Patency was restored to tibioperoneal trunk (TPT). The patient remains asymptomatic 4 years later.



***e*FIGURE 111.5.1** Thrombolysis, rheolytic thrombectomy, and percutaneous transluminal angioplasty (PTA) for acute limb ischemia in an 87-year-old woman with erythrocytosis. Baseline angiogram demonstrates occlusion **(A)** of the proximal superficial femoral artery (SFA), with reconstitution via collaterals from the profunda **(B)** at the adductor canal. The occlusion was traversed with a Glidewire and partially recanalized **(C)** with rheolytic thrombectomy (Angiojet). Luminal patency was reestablished with thrombolytic therapy (tPA), revealing moderate disease in the mid-SFA **(D)**. After balloon angioplasty, final angiographic images **(E)** and **(F)** demonstrated widely patent SFA with normal flow/caliber.

Preliminary use of rheolytic thrombectomy devices (92,93) (Angiojet; Possis Medical Systems, Minneapolis, MN) either in lieu of or in conjunction with thrombolytic therapy has demonstrated encouraging results for treatment of acute and chronic thrombus in the SFA/popliteal (as well as other sites) and highlighted the potential for this device to reduce procedure time, hospital stay, and risks associated with prolonged infusion of thrombolytic therapy (*e*Fig. 111.5.1).

The extent to which favorable acute procedural results in patients with chronic total occlusion will ultimately extend the role of percutaneous revascularization remains to be defined. Certainly for patients with nonhealing lesions or threatened limb loss in whom the risks of surgery are considered prohibitive, or in whom veins are unavailable for distal bypass, percutaneous revascularization of even lengthy occluded segments may facilitate healing. In similar types of patients with rest pain or severe claudication, PTA may be used to achieve pain relief at a lower risk than conventional surgical reconstruction. For patients with less severe symptoms, improved ability to revascularize does not in and of itself constitute a sufficient basis for routine invasive therapy.

One further issue concerning femoral arterial revascularization deserves additional specific comment. This involves embolic complications apparently related to ulcerated or thrombotic lesions of the SFA, the so-called blue toe syndrome. Emboli in such patients were initially inferred to result from friable plaque morphology that posed an unacceptable risk for percutaneous revascularization. It is now clear such patients can be effectively treated by PTA with stenting or DA with a high degree of procedural success and an acceptably low risk of further embolic complications (94,95 and 96).

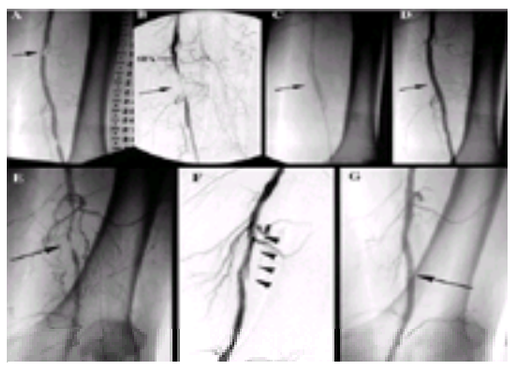
Restenosis

An important caveat in the management of patients with symptomatic SFA/popliteal disease is the issue of restenosis. Despite excellent acute procedural success using conventional guidewires and standard PTA, restenosis continues to be a frustrating and expensive consequence of this otherwise efficacious intervention, complicating the clinical course of up to 60% of patients. Its occurrence raises fundamental questions as to whether the biology and pathophysiology of plaque formation in the SFA/popliteal artery is in some way different from that in other vessels. Furthermore, even though stents may ameliorate the acute flow-limiting complications of SFA PTA, they have been thus far shown to have no significant impact on long-term patency.

Several promising strategies lie on the horizon for treating this vexing problem. First is the concept of gene transfer of angiogenic cytokines. Isner and colleagues effectively transferred genetic material to promote healing of the disrupted endovascular surface after PTA, and preclinical studies have shown reduction of restenosis by the facilitated healing response (97,98). An ongoing phase I trial in humans undergoing SFA/popliteal PTA has thus far demonstrated encouraging results, although these finding are very preliminary (99). Second, the concept of endovascular brachytherapy (100), which is currently being tested in coronary arteries, is also undergoing studies (PARIS Trial) in conjunction with SFA/popliteal PTA and showing encouraging preliminary results. Finally, drug-eluting stents, currently under investigation in coronary arteries, will likely have a role in reducing restenosis in peripheral vessels as well.

Current Recommendations for Superficial Femoral and Popliteal Disease

The acute technical success of balloon angioplasty for SFA/popliteal stenosis or occlusion is currently in the range of 90%. The principal factors in long-term patency are the status of the runoff vessels and the presence of occlusion. Long-term patency of 50% can be anticipated at 5 years; this is significantly less than that of iliac angioplasty. Thus, the threshold for intervention below the inguinal ligament should be higher. However, for patients with claudication severe enough to warrant intervention, PTA is the preferred initial treatment. This applies to both stenoses and occlusions that are amenable to revascularization. Lengthy, flush occlusions of the SFA may not be approachable. Endovascular stents as a primary approach are not indicated. However, at present they have a limited role in salvage of acute PTA failures or complications (*e*Fig. 111.5.2). For chronic critical ischemia, or even acute limb-threatening ischemia, surgery is the preferred modality. However, one caveat to that is in the case of patients in whom the need for coronary bypass grafting is anticipated; in these patients, as long as instrumentation does not preclude future surgical intervention, PTA may be preferred to preserve the leg veins for future coronary bypass surgery.



***e*FIGURE 111.5.2** Stents deployed for complication of balloon angioplasty to the superficial femoral artery after balloon dilation in patients with claudication. **A:** Baseline angiography disclosed a focal lesion (*arrow*) in the mid–superficial femoral artery (SFA). **B:** Balloon angioplasty resulted in flow-limiting dissection and occlusion (*arrow*). **C:** Deployment of self-expanding endovascular stent (*arrow*) was required. **D:** Final angiography demonstrated complete patency (*arrow*) and normal flow. **E:** Baseline angiography in a second patient disclosed focal critical stenosis (*arrow*) in the SFA at the adductor canal with patent popliteal artery. **F:** Balloon angioplasty resulted in a lengthy flow-limiting dissection (*arrowheads*). **G:** A VascuCoil endovascular prosthesis (*arrow*) was deployed repairing the dissection and preserving luminal patency. Patient has remained asymptomatic at 2 years' follow-up.

INFRAPOPLITEAL ARTERIES

Published clinical experience involving percutaneous revascularization of the anterior tibial, tibioperoneal trunk, posterior tibial, and peroneal arteries, although dating to the time of Dotter and Judkins' original work (17), has nevertheless been far more limited than that described for aortoiliac and SFA sites. This is related to several issues, including the fact that claudication is rarely due to isolated disease of the infrapopliteal arteries; knee-to-foot patency of one of the three major branches is generally regarded as sufficient to prevent critical lower limb ischemia; restenosis rates in these vessels have typically been the highest of any of the lower extremity

sites; and obstructive disease in these arteries is often occlusive or diffuse and complicated by heavy calcific deposits. Furthermore, diabetics have a high incidence of infrapopliteal disease, which is associated with diffusely atretic vessels that respond poorly to balloon dilation.

The ability to treat infrapopliteal disease has improved with technological advances, and the application of techniques used for coronary arterial revascularization has consequently resulted in a more widespread application of percutaneous revascularization for infrapopliteal disease (101). Despite this, many of the patients treated with infrapopliteal angioplasty to date have been those who were too high risk or otherwise unqualified for bypass surgery. The latter is still considered to be the standard of care for patients with critical limb ischemia due to infrapopliteal disease. Regardless of the conduit (reversed vein, *in situ* vein, or prosthetic material), patency rates are nonetheless inferior to those of more proximal reconstruction. It is conceivable that the long-term clinical outcome of percutaneous therapy may ultimately equal that of distal bypass grafting. Over the past decade, reports have documented that stenotic and even short occlusions of one or more infrapopliteal arteries can be revascularized percutaneously with a high degree of efficacy and at extraordinarily low risk (102,103) both for critical limb ischemia and for claudication. These studies have demonstrated technical and clinical success rates in the range of 80% to 95% (the success rate in stenoses is superior to that in occlusions).

It must be emphasized that the goals of infrapopliteal revascularization often differ from those of above-the-knee therapy and vary with clinical presentation. In most patients with claudication, for example, below-knee angioplasty is not necessary, as treatment of coexisting proximal disease alone is often sufficient for symptomatic relief. There is a subset of patients who claudicate due solely to infrapopliteal disease for whom percutaneous therapy is becoming more popular. Such a strategy should be reserved, at least for the present, for patients who have severe symptoms (Rutherford category 3). Infrapopliteal PTA may also be justified in claudicants who undergo proximal revascularization (either with surgery or PTA), in whom the runoff is severely impaired, as outflow may be the principal determinant of long-term patency for femoropopliteal revascularization. In patients with rest pain or ischemic ulceration, restoration of uninterrupted patency of at least one of the three major infrapopliteal arteries is generally required to obviate symptoms and/or heal a distal ischemic lesion. In this group of patients, aggressive application of percutaneous revascularization may achieve extremely gratifying results, even in patients with calcified and/or lengthy total occlusions (Fig. 111.6).

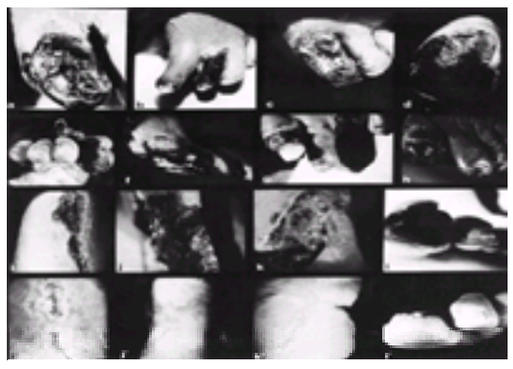


FIGURE 111.6 Composite figure showing the extent of severely ischemic alterations that typically develop before patients or their physicians seek medical consultation regarding the basis for these findings and possible treatment options. In most of these cases, amputation ultimately was required. For the patient whose limbs were photographed at the time of initial presentation in **i** through **l**, the corresponding photographs **i'** through **l'** demonstrate the appearance after percutaneous revascularization. These patients illustrate one of the most difficult groups of patients seen by specialists in vascular medicine. Earlier diagnosis and institution of therapy clearly are required to prevent the development of such extensive disease if the risk of amputation in these patients is to be reduced. It should be recognized, however, that when the extent of disease has reached even this degree, amputation and bypass surgery are not the only available treatment options. Percutaneous revascularization often may be successful in rescuing limbs of these patients; regardless of the subsequent incidence of restenosis, in the absence of recurrent foot, ankle, or lower leg trauma, such lesions will often remain clinically silent after satisfactory healing.

One point concerning percutaneous infrapopliteal revascularization requires special emphasis: the incidence of restenosis—which remains high—should not be a factor in the decision to use a percutaneous approach for what is, in many of these patients, a short-term problem. If uninterrupted patency of even one vessel can be achieved, the improvement in antegrade nutrient flow is typically adequate to facilitate limb salvage. Once healed, most patients will do satisfactorily, even in the face of documented reocclusion or restenosis. This strategy is further supported by the fact that both short- and long-term outcomes of distal surgical reconstruction for infrapopliteal disease are likewise imperfect (104). It is also conceivable that both of these revascularization strategies will be supplemented in many instances by the strategy of therapeutic angiogenesis (10,105,106).

When performing infrapopliteal PTA, care should be taken to ensure that subsequent surgical options are not compromised. For example, overdilation and disruption of a distal, previously uncompromised vessel may prohibit subsequent bypass to that site. Rotational atherectomy or excimer laser angioplasty can be useful as adjunctive therapy to angioplasty, particularly for lesions that have unfavorable morphology, such as total occlusions, heavy calcification, and ostial disease. Endovascular stents are not currently recommended for infrapopliteal vessels.

BYPASS GRAFTS

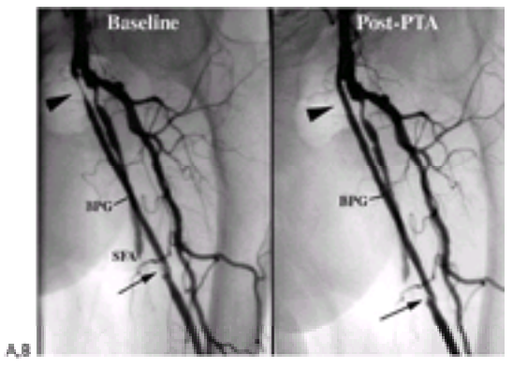
Stenosis in a lower extremity bypass graft can threaten the patency of the graft and shorten its life. Stenosis that occurs within the first few weeks of graft placement usually indicates a technical problem best treated by surgical graft revision. Graft failure within months to 1 year can be due to myointimal hyperplasia, atherosclerosis, or progressive fibrosis of a poor venous conduit. Other factors contributing to graft failure include the presence of poor inflow or poor outflow, low cardiac output, presence of a hypercoagulable state, compression of the graft due to compromised patient positions, and external compression of the graft by sclerosis and fibrosis. Prosthetic conduits are more likely to present with abrupt occlusion, whereas native venous conduits tend to present with a progressive downhill course. Of course, even in the case of the latter, abrupt thrombosis and acute limb ischemia can occur.

Graft failure or impending graft failure is often not heralded by increasing clinical symptoms. Accordingly, a strategy of regular graft surveillance using duplex ultrasonography is paramount to preserving patency and extending the life of the graft and optimizing the results of revascularization therapy (107). For impending graft failure, either detected by duplex ultrasonography or increasing symptoms, immediate arteriography is recommended, followed by either surgical or percutaneous revascularization.

Percutaneous revascularization represents an alternative to operative reconstruction for failing or failed native or prosthetic conduits. Nonsurgical revascularization has several obvious advantages: It saves the patient the morbidity and additional hospitalization associated with a repeat surgical procedure; it does not require the availability or use of additional native veins; and in certain cases it may obviate the need to use prosthetic materials for distal reconstruction, an application for which such materials have been shown to confer lower patency rates (108,109).

The published results of PTA of *stenotic* lower extremity bypass grafts are extremely variable. Series in the surgical literature suggest that, although PTA can be acutely successful, the long-term patency is inferior to that associated with surgical revision (110,111). Our own approach to stenotic grafts is to make at least one attempt at percutaneous revascularization. This approach is derived from consideration of several issues. First, percutaneous revascularization of stenotic grafts is most often technically straightforward. Second, the risk of serious complications is low. Third, the contribution of adjunctive diagnostic and therapeutic techniques, including IVUS, DA, and endovascular stents, to preservation of graft patency remains essentially untested. Fourth, surgical revision itself is complicated by imperfect long-term patency (56,112,113).

Currently, PTA is recommended for cases of graft stenosis with myointimal hyperplasia, vein fibrosis, sclerotic valves, focal proximal (eFig. 111.6.1) or distal anastomotic lesions of a femoropopliteal or femorotibial graft, and short-segment lesions (3 cm or less), particularly if the vein size is greater than or equal to 3.5 mm and the lesion is more than 3 months out from surgery (114). Lengthy lesions (especially more than 10 cm) and stenoses associated with anastomotic aneurysms are recommended to undergo surgical revision. Furthermore, in the presence of a proximal or distal anastomotic lesion, it is conceivable that the lesion may be resistant to balloon dilation alone. In these cases, DA is a useful tool for salvaging the graft and improving the outcome of the percutaneous intervention (115). Reported technical success rates in excess of 90% and 2-year patency rates of 80% compare favorably to balloon angioplasty and surgical revision. Although stents have been used in failing vein grafts, this strategy has not yet been studied in any formal trials.



***e*FIGURE 111.6.1 A:** Right anterior oblique view of critical stenosis (*arrowhead*) at origin of femoropopliteal graft (BPG) and moderate irregular lesion (*arrow*) at distal end of jump-graft placed during previous graft revision. The superficial femoral artery (SFA) is occluded proximally. Lesions were detected during routine surveillance (patient asymptomatic). Due to proximity of lesions to ipsilateral common femoral artery, contralateral access may be preferred. **B:** After percutaneous transluminal angioplasty (PTA), stenoses are eliminated, but regular surveillance will be essential to prevent graft failure. Arrowhead indicates location of original stenosis; arrow indicates location of original lesion.

The approach to *occluded* lower extremity bypass conduits varies widely from institution to institution. Revascularization strategy should be based on consideration of numerous factors, including degree of ischemia present, type of graft material (e.g., prosthetic or autogenous vein), age of the graft, level of obstruction and accessibility for catheter-directed thrombolysis, presumed etiology of occlusion, and presence of comorbid conditions. Often, determination of the factor(s) responsible for graft failure is not possible before reestablishing enough flow to visualize the graft angiographically. Review of previous angiograms, including previous baseline (pregraft) and immediate postgrafting ("completion") studies, often provides a clue as to the factors that may have contributed to thrombosis. In cases of early graft failure (e.g., less than 3 months), reexamination of the angiograms for signs of technical or anatomic problems is crucial. Findings such as inadequate inflow to the graft due to proximal atherosclerosis, absence of adequate distal runoff vessels, mild residual narrowing at proximal or distal anastomotic sites, and presence of residual venous side branches are all potential sources of graft compromise that can have been underestimated or unrecognized altogether. Reevaluation of the patient's clinical and hematologic parameters is equally important: It is not unusual to detect an occult hypercoagulable state, such as protein C or S deficiency, which predisposed the patient to graft thrombosis.

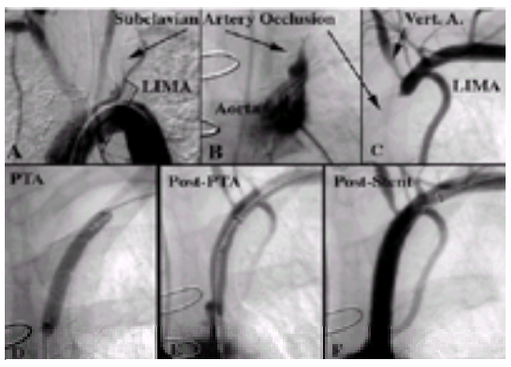
Decisions regarding revascularization of an occluded graft should be made in conjunction with vascular surgical colleagues. Thrombosis of a very recently placed graft (e.g., less than 1 month) usually suggests the presence of an underlying anatomic or technical issue that is better treated by surgical thrombectomy and revision. The exception to that is the prosthetic graft (especially infrainguinal), which may thrombose spontaneously in the absence of obvious pathology, presumably because of the presence of thrombogenic foreign material. In these patients, even with recently placed grafts, prompt initiation of catheter-directed thrombolytic therapy may rapidly restore patency and enable angiographic evaluation and treatment of flow-limiting lesions. If none is detected, aggressive treatment with combined anticoagulation and antiplatelet agents is initiated in an attempt to prevent recurrent spontaneous thrombosis. Patients presenting with acute or subacute thromboses (less than 14 days) are best treated with catheter-directed thrombolysis (49,91). An alternative is balloon embolectomy, although this strategy may be associated with a higher morbidity and mortality over the ensuing year (91). Catheter-directed thrombolysis also remains an option for late or delayed (more than 3 months) occlusion of autogenous vein grafts. Angiography after successful elimination of thrombus often identifies a stenosis—anastomotic or elsewhere—that may have been primarily responsible for the graft occlusion. Treatment of the stenotic site with balloon angioplasty or DA can successfully restore long-term patency.

SUBCLAVIAN AND INNOMINATE ARTERIES

The vast majority of disease in these vessels is due to atherosclerosis. However, giant cell arteritis, Takayasu's arteritis, and fibromuscular disease (FMD) can also cause clinically relevant disease (116,117 and 118). Clinical indications for subclavian revascularization are symptomatic ischemia of the posterior fossa (e.g., vertebral-basilar insufficiency) or upper extremity, with or without subclavian steal syndrome; preservation of flow, in which thrombosis or progressive stenosis could have devastating consequences, especially in the case of coronary artery bypass graft surgery using the internal mammary arteries (e.g., ischemia in left internal mammary artery/right internal mammary artery territory with or without coronary-subclavian steal syndrome) (*e*Fig. 111.6.2); preservation of inflow to axillary graft or dialysis conduit; and "blue digit" syndrome (embolization to fingers). Routine examination (measurement of cuff pressure and palpation of pulses in both upper extremities plus auscultation over the supra- and subclavicular areas) uncovers patients with asymptomatic subclavian disease. Initially, such patients do not require treatment but should be followed closely for progression or development of related symptoms. Noninvasive testing with duplex ultrasound is essential, with determination of the direction of flow in the vertebral arteries (antegrade or retrograde, the latter indicating the presence of a steal syndrome) and documentation as to the presence or absence of carotid disease.

