OVERVIEW

Sudden cardiac death is a manifestation of a variety of cardiovascular diseases, most commonly coronary artery disease. The usual mechanism of death is a ventricular tachyarrhythmia. Identification of high-risk subgroups by risk stratification techniques is critical to focus therapies. Aside from beta-blockers and amiodarone in some subgroups, antiarrhythmic drug therapy has no proven benefit in sudden death prevention. In contrast, the implantable cardioverter defibrillator (ICD) provides unparalleled protection from sudden cardiac death, and its role in therapeutics continues to be defined. In reality, a multifaceted approach incorporating community awareness and education in cardiopulmonary resuscitation, primary and secondary prevention of coronary disease, and accurate and timely risk prediction is essential to exact an optimal outcome.

HISTORICAL PERSPECTIVE

Cardiovascular diseases are the leading cause of death in industrialized nations (1,2), and approximately one-half of these deaths occur suddenly, accounting annually for more than 300,000 sudden death fatalities in the United States alone (3,4 and 5). The usual mechanism of death is a ventricular tachyarrhythmia in the presence of structural heart disease (6,7,8 and 9). This chapter reviews the prevalence, mechanisms, evaluation, and management of patients with sudden cardiac death.

The accurate and meaningful classification of death as an adverse outcome is of vital importance in evaluating epidemiologic trends and the outcome of clinical trials. The working definition of sudden cardiac death has been evolving and has come under much scrutiny and criticism. The earlier definition of *sudden cardiac death* established in the 1960s (10) was primarily time based and implied unexpected cardiovascular death occurring within 24 hours of the onset of the fatal event; more recent definitions use 1 hour. The mechanism of death, whether arrhythmic or nonarrhythmic, cannot be always inferred from the time course alone, however. Most sudden cardiac deaths are unwitnessed and unmonitored, and autopsies are rarely done, so categorization of death is somewhat arbitrary (11).

CAUSES OF SUDDEN CARDIAC DEATH

Epidemiology

The estimated more than 300,000 cases per year in the United States are linked primarily to underlying coronary artery disease. A declining trend in death rates from coronary artery disease over the past three decades (12,13 and 14) is related to both the declining incidence and fatality of myocardial infarction (MI) and the improved survival of these patients (15), who would have had fatal ventricular arrhythmias. This trend reflects the combined success of several interventions: primary prevention measures that have affected the incidence of MI, improved public awareness and emergency services, advances in acute medical care for MI, and secondary prevention strategies, which have improved long-term survival. Nonetheless, sudden cardiac death remains an enormous public health problem that exacts a significant toll on the economy, medical resources, and society. It spares no age, race, or gender, and its preponderance in older men is a reflection of the prevalence of coronary artery disease in the population. Based on several large-scale population-based studies, it is known that the incidence of sudden cardiac death increases with age, although it is proportionately greater in younger persons (16). Sudden cardiac death is the initial and only manifestation in 20% of coronary deaths. Women have a lower incidence of sudden cardiac death, although it may represent the first manifestation of underlying coronary artery disease (17). Cigarette smoking and left ventricular (LV) hypertrophy, on a background of coronary artery disease, have been identified as predictive of arrhythmic death (18,19). Limited information is available regarding the incidence of sudden cardiac death in minority groups. A higher incidence among African-Americans compared with white Americans has been observed in some (20,21 and 22), but not all (23), studies. A disturbingly high incidence has been observed among Hispanic persons (23). This disparity in part may be accounted for by inequitable levels of health care access and delivery for minorities compared with whites (24).

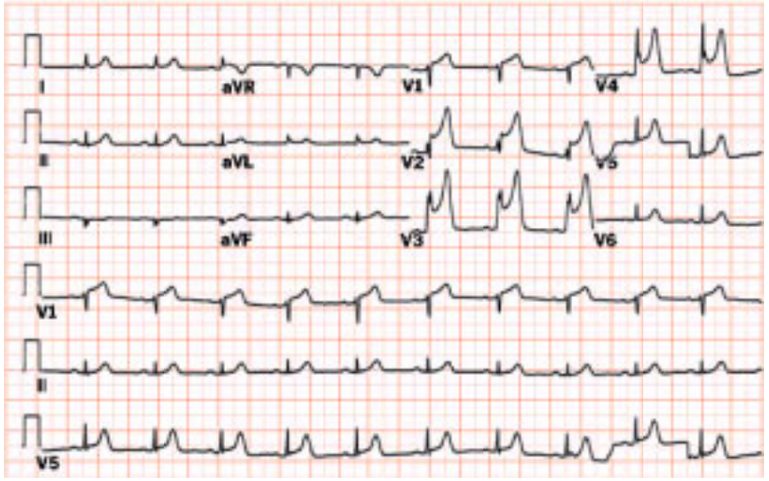
Cardiac Pathology Associated with Sudden Cardiac Death

A variety of structural abnormalities have been identified in sudden cardiac death victims (eTable 68.0.1), and atherosclerotic coronary artery disease remains unquestionably the predominant substrate in autopsy studies. Rarely, despite a thorough evaluation, neither gross examination nor histologic studies are revealing, and cellular abnormalities or transient functional disturbances are presumed to be responsible.

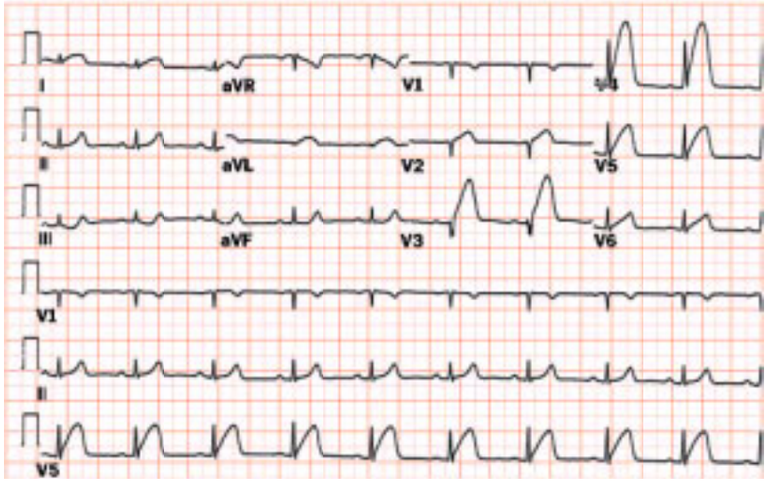
***e*TABLE 68.0.1** CAUSES OF CARDIAC ARREST
Coronary artery disease
Idiopathic dilated cardiomyopathy
Hypertrophic cardiomyopathy and left ventricular hypertrophy
Long QT syndrome (congenital or acquired)
Arrhythmogenic right ventricular dysplasia
Coronary artery anomalies or other congenital heart diseases
Myocarditis
Idiopathic ventricular fibrillation
Other causes (Wolff-Parkinson-White syndrome, conduction system disease)

Acute occlusion of a coronary artery may occur as a result of disruption of an existing plaque or consequent thrombosis or spasm, which may cause a lethal ventricular tachyarrhythmia or, rarely, acute ventricular dysfunction, cardiogenic shock, or ventricular rupture. This event usually occurs in an existing plaque of mild to moderate dimensions. Most patients are asymptomatic or have nonspecific and vague complaints of chest pain in the weeks before the event but had no known atherosclerotic coronary artery disease (25). An acute MI is noted only in approximately 20% to 40% (26,27 and 28), even when active coronary lesions are evident; histologic changes of myocardial necrosis take hours to develop. In contrast, an old MI is commonly observed and frequently active coronary lesions coexist (29,30). Spontaneous fibrinolysis of an acute thrombotic occlusion may leave no apparent trace, although it led to ventricular fibrillation (VF). In the patient with a prior MI, new

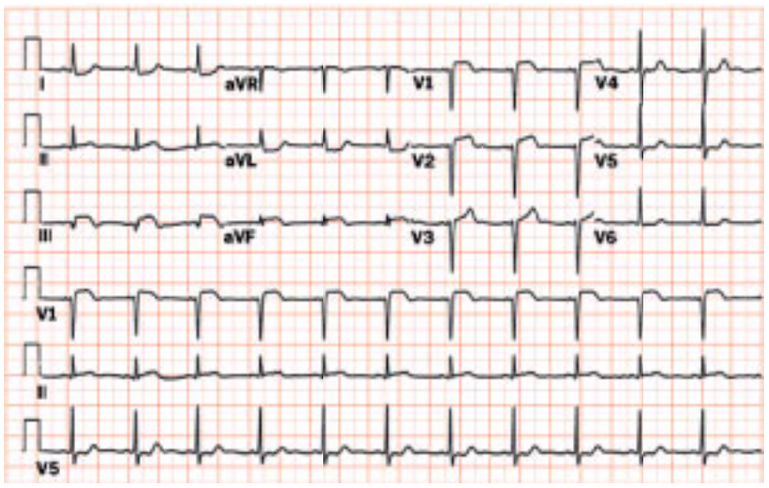
ischemia is the predominant cause of a lethal ventricular tachyarrhythmia. In addition, in approximately 20% of these persons, no evidence of active lesions or any MI is detected, although inactive plaques are observed (31). Vasospasm is a strong possibility as an alternative mechanism in these deaths.



Acute anteroseptal myocardial infarction. Dramatic ST segment elevations in leads V_1 through V_5 with associated hyperacute T-wave changes are noted.



Acute anterolateral myocardial infarction. Note classic "tombstoning" of ST-T waves in the anterolateral precordial leads.



Acute inferior myocardial infarction with right ventricular involvement. Inferior ST-segment elevation associated with elevation in lead V_1. See right precordial leads.

Cardiac rupture after acute transmural anteroseptal myocardial infarction. The yellow arrow indicates the site of rupture.

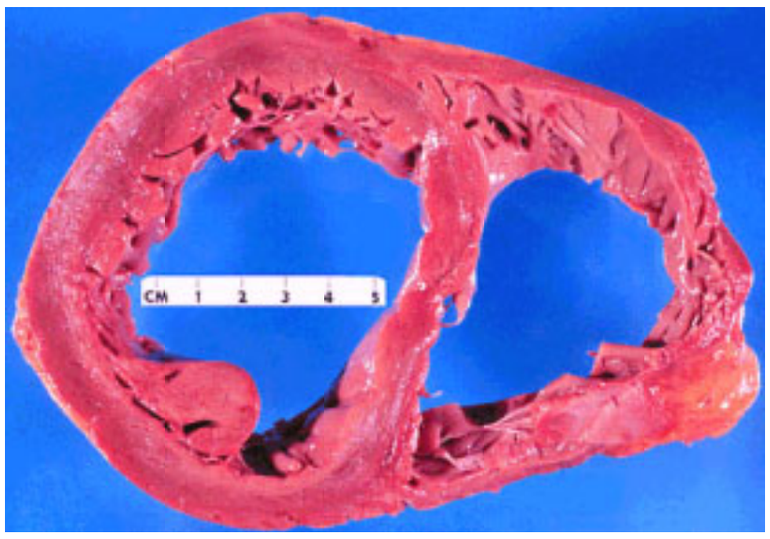
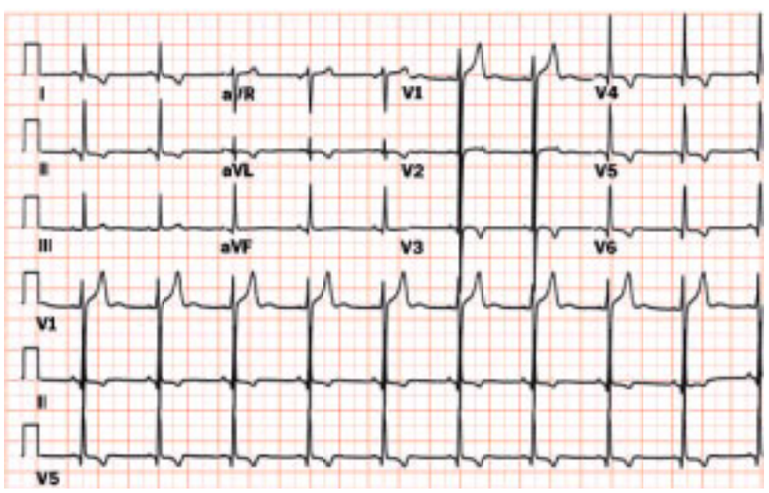
Cleveland Clinic Foundation.)

Nonischemic dilated cardiomyopathies have gained increasing importance in the spectrum of cardiac diseases underlying sudden cardiac death, especially in the face of a declining incidence of coronary artery disease. It is characterized by dilatation of the ventricles, subendocardial scarring, and patchy fibrosis, with impairment of systolic function. By definition, no cause has been identified, although viral infections, autoimmune mechanisms, or genetic abnormalities have been implicated (32,33). Histologically, the idiopathic variety of this disease is characterized by nonspecific findings of interstitial and perivascular fibrosis within the myocardium (33).



Dilated congestive cardiomyopathy. Both the left and right ventricles are significantly enlarged. In this example, the left ventricular wall thickness falls within normal limits.

The characteristic feature of hypertrophic cardiomyopathy is a variable pattern of hypertrophy in the disease, and the involvement may be primarily within the septum, posterior LV wall or the apex, or it may be restricted to the mid-LV cavity (34). Histologically, there is gross disorganization of the muscle bundles, fiber orientation, and cellular myofibrillar structure (35). Intercellular communications are disturbed as a result of abnormalities in the gap junction and accumulation of connective tissue. These complex structural and functional abnormalities constitute the altered electrophysiologic milieu in this disease.



Hypertrophic cardiomyopathy. Inverted precordial T waves associated with hypertrophic cardiomyopathy.

Arrhythmogenic right ventricular dysplasia may be difficult to diagnose even at autopsy in the mildest form of the disease, although it is obvious in the advanced form, where marked ventricular dilatation and replacement of myocardium with fibrous tissue are apparent. Histologic findings are characteristic, with fatty infiltration, thinning of the ventricular wall, and replacement with fibrous tissue (36,37). The intervening myocardial fibers form the arrhythmogenic substrate for ventricular reentry. LV involvement has been associated with a poor prognosis (38).

VIDEO

Video 68.1 Arrhythmogenic right ventricular dysplasia (transaxial). Thinning of the right ventricular wall with dyskinesia of the right ventricular free wall during systole is due to fibrous replacement of the myocardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

It is postulated that the genetic abnormality in the congenital long QT syndrome influences myocardial ionic channels (39,40), increasing cellular susceptibility to autonomic influences. The inciting mechanism for polymorphic ventricular tachycardia (VT) and VF has not been well established, although bradycardia and prolonged repolarization act as the substrate, and sympathetic stimulation acts as the trigger, in some form of interaction (eFig. 68.0.1). Congenital coronary artery malformations have been occasionally implicated in young victims of sudden death (41,42,43 and 44). The most common of these is the anomalous origin of the left coronary artery from the right sinus of Valsalva (44). Primary disease of the myocardium, such as myocarditis, sarcoidosis, and amyloidosis, and congenital or infiltrative disorders of the specialized conduction system may rarely be causative. There is a rare association of sudden death in patients with myxomatous mitral valve disease (45). The Wolff-Parkinson-White (WPW) syndrome also has been associated with sudden death (46,47), but despite its notoriety, the occurrence of sudden death is distinctly rare, especially in asymptomatic persons (48,49). LV hypertrophy in systemic hypertension is being increasingly recognized as an ominous harbinger of cardiac mortality, based on epidemiologic data (50). There is an increased incidence of ventricular arrhythmias with LV hypertrophy (51,52), and the association of asymptomatic ventricular ectopy and LV hypertrophy confers an increased risk of sudden death (53,54 and 55).

Sudden Cardiac Death in Advanced Ventricular Dysfunction

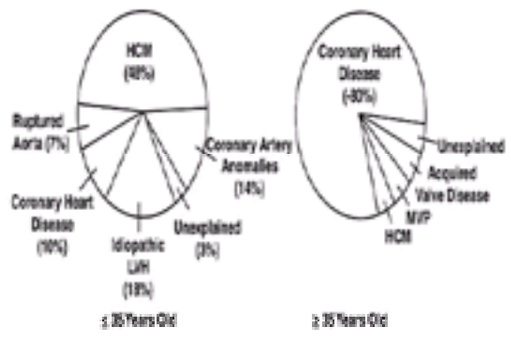
Approximately 4.8 million persons are affected by heart failure in the United States, and this population is growing (56,57). The survival of these patients is limited not only by progressive pump dysfunction but also by the risk of sudden cardiac death (58,59,60,61,62 and 63). Although VF is the usual mechanism of sudden cardiac death in the out-of-hospital setting, bradyarrhythmias and electromechanical dissociation are much more common in this population (6,64,65) (*e*Table 68.0.2). Monomorphic VT is relatively uncommon in these patients, but when induced, bundle branch reentry is identifiable as the mechanism in up to 36% of those with nonischemic cardiomyopathy (66). Intramyocardial fibrosis, small vessel disease, and ventricular hypertrophy (67,68) constitute the major substrate abnormalities and are accompanied by cellular derangements such as abnormal resting membrane potentials, increased temporal dispersion of repolarization, and abnormal intracellular handling. Fluctuations in potassium or magnesium concentrations induced by diuretic or angiotensin inhibitor use, myocardial stretch from ventricular dilatation, and a high sympathetic tone and parasympathetic withdrawal are invariable accompaniments of advanced heart failure and have been implicated in arrhythmogenesis.

***e*TABLE 68.0.2** CARDIAC ELECTRICAL ACTIVITY AT THE TIME OF CARDIAC ARREST

Sudden death	**Patients (n)**	**Bradyarrhythmia/electromechanical dissociation (%)**	**Ventricular tachycardia/ventricular fibrillation (%)**
Ambulatory (268)	157	16.5	83.5
Advanced heart failure (64,65,267)	53	58.0	42.0
Heart transplantation waiting list (64,267)	24	68.0	32.0

Athletes

The occurrence of sudden death in an athlete is an unexpected and catastrophic event, because it epitomizes the paradox of physical fitness (69). Most of these athletes are virtually asymptomatic before the event and usually collapse during intense physical activity. Epidemiologic data with regard to age, gender, and race are sparse. A heterogeneous spectrum of occult cardiovascular disease is found to be responsible (41,42,43,44,45,46,47,48,49,50,51,52,53,54 and 55,70,71 and 72) (*e*Fig. 68.0.2), although the most common underlying entity is hypertrophic cardiomyopathy. Other causes include congenital coronary anomalies (41,42,43 and 44), arrhythmogenic right ventricular dysplasia, myocarditis, idiopathic dilated cardiomyopathy, valvular and aortic root disease, and sarcoidosis. Coronary artery disease may be putative, especially in the older athlete (73,74). In a few cases, despite careful pathologic evaluation, no evidence of structural cardiovascular disease is found. In such cases, the abnormality may have been missed, substance abuse and high-risk behavior may be contributory, or a dynamic event such as the long QT syndrome or coronary spasm may be speculated as the mechanism of death. The use of drugs such as heroin, tricyclics, alcohol, and particularly cocaine poses a risk for sudden death irrespective of the dose, mode of administration, or frequency of use; heart disease is not a prerequisite (75).



***e*FIGURE 68.0.2** The causes of sudden death in competitive athletes differ in the younger (younger than 35 years) and older athlete (older than 35 years). HCM, hypertrophic cardiomyopathy; LVH, left ventricular hypertrophy; MVP, mitral valve prolapse. (From Maron BJ, Roberts WC, McAllister HA, et al. Sudden death in young athletes. *Circulation* 1980;62:218–229, with permission.)

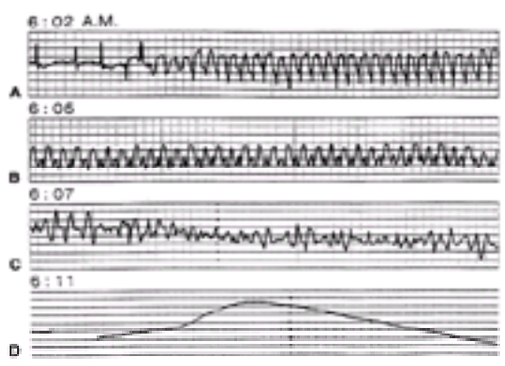
Pediatric Population

In contrast to adults, in whom coronary artery disease is the predominant etiology for sudden cardiac death, a wide variety of disorders are responsible in the pediatric population. Epidemiologic data for this population are scant, yet pooled data (76) report rates ranging from 1.3 to 8.5 per 100,000 patient-years, which translates into several thousand sudden cardiac deaths annually. Sudden death in an apparently healthy child is rare, and here hypertrophic cardiomyopathy, coronary artery anomalies, myocarditis, conduction system abnormalities, and valvular and aortic root disorders may be responsible. Most deaths mechanistically are due to ventricular tachyarrhythmia or atrioventricular (AV) block. Supraventricular tachycardias almost never cause sudden death in the pediatric population. Children who have undergone surgery for congenital heart disease remain at risk for late sudden cardiac death as well, and the risk depends on the nature of the underlying abnormality. Commotio cordis, or nonpenetrating blunt trauma to the anterior chest wall from a baseball or hockey puck, during amateur sporting activities, may lead to a fatal arrhythmia (VF or bradycardia) in a person with a healthy heart (69,77,78). Rarely, sudden death may be a result of extreme bulimia or anorexia nervosa (79) in adolescents or teenagers. Sudden infant death syndrome remains an unexplained entity, although QT abnormalities are suspected to be the basis.

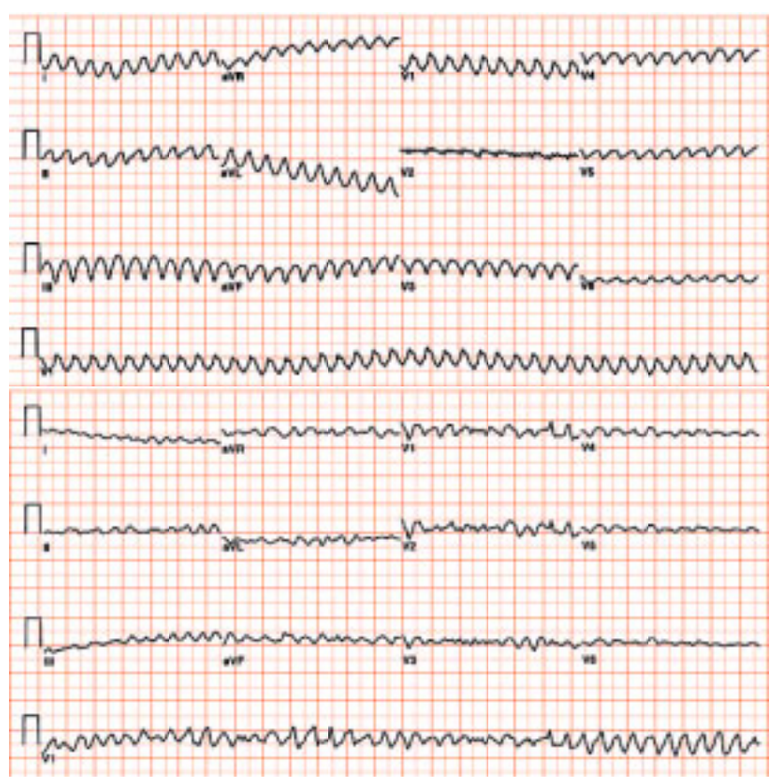
MECHANISMS OF SUDDEN CARDIAC DEATH

Arrhythmic Sudden Death

Whenever electrocardiographic monitoring is available at the onset of sudden cardiac death, it appears that VT or VF is the most common initial rhythm. Ambulatory electrocardiographic recordings obtained from a large series of patients who were wearing a Holter monitor at the time of cardiac arrest (eFig. 68.0.3) show that ventricular tachyarrhythmias, including monomorphic VT that transformed to VF, were the primary event in 83% of patients and bradyarrhythmias in 17% (6), regardless of the underlying heart disease. Similar findings were reported by others (80). These data should, however, be interpreted with caution because the patient population they represent had a high proportion of antiarrhythmic drug use. Rarely, supraventricular arrhythmias are the primary event that degenerate into VF (81).

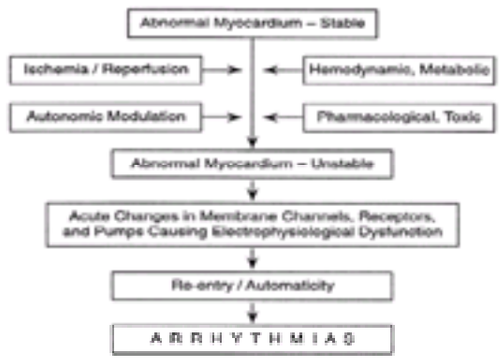


***e*FIGURE 68.0.3** Typical sequence of events culminating in sudden cardiac death are depicted in a Holter recording obtained from a patient. This figure also illustrates the transformation of rhythm from ventricular tachycardia to ventricular fibrillation and finally asystole with time. (From Akhtar M, Garan H, Lehmann H, et al. Sudden cardiac death: management of high risk patients. *Ann Intern Med* 1991;114:499, with permission.)



Ventricular flutter (A). Same patient with degeneration into ventricular fibrillation (B).

In a simplistic sense, the genesis of an arrhythmia requires the interaction between a structurally abnormal substrate and its modulation by a transient perturbation (eFig. 68.0.4). Nearly all forms of structural heart disease are associated with a roughly equal risk of sudden cardiac death, and statistically coronary artery disease and the cardiomyopathies are the most prevalent in the general population. Each may be viewed as a stable substrate with identifiable electrophysiologic abnormalities, which may be transiently altered by dynamic modulating influences, generating a lethal arrhythmia. A discussion follows of these evanescent and variable triggers, and eTable 68.0.3 outlines them.



***e*FIGURE 68.0.4** The influence of functional modulation of an underlying anatomic substrate ultimately leading to the development of ventricular arrhythmias. An electrophysiologically stable substrate is transformed by one or more factors, leading to cellular electrophysiologic dysfunction. This may result in ventricular tachyarrhythmias. (From Myerburg RJ, Kessler KM, Castellanos A. Pathophysiology of sudden cardiac death. *Pacing Clin Electrophysiol* 1991;14:935–943, with permission.)

***e*TABLE 68.0.3** POTENTIAL TRIGGERS OF SUDDEN CARDIAC DEATH
Transient ischemia or reperfusion
Sympathovagal imbalance
Metabolic derangements
Proarrhythmia (antiarrhythmic and other drug use)
Hemodynamic alterations
Electrical triggers (bradycardia, premature ventricular complex)

Transient Ischemia and Reperfusion

Both transient ischemia and reperfusion have significant electrophysiologic effects in cardiac tissue. The primary effects of ischemia are alteration in the regional conduction velocities and creating or enhancing dispersion of conduction patterns and refractoriness, thereby facilitating reentry. In the presence of prior infarction, acute ischemia is even more arrhythmogenic (82). The phenomenon of reperfusion has distinct and possibly additive electrophysiologic consequences and should not be viewed merely as undoing of ischemia. Reperfusion primarily causes calcium overloading and automatic activity (83), and its effects are proportional to the duration of the conditioning ischemic event (i.e., the most serious reperfusion arrhythmias occur with a short prior ischemic episode) (84).

Circadian variations in the occurrence of sudden cardiac death with a higher event rate in the early morning hours appear to parallel those of other cardiovascular events, such as transient myocardial ischemia, thrombotic stroke, and MI (85,86). This occurrence appears to be the culmination of a number of physiologic processes that also have diurnal variations, including morning peaks in heart rate, blood pressure, catecholamine and cortisol levels (85,87), and coronary vascular tone (88). Diurnal variations in the platelet clotting system and intrinsic fibrinolytic system also coincide in the morning hours, increasing the thrombotic risk (89,90).

Role of the Autonomic System

Compelling evidence now exists linking the autonomic nervous system and sudden cardiac death (91,92 and 93), and this is addressed more thoroughly in Chapter 77. Animal data show that in the setting of acute MI, enhanced sympathetic activity promotes malignant ventricular tachyarrhythmias, and beta-blockade or increased vagal tone provides a protective antifibrillatory effect (94,95). This phenomenon is evident even when acute ischemia is superimposed on chronic infarction. Interruption of sympathetic and parasympathetic nerve fibers in the region of transmural MI and consequent denervation hypersensitivity create vulnerability for VF (96). The consequent regional sympathovagal imbalance and hypersensitivity may thus promote VF through complex interactions in coronary artery disease. The results of the beta-blocker trials after MI showed significant reductions in subsequent sudden death and total mortality and reinfarction rates (97,98 and 99), presumably by modifying the autonomic influences. Torsades de pointes has been linked to after-depolarizations, and in the congenital variety the trigger appears to be adrenergic stimulation.

Metabolic and Proarrhythmic Factors

Metabolic disturbances are inevitable in the context of cardiovascular disease. Hypoxemia and acid–base abnormalities, especially in the setting of advanced ventricular dysfunction, can provoke lethal arrhythmias (58,100). Hypokalemia caused by diuretic use prolongs repolarization and has been linked to torsades de pointes. Diuretics have been associated with an increased risk of sudden and total cardiovascular mortality (101). Antiarrhythmic drug therapy can facilitate reentry by stabilizing preexisting circuits or by creating new areas of functional conduction block. The distribution of antiarrhythmic drugs and their actions also are significantly modulated by coronary blood flow, local pH, resting membrane potential, and disease states that alter distribution or metabolism of these drugs. Torsades de pointes as a proarrhythmic response was first observed with the use of quinidine (102). It has since been seen with other class I agents, class III agents, and noncardiovascular drugs, such as pentamidine, erythromycin, terfenadine (Seldane), and psychotropics. In contrast, flecainide and encainide contribute an additive risk to acute ischemia rather than a direct effect, occurring on a background of a prior MI, as was evident in the Cardiac Arrhythmic Suppression Trial (103). The salutary effects of oral inotropic agents, such as amrinone in heart failure, were offset by the adverse effects on mortality, presumably by a proarrhythmic mechanism.

Hemodynamic Factors

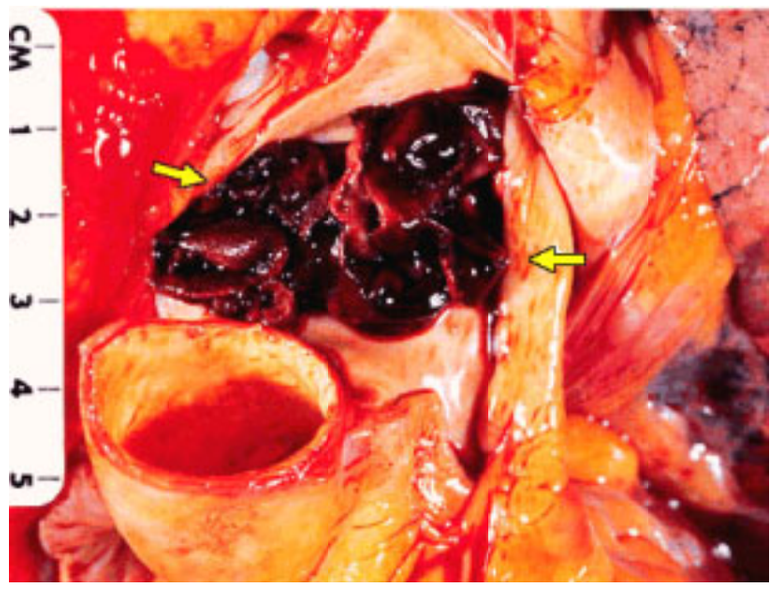
Experimental data support alteration of refractoriness with increasing ventricular volume (104,105), and in the setting of an old MI, these changes may be regionally disparate (106), facilitating ventricular arrhythmias. Clinical data support a higher sudden cardiac death risk in advancing ventricular dysfunction and an association between worsening arrhythmias and hemodynamic decompensation (107). It is likely that other triggers also may be facilitatory.

Role of Electrical Triggers

Electrical triggers are specific electrophysiologic mechanisms that can trigger ventricular tachyarrhythmias. Despite the prevalent view that premature ventricular beats trigger monomorphic VT, in reality this seldom occurs (108). It has been proposed that repetitive concealed reentry within a preexisting circuit (in association with myocardial fibrosis) continually occurs during each beat of the native rhythm; however, this process usually is aborted by depolarization of the boundaries of the reentrant circuit. The late potentials on a signal-averaged electrocardiogram (SAECG) (109) and development of incessant VT after antiarrhythmic drug therapy (110) are clinical correlates of abortive concealed reentry. Alteration of the conduction characteristics both within or around the reentrant circuit may be facilitated by autonomic, hemodynamic, or pharmacologic influences, which can lead to manifest reentry producing either a single premature ventricular complex or a repetitive response (VT). The acquired form of torsades de pointes is usually triggered not by a premature ventricular complex but by the ensuing pause. The arrhythmia also may occur in the clinical setting of sinus bradycardia or AV block, in susceptible individuals. Bradycardia is an uncommon initial event in sudden cardiac death and is more likely a result in advanced heart failure. When it occurs, even in a monitored situation, salvage by cardiac pacing is usually not feasible.

Nonarrhythmic and Noncardiac Causes of Sudden Death

Classification of death as sudden and cardiac generally implies that it was arrhythmic. Nonarrhythmic and noncardiac causes of death can simulate the clinical circumstances of instantaneous cardiac death, even when witnessed (11). Rupture of an abdominal or thoracic aortic aneurysm, intracerebral hemorrhage, massive pulmonary embolism, and prosthetic valve dysfunction also can mimic sudden cardiac death. Although clinical information may be helpful in identifying these as the mechanism of death, a carefully performed autopsy is the most credible method.

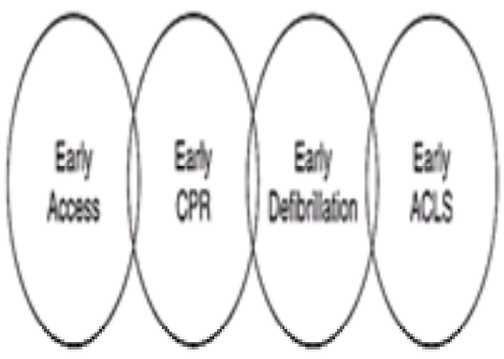


Saddle embolism of the pulmonary artery. The pulmonary artery has been opened via an anterior incision. Multiple fragments of thrombi protrude from the open pulmonary artery and are wedged into both the left and right pulmonary artery branches (*yellow arrows*).

MANAGEMENT OF OUT-OF-HOSPITAL SUDDEN CARDIAC DEATH

A substantial proportion of sudden cardiac arrests occur outside the hospital (3); however, only 1% to 20% of these patients survive to hospital discharge (111,112,113 and 114). The initial rhythm depends on the time elapsed from the onset of cardiovascular collapse to the first electrocardiographic recording (*e*Fig. 68.0.3). VF is present in 95% of cases and asystole in 5% if the elapsed time is less than 4 minutes (115). This proportion changes to 71% VF and 21% asystole when the time from collapse is 12 to 15 minutes, supporting the theory that asystole and electromechanical dissociation are usually secondary to prolonged VF and its metabolic consequences. When the elapsed time is unknown, VF is the initial rhythm in 40%, asystole in 40%, electromechanical dissociation in 20%, and VT in 1% (116). Cardiac arrest may begin as a VT that rapidly degenerates into VF, although this is less common than is generally perceived. Long-term survival is related directly to the initial recorded rhythm and is poor with asystole or electromechanical dissociation (1% and 6%, respectively), and approximately 25% with VF. Those patients who are found in VT at the time of initial contact have the best short-term outcome (117).

A person's chance of surviving cardiac arrest is influenced strongly by the time elapsed from collapse to cardiopulmonary resuscitation. The American Heart Association emphasizes the concept of the "chain of survival" in the approach toward sudden cardiac death (*e*Fig. 68.0.5). The links in this chain are defined as early access (recognition of symptoms and signs of cardiac arrest and mobilization of emergency services), early cardiopulmonary resuscitation, prompt defibrillation, and early advanced care. The success of this approach is critically dependent on the sequential activation and operation of each link. A delay in calling for help is frequently cited as a significant factor affecting outcome, despite public awareness and media campaigns. The local unavailability of a tiered emergency response system, overloaded phone lines and operators, and difficulties in reaching victims promptly because of traffic patterns also contribute to the weakness in the chain. Persons receiving bystander cardiopulmonary resuscitation are more likely to survive than those who do not (118) (*e*Table 68.0.4). However, despite this glaring fact, cardiopulmonary resuscitation is infrequently attempted by bystanders, including family members, who are the usual witnesses. This reluctance stems from a multitude of factors, such as the fear of doing more harm than good, concerns regarding transmission of the human immunodeficiency virus or other pathogens, and inadequate knowledge of cardiopulmonary resuscitation techniques.



***e*FIGURE 68.0.5** The schematic chain of survival to optimize the chance of successful resuscitation. ACLS, advanced cardiac life support; CPR, cardiopulmonary resuscitation. From Cobb LA, Hallstrom AP. Community-based cardiopulmonary resuscitation: what have we learned? *Ann N Y Acad Sci* 1982;382:330–342, with permission.

Prompt defibrillation substantially improves the likelihood of survival after out-of-hospital cardiac arrest (8,119). The newer automatic external defibrillator, which prompts commands during its use, is considerably easier to use by a less skilled person than a manual defibrillator. These automatic external defibrillators, when used in communities where prehospital defibrillation is lacking, have provided good results (113,116). Survival to hospital discharge has been up to 50% when automatic external defibrillators have been deployed by police and paramedics (120) and up to 26% when used in airline cardiac arrest programs (121). Intravenous amiodarone has been advocated in the initial resuscitative attempts for refractory VT or VF (122).

During the past two decades, prehospital care has evolved to shorten the time from collapse to defibrillation, and elaborate systems of emergency prehospital care have been established to provide improved resuscitative efforts. The best results from bystander-initiated cardiopulmonary resuscitation and rapid deployment of an experienced emergency response system are evident in Seattle, Washington, where field resuscitation rates of 43% have been noted; however, these rates are a dismal 0% to 8% for African-Americans in Chicago (123). Socioeconomic constraints may hinder widespread implementation of this "best case scenario" of rescue systems throughout the nation.

WORKUP AND MANAGEMENT OF THE CARDIAC ARREST SURVIVOR

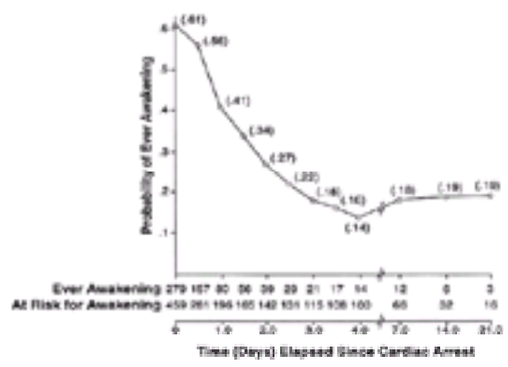
Even though each survivor represents a unique set of circumstances, the approach to the victim of sudden cardiac arrest is generally the same. It encompasses initial stabilization, determination and characterization of the underlying substrate, and assessment for future arrhythmic risk. The latter is also discussed in the context of the individual who is at risk but has not yet had a cardiac arrest.

Initial Phase

The initial phase aims at stabilization of the patient, a preliminary assessment of the cause, and developing a sense of the overall prognosis. The patient is best managed for a duration of approximately 48 to 72 hours in an intensive care unit setting. The initial rhythm documented in the field, whether bystander cardiopulmonary resuscitation was instituted promptly, the time to restoration of a perfusing rhythm ("down time"), the age of the patient, and the location of the event, whether at home or in a public place, provide important prognostic information (8,118,124). The patient should be assessed for any complications related to the resuscitative effort, particularly hemodynamic failure, oral and upper airway damage during intubation, pneumothorax, aspiration pneumonia, and chest wall trauma. The adequacy of

oxygenation and assessment of metabolic abnormalities requires appropriate laboratory analysis. Myocardial dysfunction is common following cardiopulmonary resuscitation and may transiently require some form of circulatory support. Ventilator support is often required in the initial period and may require heavy sedation or muscular paralysis to facilitate care. Interpretation of hypokalemia post–cardiac arrest is sometimes difficult because it may not reflect the prearrest state. Continuous electrocardiographic monitoring is essential because arrhythmias frequently are encountered after resuscitation and may be the mechanism of the cardiac arrest or may be unrelated and due to factors associated with resuscitation, and their management should be individualized based on some general principles. Any reversible factors such as hypokalemia, acidosis, and ischemia should be promptly identified and corrected. Antiarrhythmic therapy (such as lidocaine, procainamide, or pacing) should be appropriately selected for hemodynamically compromising arrhythmias, and these drugs should be discontinued before electrophysiologic evaluation so that they do not confound the decision regarding long-term therapy.

The patient's neurologic status on admission likely reflects the duration of the circulatory arrest (125,126). Generally, only a few patients are conscious at admission (118), and these persons have no significant residual neurologic deficit. Initial assessment of the comatose patient may be difficult, especially if sedation and muscular paralysis have been used. Often seizure activity may develop and require therapy as well. The persistence of coma beyond 72 hours after resuscitation indicates an unfavorable prognosis with a high in-hospital mortality and high likelihood of significant long-term neurologic impairment (126) (*e*Fig. 68.0.6).



***e*FIGURE 68.0.6** Likelihood of neurologic recovery after out-of-hospital cardiac arrest counts in the two rows above the *x*-axis depict actual numbers of patients ever awakening and of patients who were alive but not yet awake at each specified time. Most patients who awakened did so by day 3. (From Longstreet WT Jr, Inui TS, Cobb LA, et al. Neurologic recovery after out-of-hospital cardiac arrest. *Ann Intern Med* 1983;98:588, with permission.)

The long-term survival of patients resuscitated from cardiac arrest depends on several factors. An assessment of in-hospital mortality and outcome can be based on prearrest variables, resuscitation variables, and factors identified on admission to the hospital (*e*Table 68.0.5). The decision to withdraw life-sustaining measures is a complex one involving ethical issues and may be made with the consideration of the previously mentioned assessment and a close discussion with family members and peers (127,128).