VIDEO

Video 111.2 Severe stenosis of left subclavian artery. In this selective angiogram, a severe atherosclerotic narrowing with the left subclavian artery is evident. This lesion is proximal to the origin of the left internal mammary artery. In patient's with subclavian stenosis, angina can be produced despite a normal left internal mammary and left anterior descending bypass graft. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



***e*FIGURE 111.6.2** Subclavian artery revascularization for disabling upper limb claudication, subclavian steal syndrome, and coronary steal syndrome in an elderly patient. **A:** Arch aortogram discloses short segment occlusion of the left subclavian artery (SCA) 1 cm from the origin, with reconstitution distally. Retrograde filling of the left internal mammary artery (LIMA) is also present. **B:** Selective cannulation of SCA demonstrates a "beak-like" obstruction. **C:** Angiography via brachial artery access demonstrates reconstitution via thoracic collaterals proximal to the left internal mammary artery and vertebral artery (Vert. A.). **D:** Percutaneous transluminal angioplasty (PTA) was performed after the lesion was traversed with a Glidewire from the arm and resulted in restoration of luminal patency with residual stenosis. **E:** Stent deployment was successfully performed proximal to the vertebral artery to include the origin of the SCA. **F:** Subclavian and coronary steal syndromes resolved, as did upper limb claudication.

Angioplasty of the subclavian and innominate arteries is now considered first-line therapy for focal subclavian stenoses, with reported technical success and complication rates of more than 90% and less than 10%, respectively (119,120). Recent series using primary stenting indicate that stenting may further improve the results (121,122), which already compare favorably to surgical alternatives. Complications are generally minor and infrequent but include problems related to femoral or brachial access, inadvertent "jailing," dissection, and embolization of the vertebral or left internal mammary artery (123). PTA has potential advantages over surgery: It eliminates the need for general anesthesia, shortens hospital stay, is less invasive, and reduces overall morbidity. It also avoids concern about potential stenosis in the carotid artery, which serves as the donor for carotid-subclavian bypass.

In contrast, despite a lower chance of success (50% to 75%) and increased potential to embolize thrombus or atheroma into the cerebral, upper extremity, or coronary

circulation, PTA for subclavian occlusions has been shown to be technically feasible (124) and, based on the favorable results of several investigators (125,126), appears to be an appropriate strategy for symptomatic patients. Furthermore, primary stenting (both balloon expandable and self-expanding) has also emerged as an appropriate initial strategy for symptomatic patients (126,127). One multicenter retrospective analysis compared primary subclavian stenting with surgical reconstruction and demonstrated lower rates of stroke, mortality, complications, and recurrence for the stent group (128).

Restenosis within subclavian arteries occurs in 10% to 20% of patients. Stent compression should be treated by balloon reexpansion and placement of a self-expanding stent within the old device. A special category of patients with subclavian obstruction—those with so-called coronary subclavian steal syndrome—respond quite nicely to PTA and stent deployment. In such patients, restoration of antegrade flow into the carotid and internal mammary artery can be life-saving (*e*Fig. 111.6.2) (129).

CAROTID ARTERIES

Atherosclerotic disease predominates at the common carotid bifurcation, a site easily accessible for surgical carotid endarterectomy (CEA). Indeed, revascularization of carotid arteries has, until recently, been considered to be exclusively within the purview of surgery. Since the first CEA more than 30 years ago, the associated morbidity, mortality, cost, and patient inconvenience associated with this procedure have been reduced considerably, such that CEA is currently recognized as the gold standard of therapy for patients deemed to require carotid revascularization. Supporting this are the landmark North American Symptomatic Carotid Endarterectomy Trial and Asymptomatic Carotid Artery Study trials demonstrating that surgical endarterectomy, when performed for carotid bifurcation disease by experienced vascular surgeons on appropriately selected patients, is effective in reducing the likelihood of stroke compared with medical therapy (130,131).

Carotid balloon angioplasty (CPTA) was performed as early as 1983, but due to the excellent results associated with CEA and concerns about the potential for distal embolization (132) and vessel recoil/thrombosis, the use of PTA for carotid disease (especially at the bifurcation) was limited to single-center anecdotal reports. Currently most institutions reserve percutaneous treatment of carotid arteries for those circumstances wherein the surgical risk is increased (133,134,135 and 136), such as in patients with either high cervical stenosis (i.e., under the angle of the mandible) or stenosis within the proximal common carotid artery near the aortic arch, which would require extensive intrathoracic surgery. In addition, patients with prior neck irradiation or radical neck dissection and those with restenosis at a previous endarterectomy site have also been considered appropriate for percutaneous intervention because of the increased risk of surgery in these subsets. Successful PTA, especially with the adjunctive use of endovascular stents, in these high-risk patients has led to consideration of the possibility that the less invasive, percutaneous approach might be applied more widely for carotid artery disease (Fig. 111.7).

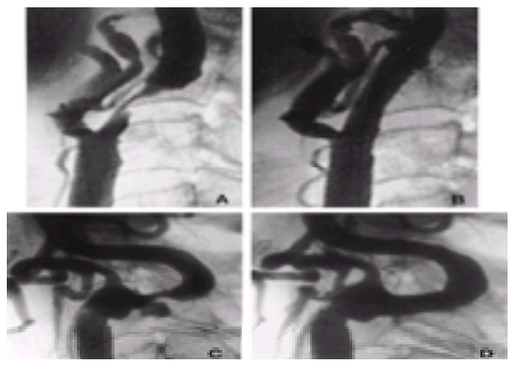


FIGURE 111.7 Bilateral carotid artery revascularization with balloon angioplasty and stent deployment in an 82-year-old asymptomatic male with “isolated hemispheres.” **A:** High-grade stenosis of right internal carotid artery. **B:** Status post-percutaneous transluminal angioplasty and Wallstent deployment, with marked improvement and only mild residual narrowing. Wallstent extends into common carotid artery. No significant compromise in external carotid artery. **C:** High-grade, ulcerated stenosis in proximal left internal carotid artery, revascularized 4 weeks after percutaneous transluminal angioplasty of the right side. **D:** Status post percutaneous transluminal angioplasty and Palmaz stent deployment in proximal left internal carotid artery. Excellent result with no residual stenosis. Both procedures were uneventful, and the patient remains asymptomatic at 1-year follow-up.

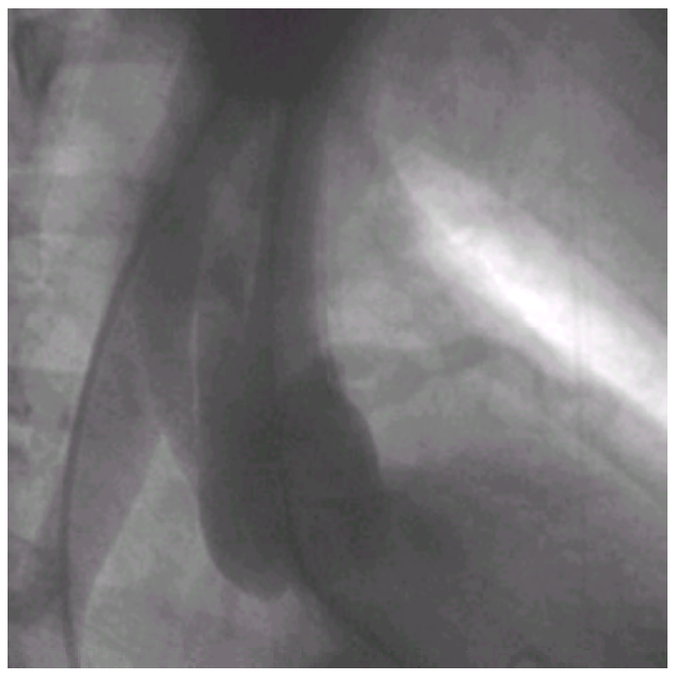

A 77-year-old male patient presented to the emergency department with severe chest pain and hypertension. Aortogram revealed type A aortic dissection.

The work of Roubin, Iyer, Yadav, Vitek (133,137,138), and others (139) demonstrated superior results of primary (as opposed to provisional) stenting (CPTA/stent) in carotid arteries, possibly due to more complete effacement of the plaque and associated ulcerations, reduction in elastic recoil, and restoration of laminar flow. Intermediate-term results demonstrate comparable safety (particularly the risk of neurologic events) and efficacy to CEA, especially when taking into account the selection of patients in higher-risk categories (lesion site, comorbid conditions) (140,141,142 and 143) (Fig. 111.8). Although technologic advances in stents, sheaths/guiding catheters, and diagnostic catheters may have contributed to the improved results, the reduction in events is principally due to increased operator experience and refinements in selection criteria.

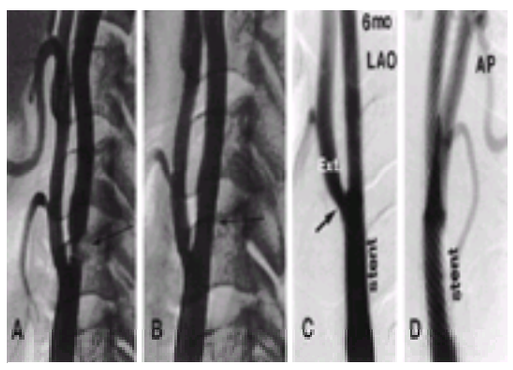

FIGURE 111.8 Carotid stent deployment in an 82-year-old patient with highly unstable angina on intravenous nitroglycerin, awaiting coronary artery bypass graft. Contralateral internal carotid artery is completely occluded, and both vertebral arteries are 95% narrowed. **A:** Before percutaneous transluminal angioplasty, internal carotid artery has severe, ulcerated, focal stenosis (*arrow*). **B:** After percutaneous transluminal angioplasty and deployment of Wallstent. Stenosis now ameliorated (*arrow*); flow improved into internal carotid artery. External carotid artery (Ext.) is minimally compromised. Patient subsequently underwent uneventful coronary artery

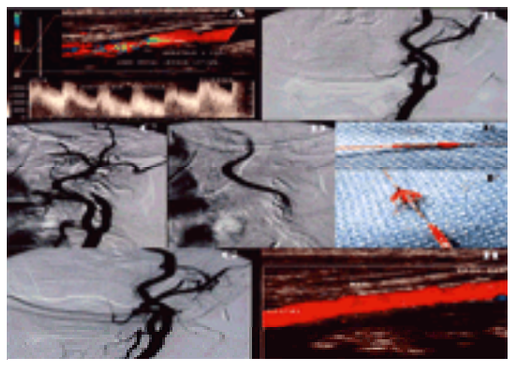
bypass graft 1 day after percutaneous transluminal angioplasty. Left anterior oblique (LAO) **(C)** and anteroposterior (AP) **(D)** angiograms of right carotid artery 6-month status post Wallstent deployment demonstrate widely patent carotid artery. In **(C)**, Wallstent covers origin (*arrow*) of external carotid artery, which remains patent. Minimal neointimal growth within stent is seen in anteroposterior view. Patient remains free of neurologic and cardiac symptoms 14 months later.

Subsequently, prospective randomized trials have been initiated to compare the percutaneous versus surgical modalities to identify the role for CPTA/stenting. CAVATAS (144) enrolled 504 patients (253 CEA, 251 CPTA) and reported comparable 30-day major stroke and mortality rates between surgery and angioplasty. The Carotid Revascularization Endarterectomy Versus Stent Trial, a large National Institutes of Health–sponsored multicenter study, promises ultimately to provide more definitive information regarding the role of CPTA/stenting, at least in patients with symptomatic disease (145,146).

It remains to be determined what will be the best stent design for use in the carotid arteries. Despite initial excellent results with balloon-expandable Palmaz biliary stents (139,140), the infrequent but troublesome occurrence of stent compression (147) has led most investigators to favor the use of self-expanding stents that are lower profile, flexible, and able to be placed accurately. There are also tremendous enthusiasm and anticipation surrounding the development of distal protection devices to avoid embolization during carotid angioplasty (eFig. 111.8.1). Clinical trials in Europe (148) and early investigational studies in the United States have shown promising results with devices involving the use of a distal trap, or umbrella, encasing a filter, which collects particulate debris. It is anticipated that these will significantly reduce the embolic complications associated with CPTA/stenting.



***e*FIGURE 111.8.1** Carotid percutaneous transluminal angioplasty and stenting with distal protection in a 78-year-old man. **A:** Duplex ultrasound with color Doppler flow demonstrates critical stenosis in the left internal carotid artery with diastolic flow velocities of more than 350 cm per second (systolic velocities were more than 500 cm per second). **B:** Selective left common carotid angiography in the anteroposterior projection demonstrated more than 90% lesion in the proximal left internal carotid artery. **C:** Angiography after percutaneous transluminal angioplasty and stent deployment revealed slow flow (TIMI-2) distal to the instrumented site. **D:** Later images demonstrated haziness in the region of the carotid siphon at the site where the distal protection device was located. **E:** The Angioguard distal protection device still constrained after removal from the patient. **F:** Particulate matter visible within the umbrella of the device. **G:** Final angiographic image after removal of the distal protection device demonstrating excellent luminal patency and normal distal antegrade flow. **H:** Duplex ultrasound 4 weeks after stent.

VERTEBRAL AND BASILAR ARTERIES

Vertebral artery stenosis is a common finding in patients undergoing arch or subclavian angiography. Although the vertebral artery is usually easy to access, revascularization is indicated only in patients with indisputable symptoms of vertebral basilar insufficiency that include diplopia, dysarthria or global aphasia, dizziness or vertigo, and altered state of consciousness. In rare instances, a patient with an obstructed carotid may present with classic carotid, as opposed to vertebral, ischemia. In such cases, if the vertebral artery gives rise to collaterals (via posterior communicating artery), PTA of the stenotic vertebral lesion is justified. The significant downside of failed or complicated vertebral PTA (including potentially fatal brainstem CVA) makes case selection critical. Before undertaking vertebral intervention, therefore, it is important to define the pattern of intracerebral blood flow and collateral circulation (with MRA or four-vessel angiography).

Intervention in the basilar artery is considered to be even more hazardous because it is a “terminal vessel,” responsible alone for perfusion to a number of critical central nervous system areas, especially the brainstem. Accordingly, basilar artery PTA is reserved for the rare instances in which patients present with symptoms unequivocally related to a critical stenosis or acute occlusion. Revascularization in the latter case often requires use of thrombolytic therapy and can produce dramatic recovery of patients who were previously near death. Given the high stakes involved in vertebral-basilar instrumentation, neurology should be involved in any decisions regarding therapy for the posterior cerebral circulation.

RENAL ARTERIES

The primary goals of renal artery revascularization are to improve control of hypertension; preserve or restore renal function; or treat the physiologic effects of severe RAS, which include congestive heart failure (CHF), recurrent flash pulmonary edema, and angina. Associated secondary benefits may include reduction in antihypertensive medications, ability to more safely administer angiotensin-converting enzyme inhibitors in patients with chronic CHF or cardiomyopathy, and, occasionally, elimination of the need for dialysis.

Since Gruentzig first reported successful application of balloon catheters for renal angioplasty (149), controversy has persisted regarding which lesions to treat by PTA, with or without stent deployment, versus surgery, and at what threshold revascularization should be recommended. The paucity of controlled trials comparing medical therapy, surgery, and PTA precludes formulation of conclusions regarding the relative merits of each strategy. Nevertheless, percutaneous revascularization offers an attractive alternative to surgical bypass or endarterectomy, which are more invasive and associated with higher morbidity. However, when analyzing indications and results, it is important to distinguish between lesion etiology—fibromuscular dysplasia (FMD) and atherosclerotic disease, the latter being much more common—and lesion location (ostial, mid-vessel, or branch). Additional considerations include the condition of the adjacent aorta and the presence of comorbid conditions, such as CAD.

Fibromuscular Disease

Surgical revascularization for severe hypertension due to FMD is exemplary in the hands of surgeons with extensive experience (150), but the role of surgery has nonetheless declined for this entity, a reflection of the fact that PTA alone is quite effective. For lesions localized within the main renal artery or its primary branches, studies report acute technical success in excess of 90%, initial clinical success (elimination or significant reduction in hypertension at 6-month follow up) of 85% to 90%, 5-year recurrence rates of less than 10%, and long-term clinical benefit in 80% to 90% (151,152 and 153). Hence, the threshold for PTA in patients with FMD is relatively low; patients with persistent, even modest, hypertension on medications should be treated, especially if they are young, so as to avoid the long-term consequences of hypertension.

The experience with PTA for FMD involving branch vessels and/or aneurysmal disease is limited. Although surgical revascularization is still advocated using extracorporeal reconstruction of the branch vessels, reports of technical and clinical outcomes approaching 85% suggest that PTA may offer an effective alternative treatment (154); the decision to attempt PTA on smaller branch vessels, however, must be weighed against the potential to cause dissection, thrombosis, and loss of the kidney.

The use of endovascular stents has not generally been advocated in FMD patients for two main reasons. First, the results with balloon angioplasty alone for FMD have been excellent, with lower recurrence rates than atherosclerotic disease. Second, the biologic effects and long-term consequences of placing stents in these lesions are unknown. Nonetheless, there have been anecdotal reports of stenting for refractory or recurrent FMD lesions.

Atherosclerotic Renal Artery Stenosis

Percutaneous treatment of atherosclerotic RAS has been less gratifying than that of FMD. However, balloon angioplasty can provide a safe and effective modality for renal revascularization, with a favorable risk-benefit ratio. In a pooled analysis of multiple early studies, percutaneous transluminal renal artery angioplasty (PTRA)

resulted in improved renal function in 43% of patients, stabilization in 35%, and continued worsening (e.g., no beneficial effect of PTRA) in 22% (155) but was hampered by a high restenosis rate, which approached 70% at 6 to 12 months, primarily related to the predilection for immediate and delayed elastic recoil as a result of the high prevalence (approximately 80% to 90%) of thick, calcified aorto-ostial plaque. The mortality rate in most series is less than 1%; contrast-related and atheroembolic events are surprisingly infrequent; and the majority of reported complications is related to vascular access.

On the other hand, primary surgical revascularization in appropriately selected good surgical candidates has shown to be effective both with respect to restoration of patency and favorable clinical outcome (preservation of renal function and reduction of hypertension) (155,156), and although the associated mortality can be significant (between 2% and 17%) (155,157,158), progression of surgical experience and technique (using extraanatomic bypass techniques) has resulted in significant reduction in mortality rates (150,159).

Weibull and colleagues, in one of the only randomized prospective trials, compared PTRA (without stenting) with surgical reconstruction in 58 patients 70 years old or younger with unilateral aorto-ostial (within 1 cm of the aorta) atherosclerotic RAS (160). There was no statistically significant difference in acute outcome. At 24 months, the primary patency in the PTRA group was only 62%, but secondary patency (90%), achieved by repeat PTRA or surgery, was comparable to that of patients initially randomized to surgery (97%). Results with regard to cure or improvement in hypertension were also similar, as was the frequency of complications. They concluded that a strategy of initial treatment with PTRA is indicated for RAS, with close clinical follow-up and additional PTRA or surgical revascularization for cases of initial failure or restenosis. Based on their data and using this strategy, one can expect that approximately 60% of patients will not require additional treatment after initial PTRA; of those with recurrent symptoms, 50% will require repeat PTRA, the other 50% surgery. Interestingly, over the 2-year study period, 14% of patients developed a new stenosis in the contralateral nonrandomized renal artery, necessitating additional treatment. This makes the case for less invasive initial therapy even more compelling.

The factor that is most predictive of initial failure or recurrence after PTRA alone is lesion location: Balloon dilation of stenoses located at the ostium are generally associated with an acute success rate of 50% or less and high restenosis rates (152,153,161). Although modifications in angioplasty technique, such as use of guiding catheters (162) and enhancement in imaging using IVUS (163), may facilitate PTRA, it is likely that the major limitation to successful dilation of ostial lesions will continue to be the elastic recoil of plaque, which is partially aortic in origin. Recent experiences using stents during PTRA to augment lumen size and reduce recoil, particularly for ostial stenoses, have clearly demonstrated much more complete amelioration of the stenosis and transstenotic pressure gradient compared with balloon angioplasty alone (Fig. 111.9) (164,165). Blum and colleagues, in a study of stent deployment for failed angioplasty of ostial lesions (166), reported 11% restenosis (more than 50% stenosis), 92% secondary patency at 60 months, 16% reversal of and 62% improvement in hypertension, and stability of renal function even in patients with baseline renal dysfunction. Palmaz (167) analyzed results from renal artery stenting in eight series (mean follow-up of 10.9 months); hypertension was improved in 56% or cured in 10%; renal function improved in 27% and stabilized (e.g., no further deterioration) in 38%; restenosis occurred in approximately 16% of patients; and major complications occurred in 4.9%. These results support the routine use of stents for renal ostial stenoses.

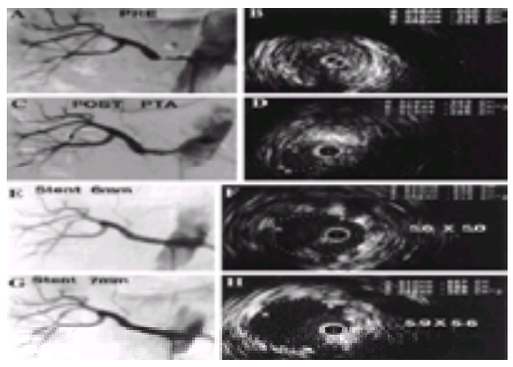


FIGURE 111.9 Percutaneous transluminal angioplasty (PTA) of the proximal renal artery lesion, guided by intravascular ultrasound (IVUS). **A:** Baseline angiogram depicts severe proximal renal artery stenosis. **B:** Corresponding IVUS image shows plaque abutting catheter circumferentially. **C:** Post-PTA, irregular lumen with plaque fracture and residual stenosis. **D:** IVUS post-PTA shows only modest enlargement of the lumen. **E:** Deployment and dilation of a Palmaz stent with a 6-mm balloon; angiographic result much improved over PTA alone. **F:** IVUS shows doubling in lumen diameter over PTA alone. However, in spite of excellent angiographic appearance, IVUS shows that the diameter of the treated segment is still less than the “reference segment.” **G:** After inflation with a 7-mm balloon, the angiographic result is slightly better. **H:** IVUS now shows the size of stented vessel is equal to that of the reference segment. This case highlights the usefulness of IVUS in renal angioplasty.

Complications related to balloon angioplasty and/or stenting of renal arteries occur in less than 10% of patients and commonly relate to access. The most feared complication, which probably occurs more frequently than is clinically appreciated, is that of atheroembolism into either renal vascular or peripheral vascular beds. Other complications of percutaneous renal revascularization include dissection of the renal artery or the wall of the aorta, acute or delayed thrombosis, and rupture of the renal artery.

Current Recommendations for the Treatment of Renal Artery Stenosis

The percutaneous approach is the initial choice of therapy for atherosclerotic renal artery stenosis. Furthermore, the evidence is overwhelming that stents, whether used primarily or provisionally, greatly enhance the results of PTA. Surgery is reserved for patients in whom PTA is less suitable, such as those with branch vessel disease, total occlusions, and stenosis in a renal artery that arises from within an AAA. The question remains of when revascularization should be undertaken. In considering this issue, 40% of patients with atherosclerotic renal artery stenosis will progress over 5 to 10 years. Furthermore, a small subset of patients (10% to 20%) will demonstrate deterioration in renal function immediately after revascularization, presumably due to cholesterol embolization or contrast toxicity. Patients with progressive renovascular disease—in association with steady decline in renal function, hypertension that is accelerated or difficult to control, or CHF—will generally benefit from renal revascularization. Patients who have recently developed end-stage renal disease, partly or wholly due to RAS, may also benefit from revascularization (158,168); PTRA may enable such patients to discontinue or avoid imminent dialysis (Fig. 111.10).

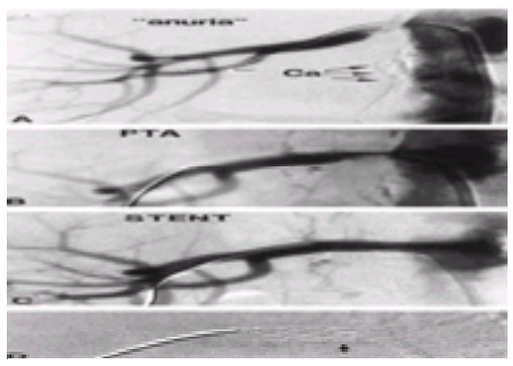

FIGURE 111.10 “Salvage” renal angioplasty and stent deployment in a woman with recent onset of renal failure, anuria, and severe, refractory congestive heart failure requiring intubation. **A:** Baseline angiogram obtained after traversing subtotal occlusion of right renal artery with guidewire. Aorta is very heavily calcified (Ca), and left renal artery is occluded; left kidney is nonfunctional. **B:** Status post balloon angioplasty alone [percutaneous transluminal angioplasty (PTA)] for this heavily calcified ostial stenosis; extensive recoil is evident. **C:** Vessel widely patent after stent deployment. Not significantly obstructive. **D:** Stent configuration without contrast demonstrates minor dimple (*arrow*) along inferior border caused by resistant aortic plaque. Patient began making urine immediately while on the angiographic table. Dialysis was discontinued immediately, and the patient left the hospital with a creatinine of 1.2 off dialysis 4 days after stent deployment. She remains off dialysis 1 year later.

Certain factors stand out as predictors of successful outcome. For patients with hypertension, the clinical factors predictive of a successful outcome include rapid acceleration of previously well-controlled hypertension or presence of malignant hypertension, hypertension in association with flash pulmonary edema,

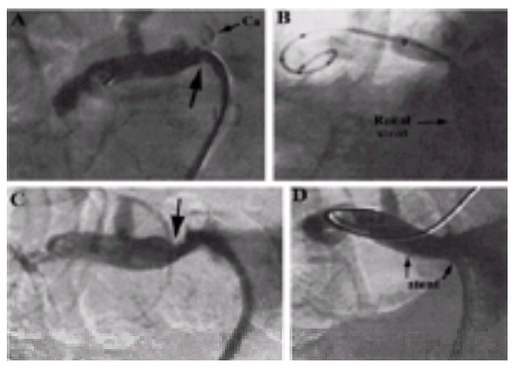
contemporaneous rise in creatinine, and development of azotemia in response to angiotensin-converting enzyme inhibitors, administered for control of hypertension. In patients with CHF, those with episodic flash pulmonary edema (as opposed to gradual fluid retention), especially in the absence of ischemic coronary disease or left ventricular dysfunction, are more likely to respond. PTRA and stents, like surgery (158,169), can be used successfully to restore or "salvage" renal function and eliminate the need for dialysis (170,171). More commonly than actually getting patients off dialysis, PTRA/stenting can slow the progression of renal dysfunction in patients with RAS (172). However, one cannot always predict which individuals with RAS, renal ischemia, and severe azotemia (creatinine of more than 2) are going to respond; factors predictive of success include recent rapid rise in creatinine unexplained by other factors, azotemia resulting from angiotensin-converting enzyme inhibitors, and absence of diabetes or other causes of intrinsic kidney disease. One strongly predictive factor is the presence of "global renal ischemia," wherein the entire functioning renal mass is subtended by bilateral critical stenoses or a severe unilateral lesion in the case of a solitary kidney. These patients can present with any combination of hypertension, congestive cardiac failure, or impaired renal function but invariably exhibit a favorable clinical response to successful intervention (173).

Some patients are less likely to benefit from renal artery revascularization. It is questionable whether patients with mild or moderate hypertension that is well-controlled medically, who also have unilateral RAS and normal renal function, will benefit from revascularization. Such patients should probably be followed longitudinally, with careful reevaluation of renal function and kidney size and control of blood pressure. Likewise, patients with severe baseline renal insufficiency secondary to nephrosclerosis (e.g., in diabetes), with superimposed RAS, are unlikely to benefit from revascularization. It is often difficult to discern what portion of the renal failure or hypertension is due to intrinsic kidney disease versus ischemic dysfunction. Hemodynamic variables such as an absent or minimal pressure gradient or renal size (less than 8 cm in length) may also help predict an unfavorable response to PTA.

MESENTERIC ARTERIES

Stenosis of mesenteric vessels is a frequent finding during routine angiographic studies of the abdominal aorta, but ischemic consequences of those stenoses occur infrequently, often with a subtle presentation not easily ascribed to mesenteric ischemia. The classic but uncommon syndrome of postprandial abdominal pain, gas, diarrhea, food avoidance, and weight loss is most likely to occur in the setting of severe global compromise of blood supply to the mesentery, such as from occlusion of two out of three mesenteric vessels and a critical stenosis in the third. There are syndromes with lesser degrees of ischemia wherein patients will present with variable symptoms, including mild postprandial aching or discomfort, diarrhea, nausea, or gaseousness, in which two mesenteric vessels are patent, but both with severe narrowing. Occasionally, even a single critically narrowed vessel can cause these symptoms.

As is the case with many other vascular sites, the standard of therapy for mesenteric disease has been surgical (endarterectomy or bypass), with a 6% mortality rate (174). In the current era, however, PTA can be effective in restoring acute patency, although restenosis rates are 50% or more because of the ostial location of these lesions (eFig. 111.10.1). Although prospective studies have yet to be done regarding long-term outcome after PTA/stenting, early indications suggest that stents reduce acute recoil and may lead to a better long-term patency (175,176 and 177). The biggest dilemma in patients with mesenteric disease is deciding who is likely to benefit. Certainly, the incidental finding of a mesenteric vessel during routine angiography for other reasons does not necessarily indicate the need for treatment. A conservative approach is indicated in situations in which symptoms of mesenteric ischemia are absent. At the other extreme, the percutaneous approach is ill advised in patients with acute mesenteric ischemia, in whom bowel infarction has already taken place. These patients are better served by surgical repair and intestinal resection.

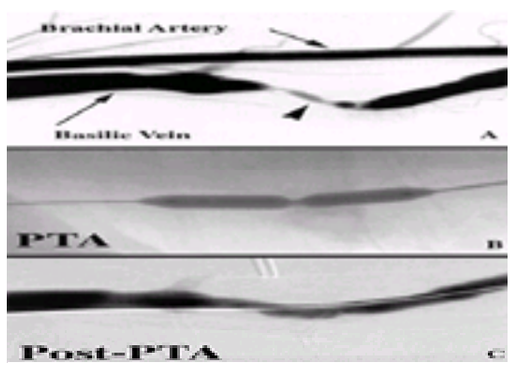


***e*FIGURE 111.10.1** Percutaneous transluminal angioplasty and stenting of celiac artery in a 68-year-old woman with severe intestinal angina and weight loss. **A:** Selective angiogram shows critical ostial stenosis (*large arrow*) due to calcific plaque (Ca). **B:** Waist (*large arrow*) in balloon at 8 atmospheres. Renal stent, placed 18 months earlier, is seen "on end." **C:** Recoil leaves residual stenosis (*arrow*) after percutaneous transluminal angioplasty. **D:** Stenosis alleviated after stent (Palmaz) deployed.

HEMODIALYSIS CONDUITS

More than 120,000 patients are dependent on hemodialysis, and recent evidence shows an increase of 10% per year (178). Nowadays, with the expanding dialysis population enjoying an increased life expectancy, preservation of vascular access sites has become increasingly important. Repeated large-gauge needle punctures, increased sheer forces and intraluminal pressure during dialysis, and postdialysis compression of puncture sites are all factors that may contribute to the high incidence of stenosis and thrombosis in dialysis conduits, be they arteriovenous fistulas or Gore Tex grafts. Arteriovenous fistulas tend to develop fibrous strictures at, and proximal to, sites of repeated puncture. Gore Tex grafts develop stenoses principally localized to the venous and arterial anastomoses; accumulation of pseudointima within the body of the graft may also predispose to graft failure. Surgical revision typically involves several days of hospitalization and placement of temporary access. A more important consequence of surgical revision, however, is the use of proximal vein, which may limit options for future surgical management. PTA has played an increasingly important role in maintaining the functional status of hemodialysis access conduits. The use of PTA for dialysis conduits requires a different perspective from PTA at other sites: Because the patency of dialysis conduits is problematic, regardless of whether surgery or other approaches are used, restenosis is tolerated at a higher frequency than in nearly all other circumstances.

Percutaneous treatment of stenotic or occluded grafts or fistulae is usually technically straightforward (eFig. 111.10.2). Acute success rates of 70% to 95% have been reported (178,179 and 180). However, primary restenosis rates are higher than for PTA in most other vascular beds, up to 60% and 80% at 1 and 2 years, respectively (180,181). *Secondary* patency, however, has been quite acceptable (more than 70% at 2 years) in series in which the investigators closely monitored graft function and performed early angiography and repeat PTA in cases of recurrent stenosis (180). Thus, although the average graft may remain functional only for 4 to 6 months after a single PTA, as opposed to 14 to 18 months after surgical revision (178), close monitoring of graft function and appropriately timed intervention can enhance the results of the percutaneous strategy and delay the need for graft revision.



***e*FIGURE 111.10.2** Percutaneous revascularization [percutaneous transluminal angioplasty (PTA)] of a hemodialysis conduit (arteriovenous fistula) in an elderly patient with chronic renal failure. **A:** Diagnostic fistulogram, obtained because of poor dialysis efficiency (high venous pressures) demonstrated a high-grade focal stenosis (*arrowhead*) in the mid-portion of the basilic vein. **B:** Angioplasty was performed using a noncompliant balloon. **C:** Final angiographic image demonstrated acute technical success with resolution of the stenosis and minimal elastic recoil.

Angioplasty of offending lesions in dialysis conduits often requires use of high-pressure (up to 20 atmospheres) inflation because of the fibrotic nature of the strictures within the venous system and at the graft anastomosis. IVUS is particularly useful for determining the reference diameter and quantifying the extent of recoil (182). Even aggressive angioplasty using oversized balloons, however, is often insufficient, in which case adjunctive treatment with DA may be useful to “cut” the fibrous band. Endovascular stents have also been investigated, but their role remains to be determined.

As suggested by several studies (178,179,183), management of dialysis conduits requires the cooperative efforts of a team consisting of nephrologists, vascular surgeons, and interventionalists. The nephrologists and dialysis nursing staff must pay close attention to the hemodynamic function of access sites during dialysis. Increase in venous pressure, decrease in arterial flow, increase in recirculation, and poor dialysis efficiency are all occurrences that should trigger the request for a diagnostic angiogram. Focal stenoses can be treated initially using PTA and, for resistant lesions, DA. Thereafter, patients should be monitored particularly closely, as one can expect a high incidence of restenosis. Repeated percutaneous interventions, in the interest of preserving the access site and avoiding the need to sacrifice additional vein, are appropriate. However, in cases of recurrent early failure and/or extensive graft degeneration, surgical revision becomes necessary.

CONTROVERSIES AND PERSONAL PERSPECTIVES

In general, the same rigorous standards that have been applied to studies evaluating management strategies in CAD have not thus far been applied to studies of peripheral artery revascularization (15). The development by Rutherford, Becker, and others of uniform standards for reporting results of interventions paves the way for the performance of prospective multicenter trials, which should enable more accurate comparison between various treatment strategies (2).

When Is It Appropriate to Revascularize?

The spectrum of thresholds for intervention is very broad, ranging from practitioners who will refer only PAD patients with advanced ischemia (Rutherford category 4) to those who consider lifestyle-limiting claudication grounds for considering revascularization. The former (conservative) approach is based on the premise that (a) this disease is not generally life-threatening and usually not limb-threatening; (b) any intervention uses up scarce health care dollars and limited resources; (c) the results of both PTA and surgery are imperfect; (d) complications can occur and are not entirely predictable; and (e) patients can occasionally be rendered worse off after (failed) intervention. However, an approach to patients solely based on these premises ignores the progress made in recent years treating PAD; the therapeutic armamentarium for and clinical experience with percutaneous revascularization has markedly improved the prospects of patients with PAD. In the bygone era, there was little reason to perform diagnostic angiography unless surgery was indicated, justifiably so given the risks of major reconstructive surgery in a high-risk population with coronary and cerebrovascular disease, thereby restricting surgery to patients with altogether disabling claudication or threatened limb loss.

In the current era, intervention at an earlier stage of symptomatic disability is possible due to the lower risks and lower costs of nonsurgical revascularization. As has been pointed out by Kumpe and Rutherford (184), “[T]he advantages to the patient able to undergo angioplasty rather than surgery . . . are lower initial morbidity and mortality, no need for general anesthesia, shorter hospital stay, [and] less trauma.” This is true even when one adds to the morbidity of PTA that of diagnostic angiography. Complications of PTA are for the most part minor and typically do not require surgical treatment (185). Access-related events account for most complications [2% to 8% in most series (184,185 and 186)]; these range from the less serious and more common (e.g., groin hematoma) to the serious but rare (e.g., retroperitoneal hematoma) (187). The incidence of complications at the angioplasty site—1% to 7% in most series (185,186,188)—is similar to that in percutaneous transluminal coronary angioplasty, and consists principally of acute occlusion; as with PTA, many of these can be managed with lytic or adjunctive mechanical therapy, including stents, so that the need for emergent surgery due to a jeopardized limb is rare. Distal embolization has been reported in up to 5% of cases (186). Most, however, are clinically silent (185), and even those that might be potentially problematic can often be obviated pre-PTA or treated successfully post-PTA by judicious use of lytic therapy.

It is nevertheless true that both the risks and cost of percutaneous revascularization increase with the complexity and extent of anatomic involvement. The decision to revascularize the patient with claudication in 2001 must therefore take into account two principal considerations. The first is the patient’s symptoms. Reduction in pulse amplitude or inability to palpate one or more pulses on physical examination altogether supports a vascular basis for the patient’s complaints. Noninvasive testing (189,190 and 191) continues to represent an indispensable and necessary initial step in the evaluation of PAD; importantly, failure to detect an abnormal ankle-brachial index at rest does not exclude the presence of severe obstruction, particularly in diabetic or other patients with calcified, noncompressible arteries. Exercise or alternative stress testing may be required to elicit hemodynamic evidence of symptomatic vascular obstructions. Duplex (189), including color-flow (191), examinations may help to clarify such discrepancies. Angiographic examination, however, is still required to define the second consideration, namely the full extent and complexity of the anatomic basis for symptomatic disability, although current advancements in magnetic resonance imaging allow a noninvasive approach.

Once having clarified the anatomic basis for claudication, the recommendation to advise percutaneous revascularization is then individualized. Two patients, for example, may be similarly limited, and in both, the degree of limitation may be inadequate to justify the risks of vascular surgical reconstruction. Diagnostic angiography may suggest that percutaneous revascularization has a high likelihood of technical success in one patient who may thus be a suitable candidate for percutaneous revascularization. In the second patient, certain risks and a complex of anatomic factors suggesting a low likelihood of acute or long-term success may dictate that only surgical revascularization would constitute effective therapy, in which case it may be appropriate to defer the risk of surgery until the patient is more critically disabled. Angiography may thus critically raise or lower the threshold for recommending that an intervention be performed. In previous days, when higher-risk and higher-cost surgery represented the sole option to medical and exercise therapy, it could be reasonably argued that the decision to proceed with angiography could come down to consideration of symptomatic disability only. The option of performing lower-risk and lower-cost PTA, however, implies that the threshold for responding to a given level of symptomatic disability may be raised or lowered, depending on the extent and complexity of anatomic findings.

Should the patient treated by percutaneous revascularization return with clinical evidence of restenosis, repeat percutaneous intervention is probably indicated for the same reasons that led to the recommendation for the original procedure. A certain proportion of these patients—as has been clearly documented in certain patients undergoing one or more repeat coronary angioplasty procedures (192,193)—will achieve a satisfactory long-term result after the second intervention. In those who fail repeated percutaneous attempts to achieve long-term patency, the decision to undergo surgical revascularization may involve a reassessment of the patient’s anatomy and clinical status.

Who Should Decide on the Revascularization Strategy, and Who Should Perform Percutaneous Interventions?

This controversy deserves but a few short lines. The concepts that are promulgated by some individuals within various specialties (vascular surgery: “our disease”; radiology: “our procedures”; cardiology: “our patients”) have no place in the workup and management of patients with PAD. Justification for so-called turf wars is difficult to find and seems to be based mainly on issues only tangentially related to patient care, at best. Such “battles” preclude cross-fertilization and exchange of knowledge and ideas among specialties. As such, patient care stands to suffer from the underuse of resources that could have been helpful.

The ideal approach to management of PAD, a truly multidisciplinary disease, requires coordinated input from experts in cardiology, vascular surgery, radiology, and vascular medicine. Formal or informal multidisciplinary vascular conferences provide an invaluable forum for exchange of knowledge and information, as well as an opportunity to develop management strategies for individual patients.

Regarding the performance of percutaneous interventions, such skills are not “specialty specific.” Whoever has acquired a good fund of knowledge and has fulfilled the requirements set forth by their institution, requirements presumably that are based more or less on the published guidelines of American College of Cardiology/American Heart Association, should be capable of performing the procedures for which he or she is trained.

THE FUTURE

As the population ages and patients are surviving with their heart disease, physicians are now grappling with the increased prevalence and disabling effects of vascular disease at other arterial sites, including carotids, renals, and lower extremities. Over the next 10 years, cardiologists will become much more aware and knowledgeable about PAD and involved in management issues related to this disease. Concurrently, detection and recognition of PAD will increase. The available treatment options, both conservative and invasive, will expand as well. Intensive efforts will be devoted to prevent the onset and halt the progression of vascular disease using powerful new lipid-lowering agents and aggressive risk factor modification. Similar resources will be used to prevent secondary recurrence after successful initial treatment. New innovative pharmaceutical agents currently under development may prove to be effective in treatment of intermittent claudication.