***e*TABLE 68.0.5** DETERMINANTS OF ADVERSE LONG-TERM SURVIVAL IN CARDIAC ARREST
Prearrest
Older age
Lower socioeconomic status
Significant comorbid disease states
Homebound lifestyle
Resuscitation
Out-of-hospital cardiac arrest
Lack of bystander cardiopulmonary resuscitation
Delay in defibrillation
Asystole or electromechanical dissociation as initial documented rhythm
Absence of spontaneous circulation for >25 min
Hospitalization
Significant comorbid disease states
Neurologic status (coma >72 h)
Structural heart disease
Left ventricular dysfunction
Nonsuppressibility of induced ventricular tachycardia by drug

Definition of the Underlying Substrate

The next logical step is to define the underlying substrate. A detailed account from all witnesses regarding the circumstances of the event, antecedent symptoms, and whether physical exertion was involved provides important information. Anginal chest pain before the event may suggest underlying coronary disease. A family history of sudden cardiac death may point toward hypertrophic cardiomyopathy, long QT syndrome, the Brugada syndrome, right ventricular dysplasia, or coronary artery disease. The social history of the individual patient may indicate high-risk behavior and implicate substance abuse as a possibility. Preexisting known coronary artery disease or other cardiac disease and noncardiac disease (sarcoidosis, vasculitides) may narrow the focus in the search for a cause. Comorbidity is a predictor of adverse survival following out-of-hospital cardiac arrest, although this is an underrecognized issue (129). A comprehensive drug history and screening (prescription and over-the-counter medications) is imperative because these may have been proarrhythmic. The physical examination may provide evidence of cardiac disease (valvular disease, cardiac enlargement, and dysfunction) and associated noncardiac disease that may have been causative or may affect management and prognosis. Markers of myocardial necrosis should be assessed serially to determine the presence of an acute MI. A toxicologic screen may be appropriate when substance abuse or drug overdose is suspected.

The initial electrocardiogram can provide useful information regarding the underlying substrate. Evidence of a prior MI is more common than an acute MI. Other specific abnormalities may indicate the presence of LV hypertrophy, hypertrophic cardiomyopathy, QT prolongation, arrhythmogenic ventricular dysplasia, an accessory pathway, the Brugada syndrome, or AV block. Further definition of the cardiac substrate requires additional evaluation. Cardiac anatomic and functional assessment may be performed by two-dimensional echocardiography, which provides an estimate of cardiac chamber dimension and relationships, valvular structure and function, and ventricular wall thickness and function. Ventricular function, including the presence of wall motion abnormalities, alternatively may be assessed by gated nuclear imaging. Global ventricular dysfunction observed early following resuscitation may resolve after a few days. The diagnosis of arrhythmogenic right ventricular dysplasia may be missed by echocardiography, and magnetic resonance imaging is a valuable tool in suspected cases (130). An endomyocardial biopsy may assist in the diagnosis of myocarditis or infiltrative myopathies, such as sarcoidosis when they are clinically uspected.

Cardiac catheterization and angiography should be performed in virtually all survivors to establish the presence and severity of atherosclerotic coronary artery disease. It also may be useful to define coronary anomalies and other forms of congenital heart disease. These results may need to be interpreted in conjunction with perfusion imaging to assess the physiologic significance of the documented coronary artery disease. Angiographic evidence of complex coronary lesions, such as an ulcerated plaque or thrombus, may point to the mechanism of the arrest. More commonly, multivessel disease on a background of a prior MI with compromised pump function is observed. A segmental wall motion abnormality or ventricular aneurysm may be seen with coronary artery disease, idiopathic cardiomyopathy, or ventricular dysplasia. Coronary artery spasm as an etiology may be identified by provocative testing, although it may not be excluded by a negative test result (131). Abnormal histologic findings also have been noted in right and LV endomyocardial biopsies (103); however, this is subject to sampling errors and the vagaries of interpretation.

In a few cardiac arrest survivors, no evidence of structural heart disease or electrical and metabolic abnormality is demonstrable despite extensive evaluation (9,132,133). The diagnosis of primary electrical disease or idiopathic ventricular tachyarrhythmia in these patients is therefore made by a process of exclusion. Typically younger, these patients, despite having experienced a documented clinical ventricular tachyarrhythmia with no demonstrable heart disease or inducible ventricular tachyarrhythmia, remain at high risk for recurrent cardiac arrest (133). A practical approach to the cardiac arrest survivor is outlined in *e*Table 68.0.6.

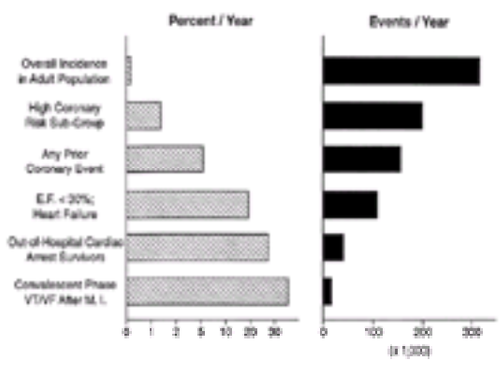
From DiMarco JP. Work-up and management of sudden cardiac death survivors. *Cardiol Clin* 1993;11:11–19, with permission.

Arrhythmic Evaluation and Risk Prediction

The primary role of arrhythmic evaluation in the cardiac arrest survivor has been to define and characterize the arrhythmic mechanism and form the basis for management strategies by risk stratification (134). Earlier data showed that patients resuscitated from cardiac arrest not associated with a new Q-wave infarction remain at high risk for recurrent cardiac arrest and sudden cardiac death during long-term follow-up (114,135,136 and 137). Two decades ago, this risk was reported as high as 30% at 1 year and 45% at the end of 2-year follow-up (114,138). More recent natural history studies are unavailable, although this risk remains significant (139). Based on two more recent studies, the significance of VT or VT in the first 72 hours following an index MI is more ominous than previously assumed. In a retrospective analysis of the Global Utilization of Streptokinase and t-PA for Occluded Arteries database, the occurrence of VT or VF during the index hospitalization conferred an adverse 1-year mortality (140). In another single-center retrospective analysis, the manifestation of nonsustained VT 13 hours after MI indicated a higher 1-year total mortality (141).

The major focus in the management of the cardiac arrest survivor was previously directed toward secondary prevention measures. However, significant attrition occurs during the primary event, and there has been a progressive change in management strategies over the past two decades, with increasing emphasis toward primary prevention measures. The rationale of this multifaceted approach is well justified because it is more cost effective and more successful in that a significant proportion of events occurs in persons known to be at high risk.

Sudden cardiac death also may be the first expression of occult heart disease. A significant proportion of these deaths may be predictable because they occur in patients who may be categorized as high risk. Naturally, screening of an unselected general population is impractical; hence, efforts at risk stratification should be directed toward those with structural heart disease. Focusing these efforts on patients within high-risk population subgroups results in increasing specificity within these subgroups so that interventions may be targeted in a cost-effective manner, without exposing a larger population to the risks of needless intervention. However, the absolute numbers of patients who experience sudden cardiac death progressively diminish as the clinical subgroups identified by currently available techniques become more specific (*e*Fig. 68.0.7). The role of arrhythmia evaluation in risk stratification for sudden cardiac death in several clinical circumstances is also addressed here.



***e*FIGURE 68.0.7** Inverse relationship between the incidence and total number of sudden cardiac deaths per year in population subgroups. Although the overall incidence in the adult population is 0.1% to 0.2% per year, this segment accounts for more than 300,000 sudden deaths per year. The addition of risk factors results in a progressively higher incidence but a progressively smaller percentage of total events. E.F., ejection fraction; M.I., myocardial infarction; VT/VF, ventricular tachycardia/ventricular fibrillation. (From Kleiger RE. The relationship between clinical features of acute myocardial infarction and ventricular runs 2 to 1 year after infarction. *Circulation* 1981;63:64–70, with permission.)

A person who has a history of coronary artery disease, even if it is asymptomatic, faces an increased risk of sudden cardiac death. A history of cardiac arrest in the absence of an acute MI is the most significant risk factor for recurrence. A history of syncope is of ominous significance in patients with idiopathic dilated cardiomyopathy (142). Sudden cardiac death in WPW is rare and almost always occurs in a previously symptomatic person. Clinical presentation at a young age and a family history of sudden cardiac death are of prognostic importance in hypertrophic cardiomyopathy, arrhythmogenic right ventricular dysplasia, or the long QT syndrome. Cigarette smoking may predispose to sudden death in those with coronary artery disease; however, no other modifiable risk factors help discriminate

between the risk of sudden versus nonsudden coronary death.

Noninvasive and invasive diagnostic data obtained during the cardiovascular evaluation have significant usefulness in risk stratification. This aspect has been studied most extensively and validated in the patient with coronary artery disease.

1. LV dysfunction is a potent predictor of risk of short- and long-term cardiac death in the post-MI population (143,144,145,146,147 and 148) and is anatomically indicative of infarct size and regardless of the location of the MI (149). LV dysfunction is also a predictor of sudden cardiac death, and the presence of frequent or complex ventricular ectopy detected by Holter monitoring provides additive risk (143,144,147,150). LV function may be assessed by a variety of techniques, such as gated radionuclide studies, echocardiography, or contrast angiography, and should be performed routinely in the evaluation of the cardiac arrest survivor.
2. Ambulatory electrocardiography: The presence of complex ventricular ectopy in cardiac arrest survivors and after MI is an independent risk factor for sudden cardiac death; hence, it was presumed that Holter monitoring may be useful both for risk stratification and assessment of response to drug therapy (143,144 and 145,151). There are some serious limitations of Holter monitoring that need to be taken into account, such as day-to-day and long-term variability in spontaneous ectopy (152,153) and that few cardiac arrest survivors have significant ambient ectopy (151). Third, although the complexity and frequency of ventricular ectopy dramatically increase with advancing ventricular dysfunction (154), this is predictive of total cardiac mortality but does not reliably discriminate between sudden and nonsudden death in this population (153,154).

   Asymptomatic nonsustained VT in the setting of a prior MI and LV dysfunction is associated with a 2-year mortality in the range of 30% (150). Holter monitoring is useful in the post-MI state for identification of the high-risk person. The value of Holter monitoring in other substrates, such as idiopathic dilated cardiomyopathy, hypertrophic cardiomyopathy, or LV hypertrophy, is not well established (155,156,157 and 158). Ischemia detected by Holter monitoring may be a marker for biologically unstable coronary artery disease, which has been predictive of an adverse short-term outcome (159). It may also be useful in monitoring patients with suspected long QT syndrome, in whom dynamic fluctuations of the QT interval may be evanescent.
3. SAECG is used as a predictor of risk because of its ability to detect late potentials. This association is more specific in coronary artery disease. The presence of late potentials is predictive of increased arrhythmic events, including sudden cardiac death in the post-MI population (148,160,161), and in those with VT or VF is predictive of inducible VT (162). The combination of late potentials with LV dysfunction has been associated with a 34% incidence of arrhythmic events (163), and the addition of frequent ventricular ectopy to these findings raises the positive predictive value to just over 50% (160,161,162 and 163). In contrast to its poor positive predictive value, SAECG combined with other markers has an excellent negative predictive value of over 90%.
4. Heart rate variability, baroreflex sensitivity, QT variability index, and T wave alternans are indices of cardiac autonomic activity that have been validated clinically in identifying persons at high risk of arrhythmic death following an MI (93,164,165,166 and 167). Their positive predictive value is somewhat improved when combined with other noninvasive variables such as ventricular function, Holter monitoring, and the SAECG (161,164,168).
5. The electrophysiologic study is an essential component of the evaluation for cardiac arrest. The study is usually performed after the underlying cardiovascular substrate has been defined, and the end point of the study is the induction or noninducibility of a sustained ventricular tachyarrhythmia. Inducibility of a sustained ventricular tachyarrhythmia is a prerequisite for using the electrophysiologically guided approach in cardiac arrest survivors. Sustained ventricular tachyarrhythmias can be initiated during the electrophysiologic study in up to 85% of cardiac arrest survivors (169,170,171,172,173,174,175 and 176). Patients with significant coronary artery disease are more likely to have an arrhythmia induced than those with idiopathic cardiomyopathy or a structurally normal heart. Sustained monomorphic VT is the most commonly identified arrhythmia in up to 51% of cardiac arrest survivors and is more likely in the subset of patients in whom this arrhythmia was identified as the initiating mechanism for cardiac arrest. The initiation of VF during the electrophysiologic study with triple extrastimuli may be a nonspecific finding (177), but the transformation to inducible monomorphic VT with the use of procainamide in the setting of a prior MI has been suggested as a specific response (178).

   The electrophysiologic study has been used for serial antiarrhythmic drug testing in cardiac arrest survivors who are inducible at a baseline study. Successful suppression of the ventricular tachyarrhythmia as inferred by noninducibility of a previously inducible arrhythmia following drug therapy has been predictive of a more favorable outcome than persistent inducibility (172,173,174 and 175) and suppression can be found in 26% to 80% of cardiac arrest survivors (169,173,174). Those most likely to be rendered noninducible are the minority who have preserved ventricular function (173,179). However, noninducibility overall has not translated into improved survival, and reported recurrent sudden death rates range from 12% to 31% at 2 years (173,176,180,181 and 182). The electrophysiologic study can also identify patients suitable for map-guided surgical ablation of monomorphic VT. Postoperative noninducibility allows prediction of arrhythmia-free outcome (103,183,184). There are no long-term supportive data for catheter ablation in this situation.

   In approximately 20% to 30% of cardiac arrest survivors, a ventricular tachyarrhythmia cannot be induced during the electrophysiologic study. This proportion is higher if the underlying substrate is idiopathic cardiomyopathy or in the absence of structural heart disease. These patients do not have a benign outcome as previously believed, particularly in the setting of LV dysfunction (171,179,185,186). Serial drug testing cannot be used as a strategy in these patients. Rarely, a supraventricular arrhythmia is identified as the initiating mechanism for cardiac arrest, especially in the WPW syndrome and hypertrophic cardiomyopathy (81,186).

   The routine use of electrophysiologically guided risk stratification in the post-MI survivor has a low positive predictive value but a high negative predictive value (187,188) and currently is not recommended. Instead, the focus has shifted to refining risk in myocardial infarct survivors, with asymptomatic nonsustained VT associated with LV dysfunction (150,189,190 and 191). Overall, however, clinical variables such as functional class, nonsustained VT, and ejection fraction used with the electrophysiologic study may provide a better risk profile than inducibility alone. The predictive value of the electrophysiologic study under similar circumstances is less clear in noncoronary heart disease such as idiopathic dilated cardiomyopathy or hypertrophic cardiomyopathy (157,182,192,193,194 and 195). In the WPW syndrome, although sudden death is rare, the risk may be assessed by the conduction characteristics of the accessory pathway. There is currently no consensus regarding the use of electrophysiologic risk stratification in the asymptomatic patient with hypertrophic cardiomyopathy, the long QT syndrome, LV hypertrophy, or arrhythmogenic right ventricular dysplasia.

The relative merits of noninvasive and invasive tests in the prediction of sudden cardiac death are outlined in *e*Table 68.0.7.

***e*TABLE 68.0.7** EVALUATION OF THE RISK OF CARDIAC ARREST

Test	Utility	Relative importance
12-Lead electrocardiogram	Old or recent myocardial infarction, QT prolongation, intraventricular conduction delay, preexcitation	+++
Left ventricular ejection fraction estimation	Strong correlate of cardiovascular mortality	+++
Echocardiogram	Identify structural disease (prior myocardial infarction, left ventricular hypertrophy, myopathy)	+++
Coronary angiography	Define need for revascularization, anomalies in circulation	+++
Electrophysiology study	Define inducibility of VT or ventricular fibrillation to guide therapy	+++
Sinoatrial electrocardiogram	Prediction of recurrence, inducibility of VT	+
Holter monitor	Premature ventricular complex density, detection of nonsustained VT	+
Heart rate variability, baroreflex sensitivity	Indices of autonomic tone for risk prediction	++
Exercise testing	Identify provocable ischemia, VT, functional class	++

VT, ventricular tachycardia.

MANAGEMENT STRATEGIES FOR CARDIAC ARREST

Primary Prevention of Sudden Cardiac Death

The goal of primary prevention is to reduce sudden death and favorably affect total mortality; however, the Achilles heel of this approach is the identification of the population at risk. Although coronary artery disease is found in the majority of cardiac arrest survivors, it is impractical to institute mass screening to identify those at risk a priori. Three groups of patients that are known to be at high risk, therefore, are the focus of discussion.

Post–Myocardial Infarction

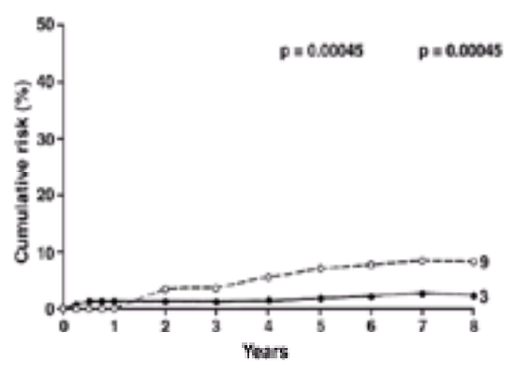
The risk of arrhythmic and nonarrhythmic cardiac death in MI survivors is highest in those with lower ejection fractions, and those with complex ventricular ectopy. Adjunctive therapy with aspirin, angiotensin-converting enzyme inhibitors, and hydroxymethylglutaryl coenzyme reductase inhibitors has also been shown to improve survival (196,197). Data from several well-designed, placebo-controlled, double-blind studies suggest that beta-adrenergic receptor blocking drugs reduce overall mortality as well as the incidence of sudden cardiac death following acute MI (97,98 and 99,198,199). The beneficial effect of beta-blockers as a class is limited to those with lipophilic properties and those without intrinsic sympathetic activity (200). It is believed that the antiarrhythmic and antiischemic properties of these drugs contribute to the observed effect, which is most evident in the highest risk population with ventricular dysfunction and complex ectopy. Suppression of ectopy is not a prerequisite for reduction in sudden death. The beta-blockers nullify the effect of the circadian rhythm in the incidence of sudden death (201) and defibrillator discharges for ventricular tachyarrhythmia. Despite this evidence, there is a low use of beta-blockers in clinical practice because of unfounded fears of side effects, and even in clinical

trials, conventional therapy with other agents noted previously is inconsistently and inadequately applied.

Although the concept of arrhythmia suppression using antiarrhythmic drugs for prevention of sudden death is appealing, the results of earlier trials have discouraged this naïve approach. Cardiac Arrhythmic Suppression Trials I and II tested the hypothesis that suppression of ventricular ectopy post-MI would translate into reduction of sudden death in this population (202,203). However, a higher incidence of sudden death in the drug-treated group led to premature termination of the study and dispelled the simplistic myth regarding the mechanism of sudden death, but it provided some important lessons. The study underscored the futility of using these drugs in an evolving substrate characterized by myocardial remodeling, neurohormonal influences, and progression of coronary artery disease, and it highlighted the serious risks of antiarrhythmic drug therapy.

Since that time, there has been a renewed interest in the class III agents, particularly amiodarone and sotalol. The BASEL Antiarrhythmic Study of Infarct Survival demonstrated reduced total mortality benefit for amiodarone in survivors of MI infarction with frequent ventricular ectopy (204). Curiously, the improved survival with low-dose amiodarone was limited to patients with LV ejection fractions over 40%, and the effect lasted for several years despite termination of therapy at 1 year (205,206). In the European Myocardial Infarction Amiodarone Trial and Canadian Amiodarone Myocardial Infarction Arrhythmia Trial, amiodarone was beneficial in reduction of arrhythmic death, but did not alter total mortality (207,208 and 209). The Polish Trial (210) showed similar results in post-MI patients who were not candidates for beta-blocker therapy. Overall, amiodarone has shown consistent safety in the post-MI population, and the effect of amiodarone was separate and complementary to that of beta-blockers. In the Survival with Oral D-Sotalol trial, the prophylactic use of sotalol in a post-MI population resulted in excess mortality, believed to be as a result of proarrhythmia (211). Both dofetilide and azimalide have similarly shown no improvement in total mortality in the post-MI patients (212,213).

Intuitively, preventing or reducing ischemia would favorably affect the incidence of sudden death in those with coronary disease. Data from large trials, such as the Coronary Artery Surgery Study and the European Coronary Artery Study Group, comparing coronary artery bypass surgery and medical therapy in patients with chronic stable angina, show surgical therapy to be associated with a significantly lower incidence of sudden and total cardiac mortality (214,215). The incidence of sudden death was 5.2% in patients assigned to medical therapy, compared with 1.8% in those who underwent surgery during a 4.6-year follow-up in the Coronary Artery Surgery Study report. The difference in favor of surgical therapy was even greater when congestive heart failure was present (216). In the European study, the risk of sudden death at 8 years was 3% in the surgical group versus 9% in the medical group (*e*Fig. 68.0.8). Myocardial revascularization is also beneficial in reducing sudden death risk in patients who have provocable ischemia during stress testing (217) and those who have silent ischemia on Holter monitoring. Accumulating evidence also supports a favorable effect of intervention at the time of acute MI on the subsequent development of ventricular tachyarrhythmias. Both short- and long-term results of thrombolytic therapy and percutaneous transluminal coronary angioplasty translate into a lower incidence of late potentials and inducibility during programmed stimulation (218,219). It is likely that these interventions extend benefit not only by preserving jeopardized myocardium but also by limiting infarct size, influencing ventricular remodeling, and stabilizing the electrophysiologic matrix.



***e*FIGURE 68.0.8** Prospective evaluation of cumulative risk of sudden cardiac death in patients assigned to medical (*open circles*) versus surgical therapy (*closed circles*) in coronary artery disease. [From Varnauskas E, and the European Surgical Study Group. Survival, myocardial infarction, and employment status in a prospective randomized study of coronary bypass surgery. *Circulation* 1985;72(Suppl V):V-90, with permission.]

The Beta-Blocker Strategy Plus Implantable Cardioverter Defibrillator (BEST-ICD) Trial is under way to determine whether in a subgroup of patients with recent MI already receiving beta-blockers, a therapeutic strategy guided by electrophysiologic testing and ICD implant in those inducible for VT, can improve survival when compared with conventional therapy (220).

Cardiomyopathy

Patients with dilated cardiomyopathy, whether ischemic or nonischemic, constitute the largest identifiable at-risk population, with a formidable mortality linked to their functional class. Both sudden and nonsudden death is high, although the more functional patient is more likely to die suddenly (221,222). In a metaanalysis of 11 studies, in which patients were classified according to their functional class, those in classes I and II had a yearly mortality of 12% to 15%, but the sudden death risk was 50% to 60%. In contrast, patients who were classes II and IV had a yearly mortality of 60%, but the sudden death rate was 20% to 30% (223) (*e*Table 68.0.8). The majority of patients with cardiomyopathy has ventricular arrhythmias, usually asymptomatic. Advances in the medical management of heart failure have led to significant amelioration of symptoms, improved functional class, and prolonged survival. This leap from palliation to prolongation of life has been effected primarily by beta-blockers, angiotensin enzyme inhibitors, and nitrates in combination with hydralazine. Carvedilol, losartan, and bisoprolol have all shown survival benefit in heart failure (62,224,225,226 and 227). A clear reduction of sudden versus nonsudden death in these trials was identified only in the Vasodilator Heart Failure Trial (V-HeFT) II trial, in which enalapril was compared with hydralazine, supporting a nonarrhythmic mechanism for the other drugs. Nonetheless, a considerable risk of sudden death remains in 28% to 68% of these patients (62,227), and cardiac transplantation remains the most viable option for long-term survival. However, almost twice as many are accepted into transplant lists each month than those undergoing transplantation (228).

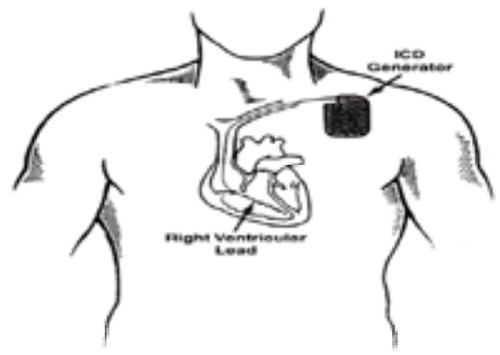
***e*TABLE 68.0.8** SUDDEN DEATH DEPENDENT ON THE SEVERITY OF CONGESTIVE HEART FAILURE

New York Heart Association functional class	Mortality per year (%)	Sudden death (%)
II	5–15	50–80
III	20–50	30–50
IV	30–70	5–30

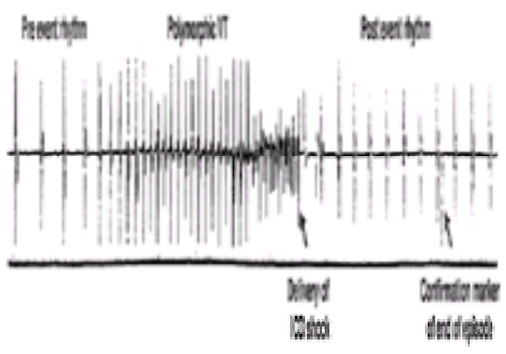
From Uretsky BF, Sheahan RG. Primary prevention of sudden cardiac death in heart failure: will the solution be shocking? *Am Coll Cardiol* 1997;30:1589–1597, with permission.

There are no data that class I antiarrhythmics prolong survival in patients with congestive heart failure, but ample evidence supports the low efficacy and high proarrhythmic rates (229,230). Amiodarone used in those with advanced ventricular dysfunction and asymptomatic ventricular arrhythmias improved survival in nonischemic dilated cardiomyopathy in the Grupo de Estudio de la Sobrevida en al Insuficiencia Cardiaca en Argentina trial (231), in which only 40% of patients had a prior MI. In contrast, in the Veterans Administration Trial, CHF-STAT, in which 70% of patients had ischemic cardiomyopathy, amiodarone did not show mortality benefit (232). Overall, although an apparently safe drug with a demonstrated statistical reduction in mortality from metaanalysis of trials, the results of an ongoing randomized trial SCD-HeFT will confirm the position of amiodarone in heart failure (233).

Because most sudden deaths are believed to result from ventricular tachyarrhythmias, prompt termination of the arrhythmia by a defibrillator conceivably would save lives. This concept was extended to the development of an implantable unit by Mirowski and Mower and has been refined further by many to its current state. In a simple sense, the unit consists of a series of components: rate-sensing electrodes that convey beat-to-beat information to logic circuitry contained in a can, which also houses a battery capable of developing a charge when a tachyarrhythmia is detected. This charge is delivered through high-voltage electrodes to the heart, invariably terminating the arrhythmia (*e*Fig. 68.0.9 and *e*Fig. 68.0.10). Currently available ICDs are sophisticated multiprogrammable units that use sensitive and more specific detection algorithms and deliver tiered therapy, depending on need: antitachycardia or dual-chamber bradycardia pacing, low- or high-energy atrial or ventricular cardioversion, and defibrillation. Implantation is performed with comparative ease and minimal risk today, using the transvenous route. Combined with impressive long-term sudden death survival results, these factors have led to an unprecedented acceptance of this form of therapy in sudden death.

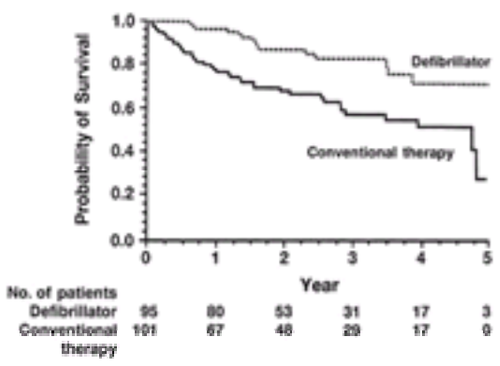


***e*FIGURE 68.0.9** Schematic representation of the currently used implantable cardioverter defibrillator (ICD). (From Deshpande S, Vora A, Axtell K, Akhtan M. Sudden cardiac death. In: Brown DL, ed. *Cardiac intensive care*. Philadelphia: WB Saunders, 1996, with permission.)

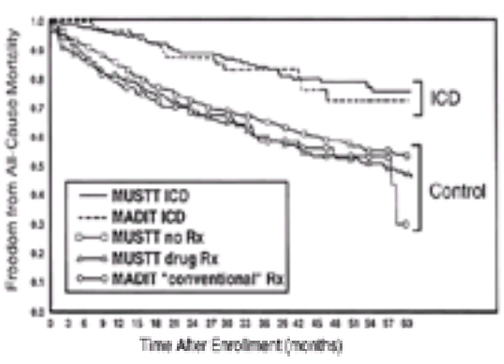


***e*FIGURE 68.0.10** Spontaneous episode of polymorphic ventricular tachycardia (VT) terminated by delivery of a shock from an implantable cardioverter defibrillator (ICD). The tracing was retrieved from the electrogram storage of the device.

The Multicenter Automatic Defibrillator Implantation Trial (MADIT) was the first randomized trial to demonstrate that the ICD could improve survival in a high-risk group of patients. It targeted post-MI patients with asymptomatic nonsustained VT and ischemic cardiomyopathy, a population associated with a mortality of 30% within 2 years (150,190). ICD implantation in patients who had inducible monomorphic VT not suppressed by procainamide at electrophysiologic testing resulted in a superior total survival compared with administration of conventional therapy (234). The 5-year total mortality was 16% in the ICD group, and 39% in the conventional arm (*e*Fig. 68.0.11). Although almost one-half of the patients in the conventional arm were on amiodarone, the study was not powered to draw any conclusions comparing amiodarone and the ICD. Cost analysis of this study estimated that this approach would cost $27,000 per life-year saved (235). The Multicenter Unsustained Tachycardia Trial (MUSTT) enrolled a similar population of 2,202 patients and randomized 704 inducible patients to no therapy or electrophysiologically guided antiarrhythmic drug therapy with class IA, propafenone, sotalol, or amiodarone, or the ICD as a last resort (191). A 27% reduction in the primary end point of arrhythmic death or cardiac arrest in the electrophysiologically guided group was entirely due to the use of the ICD during a mean follow-up of 39 months. The overall 5-year mortality for those who received an ICD was 24% compared with 55% in those who did not. Despite the differences in study design, MADIT and MUSTT both demonstrated the superior survival advantage with the ICD (*e*Fig. 68.0.12).



***e*FIGURE 68.0.11** The probability of survival in the defibrillator and conventional therapy groups in Multicenter Automatic Defibrillator Implantation Trial. The defibrillator group had a significantly increased survival over conventional therapy. (From Moss AJ, Hall WJ, Cannom DS, et al. Improved survival with an implanted defibrillator in patients with coronary disease at high risk for ventricular arrhythmia. *N Engl J Med* 1996;335:1933–1940, with permission.)



***e*FIGURE 68.0.12** Kaplan-Meier survival curves for all-cause mortality in Multicenter Unsustained Tachycardia Trial and Multicenter Automatic Defibrillator Implantation Trial. ICD, implantable cardioverter defibrillator. [From Prystowsky EN, Nisam S. Prophylactic implantable cardioverter defibrillator trials: MUSTT, MADIT, and beyond (editorial). 2000, with permission.]

The prophylactic role of the ICD in patients with LVEF less than 35% and positive SAECG who were undergoing coronary artery bypass grafting was examined in the Coronary Artery Bypass Grafting Study (236). This population of patients also has a high incidence of sudden death, as reported in data from the CASS registry. Patients were randomized to the ICD or non-ICD limb, but no reduction in total mortality was noted with the use of the ICD despite an approximately 50% device shock rate at 1 year. The SAECG may not have been the ideal marker to use in this study since it is well known that it identifies patients at risk for VT but not for VF. It is likely that the selection of patients based on the SAECG and the beneficial effect of concomitant myocardial revascularization may have accounted for the discordant results compared with MADIT and MUSTT.

The ICD has been proposed as an empirical “bridge to transplantation” in patients with advanced ventricular dysfunction (237,238). Unfortunately, despite the reduction of sudden cardiac death, the ultimate survival benefit in this population is questionable due to attrition from other causes such as heart failure, bradycardia, electromechanical dissociation, and noncardiac causes. In this setting, because the hypothetical benefit of the ICD in unselected patients with advanced heart failure is low, the ICD is probably most appropriate in those with a realistic chance of transplantation. This issue is being prospectively examined in the Cardiomyopathy Trial

with total mortality and sudden deaths as end points. The SCD-HeFT (Sudden Cardiac Death Heart Failure Trial) is a placebo-controlled trial of amiodarone versus the ICD in patients with cardiomyopathy and no prior history of sustained ventricular arrhythmias (233). MADIT II is an extension of the first trial but does not require demonstration of complex ventricular ectopy or need inducibility of VT (239). In both the latter trials, total mortality will be the primary end point, and "conventional" therapy will be used. More recent studies showing benefit of biventricular pacing have yet to show any mortality benefit, but trials are ongoing.

Structural Heart Disease

Certain rare cardiac diseases are associated with high rates of sudden death and pose a dilemma for management. Sudden death is well recognized frequently in young asymptomatic patients with hypertrophic cardiomyopathy, and its prevention continues to remain a major challenge. The role of amiodarone is unclear at this time because of the conflicting data in regard to reduction of sudden death risk, primarily to the lack of concurrent controls (240,241). Studies involving the ICD with small numbers of patients have had mixed results (242,243 and 244), and essentially, there is currently no consensus or standard prophylactic indication designated for the ICD in this disease. The clinical presentation with syncope was most likely to result in ICD implant in one multicenter study (245). Beta-blockers also serve as the cornerstone of therapy in symptomatic patients and some asymptomatic family members of patients with the long QT syndrome for the prevention of sudden cardiac death. The prophylactic use of the ICD in selected high-risk patient with long QT syndrome, arrhythmogenic right ventricular dysplasia, the Brugada syndrome, a family history of sudden death, and hypertrophic or dilated cardiomyopathy is widely practiced based on retrospective nonrandomized studies or case reports and personal experience. It is anticipated that genetic and clinical risk factors will emerge in these diseases and will aid in identifying those at risk for ventricular arrhythmias so cost effective use of therapy may be implemented (246).

Secondary Prevention Strategies for Sudden Cardiac Death

In contrast to the larger high-risk population of patients who have never experienced a cardiac arrest, the absolute numbers of patients who survive a cardiac arrest and are at high risk for recurrence are small; yet their relative risk in regard to recurrence is exceedingly high (eFig. 68.0.7). Candidates for secondary prevention strategies, therefore, are a small subset in the overall population of cardiac arrest victims, in whom aggressive intervention is warranted to optimize survival. It is equally important to realize that the risk of sudden death is predicated by the presenting clinical arrhythmia and LV function. The patients with well-tolerated VT or syncopal VT do not carry the same risk as a sudden death survivor, although they are frequently lumped together in studies regarding management strategies for sudden death. There is, however, a clearly established time dependence of risk after a cardiac event (such as cardiac arrest, MI, or onset of congestive heart failure). The risk of sudden cardiac death is highest within the first 6 to 18 months after the index cardiovascular event; following this initial attrition, this risk reduces to the preexisting level for that subgroup (151,247). This time dependence of risk should be taken into consideration when management strategies are considered.

Antiarrhythmic Drug Therapy

Empiric antiarrhythmic drug therapy with class I drugs is now considered ineffective and unsafe in the management of sustained VT or VF, but amiodarone may be used in selected cases. Drug therapy for VT or VF has also been guided either by serial electrophysiologic testing or using Holter monitoring. Several pitfalls in the utility of either strategy may limit their use. The Electrophysiologic Testing Versus Holter Monitoring trial was the most recent large-scale randomized trial of antiarrhythmic drug therapy addressing the efficacy of an electrophysiologically guided versus Holter-guided approach in the treatment of ventricular tachyarrhythmias (181). Although the study concluded that both methods were equivalent, what was evident was that class I drugs were inferior to sotalol, and neither method was effective in predicting arrhythmia-free survival because all drugs had a high failure rate. Despite this, sotalol had an arrhythmia recurrence rate of over 50%, a 20% risk of arrhythmic death at 4 years for all drugs, and a 15% sudden death risk for sotalol in apparent drug "responders" at 2-year follow-up (248). In clinical practice, this may permit the selection of sotalol for hemodynamically stable VT associated with preserved LV ejection fraction. On the background of the Electrophysiologic Testing Versus Holter Monitoring trial, the efficacy of D,L-sotalol was compared directly with the ICD in a population of patients with VT and VF (249). In this case control study, ICD therapy was more effective than electrophysiologically guided therapy with D,L-sotalol in sudden death prevention and total mortality. No sudden deaths occurred in the ICD group and total mortality at 3-year follow-up was 15%. In contrast, the sudden death rate, despite demonstrable suppressibility with D,L-sotalol, was 15%, and total mortality was 25%.

Amiodarone is a potent antiarrhythmic agent with complex electrophysiologic effects. Its ability to suppress inducible VT and VF is relatively low, yet initiation of VT during therapy does not necessarily preclude a favorable clinical response (250,251). In general, however, failure of suppression, easier mode of induction, or hemodynamic instability during the induced tachycardia foretell the recurrence of arrhythmia or cardiac arrest (250,251 and 252). This disparity in the electrophysiologic and clinical outcome has been the basis for the empirical use of amiodarone in sudden death survivors. Empirical therapy with amiodarone for VT and VF was associated with a sudden death risk of approximately 21% during a 5-year follow-up in two large series (253,254). There are no placebo-controlled trials of amiodarone in VT or VF. In the Cardiac Arrest in Seattle Conventional versus Amiodarone Drug Evaluation trial, 228 cardiac arrest survivors were randomized between empirical amiodarone or electrophysiologically guided or Holter-guided antiarrhythmic drug therapy (255). An ICD was assigned to equal numbers of patients in both limbs. This is the only randomized trial of amiodarone versus other antiarrhythmic drugs. The amiodarone group fared better than the group treated with conventional antiarrhythmics in terms of cardiac mortality, syncope, and recurrent cardiac arrest, yet only approximately 40% of the amiodarone group was free of cardiac death or sustained arrhythmia at a 6-year follow-up. Amiodarone was associated with significant toxicity in this trial. Empiric beta-blocker therapy has limited value as monotherapy for secondary prevention, even in conditions such as long QT syndrome, idiopathic VT, exercise-induced VT, or VF. It should, therefore, be used as adjunctive therapy with other specific antiarrhythmic therapy.

Role of Myocardial Revascularization

Myocardial revascularization is a rational therapeutic component of secondary prevention strategies when myocardial ischemia is suspected or documented as an acute initiating event. Both preoperative and postoperative inducibility and the type of ventricular tachyarrhythmia induced during the electrophysiologic testing are important in decision making. Revascularization may be the only therapy required in a cardiac arrest survivor with critical coronary stenosis and significant myocardium in jeopardy, with normal ventricular function, and inducible VF preoperatively, but who is noninducible postoperatively (256,257 and 258). Revascularization alone is insufficient in patients with either preoperative clinical or inducible monomorphic VT. These patients also require arrhythmia surgery, ICD implantation, antiarrhythmic drug therapy, or combinations of these. At present, extrapolating these long-term data regarding the role of myocardial revascularization to catheter-based coronary interventions such as angioplasty or intracoronary stents to protect from cardiac arrest is difficult (258). This is particularly important because restenosis or acute closure, which occasionally complicates these interventions, may have catastrophic consequences.

Role of Arrhythmia Surgery and Catheter Ablation

The ideal candidate for arrhythmia surgery is one with a single clinical monomorphic VT that is inducible and mappable, a post-MI anterior aneurysm, no significant disease in the other coronaries, and normal contractility of the other segments of the LV. Map-directed surgical cryoablation or subendocardial resection has a high success rate of cure (90% to 100%), with a perioperative mortality of approximately 10% in experienced centers (184). However, this therapy is not feasible in most survivors of cardiac arrest because monomorphic VT is uncommon as an initial rhythm, other selection criteria are usually not met, and there is a growing reluctance to use this in the era of the transvenous ICD. Catheter ablation may be curative in a few cardiac arrest survivors when the putative mechanism is VT due to bundle branch reentry or right ventricular dysplasia or is documented to be a primary supraventricular tachycardia (accessory pathway or AV nodal reentry).

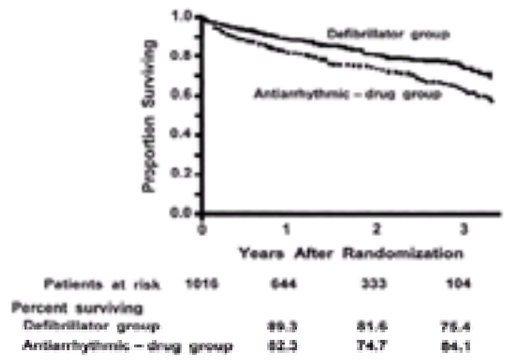
Role of the Implantable Cardioverter Defibrillator

The ICD was conceived, developed, and used as a secondary prevention strategy for those at high risk of sudden death due to failure of "conventional antiarrhythmic therapy." The effectiveness of the ICD in this regard, using historical controls, was demonstrated in several large populations over the long-term (259,260), albeit without randomization. Sudden death rates with the ICD are approximately 4% to 5% at 5-year follow-up, and the operative mortality with present systems is roughly 1%. In response to nagging doubts as to whether the sudden death reduction by the ICD translates into total mortality reduction, four prospective randomized trials were completed.

In the Dutch study, 60 cardiac arrest survivors were randomized to either early ICD as first-choice therapy or a conventional electrophysiologically guided strategy. The primary objective was to compare the effectiveness and cost of each approach. Early ICD implantation was superior for overall survival (4 deaths vs. 11 in the conventional arm) and more efficient and cost effective than the conventional electrophysiologically guided approach (261,262). The Cardiac Arrest Study Hamburg randomized cardiac arrest survivors to receive propafenone, metoprolol, amiodarone, or the ICD without concomitant drug therapy, with total mortality as a primary end point (263). The propafenone limb of the study was discontinued after an interim analysis because of excess total mortality, sudden death, and cardiac arrest recurrence compared with the ICD group. The investigators have reported a 2-year 39% reduction in total mortality in the ICD arm compared with the drug arm (amiodarone and metoprolol), and curiously, no difference in mortality between amiodarone and metoprolol (264).

The Antiarrhythmics versus Implantable Defibrillators trial (AVID) was the first large-scale randomized study comparing the ICD with antiarrhythmic drugs in patients with documented VT or VF (265). The mean follow-up for the 1,016 randomized patients was approximately 19 months. Total mortality in the ICD group was 10.7%, 18.4%, and 24.6% at 1, 2, and 3 years, which compared with the antiarrhythmic group at 17.7%, 25.3%, and 35.9%, respectively, represents a 39%, 27%, and 31% annual mortality reduction by the ICD over the 3 years (eFig. 68.0.13). The majority of the ICD benefit occurred in the first 9 months and in those patients with an

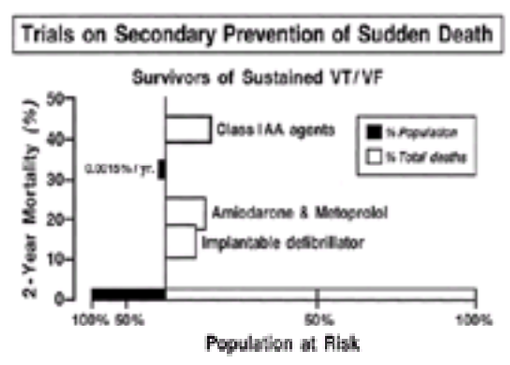
ejection fraction less than 35%.



***e*FIGURE 68.0.13** Total mortality in the Antiarrhythmics versus Implantable Defibrillators trial. [From The Antiarrhythmic versus Implantable Defibrillators (AVID) Investigators. A comparison of antiarrhythmic drug therapy with implantable defibrillators in patients resuscitated from near-fatal ventricular arrhythmias. *N Engl J Med* 1997;337:1576–1583, with permission.]

The Canadian Implantable Defibrillator Study (CIDS) (266) randomized 659 patients with hemodynamically unstable VT or cardiac arrest survivors to an ICD or empiric amiodarone. There were 98 and 83 deaths in the amiodarone and ICD groups, respectively. Those patients who were most likely to benefit from the ICD were identifiable by the clinical variables of age greater than 70, LV ejection fraction less than 35%, and New York Heart Association class III or IV. These findings suggest that those with moderate to severe LV dysfunction benefit the most, and as in AVID, this subgroup appears to bestow the mortality benefit to the entire ICD-treated group.

Overall, the results of the Dutch study, AVID, Cardiac Arrest Study Hamburg, and CIDS have established the ICD as front-line therapy in the realm of secondary prevention (eFig. 68.0.14). The magnitude of all-cause mortality benefit from ICD therapy varied depending on the competitive therapy evaluated (i.e., ICD benefit is greater than comparing it with class I drugs). Trials of ICD therapy versus amiodarone consistently demonstrate an approximate 28% relative mortality reduction with the ICD. In all these trials, ICD therapy was affected by the evolution of technology, and it is likely that ICD risk was higher with the thoracotomy systems. Patients with VF were enrolled in all four trials; patients with unstable VT were enrolled in two trials and accounted for 41% (CIDS) and 55% (AVID) of all enrollments; CIDS also enrolled patients with unmonitored syncope and otherwise documented VT, accounting for 14% of the study. Patients with cardiac arrest contribute to less than 1% of all deaths among patients at risk. The inconsistencies in the use of beta-blockers, sotalol, and amiodarone in the non-ICD limbs in these trials has confounded the interpretation of the data to some degree.

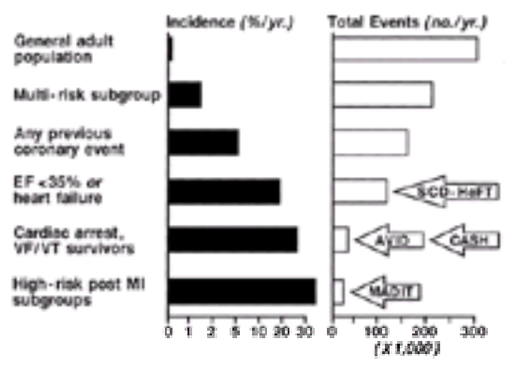


***e*FIGURE 68.0.14** Relationship of subgroup 2-year mortality risk (*vertical axis*) to subgroup size as proportion of total population (*left horizontal*) and proportion of all-cause mortality among population subgroups based on therapy assignment in the four randomized controlled trials on secondary prevention of sudden death. VT/VF, ventricular tachycardia/ventricular fibrillation. (From Cappato R, Kuck KH. Secondary prevention of sudden death. *J Intervent Cardiac Electrophysiol* 2000;4:39–44, with permission.)

CONTROVERSIES AND PERSONAL PERSPECTIVES

Bystander cardiopulmonary resuscitation is rarely performed, resulting in significant loss of life. These practices are based largely on unfounded fears of side effects and complications of intervention, when in reality the risk is far lower than perceived. Public awareness and education in cardiopulmonary resuscitation are also woefully inadequate and need to become part of the basic educational curriculum. Despite the precedence of sound clinical data, there appears to be an underuse of validated prevention strategies in sudden cardiac death. Based on surveys of physician practices, only a fraction of patients with established coronary artery disease or hypercholesterolemia actually receive aggressive cholesterol-lowering therapy. Even fewer receive beta-blockers post-MI or angiotensin-converting enzyme inhibitors, especially if they have ventricular dysfunction, although they stand to gain the most. Similarly, a significant proportion of eligible patients do not receive prompt thrombolytic therapy or revascularization to limit infarct size.

The ICD, initially used as secondary prevention therapy, has gained increasing attention in prophylactic therapy in the patient at high risk of sudden cardiac death as an alternative to the inevitable vagaries, relative inefficacy, and risks of antiarrhythmic drug therapy. There are now trial data to support the ICD in those who have survived a cardiac arrest or syncopal VT and in the high-risk patient with ischemic cardiomyopathy and asymptomatic nonsustained VT. The young cardiac arrest survivor with preserved LV function and the older survivor with advanced ventricular dysfunction are both at high risk, but one must have different expectations of the degree of ICD benefit each would receive because arrhythmic death constitutes only a fraction of total cardiac death, and this component varies with the population selected. The ICD as a bridge to cardiac transplantation is a theoretically sound concept that appears to be most appropriate for patients with a realistic chance of transplantation, because of the competing causes of mortality in this population, and ongoing studies such as SCD-HeFT will likely clarify the dilemma in the large population with advanced ventricular dysfunction (eFig. 68.0.15).



***e*FIGURE 68.0.15** Influence of emerging implantable cardioverter-defibrillator trials in at-risk population subgroups. SCD-HeFT is likely to affect larger subsets than MADIT, AVID, and CASH. EF, ejection fraction; MI, myocardial infarction; VF/VT, ventricular tachycardia/ventricular fibrillation. (From Myerburg M, Mitrani R, Interian A, et al. The interpretation and clinical application of data from trials on sudden death. *J Intervent Cardiac Electrophysiol* 2000;4:95–102, with permission.)

The issues, therefore, that need clarification are defining the high-risk population that stands to benefit the most and quantifying the degree, quality, and cost of life prolongation by the ICD as a clinical benefit. The issue of whether ICDs prolong life is a foregone conclusion.

THE FUTURE

Continued advances in several fronts will shape the future of sudden cardiac death. The application of primary prevention measures, such as cholesterol reduction and coronary substrate-oriented strategies (thrombolytics and revascularization), intuitively hold promise for the long-term reduction of risk of sudden cardiac death. Defining the person at risk by genetic markers (as in those with ventricular hypertrophy, hypertrophic cardiomyopathy, and long QT syndrome) and improved indices of autonomic dysfunction will facilitate primary prevention. Community awareness and education in cardiopulmonary resuscitation, especially with the availability of automatic external defibrillators, can greatly affect survival. Meanwhile, the role of the ICD needs to be defined and validated for primary prevention in the high-risk subgroups, such as those with advanced ventricular dysfunction.

OVERVIEW

Closed-chest cardiopulmonary resuscitation (CPR), first described in 1960, circulates blood throughout the body by two different mechanisms: direct cardiac compression (the cardiac pump) and changes in intrathoracic pressure (the thoracic pump).

The most common victim of sudden, unexpected cardiac arrest is a male who is between 50 and 75 years of age and who has underlying coronary artery disease. The most common initial rhythm is pulseless ventricular tachycardia or ventricular fibrillation.

The most effective approach to resuscitation is to establish a strong chain of survival with early access, early CPR, early defibrillation, and early advanced cardiac life support. Public access to defibrillation is a promising new strategy for strengthening the early defibrillation link in the chain.

A variety of monitoring techniques can, and should, be used during clinical resuscitation.

There is little evidence that high-dose epinephrine is any better than standard 1-mg doses of epinephrine. Vasopressin is now considered to be an acceptable alternative for the first dose only in treating pulseless ventricular tachycardia or ventricular fibrillation in the adult. Sodium bicarbonate is of very limited value in most cardiac arrest cases, unless hyperkalemia is present or the patient has taken an overdose of a tricyclic antidepressant or barbiturates. Intravenous amiodarone is now the preferred antiarrhythmic agent for treating pulseless ventricular tachycardia or ventricular fibrillation. Several promising new CPR techniques are currently undergoing clinical testing.

GLOSSARY

Automated external defibrillator (AED): A defibrillator that automatically determines the cardiac rhythm and advises rescuers of the need to defibrillate using voice prompts. Fully automated devices charge and deliver the defibrillation energy with no input from the user. Semiautomated devices prompt the user to defibrillate when ventricular fibrillation is detected by the device.

Chain of survival: A coordinated system for treating victims of cardiac arrest that provides early access to emergency medical services, early cardiopulmonary resuscitation (CPR), early defibrillation, and early advanced cardiac life support (ACLS).

High-dose epinephrine: Doses of epinephrine of greater than 1.0 mg in adults (typically 3 to 15 mg).

Public access defibrillation: The use of AEDs by laypersons.

Pulseless electrical activity (PEA): During cardiac arrest, an organized cardiac rhythm that does not generate a pulse. Previously known as electromechanical dissociation (EMD).

HISTORICAL PERSPECTIVE

Numerous and often barbaric methods to restore life to the newly deceased have been attempted for centuries (1). It was not until the last 50 years that the era of modern-day CPR was born. The field of resuscitation that exists as we enter the twenty-first century is an integrated science combining chest compression, ventilation, defibrillation, and pharmacotherapeutics with widespread use in both the prehospital and in-hospital arenas. Although it is difficult for us today to imagine these elements independently, that is precisely how they began.

Artificial Ventilation

Nearly 200 years of effort and experimentation to determine an effective method of artificial respiration culminated in the work performed by Archer Gordon in 1949. Gordon attempted to compare various methods of artificial respiration. For 1 year, with no salary and no funding, Gordon slept in Cook County Hospital in Chicago, where he was on call 24 hours a day. He would insert a tube into the trachea of fresh corpses and perform multiple posturing techniques such as lifting the arms and pressing on the back or chest, lifting the hips, or rocking the deceased patient. He would then observe the effects of these procedures via a respirometer connected to the tracheal tube. These results were first published in *Journal of the American Medical Association* in 1950 (2).

In 1951, Gordon performed similar studies on medical students anesthetized with curare. Later that year he published a wealth of data (3) supporting the notion that these techniques were able to provide some degree of manual respiration. There were two limitations to Gordon's relentless efforts. The first was that he alluded only

to the idea of mouth-to-mouth ventilation and did not evaluate this technique; the second was that all of his data were collected in intubated patients in whom the airway was fully protected.

Simultaneous with these efforts, James Elam discovered that by merely using expired air, one could oxygenate humans adequately. His discovery was born out of a need to ventilate patients suffering form acute paralysis during the polio epidemic in 1946. From his repeated experience in performing mouth-to-nose breathing over a several-year period, he was convinced of its value. To scientifically document his beliefs, in 1954 Elam studied intubated, anesthetized, nonbreathing postoperative patients. He merely blew into their tracheal tubes with his own exhaled air and documented that by doing this he could maintain normal arterial oxygen saturation.

It was not until 1956 that fate brought Elam and his data together with Peter Safar. Lively discussion enticed Safar to begin experiments with mouth-to-mouth artificial respiration. By 1957, Safar had proven that the mouth-to-mouth technique was clearly superior to the manual ventilation techniques that were currently used and that it could be performed quite easily by laypersons (4). He was also able to document that by tilting a person's head backward, the airway would usually remain open, thus enhancing previous data that used patients with protected airways.

By 1958, the works of Gordon, Elam, and Safar persuaded the American Medical Association and the U.S. military to adopt the mouth-to-mouth technique as the official means to provide artificial respiration.

Electrical Therapy

Electrotherapy was used as common practice for a variety of ailments ranging from paresis to death throughout much of the eighteenth and nineteenth centuries. Unfortunately, there was little known about electrical forces or the ailments they purportedly treated, and there was no benefit to survival from their use. Quite comically, it took several decades to link electricity to the appropriate treatment for many instances of sudden death. Until the development of the electrocardiograph, ventricular fibrillation was a diagnosis that could be made only by observing the heart. It was first described in 1850 by Karl Ludwig in the dog laboratory (5). Ludwig noted that he could induce ventricular fibrillation by applying galvanic currents directly to a dog's heart. Although this was likely the first link between electricity and sudden death, the connection was ignored for decades. In 1889, John McWilliam refuted the notion that sudden cardiac death was caused by ventricular standstill by describing a fibrillating heart in the dog laboratory. He documented, as others had before him, that electricity could induce this event in the canine model (6). Unfortunately, he never attempted to use electricity to terminate the events. Although he postulated that a similar scenario may occur in humans, he did not pursue this. It was not until a decade later that two French physiologists, Frederic Battelli and Jean Louis Prevost, reported that, although a weak current passed through the heart could cause fibrillation, a stronger current was capable of terminating it (7). This singularly important discovery remained dormant for the next several decades.

In the late 1920s the Electric Company and Edison Power Company reconsidered the idea of coupling electricity with defibrillation. They commissioned William Kouwenhoven, Donald Hooker, and Orthello Langworthy at Johns Hopkins University to research electrical effects on the heart. This group quickly documented that weak shocks could induce ventricular fibrillation and stronger shocks could eradicate it. They were the first to discover that defibrillation could be successfully performed without opening the chest (8). The group also coined the term "countershock," which was used synonymously with *defibrillation*. An initial shock placed the heart into ventricular fibrillation and a subsequent countershock could terminate it. None of these researchers pursued the possibility of using this countershock in humans to terminate ventricular fibrillation.

Two decades passed until Claude Beck successfully defibrillated a patient. Based on the work of Kouwenhoven, Hooker, and Langworthy, Beck constructed an alternating current internal defibrillator. Although he was successful in resuscitating a pediatric patient who developed ventricular fibrillation during cardiac surgery, it took another 8 years for him to successfully use his device on another patient.

In 1955, Paul Zoll developed an external alternating current defibrillator. On a case-by-case basis, he documented that external defibrillation could be performed safely and effectively (9).

Defibrillators using alternating current were quite heavy and cumbersome. It was very difficult to transport this equipment to needy patients in an emergency situation. In 1960, Bernard Lown developed a direct current defibrillator that was battery operated and readily transportable. This piece of equipment was the first in a long line of modern direct current defibrillators.

Closed-Chest Compressions

The first documented case of closed-chest compression for the treatment of cardiac arrest in the United States was in 1904 (10). Without the aid of defibrillation or pacing to restart the heart, the concept was not particularly useful and never gained extensive popularity. It was not until the late 1950s that the technique of closed-chest massage was stumbled on once again. Kouwenhoven and Guy Knickerbocker were studying fibrillation in their animal laboratory at Johns Hopkins University. While performing experiments to determine how long a canine's heart could be left fibrillating and still be successfully cardioverted, Knickerbocker noted that when he placed the defibrillator paddles snugly against the closed chest of the dog there was a slight increase in arterial pressure. The investigators noted that by applying the paddles in a repetitive motion they could prolong the time that the heart could stay in fibrillation and be defibrillated successfully. James Jude joined the group, and the team began performing multiple studies using the hands to compress the chest. Through a series of trial and error experiments, it was determined that downward pressure of 1.5 to 2.0 in. on the lower sternum at a rate of 60 to 80 per minute was the optimal way to perform this maneuver. The investigators published data derived from patients suffering from in-hospital cardiac arrest in 1960. Fourteen of 20 patients survived to discharge from the hospital (11). It was finally understood that closed-chest compressions could "buy time" for the patient with a fibrillating heart until the external defibrillator arrived.

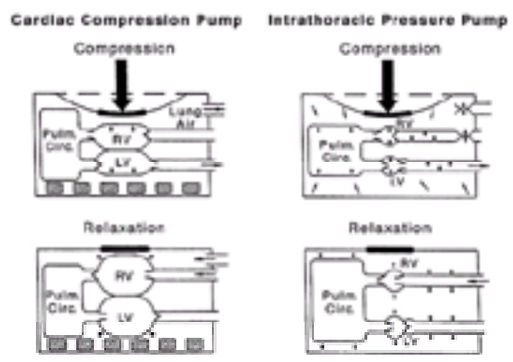
Modern-Day Cardiopulmonary Resuscitation

It was not until Safar, Kouwenhoven, and Knickerbocker presented their scientific data at the Maryland Medical Society meeting September 16, 1960, that artificial ventilation was combined with artificial circulation to create CPR. The trio lectured around the world to promote the concept of CPR. Gordon produced a training film in 1962 that coined the mnemonic ABC (*a*irway, *b*reathing, *c*irculation). The popularity of this technique that could be performed by anyone anywhere spread quickly.

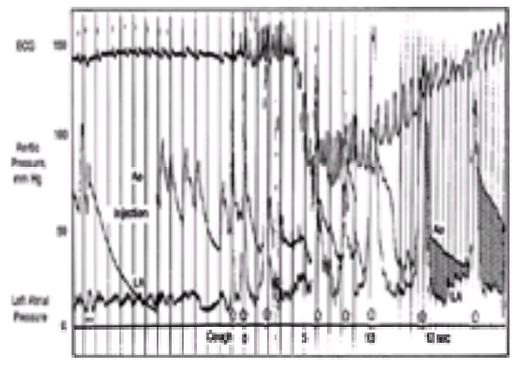
The American Heart Association officially endorsed CPR in 1963 and developed a CPR committee. In 1966 the National Research Council of the National Academy of Sciences brought together representatives from more than 30 organizations, such as the American Red Cross, and established official recommendations regarding standardized training and performance of CPR (12). Since then, the American Heart Association has hosted special conferences in 1973, 1979, 1985, 1992, and 2000 to establish consensus recommendations for resuscitation. Each of these conferences was followed by publication of educational documents that have been used worldwide to teach the science of resuscitation (13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35,36,37 and 38).

MECHANISM OF BLOOD FLOW DURING CARDIOPULMONARY RESUSCITATION

For 15 years after the discovery of closed-chest compression, it was generally believed that blood flow during CPR is caused by direct compression of the heart between the sternum and the spine ("cardiac pump" theory) (eFig. 69.0.1). In the 1970s, the cardiac pump theory was challenged by investigators who observed that increased intrathoracic pressure alone (without precordial compression) can generate blood flow. Criley et al. (39) reported that increases in intrathoracic pressure by repeated coughing could maintain adequate systemic blood pressure and flow to maintain consciousness without precordial compression in a patient who developed ventricular fibrillation during cardiac catheterization (eFig. 69.0.2). This observation was confirmed by Niemann et al. (40), lending further support to the notion that pressurization of the thoracic cavity could generate blood flow and pressure by forcing blood out of both the heart and thoracic vessels. A sudden increase in the intrathoracic pressure causes air trapping in the alveoli and small bronchioles during chest compression, creating a pressure gradient between the intrathoracic and extrathoracic cavities (41). According to this "thoracic pump" theory, the heart functions as a passive conduit (eFig. 69.0.1) (42). Pressurization of the thorax collapses veins at the thoracic inlet, preventing venous backflow (43). Forward flow occurs because the more muscular arteries remain open, particularly if epinephrine is administered exogenously.



***e*FIGURE 69.0.1** Mechanisms of blood flow during cardiopulmonary resuscitation. LV, left ventricular; Pulm. Circ., pulmonary circulation; RV, right ventricular. (From Halperin HR. Mechanisms of forward flow during external chest compression. In: Paradis NA, Halperin HR, Nowak RM, eds. *Cardiac arrest: the science and practice of resuscitation medicine*. Baltimore: Williams & Wilkins, 1996:253, with permission.)



***e*FIGURE 69.0.2** Cough cardiopulmonary resuscitation. Ao, aortic pressure; ECG, electrocardiogram; LA, left atrial pressure. (From Criley JM, Blaufuss AH, Kissel GL. Self-induced form of cardiopulmonary resuscitation. *JAMA* 1976;236:1246–1250, with permission.)

The relative contribution of the cardiac and thoracic pump mechanism has been debated (42,44,45 and 46). Transesophageal echocardiography (TEE) studies during CPR demonstrate that both mechanisms are operative in humans (45,47,48,49 and 50). Sternal compression virtually always squeezes blood out of the right ventricle (cardiac pump), whereas the amount of left ventricular compression is highly variable among patients (48). Physiologic studies in experimental models (51) and humans (52) suggest a strong role for the thoracic pump. In addition, active decompression of the chest by application of negative pressure or suction to the sternum can further enhance cardiac output by improving venous inflow (*e*Fig. 69.0.3) (53,54,55,56,57 and 58). Finally, interposing an abdominal compression between each chest compression has also been tried in an attempt to mimic the physiologic effects of intraaortic balloon counterpulsation (*e*Fig 69.0.4) (59,60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80,81 and 82).

CLINICAL PROFILE OF SUDDEN, UNEXPECTED CARDIAC ARREST

Most episodes of sudden, unexpected cardiac arrest in adults occur in the home or workplace (83,84,85 and 86). The most common victim is a male who is between 50 and 75 years of age (83,85). The majority of these individuals has significant underlying structural heart disease such as coronary artery atherosclerosis, hypertension, left ventricular hypertrophy, and/or congestive heart failure (84,87,88,89 and 90).

Most cardiac arrests occur without an obvious immediate precipitant, although many families of cardiac arrest victims will report that the patient experienced a variety of nonspecific symptoms such as chest pain, dyspnea, fatigue, or malaise in the days preceding the event (84,87). On rare occasions, a dramatic emotional event can trigger cardiac arrest (91,92,93,94 and 95).

There is a definite circadian pattern to the onset of sudden, unexpected cardiac arrest. The incidence of cardiac arrest is lowest during sleep and begins to rise rapidly soon after awakening (96,97 and 98). Heart rate variability studies show that, at such times, vagal activity is relatively low and sympathetic activity is high, especially in patients with reduced left ventricular function (99).

In more than 80% of patients who develop out-of-hospital, primary cardiac arrest during ambulatory electrocardiographic monitoring, the initiating event is a ventricular

tachyarrhythmia (ventricular tachycardia) degenerating rapidly to ventricular fibrillation in 62%, torsades de pointes in 13%, and "primary" ventricular fibrillation in 8% (100). Less than 70% of patients are in ventricular tachycardia or ventricular fibrillation by the time rescue personnel arrive on the scene [typically 5 to 10 minutes after the onset of collapse in most efficient emergency medical services (EMS) systems] (101). Most of the remaining patients (31%) are in a pulseless, bradycardic rhythm or asystole.

The outcome of field resuscitation is strongly influenced by the patient's initial cardiac rhythm. In one series of 352 consecutive out-of-hospital cardiac arrest patients, 67% of the patients with ventricular tachycardia and 23% of those who were initially in ventricular fibrillation survived to hospital discharge (102). None of the patients who presented with an initial bradyarrhythmia survived to hospital discharge. Similar observations have been made by others (103). One plausible hypothesis is that pulseless bradycardia or asystole may be a marker for a prolonged downtime interval or a more severe underlying disease process (104). Because ventricular tachyarrhythmias represent the most common, potentially treatable mechanism of sudden cardiac arrest in adults, the best in-hospital and out-of-hospital resuscitation programs have been designed to deliver rapid defibrillation to as many patients as possible.

PRINCIPLES OF MANAGEMENT

"Chain of Survival" Approach to Treatment

Survival from pulseless ventricular tachycardia or ventricular fibrillation is inversely related to the time interval between its onset and termination. Each minute that a patient remains in ventricular fibrillation, the odds of survival decrease by 7% to 10% (105). Survival is highest when CPR is started within the first 4 minutes of arrest and ACLS, including defibrillation and drug therapy, is started within the first 8 minutes (106). The American Heart Association's Emergency Cardiovascular Care Committee and its Advanced Cardiovascular Life Support Subcommittee began to widely publicize the "chain of survival" concept in 1991. This symbolic phrase represents a sequence of events that should occur in most cardiac arrest cases to maximize the odds of successful resuscitation (105). The steps include early recognition of the problem and activation of the EMS system by a bystander, early CPR, rapid provision of defibrillation for patients who need it, and ACLS (e.g., intubation, administration of medications). Schematically, this sequence can be depicted by a "chain of survival" (Fig. 69.1).

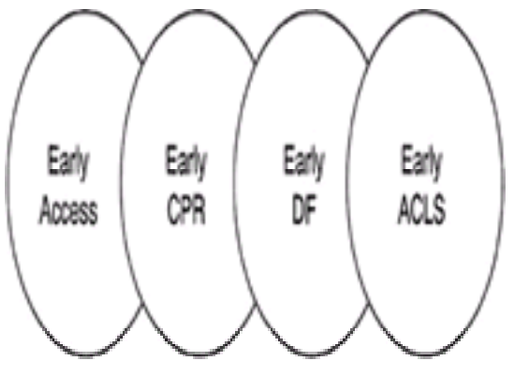

FIGURE 69.1 Chain of survival to optimize outcome from resuscitation. ACLS, advanced cardiac life support; CPR, cardiopulmonary resuscitation; DF, defibrillation.

Early Access

The victim is rarely in a position to activate the EMS system before his or her collapse because most out-of-hospital cardiac arrests occur suddenly and without immediate premonitory symptoms. The same problem exists for in-hospital cardiac arrests that occur in unmonitored patients. Bystanders who witness the event can significantly improve the victim's chance to survive by alerting the emergency response system to the presence of the problem. All too often, an untrained bystander only further delays treatment of the out-of-hospital cardiac arrest victim by attempting to inform relatives, call the neighbors, or contact the patient's personal physician instead of calling the local community emergency telephone number (in most places it is 9-1-1) (107,108).

Before EMS rescuers can aid the victim, the bystander must recognize that there is a problem, locate a telephone, make a correct call, and give accurate and precise information to the dispatcher. Once the alarm has been sounded, rescuers must travel to the scene, physically arrive at the patient's side, and perform an initial, cursory assessment.

Public education can improve bystander behavior significantly when a cardiac emergency occurs in the community. Citizens can be trained to summon help quickly and to initiate lifesaving CPR. For example, bystanders in Seattle initiated CPR in only 5% of cardiac arrests in 1970 to 1971, but by 1976, 34% of cardiac arrest victims were receiving bystander CPR as a result of a widespread, pioneering, public education campaign (105). Since then, the American Heart Association and the American Red Cross have trained millions of citizens to recognize cardiac emergencies, call for help, and perform CPR.

Availability of the simple three-digit 9-1-1 emergency number in the United States can reduce confusion and decrease delay in activating the EMS system. In Minneapolis, the percentage of emergency callers who could activate the EMS system in less than 1 minute rose from 63% before institution to 82% after institution of a 9-1-1 number (109). Only two states currently have 9-1-1 available everywhere within their borders. One community in North Carolina lists 85 different emergency numbers in the local telephone book (110,111). The American Heart Association has recommended that all communities implement an enhanced 9-1-1 system that displays the caller's location automatically on the dispatcher's terminal when the call is received (105). Having a similar, easy-to-remember number would also be useful for in-hospital emergencies.

Early Cardiopulmonary Resuscitation

The next link in the chain is early initiation of CPR, preferably by bystanders. One way to ensure initiation of early CPR is to educate and train a "critical mass" of the general population. The effectiveness of such training has varied widely. In Seattle, approximately 50% of the population has been trained to perform CPR (87), whereas in Minneapolis only 23% of adults surveyed have received such training (112). In smaller cities and in less affluent areas, the number of trained citizens is often much lower. What percentage of adults need to be trained in CPR to provide reasonable protection in the community is difficult to determine with certainty. As a rule of thumb, the American Heart Association recommends that at least 20% of the adult population should be trained in basic CPR to reduce mortality from out-of-hospital cardiac arrest (113). It is also important to train a critical mass of in-hospital personnel to ensure that proper CPR can be performed on all cardiac arrest victims in all areas of the hospital while awaiting arrival of "code team" personnel.

There are a number of problems associated with training the public to perform CPR. For example, it can be argued that we have trained the wrong rescuers. The typical cardiac arrest victim is male, is 60 to 65 years old, and usually arrests at home, often in the presence of a spouse of similar age (85). Most citizens who have taken CPR training are younger than 30 years of age; typically, less than 10% live with family members known to have heart disease (114). Most citizens who have received CPR training never actually witness or participate in managing a cardiac arrest; conversely, bystanders who witness a cardiac arrest usually do not know how to perform CPR (87,115). For example, only 10% of CPR-trained citizens in Minneapolis have witnessed an arrest, whereas only 30% of citizens present at the site of a cardiac arrest were trained in CPR (112). The majority of laypersons who attempt to perform CPR out-of-hospital are actually employed or volunteer their services as health professionals (116). The best solution to the problem seems to be targeting CPR training to "high-risk" individuals, such as middle-aged persons, senior center residents and staff, and family members (particularly the spouse) of patients who are survivors of myocardial infarction or cardiac arrest or who have other risk factors for cardiac arrest (114,117).

Skill retention is also a problem because CPR is a psychomotor technique that deteriorates rapidly over time unless practiced or used. In Belgium, 46% of bystanders who performed CPR forgot to perform mouth-to-mouth breathing; chest compressions were not done 17% of the time (118,119). It is important for laypersons or health care professionals who perform CPR infrequently to receive at least annual reinforcement. However, only about 20% of trainees return for annual training in the United States (87,112). Fear of communicable disease, particularly infection with the human immunodeficiency virus, that is disproportionate to the known minimal risk of disease transmission may decrease the likelihood that trained rescuers will actually perform mouth-to-mouth ventilation on strangers (120).

Although the value of bystander CPR was once debatable, virtually all studies have shown that initiation of bystander CPR within 4 minutes of the patient's collapse results in up to a 12-fold improvement in the odds for survival (105). The mechanism by which early CPR improves outcome is unclear but may be due to CPR's ability to keep coarse ventricular fibrillation from degenerating to asystole for a few extra minutes until rescuers arrive. Recent evidence from Seattle suggests that a brief

period (90 seconds) of CPR actually improves the odds of successful defibrillation if more than several minutes elapse before defibrillation can be provided (121).

Early Defibrillation

The rationale for the use of early defibrillation stems from four observations: (a) Ventricular tachyarrhythmias are the most common cause of sudden out-of-hospital cardiac arrest in adults; (b) defibrillation is the most effective treatment for pulseless ventricular tachyarrhythmias; (c) the effectiveness of defibrillation diminishes rapidly over time; and (d) unless treated promptly, ventricular fibrillation becomes less coarse and eventually converts to the less treatable rhythm of fine ventricular fibrillation or asystole.

The best outcomes from sudden arrhythmic cardiac arrest in adults have been reported from cardiac rehabilitation programs, where defibrillation can be performed within the first minute or two. In such “ideal” settings, 85% to 90% of patients are resuscitated and can be returned to their prearrest neurologic status (122,123 and 124). Survival from out-of-hospital cardiac arrest treated by EMS personnel has been considerably lower, averaging 15% to 20% or less, with a maximum survival of 30%, depending on the EMS system configuration (105).

The best survival is attained in EMS systems that can provide early defibrillation to a large percentage of patients. In most cases, this is most cost-effectively accomplished by a “tiered response” system, in which large numbers of rapid “first-response” firefighters or emergency medical technicians (EMTs) are trained and equipped to provide first aid, CPR, and early defibrillation using an AED.

Unfortunately, not all communities in the United States have yet implemented a comprehensive tiered EMS system. Some systems, particularly in suburban or rural areas, have only EMTs who are neither trained nor equipped to defibrillate. For such areas, adding rapid defibrillation capability offers a cost-effective alternative that can significantly improve survival from out-of-hospital ventricular fibrillation or pulseless ventricular tachycardia (125,126). In 1991, the American Heart Association issued a position statement advocating the widespread implementation of rapid defibrillation programs throughout the nation. The American Heart Association endorses the position that

“All emergency personnel should be trained and permitted to operate an appropriately maintained defibrillator if their professional activities require that they respond to persons experiencing cardiac arrest. This includes all first responding emergency personnel, both hospital and nonhospital (e.g., emergency medical technicians (EMTs), non-EMT first responders, firefighters, volunteer emergency personnel, physicians, nurses, and paramedics).

To further facilitate early defibrillation, it is essential that a defibrillator be immediately available to emergency personnel responding to a cardiac arrest. Therefore, all emergency ambulances and other emergency vehicles that respond to or transport cardiac patients should be equipped with a defibrillator” (127).

There has been continued progress in improving the chain of survival in every community. The American Heart Association is implementing “Operation Heartbeat” on a national level, which helps communities to identify and correct weaknesses in their chain of survival locally.

More novel strategies have also been tried to increase the availability of rapid defibrillation in the hospital and in the community at large. Kaye et al. pioneered the use of AEDs by non–intensive care nurses in an in-hospital setting (128,129). There has also been an increasing effort to place AEDs in high-risk public locations for use by trained laypersons.

Early Advanced Cardiac Life Support

Physicians provide prehospital ACLS by staffing specially equipped ambulances in many countries (e.g., Western Europe, Scandinavia, Canada). In the United States, “intermediate”-level EMTs or paramedics provide most prehospital ACLS intervention (e.g., defibrillation or synchronized cardioversion, endotracheal (ET) intubation, intravenous fluid therapy, drug administration). Intermediate EMTs (often called *cardiac technicians*) typically receive several hundred hours of training; paramedics usually receive 1,000 or more hours. Adding field ACLS capability appears to favorably impact survival from out-of-hospital cardiac arrest.

Some EMS systems have upgraded all transporting ambulances to ACLS status to eliminate the possibility that dispatchers might send a basic life support unit on a call that needs a higher level of care. An “all-ACLS” system eliminates the potential “failure point” in the 9-1-1 center because there is no triage of calls to an ACLS or basic cardiac life support response. Existing basic cardiac life support ambulances or first-responding vehicles can be upgraded to automated defibrillation capability with minimal expense. Automated defibrillators cost approximately $5,000 to $8,000 and require only 2 to 4 hours of additional training for first responders or EMTs. This is a nominal expense compared with the cost of a typical ambulance ($50,000 to $100,000) or fire truck ($250,000 to $500,000). In Richmond, Virginia, upgrading from a half basic cardiac life support/half ACLS system to an all-ACLS system added less than 1% to the cost of ambulance service (only $2.88 per patient transported) (130).

Algorithm Approach to Resuscitation

The American Heart Association’s ACLS algorithms provide a “framework for dealing with the life-threatening cardiopulmonary emergencies in a logical sequence” (17,18). There are algorithms for initiating CPR (Fig. 69.2), treating patients with ventricular fibrillation or pulseless ventricular tachycardia (Fig. 69.3), bradycardia (Fig. 69.4), asystole (Fig. 69.5), or PEA (Fig. 69.6), which was formerly known as EMD. However, the algorithms are “not appropriate for every unique clinical circumstance, and the team leader must adapt them and the general ACLS principles when necessary.” Resuscitation team leaders are encouraged to function as “thinking cooks” when applying these cookbook procedures.

Ventricular Fibrillation or Pulseless Ventricular Tachycardia

Electrical countershock is the treatment of choice for ventricular fibrillation and pulseless ventricular tachycardia. If three initial countershocks at increasing monophasic energies (200, 200 to 300, and 360 J), intubation, epinephrine, and a fourth countershock (360 J) fail to terminate the arrhythmia (refractory ventricular fibrillation or ventricular tachycardia) or if, as in many cases, the arrhythmia rapidly recurs (recurrent ventricular fibrillation or ventricular tachycardia), antiarrhythmic drug therapy is indicated (17). There is increasing evidence that biphasic defibrillation waveforms using lower energy (typically 125 to 175 J) defibrillate successfully and are at least as effective as higher-energy, escalating monophasic waveforms (131,132,133,134,135,136 and 137). The American Heart Association now considers biphasic waveforms to be an acceptable alternative to the traditional escalating monophasic waveforms (17,138).

Pulseless Electrical Activity

PEA is present when there is organized electrical activity on the electrocardiogram but no effective circulation. There are potentially many underlying causes, but the most common denominator may involve myocardial ischemia and dysfunction due to intramyocardial increases in carbon dioxide (139). Prognosis is generally poor unless a discrete and treatable etiology for PEA can be discerned and corrected. Because of the poor prognosis when a correctable etiology cannot be defined, efforts should be directed toward detecting causes such as hypovolemia, tension pneumothorax, and pericardial tamponade (17). Normal saline or Ringer's lactate solution should be infused rapidly if there is evidence of hypovolemia. Suspected pneumothorax or pericardial tamponade should be confirmed by needle aspiration of the chest or pericardium, respectively. If confirmed, more definitive surgical management (chest tube or thoracotomy) is usually required.

Scrutiny of the neck veins may be helpful in attempting to define an etiology for PEA. Most patients with cardiac arrest have high right-sided filling pressures and distended neck veins. When neck veins are not visible in this setting and PEA is present, hypovolemia should be suspected. In the "trauma" cardiac arrest victim (e.g., a patient with a gunshot wound of the chest), however, prominent neck veins should lead to the suspicion of pericardial tamponade or tension pneumothorax (140).

General measures such as (a) support of ventilation, (b) properly performed closed-chest compression, and (c) frequent doses of epinephrine to maintain arterial perfusion pressure and coronary and cerebral perfusion are recommended for treatment of PEA (17). Bradycardia may be treated with atropine. Although catecholamines are frequently given, there are no data to suggest a specific benefit (other than improvement in coronary and cerebral blood flow during closed-chest compression). Calcium chloride has not been shown to affect clinical survival in controlled trials (141,142). In addition, the pathologically high serum calcium levels caused by its administration (143,144) may exacerbate reperfusion injury (145).

If penetrating cardiac trauma is present, open-chest massage can be life saving (146). In other settings, open-chest massage is rarely of value, partly because it is usually initiated late after the onset of the arrest (147). Prehospital trauma victims who are pulseless and have asystole or agonal electrical cardiac activity (heart rate of less than 40 beats/min) have such a poor prognosis that some authors believe that they should be pronounced dead at the scene of injury (148).

Bradyasystole

Bradyasystole is one of the most common and least understood problems that can occur during resuscitation. For purposes of definition, *bradyasystole* efers to a cardiac rhythm that has a ventricular rate of below 60 beats/min in adults and/or periods of absent heart rhythm (asystole). Bradyasystolic states are clinical situations during which bradyasystole is the dominant heart rhythm.

Survival is poor (generally 1% to 3% or less), regardless of therapy for patients who present with bradyasystole. It is always important to exclude disconnection of a

lead or monitor electrode before concluding that a “flatline” is the patient’s rhythm. Because some patients with a flatline may have ventricular fibrillation (a rhythm more amenable to treatment) masquerading as asystole (149), the monitor lead configuration should be quickly switched to a second lead to confirm the diagnosis before treatment (17). Other general measures recommended for the treatment of bradyasystole include support of ventilation; properly performed closed-chest compression; and frequent doses of epinephrine to maintain arterial perfusion pressure and coronary and cerebral perfusion (17).

Treatment with atropine sulfate may improve outcome in patients with bradyasystolic cardiac arrest that is due to excessive vagal stimulation, but atropine is less effective when asystole or pulseless idioventricular rhythms are the result of prolonged ischemia or mechanical injury in the myocardium (150).

For patients with bradyasystolic cardiac arrest, a 1-mg dose of atropine is administered intravenously and is repeated every 3 to 5 minutes if asystole persists. Three mg (0.04 mg per kg) given intravenously is a fully vagolytic dose in most patients (151). The administration of a total vagolytic dose of atropine should be reserved for patients with bradyasystolic cardiac arrest. ET atropine produces a rapid onset of action similar to that observed with intravenous injection. The recommended adult dose of atropine for ET administration is 1.0 to 2.0 mg diluted in 10 mL of sterile water or normal saline.

Pacing (transvenous, transthoracic, or transcutaneous) rarely influences survival in the unwitnessed cardiac arrest patient who is initially found with asystole or bradycardia without a pulse (152,153 and 154). However, pacing is extremely useful for bradycardic patients with a pulse and in selected patients in whom a pacemaker can be placed immediately after the development of the conduction disturbance (153,154). In such cases, a precordial thump can also stimulate ventricular complexes and a pulse (“fist pacing”) (155).

Endogenous adenosine released during myocardial hypoxia and ischemia relaxes vascular smooth muscle, decreases atrial and ventricular contractility, depresses pacemaker automaticity, and impairs atrioventricular conduction (156). The cellular electrophysiologic effects of adenosine can be competitively antagonized by methylxanthines but not by atropine. A specific adenosine antagonist (BW-A1433U) has been shown to reverse and prevent postdefibrillation bradyasystole and hemodynamic depression in a domestic pig model (157).

Aminophylline, a competitive nonspecific adenosine antagonist, has been shown to restore cardiac electrical activity within 30 seconds in 12 of 15 in-hospital, bradyasystolic cardiac arrest patients who were refractory to atropine and epinephrine (158). Other anecdotal case reports seem to indicate that adenosine blockade may restore normal sinus rhythm in some bradyasystole patients who do not respond to conventional therapy (159). In a relatively small, randomized, prospective clinical trial on adults with asystole refractory to epinephrine and atropine, there was a trend toward improved return of spontaneous circulation (ROSC) in patients who received aminophylline versus placebo, but the results did not reach statistical significance (160). Forty-five patients were assigned to the placebo group, and 37 received aminophylline. Nine of 45 controls (20%; 95% confidence interval, 10% to 35%) achieved ROSC compared with 10 of 37 (27%; 95% confidence interval, 14% to 44%) in the aminophylline group. Although further clinical research will be necessary to determine the potential value of adenosine blockade for bradyasystolic cardiac arrest, it is clear that these agents should not be used when ventricular fibrillation is present because they may make it more difficult to terminate this arrhythmia (161).