Invasive therapy for PAD will continue to shift toward a predominantly percutaneous, as opposed to surgical, approach. As interventions become more effective and safer, the threshold for treatment will be lowered and the number of percutaneous interventions will rise, probably dramatically. Restenosis, which remains the greatest enigma of percutaneous revascularization, will continue to complicate outcomes. However, the use of endovascular stents, which have already had a favorable impact on restenosis in coronary and iliac arteries, will be applied routinely to other vascular sites, including renal, carotid, vertebral mesenteric, aortic, and femoropopliteal vessels.

Meanwhile, additional promising strategies to reduce restenosis, including genetic and molecular manipulations and x-ray therapy, will be refined and will augment the beneficial impact of endovascular stents, further reducing the incidence of restenosis. The use of sophisticated imaging techniques, such as IVUS, MRA, and spinal computed tomography, will facilitate diagnosis and enhance the results of revascularization. These will also enable complex percutaneous procedures (e.g., exclusion of aneurysms by stent-grafting) to be performed with less risk and optimal results. Although novel treatment modalities will continue to be developed, third-party payors will require more rigorous documentation of outcomes using standardized measures that have not previously seen widespread application in PAD studies. There remains a concern that scrutiny by third-party payors and reduction in resources will stifle creative new research. As a consequence of the emphasis on risk factor modification, the aging of the population, and the shift toward catheter-based therapies, cardiologists will become increasingly involved with management of PAD. Finally, for patients who previously may have had to opt for amputation in the absence of viable options for conventional revascularization, the possibility of encouraging the formation of new vascular conduits by introducing angiogenic factors may offer these patients new hope for limb salvage. Indeed, if the angiogenesis trials and other molecular investigations currently under way produce favorable results, this could profoundly alter the way we approach both peripheral vascular and cardiovascular disease.

OVERVIEW

Renal artery stenosis (RAS) is most commonly due to either fibromuscular dysplasia (FMD) or atherosclerosis. The former predominates in young women, whereas the latter is almost exclusively seen in individuals over the age of 55. Frequently, RAS is discovered incidentally during imaging studies for other reasons (atrophic or small kidney), or at autopsy. Incidental RAS is quite common (1,2), whereas renovascular hypertension occurs in only 1% to 5% of all patients with hypertension (3). The predominant clinical manifestation of FMD is hypertension. The hypertension can frequently be cured or significantly improved with percutaneous transluminal angioplasty (PTA). The predominant clinical manifestations of atherosclerotic RAS include hypertension, renal failure (ischemic nephropathy), and recurrent episodes of congestive heart failure and flash pulmonary edema (4,5).

The presence of anatomic RAS does not necessarily establish that the hypertension or renal failure is caused by the RAS. Many patients have had essential (primary) hypertension for years and then develop atherosclerotic RAS later in life. In patients with long-standing hypertension, it is unlikely to achieve a cure of the hypertension with surgical or percutaneous intervention. However, 50% to 80% of patients do experience improvement in blood pressure control (4,6,7,8,9 and 10). Ischemic nephropathy or flash pulmonary edema only occurs in the presence of bilateral renal artery disease or disease to a solitary functioning kidney. Percutaneous or surgical revascularization can lead to improvement or stabilization in renal function and improvement in congestive heart failure if the patients are selected carefully (8,11). Screening tests for RAS have improved considerably over the last decade. Although captopril renography was used almost exclusively in the past, duplex ultrasound of the renal arteries or magnetic resonance angiography (MRA) has replaced other modalities as the screening test of choice in many centers. Rarely does an arteriogram have to be performed for diagnostic purposes only.

Management of RAS consists of three possible strategies: medical management, surgical management, or percutaneous therapy with balloon angioplasty and stent implantation. The treatment of choice to control hypertension in patients with fibromuscular disease is percutaneous angioplasty. Renal artery stenting has replaced surgical revascularization for most patients with atherosclerotic disease who require an intervention.

HISTORICAL PERSPECTIVE

Richard Bright first demonstrated an association between hypertension and the kidney. In 1934, Goldblatt and colleagues (12) demonstrated that hypertension could be produced in dogs by constriction of one renal artery [two-kidney, one-clip (2K-1C) model], or both renal arteries or one renal artery if the contralateral kidney was removed (one-kidney, one-clip model). Houssay and Taquini (13) identified a pressor substance that may have been causing the hypertension, and Braun-Menendez and Fasciolo (14) named the substance *hypertensin*. They also demonstrated that this substance was formed in the blood by the actions of renin, an enzyme secreted by the ischemic kidney (15). Page demonstrated that renin produced a pressor substance that he called *angiotonin* (16). Shortly thereafter, it was noted that hypertensin and angiotonin were the same, and the substance was renamed *angiotensin*. Angiotensin was first isolated by Skeggs in 1954 (17), and its amino acid sequence described by Elliott and Peart in 1956 (18).

PATHOPHYSIOLOGY

Experimental Models of Renovascular Hypertension

Pickering clarified the difference between renovascular hypertension and RAS: "The demonstration of a RAS in a hypertensive patient does not necessarily establish a diagnosis of renovascular hypertension, because essential hypertension may accelerate the development of atheromatous plaques, which do not necessarily have any functional significance. Ideally, it is necessary to demonstrate that there is also renal ischemia, since this is thought to be the stimulus that raises the blood pressure, and leads to a decline of renal function" (19). Most investigators believe that there must be at least a 70% reduction in luminal diameter for a RAS to cause either hypertension or ischemic nephropathy (5,20,21).

Animal models for renovascular hypertension have helped to elucidate the pathophysiology of hypertension in patients with RAS (20,22,23 and 24). The renin-angiotensin-aldosterone system plays an important role, as shown in Figure 112.1 (10). In animals, the 2K-1C model is the classic model for renin-mediated hypertension and is analogous to unilateral RAS in humans. The one-kidney, one-clip model of renovascular hypertension is a model for volume-mediated hypertension and is analogous to bilateral RAS or RAS to a solitary functioning kidney in humans. Although the acute phases of both of these models are similar, different events occur in the chronic phase.

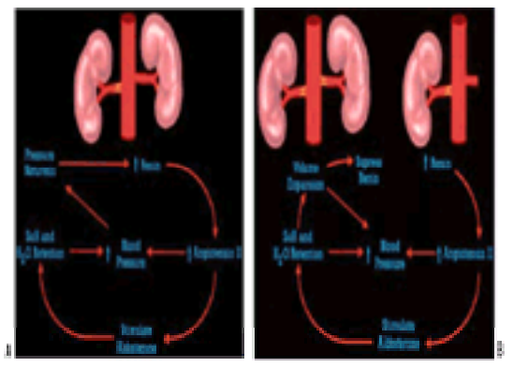

FIGURE 112.1 Pathogenesis of renovascular hypertension in unilateral **(A)** and bilateral **(B)** renal artery stenosis. (From Olin JW, Novick AC. Renovascular disease. In: Young JR, Olin JW, Bartholomew JR, eds. *Peripheral vascular diseases*, 2nd ed. St. Louis: Mosby, 1996:321–342, with permission.)

In the 2K-1C model (unilateral RAS), decreased renal blood flow stimulates the production of renin (Fig. 112.1A). Renin cleaves the proenzyme angiotensinogen to form angiotensin I and, in the presence of angiotensin-converting enzyme (ACE), is converted to angiotensin II. Angiotensin II has several important functions: (1) It elevates blood pressure directly by causing systemic vasoconstriction; (2) it stimulates aldosterone secretion, causing sodium reabsorption and potassium and hydrogen ion secretion in the cortical collecting duct; and (3) it changes the intrarenal hemodynamics, such as diminishing glomerular filtration, by decreasing glomerular capillary surface area and redistributing intrarenal blood flow. The salt and water retention (caused by excess aldosterone production) is rapidly excreted by the contralateral (normal) kidney by pressure natriuresis. This produces a cycle of renin-dependent hypertension (25,26 and 27).

Administration of an ACE inhibitor blocks this cycle and early in the course of renovascular hypertension returns the blood pressure to normal. There is decreased blood flow to the kidney with the clipped (stenotic) artery, increased renin secretion from the ischemic kidney, and suppressed renin secretion from the unaffected contralateral kidney in the 2K-1C model. It is important to differentiate the acute events from the more chronic events. Rats with the 2K-1C model of Goldblatt's hypertension have a rapid increase in plasma renin activity shortly after clipping the renal artery. When an ACE inhibitor or angiotensin receptor blocker (ARB) is administered, the blood pressure immediately declines (20,28). In the chronic phase, the blood pressure remains elevated, even though the plasma renin activity returns to baseline. When an ACE inhibitor or ARB is administered, the blood pressure does not immediately decline but takes 5 to 7 days (29) to return to normal. The delayed blood pressure response suggests that the blood pressure is no longer primarily caused by the direct effects of angiotensin II but involves some degree of salt retention as well. Reasons that have been proposed for this delayed response of an ACE inhibitor and ARB in 2K-1C Goldblatt's hypertension include a delay in drug penetration to sites of angiotensin II action such as the brain (30,31), and some functional effects of prolonged angiotensin II are transcriptionally mediated. This leads to the expression of nicotine adenine diphosphate oxidase, which provides a memory of past angiotensin II effects, thus sustaining the hypertension (32).

In the one-kidney, one-clip model of renovascular hypertension, there is a similar decrease in blood flow to the affected kidney(s), acutely causing the secretion of renin and synthesis of angiotensin II and aldosterone (Fig. 112.1B) (10). Angiotensin II directly elevates blood pressure, and aldosterone causes salt and water retention. In this model there is not a normal kidney that can *sense* the elevated blood pressure; therefore, pressure natriuresis does not occur. The increased aldosterone causes sodium and water retention and volume expansion. The expanded plasma volume suppresses plasma renin activity, thus converting the animal from renin-mediated hypertension to volume-mediated hypertension (28,33). During this stage, administration of an ACE inhibitor or ARB does not decrease blood pressure or change renal blood flow (35). Dietary restriction of sodium or administration of diuretics returns the subject to a renin-mediated form of hypertension and restores sensitivity to an ACE inhibitor or ARB. Functional renal insufficiency may occur in humans when ACE inhibitors are administered to patients with bilateral RAS or RAS to a solitary kidney, especially in the volume-contracted state.

The time course for the chronic phase to occur may be weeks in the one-kidney, one-clip rat model, whereas it may take up to 4 months in the 2K-1C rat model (34). In the 2K-1C model, loss of renin sensitivity in the chronic state may also occur and is caused by an inability of the contralateral (normal) kidney to excrete an increased sodium load when the blood pressure is increased (pressure natriuresis). This attenuation may occur due to changes in intrarenal hemodynamics and structural changes in the microvasculature of the kidney (35). For example, nephrosclerosis commonly occurs in patients with long-standing hypertension. If this patient later develops unilateral RAS, he or she may behave like a patient with bilateral disease since the contralateral kidney would not be able to excrete a salt load normally. Numerous other mechanisms have been shown to be important to varying degrees in the generation and maintenance of hypertension in animals and patients with RAS (23,38). Several newer concepts regarding the renin-angiotensin system have emerged. These include local production of angiotensins in various vascular beds, the discovery of biologically active peptides other than angiotensin II, and the identification of multiple angiotensin receptor subtypes. In addition, there is a body of evidence accumulating that nitric oxide, an endothelium-dependent vasodilator, plays an important role in blood pressure regulation (36). Endothelium-derived constricting factors (prostaglandin H_2 and thromboxane A_2) and endothelium-derived relaxing factors (nitric oxide) are both important in regulating vascular tone in the renal circulation (37).

Pathophysiologic Differences between Unilateral and Bilateral Stenosis

Whereas unilateral RAS closely resembles the 2K-1C model in animals, patients with bilateral RAS or RAS to a solitary functioning kidney probably have components of both renin-mediated and volume-mediated hypertension. Patients with bilateral disease may have high, normal, or low renin values depending on their volume status (38,39). Therefore, peripheral venous measurement of plasma renin activity is not a useful screening test for RAS.

There are three pieces of evidence that there is volume expansion in patients with bilateral disease: The cardiac output is usually higher than in patients with unilateral disease (40), recurrent pulmonary edema occurs almost exclusively in patients with bilateral disease or disease to a solitary functioning kidney (11,41,42), and restoration of blood flow to patients with bilateral disease or disease to a solitary functioning kidney is often accompanied by prompt diuresis (43).

Pathophysiology of Ischemic Nephropathy

There are numerous reports suggesting that patients who develop azotemia while receiving ACE inhibitors have bilateral RAS, RAS to a solitary kidney, or decompensated congestive heart failure in the sodium-depleted state (44,45,46,47,48 and 49).

There are two mechanisms by which renal functional impairment may occur with the use of antihypertensive agents. The first may occur with any antihypertensive agent when a critical perfusion pressure is reached below which the kidney no longer receives adequate perfusion. This has been shown by the infusion of sodium nitroprusside in patients with high-grade bilateral RAS. When the critical perfusion pressure was reached, the urine output, renal blood flow, and glomerular filtration rate declined and later returned to normal when the blood pressure increased above this critical perfusion pressure (44). The exact pressure necessary to perfuse a kidney with RAS varies with the degree of stenosis and is different among different patients.

The second mechanism is confined to patients receiving ACE inhibitor or ARB agents and may occur despite no significant change in blood pressure (49). Patients with high-grade bilateral RAS or RAS to a solitary kidney may be highly dependent on angiotensin II for glomerular filtration. This is particularly common in patients who receive a combination of ACE inhibitor and diuretic (50) or in patients who are placed on a sodium-restricted diet (51). Under these circumstances, the constrictive effect of angiotensin II on the efferent arteriole allows for the maintenance of normal transglomerular capillary hydraulic pressure, thus allowing glomerular filtration to remain normal in the presence of markedly diminished blood flow (Fig. 112.2). In this instance, glomerular filtration is highly dependent on angiotensin II. When an ACE inhibitor is administered, the efferent arteriolar tone is no longer maintained, and glomerular filtration is therefore decreased. A similar situation occurs in patients with decompensated congestive heart failure who are sodium depleted (47). Hricik and associates (51) demonstrated the important role that sodium balance plays in the azotemia associated with bilateral RAS or RAS to a solitary functioning kidney (*e*Table 112.0.1). When an ACE inhibitor alone was given, there was no change in renal function. However, if the patient was sodium depleted and then an ACE inhibitor was administered, the patient developed acute renal failure. This was rapidly reversed with the administration of intravenous fluids.

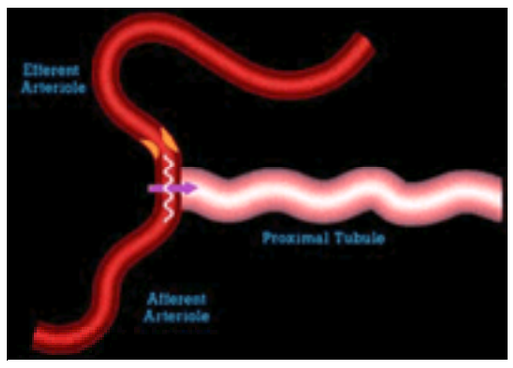

FIGURE 112.2 Patients with high-grade bilateral renal artery stenosis or renal artery stenosis to a solitary kidney may be highly dependent on the efferent arteriolar constriction caused by angiotensin II in preserving transglomerular capillary hydraulic pressure (*arrow*) and glomerular filtration rate. When an angiotensin-converting enzyme inhibitor is given, the efferent arteriole dilates, transglomerular capillary hydraulic pressure is not maintained, and blood is shunted from the afferent arteriole to the efferent arteriole, bypassing glomerular filtration.

***e*TABLE 112.0.1** ROLE OF SODIUM BALANCE IN RENAL INSUFFICIENCY CAUSED BY ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

From Hricik D, Browning PJ, Kopelman R, et al. Captopril-induced functional renal insufficiency in patients with bilateral renal-artery stenosis or renal-artery stenosis to a solitary kidney. *N Engl J Med* 1983;308:373, with permission.

There have been several animal studies suggesting that ACE inhibitor–induced acute renal failure may not be functional or reversible. Grone and Helmchen (52) have demonstrated that after 14 days of treatment with enalapril in rats with 2K-1C renovascular hypertension, proximal tubular atrophy occurred. This was not demonstrated in rats treated with dihydralazine. Jackson and colleagues (53) demonstrated more marked irreversible fibrotic atrophy in the clipped kidney in animals receiving enalapril compared with those receiving minoxidil or no antihypertensive treatment. These data have led some investigators (54) to suggest that the tubular interstitial changes represented a form of “disuse atrophy” due to hypofiltration.

Pathology of Renovascular Disease

Shanley suggested that loss of renal mass, loss of nephrons, and renal atrophy predominate in the pathologic picture of patients with renovascular disease (55). There is a point at which many of these changes are reversible, and the goal of management is to identify the patients early and treat them to prevent progressive renal failure. Prolonged ischemia leads to wrinkling and collapse of the glomerular capillaries (56). Long-standing renovascular disease is associated with small cortical infarcts and significant thickening, hyalinosis, and endothelial damage of the arterioles (57). Atheromatous embolization has also been associated with renovascular disease (58). The compilation of injury leads to cortical scarring, interstitial fibrosis, tubular collapse, and destruction of the renal architecture.

Systemic and glomerular pressure plays an important role in renal injury in patients with renovascular disease. In the 2K-1C model of renovascular hypertension, the unclipped kidney demonstrates significantly more vascular and glomerular damage than the clipped kidney (59,60). It is not clear whether this is due to a direct hemodynamic effect of the elevated blood pressure or the mitogenic and hypertrophic effects of angiotensin.

Nephrotic syndrome has been occasionally reported in patients with renovascular disease. There are observations that the nephrotic syndrome remits after correction of the RAS (61,62,63,64 and 65). The exact mechanism of nephrotic range proteinuria in renal artery disease is not well defined (66,67).

ANATOMIC CONSIDERATIONS

Atheromatous Lesions

Approximately 90% of all renovascular lesions are secondary to atherosclerosis (5). Although atherosclerotic RAS may occasionally be isolated to the renal artery alone, it is more commonly a manifestation of generalized atherosclerosis involving the aorta, coronary, cerebral, and peripheral vessels. Atherosclerotic RAS most often occurs at the ostium or the proximal 2 cm of the renal artery (Fig. 112.3). Distal arterial or branch involvement is distinctly uncommon (10).

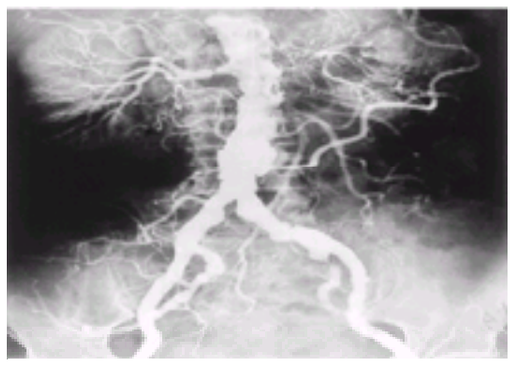

FIGURE 112.3 Aortogram showing severe proximal stenosis of the right renal artery. The left renal artery is occluded. Note the severe atherosclerosis in the aorta and iliac arteries. There is a large wandering artery of Drummond, indicating severe stenosis or occlusion of the superior mesenteric artery.

Fibromuscular Dysplasia

FMD is a nonatherosclerotic, noninflammatory disease that most commonly affects the renal arteries and is the second most common cause of RAS. The most common clinical presentation is that of hypertension in a young woman. FMD has been demonstrated in virtually every vascular bed. Renal artery involvement occurs in 60% to 75% of patients with FMD, followed by cervicocranial arteries in 25% to 30%, visceral arteries in 9%, and arteries of the extremities in approximately 5% of patients (68). It may present as a systemic disease (affecting a combination of the carotids, mesenteric, subclavian, and extremity vessels) in up to 28% of patients (69). The diagnosis is rarely made pathologically, but is usually determined by its typical angiographic appearance (Fig. 112.4). Although atherosclerosis involves the origin and proximal portion of the renal arteries, FMD characteristically involves the distal two-thirds of the artery and may involve the branches (70).

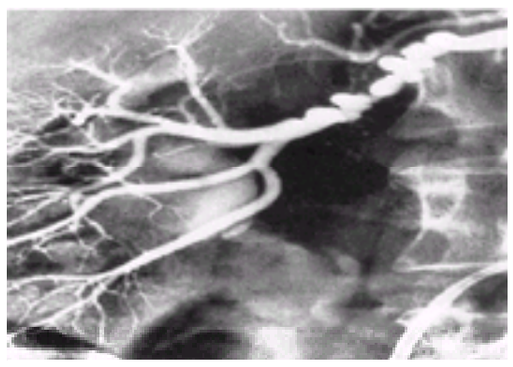

FIGURE 112.4 This renal arteriogram demonstrates typical medial fibroplasias of the renal artery. The “string of beads” appearance of the renal artery involves the distal portion of the main renal artery, and the “beads” are larger than the normal diameter of the artery. (From Olin JW, Novick AC. Renovascular disease. In: Young JR, Olin JW, Bartholomew JR, eds. *Peripheral vascular diseases*, 2nd ed. St. Louis: Mosby, 1996:321–342, with permission.)