Physiologic Monitoring during Resuscitation

Real-time hemodynamic data can provide the team leader with a sound physiologic basis for altering the approach to clinical resuscitation when the standard algorithms either fail or do not apply.

Arterial Pressure Measurement during Cardiopulmonary Resuscitation

Maintenance of both the systolic and diastolic arterial pressure is vital during CPR. Because flow to most vital organs (except the heart) occurs during systole, a minimal systolic arterial pressure of 50 to 60 mm Hg is usually required to resist arteriolar collapse (162). Diastolic pressure is also important because it is a critical determinant of the coronary perfusion pressure (CPP) (CPP = aortic diastolic – right atrial pressure) during CPR. CPP is one of the best hemodynamic predictors of ROSC in both animal models (46,163,164,165,166,167,168,169,170,171,172 and 173) and humans (174). A minimal threshold gradient for CPP of approximately 15 mm Hg (usually corresponding to an aortic diastolic pressure of 30 to 40 mm Hg) provides a level of myocardial blood flow that is necessary to meet the metabolic needs of the arrested myocardium (175) and to achieve ROSC (174).

A cuff manometer can be used to estimate the systolic arterial pressure during CPR by palpating the brachial artery or listening over it for flow with a peripheral Doppler device (176). More accurate, invasive measurements of systolic and diastolic pressure can be obtained by inserting an arterial line into the radial, brachial, or femoral artery (52,177,178,179,180,181,182,183 and 184). *e*Table 69.0.1 summarizes recent published invasive arterial pressure measurements during resuscitation in adult humans. Conventional CPR generates systolic, diastolic, and CPPs that are inadequate to sustain blood flow and function in vital organs (e.g., the brain). These measurements explain why cardiac arrest patients are rarely conscious during CPR.

Pulmonary Artery Catheter Recordings

Generation of a satisfactory arterial pressure is a prerequisite for adequate flow to vital organs; however, the presence of a reasonable arterial pressure does not ensure that there will be sufficient flow to meet metabolic needs. Pulmonary artery catheters are inserted infrequently during resuscitation because they are time-consuming to set up and technically difficult to position. The low flows generated by CPR do not favor ready passage of the balloon-flotation catheter through the right heart. In addition, it is difficult to determine the catheter tip’s position from pressure recordings because the pressures in the intracardiac chambers and great vessels are similar to each other during closed-chest CPR (51,185,186,187,188 and 189). Fluoroscopy is of little value during CPR, even if it is available, because it is not easy to continue chest compression impeded by the machine’s C-arm. TEE offers the greatest promise as a means to visualize and help position intracardiac catheters successfully during CPR.

Despite these technical limitations, there have been several published reports of intracardiac pressure and flow measurements in humans who were already being monitored invasively in an intensive care unit at the time of their cardiac arrest (190,191,192 and 193). Conventional closed-chest CPR in adult humans produces a hemodynamic state resembling profound cardiogenic shock, with a low systemic arterial pressure, markedly reduced cardiac output, and high intravascular filling pressures.

Pulmonary edema is noted commonly after CPR, either clinically if the resuscitation is successful or on autopsy if it is not. Dohi (192) found that 20 of 71 short-term survivors of CPR showed clinical signs of pulmonary edema; nine of these patients had overt signs of pulmonary edema (e.g., massive discharge of pink-foaming secretions through the ET tube). Nagel et al. (194) reported that 46% of 2,228 victims of out-of-hospital cardiac arrest had pulmonary edema on autopsy. Although there are multiple causes for pulmonary edema after CPR (e.g., aspiration, iatrogenous fluid overload, neurogenic stimuli, physical damage to the pulmonary capillary membrane, alteration of lymphatic drainage), the finding that pulmonary capillary pressure is high during CPR and returns to the patient’s baseline quickly after successful resuscitation suggests that hydraulic forces during the low blood flow state may be the most common mechanism responsible for the development of pulmonary edema during resuscitation (190). Hemodynamic monitoring post-CPR may be useful for managing selected patients who survive resuscitation, but the risks, potential benefits, and cost implications must be weighed on a case-by-case basis (193).

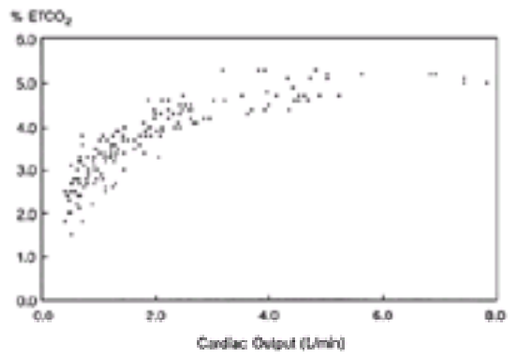
End-Tidal Carbon Dioxide Monitoring and Use of the Esophageal Detector Device during Resuscitation

The percentage of carbon dioxide contained in the last few milliliters of gas exhaled from the lungs with each breath is known as the end-tidal carbon dioxide

concentration (P_{ETCO_2}) (195,196). It can be measured by passing an infrared beam through exhaled gases and measuring the decrease in voltage output from a photoelectric cell calibrated to the wavelength at which carbon dioxide absorbs light. It can also be estimated by attaching an inexpensive, disposable, plastic, colorimetric device in-line between the ET tube and the ventilation device. Color indicators on the device change hue as the exhaled gases pass through the monitor's pH-sensitive membranes. The membrane's color can be compared with the adjacent color chart on the device, thus indicating the percentage P_{ETCO_2}.

Two important terms need to be defined with respect to end-tidal carbon dioxide monitoring. *Capnography* refers to any technology that displays and/or prints the actual capnographic waveform. If an unmistakable capnographic waveform is detected when a capnographic probe is attached to a patient who is being ventilated, then the airway device is unequivocally ventilating the lungs. *Capnometry* refers to the measurement or estimation of the P_{ETCO_2}. It can be displayed in analog or digital format, or it can be approximated using a colorimetric detection device. Capnometry often provides useful information as to the anatomic location of an airway device (e.g., ET tube); however, it does not provide the degree of definitive certainty as does the presence of a capnographic waveform.

During normal respiration and circulation, the P_{ETCO_2} averages 4% to 5%. Two units of measure are popularly used in reporting the P_{ETCO_2}: % and mm Hg (1% is approximately 7 mm Hg). There is a logarithmic relationship between the P_{ETCO_2} and the cardiac output (eFig. 69.6.1) (197). At normal or elevated levels of cardiac output, ventilation is the rate-limiting factor responsible for eliminating the large amount of carbon dioxide traversing the pulmonary circuit (e.g., hyperventilation lowers, and hypoventilation raises, the P_{ETCO_2}). In this range, if blood flow and arterial pressure are kept reasonably constant, the P_{ETCO_2} closely approximates arterial carbon dioxide tension (P_{aCO_2}) and can be used as a "real-time" guide to the adequacy of ventilation (the P_{ETCO_2} actually lags behind real-time events by a few seconds, the amount of time it takes for exhaled gas to be drawn into the machine and analyzed) (198).



***e*FIGURE 69.6.1** Relationship between cardiac output and the end-tidal carbon dioxide concentration ($ETCO_2$). (From Ornato JP, Garnett AR, Glauser FL. Relationship between cardiac output and the end-tidal carbon dioxide tension. *Ann Emerg Med* 1990;19:1104–1106, with permission.)

The P_{ETCO_2} can also be used to confirm ET tube airway placement, particularly in the non–cardiac arrest patient who has a pulse and an adequate blood pressure (where the sensitivity and specificity of the P_{ETCO_2} for detecting correct ET tube placement approach 100% and 90%, respectively) (183,199,200,201,202 and 203). The ET tube cuff should be inflated when the P_{ETCO_2} monitoring device is attached to be sure the gas being sampled is from the structure (i.e., trachea or esophagus) in which the tube resides. Ventilation through an ET tube that has been properly inserted in the trachea yields a P_{ETCO_2} of 4% to 5% in a patient with a normal cardiac output and no significant ventilation-perfusion gradient; ventilation through an ET tube that has been inadvertently inserted into the esophagus results in a P_{ETCO_2} of less than 0.5%. The only important exception occurs when the ET tube is inserted into the esophagus of a patient who has recently ingested a carbonated beverage (e.g., beer, soda). In such a case, the initial P_{ETCO_2} will appear to be normal or high on the first few ventilations but will typically decrease rapidly to less than 0.5% by the sixth or seventh ventilation (204).

At low levels of cardiac output (below approximately 50% of normal in animal models), ventilation has much less effect on the P_{ETCO_2}. Instead, the pulmonary blood flow (and the subsequent ventilation/perfusion mismatch) is the rate-limiting factor determining the P_{ETCO_2}. If ventilation is kept relatively constant in this range, an increase or a decrease in the cardiac output will usually be reflected by a rise or fall in the P_{ETCO_2}, respectively.

During CPR, the cardiac output falls typically to between one-fourth and one-third of normal (191,205,206 and 207). The P_{ETCO_2} also decreases to between one-fourth and one-third of normal as the reduced cardiac output and pulmonary blood flow present less blood and carbon dioxide to the lungs for exchange with oxygen in the pulmonary capillary (208,209,210,211,212,213,214 and 215). As carbon dioxide builds up in venous blood, hyperventilation cleanses the reduced quantity of venous blood traversing the lungs of carbon dioxide. The result is a low arterial (P_{aCO_2}) and a high central venous carbon dioxide concentration (a venoarterial carbon dioxide and pH gradient) (216). Within seconds after ROSC, the improved cardiac output returns large quantities of carbon dioxide–rich venous blood to the lungs, and the P_{ETCO_2} suddenly climbs to normal or above normal levels (208,216). The dramatic change from a low to a high P_{ETCO_2} due to venous carbon dioxide washout is often the first clinical indicator that ROSC has occurred (208). The P_{ETCO_2} typically returns to normal (4% to 5%) within 2 to 5 minutes after ROSC if the patient maintains a good cardiac output.

Knowledge of the physiologic relationship between P_{ETCO_2} and the cardiac output can guide clinicians during low blood flow states such as CPR. There are several important clinical corollaries and pitfalls. For example, inadequate chest compression is usually accompanied by a very low (i.e., less than 1%) P_{ETCO_2}, which increases linearly with increasing sternal compression depth and force (179,197). Administration of sodium bicarbonate intravenously causes a transient rise in P_{ETCO_2} (197). Epinephrine causes a dose-dependent decrease in P_{ETCO_2} (183,217,218 and 219). Disorders that cause significant ventilation-perfusion mismatch (e.g., pulmonary embolization), or decrease in production of carbon dioxide (e.g., hypothermia) are accompanied by a low P_{ETCO_2} (220). Disorders that increase the production of carbon dioxide (e.g., fever) increase the P_{ETCO_2} (197).

The P_{ETCO_2} can also be used to help confirm whether an ET tube has been positioned in the trachea or the esophagus in the cardiac arrest patient. If the P_{ETCO_2} during CPR is very low (below 0.5%) on at least the seventh breath after intubation, it is highly likely that esophageal insertion has occurred (204). Conversely, a moderately low (above 0.5% but below 2.0%) P_{ETCO_2} does not necessarily indicate esophageal placement of the ET tube because there are many other causes for this finding during CPR. Thus, a low P_{ETCO_2} during resuscitation should alert the rescuers that something is wrong with ventilation, perfusion, and/or carbon dioxide production and should prompt a search for correctable causes (221).

The American Heart Association recommends secondary confirmation of ET tube location immediately after intubation in all patients using either an end-tidal carbon dioxide detector device and/or an esophageal detector device (33). The latter devices create a suction force at the tracheal end of the ET tube, either from pulling back a plunger on a large syringe or compressing a flexible bulb. If the ET tube is in the esophagus, the suction will pull the esophageal mucosa against the distal end of the detector and prevent movement of the device plunger or reexpansion of the suction bulb (eTable 69.0.2).

***e*TABLE 69.0.2** COMMON CAUSES OF A LOW (<2%) END-TIDAL CARBON DIOXIDE CONCENTRATION DURING CARDIOPULMONARY RESUSCITATION

Inadequate ventilation
Unrecognized esophageal intubation
Airway obstruction
Inadequate blood flow
Inadequate chest compression
Tension pneumothorax
Pericardial tamponade
Ventilation-perfusion mismatch
Pulmonary embolism
Decreased metabolic production of carbon dioxide
Hypothermia

The initial P_{ETCO_2} has prognostic value in animal models and humans (203,214,215,222,223,224,225,226,227 and 228). Patients or animal models that attain ROSC

tend to have a higher initial P_{ETCO_2} before the use of agents that can significantly affect its value such as high-dose adrenergic agents than those who never attain ROSC (approximately 2% vs. 1% P_{ETCO_2}, respectively) (183,209,218,219,229,230,231 and 232). In pre-hospital cardiac arrest patients, there is suggestive evidence that the P_{ETCO_2} is lower in patients who have a prolonged "downtime interval" before initiation of resuscitation (203). Further clinical research is needed to determine whether it is appropriate to consider the P_{ETCO_2} as a factor in the decision to continue resuscitative efforts.

Echocardiographic Monitoring during Resuscitation

Echocardiography is one of the most promising technologies that has recently been applied as a research tool during resuscitation (45,47,48,49 and 50,233,234,235,236,237,238,239,240,241,242,243 and 244). Conventional transthoracic echocardiography is of limited value because it is difficult to image the heart from a chest wall that is in motion during closed-chest compression. In contrast, TEE can provide high-resolution, real-time images of all four cardiac chambers and the great vessels by positioning a single or biplane Doppler ultrasound probe in the esophagus. Clinical experience indicates that TEE provides a stable platform for imaging during CPR. So far, TEE has been used to better define the mechanisms of blood flow during chest compression. It has also been helpful during resuscitation to (a) determine the presence of pericardial effusion, intracardiac tumor, chamber enlargement or hypertrophy, severe volume depletion, pneumothorax, or thoracic aortic dissection; (b) better define the cause of PEA; (c) evaluate global and regional wall motion after ROSC; and (d) provide a visual guide for positioning intracardiac catheters and pacemaker wires.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Need for Mouth-to-Mouth Ventilation during the First Few Minutes of Cardiopulmonary Resuscitation

In the United States, debate continues about the need to provide artificial ventilation during the first few minutes of CPR because of fear of contracting infectious diseases. Surveys of CPR instructors and other health care providers indicate great reluctance on the part of many rescuers to perform mouth-to-mouth ventilation on strangers (120,245,246,247,248,249,250,251 and 252).

It is not clear that it is necessary to provide mouth-to-mouth ventilation for the first several minutes of resuscitation as long as chest compression is performed and the airway is patent. Chandra et al. (253) assessed the time course of change in arterial blood gases during resuscitation in a canine experimental model during ventricular fibrillation. The dogs had no ET tube in place during CPR and received only chest compression (no ventilation). Prearrest arterial pH, carbon dioxide partial pressure (P_{CO_2}), and oxygen saturation were 7.39 ± 0.02, 27.0 ± 1.5 mm Hg, and 97% ± 11.5%, respectively. After 4 minutes of chest compression alone, the corresponding values were 7.39 ± 0.03, 24.3 ± 3.1 mm Hg, and 93.9% ± 3.0%. Mean minute ventilation during the fourth minute of CPR, measured with a face mask pneumotachometer, was 5.2 ± 1.1 L per minute. These findings suggest that, in the dog model of witnessed arrest, chest compression alone during CPR can maintain adequate gas exchange to sustain the oxygen saturation above 90% for at least 4 minutes. These findings appear to be confirmed by the observation that survival from cardiac arrest is almost as good in humans when bystanders perform only chest compressions as occurs when bystanders perform both chest compressions and mouth-to-mouth ventilation (119). Some investigators believe that mouth-to-mouth ventilation may not be essential during the first few minutes of CPR because chest compression alone with a patent airway generates a reasonable minute ventilation and the quantity of oxygen needed is reduced significantly during low blood flow states (249). Some investigators have even questioned whether mouth-to-mouth ventilation with exhaled gas containing as much as 4% carbon dioxide and less oxygen than air might even have adverse effects during CPR (248).

The American Heart Association recommends that rescuers perform mouth-to-mouth ventilation along with chest compressions because clinical data indicate that this combination results in the highest rate of neurologically intact survival (38,119). If rescuers are unwilling to perform mouth-to-mouth ventilation, bystanders should activate the EMS system immediately and initiate chest compressions (38).

In a recent prospective clinical trial in Seattle, telephone EMS dispatchers gave bystanders at the scene of apparent cardiac arrest instructions to perform chest compressions alone or chest compression plus mouth-to-mouth ventilation (254). Data were analyzed for 241 patients randomly assigned to receive chest compression alone and 279 assigned to chest compression plus mouth-to-mouth ventilation. Complete instructions were delivered in 62% of episodes for the group receiving chest compression plus mouth-to-mouth ventilation and 81% of episodes for the group receiving chest compression alone (p = .005). Instructions for compression required 1.4 minutes less to complete than instructions for compression plus mouth-to-mouth ventilation. Survival to hospital discharge was better among patients assigned to chest compression alone than among those assigned to chest compression plus mouth-to-mouth ventilation (14.6% vs. 10.4%), but the difference was not statistically significant (p = .18). The authors concluded that the outcome after CPR with chest compression alone is similar to that after chest compression with mouth-to-mouth ventilation, and chest compression alone may be the preferred approach for bystanders inexperienced in CPR.

Spontaneous agonal respirations often contribute to respiratory exchange of gases. In one case series, agonal respirations occurred in 40% of 445 out-of-hospital cardiac arrests (255). Agonal respirations were present in 46% of arrests caused by a cardiac etiology compared with 32% in other etiologies (p <.01). Fifty-five percent of witnessed arrest patients had agonal activity compared with 16% of unwitnessed arrest patients (p <.001). Agonal respirations occurred in 56% of arrests due to ventricular fibrillation compared with 34% of cases with a non–ventricular fibrillation rhythm (p <.001). Twenty-seven percent of patients with agonal respirations were discharged alive compared with 9% without them (p <.001). These findings suggest that there is a high incidence of agonal respiratory activity associated with out-of-hospital cardiac arrest, and the presence of agonal respirations appears to be associated with increased survival.

It is important to point out that assisted ventilation, particularly when performed with supplemental oxygen through a properly inserted ET tube, is clearly beneficial during CPR if resuscitation efforts continue beyond the first few minutes (246). Until the airway is protected by a properly inserted and secured ET tube, each mouth-to-mouth or bag-valve-mask ventilation must be delivered with a slow inspiratory flow rate to allow adequate time for lung inflation and to prevent gastric insufflation (38). This is necessary because the lungs become very stiff during resuscitation due to decreased compliance (256). Forceful efforts to inflate the lungs rapidly will only result in elevation of the pharyngeal pressure effect, which will be transmitted down the esophagus to the esophageal-gastric sphincter, causing it to open and allow passage of air into the stomach (257).

Is There a Need for "High-Dose" Epinephrine during Resuscitation?

Epinephrine, an endogenous catecholamine with both alpha-and beta-adrenergic activity, is the vasopressor of choice for use during resuscitation. Epinephrine's potent $alpha_1$- and $alpha_2$-adrenergic effects improve cerebral blood flow by preventing arterial collapse and by increasing peripheral vasoconstriction (163,166,167,168,169 and 170,258,259). Epinephrine also enhances CPP, which is the major determinant of the ROSC after cardiac arrest (164,167,260). An aortic diastolic blood pressure of 30 to 40 mm Hg markedly improves survival during resuscitation in animal models (64,164,167,171,173,217,260,261,262,263 and 264). Restoration of myocardial blood flow facilitates the resynthesis of high-energy phosphates within myocardial mitochondria and enhances cellular viability and contractile force. However, the increased myocardial blood flow is at least partially antagonized by the increased myocardial oxygen consumption caused by epinephrine's beta-adrenergic actions (265,266).

The optimal dose of epinephrine to augment aortic diastolic blood pressure in humans during closed-chest compression is unknown. The American Heart Association currently recommends a 1.0-mg dose based on studies in dogs weighing approximately 20 kg (17). In a 70-kg male, the current recommendations provide only 7.5 to 15 µg per kg of epinephrine every 5 minutes.

Some studies have concluded that dosages of more than 15 µg per kg may be required during closed-chest CPR in animal models. Kosnik et al. showed that a dose of epinephrine of 15 µg per kg (the upper range of the recommended human dose) did not maintain an aortic diastolic blood pressure above 40 mm Hg during closed-chest compression in dogs (267). Larger doses (45, 75, and 150 µg per kg) effectively raised aortic diastolic blood pressure. High-dose (10 µg per kg) constant infusions of epinephrine have been shown to significantly increase aortic diastolic blood pressure and coronary blood flow during closed-chest compression in dogs (268). Epinephrine (0.02, 0.2, and 2.0 mg per kg) also produced significant dose-dependent improvement in regional myocardial and cerebral blood flow during closed-chest compression in animal models (269,270,271,272,273,274,275 and 276). Preliminary data in humans suggested a similar dose dependence with respect to aortic blood pressure (277).

From these studies it appeared that higher doses of epinephrine might be required in adult humans to improve hemodynamics and to achieve successful resuscitation. Anecdotal case series and retrospective studies published in the late 1980s and early 1990s (277,278,279,280 and 281) set the stage for prospective randomized clinical trials. Unfortunately, none of these trials has shown any convincing evidence that higher doses of epinephrine than those which are used customarily (1 mg) are associated with any better survival to hospital discharge in adults or children (232,282,283,284,285,286,287,288,289 and 290).

Could higher doses of epinephrine be of value to some subgroups of patients and harmful to others? One of the high-dose epinephrine trials showed a threefold increase in hospital discharge rates in patients presenting with EMD and asystole when treated with 5.0 mg versus 1.0 mg of epinephrine as the initial dose, but this difference did not reach statistical significance (285). Another study showed that patients older than 65 years and those in ventricular fibrillation did better with standard doses of epinephrine (284). However, additional clinical trials have failed to show benefit from the use of high versus standard doses of epinephrine in adults

(288,290,291) or in children (282,289).

Most of the patients who survive cardiac arrest respond to early defibrillation and never receive epinephrine. What percent of those who do not respond are salvageable is unclear. However, because patients who are defibrillated did not qualify for these clinical trials, the survival rates of patients studied were low regardless of the dosage of epinephrine. Of some comfort is the fact that these trials did not demonstrate significant harm from higher doses of epinephrine. These studies emphasize the importance of the “standard” early interventions: airway management, chest compression, and rapid defibrillation. They suggest that epinephrine (whether at low or high dosages) as well as other late interventions represent a last desperate effort to resuscitate individuals who have a very poor chance for survival.

Based on available clinical data, the American Heart Association continues to recommend an intravenous epinephrine dosage of 1 mg (10 mL of a 1:10,000 solution) every 3 to 5 minutes during resuscitation in adults (30). If the dose is given by peripheral injection, it should be followed by a 20-mL flush of intravenous fluid to ensure drug delivery into the central compartment. Higher doses of epinephrine are not recommended for routine use but can be considered if 1-mg doses fail.

The recommended pediatric epinephrine dosage for bradycardia, asystolic, or pulseless arrest is 0.01 mg per kg (0.1 mL per kg of a 1:10,000 solution) by the intravenous or intraosseous route or 0.1 mg per kg (0.1 mL per kg of a 1:1,000 solution) by the ET route (17). Repeated doses are recommended every 3 to 5 minutes for ongoing arrest. The same dose of epinephrine is recommended for second and subsequent doses for unresponsive asystolic and pulseless arrest, but higher doses of epinephrine (0.1 to 0.2 mg per kg; 0.1 to 0.2 mL per kg of a 1:1,000 solution) by any intravascular route may be considered. If high-dose epinephrine is used, extra care should be taken to avoid dosing errors because two different dilutions of epinephrine are needed. The recommended pediatric ET dosage of epinephrine is 0.1 mg per kg (0.1 mL per kg of a 1:1,000 solution).

Intracardiac administration should be used only during open cardiac compression or when other routes of administration are unavailable. Intracardiac injections increase the risk of coronary artery laceration, cardiac tamponade, and pneumothorax and cause interruption of external chest compression and ventilation.

During cardiac arrest, epinephrine also may be administered by continuous intravenous infusion. The dose should be comparable to the standard intravenous dose of epinephrine (1 mg every 3 to 5 minutes). This is accomplished by adding 1 mg of epinephrine hydrochloride to 250 mL of normal saline or dextrose 5% in water (D5W) to run at 1 µg per minute and increased to 3 to 4 µg per minute (30). A continuous infusion of epinephrine should be administered by central venous access to reduce the risk of extravasation and to ensure good bioavailability.

Autooxidation of catecholamines and related sympathomimetic compounds is pH-dependent. Contact of epinephrine with other drugs that have an alkaline pH (e.g., sodium bicarbonate) can cause autooxidation, but the reaction rate is too slow to be clinically important when epinephrine is given by bolus injection or when it is infused rapidly. Epinephrine should not be added to infusion bags or bottles that contain alkaline solutions.

H4>Use of Vasopressin during Resuscitation

Vasopressin produces significantly higher CPP and myocardial blood flow than epinephrine during closed-chest CPR in a pig model of ventricular fibrillation (292) and in humans during CPR (293). Both vasopressin and adrenocorticotropin concentrations are higher during CPR in patients in whom resuscitation is successful compared with those in whom it fails (294). Because of these observations, there has been considerable interest in the use of vasopressin for supporting CPP during CPR in humans.

In a small, blinded, randomized clinical study, 40 patients with out-of-hospital ventricular fibrillation resistant to electrical defibrillation were treated with either epinephrine (1 mg intravenously; n = 20) or vasopressin (40 U intravenously; n = 20) during resuscitation (295). Seven (35%) patients in the epinephrine group and 14 (70%) in the vasopressin group survived to hospital admission (p = .06). At 24 hours, four (20%) epinephrine-treated patients and 12 (60%) vasopressin-treated patients were alive (p = .02). Three (15%) patients in the epinephrine group and eight (40%) in the vasopressin group survived to hospital discharge (p = .16). Neurologic outcomes were similar in both groups.

The *American Heart Association Guidelines* considers vasopressin to be an effective vasopressor and recommends it as an alternative to epinephrine for the treatment of adult shock refractory ventricular fibrillation cardiac arrest (30). Although vasopressin may also be effective in patients with asystole or PEA, data were insufficient to recommend the use of vasopressin for these conditions in the latest *Guidelines* recommendations. The recommended dosage is 40 units intravenously in place of the first dose of epinephrine in the pulseless ventricular tachycardia/ventricular fibrillation algorithm. Although its pharmacokinetics are not fully understood yet, it is generally believed that this single dose should last approximately 10 to 20 minutes, after which epinephrine should be resumed if ROSC has not occurred.

It is not clear whether vasopressin should be used at all in children or infants. Unfortunately, vasopressin was less effective than epinephrine in a piglet model of prolonged asphyxial cardiac arrest (296). At this time, the American Heart Association does not recommend the use of vasopressin in infants or children because data are inadequate to evaluate its efficacy and safety (21).

Use of Buffers during Resuscitation

The marked fall in cardiac output during closed-chest compression critically reduces tissue oxygen delivery. Cells shift to anaerobic metabolism, gradual building up lactic acid as a waste product (297,298,299 and 300). During anaerobic metabolism, the carbon dioxide concentration increases rapidly inside cells. Anoxic arrest of the heart causes a progressive increase in the concentration of P_{CO_2} inside heart muscle cells that may reach very high levels (90 to 475 mm Hg) (301). Above an intramyocardial P_{CO_2} of approximately 475 mm Hg, PEA is present, and the heart cannot be resuscitated (301). Intracellular carbon dioxide eventually diffuses into capillary blood and returns to the heart and lungs in venous blood.

Central (mixed) venous blood during closed-chest compression is acidotic (pH f approximately 7.15) and hypercarbic (Pa_{CO_2} of approximately 74 mm Hg) (216). With hyperventilation, carbon dioxide is removed as blood flows through the lungs. Accordingly, arterial blood is less acidotic. Arterial blood pH during well-performed closed-chest compression is usually normal, slightly acidotic, or mildly alkalotic (152,154,155 and 156,216,300,302,303). Arterial blood can be slightly alkalotic while the venous blood is acidotic because pulmonary blood flow is only a fourth to a third of normal amount during closed-chest compression (this phenomenon has been termed the *venous paradox*) (216). It is, in fact, not a paradox but part of normal physiology that occurs when anaerobic metabolism is required (e.g., during strenuous exercise), at which time the intramyocardial pH is much closer to the venous than the arterial pH.

Severe arterial acidosis during closed-chest compression is usually due to inadequate ventilation (304). The best solution is usually to improve the technique of closed-chest compression and to increase ventilation, if possible. If severe acidosis is present despite hyperventilation, correct intubation, and properly performed external chest compression, an alternate method for providing assisted circulation (e.g., open-chest compressions or venoarterial bypass) may need to be considered.

In the past, administration of sodium bicarbonate was recommended during closed-chest compression because of the belief that bicarbonate would buffer the H+ ion produced during anaerobic metabolism. However, sodium bicarbonate itself contains a high concentration of carbon dioxide (260 to 280 mm Hg) (305). In plasma, the carbon dioxide is released and diffuses into cells more rapidly than HCO_3^-, causing a paradoxical rise in intracellular P_{CO_2} and a fall in intracellular pH. The increases in intracellular P_{CO_2} in heart muscle cells decrease cardiac contractility, cardiac output, and blood pressure (306,307). Paradoxical acidosis of cerebrospinal fluid also can occur after the use of sodium bicarbonate (308) and may be responsible for prolonged confusion after a successful resuscitation as the venous acidosis increases. Sodium bicarbonate causes other potentially harmful effects, including hyperosmolality, alkalemia, and sodium overload.

At present, there are no convincing data proving treatment with sodium bicarbonate is of benefit during closed-chest compression and it does not improve survival in experimental animals (166,309,310 and 311). Sodium bicarbonate should not be given during a routine cardiac arrest because it provides minimal, if any, benefit and adds significant risk. If used at all, bicarbonate should not be used until proven interventions such as defibrillation, cardiac compression, support of ventilation including intubation, and pharmacologic therapies such as epinephrine and antiarrhythmic agents have been used (17). If used, the initial dose of sodium bicarbonate is 1 mEq per kg. No more than half of the original dose should be given every 10 minutes thereafter.

Measurement of arterial pH during closed-chest compression is rarely helpful because of the markedly reduced cardiac output and the venous paradox in pH. P_{ETCO_2} will increase in keeping with the delivered load of carbon dioxide and will no longer reflect pulmonary perfusion (312). Ready-to-use, prefilled injection syringes containing 8.4% sodium bicarbonate (50 mEq per 50 mL) are recommended for use during CPR. The administration of sodium bicarbonate may help to buffer hydrogen ions washed out after reestablishment of spontaneous circulation. In this situation, the use of bicarbonate should be guided by arterial blood gas measurement. However, bicarbonate in this situation may still depress cardiac function (313,314). In certain circumstances, such as patients with preexisting metabolic acidosis, hyperkalemia, or tricyclic or phenobarbital overdose, bicarbonate is beneficial. Sodium bicarbonate can be administered by continuous infusion when the therapeutic goal is gradual correction of acidosis or alkalinization of blood (i.e., tricyclic antidepressant overdose) or urine (e.g., barbiturate overdose). A 5% sodium bicarbonate solution (297.5 mEq per 500 mL) can be used to administer a sodium bicarbonate infusion. The infusion rate should be guided by arterial blood gas

monitoring. Avoid attempting to completely correct the base deficit to minimize the risk of alkalosis.

Alternate buffer agents have not yet been shown to improve survival during cardiac resuscitation. Tromethamine (THAM) (TRIS buffer) is a potent amine buffer that actively binds H^+ ions. It combines with carbonic acid, increasing the amount of bicarbonate anion available. THAM penetrates into cells and may neutralize acidic ions in the intracellular fluid. In dogs, THAM corrects the metabolic acidosis that occurs during cardiac arrest (315). Anecdotal reports suggest that THAM may be of value during prolonged cardiac resuscitations in humans (316), but more research is needed. Dichloroacetate reduces the serum lactate concentration by stimulating pyruvate dehydrogenase, the enzyme that catalyzes the rate-limiting step in the oxidation of lactate to pyruvate (317). It is a safe and effective adjunct for the treatment of patients with lactic acidosis but does not affect intramyocardial pH during closed-chest compression in experimental animals (303).

In a recent Scandinavian study, 502 adults with asystole or ventricular fibrillation with failure of the first defibrillation attempt were entered into a prospective, randomized, double-blind, controlled trial comparing the use of a combination buffer agent (Tribonat, containing 250 mL of a sodium bicarbonate-THAM-acetate-phosphate mixture with a buffering capacity of 500 mmol per L) and 250 mL of 0.9% saline placebo (318). Eighty-seven patients (36%) receiving buffer were admitted to the hospital, and 24 (10%) were discharged from the hospital alive versus 92 (36%) and 35 (14%) receiving saline (no significant difference between groups). Thus, this landmark clinical trial lends further evidence to the belief that buffer therapy does not improve patient outcome from routine cardiac arrest.

Use of Antiarrhythmic Drugs for Refractory Ventricular Fibrillation

Frequently used agents for treatment of refractory ventricular fibrillation or pulseless ventricular tachycardia include lidocaine, bretylium tosylate, procainamide, beta blockers, magnesium sulfate, and intravenous amiodarone. With the exception of intravenous amiodarone, there are no randomized controlled clinical trial data confirming whether any of the other agents are any better than just repeated electrical countershocks.

The American Heart Association considers lidocaine to be acceptable therapy for pulseless ventricular tachycardia/ventricular fibrillation that persists after defibrillation and administration of a vasopressor agent (epinephrine or vasopressin). The primary basis for this recommendation is historical precedent and no evidence of significant harm (31). An initial dose of 1.0 to 1.5 mg per kg is suggested. For refractory ventricular fibrillation and pulseless ventricular tachycardia, an additional bolus of 0.5 to 0.75 mg per kg can be given over 3 to 5 minutes if necessary. The total dose should not exceed 3 mg per kg (or more than 200 to 300 mg during a 1-hour period). Administration of antiarrhythmic agents after ROSC is controversial, but it is common to initiate a lidocaine intravenous infusion at a rate of 1 to 4 mg per minute. Recurrence of ventricular tachyarrhythmias during a constant infusion should be treated with a small bolus dose (0.5 mg per kg) and an increase in the infusion rate in incremental doses (maximal infusion rate of 4 mg per minute). The dosage should be reduced and/or blood levels monitored if the patient remains on lidocaine for 24 hours or more because the half-life of the drug increases after 24 to 48 hours of continuous therapy.

Bretylium is a class 3 antiarrhythmic that increases myocardial electrical stability by elevating the ventricular fibrillation threshold and by reducing the disparity in action potential duration and refractory periods between ischemic and nonischemic myocardium. Nowak et al. (319) reported a higher rate of successful resuscitation when bretylium was used (35%) than after placebo (6%) alone in prehospital cardiac arrest victims but their retrospective analysis left substantial questions concerning the comparability of the groups. Other studies also support the efficacy of bretylium for prehospital ventricular fibrillation (320,321). However, no difference in clinical outcome has been observed in prospective randomized studies comparing bretylium and lidocaine for the treatment of prehospital ventricular fibrillation using intravenous doses of bretylium (0.5 to 1.0 g) and lidocaine (100 to 200 mg) (322) or bretylium (10 to 30 mg per kg) and lidocaine (2 to 3 mg per kg) (320). Neither study found a significant difference in the incidence of conversion from ventricular fibrillation and tachycardia to a more organized rhythm or survival. Bretylium is presently unavailable due to a shortage of substrate to manufacture the agent. It has been removed from the American Heart Association treatment algorithms and guidelines because of its high incidence of side effects, the availability of other equally effective alternatives, and limited availability (31).

Procainamide, a class 1A antiarrhythmic agent, is a presynaptic ganglionic blocker; it vasodilates and induces modest negative inotropic effects, especially in patients with left ventricular dysfunction. Procainamide-induced hypotension is most pronounced after rapid intravenous injection or when high plasma concentrations of procainamide are present.

During resuscitation, procainamide is usually given by infusion at 20 mg per minute until the tachyarrhythmia is suppressed, hypotension and/or QRS prolongation by 50% from its original duration has occurred, or 17 mg per kg has been given (31). Bolus administration can result in significant hypotension and toxicity. In urgent situations, up to 50 mg per minute can be given up to a total of 17 mg per kg. The maintenance infusion dosage of procainamide is 1 to 4 mg per minute. Blood levels should be monitored in renal failure patients or in those receiving more than a 3-mg-per-minute intravenous infusion for more than 24 hours.

Occasionally, ventricular fibrillation or ventricular tachycardia without a pulse will remain refractory to, or will recur incessantly, despite repeated electrical countershocks and conventional pharmacologic treatment. In such cases, additional treatment options should be considered. The use of intravenous beta-blockers, traditionally with intravenous propranolol (1 mg every 5 minutes intravenously up to a total dose of 0.1 mg per kg) or esmolol, is worthy of consideration.

Underlying metabolic derangements should also be sought and corrected. Arterial hypoxemia should be reversed or minimized by ET intubation and ventilation with 100% oxygen. Acidosis is best prevented (or treated) during closed-chest compression by optimizing CPR techniques to improve blood flow and hyperventilation. Electrolyte abnormalities are common during resuscitation, either as primary disturbances that may have triggered the arrest or as secondary phenomena due to intracellular shifts and therapeutic interventions; such electrolyte abnormalities should be corrected if present.

Resuscitation from refractory ventricular fibrillation is less likely to be successful if hypokalemia and/or hypomagnesemia are present. Hypokalemia is common in cardiac patients and occurs in 23% to 40% of individuals treated with thiazide diuretics (323). When loop and thiazide diuretics are used in combination, the incidence approaches 100% (323,324). Hypokalemia can trigger ventricular fibrillation in experimental animal models and in patients with heart disease (especially acute myocardial infarction) (324,325). Hypokalemia is also common (up to 50%) in survivors of out-of-hospital ventricular fibrillation (326,327). Hypokalemia after resuscitation may be due to a shift in the distribution of potassium between the extracellular and intracellular space induced by metabolic events during resuscitation. Many patients (55% in one study) have predisposing risk factors for the development of hypokalemia before cardiac arrest (327).

Hypokalemia in the patient with cardiac arrest and refractory ventricular fibrillation must be treated aggressively. Guidelines for potassium replacement that are acceptable in the less emergent clinical circumstance may be inadequate to correct hypokalemia in a timely fashion during cardiac arrest (328). One regimen that has been suggested includes administration of 10 mEq of potassium chloride diluted in 50 mL D5W over 20 minutes. This dose can be repeated as necessary while rechecking serum levels.

Hypomagnesemia should be corrected if present because it can precipitate ventricular fibrillation in experimental models in association with hypokalemia and can hinder the replenishment of intracellular potassium (329,330). Magnesium sulfate is no longer recommended for routine management of pulseless ventricular tachycardia or ventricular fibrillation unless hypomagnesemia is suspected or present or the patient has torsades de pointes because two clinical in-hospital trials have not shown benefit (31,331,332).

For acute administration during ventricular tachycardia or fibrillation with known or suspected hypomagnesemia or for torsades de pointes, 1 or 2 g of magnesium sulfate (2 to 4 mL of a 50% solution) is diluted in 50 to 100 mL of D5W and administered over 5 to 60 minutes. Caution should be used when magnesium is administered to safeguard against clinically significant hypotension or asystole. A 24-hour magnesium infusion (8 g of magnesium sulfate in 500 mL D5W at eight drops per minute) should be considered in patients with documented magnesium deficiency. Magnesium toxicity is rare, but side effects from rapid administration include flushing, sweating, mild bradycardia, and hypotension. Hypermagnesemia can produce depressed reflexes, flaccid paralysis, circulatory collapse, respiratory paralysis, or diarrhea.

Other treatment strategies can also be used in managing incessantly refractory or recurrent ventricular fibrillation or pulseless ventricular tachycardia. The possibility that there has been a proarrhythmic drug effect that may be exacerbating the arrhythmia must be considered. Proarrhythmic drug effects, hypokalemia, and/or hypomagnesemia can induce ventricular arrhythmias such as torsades de pointes. Torsades de pointes should be treated by stopping medications known to prolong the QT interval and correcting any electrolyte abnormalities. Other interventions can be tried, including administration of magnesium sulfate or the use of pacing or other forms of overdrive suppression (including the cautious use of isoproterenol if there are no contraindications) (333).

There has been considerable interest in the use of intravenous amiodarone to treat patients with recurrent arrhythmias (334,335,336,337,338,339,340,341,342,343 and 344). Despite prolonged resuscitative efforts before the administration of intravenous amiodarone, 11 of 12 patients with refractory ventricular tachyarrhythmias responded, and eight left the hospital alive (334). In one recent double-blind clinical trial, 302 patients with refractory hemodynamically destabilizing ventricular tachycardia or ventricular fibrillation were randomly assigned to therapy with intravenous bretylium (4.7 g) or intravenous amiodarone administered in a high dose (1.8 g) or a low dose (0.2 g). The arrhythmia event rate during the first 48 hours of therapy showed comparable efficacy between bretylium and high-dose (1,000 mg per 24 hours) amiodarone, and both bretylium and high-dose amiodarone were better than low-dose (125 mg per 24 hours) amiodarone. Overall mortality in the 48-hour double-blind period was 13.6% and was not significantly different among the three treatment groups. Significantly more patients treated with bretylium had hypotension compared with the two amiodarone groups. It was concluded that bretylium and amiodarone have comparable efficacy for the treatment of highly malignant ventricular

arrhythmias. Bretylium use, however, may be limited by a high incidence of hypotension.

In a recent randomized controlled clinical prehospital trial conducted on 504 cardiac arrest patients with recurrent and/or refractory ventricular tachyarrhythmias, the administration of a single 300-mg bolus of intravenous amiodarone at the time of the first intravenous epinephrine administration resulted in 26% greater survival to hospital admission compared with standard ACLS therapy (345,346). There was no significant difference between the amiodarone and placebo groups in the duration of the resuscitation attempt (42 ± 16.4 and 43 ± 16.3 minutes, respectively), the number of shocks delivered (4 ± 3 and 6 ± 5), or the proportion of patients who required additional antiarrhythmic drugs after the administration of the study drug (66% and 73%). More patients in the amiodarone group than in the placebo group had hypotension (59% vs. 48%, $p = .04$) or bradycardia (41% vs. 25%, $p = .004$) after receiving the study drug. These side effects usually respond readily to therapy (volume infusion and vasopressors; atropine and/or electrical pacing). Recipients of amiodarone were more likely to survive to hospital admission (44% vs. 34% of the placebo group; $p = .03$). The adjusted odds ratio for survival to admission to the hospital in the amiodarone group as compared with the placebo group was 1.6 (95% confidence interval of 1.1 to 2.4; $p = .02$). The trial did not have sufficient statistical power to detect differences in survival to hospital discharge, which differed only slightly between the two groups.

The manufacturer adds polysorbate 80 to the intravenous amiodarone preparation to keep the latter in solution (amiodarone is relatively insoluble in water). Because diluent is a “soapy” compound, it can create bubbles if the vial is shaken before the amiodarone is drawn up into the syringe. It is recommended that the vial not be shaken. The bubbling phenomenon can usually be kept to a minimum by drawing up the drug with a large needle (18 gauge or larger). If bubbles do appear in the syringe, it should be held vertically as it is being injected into the intravenous tubing, and the bubbles should not be injected into the patient.

The American Heart Association currently recommends the use of amiodarone after defibrillation and a vasopressor (either epinephrine or vasopressin) in cardiac arrest with persistent or recurrent pulseless ventricular tachycardia or ventricular fibrillation (31). In this setting, it is usually administered as a 300-mg rapid infusion diluted to 20 to 30 mL with saline or D5W. Supplementary doses of 150 mg by rapid infusion can be given for recurrent or refractory pulseless ventricular tachycardia or ventricular fibrillation up to a maximum dosage of 2,000 mg for 24 hours (31,346). For patients not in cardiac arrest, intravenous amiodarone is usually diluted and administered as 150 mg over 10 minutes followed by a 1-mg-per-minute infusion for 6 hours, and then 0.6 mg per minute.

U.S. Food and Drug Administration Issues of Informed Consent

Most clinical trials that involve research on emergency patients who cannot give prospective informed consent (including all resuscitation research) have been halted in the United States by a regulatory moratorium. The issues and problems surrounding the ban were of concern to federal regulators and many researchers for several years. In May 1993, the U.S. Food and Drug Administration (FDA) prematurely terminated a clinical resuscitation trial involving a comparison of the Ambu CardioPump (Ambu Inc., Denmark) and standard CPR because the FDA believed that the device involved “significant risk” to the subjects and that there were no means for the subjects to give informed consent to participate in the trial (347,348).

Widespread public attention became focused on the issue in May 1994 when a congressional subcommittee questioned whether existing laws and regulations governing the FDA and the U.S. Department of Health and Human Services (DHHS)/National Institutes of Health permit inclusion of unconscious human subjects who cannot give informed consent in clinical trials dealing with emergency medical conditions. The subcommittee charged these two federal agencies with the task of working together with other interested parties to develop consistent guidelines that local institutional review boards (IRBs) can follow to permit such research.

Until the congressional hearing, investigators in the United States customarily conducted such research by receiving a waiver of informed consent from their IRB or by using the method known as “deferred consent” (349). In retrospect, IRBs have creatively interpreted and adapted prevailing rules to permit such research.

FDA regulations require informed consent in all clinical trials over which they have jurisdiction. The FDA regulations permit an “emergency exception” to this requirement for immediate, one-time use of an investigational device or drug for compassionate use to a single individual when (a) a patient is confronted by a life-threatening situation necessitating the investigational use of the drug or device; (b) informed consent cannot be obtained from the patient because of an inability to communicate with, or to obtain legally effective consent from, the patient; (c) time is insufficient to obtain consent from the patient’s legal representative; and (d) no alternative method of approved or generally recognized therapy is available that provides an equal or greater likelihood of saving the patient’s life.

The DHHS also has jurisdiction over the conduct of research in humans by means of its Office for Protection from Research Risks. This agency oversees research in humans by a different set of rules and regulations than that of the FDA. DHHS regulations do not contain an emergency exception. However, they provide a mechanism for waiver or alteration of informed consent when (a) the research involves no more than “minimal risk” to the subjects; (b) the waiver or alteration will not adversely affect the rights and welfare of the subjects; and (c) the research could not practicably be carried out without the waiver or alteration. Whenever appropriate, the subjects will be provided with additional pertinent information after participation.

“Minimal risk” is defined in the DHHS regulations by the following test: “[T]he probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests.” No resuscitation technique (standard or experimental) would pass this test of “minimal risk.”

Thus, neither the FDA nor the DHHS rules and regulations provide a legal means for IRBs to approve emergency medical research in humans where it is impossible to obtain informed consent. On October 25, 1994, the Coalition Conference of Acute Resuscitation and Critical Care Researchers was held in Washington, D.C., to discuss informed consent in emergency research. Representatives from more than 20 organizations worked diligently to explore the issues and produced consensus recommendations for resolving some of the difficult issues that surround emergency medical research.

These recommendations and many other ideas were presented and discussed at the FDA/National Institutes of Health Public Forum on Informed Consent in Clinical Research Conducted in Emergency Circumstances, held in Bethesda, Maryland, January 9–10, 1995. Although this was not a consensus conference, the discussion appeared to indicate that legislative change is needed to give the FDA and the DHHS a common set of tools that will make it legal for them to oversee the conduct of legitimate, ethical, scientifically sound emergency care research. The next step is to translate the consensus statement drafted at the October meeting and ideas emanating from the Bethesda conference into legislative language and to introduce a congressional bill that will correct the deficiencies in the existing rules and regulations.

In the meantime, the only clinical resuscitation trials that are permitted in the United States are in-hospital studies in which potential cardiac arrest victims are approached and give their informed consent to participate in the trial if, by chance, they should experience a cardiac arrest during their hospitalization. Such a process has been used successfully before (80,350) but may require the screening of hundreds of potential individuals for every subject enrolled in the trial. Such a procedure is expensive and time-consuming. More important, it may result in a biased sample of patients.

Clearly, these have sobering implications for resuscitation research in the United States and throughout the world. The issue is not whether such research is morally, ethically, scientifically necessary and justifiable. These are, of course, absolute prerequisites. The real question is whether each country’s laws, rules, and regulations explicitly permit emergency medical research when subjects cannot give informed consent. The FDA and the DHHS have recently released new rules that are intended to allow at least limited resumption of resuscitation research in humans.

Unfortunately, initial experience with these new rules has been problematic. In the first 4 years of the new FDA/DHHS rules, no prospective resuscitation drug or device trials have been completed or initiated successfully in the United States. In fact, several trials have been abandoned because of the expense and difficulty of complying with the new regulations (351,352 and 353). The American College of Cardiology has recently convened a Bethesda Conference on Emergency Cardiac Care that, in part, discussed problems with the waiver of informed consent procedures and proposed potential solutions (354).

New Experimental Cardiopulmonary Resuscitation Techniques

Investigators have begun to exploit the physiologic opportunities afforded by understanding the mechanisms of blood flow during CPR in an attempt to overcome the hemodynamic shortcomings of conventional chest compression. Standard chest compression of the sternum to a depth of 1.5 to 2.0 in. at a rate of 80 per minute as recommended by the American Heart Association produces only about one-fourth to one-third of the normal cardiac output and less than half of the normal arterial perfusion pressure (14,221). This is usually inadequate to generate the 25 to 35 mm Hg aortic diastolic pressure needed to restart the arrested heart (184,262).

Applying higher compression force to displace the sternum farther than the 1.5 to 2.0 in. recommended by the American Heart Association can improve arterial systolic pressure and cardiac output significantly (179). However, there is a practical limit to the amount of extra force that can be applied safely without causing physical injury to the chest and underlying structures. Computer modeling indicates that substantially greater force is required to generate adequate coronary and cerebral pressure and flow than that which can be provided safely by conventional sternal compression (355).

Circumferential Compression Cardiopulmonary Resuscitation

Circumferential application of force to the chest using a pneumatic vest can generate enough intrathoracic pressure to provide virtually normal systemic arterial pressure and flow in animals and humans during cardiac arrest (356,357,358 and 359). The device looks like a large blood pressure cuff that is wrapped around the patient's thorax. It contains a bladder that can be inflated and deflated in cycles by a pneumatic pump. Compression duration, inflation pressure, and rate are all controlled by the device. Typical inflation pressure is 250 mm Hg, and the chest compression rate is 60 per minute. A small positive pressure is maintained between the chest and the vest to provide a tight fit between the two, but the device totally deflates during ventilation to provide for chest expansion. The total force applied to the chest with "vest CPR" is much greater than that which can be applied safely with conventional CPR. Despite this, "vest CPR" is much less traumatic than standard CPR because it distributes force over a much larger surface area (the entire chest).

When the pneumatic vest was applied to 29 patients who repeatedly did not respond to conventional CPR, defibrillation, and drug therapy for 42 ± 16 minutes, vest CPR increased the peak aortic pressure from 78 ± 26 mm Hg to 138 ± 28 mm Hg (p <.001) and the CPP from 15 ± 8 mm Hg to 23 ± 11 mm Hg (p <.003) (358). Despite prolonged unsuccessful manual CPR, spontaneous circulation returned with vest CPR in 4 of the 29 patients. An additional 34 patients were randomly assigned to undergo vest CPR (17 patients) or continued manual CPR (17 patients) after initial manual CPR (mean duration, 11 ± 4 minutes) was unsuccessful. Spontaneous circulation returned in eight of the 17 patients who underwent vest CPR as compared with only three of the 17 patients who received continued manual CPR (p = .14) (358). More patients in the vest CPR group than in the manual CPR group were alive 6 hours after attempted resuscitation (six of 17 vs. one of 17) and 24 hours after attempted resuscitation (three of 17 vs. one of 17), but none survived to leave the hospital.

Despite the fact that preliminary experience with the pneumatic vest has been encouraging, clinical trials using the device early in resuscitation have been halted due to the difficulties with the FDA/DHHS process of obtaining a waiver of informed consent (352). Alternative mechanical methods for providing circumferential chest compression using less energy than that required by a pneumatic device are being explored. Although the device is not presently FDA-approved or marketed in the United States, the American Heart Association considers vest CPR to be an acceptable alternative to standard CPR in-hospital or during ambulance transport (32).

Active Compression-Decompression Cardiopulmonary Resuscitation

Active compression-decompression CPR (ACD-CPR) is similar to conventional CPR, but it also provides negative intrathoracic pressure during the relaxation phase using a device that resembles a toilet plunger (eFig 69.0.3). ACD-CPR is performed with a suction-cup device called the *Ambu CardioPump*.

The ACD-CPR device consists of three parts: (a) a neoprene suction cup, (b) a plastic circular handle with an undercut handgrip, and (c) a force gauge. The gauge can be calibrated to a fixed depth, which usually is similar to standard CPR (1.5 to 2.0 in.). To ensure proper function by the operator, the decompression force is also measured up to –30 pounds by the gauge. The device is positioned at the midsternum in alignment with the nipples.

Initial studies on ACD-CPR in both experimental animal models and human subjects late after cardiac arrest have demonstrated improved cardiopulmonary hemodynamics when compared with standard manual CPR (54,55,58,360,361 and 362). In one clinical study, conventional CPR was compared with ACD-CPR in 21 patients undergoing routine induction of ventricular fibrillation as part of a transvenous lead cardioverter/defibrillator implantation procedure (360). Mean CPP was increased throughout the entire CPR cycle with ACD-CPR (compression of 21.5 ± 9.0 mm Hg; decompression of 21.9 ± 8.7 mm Hg) compared with conventional CPR (compression of 17.9 ± 8.2 mm Hg; decompression of 18.5 ± 6.9 mm Hg; p <.02 and p <.02, respectively). Unfortunately, despite promising initial clinical results (347), several recent randomized clinical trials have not shown any superiority of ACD-CPR over conventional CPR (363,364,365 and 366). However, one trial conducted in Paris has reported benefit in short-term survival with this technique (367).

The American Heart Association considers ACD-CPR to be an acceptable alternative to standard CPR when rescue personnel adequately trained in use of the device are available (32); however, the device is not FDA approved for sale in the United States.

Interposed Abdominal Compression

Interposed abdominal compression CPR (IAC-CPR) (eFig 69.0.4), also known as *abdominal counterpulsation CPR*, attempts to mimic intraaortic balloon counterpulsation. Two rescuers are needed to perform this technique: One rescuer compresses the sternum, and the other rescuer interposes abdominal compressions between each chest compression. Several investigators have demonstrated improvements in coronary perfusion, carotid and cerebral blood flows, and augmented venous return using IAC-CPR compared with standard CPR (59,61,71).

An early prehospital clinical trial in the mid-1980s failed to demonstrate any improvement in survival when IAC-CPR was compared with conventional CPR (368). Recently, IAC-CPR has been shown to improve survival in 143 consecutive patients experiencing in-hospital cardiac arrest with an initial arrest rhythm of asystole or EMD (78). Patients were randomized to receive either IAC-CPR or conventional CPR. The rate of ROSC was significantly higher in the group receiving IAC-CPR compared with the group receiving conventional CPR (49% vs. 28%, p = .01). At 24 hours, there were significantly more patients alive in the IAC-CPR group than in the conventional CPR group (33% vs. 13%, p = .009). No complications were demonstrated in a small subset of patients who died and underwent autopsy.

Similar findings were noted in another randomized clinical trial involving 135 resuscitation attempts in 103 patients (80). The rate of ROSC was significantly greater in the group receiving IAC-CPR compared with the group receiving conventional CPR (51% vs. 27%, p = .007). At hospital discharge, a significantly greater proportion of patients were alive in the IAC-CPR group than in the conventional CPR group (25% vs. 7%, p = .02). Eight (17%) of 48 patients who received IAC-CPR survived to hospital discharge neurologically intact compared with only three (6%) of 55 patients from the conventional CPR group (not significant). Thus, IAC-CPR appears to be a promising technique that may improve survival in selected cardiac arrest patients. The American Heart Association recommends the use of IAC-CPR for in-hospital resuscitation as an alternative to standard CPR whenever sufficient personnel trained in the technique are available (32).

Other Cardiopulmonary Resuscitation Techniques

A number of other interesting CPR techniques have been evaluated recently. Some of these techniques have been unequivocally shown to be of little or no clinical value. For example, the use of abdominal binding with a pneumatic antishock garment (also known as *military antishock trousers*, or *MAST*) during resuscitation does not improve survival even though it increases mean arterial pressure (369). The problem is that it raises central venous pressure by the same amount as the increase in arterial pressure, thus failing to increase the CPP. Similarly, simultaneous compression-ventilation CPR has been shown to decrease survival from cardiac arrest compared with conventional CPR, perhaps by causing collapse of arteries exiting the thorax and/or by creating significant barotrauma (370,371).

On the other hand, "cough" CPR has been shown to be of value in experimental animals and in clinical use (40,372,373,374 and 375). At the onset of lethal arrhythmias such as asystole, profound bradycardia, ventricular tachycardia, or fibrillation, coughing may assist in maintaining consciousness and an adequate systolic blood pressure. In some cases, it may also play a role in terminating the arrhythmia. The simplicity and effectiveness of this technique warrant its consideration for greater clinical use by health care providers. Similarly, "high-impulse CPR" using a rapid downstroke velocity may, in some circumstances, improve blood flow by transferring greater energy into the thorax and, perhaps, by enhancing the "cardiac pump" mechanism (44,45).

An impedance threshold valve has been developed to enhance the return of blood to the thorax during the chest decompression phase (376). This new device enhances negative intrathoracic pressure during chest wall recoil or the decompression phase, leading to improved vital organ perfusion during both standard CPR and ACD-CPR (376,377,378,379,380 and 381). With ACD-CPR, addition of the impedance threshold valve results in sustained diastolic pressures of more than 55 mm Hg in patients in cardiac arrest. The new valve shows promise for patients in asystole or shock refractory ventricular fibrillation, when enhanced return of blood flow to the chest is needed to "prime the pump." The American Heart Association considers this device to be acceptable as an adjunct to be used with ACD-CPR (32).

Public Access Defibrillation

Another innovative idea is termed "public access defibrillation," so named because the intent is to have non–health care citizens perform early defibrillation. So far, early attempts to train family members of high-risk patients or community workers in the use of AEDs have met with variable success. For example, Eisenberg et al. trained family members of 59 patients who had survived out-of-hospital cardiac arrest in King County, Washington (382). Only six of the 10 cardiac arrests that occurred in these patients were defibrillated successfully, and only one patient survived for a few months and sustained new neurologic impairment.

In contrast, Swenson et al. reported three successful resuscitations out of five cardiac arrests in 48 patients whose families had been trained to use an AED (383). More encouraging results have been obtained when community first responders have been trained to use automated defibrillators. For example, 160 security officers were trained to use these devices at Vancouver's World Expo 1986. Five cardiac arrests occurred among the 22.1 million visitors. Security personnel applied the AED correctly in all cases. In two cases, the initial rhythm was ventricular fibrillation. and defibrillation was successful. Both patients had a pulse and were regaining consciousness by the time EMS personnel arrived on the scene (384). Other experimental approaches to rapid defibrillation in the workplace include use on

commercial aircraft, airports, British rail stations, oil platforms in the North Sea, electricity plants, casinos, passenger cruise ships, and merchant marine vessels (385,386,387,388,389,390 and 391).

In Las Vegas casinos, security officers were trained and equipped to use AEDs on suspected cardiac arrest victims (388). AEDs were placed in the casinos at strategic locations to permit rapid defibrillation in 3 minutes or less from collapse. Out of 105 patients whose initial cardiac rhythm was ventricular fibrillation, 56 (53%) survived to hospital discharge. Among the 90 patients whose collapse was witnessed (86%), the clinically relevant time intervals were a mean (± standard deviation) of 3.5 ± 2.9 minutes from collapse to attachment of the defibrillator, 4.4 ± 2.9 minutes from collapse to the delivery of the first defibrillation shock, and 9.8 ± 4.3 minutes from collapse to the arrival of the paramedics. The survival rate was 74% for patients who received their first defibrillation no later than 3 minutes after a witnessed collapse and 49% for those who received their first defibrillation after more than 3 minutes.

AEDs are also becoming common on commercial aircraft (389,390,391 and 392). American Airlines was the first U.S. carrier to deploy this technology. In a recent report on the carrier's experience, American Airlines reported that AEDs were attached to 200 patients (191 on the aircraft and nine in the terminal), including 99 with documented loss of consciousness. Electrocardiographic data were available for 185 patients. A shock was advised in all 14 patients who had electrocardiographically documented ventricular fibrillation, and no shock was advised in the remaining patients (sensitivity and specificity of the defibrillator in identifying ventricular fibrillation of 100%). The first shock successfully defibrillated the heart in 13 patients (defibrillation was withheld in one case at the family's request). The rate of survival to discharge from the hospital after shock with the AED was 40%. A total of 36 patients either died or were resuscitated after cardiac arrest. No complications arose from use of the AED as a monitor in conscious passengers.

The National Heart, Lung, and Blood Institute and the American Heart Association are encouraging research into the safety, efficacy, and potential cost-benefit of this interesting concept (393,394,395,396 and 397). A multicenter, prospective, randomized, controlled clinical trial is currently under way to further assess the safety, efficacy, and cost-benefit of more widespread use of AEDs by trained laypersons in a public setting (397).

THE FUTURE

Better understanding of the mechanisms responsible for blood flow during closed-chest compression is leading to new CPR devices and techniques. It is highly probable that one or more of these innovations will result in significant improvement in the likelihood of successful resuscitation. If this occurs, the greatest challenge will be to better define from a medical and ethical perspective who should, or should not, receive such intervention. In addition, there will likely be much broader implementation of public access defibrillation.

Overview
Glossary
Introduction
Arrhythmias Associated with Unoperated Congenital Heart Defects
Atrial Septal Defect
Ebstein's Anomaly of the Tricuspid Valve
Pulmonary Valve Stenosis
Ventricular Septal Defect
Atrioventricular Septal Defect
Patent Ductus Arteriosus
Tetralogy of Fallot
Defects Causing Left Ventricular Outflow Tract Obstruction
D-Transposition of the Great Arteries
L-Transposition of the Great Arteries
Cardiac Defects Associated with Heterotaxy Syndromes
Tricuspid Atresia
Hypoplastic Left Heart Syndrome
Single Ventricle
Eisenmenger's Syndrome
Persistent Left Superior Vena Cava
Congenital Abnormalities of the Coronary Arteries
Ventricular Aneurysms and Diverticula and Left Ventricular False Tendons
Primary Cardiac Tumors in Children
Arrhythmias Immediately after Congenital Heart Surgery
Junctional Tachycardia
Other Arrhythmias in the Immediate Postoperative Period
Evaluation and Management of Patients with Chronic Arrhythmias after Surgery for Congenital Heart Disease
Chronic Arrhythmias after Operations on the Atria
Chronic Arrhythmias after Operation on the Ventricles
Arrhythmias after Repair of Other Congenital Heart Defects
Controversies and Personal Perspectives
Chapter References

OVERVIEW

Atrial tachyarrhythmias, especially atrial fibrillation (AF), are associated with certain unoperated congenital heart defects as patients get older and the atria become progressively more volume overloaded, especially in cases of atrial septal defect (ASD), Ebstein's anomaly of the tricuspid valve, and patent ductus arteriosus (PDA). Other unoperated congenital heart defects may be associated with increased risk for high-grade ventricular ectopy or sudden death as hemodynamics worsen, such as elevated pulmonary artery pressure in patients with ventricular septal defect (VSD) and increased wall stress in patients with aortic valve stenosis. There is an increased incidence of atrioventricular (AV) reciprocating tachycardia related to coexisting accessory AV connections in patients with Ebstein's anomaly of the tricuspid valve, L-transposition of the great arteries (L-TGA), and tricuspid atresia (TA). In contrast, congenital or progressive AV block may occur in patients with L-TGA or the heterotaxes due to coexisting abnormalities of the penetrating AV bundle. There is an increased incidence of sudden cardiac death (SCD) in patients with severe Ebstein's anomaly of the tricuspid valve, severe aortic valve stenosis, Eisenmenger physiology, and certain congenital coronary artery anomalies.

After congenital heart surgery involving the atria, especially the Mustard or Senning operations for D-TGA and the modified Fontan operation for single-ventricle variants, there is a progressive incidence of sinoatrial node dysfunction (SAND) (the "tachy-brady syndrome") over time, which may be difficult to control despite antiarrhythmic drugs, bradycardia pacing, antitachycardia pacing, and radiofrequency ablation. After surgery on the ventricles, especially for tetralogy of Fallot, there is a progressive risk over time for ventricular tachycardia (VT) or SCD, which seems to be related to older age at repair and to residual hemodynamic abnormalities.

GLOSSARY

Atrial effective refractory period: A clinical measurement of atrial muscle refractoriness, defined as the longest atrial paced interval not resulting in an atrial propagated response by the second pacing stimulus.

Bulboventricular foramen: The continued patent channel between the primitive ventricle and the *bulbus cordis* after fusion of the cushions of the *bulbus cordis* and after development of the primitive ventricular septum. This channel is the VSD in patients having a double-inlet left ventricle.

Concealed entrainment: Pacing from an anatomic point in the critical tachycardia circuit that does not fulfill the four primary criteria for entrainment but that is associated with a postpacing interval identical with the tachycardia cycle length. During concealed entrainment the tachycardia speeds up to the pacing rate but with no change in the tachycardia morphology or activation sequence.

Corrected sinus node recovery time: The time between the last atrial paced event and the first sinus recovery beat after a 30-second period of atrial pacing at a rate faster than the intrinsic sinus rate, corrected for the intrinsic sinus rate, either by subtracting the intrinsic sinus cycle length from the recovery interval or by dividing them. This is thought to represent one measurement of sinus node automaticity.

Drive train cycle length: A stable pacing rate, usually of eight beats' duration, used as part of standard pacing protocols for evaluating conduction properties or induction of reentry tachycardias.

Entrainment with termination: Pacing during a reentry tachycardia at a rate faster than the tachycardia rate for a sufficient duration that the paced wavefronts collide with the previous wavefront in both orthodromic and antidromic directions, resulting in termination of tachycardia when pacing is stopped.

Fontan operation: Any of a variety of operations designed to direct systemic venous return to the pulmonary arteries without the interposition of a ventricle. This is performed in patients with single-ventricle physiology.

Mustard operation: Operation designed for patients with D-TGA in which there is redirection of systemic and pulmonary venous returns to the mitral and tricuspid valves, respectively. Prosthetic material or pericardium is used.

Orthodromic reciprocating tachycardia: Any paroxysmal reentry supraventricular tachycardia that uses as a necessary component of the circuit the normal AV conduction system and whereby the circuit progresses down the normal conduction system in the antegrade direction.

Primary interventricular foramen: An embryologic term representing the connection between the primitive ventricle and the *bulbus cordis* in the developing

embryologic heart tube.

Senning operation: Similar to the Mustard operation in principle, but it consists almost exclusively of native atrial wall.

Sinoatrial conduction time: A measurement of conduction from the sinus node into the atrium, either by placing single premature atrial beats at progressively closer coupling intervals to sinus beats or after an eight-beat drive train. The two methods used are the Strauss method and the Narula method, respectively.

Triple extrastimuli: The placement of three premature beats into an intrinsic or paced rhythm for purposes of inducing a reentry tachycardia.

Ventricular paired pacing: The pacing technique designed to effectively slow the hemodynamic response rate to a pathologically accelerated ventricular rate, whereby an externally paced event is closely coupled to the previous intrinsic or paced event, resulting in ventricular electrical activation but no hemodynamic response.

Zones of slow conduction: Critical parts of reentry tachycardia circuits that may be identified by concealed entrainment and appear to be especially vulnerable to radiofrequency ablation for treatment of reentry tachycardia.

INTRODUCTION

Cardiac rhythm abnormalities related to congenital heart defects may occur in response to hemodynamic influences on chamber dimensions, muscle mass, and the specialized conduction system; may occur in response to metabolic effects on myocardial tissue; or may be due to coexisting congenital abnormalities of the specialized conduction system. This chapter reviews the clinical arrhythmias associated with unoperated congenital heart defects, arrhythmias of clinical importance that occur immediately after congenital heart surgery, and arrhythmias that occur long term after surgery for congenital heart defects. Management issues are emphasized in the sections regarding postoperative arrhythmias, with emphasis on newer treatment modalities.

ARRHYTHMIAS ASSOCIATED WITH UNOPERATED CONGENITAL HEART DEFECTS

Rhythm abnormalities in children with congenital heart defects before surgical intervention may occur directly related to the malformation complex or may occur secondary to progressive alterations caused by the defect(s). eTable 70.0.1 summarizes the incidences of arrhythmias in the more common unoperated congenital heart defects.

***e*TABLE 70.0.1** INCIDENCE OF PREOPERATIVE ARRHYTHMIAS IN PATIENTS WITH RELATED CONGENITAL HEART DEFECTS

Congenital heart defect	Atrial fibrillation/flutter	Paroxysmal supraventricular tachycardia	Ventricular tachycardia	Sudden death	Sinus bradycardial junctional rhythm	Atrioventricular block
Secondary and sinus venosus atrial septal defect	$^{+}$ to $^{+++}$ [a]				$^{+}$ to $^{++}$	0 to $^{+}$
Ebstein's anomaly	$^{+}$ to $^{++}$ [a]	$^{++}$		[b]		
Ventricular septal defect			$^{+}$	$^{+}$		
Patent ductus arteriosus	0 to $^{++++}$ [a]					
Tetralogy of Fallot			0 to $^{+++}$ [a]			
Aortic valve stenosis				[b]		
L-Transposition of the great arteries		$^{++}$		[b]		
Eisenmenger physiology			$^{++}$	$^{++}$	[b]	
Polysplenia		$^{++}$			$^{+}$ to $^{++++}$ [a]	$^{++}$
Asplenia		$^{+}$		[b]		$^{+}$

$^{+}$, up to 10% incidence; $^{++}$, 10% to 40% incidence; $^{+++}$, 40% to 60% incidence; $^{++++}$, 60% to 90% incidence.
[a]Incidence increases with age.
[b]Incidence increases with lesion severity or associated defects.

Atrial Septal Defect

In both ostium secundum and sinus venosus ASDs, chronic left-to-right shunting results in dilatation of the right atrium and right ventricle. Compared with children having other types of congenital heart defects, those having ASDs had longer PR (154 vs. 135 ms) and PA (52 vs. 29 ms) intervals, but AH and HV intervals were not significantly different (1). It has been believed that the dilated right atrium in those with ASDs resulted in slowed intraatrial conduction. Typically, the electrocardiogram (ECG) in patients with an ASD also shows right ventricular hypertrophy, manifest as an RSR' in V_1 and an RS in I and V_6.

Chest x-ray in atrial septal defect. There is plethora of the pulmonary vasculature with prominent main pulmonary arteries (*white arrows*).

Clark and Kugler evaluated 15 children (16 months to 18 years old) preoperatively with 24-hour ambulatory ECG monitoring and intracardiac electrophysiologic testing (2). Ten had prolonged corrected sinus node recovery times, five had evidence of AV nodal dysfunction (prolonged AH interval or abnormally slow AV nodal Wenckebach periodicity), but only two had ectopic atrial rhythms during ambulatory monitoring. Those having evidence of SAND tended to be older and to have a greater pulmonary-to-systemic flow ratio. In a separate report, Clark et al. demonstrated SAND in 18% of patients having sinus venosus but only 4% of those having secundum ASDs (2). From among 109 patients having sinus venosus defects, Kyger et al. reported the clinical courses of 109 patients (1 to 72 years old; median age, 14 years) with sinus venosus ASDs (3). Fourteen percent had preoperative arrhythmias, including four who were 10 years and younger (three with low atrial rhythms

and one with junctional rhythm).

A great deal more data are available in adults having ASDs. Older patients having unrepaired defects have increased likelihood of having atrial flutter or AF. Combining data from 454 patients from four reports, this incidence ranged from 4% to 24% of patients younger than 40 years old up to 51% to 63% of those 50 to 79 years old (4,5,6 and 7). This risk has also been demonstrated to increase with increasing pulmonary-to-systemic flow ratio (4), pulmonary resistance (8), or pulmonary artery pressure (9). Benedini et al. reported preoperative sinus node function in 26 adults (17 to 56 years old) having secundum ASDs (10). Both ambulatory ECG monitoring and intracardiac electrophysiologic measurements were used to identify SAND, but all 17 patients who were described as having SAND had only prolonged sinoatrial conduction times or sinus node recovery times. The Holter evaluations were normal. The authors concluded that SAND was “concealed” and could manifest itself postoperatively. In a large report of 384 patients (16 to 72 years old) by Hamilton et al., 8% had AF or flutter on routine ECG, 1% had third-degree AV block, 8% had minor conduction abnormalities, and 82% were in sinus rhythm (8). Although 44% complained of palpitations, only 20% had documented arrhythmias, with only eight patients having AF or flutter.

In summary, preoperatively, ASDs are infrequently associated with SAND, with the possible exception of sinus venosus defects, perhaps related to the anatomic proximity of the defect to the sinus node. Atrial tachyarrhythmias are more common in older persons and in those having the greatest degree of hemodynamic derangement. Although measurements of sinus node and atrial muscle automaticity or conduction may be abnormal in children, clinically important arrhythmias are uncommon.

Ebstein’s Anomaly of the Tricuspid Valve

Ebstein’s anomaly of the tricuspid valve occurs when there is an abnormality in separation of the right atrium from the right ventricle with downward displacement of the tricuspid valve leaflets into the right ventricle. This results in the presence of an “atrialized” portion of the right ventricle, often resulting in significant tricuspid regurgitation. In moderate or severe cases, it is associated with chronic cyanosis, severe volume overload of both atria, and sometimes right ventricular outflow tract obstruction. Dysplasia of part of the right ventricle and accessory AV connections are intrinsic malformations which are variably present. This combination of physiologic and anatomic abnormalities results in a patient group with a high incidence of arrhythmias. Even from early childhood, the ECG from moderately or severely affected patients shows marked right atrial enlargement and right ventricular conduction delay (*e*Fig. 70.0.1).

***e*FIGURE 70.0.1** Typical electrocardiogram from a teenager with moderately severe Ebstein's anomaly, showing right atrial enlargement, first-degree atrioventricular block, and right ventricular conduction delay. (From Hypoplastic right heart. In: Krovetz LJ, Gessner IH, Schiebler GL, eds. *Handbook of pediatric cardiology*, 2nd ed. Baltimore: University Park Press, 1979:297–308, with permission.)

In a large collaborative study reported by Watson (11), data from 505 patients were reviewed. Four hundred thirty-eight were younger than 25 years old. In the total group, 28% had reported paroxysmal arrhythmias, and 10% had Wolff-Parkinson-White (WPW) syndrome. Of 363 who underwent cardiac catheterization, 90 (25%) had arrhythmias during the procedure, including 46 (13%) with paroxysmal supraventricular tachycardia (PSVT), 11 (3%) with AF/flutter, 10 (3%) with VT, 23 (6%) with more than one tachyarrhythmia, and 1% each with complete AV block or severe bradycardia. During catheterization, 13 patients died (3.6%), and six additional patients survived after cardiopulmonary resuscitation (1.7%), all related to arrhythmias. Neither the presence of WPW syndrome nor a history of paroxysmal arrhythmias was predictive of arrhythmias or death at cardiac catheterization or for subsequent SCD. Gentles' retrospective analysis of 48 patients also failed to demonstrate a relationship between the coexistence of either WPW syndrome (21% of patients) or PSVT and early death (12). However, from among older patients, of 32% who had died, a history of AF was more common than in survivors (p = .03). From among 17 patients who had presented in infancy, seven (41%) died by 5 months, none due to arrhythmia.

In natural history studies, the incidence of arrhythmia increased with age at presentation (13,14 and 15). In Celermajer's report of 220 cases of Ebstein's (13), actuarial survival was only 59% at 10 years, but among 58 deaths, only eight were sudden. Although arrhythmias were the major contributor to morbidity, they rarely were fatal. Oh et al. reviewed 52 consecutive patients with Ebstein's anomaly at the Mayo Clinic (15), 12% of whom had WPW syndrome. Although a variety of arrhythmias were observed in 79% of patients, they were older than the group not having symptomatic or proven arrhythmias (21 vs. 9 years, p £.01).

Supraventricular tachycardias associated with accessory pathways can now be treated using catheter ablation techniques. Due to the abnormal anatomy and complex electrophysiology in Ebstein's patients, this technique is more challenging than in patients having normal hearts. In a multiinstitution report involving 65 Ebstein's patients, there were 82 nondecremental accessory pathways, nearly all right free wall or septal, and 17 other supraventricular tachycardias (one atrial ectopic tachycardia, seven AV node reentry tachycardias, five Mahaim fiber–related tachycardias, and four intraatrial reentry tachycardias) (16). Catheter ablation success rates ranged from 75% for those not involving accessory pathways to 89% for septal accessory pathways. The overall recurrence rate was 30%. Smaller patient size and lesser degrees of tricuspid regurgitation predicted better acute and long-term success rates.

Pulmonary Valve Stenosis

Valvar pulmonic stenosis causes right ventricular hypertrophy relative to the severity of outflow tract obstruction. Surgical or balloon valvuloplasty may relieve obstruction but result in pulmonary valve regurgitation with subsequent right ventricular volume overload. In their Report from the Second Joint Study on the Natural History of Congenital Heart Defects (NHS-2), Wolfe et al. reviewed arrhythmias from 182 patients with pulmonic stenosis (17). The only significant arrhythmia in this group was premature supraventricular beats (PSVBs), occurring at a rate exceeding 0.5 per hour (upper limits of normal) in 22% of patients. The remainder of this report involves patients who had undergone surgical valvotomy, which is discussed in the section Arrhythmias after Repair of Other Congenital Heart Defects.

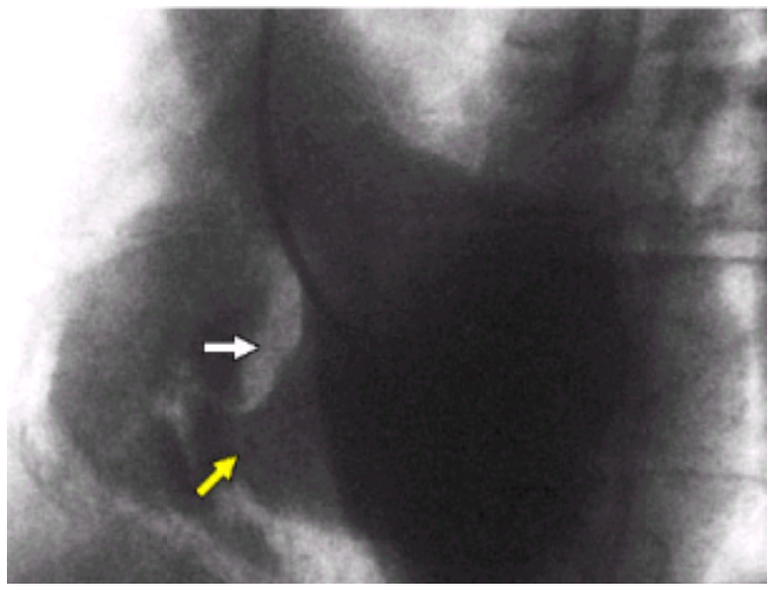
Ventricular Septal Defect

Patients having an unoperated VSD generally have ECG abnormalities or arrhythmias related to the severity of hemodynamic disturbance. Most moderate or large defects are associated with ECG findings of right and left ventricular hypertrophy and left atrial enlargement, as well as a variety of arrhythmias in both children and adults. In the NHS-2, Wolfe et al. reviewed 24-hour ECG data from 439 patients having a VSD (17). Of the younger group (younger than 40 years), 58 (15.3%) had more PSVBs and 22 (10.6%) had more premature ventricular beats (PVBs) than the control population. Ventricular couplets (17.3%) and multiform PVBs (26.3%) were more prevalent than expected among patients younger than 50 years old, and 5.7% of all patients had at least one episode of ventricular tachycardia (p <.0001 vs. controls). In this group of patients who had not had surgery, the best independent predictors for having serious arrhythmias were the mean pulmonary artery pressure at the time of entry into the first Natural History Study (NHS-1) and age at the NHS-2.



Muscular ventricular septal defect. This left anterior oblique left ventriculogram demonstrates the presence of a muscular ventricular septal defect (*yellow arrow*) with opacification of the right ventricular cavity and pulmonary outflow tract. The ventricular septum (*white arrow*) is seen to divide the right and left ventricular chambers.

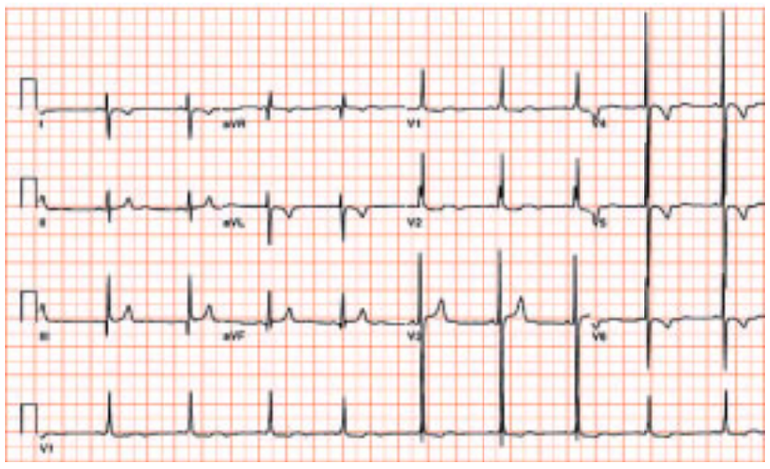
Chest x-ray in patient with a congenital ventricular septal defect. There is fullness in the hilum secondary to an enlarged pulmonary artery (*white arrow*).



A 16-year-old male patient with biventricular hypertrophy secondary to ventricular septal defect and Eisenmenger's syndrome.

In a separate study, among 109 Norwegian adults 16 to 65 years old (52 were younger than 25 years old) having VSD, 37 complained of palpitations and atypical chest pain, although AF was documented in only one patient with a large defect (18). In a more recent report of 188 young adults (mean age, 29.2 years), all of whom had a *small* VSD (19), age-related symptomatic tachycardias were documented in 8.5%, mostly AF.

Atrioventricular Septal Defect

In all forms of AV septal defect (AVSD), the AV node maintains its position between the insertion of the inlet ventricular septum and the atrial septum (20). This results in postero-inferior displacement of the AV node and left bundle branch (21), a longer than normal penetrating bundle (20), and relative hypoplasia of the anterior portion of the left bundle branch (21). This gives the familiar left-axis deviation of the QRS complex with the superior counterclockwise vector loop in the frontal plane. Chamber enlargement as reflected by the ECG depends on the associated hemodynamics. For example, in the presence of "complete AVSD," the ECG typically shows biventricular hypertrophy and biatrial enlargement. In patients with an ostium primum ASD or with a complete AVSD but a small VSD, the ECG will show left-axis deviation and right atrial and ventricular enlargement. In older children or adults with unoperated AVSDs, Eisenmenger physiology will have supervened, resulting in marked right ventricular hypertrophy.

Electrophysiologic data from 18 children (median age, 3 years) with preoperative AVSDs showed only first-degree AV block in five (prolonged PA interval in one, prolonged AH intervals in two, and normal intervals in two), prolonged PA intervals with normal PR intervals in four, and sinus node dysfunction in one (22). Accessory AV connections and PSVT may also exist in association with this congenital defect. In our experience, they tend to be posteroseptal in location.