The lesions of FMD are thought to be congenital dysplasias with maldevelopment of the fibrous, muscular, and elastic tissues of the renal artery. They are subcategorized according to the layer of the arterial wall involved (71). This classification is important since each type of fibrous dysplasia has distinct histologic and angiographic features, and each type occurs in a different clinical setting (Table 112.1).

Classification	Frequency	Pathology	Angiographic appearance
Medial dysplasia			
Medial fibroplasia	75–80%	Alternating areas of thinned media and thickened fibromuscular ridges containing collagen; internal elastic membrane may be lost in some areas.	“String of beads” appearance in which the diameter of the “beading” is larger than the diameter of the artery
Perimedial fibroplasia	10–15%	Extensive collagen deposition in the outer half of the media.	“Beading” in which the “beads” are smaller than the diameter of the artery
Medial hyperplasia	1–2%	True smooth muscle cell hyperplasia without fibrosis.	Concentric smooth stenosis (similar to intimal disease)
Intimal fibroplasia	<10%	Circumferential or eccentric deposition of collagen in the intima. No lipid or inflammatory component; internal elastic lamina fragmented or duplicated.	Concentric focal band; long smooth narrowing
Adventitial (periarterial) fibroplasia	<1%	Dense collagen replaces the fibrous tissue of the adventitia and may extend into surrounding tissue.	

From Begelman SM, Olin JW. Fibromuscular dysplasia. *Curr Opin Rheumatol* 2000;12:41–47, with permission.

TABLE 112.1 CLASSIFICATION OF FIBROMUSCULAR DYSPLASIA

Medial FMD has been further divided into medial hyperplasia (the only type in which there is true smooth muscle hyperplasia), perimedial dysplasia, and medial fibroplasia. Medial fibroplasia is the histologic finding in nearly 80% of all cases of FMD. It tends to occur in 25- to 50-year-old women and often involves both renal arteries. It has a “string of beads” appearance angiographically, with the “bead” diameter larger than the proximal, unaffected artery (Fig. 112.4). The areas of stenosis are often overshadowed by contrast medium in the microaneurysms, making the degree of actual stenosis difficult to assess. This beading is due to thickening of the media, interspersed by areas of aneurysmal dilatation. Microscopically, the internal elastic membrane is focally variably thinned and lost. Within the alternating thickened areas much of the muscle is replaced by collagen, hence the term *medial fibroplasia*. In other areas, thinning of the media occurs to the point of complete loss, and microaneurysms can be seen as saccules lined by only the external elastica. In extreme cases, giant aneurysms may be found in association with medial fibroplasia. Progression to total occlusion is rare in this subtype. Medial fibroplasia responds well to PTA.

Perimedial fibroplasia occurs predominantly in 15- to 30-year-old women. Of all fibrous lesions 10% to 15% are perimedial fibroplasias (10). These tightly stenotic lesions only occur in the renal artery and consist pathologically of a collar of dense collagen enveloping the renal artery for variable lengths and thicknesses. The collagen is deposited in the outer border of the media and usually replaces a considerable portion of it; in some areas of collagen it may completely replace the media.

The arteriogram of perimedial fibroplasia may give the appearance of arterial beading, but careful observation shows that the caliber of the normal segment of the vessel is not exceeded by the “bead.” This fact, along with the frequent occurrence of external collateral circulation, differentiates this lesion angiographically from that of medial fibroplasia. Perimedial fibroplasia produces severe stenosis and, although complicating thrombosis or dissection is relatively uncommon, progressive obstruction with ischemic renal atrophy occurs frequently.

Medial hyperplasia is an extremely rare disease, accounting for only 1% to 2% of fibrous lesions, and tends to occur in children and young adults. This is the only renal arterial disease in which true hyperplasia of the smooth muscle cell is present. The renal artery shows a concentric thickening of its wall with a mixture of proliferating smooth muscle and fibrous tissue in variable quantity. Arteriographically, medial hyperplasia appears as a smooth stenosis of the renal artery or its branches and, from a radiographic standpoint, may be indistinguishable from intimal fibroplasia. Most patients with this disease develop progressive vascular obstruction.

Intimal fibroplasia occurs in children and young adults and accounts for approximately 10% of the total number of fibrous lesions. This lesion is characterized by a circumferential accumulation of collagen inside the internal elastica lamina (72). Disruption and duplication of the elastica interna occur more often in younger patients, with dissecting hematomas as a complication in some patients. Intimal fibroplasia with complicating medial dissection is characterized pathologically by large dissecting channels in the outer one-half of the media. Arteriography in intimal fibroplasia reveals either a smooth long area of narrowing or a concentric band-like focal stenosis usually involving the midportion of the vessel or its branches. Dissecting hematomas may distort the area of the stenosis. Progressive renal artery obstruction and ischemic atrophy of the involved kidney may occur. Although intimal fibroplasia most commonly affects the renal arteries, this may also occur as a generalized disorder with concomitant involvement of the carotid, upper and lower extremities, and mesenteric vessels and may mimic a necrotizing vasculitis (73).

Some investigators consider the moyamoya syndrome to be a variant of FMD. In the moyamoya syndrome, there is RAS associated with abnormalities of the cerebral circulation. These may include stenoses of the carotid or intracranial arteries with an associated network of collateral vessels, the so-called puff of smoke appearance. There is an increased risk of intracerebral hemorrhage when these cerebrovascular abnormalities occur along with hypertension (74,75 and 76).

Miscellaneous Causes of Renovascular Disease

Renal Artery Aneurysms

Renal artery aneurysms may require surgical treatment when they are the cause of significant hypertension or to obviate the risk of rupture. The latter is of greatest concern with aneurysms that are larger than 2 cm in diameter and noncalcified, particularly when they occur in premenopausal women because of the predisposition for aneurysmal rupture during pregnancy (77,78). According to the classification of Poutasse (79), there are four basic types of renal artery aneurysms: saccular, fusiform, dissecting, and intrarenal.

Saccular aneurysms, which account for approximately 75% of renal artery aneurysms, are the most common. They generally occur at the bifurcation of the renal artery, perhaps due to an inherent weakness in the wall of the artery at this point. These aneurysms may become involved with secondary atherosclerotic degeneration, intramural calcification, or both. There are several mechanisms by which saccular aneurysms may be causally related to hypertension. These include compression or displacement of renal artery branches with resulting ischemia, aneurysmal erosion into a renal vein with formation of an arterial venous fistula, mural thrombus formation within the aneurysm with peripheral renal embolization, and the association of some aneurysms with stenosing fibrous renal artery disease. It is also well appreciated that saccular aneurysms can cause hypertension in the absence of these sequelae, most likely because of relative renal ischemia caused by the turbulent flow of blood as it passes through the aneurysmally dilated arterial segment. Fusiform renal artery aneurysms are almost always associated with stenosing fibrous renal artery disease. The latter is the cause for the severe hypertension generally seen in these patients. Fusiform aneurysms actually represent a severe poststenotic dilation of the renal artery. Dissecting renal artery aneurysms are most often a complication of intimal fibroplasia or atherosclerosis. These are often manifested clinically by the sudden onset of pain that stimulates renal colic and the development of gross or microscopic hematuria, which is quite common. In some patients, the

dissection in the wall of the vessel may reenter the lumen more distally. In other patients, total arterial occlusion with renal infarction may ensue.

Intrarenal arterial aneurysms are of mixed origin and may be congenital, posttraumatic, iatrogenic, neoplastic, or associated with polyarteritis nodosa. Intrarenal aneurysms that occur following blunt trauma or closed renal biopsy occasionally resolve spontaneously with expectant management. Intrarenal aneurysms do have the propensity for rupture, and surgical treatment may be indicated if their diameter is greater than 2 cm.

Other causes of renovascular disease include Takayasu's arteritis, atheroemboli, thromboemboli, spontaneous renal artery dissection, arteriovenous malformations or fistulas, trauma (e.g., from radiation, lithotripsy, direct injury, or surgery), and neurofibromatosis. Retroperitoneal fibrosis producing external compression has also been associated with RAS.

CLINICAL ASPECTS OF RENAL ARTERY STENOSIS

Primary or essential hypertension is present in over 60 million Americans. Renovascular disease and renal parenchymal disease are the most common secondary causes of hypertension after obesity, excess alcohol ingestion, drug abuse, and oral contraceptives. Patients with atherosclerotic RAS have the usual risk factors for atherosclerosis. Past or present smoking is especially common in patients with renovascular disease (80,81). There is conflicting information on the prevalence of RAS in blacks. Although Keith et al. reported that renovascular disease was much more common in whites than it was in blacks (82), others (83) have shown that the prevalence of renovascular hypertension is similar in blacks and whites. Blacks with primary (essential) hypertension are more likely to have severe hypertension leading to vital organ damage [i.e., stroke, end-stage renal disease (ESRD)] than whites.

Although the effect of atherosclerosis on the coronary and carotid arteries is well recognized, involvement of the renal arteries is frequently overlooked. It is known that patients with atherosclerotic RAS succumb prematurely from myocardial infarction and stroke (8,84,85 and 86). Therefore, early diagnosis and treatment are of vital importance to avoid premature morbidity and mortality.

Prevalence of Renal Artery Stenosis

Although there are excellent prevalence data in specific patient populations (i.e., those with coronary artery disease, aortic aneurysm, peripheral arterial disease), the prevalence of RAS in the general population is not known. Not all cases of RAS are clinically significant. Dustan et al. (87) reviewed 149 aortograms and found that approximately one-half of patients with greater than or equal to 50% RAS did *not* have hypertension.

The prevalence of atherosclerotic RAS has been reported in several autopsy series. Holley et al. (88) examined 295 consecutive patients and found RAS (defined as greater than or equal to 50% stenosis) in 53%. The prevalence increased to 74% when only those individuals older than 70 were considered. Likewise, Schwartz et al. (89) prospectively studied 154 consecutive patients at autopsy. They found RAS in 24% of all patients and in 86% of patients age 75 or older. More recently, 297 patients greater than 40 years old with autopsy-proven myocardial infarction were examined for evidence of atherosclerotic RAS (90). Significant stenosis (greater than 75% luminal narrowing) was documented in 12% of patients. Because atherosclerosis increases with age, it is understandable why the prevalence of atherosclerotic RAS would be greater among the elderly.

Several series have looked at the prevalence of renovascular disease in patients who have atherosclerotic disease elsewhere (91,92,93,94 and 95). To determine the prevalence of atherosclerotic RAS, we studied 395 consecutive patients who had undergone arteriography as part of an evaluation for an abdominal aortic aneurysm, aortoiliac occlusive disease, and peripheral arterial disease. In addition, 78 patients had an aortogram performed for suspected RAS (*e*Table 112.1.1) (1). These patients did not have the usual clinical clues to suggest RAS. High-grade bilateral renal artery disease was present in approximately 13% of patients. In the 319 patients reported in six different studies, 44% of patients had bilateral RAS (9). Other studies have shown that 22% to 59% of patients with peripheral arterial disease have significant RAS (96).

***e*TABLE 112.1.1** PREVALENCE OF ATHEROSCLEROTIC RENAL ARTERY STENOSIS

³50% stenosis	Abdominal aortic aneurysm (n = 109)	Aortoiliac occlusive disease (n = 21)	Peripheral arterial disease (n = 189)	Renal artery stenosis (n = 76)

From Olin JW, Melia M, Young JR, et al. Prevalence of atherosclerotic renal artery stenosis in patients with atherosclerosis elsewhere. *Am J Med* 1990;88:46N–51N, with permission.

It has also been established that RAS is common in patients with coronary artery disease (97,98). Harding et al. (2) performed abdominal aortography at the time of cardiac catheterization in 1,235 patients and found that 30% had renal artery disease. Only one-half of the patients had documented luminal narrowing of at least 50%. It has also been shown that patients with RAS are more likely to have significant carotid or peripheral arterial disease (99,100,101 and 102). Louie and associates demonstrated that 46% of patients with greater than 60% RAS had greater than 50% carotid stenosis (100).

Some studies report disease prevalence for individuals in whom there are clinical clues to suggest the presence of RAS. This increases the pretest probability for underlying RAS and, as one would suspect, increases the prevalence of the disease. For example, we have demonstrated that 70% of patients with a suggestive history of RAS were found to have significant disease (1). The prevalence of renovascular hypertension was found to be high in patients with accelerated or malignant hypertension (103).

Natural History of Renal Artery Stenosis

Knowledge of the natural history of atherosclerotic renovascular disease is extremely important in the subsequent management of patients with RAS. Most natural history studies reported in the literature were retrospective studies. It is not only important to study anatomic end points (i.e., progression of stenosis), but also clinical end points (i.e., frequency of chronic renal failure and ESRD). These clinical end points have been lacking in many reports.

Anatomic Progression of Renal Artery Stenosis

In 1984, Schreiber and colleagues (107) retrospectively evaluated the angiograms of 169 patients: 85 patients had atherosclerotic renovascular disease, 75 patients had fibrous renal arterial disease, and 9 patients had components of both atherosclerosis and fibrous disease (*e*Table 112.1.2) (104,105 and 106). Of the 85 patients with atherosclerosis, 37 patients (44%) were found to have anatomic progression of RAS on repeat angiography, and 14 patients (16%) progressed to complete occlusion. The mean angiographic follow-up was 52 months (range, 12 to greater than 60 months). The rate of progression to total occlusion occurred more frequently (39%) when there was greater than 75% stenosis on the initial renal arteriogram.

***e*TABLE 112.1.2** NATURAL HISTORY OF ATHEROSCLEROTIC RENAL ARTERY STENOSIS

Series	Year	Reference	Follow-up (mo)	No. of patients	Progression no. (%)	Occlusion no. (%)
Wollenweber et al.	1998	104	3–88	30	21 (70)	—

Dean et al.	1981	106	6–102	35	10 (29)	4 (11)
Schreiber et al.	1984	107	12–60+	85	37 (44)	14 (16)[a]
Tollefson et al.	1991	108	15–180	48	34 (71)	7 (15)
Total				237	116 (49)	28 (14)

[a]The rate of occlusion occurred in 39% of patients when the stenosis was ³75%.
From Rimmer JM, Gennari FJ. Atherosclerotic renovascular disease and progressive renal failure. *Ann Intern Med* 1993;118:712–719, with permission.

Tollefson et al. (108) studied 48 patients with 194 sequential aortograms over a mean period of 4.5 years. The renovascular disease progressed in 53% of the 79 vessels (34 of 48 patients, or 71%). Seven renal arterial stenoses in seven patients (15%) progressed to complete occlusion. Crowley et al. (109) assessed progression in 1,189 patients who had undergone renal angiography at the time of cardiac catheterization and later had a repeat cardiac catheterization. The disease progressed in 11.1%.

Zierler et al. (110,111) used renal duplex ultrasound to prospectively study anatomic progression of atherosclerotic renovascular disease. This study classified the RAS as follows: *normal* [peak systolic velocity (PSV) <180 cm per second and renal aortic ratio (RAR) <3.5]; *less than 60% stenosis* (PSV greater than or equal to 180 cm per second, RAR <3.5); *greater than or equal to 60% stenosis* (PSV greater than or equal to 180 cm per second, RAR greater than or equal to 3.5); and *occlusion* (no signal detected). If the renal arteries were normal, only 8% progressed over 36 months. However, at 3 years, 48% of patients progressed from less than 60% stenosis to greater than or equal to 60% stenosis. The four renal arteries that progressed to occlusion all had greater than or equal to 60% stenosis at the initial visit. Progression of RAS occurred at an average rate of 7% per year for all categories of baseline disease combined.

Clinical End Points

Several studies have evaluated clinical end points (deterioration of renal function, loss of renal mass, survival) as they relate to patients with progressive RAS. Dean et al. (106) evaluated 41 patients with atherosclerotic renovascular disease and renovascular hypertension randomly selected for nonoperative management. Serial renal function studies were performed prospectively on these 41 patients with a mean follow-up of 28 months (range, 6 to 102 months). Nineteen of 41 patients (46%) experienced an increase in serum creatinine between 25% and 120%, and the glomerular filtration rates dropped 25% to 50% in 12 (29%) patients. Fourteen patients (37%) experienced a reduction in renal length of more than 10%. Although not a direct measure of renal function, loss of renal mass has been associated with a loss of renal function.

The effect of RAS on kidney size has been well studied (112,113). Using duplex ultrasound, Caps and colleagues (113) prospectively followed 204 kidneys in 122 patients with known RAS for a mean of 33 months. The 2-year cumulative incidence of renal atrophy was 5.5%, 11.7%, and 20.8% in kidneys with a baseline renal artery disease classification of normal, less than 60% stenosis, and greater than or equal to 60% stenosis (p = .009, log rank test).

However, a question that has really never been satisfactorily answered is how common is atherosclerotic RAS as a cause of ESRD? Scoble et al. (114) found that atherosclerotic renovascular disease was the cause of ESRD in 14% of patients starting dialysis therapy. Mailloux and colleagues (86) reviewed the causes of ESRD in 683 patients over a 20-year period. Eighty-three patients (12%) had documented RAS as a cause of ESRD. Because these investigators only performed arteriography in patients in whom they highly suspected RAS, it is entirely possible that the true incidence of RAS as a cause of ESRD was seriously underestimated. RAS should be searched for in every patient starting dialysis if a clear-cut etiology for the ESRD is not known.

Connolly et al. (84) showed that the 2-year actuarial *renal* survival (percent of patients remaining off dialysis) was 97.3% for patients with unilateral RAS, 82.4% in patients with bilateral RAS, and 44.7% in patients who have stenosis or occlusion to a solitary functioning kidney. Patients on dialysis have a shortened life expectancy. The average life expectancy in a patient with ESRD greater than age 65 is only 2.7 years (115,116). The survival estimates are even worse if the patient has atherosclerotic renovascular disease as the cause of ESRD. Mailloux and associates (86) have shown that median survival for patients with renovascular disease was 25 months compared with 55 months in patients with malignant hypertension and 133 months for patients with polycystic kidney disease. The 2-year survival on dialysis in patients with renovascular disease was 56%, 5-year survival 18%, and 10-year survival only 5%. These data underscore the fact that patients with atherosclerotic RAS who progress to ESRD and require dialysis have extremely high mortality.

In addition, the mere presence of RAS, even before developing ESRD, portends a poor prognosis. Patient survival decreases as the severity of RAS increases (117), with 2-year survival rates of 96% in patients with unilateral RAS, 74% in patients with bilateral RAS, and 47% in patients with stenosis or occlusion to a solitary functioning kidney. Dorros and associates (9) demonstrated that as the serum creatinine increases, the survival decreases in patients with atherosclerotic RAS. The 3-year probability of survival was 92 ± 4% for patients with a serum creatinine less than 1.4 mg per dL, 74 ± 8% for patients with a serum creatinine of 1.5 to 1.9 mg per dL, and 51 ± 8% for patients with a serum creatinine greater than or equal to 2.0 mg per dL.

Long-term survival was investigated at Duke University in a cohort of 1,235 patients who underwent abdominal aortography at the time of cardiac catheterization. The 4-year survival rate of subjects without RAS was 88% versus 67% for those with RAS (117).

Clinical Clues to the Diagnosis of Renal Artery Stenosis

A multicenter study was performed to determine a set of clinical characteristics that would identify individuals with a higher likelihood of having hypertension due to renal arterial disease (118). The clinical clues to suggest renal artery disease have changed considerably since that time (Table 112.2) (9).

Onset of hypertension after the age of 55
Exacerbation of previously well-controlled hypertension
Malignant hypertension
Resistant hypertension
Epigastric bruit (systolic/diastolic)
Unexplained azotemia
Azotemia while receiving angiotensin-converting enzyme inhibitors or angiotensin-receptor blocking agents
Atrophic kidney or discrepancy in size between the two kidneys
Recurrent congestive heart failure or "flash" pulmonary edema
Atherosclerosis elsewhere

TABLE 112.2 CLINICAL CLUES TO THE DIAGNOSIS OF RENAL ARTERY STENOSIS

Hypertension

- What was the age of onset?
- Has the hypertension suddenly become more difficult to control?
- Did the patient have malignant or accelerated hypertension?
- Does the patient have resistant hypertension?

Individuals who develop hypertension between the ages of 30 and 55 usually have primary (essential) hypertension. If the initial diagnosis of hypertension is made before the age of 30, it is usually due to FMD. Because atherosclerosis occurs in older individuals, it is usually the cause of RAS after the age of 55. It is not uncommon for patients to have years of primary hypertension and as they age, develop atherosclerotic RAS. This cohort of patients may have had well-controlled blood pressure that suddenly became more difficult to control. Accelerated or malignant hypertension has also been associated with a high prevalence of RAS. Davis and colleagues (103) demonstrated that renovascular hypertension was present in 32% of 76 white patients and 11% of 29 black patients studied with grade III or IV hypertensive retinopathy. *Resistant hypertension* is defined as failure to normalize blood pressure less than 140/90 mm Hg (119) after a good medical regimen consisting of at least three drugs with different mechanisms of action. The diagnosis of renovascular disease should be strongly considered in patients with resistant hypertension.