Patent Ductus Arteriosus

Like VSD, PDA results in volume loading of the left atrium and the left ventricle as long as the shunt remains left-to-right. Arrhythmias are most unusual in the infant, child, or teenager with an isolated PDA. Marquis et al. (23) reported the 37 patients who survived beyond 50 years from among 804 with PDAs who were seen in Edinburgh from 1940 to 1979. AF accompanied congestive heart failure by the fifth or sixth decades of life inexorably among those not undergoing surgical repair and persisted even in the majority undergoing ligation. Other arrhythmias were uncommon. These findings were corroborated by McManus' report of 46 adults with a PDA (24). When ECGs were available, 18 of 21 patients had persistent or intermittent AF.

Tetralogy of Fallot

Tetralogy of Fallot is characterized by hypoplasia and anterior malalignment of the infundibular septum, infundibular and often valvar pulmonic stenosis, overriding aorta, and perimembranous-to-outlet VSD. The hemodynamic findings in patients preoperatively with tetralogy of Fallot include right ventricular hypertension with associated hypertrophy, normal pulmonary arteriolar resistance, and variable degrees of systemic arterial desaturation with secondary polycythemia. The preoperative ECG shows right ventricular hypertrophy and right-axis deviation. There is an age-related increase in ventricular arrhythmia in these patients. Among 60 unrepaired patients (3 months to 63 years old), Deanfield et al. noted that 20% of those older than 8 years had significant ventricular ectopy (Lown grade II or higher), and 58% of those 16 years and older were affected, including four (21%) with 3- to 12-beat runs (25). Similarly, supraventricular arrhythmias were only found in children older than 8 years; three children had episodes of PSVT. These findings were corroborated by Sullivan et al. who noted that, among 50 preoperative patients, those younger than 7 years old never had ectopy worse than Lown grade I preoperatively compared with 44% of 18 patients 30 to 43 years old (26).

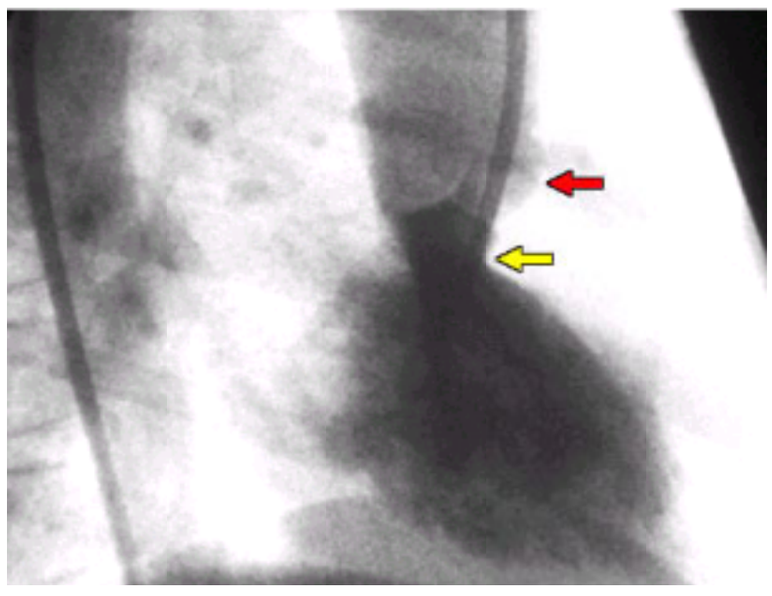
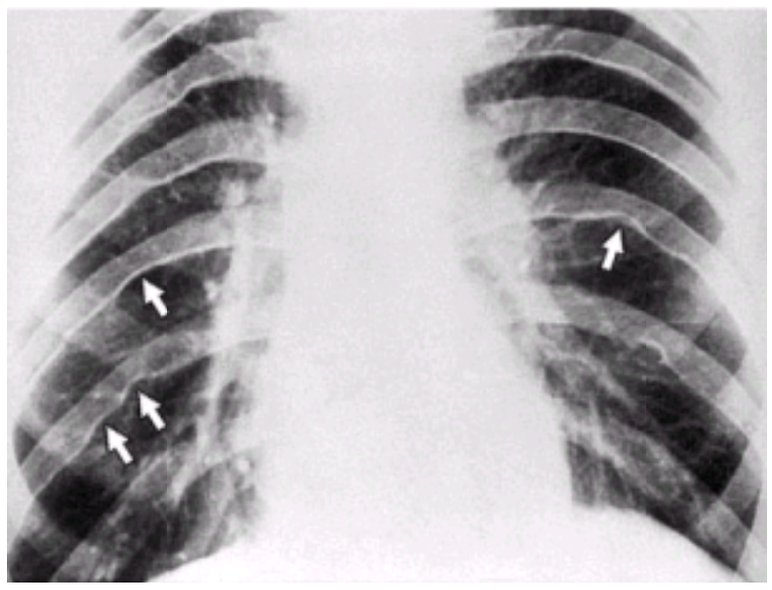
Defects Causing Left Ventricular Outflow Tract Obstruction

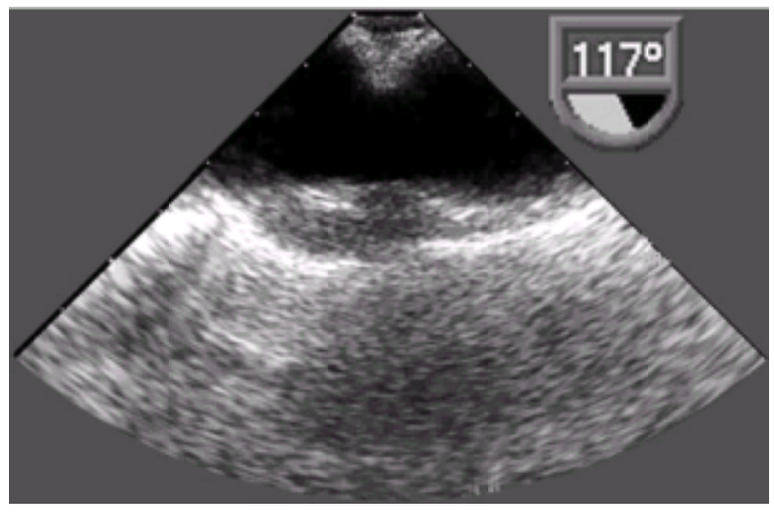
Congenital heart defects causing left ventricular outflow tract obstruction include subvalvar, valvar, and supravalvar aortic stenosis (AS) and coarctation of the aorta. Increased left ventricular wall stress with secondary hypertrophy occurs related to severity of obstruction. Bush et al. performed electrophysiologic evaluations on right atrial tissue obtained from 58 children and adults having valvar AS at the time of aortic valve surgery (27). Only 18% of those younger than age 20 years but 67% of those older than age 40 years had postoperative supraventricular arrhythmias—almost entirely AF/flutter in the older group. Diffuse phase 4 depolarizations and local conduction abnormalities were present in right atrial tissue from the older patients. These findings were absent from both the younger patients and from age-matched older patients not having AS, suggesting that there is a progressive influence on the electrophysiologic milieu of the right atrium by the long-standing hemodynamic effects of AS.



Subaortic stenosis. This right anterior oblique left ventriculogram demonstrates the presence of a stenosis in the left ventricular outflow tract (*yellow arrow*) just below the level of the aortic valve (*red arrow*).



Chest x-ray in coarctation of the aorta. There is prominent rib notching (*white arrows*).



A still frame of a transesophageal echo demonstrating a coarctation of the aorta. Note the local narrowing of the aorta located at the junction of the distal arch and descending aorta. There was a 100–mm Hg pressure gradient across the coarctation as determined by continuous wave Doppler.

Video 70.12 Color Doppler interrogation of the coarctation demonstrating the high-velocity, turbulent flow across the focal narrowing in the aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

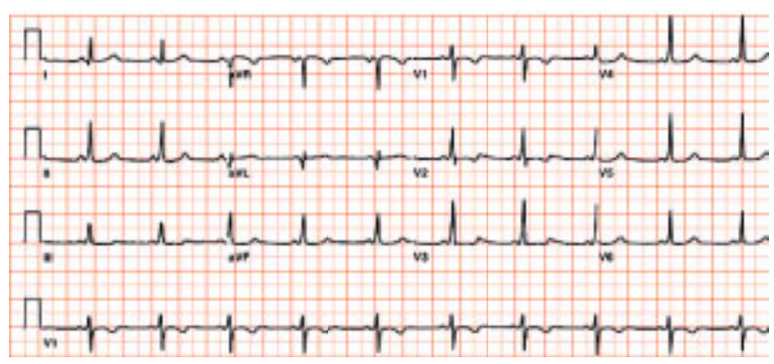
AS in children is only occasionally associated with arrhythmias. Bisset et al. identified no conduction defects or arrhythmias in 15 children about to undergo aortic valve replacement (28). In a study by Bricker et al., of 2,761 children and young adults who had undergone exercise testing at Baylor University, only six patients had developed exercise-related bundle branch block, but two had subvalvar AS and one valvar AS (29). These three represented a relatively significant percentage (0.5%) of the total number having AS.

In distinction from children, Klein demonstrated high-grade ventricular ectopy by ambulatory ECG monitoring in 34% of adult patients having AS and no coronary artery disease compared with only 6% of controls (30). von Olshausen et al. (31) and Santinga et al. (32) confirmed these findings and further showed that the degree of ectopy correlated with a lower left ventricular ejection fraction and higher wall stress and not with the magnitude of peak systolic ejection gradient across the aortic valve. Possible mechanisms for sudden death in this lesion are paroxysmal ischemic changes, AV dissociation, electrical standstill, VT, and nonsustained ventricular flutter.

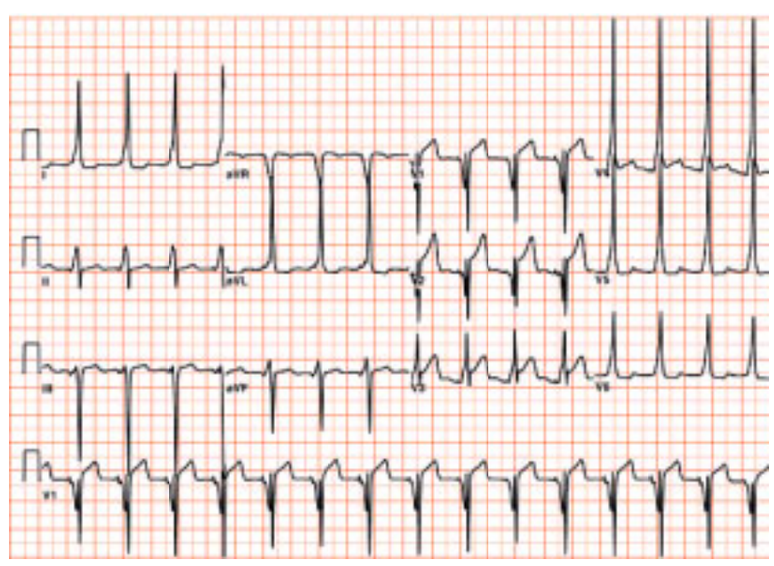
Wolfe et al. reviewed 24-hour ECG monitored data from 134 patients with AS as part of the ongoing NHS-2 investigation (17). PSVBs occurred with greater than normal frequency in this patient group than in controls. However, the prevalence of PVBs was not greater than expected.

Conduction abnormalities may complicate native aortic valve infective endocarditis. In a report by DiNubile et al., 9% of 211 patients with infective endocarditis developed conduction abnormalities (33). This was more likely in those having aortic valve disease than in those having other valve involvement, especially if the infection had spread beyond the valve anulus. Progressive AV or bundle branch block was an independent predictor of death, suggesting that valve replacement is indicated in the presence of unstable AV conduction, especially when the aortic valve is involved. Similarly, echocardiographic demonstration of a perivalvular abscess involving the right and/or noncoronary cusps mandates particularly close monitoring of AV conduction.

In patients having unrepaired coarctation of the aorta, there usually is discrete narrowing of the aorta just distal to the takeoff of the left subclavian artery. This results in hypertension of the proximal aorta and left ventricle, manifest as left ventricular hypertrophy on the ECG. Coarctation is rarely associated with congenital AV block (34) and with WPW syndrome (35). Two cases of sudden death have been reported, one in a 31-year-old after several years of Stokes-Adams attacks and progressive AV block (36) and the other in a 20-year-old with recurrent episodes of AF 9 years after surgical repair of coarctation of the aorta (37). Although subarachnoid hemorrhage and ruptured aorta are the most frequently considered causes of sudden death in those with coarctation of the aorta, both of these patients had marked histologic abnormalities of the AV conduction system at postmortem examination.



A 44-year-old female patient with Wolff-Parkinson-White syndrome.



A 16-year-old male patient with Wolff-Parkinson-White syndrome.

Supravalvar AS may exist as an isolated defect or in association with Williams syndrome, in which case pulmonary and coronary artery hypoplasia may also exist. Sudden death from myocardial infarction may occur in severely affected patients (38).

D-Transposition of the Great Arteries

Babies born with D-TGA have ventriculoarterial discordance with an anterior aorta arising from the right ventricular outflow tract and a pulmonary artery arising posteriorly from the left ventricle. As long as the right ventricle remains the systemic ventricle (as it must preoperatively or after an atrial redirection operation), the ECG maintains a pattern of right ventricular hypertrophy in these patients. Because the normal newborn's right ventricle has been at systemic pressure antenatally anyway,

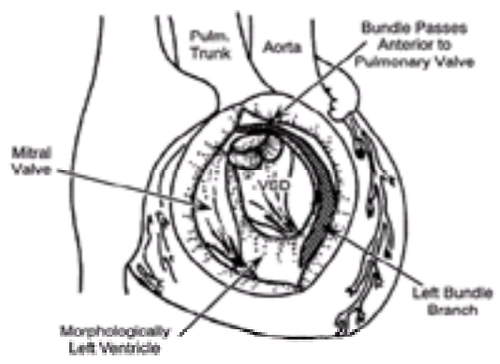
the newborn with D-TGA usually has a normal ECG (for age). The high incidence of rhythm disturbances after atrial redirection procedures for simple D-TGA prompted two large investigations on preoperative patients with this malformation.

Southall et al. reviewed the heart rhythms from 120 consecutive patients with D-TGA, admitted over a 6-year period (39). Eighty percent had undergone balloon atrial septostomy, 2.5% atrial septectomy, and 17.5% neither. One of the 120 had first-degree AV block, and a second acquired first-degree AV block during cardiac catheterization. Both had complete AV block postoperatively. Preoperative 24-hour ambulatory ECG monitoring from 19 patients demonstrated periods of second-degree and complete sinoatrial block in 10 (one with additional premature atrial beats and six with periods of junctional rhythm), premature atrial beats alone at less than 12 per hour in two others; and periods of junctional rhythm in one additional patient. The lowest rates observed were at least 50 per minutes in all but two children. When compared with results of 134 healthy newborns and 92 healthy juveniles, the authors concluded that the ECG patterns in these 19 children were normal.

Martin et al. reported their preoperative findings from 92 survivors of the Mustard operation from among 115 patients over a 10-year period (40). Eighty-three percent of children were in normal sinus rhythm; 12.2% had Lown grade I ventricular ectopy; and there was one child each with frequent premature atrial beats, AF, and Lown grade V ventricular ectopy. These authors also concluded that the preoperative rhythm in children with D-TGA was not different from that of normal children.

L-Transposition of the Great Arteries

In patients with L-TGA (also known as *congenitally corrected transposition* or *ventricular inversion*), there is AV and ventriculoarterial discordance; hence, desaturated systemic venous return enters the pulmonary arteries, and fully saturated pulmonary venous return is directed to the aorta as it should. The aorta arises from a left-sided right ventricular outflow tract, leftward and anterior to the pulmonary artery. In this condition, the ventricles are said to be levo-looped (L-looped), as contrasted to the normal ventricular dextro-looping (D-looping). Associated congenital heart defects include VSD and/or pulmonic stenosis in the majority and tricuspid valve (the left AV valve that functions as the systemic AV valve) insufficiency in up to one-third of patients (41). The specialized AV conduction system is structurally different as well, usually giving a QS or qR pattern in V_1 and an rS or RS pattern in V_6 on standard ECG (*e*Fig. 70.0.2).



***e*FIGURE 70.0.2** The specialized conduction system in a heart having L-transposition of the great arteries, illustrating its relationship to the pulmonary valve and, when present, a ventricular septal defect (VSD).

As described by Anderson et al. from a small series of explanted hearts having L-TGA (42), the connecting AV node is located anteriorly in the right atrium at the mitral-pulmonary junction with an anteriorly positioned bundle of His that encircles the anterolateral region of the pulmonary valve. The bundle of His bifurcates on the anterior ventricular septum and always borders the anterior/superior quadrant of a VSD, when present. A hypoplastic posterior AV node is also usually present just anterior to the coronary sinus, but rarely does it connect with the ventricular mass. In specimens from older patients, the elongated encircling bundles were infiltrated with fibrous tissue or completely disrupted. Five patients had ECG evidence of complete AV block. Congenital AV block due to a lack of continuity between the atria and specialized conduction system in patients with L-TGA has also been reported (42).

Further clinical correlation with these pathologic findings is provided by a large series by Huhta et al., who reviewed the data on 107 patients with L-TGA ranging in age from 2 to 76 years at follow-up (41). Twenty-two percent of patients had complete AV block: 4% congenitally, and 19 others developmentally from ages 4 months to 52 years (mean, 18.1 years). Data analysis showed an approximately 2% per year risk of developing AV block after diagnosis. The risk was higher in those *not* having a VSD, and the risk was not increased after VSD closure if intraoperative AV block did not occur. The only death in their series was a 28-year-old patient who died suddenly during exercise 4 years after onset of AV block. The authors concluded that prophylactic pacemaker placement was not necessary in children as long as their heart rates were greater than 50 beats/min.

Tachyarrhythmias also occur more frequently than in the general population, although the actual incidence is unreported. PSVT, usually AV reentry tachycardia using an accessory AV connection associated with the tricuspid valve (generally left free wall or septal if patient has situs solitus), is most common among these (*e*Fig. 70.0.3) (43,44); multiple left-sided pathways may be present. Symptomatic VT has also been reported in unoperated older patients having L-TGA (45,46).

***e*FIGURE 70.0.3** Electrocardiogram using mirror-image lead placement from a 12-year-old patient having *situs inversus totalis*, “corrected” transposition of the great arteries in *situs inversus*, and two manifest accessory pathways related to the pulmonary venous right-sided tricuspid valve—one posterior and one posteroseptal. (From Kanter RJ, Garson A. Arrhythmia in congenital heart disease. In: Podrid PJ, Kowey PR, eds. *Cardiac arrhythmia.* Baltimore: Williams & Wilkins, 1995:1131–1160, with permission.)

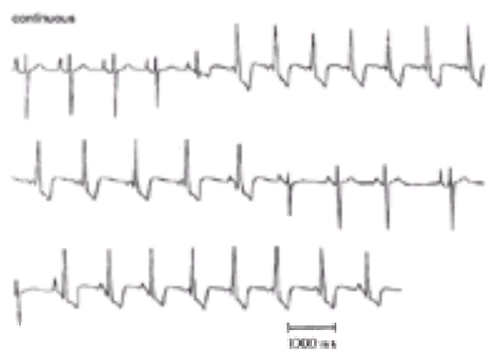
Arrhythmias secondary to hemodynamic abnormalities include atrial tachycardias, which seem to be ubiquitous in these patients starting in the fifth decade (46), especially in the presence of tricuspid (left-sided AV valve) regurgitation. Tricuspid valve replacement carries risk for AV block. In the report by Prieto et al. of 40 patients with L-TGA (47), the 20-year survival rates in unoperated patients were 60% for those having and 100% for those not having significant tricuspid regurgitation (systemic AV valve); not all deaths were arrhythmic, however.

Cardiac Defects Associated with Heterotaxy Syndromes

Heterotaxy syndromes refer to patterns of malformation thought to occur after failure of lateralization of thoracic and abdominal viscera into either situs solitus or situs inversus. They frequently involve the cardiovascular system, often with severe congenital malformations (*e*Fig. 70.0.4). Although they are usually categorized as either right (RAI) or left atrial isomerism (LAI), there is great variability within each group. The cardiac conduction system is usually structurally abnormal, and congenital or acquired AV block is the most important clinical conduction defect.

***e*FIGURE 70.0.4** Characteristic visceral abnormalities, including congenital heart defects in patients having right atrial isomerism or "asplenia" **(A)** and left atrial isomerism or "polysplenia" **(B)**. **A:** Characteristic features of asplenia: (1) bilateral eparterial bronchi, (2) bilateral trilobed lungs, (3) bilateral morphologic right atria, (4) pulmonary venous anomalies, (5) cardiac malformations, (6) systemic venous anomalies, and (7) symmetric liver and right- or left-sided stomach. **B:** Characteristic features of polysplenia: (1) bilateral hyparterial bronchi, (2) bilateral lobed lungs, (3) bilateral morphologic left atria, (4) pulmonary venous anomalies, (5) cardiac malformations, (6) systemic venous anomalies, (7) symmetric liver and right- or left-sided stomach, and (8) multiple spleens. (From Van Mierop LHS, Gessner IH, Schiebler GL. Asplenia and polysplenia syndromes. *Birth Defects* 1972;8:36–43, with permission.)

Histopathologic studies have demonstrated bilateral sinus node–like structures in patients with RAI, each at the superior vena caval–right atrial junction when bilateral cavae are present (48,49). This is consistent with the observed inferior P-wave axis or axes in almost every ECG from the combined 109 patients with RAI reported by Wren et al. (50) and by Momma et al. (51). In the latter series, the sinus rate remained stable over time in all but two patients. We have observed two P-wave axes at different times in two patients each with RAI (*e*Fig. 70.0.5).



***e*FIGURE 70.0.5** Continuous rhythm strip from a 16-year-old boy having right atrial isomerism. A change in atrial pacemaker is followed by a change in PR interval, followed in turn by a change in QRS polarity and morphology. The patient had duplication of the atrioventricular node and penetrating bundle of His. (From Kanter RJ, Garson A. Arrhythmia in congenital heart disease. In: Podrid PJ, Kowey PR, eds. *Cardiac arrhythmia*. Baltimore: Williams & Wilkins, 1995:1131–1160, with permission.)

In the report by Wren et al., 67 patients had LAI, and the P-wave axis was 0 degrees to –90 degrees in 8%, –90 degrees to –180 degrees in 41%, 0 degrees to 90 degrees in 37%, and 90 degrees to 180 degrees in 14% of the ECGs reviewed (50). Among 14 patients who had 24-hour ECG monitoring, only four had a stable "sinus" P-wave axis and almost one-third demonstrated subsequent P-wave shifts of 90 degrees or more. Momma et al. also reported a dominance of superior P-wave axes in children (mean age, 7.4 years) with LAI, with 70% being –30 degrees to –90 degrees (51). There was also a tendency toward atrial rate slowing over time. By age 15 years, two-thirds had slow atrial or junctional rhythms. Dickinson et al. showed that patients with LAI had sinus node–like tissue, often hypoplastic, in the lateral atrial wall of seven of nine patients, and it was entirely absent in two (49).

Complete AV block, congenital or acquired, occurs in up to 15% of patients with LAI (50). Case reports of congenital AV block also exist in instances of RAI (48), although the incidence appears to be lower in patients with RAI than in those with LAI. In the report by Dickenson et al., a detailed analysis of the histopathology of the AV conduction system of 13 patients with LAI and RAI may explain this clinical observation (49). All four patients with RAI had anterior and posterior AV nodes and penetrating bundles. In only one was there discontinuity between the anterior AV node and corresponding bundle. However, of nine with LAI, two had discontinuity between anterior and posterior AV nodes and their bundles. All three patients with LAI, ventricular D-looping, and two ventricles had a normal (single posterior) AV node and continuous bundle of His, meaning that among those six patients with LAI and single ventricle and/or ventricular L-looping, two had complete AV block. A connecting sling of conduction tissue between the anterior and posterior penetrating bundles was identified in all patients in whom both penetrating bundles existed. Its clinical relevance is unknown. One patient with LAI had an accessory AV connection and WPW syndrome on ECG.

Clinically important tachycardias are less frequent than AV block. When WPW syndrome is present, AV reentry tachycardia may occur. A macroreentry supraventricular tachycardia involving two AV nodes and successful catheter ablation of the AV node having poorer anterograde conduction has also been reported (52). Atrial flutter (50) may be related to atrial stretch from volume loading due to AV valve regurgitation, left atrial enlargement from left-to-right shunting in the presence of a VSD, or to chronic changes caused by chronic tissue hypoxemia and polycythemia.

The clinical relevance of all arrhythmias in this group of patients is heightened by the associated hemodynamic abnormalities imposed by the structural defects. Tachycardia suppression and support of unduly slow rate with artificial pacing are of great importance.

Tricuspid Atresia

TA is a congenital abnormality of alignment in which there is absence of AV connection to the morphologically right ventricle (53). The ventricular septum maintains its early developmental position; therefore, the AV node is located in the normal location or posterolateral to the blind-ending dimple in the floor of the right atrium. It is related normally to the tendon of Todaro and coronary sinus (20).

The surface ECG in these patients demonstrates right atrial enlargement in almost all, left-axis deviation in approximately three-fourths (54), a short PR interval in approximately 12% (55), and the WPW syndrome in between 0.29% (56) and 0.51% (55). When Zellers et al. systematically evaluated 183 patients with TA, they found that only one of nine fulfilling ECG criteria for WPW syndrome had an accessory pathway (55). The other eight had normal or enhanced AV nodal conduction, prompting the term "pseudopreexcitation." Surprisingly, of those nine patients, five had had clinical PSVT.

As in all patients requiring aortopulmonary shunts to augment pulmonary blood flow, atrial tachyarrhythmias become problematic if atrial volume overloading is long-standing.

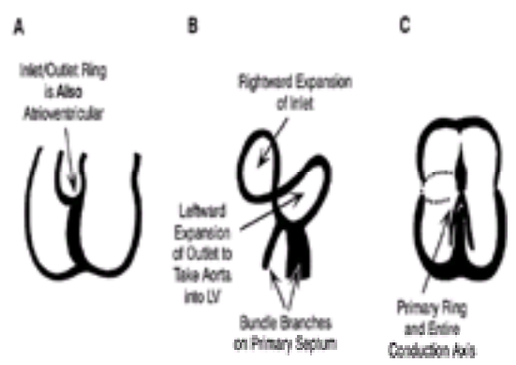
Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome includes a spectrum of abnormalities ranging from mitral and aortic atresia with no demonstrable left ventricular chamber to a very small left ventricle with mitral and/or aortic valve hypoplasia. It is the most common form of functional single ventricle but before recent improvements in surgical technique and perioperative management, interest in arrhythmias in these patients was academic. The specialized conduction system in hypoplastic left heart syndrome is normal, but there may be a higher than expected incidence of atrial ectopic tachycardia, especially in cases of familial hypoplastic left heart syndrome (57).

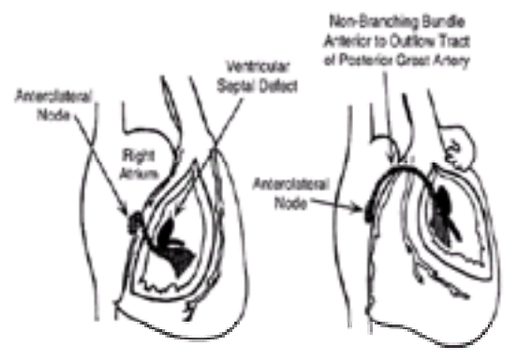
Single Ventricle

Other congenital heart defects in which there is only one functional ventricle include defects that usually have abnormalities of the specialized conduction system. Knowledge of the embryology of the specialized conduction system in the normal heart may help explain the abnormalities encountered in these malformed hearts

(eFig. 70.0.6). It is also useful to consider these entities according to whether there is left ventricular dominance or right ventricular dominance and according to whether there is ventricular D-looping or L-looping. When the main ventricle is L-looped, there may be two AV nodes, one posteriorly located and the other along the anterolateral margin of the right AV orifice. All of these considerations influence the course of the conduction system and potential for natural or surgical AV block (eFig. 70.0.7).



***e*FIGURE 70.0.6** Development of the specialized atrioventricular conduction system. Initially, it forms a ring around the primary interventricular foramen **(A)**. As the heart tube loops rightward and the atria gain their eventual relationship with both the primitive ventricle and the *bulbus cordis*, the dorsal portion of the ring of conduction tissue occupies the inner margin of the heart tube **(B)** as well as the right margin of the atrioventricular junction **(C)**. LV, left ventricle. (From Anderson RH, Ho SY. The morphologic substrates for pediatric arrhythmias. *Cardiol Young* 1991;1:159–176, with permission.)



***e*FIGURE 70.0.7** The relationship between the specialized atrioventricular conduction system to the ventricular septal defect in double-inlet left ventricle in hearts that have ventricular D-looping **(left)** and ventricular L-looping **(right)**. Because the vestigial right ventricle usually gives rise to the aorta, the ventricular septal defect must be unrestrictive for the patient to maintain systemic blood flow. Knowledge of the conduction system location will permit surgical enlargement, when necessary.

Double-inlet left ventricle may occur with either D- or L-looping of the ventricular mass and results from persistent connection of the right atrium to the left ventricle. Neither atrium connects with a vestigial right ventricular outlet chamber, and the ventricular septum does not extend to the crux but contacts the AV ring anteriorly. Embryologically, the primary ring of conduction tissue forms to the right of the interatrial septum, causing the AV node to form anterior and lateral to the atrial septum to connect to the trabecular septum (20). There is a difference in location of the penetrating bundle with respect to the persistent bulboventricular foramen (functional VSD) in L- versus D-looped hearts (20). Additionally, as in hearts with two ventricles and L-TGA, hearts with double-inlet left ventricle and ventricular L-looping (a) may have two AV nodes (in which case the posterior rarely makes contact with the ventricular septum) and (b) are prone to fibrous degeneration of the bundle of His and complete AV block. When complete atresia of the right AV orifice occurs, there is a single anterolateral or posterolateral AV node, similar to that found in classic TA (58).

When there is a dominant right ventricle, the ventricular septum contacts the crux of the heart and the AV node is normally located. In patients with double-inlet right ventricle, or straddling of the right AV valve plus ventricular L-looping, there may be an additional “sling” of conduction tissue between two AV nodes (58). In the presence of ventricular D-looping and a dominant right ventricle, the AV node is normally positioned with respect to atrial landmarks, and the penetrating bundle directly enters the ventricular septum (59).

Eisenmenger’s Syndrome

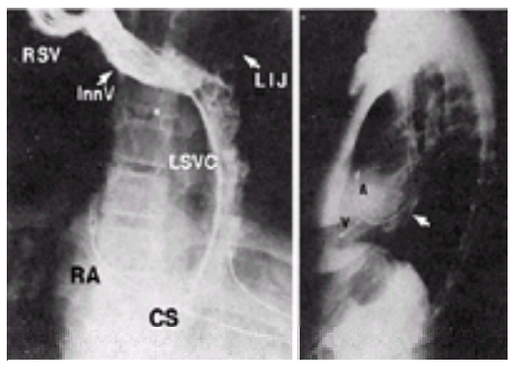
Eisenmenger’s syndrome is defined as the presence of irreversible elevation of pulmonary vascular resistance in certain congenital heart defects in which there initially was increased pulmonary artery blood flow or increased pulmonary artery pressure. With the elevation in pulmonary arteriolar resistance, patients shunt right to left, resulting in myocardial hypoxia, polycythemia, increased blood viscosity, and interstitial fibrosis. Sudden unexpected death has been reported to occur in 12% (60) and 18% (61) of patients, and the prior existence of supraventricular tachyarrhythmias has been identified as an independent predictor of mortality in affected adults (62).

In Wolfe’s natural history series of VSD patients (17), 20 had Eisenmenger’s syndrome. During 24-hour ECG monitoring, 80% had a frequency of PVBs exceeding that of a normal population, 72.2% had ventricular couplets, 88.9% had multiform PVBs, and 20% had greater than one ventricular tachycardia episode. These prevalences far exceeded those from all other patient groups with VSDs, AS, or pulmonic stenosis. However, the relationship of these findings to risk of sudden unexpected death is unproved, and hemodynamic etiologies may be more important. There is speculation that a sudden additional rise in pulmonary vascular resistance could be the cause of sudden death in some of these patients.

Persistent Left Superior Vena Cava

Persistent left superior vena cava occurs as an isolated finding in approximately 0.5% of the general population and has no hemodynamic significance. This structure courses across the posterolateral wall of the left atrium where the oblique ligament of Marshall would have existed, before it enters the right atrium by way of the great cardiac vein and coronary sinus. When it accompanies a sinus venosus–type ASD, a low atrial rhythm (so-called coronary sinus rhythm) having a superior P-wave axis may be expected (63). If there is a persistent left and no right superior vena cava, impaired sinus node function may occur. This combination plus AV node dysfunction was thought to cause fatal bradycardia in a report of two children (64).

If transvenous pacemaker implantation is required, there are special considerations. In the presence of a coexisting right superior vena cava, that approach is preferable. If the left subclavian vein must be used, the size of the innominate vein must be assessed, as it is often small. In such cases and when there is no right cava, the ventricular lead must be passed through the coronary sinus and looped in the right atrium so that it may enter the right ventricle. Prior knowledge of the existence of a left superior vena cava should permit successful placement of an active fixation system using biplane imaging (eFig. 70.0.8). Reported complications have included atrial perforation and thrombosis of the coronary sinus (65,66).



***e*FIGURE 70.0.8 Left:** Anteroposterior projection of a right innominate venogram in a 13-year-old patient having absent right superior vena cava and mirror-image venous return to a left superior vena cava (LSVC), which enters the right atrium (RA) via the coronary sinus (CS). His rhythm was low atrial and junctional. **Right:** Lateral chest radiograph from an adult with similar anatomy, illustrating the posterior and inferior location (*arrowhead*) of both atrial and ventricular pacing leads as they enter the right atrium. The ventricular lead must then loop almost 180 degrees before entering the tricuspid valve and right ventricle. A, atrium; InnV, innominate vein; LIJ, left internal jugular vein; RSV, right subclavian vein; V, ventricle. (From Van Nooten G, Verbeet T, Deuvaert FE. Atrial perforation by a screw-in electrode via a left superior vena cava. *Am Heart J* 1990;119:1439–1440, with permission.)

Congenital Abnormalities of the Coronary Arteries

Congenital abnormalities of the origin and courses of the coronary arteries are rare but disproportionately important defects because they may be associated with sudden myocardial ischemia, ventricular fibrillation, and death. When the left coronary artery arises from the pulmonary artery, symptoms almost always occur, usually in early infancy, but if collateral coronary blood supply from the right coronary artery is adequate, symptoms may occur as late as adolescence (67).

In another group of defects, the left main coronary artery may arise from the right sinus of Valsalva (68,69,70 and 71), or less frequently, the right may arise from the left sinus (72,73). In either instance, the aberrantly arising coronary artery tends to have a partial intramural course, may have a narrowed origin, and may be prone to compression between the ascending aorta and pulmonary artery during exercise. Sudden death may result, and ventricular tachycardia has been observed in nonfatal cases. In four autopsy series reporting sudden death in children and young adults, one of these defects existed in 5% to 35% of cases (74,75,76 and 77). In another autopsy series by Barth and Roberts, 61% of 38 patients having the left main coronary artery arising from the right sinus had died by 20 years of age (71), and when the clinical histories from autopsy specimens having this defect were reviewed, death was sudden and unexpected in the great majority. The risk of sudden death in the case of anomalous right coronary artery is less well established, but probably is not as great (78).

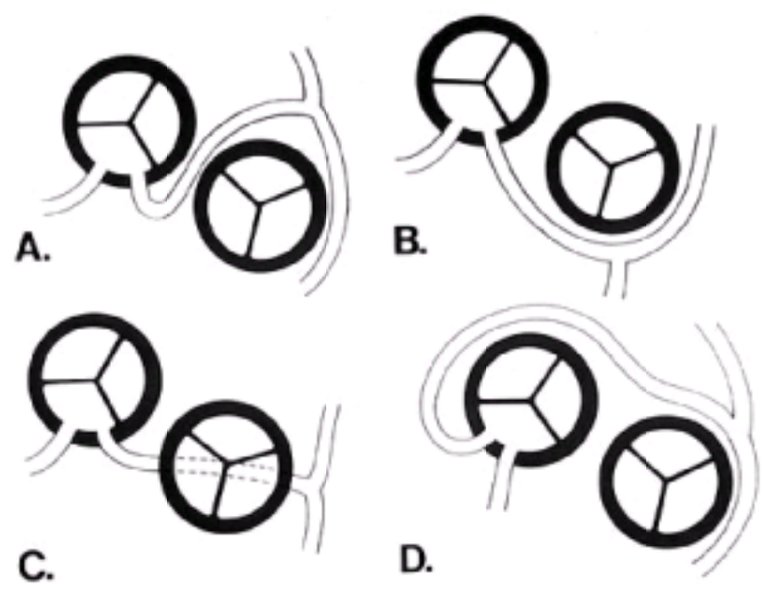


Diagram depicting the variations of the left coronary artery originating from the right sinus of Valsalva. Panel A depicts the left coronary artery arising from the right sinus of Valsalva and coursing between the pulmonary artery and the aorta. Panel B depicts origin of the left coronary artery from the right sinus of Valsalva coursing anterior to pulmonary artery. Myocardial overbridging of the left anterior descending coronary artery in association with hypoplasia or absence of the posterior descending coronary artery and septal fibrosis has been found in otherwise healthy teenagers or young adults dying during strenuous exercise (78). Isolated myocardial overbridges may be a normal variant, however, and have been identified in 0.5% to 2.7% of otherwise normal coronary angiograms (79).

Ventricular Aneurysms and Diverticula and Left Ventricular False Tendons

Congenital ventricular diverticula may be muscular and arise from the apex in association with midline abnormalities in other parts of the body or may be fibrous and arise from the apex or left ventricular base (80). Although these patients most commonly present with congestive heart failure, valvular insufficiency, or embolic events, nonsustained and sustained ventricular tachycardia and sudden death have been reported (80,81). These rare lesions may present at any age, and reports of successful abolition of ventricular tachycardia after surgical repair exist (80). Even rarer are right ventricular diverticula.

Left ventricular false tendons are chordal strands that connect the ventricular septum to other left ventricular structures. They are present in more than 50% of healthy persons (82), so their association with ventricular ectopy is difficult to interpret. Suwa et al. reported surgical correction of paroxysmal sustained ventricular tachycardia in a 31-year-old man by resecting one such false tendon (83). The mechanism for tachycardia was not proved, but the false tendon did contain Purkinje fibers,

prompting speculation that postural and other volume changes might have caused traction on this structure with resultant ectopic beats.

Primary Cardiac Tumors in Children

Primary cardiac tumors in infants and children are rare, accounting for 0.002% to 0.080% (84,85 and 86) of cases in autopsy series. Tumor types most frequently observed to be associated with cardiac rhythm disturbances are rhabdomyomas, fibromas, histiocytoid tumors, and—even more rarely—hemangiomas, teratomas, and primary malignant cardiac tumors.

Rhabdomyomas are associated with tuberous sclerosis; tend to be multiple; and involve the ventricular septum, ventricular free wall, papillary muscles, and atrial wall (87). Rhabdomyomas usually present younger than 2 years of age and therefore are considered true congenital lesions. Although their hemodynamic effects are emphasized in most reports, ventricular tachycardia is frequent (84,87), and complete AV block (87) and WPW syndrome with PSVT (87,88) have also been reported. In a report by Case et al., the management difficulties of such arrhythmias are highlighted by an infant who died despite tumor cryoablation, pacemaker implantation, and aggressive antiarrhythmic drug therapy (88). This infant had monomorphic ventricular tachycardia, polymorphic ventricular tachycardia, and antidromic reciprocating tachycardia.

Another benign cardiac tumor of early infancy is the fibroma. It tends to be single; occurs most commonly in the left ventricular free wall or septum; and has been associated with PSVT, VT, and sudden death (87).

Incessant and frequently fatal VT may occur in patients who at autopsy or surgery are found to have single or multiple small, flat, pale, tan-colored lesions variously described as localized histiocytoid cardiomyopathy, Purkinje cell tumors, or myocardial hamartomas. They present from birth to 30 months of age (mean, 10 months) (89,90) and seem to have a female predilection. In Garson's series of 21 infants, the clinical presentation was cardiac arrest in 11 and congestive heart failure in six, and three had coexisting WPW syndrome (90). Electrophysiologic studies localized the VT focus to the left ventricle in 17 and the right ventricle in four patients. Because antiarrhythmic drugs failed to eliminate incessant VT, all patients underwent surgery. Myocardial hamartoma was the diagnosis in 15 patients, all of whom underwent successful resection or cryoablation.

Myxosarcoma, hemangiosarcoma, and malignant teratomas are very rare malignant childhood cardiac tumors that have been associated with right ventricular conduction delay, right bundle branch block, left bundle branch block, short PR interval, and complete AV block (87).

ARRHYTHMIAS IMMEDIATELY AFTER CONGENITAL HEART SURGERY

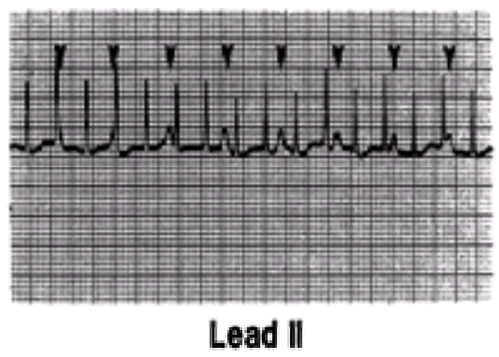
In the immediate postoperative period, children with congenital heart defects may develop tachyarrhythmias due to impaired ventricular contractility, subendocardial ischemia, effects of residual defects, injury to the specialized conduction system, metabolic imbalances, or central nervous system injury. Rarely, postoperative endocarditis will present with new-onset ventricular or atrial ectopy.