Physical Examination

- Does the patient have evidence of atherosclerosis elsewhere?
- Does the patient have an epigastric bruit?

In general, the physical examination is of limited help. Evidence of coronary, cerebral, or peripheral arterial disease is associated with a higher likelihood of renal artery disease due to the systemic nature of atherosclerosis. Although a systolic abdominal bruit is common and nonspecific, the presence of a systolic/diastolic bruit, especially over the epigastrium, may point to underlying renal artery disease (120). The presence of a diastolic component to the bruit indicates that the degree of narrowing of the artery is severe since there is continued flow during diastole (120). A systolic/diastolic bruit more often occurs in patients with fibromuscular disease (53%) than in patients who have atherosclerotic disease (12.5%) (121). Hunt et al. found a systolic/diastolic bruit in one-third of patients with atherosclerotic renovascular disease and in 75% of patients with fibromuscular disease (122). The presence of a bruit is helpful, but the absence does not exclude the diagnosis of either atherosclerotic renovascular disease or FMD.

Renal Function

- Are the kidneys of differing sizes?
- Has the patient ever developed azotemia associated with ACE inhibitors or angiotensin II receptor blocking agents?
- Does the patient have unexplained azotemia?
- Is the patient receiving dialysis without a clear cause for end-stage renal disease?

Gifford et al. (123) found that 71% of patients (53 of 75 patients) with an atrophic kidney had severe stenosis or complete occlusion of the renal artery ipsilateral to the small kidney. Three studies have shown that if there is a discrepancy in the size between the two kidneys or if one kidney is atrophic, there is a 60% chance that the contralateral renal artery (normal-sized kidney) is severely stenotic (10,124). Therefore, the presence of an atrophic kidney or a discrepancy in size between the two kidneys demands a thorough investigation for the presence of renovascular disease.

There are numerous reports suggesting that patients who develop azotemia while receiving ACE inhibitors have bilateral RAS, RAS to a solitary kidney, or decompensated congestive heart failure in the sodium-depleted state (44,45,46,47 and 48). The mechanisms have been discussed in detail earlier in this chapter.

Congestive Heart Failure and Pulmonary Edema

- Does the patient have unexplained congestive heart failure?
- Has the patient had recurrent episodes of “flash” pulmonary edema?

Recurrent congestive heart failure and flash pulmonary edema not related to ischemic heart disease can result from bilateral RAS (or unilateral RAS to a single functioning kidney). In our renal artery stent series, 39 patients (19% of all patients undergoing renal artery stent implantation from 1991 to 1997) had recurrent episodes of congestive heart failure or flash pulmonary edema as the primary indication for renal artery stenting (11). Although it is not completely understood, the mechanism of congestive heart failure may be related in part to the inability to use ACE inhibitors or ARBs, direct toxic effects of angiotensin II on myocardial function, or the inability to adequately control volume.

DIAGNOSIS OF RENOVASCULAR DISEASE

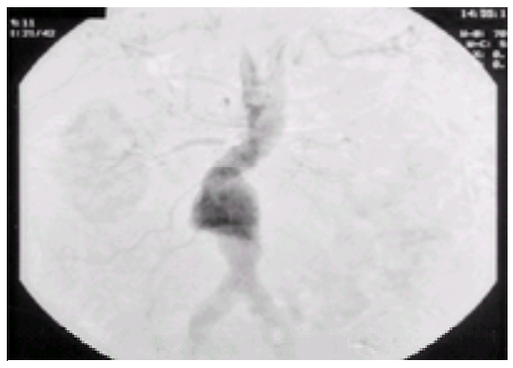
The ideal imaging procedure should (a) identify the main renal arteries as well as accessory or polar vessels; (b) localize the site of stenosis or disease; (c) provide evidence for the hemodynamic significance of the lesion; and (d) identify associated pathology (i.e., abdominal aortic aneurysm, renal mass, and so forth) that may have an effect on the treatment of the renal artery disease (124,125). The most sensitive and specific methods to identify RAS include the noninvasive imaging techniques such as duplex ultrasound, computed tomographic (CT) angiography, and MRA. Although intravenous digital subtraction angiography was used in the past, it no longer is used because of the large contrast loads required and poor image quality.

Arteriography

Angiography, the gold standard for arterial imaging, is rarely required to make the *diagnosis* of RAS. Usually one or more of the noninvasive modalities can accurately make the diagnosis. Exceptions to this general rule may occur in patients with FMD that primarily affects the branches of the renal arteries and patients with renal artery aneurysms. Angiography or intraarterial digital subtraction angiography has several distinct advantages as an imaging modality. All portions of the renal artery, including the intrarenal branches, can be well visualized. In addition, accessory renal arteries can be identified, and one can determine kidney size and gross function (the presence of a nephrogram). However, angiography is invasive and costly compared with other imaging modalities. Although not common, complications associated with angiography include access site complications such as a hematoma, pseudoaneurysm, arterial venous fistula, as well as acute renal failure from contrast-induced nephrotoxicity and atheromatous embolization to the kidneys, bowel, or lower extremities. Therefore, angiography is a poor *screening* test for RAS, but an excellent confirmatory test once it has been decided that revascularization (PTA, stent, surgery) is indicated.

It is important to recognize that the renal arteries often come off of the aorta posteriorly and, therefore, oblique views of the aorta may be needed to visualize the origins of the renal arteries well. Pressure gradients should also be obtained to confirm the physiologic significance of a given lesion.

CO_2 angiography provides an alternative to conventional angiography or digital-subtraction angiography using iodinated contrast agents (eFig. 112.4.1). This may be particularly useful in patients with renal insufficiency in whom contrast exposure may accelerate decline of renal function. When compared with angiography, CO_2 angiography demonstrates a sensitivity of 83% and a specificity of 99% (126,127). CO_2 is rapidly eliminated via the lungs, allowing repeated injections without increased risk of toxicity. The disadvantages of using CO_2 can be related to the buoyancy, compressibility, and solubility of the gas. Due to its buoyancy, CO_2 does not optimally visualize posteriorly placed structures. Large boluses may be necessary to completely displace the blood from the vessel and obtain quality images. This may be difficult because the compressibility of the gas can make injection difficult, and CO_2 dissolves rapidly in the blood; thus, the image degrades in a few seconds (127,128). Although the use of CO_2 does prevent nephrotoxicity from contrast, the patient can still develop atheromatous embolization (from catheter manipulation in the aorta or renal artery) to the kidney. The major drawback from using CO_2 as a contrast agent is that the resolution and clarity are not as good as with iodinated contrast.



***e*FIGURE 112.4.1** CO_2 angiogram demonstrates a small infrarenal abdominal aortic aneurysm, occluded left renal artery, and severe stenosis of the right renal artery.

We do not advocate the use of CO_2 angiography as a screening test for RAS. However, once the diagnosis of RAS is made by some other imaging modality, CO_2 angiography is useful to identify the origins of the renal arteries. When using CO_2 alone or with a small amount of contrast, one can perform an angioplasty and stent placement (129,130). The use of gadolinamide as a contrast agent either alone or with CO_2 in patients with renal insufficiency is becoming more common (131). Gadolinium provides excellent images and may supplant the use of CO_2 in the future.

Renal Arteriography at the Time of Cardiac Catheterization

Because RAS is so common in patients with coronary artery disease, some physicians recommend the routine performance of an aortogram on the “way out” after performing a cardiac catheterization (2,132). We are opposed to routine “drive-by angiography” at the time of cardiac catheterization. It adds additional time and contrast to the procedure. In addition, the quality of the images is often suboptimal. There may not be adequate views of the origin of the renal arteries, especially when they arise posteriorly from the aorta.

However, if the patient has a clear-cut indication for intervention (inability to control the blood pressure with a good antihypertensive regimen, jeopardy of renal function, or recurrent episodes of congestive heart failure), and the clinician is prepared to perform angioplasty and stenting should significant RAS be discovered, then an

aortogram at the time of cardiac catheterization is not an unreasonable approach.

Knowing that the patient has RAS adds nothing to the patient's overall management other than to tempt the angiographer to stent this renal artery lesion in the absence of accepted clinical indications. This has been termed the *renal oculosten(t)otic reflex* (133).

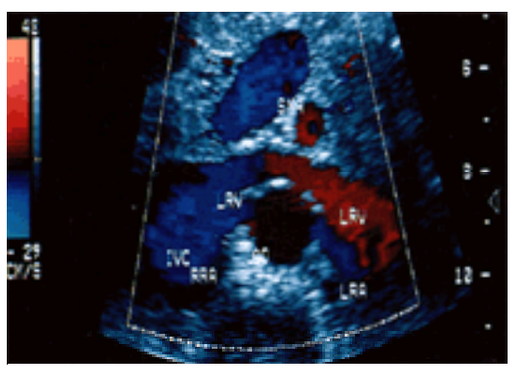
Direct Screening Tests

Evaluation of the renal arteries is essential in acute or chronic renal failure, poorly controlled hypertension, or recurrent congestive heart failure that is not directly caused by myocardial ischemia (134). Imaging modalities are also useful to screen for restenosis after percutaneous or surgical revascularization of the renal arteries. Every patient who has undergone percutaneous intervention for RAS should be put in a surveillance program to detect restenosis. Technological advances in spiral CT angiography and MRA provide aortic and renal artery imaging that compares well with the quality and accuracy of angiography. In fact, MRA has virtually replaced diagnostic angiography for the evaluation of aortic and renal artery disease. Factors such as the patient's body habitus, the degree of renal impairment, and cost may help to determine which screening test is used. However, institutional experience and expertise are perhaps the most important factors determining which of the noninvasive imaging studies is used as a screening test for renovascular disease.

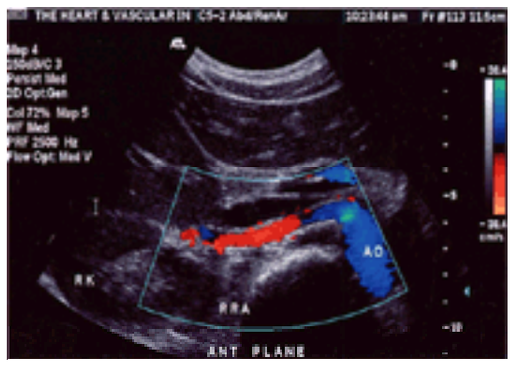
Duplex Ultrasonography

Duplex ultrasonography is an excellent test to detect RAS. It is the least expensive of the imaging modalities and provides useful information about the degree of stenosis, the kidney size, and other associated disease processes, such as obstruction, and may even predict which patients can expect an improvement in blood pressure control or renal function after renal artery angioplasty and stenting (135). The location and degree of stenosis can accurately be determined by duplex ultrasound of the renal artery. Duplex ultrasound can be performed without altering the antihypertensive regimen and does not require contrast agents that may have an adverse effect on renal function.

Duplex ultrasonography combines B-mode ultrasound and Doppler examination. Improvements in ultrasound hardware, software, and transducer technology are responsible for improved visualization of the arteries and more precise Doppler interrogation of the entire artery. Renal artery ultrasound should be performed from both an anterior (*e*Fig. 112.4.2) and oblique [or posterior (flank)] (*e*Fig. 112.4.3) approach. In the longitudinal (long-axis) view, the peak systolic flow velocity in the aorta is recorded at the level of the renal arteries. The aortic velocity and the highest renal artery PSV are used to calculate the RAR.

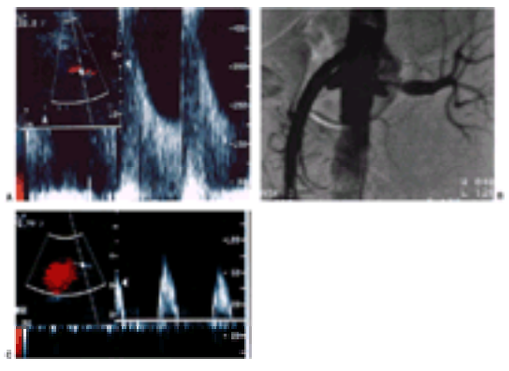


***e*FIGURE 112.4.2** Duplex ultrasound demonstrating the anatomic relationship of the renal arteries, left renal vein (LRV), and superior mesenteric artery (SMA). AO, aorta; IVC, inferior venous cava; LRA, left renal artery; RRA, right renal artery.



***e*FIGURE 112.4.3** Normal renal artery duplex of right renal artery from a flank view. Note excellent visualization of the right renal artery from the origin to the distal portion. AO, aorta; RK, right kidney; RRA, right renal artery.

The renal arteries are best visualized in a transverse (short-axis) view. *e*Figure 112.4.4 demonstrates a high-grade stenosis of the left renal artery before (A and B) and after (C) renal artery stent implantation. Using the B-mode image and a 60-degree angle of insonance, the arteries are interrogated with pulse wave Doppler. The Doppler should be swept through the artery from its origin to the renal hilum. This allows the examiner to survey the artery for velocity shifts along the entire course of the renal artery. Velocities should be recorded at the origin, proximal, mid-, and distal arterial segments. From an oblique approach, the renal artery can be visualized at the renal hilum and followed to the aorta (*e*Fig. 112.4.3). By studying the patient from an anterior and an oblique approach, Doppler velocity measurements are obtained in two views, ensuring that a focal stenosis is not missed and that the angle of insonation is correct. Because medial fibroplasia most often occurs in the mid- to distal renal artery, the oblique approach is particularly good for identifying these entities. It is important to note that segmental Doppler interrogation (spot-checking) of the renal artery velocities is inadequate and often leads to an inaccurate result (136,137).



***e*FIGURE 112.4.4 A:** Renal artery duplex ultrasound from the anterior approach. The Doppler is placed in the proximal left renal artery. The peak systolic velocity is 485 cm per second and the end diastolic velocity (*arrow*) is 210 cm per second, indicating a stenosis of greater than 80% of the left renal artery. **B:** The aortogram shows a total occlusion of the right renal artery and a severe eccentric stenosis of the left renal artery with poststenotic dilatation. **C:** Duplex of the left renal artery after a renal artery stent was placed. Note normal velocities compared with prestenting.

Overall, when compared with angiography, duplex ultrasound has a sensitivity and specificity of 84% to 98% and 62% to 99%, respectively, when used to diagnose RAS (138,139,140,141,142 and 143). We performed a prospective study comparing duplex ultrasound with angiography (*e*Table 112.2.1) (143). If the end diastolic

velocity was greater than or equal to 150 cm per second, then the degree of stenosis was likely to be greater than or equal to 80% (143).

***e*TABLE 112.2.1** COMPARISON OF DUPLEX ULTRASOUND WITH ARTERIOGRAPHY[a]

	Stenosis by arteriography				
Stenosis by ultrasound	0–59%	60–79%	80–99%	100%	Total
0–59%	62	0	1	1	64
60–99%	1	31	67	0	99
100%	0	1	1	22	24
Total	63	32	69	23	187

[a]Sensitivity, 0.98; specificity, 0.98; positive predictive value, 0.99; and negative predictive value, 0.97.
From Olin JW, Piedmonte MR, Young JR, et al. The utility of duplex ultrasound scanning of the renal arteries for diagnosing significant renal artery stenosis. *Ann Intern Med* 1995;122:833–838, with permission.

The RAR, the ratio of the PSV in the renal arteries to the PSV in the aorta, is used to classify the degree of stenosis. A three-category classification scheme is commonly used: 0% to 59% stenosis, 60% to 99% stenosis, and total occlusion (*e*Table 112.2.2). When the aortic velocity is less than 40 cm per second or greater than 100 cm per second, the RAR is not an accurate representation of the degree of stenosis. In these instances, if the PSV is greater than 200 cm per second and turbulence is present on color flow, the stenosis would be classified as 60% to 99%. When there is a discrepancy in kidney size of 2.0 cm or greater, the ultrasonographer should search carefully for the presence of RAS or an occluded renal artery.

***e*TABLE 112.2.2** DUPLEX ULTRASOUND CRITERIA FOR RENAL ARTERY STENOSIS

Stenosis	**Duplex criteria**
<60% stenosis	Renal-to-aortic ratio <3.5
60–99% stenosis	Renal-to-aortic ratio ³3.5 and peak systolic velocity >200 cm/sec
Occlusion	No flow signal from renal artery; low-amplitude parenchymal signal ± small kidney

The acceleration time, acceleration index, and resistive index have been used by some investigators to diagnose RAS. These measurements are obtained by Doppler examination in the renal parenchyma. The Doppler measurements are made with a 0-degree angle to obtain the best Doppler waveform possible. Acceleration time, measured in milliseconds, is the time from the onset of the upstroke of the arterial wave to the systolic peak. The acceleration index is the slope of the acceleration adjusted by the transmitted frequency. The resistive index is calculated as the (PSV – end diastolic velocity)/PSV (144) and is a measure of the resistance within the renal circulation. An elevated resistive index may be present in renal parenchymal disease (142) and the resistive index may be influenced by some antihypertensive drugs and age. It is not useful for predicting the degree of RAS. In our noninvasive vascular laboratory, we rely on the RAR and PSV in the main renal arteries to determine the degree of stenosis. Parameters such as the acceleration time and acceleration index may provide corroborative evidence, but are not often used to diagnose RAS.

A recent study used Doppler ultrasonography to predict the outcome of therapy in patients with RAS (136). One hundred thirty-eight patients with greater than 50% RAS underwent renal artery angioplasty or surgery for blood pressure control or preservation of renal function. A renal resistance index of at least 80 accurately identified patients in whom angioplasty or surgery was not associated with improved blood pressure, renal function, or kidney survival. Ninety-seven percent of patients with an increased renal resistance index demonstrated no improvement in blood pressure, and 80% had no improvement in renal function. The authors suggest that the increased resistive index identifies structural abnormalities in the small vessels of the kidney. Such small vessel disease has been seen with long-standing hypertension associated with nephrosclerosis or glomerulosclerosis (145). If this study is confirmed, it could provide a method for predicting which patients will improve after percutaneous intervention.

Renal artery duplex is an excellent test for the follow-up of RAS after percutaneous therapy or surgical bypass (*e*Fig. 112.4.4C) (7,146,147 and 148). Unlike MRA and CT angiography (which may be affected by artifact or scatter produced by the stent), ultrasound transmission through the stent is not a problem. Hudspeth et al. (147) compared angiography with duplex ultrasound for follow-up of RAS after angioplasty and demonstrated a sensitivity and specificity of 69% and 98%, respectively, for detecting stenosis greater than 60%. All patients who have undergone percutaneous intervention should be placed in a surveillance program in an attempt to identify restenosis and treat it before the artery occludes. After PTA and stent implantation, a renal artery duplex should be obtained at 6 months, 12 months, and yearly thereafter.

The sensitivity of identifying accessory renal arteries is approximately 67%. If there is a high index of suspicion for RAS and the duplex examination fails to reveal a significant stenosis, one may suspect an accessory vessel as the culprit.

Computed Tomographic Angiography

CT angiography can produce excellent images of the abdominal vasculature (*e*Fig. 112.4.5). The angiography protocol is performed using a peripheral intravenous iodinated contrast bolus of 100 to 150 mL followed by limited spiral CT. Typically, scanning intervals of 1 to 2 mm are used for image acquisition.

***e*FIGURE 112.4.5** Computed tomographic angiogram showing a low takeoff of an accessory left renal artery.

After the initial axial images are acquired, several different software programs are commercially available to reformat the data into two-dimensional and three-dimensional reconstruction images. The most commonly used reformatting techniques are the shaded surface display, maximal intensity projection, and volume rendering.

Depending on the techniques used, CT angiography has a sensitivity and specificity for detecting RAS of 59% to 96% and 82% to 99%, respectively, when compared with conventional angiography (149,150,151,152,153 and 154). In some techniques, when the stenosis is severe, discontinuity of arteries may be seen on reconstruction images due to partial volume averaging. However, CT angiography with real-time interactive volume rendering had a specificity of 99%, whereas maximum intensity projection had a specificity of 87% (152).

Because a limited CT scan of the abdomen is often performed before CT angiography, additional anatomic information may be available. This includes information regarding associated calcification, aortic aneurysm or dissection, and renal or adrenal pathology. During the examination of 50 hypertensive patients, Beregi et al. (149) identified five unexpected abnormalities in patients free of renal artery disease; two patients had bilateral adrenal hyperplasia (primary aldosteronism), one patient had papillary adenocarcinoma, and two patients had abdominal aortic aneurysms.

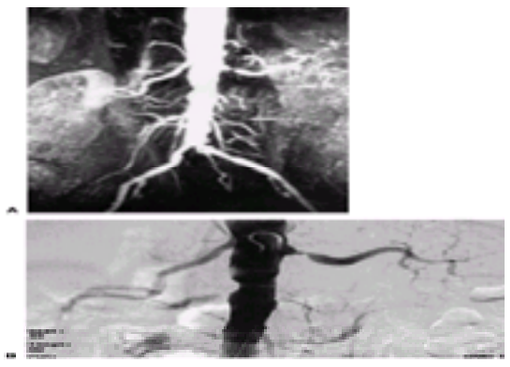
There are some technical limitations of the procedure. The protocol parameters for table speed, time delay to image acquisition, and scan volume may vary between institutions. It is important to understand how some of these parameters may affect the accuracy of the procedure. If the time delay is insufficient or if an inadequate volume of contrast is infused, the opacification of the vessels may be suboptimal. This could be interpreted erroneously as a stenosis or occlusion. The scan volume must include the entire renal artery from the aorta to the hilum to avoid missing a stenosis in the distal portion of the artery. In addition, an adequate length of scan volume is required so that accessory arteries arising in the distal aorta are not overlooked. Beregi et al. (149) used a 6-cm scan volume and failed to identify 7 of 32 accessory renal arteries because they originated outside the scan area. Conversely, Kim et al. (152) used a variable scan range based on the patient's height and

detected 27 of 28 accessory arteries identified by intraarterial digital subtraction angiography.

CT angiography may not be suitable for all patients. The required contrast volume is significant. In the patient with renal insufficiency, CT angiography is not an ideal screening test for RAS. Similar to renal duplex, CT angiography may be limited in obese patients. Patients must be able to suspend respiration during image acquisition since respiratory artifact may significantly degrade the image quality. CT angiography is generally well tolerated by most individuals. The gantry is open, thus claustrophobia is not commonly a limiting factor.

Magnetic Resonance Angiography

Like CT angiography, MRA provides excellent imaging of the abdominal vasculature and associated anatomic structures (eFig. 112.4.6). The examination does not require nephrotoxic contrast agents and therefore provides a good alternative to CT angiography in patients with renal insufficiency, congestive heart failure, or a contrast allergy. In general, the procedure is similar to CT angiography. The examination is performed with the patient supine. The patient must be able to cooperate and refrain from breathing during contrast-enhanced sequences or the quality of the study may be compromised.



***e*FIGURE 112.4.6 A:** Magnetic resonance angiogram demonstrating a severe stenosis of the left renal artery and a normal right renal artery. **B:** Arteriography of the same renal artery at the time of renal artery stenting.

Each examination should begin with acquisition of routine T1- and T2-weighted images to evaluate the kidneys, adrenal glands, and associated soft tissues. Time-of-flight and phase contrast are noncontrast techniques commonly used for vascular imaging. Software is available for both two-dimensional and three-dimensional imaging. The initial source images are completed in approximately 20 minutes. The reformatting process usually requires an additional 30 to 45 minutes. Maximum intensity projection and multiplanar reconstructions are the most commonly used postprocessing algorithms.

When compared with angiography, MRA has demonstrated a sensitivity of 90% to 100% and a specificity of 76% to 94% (155,156,157,158 and 159). However, MRA does not have the same sensitivity and specificity in patients with FMD.

Contrast-enhanced MRA provides a superior quality study when compared with noncontrast studies. Gadolinium chelate is the contrast agent of choice. Other contrast agents are under development and may improve the current imaging techniques. Unlike ionic and nonionic iodinated contrast agents, gadolinium is not nephrotoxic and can be used safely in patients with renal insufficiency. The imaging time is substantially shortened, and 20- to 40-second acquisition times are not uncommon. This eliminates some artifact created by gross patient movement (160). Signal strength is increased, providing for better visualization of distal small caliber vessels (161). Unlike flow-based techniques (time-of-flight, phase contrast), areas of slow flow or turbulence may be better visualized. The signal depends only on gadolinium concentration in the vessel. Thus, flow-related artifacts are almost entirely avoided. Thornton et al. (161) compared breath-hold MRA with conventional digital subtraction angiography in 42 patients. They demonstrated a sensitivity of 100% and a specificity of 98% for detecting greater than 50% stenosis. Overall MRA revealed 85 of 87 renal arteries, 20 of 20 stenoses, and 5 of 5 occlusions. The two arteries not identified were accessory vessels. Other studies have demonstrated a sensitivity and specificity between 91% and 100% and 79% and 98%, respectively (162,163,174).

In addition to the technical considerations of MRA, there are several other considerations in choosing MRA as a screening or diagnostic test. At most centers, the cost of performing MRA exceeds that of duplex ultrasonography or CT angiography. In addition, some patients are not good candidates for the examination. Patients with metallic implants—such as some mechanical heart valves, cerebral aneurysm clips, and electrically activated implants (pacemakers, spinal cord stimulators)—are not able to be studied. Most patients with inferior vena cava filters can be safely studied. Claustrophobia is a common problem. The scan time can be significantly shortened with the use of gadolinium. If patients are still apprehensive, they can usually be premedicated with a sedative hypnotic agent.

Indirect Screening Tests

Intravenous Urography

The rapid sequence intravenous pyelogram to screen for the presence of RAS was first described in the early 1960s (164). In the Cooperative Study of Renovascular Hypertension (165), 11.4% of patients with essential hypertension had an abnormal intravenous urogram, and 17% of patients with significant RAS documented by arteriography had a normal intravenous urogram. A false-positive rate of up to 41% has been reported (166,167). Therefore, this test should no longer be used to screen for RAS.

Peripheral Plasma Renin Activity

Maxwell et al. (168) reviewed 540 patients reported in the literature to assess the value of plasma renin activity in the diagnosis of renovascular hypertension. There was a sensitivity of 57% and a specificity of 66%. The false-negative and false-positive rates were extremely high at 43% and 34%, respectively. The PRA did not predict which patients benefited from renal revascularization. Elevated plasma renin activity may be present in approximately 15% of patients with essential hypertension and patients with bilateral disease or disease to a solitary functioning kidney may have normal or low PRA. Therefore, PRA should not be used as a reliable screening test for renovascular disease.

Captopril Test

In an attempt to increase the utility of measuring plasma renin activity, Muller and colleagues administered captopril, 50 mg orally, and obtained PRA 60 minutes later. The criteria that they found to be the most reliable for distinguishing patients with renovascular hypertension are a postcaptopril renin of more than 12 ng per mL per hour, an absolute increase of 10 ng per mL per hour or more, and a percent increase of 150% or more, or 400% if the baseline renin is below 3 (169). The overall sensitivity is approximately 61%, and specificity is 86% (170). This test can be affected by volume status, position of the patient during the test, and medications the patient is taking. The test is less accurate in azotemic patients and in African-American patients (171). The captopril test is not an ideal screening test and is rarely used anymore.

Renal Vein Renin Measurements

Renal vein renin measurements are not a useful test to screen for RAS. However, measurement of renin produced from the renal vein of the kidney with RAS compared with the renal vein of the healthy kidney has been used as a method for predicting which patients may benefit from intervention such as surgery, percutaneous angioplasty, or stent placement. Technical factors can interfere with the interpretation of the results and therefore limit the utility of the test. Ideally, patients should be off all medications that can either stimulate or suppress renin for a period of at least 3 days. Blood should be taken from the right and left renal vein and the inferior vena cava above and below the renal veins as a baseline. Either 40 mg of furosemide or 25 mg of captopril should then be administered and repeat blood samples taken 30 minutes later. If these guidelines are followed, renal vein renin measurements may be accurate in predicting in whom a *cure* of renovascular hypertension may occur with revascularization (172,173).

A renal vein renin ratio of 1.5:1 or greater with suppression of renin production by the contralateral (nonstenotic) kidney is considered a positive renal vein renin

response (174,175). Hughes et al. (173) demonstrated that when a renal vein renin ratio greater than 1.4:1 was combined with a duration of hypertension of less than 5 years, 19 of 20 patients (95%) had a cure of their renovascular hypertension. Several reports have now been published that show that renal vein renin lateralization does not predict which patient will have an *improvement* in blood pressure after surgical revascularization or percutaneous intervention (176,177,178 and 179).

Nuclear Imaging Modalities

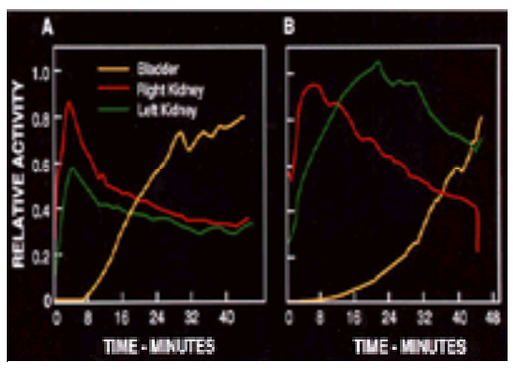
Radionuclide imaging techniques are a noninvasive and safe way of evaluating renal blood flow and excretory function. However, the renal flow scan has unacceptably high false-positive and false-negative rates (180). When an ACE inhibitor such as captopril is added to isotope renography, the sensitivity and specificity of the test improve considerably, especially for patients with unilateral RAS. In most instances of unilateral RAS, the glomerular filtration rate of the stenotic kidney falls by approximately 30% after captopril administration (181,182). In contrast, the contralateral normal kidney exhibits an increase in glomerular filtration rate, urine flow, and salt excretion despite a reduction in systemic blood pressure. These expected physiologic changes within the stenotic and contralateral kidneys are the basis of the asymmetry of renal function following ACE inhibition detected by renal scintigraphy (183,184 and 185).

Oral hydration (water, 10 mL per kg) is encouraged the morning of the test. A peripheral venous catheter for sampling, injection, or both is inserted, and baseline blood pressure is measured and repeated at 15- to 20-minute intervals. Captopril (25 to 50 mg orally crushed) is administered and a conventional radionuclide study of the kidneys is begun 60 minutes after captopril.

The majority of captopril renography studies to date has been performed with technetium-99m (Tc-99m) diethylenetriaminepentaacetic acid (DTPA), Tc-99m mercaptoacetyltriglycine (Tc-MAG_3), or [^{131}I]OIH using a medium-energy collimator and conventional software (186,187). DTPA is the preferred agent because it is excreted by the kidneys by glomerular filtration and it provides an index of renal perfusion and kidney size.

However, Tc-99m-MAG_3, which is excreted by the kidney similar to PAH or OIH, has become clinically available for renography and has been systematically studied. Tc-99m-MAG_3 may become the radionuclide of choice because it offers both the advantageous technetium-labeling characteristics and optimal renal handling and excretion. Tc-99m-MAG_3 for captopril renography has shown good results, especially in patients with azotemia because of its higher extraction capabilities (188,189). The one drawback of Tc-99m-MAG_3 is cost compared with the other two radionuclide agents.

The Consensus Report on Captopril Renography suggested that both the scintigraphic images and computer-generated time-activity curves provided information about renal size, perfusion, and excretory capacity (183). The diagnostic criteria to suggest RAS were (a) delayed time to maximal activity (T_{max}) (greater than or equal to 11 minutes after captopril); (b) significant asymmetry of peak activity of each kidney; (c) marked cortical retention of the radionuclide after captopril; and (d) marked reduction in calculated glomerular filtration rate of the ipsilateral kidney after ACE (eFig. 112.4.7).



***e*FIGURE 112.4.7** Captopril renogram demonstrating unilateral left renal artery stenosis. **A:** Tc-99m diethylenetriamine pentaacetic acid (DTPA) time-activity curves during baseline. **B:** Tc-99m DTPA time-activity curves following captopril stimulation. (From Nally JV. Provocative captopril testing in the diagnosis of renovascular hypertension. *Urol Clin North Am* 1994;21:232, with permission.)

Geyskes, Oei, and colleagues (190) demonstrated that captopril renography accurately identified those patients with significant unilateral RAS and was predictive of a successful outcome in 13 of 15 patients who underwent percutaneous balloon dilatation of the renal artery. eTable 112.2.3 represents a synopsis of the captopril renography studies in hypertensive patients suspected of renovascular disease (184,186,189,190,191,192,193,194,195,196,197 and 198). Overall, the accuracy of captopril renography in identifying patients with renovascular disease appears quite acceptable with a sensitivity approximately 85% to 90% (range, 45 to 94) and specificity approximately 93% to 98% (range, 81 to 100). Those patients with unilateral disease and normal renal function would be best suited for a captopril renogram.

The presence of significant azotemia or bilateral RAS may adversely affect the accuracy of captopril renography. Many investigators have excluded patients with serum creatinine exceeding 2.5 to 3.0 mg per dL. In patients with a serum creatinine greater than or equal to 1.5 mg per dL and less than or equal to 3.0 mg per dL, Fommei et al. (189) reported a reduction in the positive predictive value from 88% to 57% while there was a minimum reduction in sensitivity and specificity in patients with serum creatinine of 1.5 mg per dL.

It is controversial whether the captopril renogram can predict which patients will exhibit a cure or improvement in blood pressure after revascularization (186,190,192,195,196). There are no reliable data using the captopril renogram to predict whether revascularization will result in preservation or improvement in renal function.

Although the captopril renogram was once the noninvasive diagnostic test of choice for patients with RAS, it is now relegated to a secondary screening modality because the quality of the images of duplex ultrasound, MRA, and CT angiography are excellent.

PRINCIPLES OF MANAGEMENT

There has been a paradigm shift in management of atherosclerotic renal artery stenosis. Before 1990, if a patient met the criteria for intervention, surgical renal artery revascularization was almost always performed. However, since the introduction of stents, surgical revascularization is rarely performed solely for the treatment of renal artery disease. Despite advances in the technical aspects of angioplasty and stent implantation, there has been a paucity of controlled clinical trials assessing the role of renal artery angioplasty and stenting to control hypertension or preserve renal function. Because of a lack of controlled clinical trials, there remains some controversy as to the most appropriate treatment of atherosclerotic renal artery disease.

The four modalities currently available for the treatment of RAS are medical therapy, percutaneous balloon angioplasty, angioplasty with stent placement, and surgical revascularization. For the purpose of this discussion, *revascularization* is defined as restoration of blood flow to the kidney. This includes both percutaneous as well as surgical techniques. The etiology of the lesion, the patient's comorbidities, and the technical expertise of the treating physician must be taken into consideration when considering the type of treatment that will be employed.

The following items are the indications for revascularization:

- At least a 70% stenosis of one or both renal arteries *and*
- Inability to adequately control the blood pressure despite a good antihypertensive regimen *or*
- Chronic renal insufficiency not related to another clear-cut cause (disease should be bilateral or stenosis to a solitary functioning kidney). The treatment of an elevated serum creatinine with unilateral disease is controversial, and there are no good clinical trials to help guide the clinician (199).
- Dialysis-dependent renal failure in a patient without a definite cause of ESRD (200,201 and 202).
- Recurrent congestive heart failure or flash pulmonary edema not attributable to a cardiac cause (11,46,203).

In all patients, risk factor modification is important. Patients should be advised to stop smoking, lose weight, and exercise. Control of diabetes and appropriate management of hyperlipidemia are equally important. Because the majority of lesions is attributable to atherosclerosis or FMD, comments regarding therapy focus on these two diseases.

Medical Therapy

All patients with hypertension should be treated medically, even if they undergo intervention. Antiplatelet agents should be prescribed to help to lower the extremely high cardiovascular morbidity and mortality that occur in this patient population. Many patients have superimposed essential hypertension and will still require medications long term. Despite the etiology, the guidelines of the Sixth Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure should be followed (204). Patients with unilateral disease often have renin-mediated hypertension. They should be placed on an ACE inhibitor or an ARB. Beta-blockers, which block renin secretion, and calcium channel blockers, which may counteract the direct effects of angiotensin II on the smooth muscle wall, are also first-line therapy. In individuals with bilateral disease or disease to a solitary functioning kidney, ACE inhibitors or ARBs should be used with caution, because this class of drugs can precipitate acute renal failure.

Patients with RAS who are treated solely with medical therapy should be carefully followed for progression of disease. This should include three important strategies:

- Follow the blood pressure closely and work to achieve a goal blood pressure within the guidelines of Sixth Joint National Committee.
- Follow the renal function every 3 months. If the serum creatinine begins to rise and there is no other explanation, consider revascularization.
- Place the patient into a surveillance program with serial duplex ultrasound imaging. The kidney size, volume, and severity of the stenosis can be closely followed. If the patient begins to lose volume to the affected kidney, consider revascularization.

Percutaneous Transluminal Angioplasty

PTA for RAS was first performed successfully by Gruntzig in 1978 (205). PTA has become widely used to treat individuals with renovascular disease. Technical success reflects the immediate outcome of the intervention (i.e., angiographic result and improvement in the pressure gradient), whereas long-term success is related to improvement in clinical parameters (i.e., blood pressure, renal function, and congestive heart failure).

PTA is the treatment of choice for FMD. Stenting is generally not indicated for patients with FMD because they respond so well to PTA alone. Sos et al. (206) performed PTA in 31 patients with FMD and demonstrated a technical success rate of 87.1%. Blood pressure was cured in 59.3% and improved in 33.3%. The cure or improvement in blood pressure was maintained in 93% of patients over an average follow-up of 16 months. Ramsay and Waller (207) reviewed ten published series of patients with FMD and reported that the hypertension was cured in 50% and improved in 42%. In a series of 85 lesions in 66 patients, PTA was technically successful in 100%. There was an 8% late recurrence rate at a mean of 15.7 months. Blood pressure was cured in 39% and improved in 59% of patients over a mean follow-up period of 39 months (208). Fourteen of these patients were treated for both hypertension and preservation of renal function. Before PTA, the mean serum creatinine was 2.4 mg per dL and after PTA the serum creatinine was 1.7 mg per dL (mean follow-up of 33 months). This represented an overall improvement of renal function in 86% of individuals.

Although the trend toward greater success for lesions due to FMD than atherosclerosis has been duplicated in many studies, the degree of overall cure has not been consistently demonstrated. A large retrospective series from the Mayo Clinic evaluated 105 patients with FMD who underwent PTA. While PTA resulted in blood pressure improvement in 85%, only 22% were classified as "cured" (mean follow-up of 42.7 months) (209).

Most studies looking at PTA in patients with FMD have concentrated on disease in the main renal artery. However, intimal, medial, and perimedial fibroplasia may occur in the branch renal arteries as well. In the past, surgical reconstruction has been the primary therapeutic modality to treat these lesions. However, with better catheter and balloon technology, virtually all of these lesions can be treated with PTA, even in the small renal artery branches (210). In 25 branch renal artery lesions, the technical success of dilatation was 84%. At 6 months, stenosis recurred in only 9%, all of which were successfully redilated.

The larger majority of patients with RAS has underlying atherosclerosis. Unlike FMD, disease due to atherosclerosis is found in the proximal arterial segment and, even more often, at the ostium of the artery. Ostial lesions respond poorly to PTA alone.

The ten-case series reviewed by Ramsay and Waller (207) included 464 atherosclerotic lesions. Technically successful angioplasty was performed for 391 lesions. Overall, blood pressure was cured in 19% and improved in an additional 52%. Bonelli et al. (209) retrospectively reviewed 190 atherosclerotic renal artery lesions that had undergone PTA and reported a cure rate of only 8.4%. The technical success rate was 81.6% and was higher for those lesions that occurred in the main branch as opposed to the origin of the renal artery (82.4% vs. 60.4%). In another larger series of atherosclerotic lesions (n = 289), technical failure rate was 8%, with a primary patency of 57% and a secondary patency of 77% (211). Blood pressure was cured in 8% and improved in 59%.

Several studies have looked at PTA to restore renal function. Rimmer and Gennari (9) reviewed several studies in which angioplasty was performed in azotemic patients. Renal function improved in 25% to 53% of patients (212,213,214,215,216 and 217).

In general, PTA is less effective for treating ostial lesions than nonostial disease (213,218,219). Canzanello et al. (216) evaluated 100 consecutive patients with high-grade atherosclerotic RAS. Technical success was achieved in 76%, 74%, and 68% of patients with unilateral RAS, bilateral RAS, or RAS to a solitary kidney, respectively. Of the technical successes, 59% of patients had a sustained improvement in blood pressure control over a mean follow-up of 22 months. Most blood pressure failures and most restenoses occurred in the ostial group. Only 25% of patients with ostial disease had blood pressure improvement. One study showed that PTA can be performed safely as an outpatient procedure (220).

Comparison of Medical Therapy and Percutaneous Transluminal Angioplasty

There are three randomized prospective trials comparing medical management with angioplasty for blood pressure control in patients with atherosclerotic RAS. Each of the three studies has significant drawbacks precluding any definite conclusions. Plouin et al. (221) randomized 49 patients with unilateral RAS and found no significant difference in blood pressure control at 6 months (140/81 mm Hg in the PTA group vs. 141/84 mm Hg in the medical therapy–alone group). However, patients in the angioplasty group required less antihypertensive medication. In the medical group, 7 of 26 patients developed refractory hypertension and subsequently underwent

PTA.

Webster et al. (222) randomized 55 of 135 eligible patients (44%) and followed them for 6 months. A significant fall in blood pressure from baseline occurred in the patients with bilateral RAS who were randomized to PTA (152/83 mm Hg in the PTA group vs. 171/91 mm Hg in the medical therapy group). This difference was not seen in patients with unilateral RAS.