Junctional Tachycardia

Junctional tachycardia (JT), also called *junctional ectopic* or *His bundle tachycardia*, generally occurs within 24 hours of congenital heart operations and has been reported to occur in up to 8% of open-heart operations (91). It most commonly occurs after tetralogy of Fallot repair, Mustard operation for D-TGA, VSD closure, AVSD repair, repair of total anomalous pulmonary venous return, and the Fontan operation (91,92 and 93).

When there are suture lines near the bundle of His, the pathogenesis of JT is thought to be related to local edema. Procedures remote from this structure may also cause JT, probably from stretch on the bundle, as may occur with postoperative pulmonary artery hypertension. JT has a significant mortality rate, caused by the adverse effects of both rate-related reduction in ventricular filling and AV asynchrony.

Clinically, postoperative JT is a regular tachycardia with a rate usually greater than 200 per minute and a QRS morphology identical to that seen during sinus rhythm. There is usually ventriculoatrial dissociation, with a ventricular rate faster than atrial and with occasional sinus capture beats (*e*Fig. 70.0.9). This can be best demonstrated by epicardial wire electrograms. Occasionally there is ventriculoatrial conduction, with negative P-waves in the inferior leads. In those instances, JT may be confused with supraventricular tachycardia. JT appears to be due to an automatic mechanism and cannot be terminated by pacing maneuvers or by direct current cardioversion. These maneuvers may result in overdrive suppression, which may last a few seconds before a gradual "warm-up" to the previous rate (94).



***e*FIGURE 70.0.9** Junctional tachycardia after congenital heart surgery. Atrioventricular dissociation is evident. Sinus P waves are indicated by arrowheads. (Full standard; 25 mm per second.)

JT resolves as the patient's hemodynamic status improves, generally within 2 to 10 days (93). Because the agents used to improve inotropic function tend to increase the rate of JT, attempts should be made to limit exogenous catecholamine therapy. The goals of therapy are to reduce the ventricular rate so that the atria may be paced at a slightly faster rate (93). Successful reduction in rate has been reported in small series of patients using a variety of antiarrhythmic agents, including digoxin (91), flecainide (93), propafenone (94), moricizine (95), and amiodarone (96) or by creating moderate hypothermia (32°C to 34°C) by surface cooling. Hypotension may result from intravenous propafenone (97) or amiodarone (96), and hypothermia requires paralysis to avoid shivering and acidosis (98). Walsh et al. used a systematic approach in evaluating treatment options in 71 consecutive children having postoperative JT (99). They proceeded in the following order: reduction in exogenous catecholamines, correction of fever, atrial pacing, digoxin, phenytoin or propranolol or verapamil, procainamide or hypothermia, and finally, procainamide plus hypothermia. Only correction of fever and combined procainamide plus hypothermia appeared to be efficacious. Amiodarone was not used in this study.

Patients refractory to all measures may be considered for transcatheter (100,101,102 and 103) or surgical bundle of His ablation and dual chamber pacemaker implantation.

Other Arrhythmias in the Immediate Postoperative Period

Virtually any arrhythmia may occur immediately postoperatively, depending on hemodynamic or metabolic alterations. In general, onset of new tachyarrhythmias in the early postoperative period warrants investigation of the etiology. Correction of the hemodynamic, mechanical, or metabolic problem should be attempted first. The decision to use pharmacologic therapy must weigh the risks of coexisting hemodynamic deterioration caused by the arrhythmia or potential for worse arrhythmias against adverse side effects from the drugs themselves.

An unusual but recognized cause for sudden hypotension and bradycardia in the immediate postoperative period has been reported in four infants within 18 hours of completion of intracardiac surgery (104). Their responses to intravenous atropine boluses and infusions suggested to the authors that a hypervagotonic response to myocardial stretch (Bezold-Jarisch reflex) was the etiology. If other causes of sudden hypotension and bradycardia have been ruled out (e.g., airway obstruction, pericardial tamponade), this etiology should be considered and treated with atropine.

EVALUATION AND MANAGEMENT OF PATIENTS WITH CHRONIC ARRHYTHMIAS AFTER SURGERY FOR CONGENITAL HEART

DISEASE

eTable 70.0.2 summarizes the incidences of arrhythmias after the more commonly performed congenital heart operations.

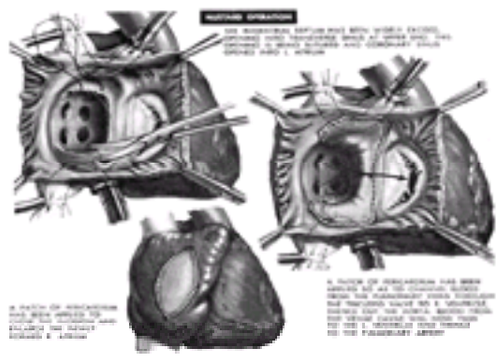
***e*TABLE 70.0.2** INCIDENCE OF ARRHYTHMIAS AND RELATED PROBLEMS IN PATIENTS FOLLOWING SELECTED OPERATIONS FOR CONGENITAL HEART DEFECTS

Operation	Atrial fibrillation/flutter	Ventricular tachycardia	Sudden death	Sinus/junctional bradycardia	Atrioventricular block	Pacemaker requirement
Mustard/Senning operation	++ to +++	+++[a]	++ to ++++[a]	+++ to ++++[b]	+ to ++	+++
Fontan operation	+++++	+++[a]	++[a]	++++	++[a]	+++
Tetralogy of Fallot repair	+ to ++	+ to ++++[a]	++[a]		++	+ to ++
Atrial septal defect closure	+ to +++++[c]			+ to ++	+	+ to ++
Ventricular septal defect closure		+ to +++++[a]	+ to ++[a]			0 to +++[a]
Pulmonic stenosis repair		0 to +++[b]	+			
Aortic stenosis repair		+++ to ++++[a]	++ to +++[a]			

+, 0% to 1% incidence; ++, 1% to 5% incidence; +++, 5% to 10% incidence; ++++, 10% to 20% incidence; +++++, 20% to 60% incidence.
[a]Increased with worse hemodynamic status or associated defects.
[b]Related to increased time since surgery.
[c]Increased with older age at time of surgery.

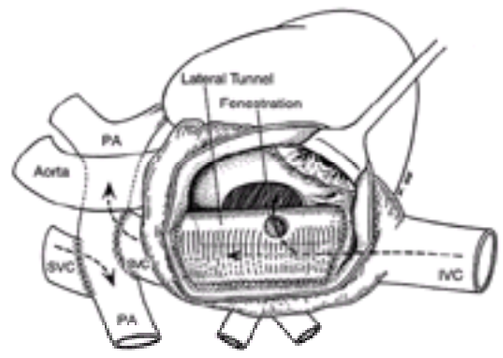
Chronic Arrhythmias after Operations on the Atria

The greatest experience with arrhythmias after atrial surgery is with the Mustard and Senning operations for D-TGA. Creation of an intraatrial baffle with prosthetic material or pericardium (Mustard operation) (eFig. 70.0.10) or with atrial wall itself (Senning) results in damage to the sinus node, perinodal structures, and their blood supplies (105) and to atrial pacemaking tissue throughout the atrium. Symptomatic bradycardia presents as exercise intolerance, fatigue, early morning headaches, or rarely presyncope and syncope. Intraatrial reentry tachycardia (or flutter) also occurs and in certain circumstances may rarely predispose to sudden death.



***e*FIGURE 70.0.10** Netter figures illustrating the Mustard operation. The salient features of the procedure include an atrial septectomy and placement of an intraatrial baffle. Suture lines involve the region of the head of the sinus node, the anterior remnant of the atrial septum, and the isthmus between the tricuspid valve and the inferior vena cava. (From Netter FH. Transposition of the great vessels. In: Yonkman FF, ed. *The Ciba collection of medical illustrations: heart*, vol 5. Rochester: CIBA, 1978:155–156, with permission.)

All variations of the Fontan operation are designed to direct systemic venous return to the pulmonary arteries in patients with a single ventricle (eFig. 70.0.11). These operations usually result in all or part of the right atrium having a chronically elevated mean pressure. Hence, hemodynamic factors in addition to surgical scars likely account for the atrial tachycardias observed in these patients.

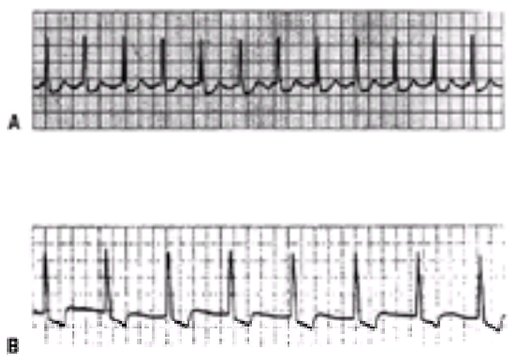


***e*FIGURE 70.0.11** At present, the most frequently performed type of modified Fontan operation, also called *total cavopulmonary anastomosis* or *lateral tunnel*, in which inferior vena cava return is directed to the superior vena cava by a partial intraatrial tube. It is hoped that this arrangement will result in a lower incidence of atrial arrhythmias. IVC, inferior vena cava; PA, pulmonary artery; SVC, superior vena cava.

After repair of ostium secundum or sinus venosus atrial septal defects or partial or total anomalous pulmonary venous return, sick sinus syndrome may also occur.

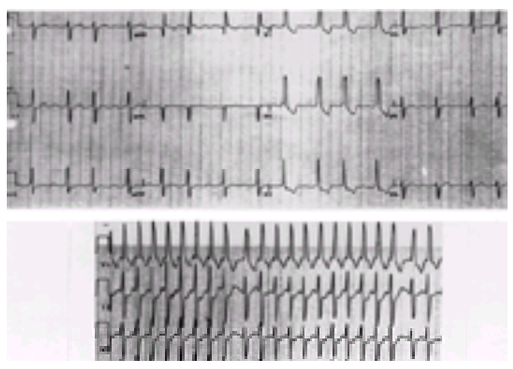
Incidence and "Natural History"

After the Mustard operation, there is a progressive decrease in the percentage of patients having sinus rhythm. When evaluated by routine ECG or 24-hour Holter 5 to 10 years postoperatively, between 20% and 40% are in sinus rhythm (106,107,108 and 109), between 7% and 35% are in junctional rhythm (106,108,109), up to 40% are in slow ectopic atrial rhythm (109), and 10% have atrial flutter (eFig. 70.0.12) (106,108,110,111). In their series of 249 patients, Gewillig et al. reported a 2.4% per year loss of sinus rhythm, and the presence of junctional rhythm carried a 2.1-fold increased risk of developing atrial flutter (p <.05) (108). In a multiinstitution report of 182 patients, the prevalence of atrial tachyarrhythmias was relatively constant, at 2.1% to 7.1% over 4.5 to 8.3 years of mean follow-up (111). In these reports, pacemakers were implanted in 5% to 11% of patients (112,113), usually for unacceptably low heart rates, for syncope, or as adjunctive therapy to antiarrhythmic drugs other than digoxin. Recently, even longer-term follow-up (23 years' median follow-up) after the Mustard operation in 86 patients has shown a 48% incidence of supraventricular tachycardia (mostly atrial flutter), and 22% had pacemakers (114). Risk factors for supraventricular tachycardia included pulmonary hypertension, right ventricular dysfunction, and junctional rhythm. This high incidence of SAND appears to be significantly greater in Mustard than in Senning patients late after repair (115).

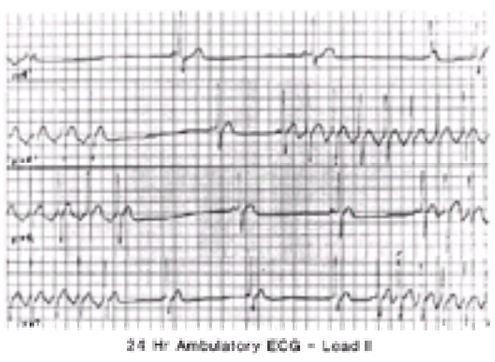


***e*FIGURE 70.0.12** Atrial flutter with 2:1 atrioventricular conduction **(A)** in a 25-year-old patient after Mustard operation. After cardioversion, rhythm is junctional **(B)**.

Sudden death occurs late after these operations in between 3% and 15% of patients (106,108,114,116), and this risk appears to be higher in the presence of poorer right ventricular function (117) and in patients having a history of atrial flutter (108). The latter point was also emphasized in a large collaborative study of 380 children with atrial flutter (110). The most frequent diagnosis was "postoperative Mustard operation," and the 6-year mortality rate in this subgroup was 21%. The risk of sudden death among those whose atrial flutter could not be eliminated was fourfold that of those who had had no recurrences. The mechanism of sudden death was thought to be 1:1 AV conduction during atrial flutter either directly causing ventricular fibrillation or followed by marked overdrive suppression of all subsidiary pacemakers with resultant asystole (*e*Fig. 70.0.13 and *e*Fig. 70.0.14). It is probable that another cause of sudden death in this group of patients is ventricular tachycardia, especially in those patients who have depressed right ventricular function or in those who have had additional ventricular surgery for VSDs or left ventricular outflow tract obstruction.



***e*FIGURE 70.0.13** Chronic atrial flutter in a 30-year-old man after Mustard operation. At rest, there is 2 to 3:1 atrioventricular conduction **(top)**, but with exercise there is 1:1 atrioventricular conduction **(bottom)**. (From Kanter RJ, Garson A. Arrhythmia in congenital heart disease. In: Podrid PJ, Kowey PR, eds. *Cardiac arrhythmia*. Baltimore: Williams & Wilkins, 1995:1131–1160, with permission.)



***e*FIGURE 70.0.14** The "tachy-brady syndrome" after the Mustard operation, in which atrial flutter, spontaneous terminations, and severe bradycardias are illustrated. ECG, electrocardiogram. (From Kanter RJ, Garson A. Arrhythmia in congenital heart disease. In: Podrid PJ, Kowey PR, eds. *Cardiac arrhythmia*. Baltimore: Williams & Wilkins, 1995:1131–1160, with permission.)

Arrhythmias after Fontan operation are of increasing interest because of improved long-term survival in this patient group. Driscoll et al. found 20% of 352 Fontan patients required antiarrhythmic drugs and/or pacemaker implantation at 5 to 15 years' follow-up (118). They attributed right atrial stretch, impaired ventricular function, and AV valve insufficiency as potential causes for the tachy-brady syndrome, although postoperative AV block occurred in several instances, and VT occurred in 6% of patients. Gewillig et al. found an 18% incidence of arrhythmias at 8-year follow-up, based on 78 long-term modified Fontan survivors (119). Multivariate analysis disclosed older age, increased right atrial size, and elevated pulmonary artery pressures as risk factors for arrhythmia development (p <.001). The most sobering report comes from the National Heart Hospital in London, England, where the actuarial arrhythmia-free survival for hospital survivors was only 60% at 10 years (120). Again, these patients tended to have higher mean right atrial pressures and lower ejection fractions.

Among Fontan patients, the specific surgical technique probably plays a role in the short- and medium-term incidences of supraventricular tachycardias. Animal studies have suggested that the total cavopulmonary connection (TCPC) is less arrhythmogenic acutely than the atriopulmonary connection, especially if the anterior suture line does not involve the crista terminalis (121). Clinical reports have shown a lower incidence of immediate and medium-term (2 to 8 years) postoperative atrial tachycardias in TCPC patients (122,123,124 and 125), and the 5-year arrhythmia-free survival rate is as high as 78% (122). The logic of reducing the portion of the right atrium included in the higher pressure systemic venous part of the circuit has been furthered by use of a complete extracardiac conduit. Amodeo et al. (126) reported late tachyarrhythmias in only four of 54 such patients, with a 5-year arrhythmia-free survival rate of 92%. Orthodromic reciprocating tachycardia has occasionally been observed in patients having undergone a Bjork-type Fontan operation (direct right atrial appendage to right ventricular outflow tract anastomosis) for TA. Presumably, they acquire conduction across the suture line (127).

Infants having hypoplastic left heart syndrome generally undergo the final stage (Fontan) at ages younger than has been conventional for other forms of single ventricle, often at younger than 2 years. Limited long-term follow-up has not shown more atrial tachyarrhythmias than have been observed in the other patient groups (128).

The incidence of pacemaker requirement after the Fontan operation ranges from 5% to 15% (118,129,130). The indications include tachy-brady syndrome, congenital AV block, or postoperative AV block and may be affected by surgical technique. There is evidence that the staged approach involving the "hemi-Fontan" procedure before the TCPC may increase risk of developing SAND (131). Finally, the reported incidence of late arrhythmic death overall is 2% to 3% (118,129,132).

Reports of small numbers of patients after total anomalous pulmonary venous connection (133) or ostium primum ASD (134) repairs have shown a high incidence of conduction abnormalities, including sinus, ectopic atrial, or junctional bradycardia or atrial flutter or fibrillation. Complete AV block may occur after ostium primum repair. Murphy et al. reported the natural history of 123 patients who had undergone repair of ostium secundum or sinus venosus ASDs at the Mayo Clinic (135). Late follow-up (27 to 32 years) revealed that the incidence of atrial flutter or fibrillation increased directly with age at repair: 4% if operated on at 11 years old or younger, 17% if at 12 to 24 years, 41% if at 25 to 41 years, and 59% if at older than 41 years. The incidence of pacemaker requirement was low for all groups (4% of total, including two with AV block). A more recent report has also shown that late postoperative atrial flutter or fibrillation was associated with older age at surgery (older than 40 years), the presence of preoperative atrial flutter or fibrillation, or the occurrence of immediate postoperative atrial arrhythmias (136).

It is pertinent to this discussion to note that most babies born today with simple D-TGA undergo the arterial switch operation instead of the Mustard or Senning procedure. Mid-term follow-up (24 to 29 months) after the arterial switch operation at two centers failed to demonstrate significant rhythm disturbances by 24-hour ECG monitoring from 250 infants (137,138). Electrophysiologic testing of 158 patients undergoing the arterial switch operation at Children's Hospital, Boston, revealed normal corrected sinus node recovery times and AH intervals in 97% of patients but a high incidence of simple atrial ectopy (139). At 2.1 years' mean follow-up, the incidence of supraventricular tachycardia was 5% and of VT, less than 1%.

Noninvasive Evaluation

Ambulatory rhythm recording is the cornerstone of patient surveillance after atrial surgery. Unless there are symptoms of sinus node dysfunction, 24-hour ambulatory ECGs are sufficient every 2 to 5 years. In patients having chronic fatigue and in those having syncope or dizziness at rest or with exercise, a 24-hour ECG and exercise test should be performed. Hesslein et al. performed treadmill tests on 25 children after Mustard operation at an average age of 10.2 years (140). Using a modified Bruce protocol, the maximum attained heart rates were more than two standard deviations below predicted in 70.4% of patients (p <.001). In 59.3%, heart rates remained abnormally low 5 minutes after exercise (p <.001). This relatively sudden drop in heart rate immediately after exercise may correlate with the frequently observed fatigue and dizziness that many patients experience immediately after exercise. Forty-seven percent of the patients tested had abnormally low exercise capacity. For patients having less frequent paroxysmal episodes of dizziness or palpitations, newer ambulatory ECG monitoring systems are invaluable. Syncopal episodes may merit a combined approach of invasive electrophysiologic testing and ambulatory event recording.

Electrophysiologic Testing

Electrophysiologic measures of sinoatrial node function have been reported to be abnormal in 33% to 50% of Mustard patients (141,142) and in 50% of Fontan patients (143). Atrial muscle electrophysiologic properties are abnormal in 41% to 90% (141,142 and 143), and atrial reentry tachycardia is inducible in 27% of Fontan patients (143) and in approximately one-half of Mustard patients (109). The clinical usefulness of these findings in the absence of symptoms is unproved. Therefore, we recommend *diagnostic* electrophysiologic studies after atrial surgery only in patients who have developed syncope or in those having palpitations suggestive of a sustained tachyarrhythmia and in whom noninvasive studies are inconclusive. Diagnostic cardiac catheterization and electrophysiologic study may also be helpful before pacemaker implantation to evaluate AV nodal function and to demonstrate anatomic patency of venous and atrial structures pertinent to permanent lead implantation. The usefulness of electrophysiologic studies for catheter ablation is discussed below.

Management

The recommendations of the American Heart Association/American College of Cardiology Joint Committee on Pacing as they relate to patients who have undergone atrial surgery (144) are to insert a pacemaker in any patient with (a) "symptomatic" bradycardia, defined as dizziness, lightheadedness, and near or frank syncope; marked exercise intolerance; or congestive heart failure (class I indication); (b) tachy-brady syndrome and a tachyarrhythmia requiring treatment with an antiarrhythmic drug other than digitalis that could suppress the sinus node (i.e., beta-blocking drugs, verapamil, quinidine, procainamide, disopyramide, flecainide, propafenone, sotalol, and amiodarone) (class IIa indication); or (c) complex congenital heart disease and asymptomatic sinus bradycardia with a resting rate of less than 35 beats/min or pauses exceeding 3 seconds (class IIa indication for children; class IIb indication for adolescents).

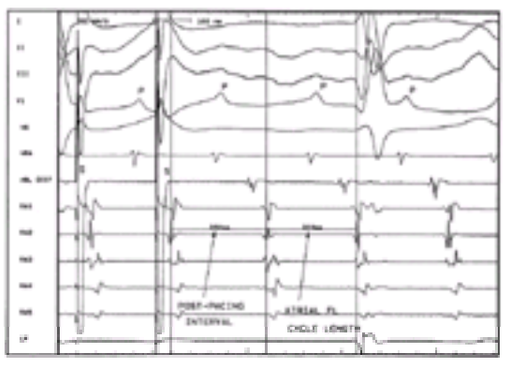
If symptoms are convincing but cannot be reproduced by ambulatory monitoring, tachyarrhythmias are not inducible, and there is moderate bradycardia while awake (less than 60 per minute in an infant younger than 2 years, less than 50 per minute in children aged 2 to 10 years, or less than 40 per minute in patients older than 10 years), then we recommend pacemaker implantation.

The second indication is reasonable in view of most clinicians' observations that progressive bradycardia and AV conduction abnormalities may occur in patients treated with many of these drugs. Implanting a pacemaker in such a patient may also protect against the severe bradycardia that may result after an episode of atrial flutter.

Atrial pacing after Mustard, Senning, or Fontan operations is now a standard part of the care of some of these patients (*e*Fig. 70.0.15) (145,146 and 147). In some instances, novel approaches to lead placement may be required. Advances in interventional catheterization have benefited some patients when superior vena caval baffle obstruction is present. Catheter-delivered stents not only relieve untoward hemodynamic abnormalities, but also may permit placement of intravenous pacing systems. If inadequate AV conduction is also present, dual chamber pacing is necessary. AV synchrony is especially important in Fontan patients, and ventricular pacing alone—even with rate adaptiveness—may not be acceptable (148). Dual-chamber epicardial lead systems or transvenous atrial and epicardial ventricular lead systems are required in these instances.

***e*FIGURE 70.0.15** Chest radiograph **(top)** from an 18-year-old woman after Mustard operation who has atrial reentry tachycardia requiring sotalol. Single-chamber pacing was performed with an active fixation atrial lead in the anatomic left (systemic venous) atrium. During electrophysiologic study, 1:1 atrioventricular conduction continued up to 150 beats/min. Twelve-lead electrocardiogram **(bottom)** from same patient showing atrial pacing, 1:1 atrioventricular conduction, and severe right ventricular hypertrophy.

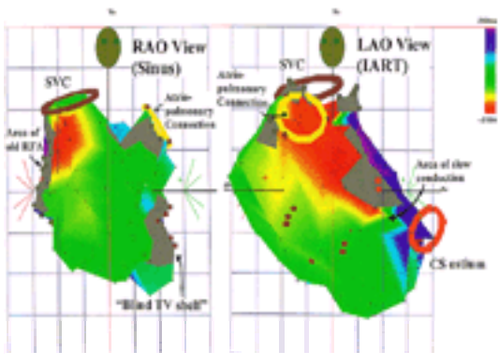
Tachyarrhythmias after the Senning or Mustard operations usually must be aggressively treated because sudden death in these patients is most likely linked to *tachy*arrhythmias. Patients who present with atrial flutter should undergo transvenous or transesophageal overdrive pacing termination or direct current cardioversion. Chronic therapy may not be necessary after an initial episode unless associated symptoms are severe or the patient has poor ventricular function. Treatment options include class III antiarrhythmic drug therapy, antitachycardia pacing (plus AV node–blocking drugs), and radiofrequency catheter ablation. Implantation of an antitachycardia pacemaker may obviate the need for second-line drugs, but efficacy of this modality must be demonstrated by electrophysiologic testing in the drug-free state. Radiofrequency ablation of atrial reentry tachycardia can now be performed with success rates at medium-term follow-up of 70% to 80% (149,150). This is now our preferred approach in patients with recurrent intraatrial reentry tachycardia (*e*Fig. 70.0.16).



***e*FIGURE 70.0.16** Electrophysiologic study from a 10-year-old patient with atrial flutter (FL) after Mustard operation. Illustrated is concealed entrainment with the postpacing interval approximating the tachycardia cycle length from the medial isthmus on the systemic venous side near the orifice of the inferior vena cava. Application of radiofrequency energy at the site interrupted the atrial flutter circuit. ABL DIST, proximal bipole atrial recording from mapping catheter within medial

isthmus; HRA, high right atrial channel; LV, left ventricular channel; P, surface P waves during atrial flutter; RA1–5, atrial recordings from a multipole electrode catheter positioned along the inferior limb of the systemic venous baffle, with RA5 being most superior and RA1 being at the mid-isthmus.

After the modified Fontan operation, medical suppression of tachyarrhythmias may be difficult. The requirements for AV synchrony and adequate diastolic filling time make arrhythmia control especially crucial (151). For these challenging patients, combinations of antiarrhythmic drugs, often including amiodarone, is sometimes necessary. Antitachycardia pacing is sometimes possible (147) but may result in acceleration of one atrial tachycardia to another. Radiofrequency catheter ablation of intraatrial reentry tachycardia substrates is being performed in these patients with increasing success rates. Standard techniques to identify areas critical to common atrial flutter circuits in the normal heart are being successfully applied, including recognition of presystolic and split potentials and entrainment with concealed conduction and a short postpacing interval. Successful ablation of more than 70% of these circuits is now being achieved (152,153 and 154). Even better results can be expected with the recent advent of electroanatomic mapping techniques (*e*Fig. 70.0.17) (155) and chilled-tip ablation catheters.



***e*FIGURE 70.0.17** Electroanatomic maps from a 27-year-old man who had undergone Fontan operation (atriopulmonary connection) for tricuspid atresia and who had undergone a prior attempt at radiofrequency ablation (RFA) (old radiofrequency ablation) for intraatrial reentry tachycardia (IART) with recurrence. On the left is a right anterior oblique (RAO) projection of the right atrium in sinus rhythm. On the right is a left anterior oblique (LAO) projection of the right atrium during IART. Successful RFA was performed in the “area of slow conduction.” CS, coronary sinus; SVC, superior vena cava.

Among Fontan patients having undergone an atriopulmonary connection and who have intraatrial reentry tachycardia and suboptimal hemodynamics, a surgical approach has recently been reported (156). This involves conversion to a TCPC-type Fontan with concomitant intraoperative mapping and cryoablation of intraatrial reentry tachycardia circuits. These patients experienced improvement in hemodynamic status as well as arrhythmia control. The inferomedial right atrium, superior rim of the old ASD patch, and the lateral right atrium were the regions generally requiring cryoablation lesions. At 25 months’ median follow-up, only two of 12 patients still required antiarrhythmic drugs (157).

Chronic Arrhythmias after Operation on the Ventricles

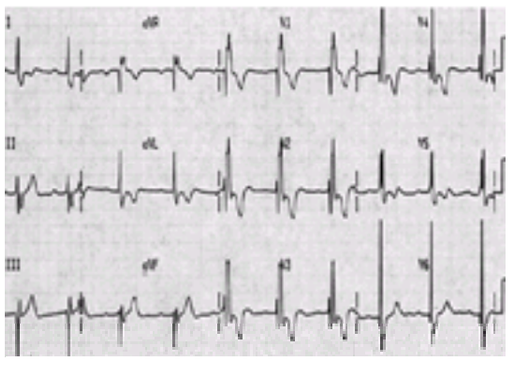
Most studies of chronic arrhythmias occurring after operation on the ventricles have been done in patients with tetralogy of Fallot (158,159,160,161,162 and 163). In general, the less serious the defect, the less serious the outcome. For example, late sudden death occurs in approximately 4% of patients who have had VSD repair (22,164), 0% to 5% of those who have had tetralogy of Fallot repair (158,163), 18% of those who have had double-outlet right ventricle repair (165), and 18% of those who have had surgery for truncus arteriosus with single pulmonary artery (166).

The surgical repair of tetralogy of Fallot always involves patch closure of the VSD and resection of some infundibular muscle, usually through a right infundibulotomy. Pulmonary regurgitation will always result if the right ventricular outflow tract enlargement must extend across the pulmonary valve annulus.

Conduction Disturbance

Incidence

After repair of tetralogy of Fallot, approximately 80% of patients have complete right bundle branch block; an additional 11% have the combination of right bundle branch block with left-axis deviation; and 3% have the combination of right bundle branch block, left-axis deviation, and first-degree AV block (*e*Fig. 70.0.18) (158). Early studies in these patients suggested that the combination of right bundle branch block with left-axis deviation (167) or with additional first-degree AV block (168) was a predictor of late sudden death. More recent experience has found that late sudden death is not often due to conduction disturbances.



***e*FIGURE 70.0.18** Twelve-lead electrocardiogram from a 15-year-old patient after repair of tetralogy of Fallot, illustrating first-degree atrioventricular block, left-axis deviation, and right bundle branch block.

Clinical Significance

Among patients having syncope after ventricular repair of congenital heart defects, electrophysiologic findings of prolonged HV interval or abnormally slow rate of AV Wenckebach block may help guide clinical decision making (see below). However, the very common finding of right bundle branch block after right ventriculotomy appears to carry a benign early- and mid-term prognosis. It only obscures the ECG with regard to interpretation of ventricular dilatation or hypertrophy. Perhaps more important, in those patients with “true” (proximal?) right bundle branch block, the development of left bundle branch block that occasionally accompanies atherosclerotic heart disease later in life will place these patients at risk for complete AV block.

Evaluation

On follow-up ECG, the patterns of right bundle branch block, right bundle branch block/left-axis deviation, and right bundle branch block/left-axis deviation/first-degree AV block are usually associated with normal HV intervals in instances when intracardiac studies were performed (169). The recommendation has therefore been made that terms such as *bifascicular* and *trifascicular block* not be applied to these patients.

Even if intracardiac conduction intervals support the diagnosis of “true” bifascicular or trifascicular block, we become concerned only if there is type II second-degree AV block, complete AV block, marked HV interval prolongation (more than 100 ms) (even in the absence of symptoms), or syncope with any HV interval prolongation (and no inducible tachyarrhythmias). In the presence of transient postoperative second-degree AV block or complete AV block (lasting less than 7 days

postoperatively), 24-hour ECG monitoring should be performed before discharge and then regularly. All patients after ventricular surgery involving the ventricular septum should have 24-hour ECG monitoring every 2 to 5 years. In the patient who has had an operation on the ventricles and a negative noninvasive evaluation but has syncope or presyncope, electrophysiology study is indicated. The cause of syncope could be AV block, ventricular arrhythmias, or atrial flutter with rapid AV conduction.

Limited data are available from intracardiac assessment of the conduction system in these patients. Friedli and Bolens found AV conduction abnormalities in 10 of 52 patients after repair of tetralogy of Fallot (169). Three patients developed block below the bundle of His with atrial pacing rates of less than 120 per minute, and two of them developed complete AV block within 5 years. Based on these limited data, we would consider electrophysiologic testing in a patient with AV Wenckebach rates of less than 120 per minute during exercise testing to assess the level of block. Otherwise, routine electrophysiologic testing in an asymptomatic patient is not indicated.

Management

A pacemaker should be implanted in any child with second-or third-degree AV block lasting more than 7 days postoperatively after heart surgery. Otherwise, the late onset of paroxysmal changes in level of consciousness merit some combination of 24-hour Holter monitoring, ambulatory event monitor placement, and invasive electrophysiologic testing. If for any reason electrophysiologic testing is performed and there is a prolonged HV interval or AV block below the His at atrial paced rates of less than 120 per minute, these patients should be followed closely even if asymptomatic. The value of exercise testing to determine the maximum conducted sinus rate in these patients is unproved.

Occasional patients undergo pacemaker insertion in the postoperative period but regain AV conduction shortly thereafter. Data are not available to predict their risk of recurring AV block. The issue usually comes to bear once their pulse generator reaches depletion parameters and elective replacement is required. In such instances, we would use stringent criteria from 24-hour ECG monitoring and electrophysiologic testing (normal AV Wenckebach rate and normal HV interval) before considering discontinuation of pacing.

Ventricular Tachyarrhythmias

Incidence

During long-term follow-up of repair of tetralogy of Fallot (5 to 10 years), ventricular arrhythmias were evident in approximately 5% to 10% of patients on routine ECG (158,170,171), 20% to 40% on treadmill testing (158,170,171), and 40% to 60% by 24-hour ECG monitoring (158,163,170,171). The severity of ventricular ectopy appears be related to older age at repair (163,172,173), elevation of right ventricular systolic pressure (158,163,170,173), and duration since surgery (163,170,173). Depressed right ventricular ejection fraction (173), elevation of right ventricular end diastolic pressure (170), duration of cardiopulmonary bypass during repair, and presence of a Potts anastomosis (172) have also correlated with incidence of ventricular arrhythmia in single reports. In contrast to these reports, Walsh et al. reported on 184 late-surviving patients, all of whom had had tetralogy of Fallot repair before 18 months of age (161). At a mean of 60 months' follow-up, there were no late deaths caused by arrhythmias, and only one of 41 patients had greater than Lown grade I ventricular ectopy by Holter monitoring. It appears that the earlier age of repair may protect the heart from deleterious changes accrued from long-standing right ventricular hypertension, left ventricular volume overloading, and systemic desaturation.

The overall incidence of late SCD after repair of tetralogy of Fallot ranges from 1.5% to 5% (158,163,168,172). Most recent reports suggest ventricular arrhythmias to be the etiology (158,163,168,170,172).

Experimental Basis for Ventricular Arrhythmias

The histopathologic findings in the right ventricles in patients who have died after repair of tetralogy of Fallot include obvious scars in the infundibular region and generalized increase of fibrous tissues throughout the right ventricle compared with age-matched controls (20). In the investigation of Anderson and Ho, this was most prominent in the hearts of children repaired after age 5 years (20).

Insight into the pathogenesis of ventricular arrhythmias after right ventricular surgery is provided by a canine model, in which puppies underwent right ventriculotomy, pulmonary artery banding, or both (174). At a follow-up period representing adolescence, ambulatory ECG monitoring and ventricular programmed stimulation revealed a higher incidence of nonsustained ventricular ectopy in the group having right ventricular hypertension from pulmonary artery banding compared with both control animals and those having undergone only ventriculotomy. The group having undergone both ventriculotomy and banding had, in addition, a higher incidence of inducible sustained ventricular tachycardia.

The effect of postoperative right ventricular volume overloading caused by pulmonary valve insufficiency has also been investigated in dogs (175). When compared with control animals undergoing only right ventriculotomy, dogs having pulmonary valve insufficiency, with and without right ventricular outflow tract obstruction, had more PVBs by postoperative Holter monitoring. The relationship of spontaneous single PVBs to development of sustained arrhythmias in this group was not reported.

In summary, the preoperative milieu of chronic right ventricular hypertension and systemic desaturation likely predisposes patients to postoperative ventricular arrhythmias, making earlier age of repair standard practice at the present time. *Post*operative right ventricular hypertension and probably volume overloading place patients at additional risk.

Evaluation

The main goal of routine evaluation of patients after ventricular surgery is to identify individuals who are at risk for symptoms or death from ventricular arrhythmias. Unfortunately, there is no gold standard for determining such risk. he 12-lead ECG, chest radiograph, 24-hour rhythm monitoring, treadmill exercise test, and echocardiogram all have roles in the outpatient surveillance of these patients. In those with poor hemodynamics, follow-up is stricter than in those with excellent hemodynamics (eFig. 70.0.19). Equivocal or minor symptoms may be evaluated with event recorders, but paroxysmal palpitations or syncope merit invasive electrophysiologic study.

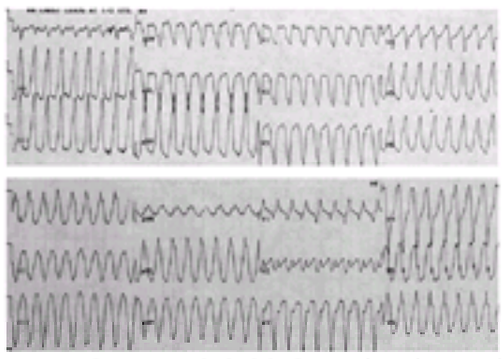
***e*FIGURE 70.0.19** Continuous Holter recording from a 13-year-old patient after repair of tetralogy of Fallot with residual right ventricular hypertension due to multiple peripheral pulmonary artery stenoses. Patient was receiving quinidine at the time. Illustrated is ventricular bigeminy, nonsustained monomorphic ventricular tachycardia, and nonsustained torsades de pointes ventricular tachycardia. During electrophysiology study, polymorphic ventricular tachycardia was inducible with double ventricular extrastimuli. Patient's Holter normalized and the tachycardia was rendered noninducible with mexiletine. (From Kanter RJ, Garson A. Arrhythmia in congenital heart disease. In: Podrid PJ, Kowey PR, eds. *Cardiac arrhythmia*. Baltimore: Williams & Wilkins, 1995:1131–1160, with permission.)

Recent reports have shown that excessive duration of the QRS complex may prove to be a valuable screen for patients at risk of having dangerous ventricular arrhythmias (ventricular tachycardia and sudden death). The QRS duration appears to be sensitive (176) and perhaps specific (177) for such risk, with a cutoff value of 180 ms or more providing the greatest accuracy. The coexistence of increased JT interval dispersion may enhance the predictive value, suggesting that both repolarization and depolarization abnormalities are important. One study also found a correlation between an increased cardiothoracic ratio by chest radiograph and QRS prolongation (176).

Although there may be some correlation between the occurrence of complex ventricular arrhythmias (couplets, multiform PVBs, or ventricular tachycardia) on 24-hour rhythm monitoring and inducibility of ventricular tachycardia by electrophysiologic testing (163), the relationship of such ectopy to clinical events is controversial. Garson et al.'s report of 488 patients showed that 33% of 21 patients having high-grade ventricular ectopy by Holter monitoring later died, compared with none of the 421 having no ventricular ectopy (178). These findings were recently corroborated, particularly in patients having poor ventricular function or residual structural defects (179). However, the value of Holter monitoring has been called into question by Cullen et al.'s report of 47 patients prospectively followed for 12 years after an original postoperative Holter (180). Those originally having high-grade ventricular ectopy (including seven with nonsustained ventricular tachycardia) were no more likely to later have clinical VT or to die suddenly than those not originally having ventricular ectopy, irrespective of hemodynamic status. To summarize, we view the presence of high-grade ventricular arrhythmias by ambulatory monitoring to merit further investigation and/or treatment when associated with poor ventricular function, pressure or volume loading of the right ventricle, significant cardiomegaly, or a QRS duration of 180 ms or more.

The value of other noninvasive tests to help manage patients who have undergone ventricular surgery for congenital heart disease is in evolution. Exercise testing (170), cardiopulmonary testing with inspired gas analysis, signal-averaged ECG (181), spectral analysis of heart rate variability, and magnetic resonance imaging will all likely play roles in the care of this diverse patient group.

Symptoms requiring invasive electrophysiologic testing after ventricular surgery include sustained palpitations and syncope (eFig. 70.0.20). The demonstration of symptomatic sustained monomorphic ventricular tachycardia by noninvasive means is an indication for electrophysiologic testing as a guide for antiarrhythmic drug selection (162) or for radiofrequency catheter ablation. In the absence of symptoms, we would also consider ventricular programmed stimulation if a patient has echocardiographic or catheterization-proven impairment of hemodynamics (see above), as well as either Lown grade III ectopy or greater by 24-hour ECG or high-grade ventricular ectopy during exercise testing.



P>***e*FIGURE 70.0.20** Sustained ventricular tachycardia having two morphologies during electrophysiologic study from a 25-year-old man having recurrent syncopal episodes after tetralogy of Fallot repair. Photoargon- and cryoablation during surgery successfully interrupted the tachycardia circuit(s) emanating from around the right ventricular outflow tract patch. (From Kanter RJ, Garson A. Arrhythmia in congenital heart disease. In: Podrid PJ, Kowey PR, eds. *Cardiac arrhythmia.* Baltimore: Williams & Wilkins, 1995:1131–1160, with permission.)

Electrophysiologic studies have not been standardized in this patient group with respect to indications and pacing protocols. Using a high-specificity protocol (two extrastimuli) from a single institution, Garson et al. showed that sustained or nonsustained VT was more commonly inducible in patients having elevated right ventricular systolic pressure, reduced right ventricular ejection fraction, high-grade ventricular ectopy by Holter monitoring, or a history of syncope compared with control tetralogy patients (170). Similar results were reported by Chandar et al. in a multicenter study (163). Interestingly, in this report, of five late deaths, none had had inducible ventricular tachycardia, but all had at least one risk factor as defined above. More recently, Alexander and coworkers applied sophisticated statistical methods to a group of 130 patients who had undergone programmed ventricular stimulation; 33% had tetralogy of Fallot, 25% D-TGA, and 12% left ventricular outflow tract obstructive lesions (182). A positive study was associated with a six-fold increased risk of decreased survival and was 87% sensitive in predicting mortality. However, of 21 patients having had documented clinical VT, only 14 had a positive study. Further, the positive predictive value of SCD was only 20%. This group of patients had a 3% annual mortality and event risk, much higher than any previous reports. The subjective decision to perform ventricular programmed stimulation identified a group with a high prevalence of poor outcome.