The largest randomized, prospective study was published by van Jaarsveld et al. (223). One hundred six patients with angiographically documented RAS were randomly assigned to PTA or medical therapy and had blood pressure and renal function assessed at 3 and 12 months. Baseline blood pressure was 179/104 mm Hg and 180/103 mm Hg in the angioplasty and drug therapy groups, respectively. At 3 and 12 months, there was no significant difference in blood pressure control between the two groups, but the PTA group was on fewer antihypertensive medications. There were several rather serious problems with this study (224). Forty-four percent of patients randomized to medical therapy crossed over to the balloon angioplasty group, resulting in dilution of the long-term outcome differences. In spite of this, the initial angioplasty group required less antihypertensive therapy than the medical group (p <.001). There was a favorable trend to all primary outcome events, and with the small sample size we calculated that the chance of a type II error was substantial. Perhaps most importantly, the authors chose a 50% diameter reduction as the cut-off for “hemodynamically significant” renal artery lesions despite the fact that the evidence is clear that a lesion of at least 70% stenosis is required to cause significant hypertension or a decrement in renal function (5). Only 57% of patients had stenosis of greater than 70%.

The primary problems with PTA alone are that a good technical result is virtually impossible with ostial lesions (221) and the restenosis rate is high (211,225).

Renal Artery Stents

Due to the high restenosis rate with angioplasty alone, endovascular stents offer a significant advantage over PTA in patients with atherosclerotic disease, especially those with ostial stenosis. The degree of stenosis poststenting approaches zero and most dissection flaps caused by PTA alone are successfully sealed with stents (Fig. 112.5). Despite the widespread use of stents in thousands of renal arteries since the late 1980s, there is still no U.S. Food and Drug Administration approval of these devices for the renal circulation.

FIGURE 112.5 A: Severe stenosis to the right renal artery. **B:** Excellent angiographic result after stent placement.

There are a few important technical caveats when stenting the renal arteries:

- The shortest stent to adequately cover the lesion should be used.
- The stent must extend 1 to 2 mm into the aorta in patients with ostial disease.
- The stent must be fully expanded. A common problem encountered is to underdeploy the stent. It may be worthwhile to do the first 15 to 20 cases with intravascular ultrasound to be certain the stent is adequately expanded. It is also important to make sure that no postprocedure pressure gradient exists.

Rees and colleagues (226), using the Palmaz stent for ostial atherosclerotic RAS, achieved technical success in 27 of 28 patients. Sixty-four percent of patients had their blood pressure cured or improved, and 10 of 14 patients had stabilization of renal function. However, restenosis occurred in 7 of the 18 patients studied (39%). In those patients with greater than 15% residual stenosis, all 4 patients had restenoses, whereas in those patients with less than 15% residual stenosis, only 3 of 14 (21%) patients had restenoses.

White, Ramee, and associates (227) evaluated the safety and efficacy of renal artery stent implantation in patients with lesions that did not respond well to angioplasty alone. Balloon-expandable stents were placed in 100 consecutive patients (133 renal arteries). The technical success (as assessed by quantitative angiography) was 99%. The mean blood pressure values were 173 ± 25/88 ± 17 mm Hg before stent implantation and 146 ± 20/77 ± 12 mm Hg 6 months after renal artery stenting (p <.01). Angiographic follow-up in 67 patients (mean, 8.7 ± 5.0 months) demonstrated restenosis (greater than 50%) in 15 (19%) patients.

Dorros and colleagues (8) performed Palmaz-Schatz stent revascularization in 163 consecutive patients (202 arteries) with poorly controlled hypertension or jeopardy of renal function. The immediate technical success rate was 99%. One hundred forty-five patients were followed for more than 6 months. The mean blood pressure was 166 ± 26/86 ± 14 mm Hg at baseline and 148 ± 22/80 ± 11 mm Hg after 4 years of follow-up.

Blum et al. (7) prospectively placed a Palmaz stent in 68 patients (74 lesions) with ostial RAS and suboptimal PTA. All patients were hypertensive and 20 had mild or severe renal dysfunction. Stents were placed due to elastic recoil (63 arteries), post-PTA dissection (1 artery), or late restenosis (10 arteries) with 100% technical success rate. Five-year patency was 84.5% (mean follow-up was 27 months). Restenosis occurred in 8 of 74 arteries (11%), but after reintervention the secondary 5-year patency rate was 92.4%. Blood pressure was cured or improved in 78% of patients. There was no significant change in the serum creatinine values after stent implantation.

Comparison of Percutaneous Transluminal Angioplasty and Endovascular Therapy with Stenting

The first randomized, prospective study comparing angioplasty alone with angioplasty and stenting was published (228): Eighty-five patients with ostial lesions were randomized to receive PTA alone (42 patients, 51 arteries) or PTA and stent (42 patients, 52 arteries). Secondary stent implantation was allowed if the PTA failed immediately or during the first 6 months of therapy. The primary technical success rate (individual arteries) was 57% for PTA group and 88% for PTA with stent group. At 6 months, the primary patency was 29% for the PTA group and 75% for the stent group. Because this was an intention-to-treat analysis and 12 patients underwent stenting in the PTA group, there were no clinical differences between the two groups.

A publication of 163 patients (200 arteries) with atherosclerotic RAS evaluated the patency rates in patients undergoing PTA alone and those undergoing PTA and stent implantation. For ostial disease, the 12-month primary patency rate for PTA was 21 of 33 arteries (34%) and for PTA and stent was 4 of 21 arteries (80%) (p = .002) (229).

A metaanalysis of 14 studies compared the technical and clinical effect of renal artery PTA and stent implantation (Table 112.3) (7,8,228,229,230,231,232,233,234,235,236,237,238 and 239). The stent patients had a higher technical success rate and a lower restenosis rate when compared with patients only receiving PTA (98% vs. 77% and 17% vs. 26%; p <.001). The mean follow-up was 17 months for patients receiving a stent and 19 months for PTA patients. Complications of renal artery stent placement are shown in *e*Table 112.3.1. Hypertension was improved or cured in 69% of patients, and renal function improved or stabilized in 68% of patients. It should be noted that the complication rate varies considerably between centers, and high-volume centers generally can perform renal artery stenting with minimal morbidity and mortality. Although all studies reported use of an antithrombotic agent during the procedure and most patients were discharged on an antiplatelet agent, the regimens varied.

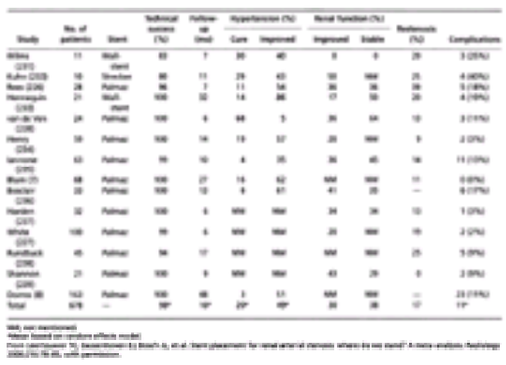

TABLE 112.3 CLINICAL AND ANGIOGRAPHIC FOLLOW-UP IN PATIENTS WHO UNDERWENT RENAL ARTERY STENT PLACEMENT

From Leertouwer TC, Gussenhoven EJ, Bosch JL, et al. Stent placement for renal arterial stenosis: where do we stand? A meta-analysis. *Radiology* 2000;216:78–85, with permission.

Two studies evaluated the effect that renal artery stent implantation had on preserving renal function (237,240). Both studies used the reciprocal of the serum creatinine to determine the rate of decline or improvement in renal function. Harden et al. (237) placed renal artery stents in 32 patients (33 arteries) and reported that renal function improved or stabilized in 22 (69%) patients. In 25 patients with complete follow-up, Watson and associates (240) demonstrated that all exhibited a negative slope to the reciprocal of the serum creatinine. After stent placement, the slopes were positive in 18 patients and less negative in 7 patients.

Surgical Revascularization

Surgical revascularization has been used much less frequently than in the past. This is due in large part to the excellent technical results that can be achieved with angioplasty and stents. As previously noted, many patients can now undergo renal artery stent implantation as an outpatient procedure at a fraction of the cost of surgical revascularization.

Current indications for surgical revascularization include the following items:

- Patients with branch disease from FMD that cannot be adequately treated with balloon angioplasty (241).
- Patients with recurrent stenosis after stenting; however, this has been extremely rare in our experience (11).
- Patients who require simultaneous aortic surgery (abdominal aortic aneurysm repair or symptomatic aortoiliac disease); even in this circumstance, it may be advisable to stent the renal artery first and then proceed with aortic reconstruction. The mortality of aortic replacement and renal artery revascularization is higher than either procedure alone (242).

A variety of surgical revascularization techniques are available for treating patients with significant renal artery disease. Aortorenal bypass with autogenous saphenous vein was an excellent method in patients with a nondiseased abdominal aorta (243,244). However, severe aortic disease almost always accompanies atherosclerotic RAS. Polytetrafluoroethylene aortorenal bypass grafts have been successfully employed usually when an autogenous graft is not available (245). Renal endarterectomy also continues to be used to treat atherosclerotic renal artery disease. Patients with complex branch renal artery lesions can be managed with extracorporeal microvascular reconstruction and autotransplantation (246,247).

In older patients, severe atherosclerosis of the abdominal aorta may render an aortorenal bypass or endarterectomy technically difficult and potentially hazardous to perform. In such cases, alternate surgical approaches often allow renal revascularization to be safely and effectively accomplished while avoiding operation on a badly diseased aorta. The most effective alternate bypass techniques have been a splenorenal bypass for left renal revascularization (248,249) and a hepatorenal bypass for right renal revascularization (250). The absence of occlusive disease involving the origin of the celiac artery is an important prerequisite for these operations. Significant celiac artery stenosis may occur in up to 50% of patients with atherosclerotic RAS (251). This information underscores the importance of obtaining preoperative lateral aortography to evaluate the celiac artery origin in patients who are being considered for hepatorenal or splenorenal bypass. The supraceliac or lower thoracic aorta for renal revascularization has also been used successfully in patients with significant aortic disease (252,253). The supraceliac aorta is often relatively disease free in such patients and can be used to achieve renovascular reconstruction with an interposition saphenous vein graft.

Reports from several large centers have demonstrated that surgical renal revascularization can be performed with operative mortality of 2.1% (243), 3.1% (254), 3.4% (255), and 6.1% (256) in patients with atherosclerotic RAS. The mortality is increased with bilateral simultaneous renal revascularizations or when renal revascularization is performed with aortic replacement (257,258). Most studies have indicated a high technical success rate for surgical vascular reconstruction with postoperative thrombosis or stenosis rates of less than 10% (243,259). In patients with fibrous dysplasia, 50% to 60% are cured, 30% to 40% are improved, and the failure rate is less than 10% (243,256). In patients undergoing revascularization for atherosclerotic renovascular hypertension, the cure rate is lower. *e*Table 112.3.2 and *e*Table 112.3.3 demonstrate the results of surgical revascularization on blood pressure control and preservation of renal function (243,249,256,257 and 258,260).

***e*TABLE 112.3.2** RESULTS OF SURGICAL REVASCULARIZATION FOR THE TREATMENT OF RENOVASCULAR HYPERTENSION

Series	No. of patients	No. cured (%)	No. improved (%)	No. failed (%)

Comparison of Surgery and Percutaneous Transluminal Angioplasty

The only randomized prospective trial comparing PTA with surgical revascularization was conducted by Weibull and colleagues (261). Fifty-eight patients with a blood pressure of at least 160/100 mm Hg and significant unilateral RAS were assigned to have either surgery or PTA of the renal artery. Technical result, primary patency (at 24 months), and secondary patency were 83%, 75%, and 90% for the group randomized to PTA and 97%, 96%, and 97% for the surgically treated group. Surgery resulted in the improvement or cure of high blood pressure in 86% of patients, whereas PTA cured or improved blood pressure in 90% of patients. Improved or cured renal function was documented in 83% of individuals after PTA and 72% after surgery. Ultimately, 17% of patients in the PTA group required surgical intervention.

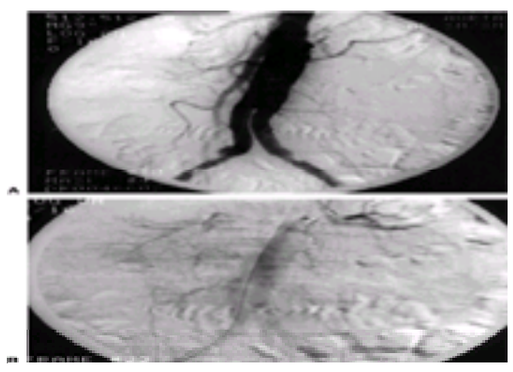
Patient Selection for Intervention to Preserve Renal Function

One can often identify those patients in whom such disease poses a significant threat to overall renal function. Patients who are at a markedly increased risk are those with greater than 75% bilateral RAS or severe stenosis to a single functioning kidney. In this patient subgroup, the risk of total occlusion of the renal artery is significant, and if this occurs, the clinical outcome is a critical decrease in functioning renal mass with resulting renal failure (21,46,86,108,114,201,204).

The benefit of undertaking revascularization for preservation of renal function in patients with unilateral RAS and a normal contralateral renal artery is not established. If the contralateral kidney is anatomically and functionally normal, revascularization for this purpose is clearly not warranted. If the opposite kidney is functioning but involved with some type of parenchymal disorder, revascularization of the ischemic kidney may benefit some patients, but specific indications for this approach are not well defined.

Complete occlusion of the renal artery most often eventuates in irreversible ischemic damage of the involved kidney. However, in some patients with gradual arterial occlusion, the viability of the kidney can be maintained through the development of collateral arterial supply (262,263). There are certain clues that may help to predict renal salvageability in patients with an occluded renal artery:

- Angiographic demonstration of late filling of the distal renal arterial tree by collateral vessels on the side of total arterial occlusion (eFig. 112.5.1) (264)
- Renal size of 8 to 9 cm
- Function of the involved kidney on a renal flow scan
- The presence of a nephrogram after a contrast arteriogram
- A renal biopsy showing well-preserved glomeruli and an absence of significant glomerulosclerosis



***e*FIGURE 112.5.1 A:** Patient underwent an aortoiliac bypass graft with a swing graft to the left renal artery 6 months before this angiogram. Note that the bypass graft is occluded. The right renal artery has a long-standing occlusion. **B:** Distal late reconstitution of the left renal artery. The patient underwent catheter-directed urokinase infusion, and flow to the left kidney was reestablished (not shown). (From Olin JW, Young JR, Graor RA. Thrombolytic therapy for renal artery occlusions. *Cleve Clin J Med* 1989;56:432–438, with permission.)

Revascularization to preserve renal function in patients with atherosclerotic RAS is most likely to be beneficial in patients with less severe renal impairment (serum creatinine less than 3.0 mg per dL) (265,266). When the serum creatinine is greater than 4.0 mg per dL, there is a greater chance that significant parenchymal renal disease exists along with main RAS. The most common underlying parenchymal renal disease in patients with RAS is severe nephrosclerosis or atheromatous embolization.

Some patients may develop acute renal failure shortly after the initiation of antihypertensive therapy (54,267). Acute renal failure in this setting is often a manifestation of perfusion-dependent renal function due to underlying RAS. Prompt intervention to relieve renal arterial obstruction can prevent permanent renal damage in patients with this type of severe acute renal insufficiency.

In addition to the absolute level of renal function, the rate of decline in overall renal function is an important determinant of the outcome following intervention in atherosclerotic ischemic renal disease. Dean and associates demonstrated that patients with a rapid deterioration in the glomerular filtration rate during the 6 months preceding surgical revascularization achieved the greatest benefit in terms of postoperative improvement in renal function (268).

There are several anecdotal reports showing that restoration of renal function in patients with totally occluded renal arteries with either endovascular therapy or surgical revascularization is feasible (269). Kaylor et al. (201) reported on nine patients who were on dialysis from 1 week to 13 months secondary to atherosclerotic RAS. Reversal of end-stage renal failure occurred in all nine patients with surgical revascularization. The serum creatinine at 1 month ranged from 1.1 to 4.2 mg per dL, with a mean of 2.5 mg per dL. Hansen and colleagues (202) have also shown that it is possible to restore renal function with surgical revascularization in some patients who have been on chronic hemodialysis therapy. From 1987 to 1993, 340 patients underwent surgical renal revascularization. Twenty patients were receiving hemodialysis before renal artery repair. Hemodialysis was discontinued in 16 of the 20 patients (80%). Two of the 16 patients resumed dialysis 4 and 6 months after surgery. A favorable response in this series occurred in those patients who had a relatively rapid decline in their glomerular filtration rate in the 14 weeks preceding renal revascularization. If a rapid decline occurred, there was a statistically significant likelihood of having the patient discontinue treatment. However, if there was a slow decrease in glomerular filtration rate over weeks to months, the chances of becoming dialysis independent were quite small. The long-term survival was better in those who were dialysis independent compared with those who required ongoing dialysis therapy. There were only two late deaths among the 14 patients not receiving dialysis compared with five late deaths among the six patients who continued to receive dialysis after surgical revascularization (p <.01).

Revascularization for Control of Congestive Heart Failure or Flash Pulmonary Edema

There have been numerous reports demonstrating that surgical or endovascular revascularization is indicated for the treatment of congestive heart failure or flash pulmonary edema in some patients (11,41,42,201,205,270,271). This subgroup of patients most often has significant bilateral RAS or RAS to a single functioning kidney. The left ventricular systolic function may be normal or impaired (11). We reported 39 patients who underwent renal artery stent implantation for control of congestive heart failure (11). This represented 19% of our renal artery stent population. In this series, 18 (46%) patients had bilateral RAS and 21 (54%) patients had stenosis to a solitary functioning kidney. Renal artery stent implantation was technically successful in all 39 patients. The blood pressure was improved in 72% of patients. Renal function was improved in 51%, stable in 26%, and the renal function deteriorated in 23% of patients. The mean number of hospitalizations for congestive heart failure before stenting was 2.37 ± 1.42 (range, 1 to 6) and poststenting was 0.30 ± 0.65 (range, 0 to 3; p <.001). Seventy-seven percent of patients had no further hospitalizations after renal artery stenting over a mean follow-up period of 21.3 months. It was anecdotally noted that some patients were unable to be diuresed despite large doses of loop diuretics before stenting. Several patients began diuresing in the angiography suite immediately following stent placement.

The mechanism by which RAS causes congestive heart failure and pulmonary edema is not well defined. The improvement poststenting may in part be related to the ability to use ACE inhibitors, especially for those with impaired left ventricular function and the ability to better control volume.

CONTROVERSIES AND PERSONAL PERSPECTIVES

There have been many advances in the diagnosis of RAS in the last decade. In addition, catheter, balloon, and stent technology have revolutionized the treatment of renal artery disease. Whereas surgical revascularization was the treatment of choice a decade ago, endovascular stent implantation is now used to treat virtually all patients with RAS who require treatment. There is a large body of literature supporting the use of angioplasty and stent implantation for atherosclerotic RAS. However,

there is a paucity of randomized prospective trials comparing renal artery stents with medical therapy and surgical revascularization. There will probably never be a randomized trial comparing stents with surgical bypass, because most clinicians now believe that that would not be ethical. Although there is compelling evidence to suggest that stent implantation can improve or at least stabilize renal function in many patients, there remain 15% to 20% of patients in whom renal function deteriorates after percutaneous intervention. Reasons for this deterioration include contrast injury, atheromatous embolization, or perhaps the renal failure was not caused by the RAS per se, but some other etiology (i.e., nephrosclerosis). It is often difficult to predict which patients will exhibit a decline in renal function after percutaneous intervention. The time has come for a prospective, controlled, randomized trial comparing renal artery stent implantation with medical therapy for preservation of renal function. This trial should randomize three distinct groups: bilateral RAS greater than 75%; RAS (greater than 75%) to a single functioning kidney; and unilateral RAS (greater than 75%) with an elevated serum creatinine level.

Just because the renal artery obstruction can be corrected safely does not mean that it should be corrected. Despite better balloons, catheters, and stents and better training in endovascular techniques, the temptation to dilate a RAS because it is there should be suppressed. Percutaneous renal intervention should be performed for one of three indications: to better control the blood pressure in patients with suboptimal control despite a good antihypertensive regimen, preserve renal function, or treat congestive heart failure.

THE FUTURE

Over the last decade, renal artery angioplasty and stenting have become much safer because of better equipment and more experienced operators. However, renal function does not improve or may even worsen in 15% to 20% of patients undergoing stent implantation, and blood pressure is not improved in 20% to 50% of patients after intervention. Two important advances will occur in the future: more accurate ways to predict response to therapy (i.e., identify the patient most likely to demonstrate improvement in blood pressure control and preservation of renal function), and protection of the kidneys during the procedure. The first will occur by measuring such parameters as the resistive index and functional flow reserve. The second will occur with emboli protection devices similar to those used in the carotid and coronary circulations.