It is becoming evident that a search for supraventricular tachycardias is also indicated in symptomatic patients after ventricular surgery (182,183), especially atrial flutter and AV node reentry tachycardia. Among 53 tetralogy patients at 23 years' median age, Roos-Hesselink et al. demonstrated atrial flutter or fibrillation in 23% and other supraventricular tachycardias in 11% (183).

Management

When considering treatment for ventricular arrhythmias after ventricular surgery, two questions usually need to be answered: whom to treat and by what means should efficacy be established?

In two small series, serial electrophysiology studies identified antiarrhythmic drugs (mostly phenytoin and propranolol) that effectively suppressed ventricular tachycardia reinducibility (162,184). In follow-up, no patient had clinical ventricular tachycardia, but the positive predictive value is less well established. We have found that quinidine and procainamide are not very useful drugs for sustained ventricular tachycardia in these patients, and class IC agents may be especially proarrhythmic (185). Anecdotal experience has shown the value of amiodarone or sotalol in some patients.

Because of potential drug side effects, nonpharmacologic therapy has become more attractive in recent years. After complete tachycardia circuit mapping in the electrophysiology laboratory, surgical resection, cryoablation (186), and argon photoablation have all met with variable success. Radiofrequency catheter ablation has been used to successfully interrupt macroreentry VT circuits in several patients (187,188), even when there are multiple VT circuits and when VT is poorly hemodynamically tolerated (188). Finally, implantable cardioverter-defibrillators provide antitachycardia pacing as well as the safety net of cardioversion or defibrillation, if necessary (189).

Less clear are the indications for treating asymptomatic patients with high-grade ventricular ectopy by 24-hour ECG monitoring or exercise testing. If their hemodynamics are acceptable, we would only follow these patients closely. In those with poor hemodynamics, we would consider ventricular programmed stimulation to help identify patients with inducible sustained tachycardia and to help guide medical therapy. Until there are randomized clinical trials involving treatment and nontreatment of such patients with induced ventricular tachycardia, we recommend treatment with antiarrhythmic drugs. Drugs with low proarrhythmic risk (beta-blocker, phenytoin, mexiletine, and perhaps sotalol) are emphasized in these patients.

Arrhythmias after Repair of Other Congenital Heart Defects

Ebstein's Anomaly of the Tricuspid Valve

In the oldest series of Ebstein's patients undergoing surgical repair, the procedure included accessory pathway interruption in those six with WPW syndrome (15). At 40 months' mean follow-up, one patient still had WPW syndrome, 22% of 18 having PSVT had persistent symptoms, and 30% of those having had AF/flutter had recurrences. Newer surgical techniques for improving tricuspid valve and right heart function, as introduced by Carpentier, have been shown to nearly eliminate atrial tachycardias at 58 months' median follow-up (190).

Although surgical ablation of accessory pathways is rarely currently required, it is at least of historical interest that in the Duke University experience of 422 patients having WPW syndrome and undergoing surgical ablation, those 38 also having Ebstein's had similar postoperative 10-year survival (92.4%), freedom from significant arrhythmias (82%), incidence of AF (9%), and incidence of becoming disabled (9.4%) to the control group having only WPW syndrome (191). Transcatheter ablation of accessory pathways is nevertheless more attractive than surgical and may make subsequent congenital surgery less risky in this disease.

Pulmonary Valve Stenosis

The NHS-2 by Wolfe et al. followed 182 patients with pulmonary valve stenosis, and 92.8% had undergone surgical valvotomy (17). Patients in all age groups had supraventricular premature beats at a rate exceeding the upper limits of normal for age. For all ages, 11.2% of the 169 surgically managed patients (p <.001 vs. control) had PVBs at a rate exceeding upper limits of normal, and six (8.3%) had ventricular tachycardia. At least one serious arrhythmia was present in 28% of the surgically treated group. Age on admission was the only independent predictor of occurrence of a serious arrhythmia. The authors concluded that prevalence of arrhythmias was higher for these patients than for the control population but that serious arrhythmias were less commonly observed than in patients with either aortic

valve stenosis or VSD. Furthermore, the occurrence of sudden unexpected death (0.05%) was significantly lower than in patients with either of the other defects (p <.0001).

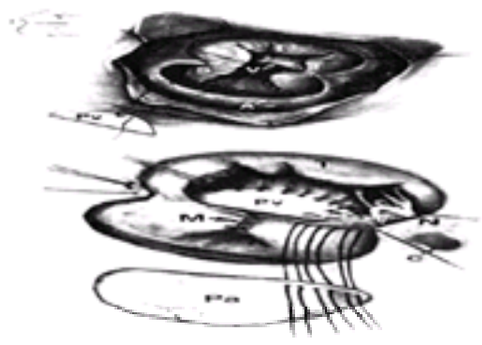
There is new evidence that balloon valvotomy may be associated with less ventricular ectopy than observed after surgical valvotomy at medium-term follow-up (192), probably due to the fact that there is less pulmonary insufficiency after balloon valvotomy. It has not yet been proved whether reduction in pulmonary insufficiency by homograft valve insertion will reduce ventricular ectopy (193).

Ventricular Septal Defect

The most extensive data from patients after surgical closure of VSD comes from the NHS-2 (15). Serious arrhythmias (as defined in the section Pulmonary Valve Stenosis and excluding patients with Eisenmenger physiology) were present in 36.8% of patients. Of those having undergone surgery, the risk of having serious arrhythmias was increased in those functioning at worse than New York Heart Association class I or in those having cardiomegaly. At the time of final status, the occurrence of sudden unexpected death was 4.2%.

Atrioventricular Septal Defect

Repair of this defect requires suture lines near the specialized conduction system. In a small series of 14 patients, postoperative electrophysiologic studies demonstrated first-degree AV block in nine (AH prolongation in two, HV prolongation in one, and both in three), sinus node dysfunction in three, “AV nodal dysfunction” in four, and right bundle branch block in 13 (22). Postoperative complete AV block is now uncommon after repair of this lesion, related to modification in surgical technique (eFig. 70.0.21).



***e*FIGURE 70.0.21** Modern repair of complete atrioventricular septal defect. An atrial septal defect patch (Pa) is sutured along the mitral side of the inferior bridging leaflet of the common atrioventricular valve to avoid damage to the posteriorly deviated atrioventricular node (N). The ventricular septal defect patch (Pv) is sutured slightly off the margin of the crest of the ventricular septum (V) to avoid damage to the penetrating bundle. A, rim of atrial septum; C, coronary sinus ostium; M, sutured cleft in newly formed mitral valve; S, superior bridging leaflet of common atrioventricular valve; T, tricuspid. (From Ungerleider RM. Congenital heart disease. In: Sabiston DC, ed. *Atlas of cardiothoracic surgery.* Philadelphia: WB Saunders, 1995:255–372. with permission.)

Postoperative evaluation by Holter monitoring has demonstrated a 33% incidence of ventricular and a 10% incidence of atrial arrhythmias in 106 patients (194). Ectopy was more likely in larger (and therefore older) patients if they had a higher postoperative right ventricular end diastolic dimension, if they had a larger VSD, or if there was postoperative right bundle branch block. There were no reported episodes of sudden death.

Left Ventricular Outflow Tract Obstructive Lesions

In a series of 117 young patients with AS (younger than 40 years old), in which 61 underwent surgical valvulotomy and 30 underwent valve replacement (17), the prevalences of both PSVBs and PVBs were higher than a control population. Serious arrhythmias occurred in 44.8% of patients and were significantly more likely in surgically managed patients (p = .0056), although ventricular tachycardia occurred in 10.1% of the valvotomy and 13.9% of the valve replacement groups. Both were significantly greater than the general population (p <.0001). An elevated left ventricular end diastolic pressure, the coexistence of aortic insufficiency, and male gender were associated with increased risk of having a serious arrhythmia. Of greatest concern, at last follow-up, the occurrence of sudden unexpected death was 5.4%, significantly higher than in the group with pulmonic stenosis. Silka et al. demonstrated incremental risk of sudden death after 20 years *despite repair* of AS or coarctation of the aorta (195).

CONTROVERSIES AND PERSONAL PERSPECTIVES

The majority of clinically important arrhythmias associated with congenital heart disease are either bradycardias caused by surgical injury to the specialized conduction system or reentrant tachycardias related to artificial or natural conduction obstacles often in combination with residual hemodynamic perturbations.

Most patients having postoperative sinus or AV node dysfunction may be adequately paced using current technology. However, when epicardial pacing is required in a heavily scarred heart, such as after the Fontan procedure or when there are residual intracardiac shunts, active fixation leads having a high impedance and a low chronic pacing threshold are still not available. The only current steroid-eluting epicardial lead must be sutured to the epicardium, which may be covered by fibrotic scar from prior surgeries. Thus, a permanent plunge electrode having all of the desired electrical properties would be ideal. Implantation of epicardial systems may someday be performed thoracoscopically, eliminating the need for repeat thoracotomies. This will be important even for atrial leads following the newer types of Fontan surgery because transvenous lead placement may be obviated by the exclusion of natural atrial tissue from the systemic venous circulation. With regard to replacing old systems, removal of transvenous leads because of lead failure or fracture or because of infection will soon be facilitated by new laser extractor technology.

Physiologic sensors for patients with chronotropic incompetence and who require epicardial pacing systems are not yet available. Motion sensors are adequate for most of these patients, but for those with sinus node dysfunction and poor ventricular function, a system responding more to the autonomic nervous system would be desirable.

Atrial reentrant tachycardias after Mustard or Senning surgery will be only of historical interest within about four decades, as the indications to perform those procedures will continue to be very limited compared with those in the past because the success of the arterial switch operation for simple transposition of the great arteries. But until then, improved catheter ablation techniques hold promise for the majority of these patients. Newer channel-specific, potassium channel–blocking drugs may be of value for the remainder. After the Fontan operation, catheter ablative therapies of atrial reentry tachycardias will improve with multiplane mapping systems and electrical activation–directed targets instead of fluoroscopy guidance. However, the best option will be surgical innovations designed to eliminate the atria altogether from the high-pressure systemic venous circuit, reducing the incidence of these tachyarrhythmias. When this is not possible, collaboration between the surgeon and electrophysiologist to create “prophylactic incisions” that prevent reentrant circuits at the time of the Fontan operation is an exciting concept on the horizon.

Therapies for ventricular tachyarrhythmias after ventricular surgery are sufficiently advanced to prevent SCD and maintain a reasonably good quality of life in the vast majority of affected individuals. Improved outcomes from radiofrequency ablation of macroreentrant circuits related to suture lines will be seen when higher energies can be used with chilled-tip catheters. Among patients having hemodynamically stable monomorphic VT, radiofrequency ablation should become first-line therapy. Patients having faster VT or who have survived episodes of near SCD will continue to benefit from the rapid advances in implantable cardioverter-defibrillator technology. However, far more difficult than the therapeutic options remains the task of ascertaining which patients are at risk for VT or SCD. Controlled studies are hampered by (a) the inability to ethically create control groups; (b) the relatively low incidence of these diseases compared with that of other cardiovascular diseases in Western society and, hence, the dependence on multiinstitution trials; and (c) the nonuniformity of surgical techniques between institutions and between surgical eras within each institution. The specific questions to be answered appear to center around the value of noninvasive testing—that is, ventricular ectopy by ambulatory monitoring, ectopy produced by exercise testing, right ventricular systolic function and diastolic volume, left ventricular function, the presence of late potentials, and the QRS duration—and of ventricular programmed stimulation in predicting which patients are at risk for SCD or sustained VT. It is likely that the risk factors are quite different and that ventricular function is relatively more important in predicting those at risk for SCD, whereas macroreentrant VT is more determined by a combination of surgical technique and ventricular dilatation. A prospective approach uniformly using serial invasive and noninvasive techniques in all patients with any of the currently accepted risk factors—that is, age at repair, elevated right ventricular systolic pressure, severe pulmonary valve insufficiency, left ventricular dysfunction, QRS

duration of more than 0.14 seconds, increase in ectopy during exercise, or high-grade ectopy during ambulatory monitoring—would be most likely to bring order to the field. This would require institutional commitment, as its completion would take decades and, therefore, generations of investigators.

THE FUTURE

Ongoing natural history studies will continue to help determine the optimal timing of congenital heart surgery in an effort to minimize long-term postoperative arrhythmias. Modifications in surgical techniques are also being designed to help reduce the risk for postoperative arrhythmias. This is especially important in the Fontan operation. New therapeutic techniques include (a) development of steroid-eluting active fixation leads, so vital after many congenital heart operations; (b) new antiarrhythmic drugs, especially channel-specific potassium channel blockers; and (c) advances in intracardiac mapping of reentry tachycardias to help guide radiofrequency ablation of intramuscular reentrant circuits. Finally, it is likely that multiinstitution collaborative efforts similar to the study of coronary artery disease will be performed in patients after tetralogy of Fallot repair so that we may determine who truly is at risk for ventricular tachyarrhythmias and SCD, thus making possible a standard approach to screening these patients.

OVERVIEW

Syncope—a syndrome of relatively limited duration with subsequent spontaneous recovery and characterized by the sudden loss of consciousness and postural tone—is a common medical problem and an important cause of emergency department visits and hospital admissions (1,2,3,4,5,6,7,8,9 and 10). It has been estimated that approximately one-third of individuals experience a syncopal episode during their lifetime (10). Susceptibility to syncope increases in association with advancing age and increasing infirmity (10,11). Thus, in the Framingham experience (10), the prevalence of “isolated” syncope (i.e., syncope in the absence of apparent neurologic or cardiovascular disease) increased from 8 in 1,000 person-examinations in the 35- to 44-year-old age group to approximately 40 in 1,000 person-examinations in the >75-year-old age group. However, in a presumably more infirm population (i.e., elderly individuals confined to long-term care institutions), Lipsitz et al. (11) reported an annual incidence of syncope as high as 6%.

Apart from first syncopal events, approximately 35% of syncope patients experience recurrences within 3 years of follow-up (10,11,12 and 13). A history of recurrent syncope at the time of initial presentation—especially if the recurrences have been spread over a relatively long period—is a strong predictor of future recurrences (12,13). In one report, more than five lifetime syncope recurrences were associated with a 50% chance of recurrence in the following year (12).

PATHOPHYSIOLOGY

The minimum oxygen requirements needed to maintain consciousness have been estimated to be in the range of 3.5 mL per 100 g tissue per minute (14,15). In healthy young or middle-aged individuals, cerebral blood flows are typically 50 to 60 mL per 100 g tissue per minute; consequently, minimum oxygen delivery requirements are easily met. However, in older or ill patients with reduced oxygen carrying capacity or diminished cardiac output, the safety factor for oxygen delivery may be more precarious. It has been estimated that a drop in cerebral oxygen delivery of ³20% is sufficient to cause loss of consciousness.

Cerebral perfusion is critically dependent on systemic arterial pressure. Thus, factors that diminish systemic arterial pressure (e.g., decreased cardiac output or peripheral vascular resistance) may impair cerebral perfusion. In syncope patients, decreased venous filling is often a major factor in triggering a reduced cardiac output. Excessive pooling of blood in dependent parts of the body or diminished blood volume predisposes the patient to syncope. Impaired cardiac output may also be the result of tachyarrhythmias or bradyarrhythmias, especially in the setting of left ventricular dysfunction, valvular heart disease, volume depletion, or abnormal vascular reactivity. In terms of vascular resistance, inadequate vasoconstriction or inappropriate vasodilatation may contribute to syncope by undermining cerebral perfusion pressure. In fact, inappropriate vasodilatation is the main cause of fainting in reflex syncopal syndromes. Vasodilatation resulting in diminished cerebral perfusion also can contribute to lightheadedness and syncope in association with thermal stress (e.g., hot environments, excessive exercise). Impaired capacity to increase vascular resistance adequately during upright posture is critical in orthostatic hypotension, syncope associated with use of vasoactive drugs, and patients with autonomic neuropathies (14,15,16,17 and 18). Cerebral hypoperfusion may also result from an abnormally high cerebral vascular resistance (e.g., due to low carbon dioxide tension in hyperventilation syndromes).

CLASSIFICATION OF THE CAUSES OF SYNCOPE

The classification of the causes of syncope is found in Table 71.1.

TABLE 71.1 SYNCOPE: DIAGNOSTIC CLASSIFICATION

Neurally Mediated Reflex Syncopal Syndromes

The neurally mediated syncopal syndromes (Table 71.2) comprise a variety of pathophysiologically related conditions. For the most part, clinical distinctions are based on the source of the “trigger” for the episodes (e.g., pain, carotid sinus stimulation, cough, micturition). In this regard, the presumed triggering neural signals may arise

within the central nervous system (CNS) itself (e.g., syncope associated with fear or anxiety), or from any of a number of peripheral “receptors” that respond to stimuli of various types (e.g., mechanical, chemical, painful). The nature of these receptors is perhaps best understood in carotid sinus syncope and postmicturition syncope. In carotid sinus syndrome, the afferent aspect of the reflex loop typically is believed to arise from stimulation of autonomic receptors in the cervical region. However, it now seems likely that, to trigger the syndrome, carotid sinus stimulation may need to interact with the failure of parallel CNS inputs from the ipsilateral neck muscles (19). In typical vasovagal syncope (Fig. 71.1), the location and nature of the trigger sites are usually less certain. Cardiac mechanoreceptors, along with other central mechanoreceptors and chemoreceptors, appear to contribute to the afferent neural traffic (20,21,22,23,24,25 and 26).

Emotional syncope (common or vasovagal faint, malignant vasovagal faint)
Carotid sinus syncope
Gastrointestinal stimulation
Swallow syncope, defecation syncope
Micturition syncope
Cough syncope
Sneeze syncope
Glossopharyngeal neuralgia
Airway stimulation
Raised intrathoracic pressure
Brass or wind instrument playing, weightlifting

TABLE 71.2 NEURALLY MEDIATED SYNCOPAL SYNDROMES

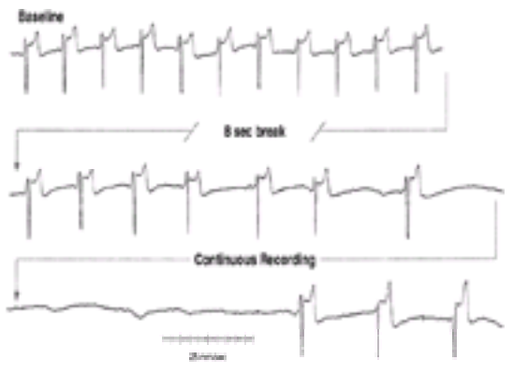

FIGURE 71.1 Recording from an in-hospital electrocardiogram monitor illustrating bradycardia associated with a spontaneous vasovagal faint accompanying an abrupt hemorrhage after an invasive cardiac procedure.

The afferent neural signals in neurally mediated syncopal syndromes initiate (via the medullary cardiovascular control areas) an efferent response comprised of bradycardia, which may be marked or “relative,” and vasodilation. In terms of causing symptomatic hypotension, the relative importance of bradycardia and vasodilatation differs among patients—perhaps even within patients at various times. Thus, certain syncopal events may be characterized as primarily “cardioinhibitory” (due to bradycardia), whereas other events are principally “vasodepressor” (due to vasodilation). The majority of cases are, in fact, due to a combination of bradycardia and vasodilation (“mixed” response).

Orthostatic Syncope

Orthostatic syncope is often termed *postural hypotension* or *orthostatic hypotension* (Table 71.3). Volume depletion (often iatrogenic) (22,23,27,28,29,30,31,32,33 and 34) or neurologic disturbances of vascular control due to concomitant disease are the most frequent causes of orthostatic syncope. In certain cases, however, patients may manifest a form of primary autonomic failure with inadequate reflex adaptations to upright posture.

Primary autonomic failure
Pure autonomic failure
Autonomic failure with multiple system atrophy
Parkinson’s disease with autonomic failure
Secondary autonomic failure
Diabetes mellitus
Volume/fluid depletion
Autoimmune acute and subacute dysautonomias (e.g., Guillain-Barré syndrome, myasthenia gravis)
Autonomic neuropathy associated with malignancies
Metabolic diseases (e.g., porphyria, Fabry’s disease)
Central nervous system infections (e.g., syphilis, Chagas disease)
Hypothalamic and midbrain lesions/tumors (e.g., craniopharyngioma)
Spinal cord lesions/tumors
Drug/toxin-induced autonomic failure
Alcohol
Diuretics
Sedatives/tranquilizers: phenothiazines, barbiturates
Vasodilators (e.g., peripheral and central sympatholytic agents)
Angiotensin-converting enzyme inhibitors
Tricyclic antidepressants

Modified from Bannister R, ed. Autonomic failure. A textbook of clinical disorders of the autonomic nervous system. Oxford: Oxford University Press, 1988.

TABLE 71.3 SYNCOPE OF ORTHOSTATIC ORIGIN: A CLASSIFICATION OF CAUSES

Several forms of primary neurologic disturbance may cause orthostatic syncope. The most important disturbances are pure autonomic failure, multisystem atrophy, or Parkinson’s disease with autonomic failure. However, secondary causes of autonomic failure due to other disease processes (e.g., diabetic neuropathy, infectious neuropathies) or drugs (e.g., diuretics, vasodilators) and alcohol are far more common.

Volume depletion is also a common cause of orthostatic syncope. Often, volume depletion is a consequence of drug treatment (e.g., diuretics), but it may also occur as a result of inadequate volume intake in hot or dry environments, excessive fluid loss with diarrhea or vomiting, or as a result of hemorrhage (Table 71.3). In regard to the latter, the occurrence of syncope in association with acute blood loss—even small amounts, as in venipuncture—is a relatively frequent event; in this case, blood loss and other associated neurally mediated reflexes contribute to symptoms (22,23,27,28,29,30,31,32,33 and 34).

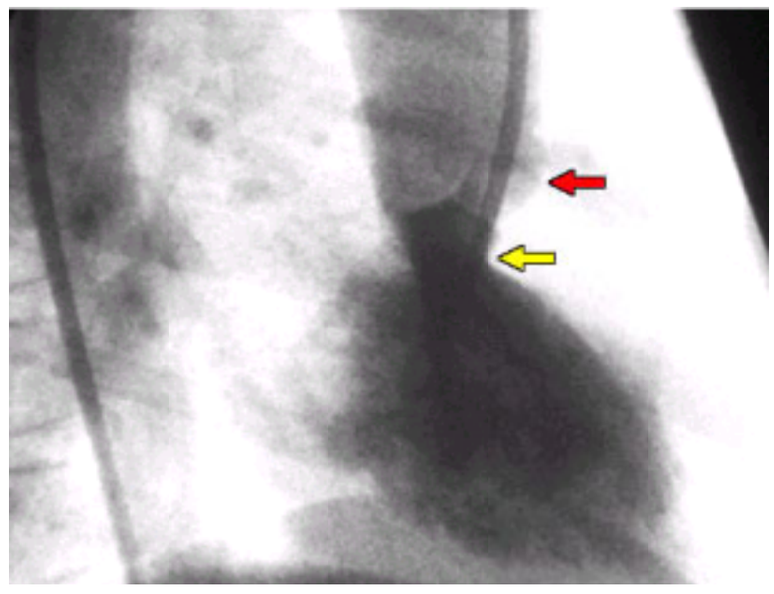
Cardiac Arrhythmias as Primary Causes of Syncope

Among syncope patients with underlying congenital or acquired structural heart disease, a primary cardiac arrhythmia is probably the most common cause of symptoms. Primary cardiac arrhythmias encompass those rhythm disturbances associated with intrinsic cardiac disease, accessory conduction pathways, or other structural abnormalities (e.g. congenital anomalies, postoperative disturbances), as well as disturbances due to proarrhythmic effects of cardioactive drugs (e.g., cardiac glycosides, positive inotropic agents, antiarrhythmic drugs).

The basis for syncope is readily apparent in patients with long periods of severe bradycardia or cardiac asystole in the setting of sinus node dysfunction or atrioventricular (AV) conduction disease. The same is true in individuals with extremely rapid tachyarrhythmias. However, in many cases, hypotension is multifactorial; it is dependent on the interaction between heart rate, ventricular function, central volume status, and peripheral vascular reactivity. In this regard, assessment of response to upright posture (i.e., tilt-table testing during induced or spontaneous arrhythmia) may be crucial in understanding the hemodynamic impact of arrhythmias (35).

Structural Cardiovascular or Cardiopulmonary Disease

Cardiac arrhythmias are the most frequent causes of syncope in patients with structural cardiac disease. However, other hemodynamic disturbances may also be responsible for symptomatic hypotension. Acute myocardial ischemia or infarction is probably the most important of these disturbances (36,37). In this setting, the basis of the faint is multifactorial; it is, in part, dependent on neural reflex effects leading to inadequate peripheral vascular compensatory response. Similarly, syncope associated with aortic stenosis or hypertrophic obstructive cardiomyopathy (HOCM) is due not only to mechanical obstruction, but also to neurally mediated inappropriate vascular responsiveness (38,39 and 40). Prosthetic valve disorders also require consideration as causes of syncope in patients who have previously undergone such surgery.



Subaortic stenosis. This right anterior oblique left ventriculogram demonstrates the presence of a stenosis in the left ventricular outflow tract (*yellow arrow*) just below the level of the aortic valve (*red arrow*).

Noncardiac cardiovascular structural disturbances may also be associated with syncope. For instance, in subclavian steal syndrome, dizziness and syncope may develop during upper extremity exercise in association with ipsilateral stenosis of the subclavian artery near its origin. Syncope also is associated with pulmonary hypertension and acute pulmonary embolism. In these latter conditions, the basis for the faint encompasses reduced blood flow, diminished oxygenation, and neural reflex vascular disturbances.

Cerebrovascular Syncope

Transient global diminution of cerebral nutrient flow is, for the most part, a necessary requirement for development of syncope. However, it is exceedingly rare for this diminution to occur solely as a result of cerebrovascular disease (i.e., in the absence of a cardiac arrhythmia, orthostatic stress, or other precipitating factor). One example in which cerebrovascular disease could cause transient loss of consciousness without global disturbance of nutrient supply is in intracerebral vascular “steal.” In this case, diversion of blood flow away from regions of the brain controlling wakefulness is presumed to be the basis for syncope. Currently, establishing such a diagnosis in the clinic is, essentially, impossible.

Miscellaneous Nonsyncopal Conditions Associated with Impaired Consciousness

In most circumstances, metabolic disturbances of sufficient severity to cause loss of consciousness are not typically transient and self-correcting. Consequently, the clinical picture is not that of true syncope. However, impaired consciousness associated with metabolic and endocrine disturbances does occur. The presumed pathophysiology of this condition is a disturbance of cerebral nutrient availability (e.g., marked hypoglycemia), a major perturbation of acid/base or electrolyte environment, or both. Hyperventilation of presumably psychogenic origin, with consequent marked reduction of the partial pressure of carbon dioxide and reduced cerebral blood flow due to vasospasm, is probably the only relatively common problem in this class.

In regard to more well-established primary neurologic diseases (e.g., aneurysms, tumors, seizure disorders), episodes of loss of consciousness are, once again, usually not true syncope. Nevertheless, making a clinical diagnostic distinction can prove challenging. Astatic or akinetic seizures are particularly difficult to distinguish from syncope (41). Drop attacks may also be included in this category. The basis of drop attacks remains unclear, but because loss of consciousness is not an issue,

these attacks are excluded from the category of true syncope.

The pathophysiology of psychiatric disturbances (e.g., somatization disorders) known to mimic syncope (see the section Psychiatric Disorders) is poorly understood. For the most part, these disturbances do not result in true syncopal events. However, patients manifesting such disturbances may have a greater tendency to be subject to the emotional faint or other forms of neurally mediated syncope (see the section Neurally Mediated Reflex Syncopal Syndromes). Additionally, these patients may be prescribed certain medications that increase syncope risk (e.g., phenothiazines, tricyclics).

GENERAL CLINICAL CONSIDERATIONS IN THE EVALUATION OF SYNCOPE

In the clinical evaluation of the syncope patient, the principal goal is to establish an accurate diagnosis; only after a definitive diagnosis is made can an appropriate treatment strategy be embarked on. Given the numerous causes of syncope and the unpredictable nature of syncopal events, achieving this goal is difficult, and special testing is often essential (Fig. 71.2). This is especially true when symptoms are recurrent. However, even solitary syncopal events may warrant such steps when risks to the patient or public may be excessive (e.g., syncope associated with substantial physical injury or motor vehicle accident, syncope in individuals with high-risk occupations such as pilots, commercial truck drivers, or competitive athletes).

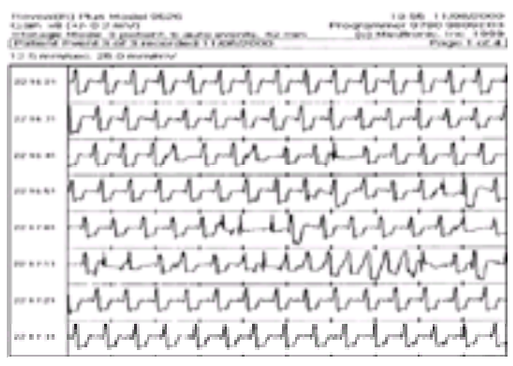

FIGURE 71.2 Recording from an implantable loop recorder. Patient complained of lightheadedness but had no symptoms of rapid heart action. The recording illustrates a wide-QRS nonsustained tachycardia suggestive of nonsustained ventricular tachycardia.

The circumstances surrounding syncopal episodes are highly variable. However, upright posture (standing or, occasionally, sitting) is usually implicated. Thereafter, the clinical picture is dictated by the underlying problem. Thus, in patients with syncope due to supraventricular tachycardia (SVT) or ventricular tachycardia (VT), palpitations may be reported. Frequently, however, rapid beating of the heart is not perceived and, consequently, is not part of the medical history (Fig. 71.2). In patients with vasovagal syncope, hypotension often is associated with a preceding sense of apprehension and nausea and is characterized by pallor and diaphoresis. On the other hand, in many individuals, warning symptoms are entirely absent. This seems to be the case in older patients, and a lack of symptoms of hypotension is common with carotid sinus syndrome. Consequently, while there is no doubt that the medical history of a syncopal event is crucial for differentiating syncope from other conditions—especially seizures—and providing clues to possible causes, it is often inconclusive (42).

SPECIFIC CONDITIONS

Neurally Mediated Syncopal Syndromes

Syncope of neurally mediated reflex origin encompasses vasovagal syncope, carotid sinus syndrome, and other, much less frequent forms of neurally mediated syncope (e.g., cough, deglutition, and micturition syncope) (Table 71.2). The electrophysiologic and hemodynamic picture associated with a neurally mediated syncopal event may be quite variable (43). Most patients present a mixed vasodepressor and cardioinhibitory response (43,44,45,46,47 and 48).

Vasovagal syncope may be triggered by any of a variety of situational factors. Some of these factors are unpleasant sights (e.g., sight of blood), pain, and extreme emotion. Common venues for fainting are churches, hospitals, queues, and restaurants. In many, but not all, cases, this type of faint is easy to diagnose because a clear history of preceding dizziness, together with other typical phenomena, is obtained (49). The patient may report feelings of lack of air, a change in breathing pattern, sweating, loss of hearing, and nausea before partial or total loss of consciousness. Pallor is a common physical finding in association with these faints, and witnesses to the event should be queried directly in regard to their recollection of this finding. During the recovery phase, there is rapid return of orientation. However, fatigue, weakness, nausea, and headache may last from minutes to hours. Often, in older individuals, warning symptoms may be brief or nonexistent, thereby complicating establishment of the diagnosis. In such cases, syncope may occur without apparent warning. Such an outcome often results in falls and physical injury—presentations difficult to distinguish by history alone from syncope complicating conduction disturbances of the heart. This variant of the vasovagal faint has been termed *malignant vasovagal syndrome* (50).

In instances in which vasovagal syncope is suspected by clinical history but in which uncertainty remains, tilt-table testing diagnostic techniques have been of value (23,45,46,47,48,49,50,51,52,53 and 54). Tilt-table testing has a specificity of approximately 90%, a reproducibility in the short term of 80% to 90%, and a reproducibility in the longer term (i.e., more than 1 year) of approximately 60% (54). Tilt-table testing is the only investigation that provides the opportunity to precipitate a typical attack under the eyes of the investigator and allows the victim to confirm the associated symptoms. A recent American College of Cardiology expert consensus document addresses the role of tilt-table testing and appropriate laboratory protocols (54).

Carotid sinus syndrome is probably the second most common form of the neurally mediated syncopal syndromes (55,56,57 and 58). In this setting, syncope often presents without warning (i.e., absence of premonitory symptoms). Although rare, a history suggesting that head movements trigger dizziness or syncope supports this diagnosis. As a rule, the condition almost exclusively afflicts older people, especially men.

In clinical practice, carotid sinus syndrome is often overlooked. The reasons for this include failure to perform carotid sinus massage routinely in syncope patients or failure to record blood pressure and heart rate responses when carotid massage is undertaken. As in other forms of neurally mediated reflex syncope, vasodepressor and cardioinhibitory features participate in most cases of carotid sinus syncope. In the absence of adequate arterial pressure measurements, a clinically important vasodepressor response may be missed.

Carotid massage resulting in dizziness or syncope due to hypotension with or without bradycardia is the key diagnostic finding in patients suspected of having carotid sinus syndrome. Testing is best conducted with the patient upright on a tilt table, using continuous digital plethysmography or intraarterial pressure measurements to record beat-to-beat arterial pressure changes. Firm carotid sinus massage for 5 to 10 seconds is recommended. A cardioinhibitory response is presumed to predominate when carotid sinus massage is associated with symptom reproduction in conjunction with asystole or a paroxysmal AV block of 8 to 10 seconds or longer (23,44,55,56). However, the vasodepressor component must be assessed separately during the maneuver by beat-to-beat arterial pressure monitoring while preventing bradycardia with a temporary dual-chamber pacing system. The magnitude of the vasodepressor part of the reflex can also be estimated by examining the rate of blood pressure recovery after resumption of the native heart rate. A systolic blood pressure drop ³50 mm Hg is generally accepted as diagnostic of a clinically important vasodepressor response. In most cases, both the cardioinhibitory and vasodepressor features are present (i.e., mixed response). In the absence of symptom reproduction, the demonstration of a pause of 5 seconds or longer, a systolic blood pressure fall ³50 mm Hg, or both is probably relevant and can be considered to support a “presumptive diagnosis” (54,57,58).

Among the other forms of neurally mediated reflex syncope, postmicturition syncope, swallow syncope, and cough syncope are probably the next most frequent. The remaining conditions (Table 71.2) are only rarely encountered.

Orthostatic Syncope

Presyncopal or syncopal symptoms associated with abrupt assumption of upright posture are common occurrences (Table 71.3). Elderly persons, less physically fit individuals, or patients who are, for whatever reason, dehydrated or volume depleted are at greatest risk for orthostatic syncope. Iatrogenic factors such as excessive diuresis or overly aggressive use of certain antihypertensive agents are important contributors. Environmental factors (e.g., excessive heat), complications associated with certain medical conditions (e.g., hemorrhage), or diseases (e.g., diabetes insipidus, adrenal insufficiency) may also play a role in specific cases. Patients

previously diagnosed with idiopathic orthostatic hypotension may be considered to be manifesting autonomic dysfunctions; these dysfunctions may be primary neurologic disturbances (e.g., pure autonomic failure) or secondary to other diseases or drug effects.

In general medical practice, specific primary autonomic nervous system dysfunctions leading to disturbances of vascular control are considered to be relatively infrequent causes of syncope. Nevertheless, as the broad spectrum of these disturbances and their potentially subtle manifestations become more widely appreciated by physicians, these diagnoses will be made more often (41,59,60,61 and 62). More commonly, neuropathies associated with chronic diseases (e.g., diabetes) or toxic agents (e.g., alcohol) are the source of the problem.

Clinically, syncope associated with orthostatic disturbances of blood pressure control tends to be most frequent early in the day. Susceptibility is accentuated if the patient has recently had an enforced period of bedrest, is exposed to hot environments, has recently completed a period of vigorous exercise, or is being treated with any of a variety of cardioactive drugs that deplete central circulatory volume (e.g., diuretics, sympatholytics). Furthermore, unlike vasovagal faints, these syncopal episodes typically are not associated with bradycardia, sweating, or marked pallor.

In a review of 155 patients referred for assessment of suspected orthostatic hypotension, Low et al. (63) found that among the most severely affected symptomatic patients (n = 90; mean age, 64 years), pure autonomic failure accounted for 33%, multisystem atrophy accounted for 26%, and autonomic/diabetic neuropathy accounted for 31%. The most frequently reported symptoms in these individuals were lightheadedness (88%), weakness or tiredness (72%), cognitive difficulties (47%), blurred vision (47%), tremulousness (38%), and vertigo (37%). The prominence of fatigue and weakness has raised the as-yet-unsettled issue regarding the possible relationship between these conditions and so-called “chronic fatigue syndrome” (64). Patients with postural orthostatic tachycardia syndrome, on the other hand, tended to be symptomatic during upright posture but did not typically manifest sufficient hypotension to result in syncope or marked hypotension.

The clinical evaluation of orthostatic hypotension is facilitated by the availability of tilt-table testing facilities. However, tilt-table test results, as in the case of vasovagal syncope, are affected by various factors such as the volume status of the patient, temperature, and chronobiologic issues. Consequently, the diagnosis of the various forms of autonomic failure using tilt-table testing and other autonomic testing procedures (63,65,66) require a level of experience that is available in relatively few centers. A relatively abrupt drop in systolic pressure of ³50 mm Hg is probably diagnostic, but it is better supported by the concomitant development of symptoms.

Cardiac Arrhythmias as Primary Causes of Syncope

Arrhythmias due to intrinsic conduction system disturbances—usually acquired but occasionally congenital—are important causes of syncope. However, it is often difficult to substantiate the relationship between syncope and a suspected arrhythmia in free-living individuals (e.g., by ambulatory electrocardiographic monitoring) due to the unpredictable occurrence of symptomatic events. Thus, implantable long-term loop recorders are becoming more widely applied. In some cases, invasive electrophysiologic testing may be indicated.

Sinus node dysfunction—commonly termed *sick sinus syndrome*—encompasses an array of sinus node and atrial arrhythmias that result in persistent or intermittent periods of inappropriate slow or fast beating of the heart (67,68,69,70,71 and 72). The electrocardiographic manifestations of sinus node dysfunction include sinus bradycardia, sinus pauses, sinoatrial exit block, inexcitable atrium, and chronotropic incompetence, as well as various atrial tachyarrhythmias—principally, atrial fibrillation or atrial flutter (Fig. 71.3). For the most part, sinus node dysfunction is closely associated with underlying fibrosis or chamber enlargement. However, extrinsic factors (e.g., autonomic nervous system influences, cardioactive drugs) are also frequent contributors. Of these factors, drug-induced disturbances are, clinically, the most important (69,70 and 71).

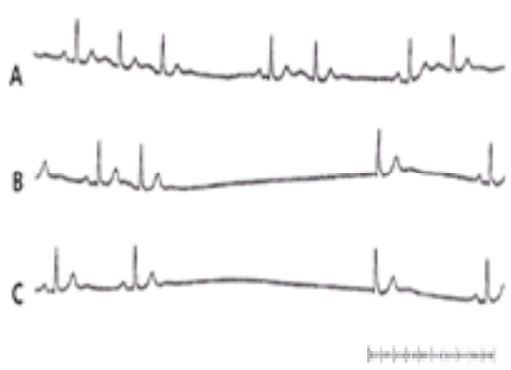

FIGURE 71.3 Symptomatic sinus pauses of varying duration recorded during ambulatory electrocardiogram monitoring in a 70-year-old woman with recurrent dizziness.

In the sinus node dysfunction patient with syncope, the cause may be a transient severe bradyarrhythmia, tachyarrhythmia, or both. Most often, it is believed that the arrhythmias associated with syncope in sinus node dysfunction patients are those that produce relatively long periods (i.e., 10 to 15 seconds or longer) of severe bradycardia (i.e., sinus pauses and sinoatrial block) with consequent inadequate cerebral blood flow. For example, Rubenstein et al. (67) found that among 56 patients with severe bradyarrhythmias or bradycardia-tachycardia syndrome, 25 (45%) presented with syncope, and an additional 15 (27%) reported various presyncopal symptoms. In the majority of these cases (80%), bradyarrhythmias were considered to be the principally responsible rhythm disturbance. Similarly, among 22 patients with sinus node dysfunction and syncope, Sutton and Perrins (72) reported resolution of symptoms with prevention of bradycardia by cardiac pacing in 16 (73%) cases. Of the patients with residual symptoms, treatment failure due to pacing system dysfunction occurred in one case, whereas symptomatic tachyarrhythmias were ultimately uncovered in several others.

Sinus node dysfunction patients, in large part due to their age and tendency to harbor coexisting diseases (especially cardiovascular disorders), are also susceptible to loss-of-consciousness spells that may not be due to primary arrhythmias. Orthostatic syncope, thromboembolism, myocardial ischemia, and new onset seizure disturbances are important considerations. In the past (i.e., before more widespread use of anticoagulation), it is notable that thromboembolism was the principal factor accounting for the excess morbidity and mortality in sinus node dysfunction patients (69,73,74 and 75).

Atrioventricular Conduction Disturbances

Acquired disturbances of AV conduction are most often associated with syncopal symptoms. Progressive idiopathic fibrosis of the cardiac conduction system is the most common cause of acquired conduction system disease with AV block (76,77). Acute myocardial infarction is also associated with the various forms of AV block and is another common cause of acquired complete AV block. Chronic ischemic and valvular heart disease, complications associated with cardiac surgical procedures, and administration of various antiarrhythmic drugs are other potential contributors.

Drug effects also deserve special consideration because they are a particularly common and potentially reversible cause of AV conduction disturbances (69,78,79). Cardiac glycosides, beta-blockers, and calcium-channel blockers are, perhaps, the most widely recognized drugs in this regard. Antiarrhythmic drugs may act directly, as well as through effects on the autonomic nervous system, to alter conduction in the AV node. At usual doses, however, antiarrhythmic drugs are rarely associated with *de novo* development of complete AV block. Patients with preexisting infranodal conduction system disease are at highest risk. Once again, however, syncope in this setting cannot be assumed to be bradycardic in origin because drug-induced tachycardias (i.e., the proarrhythmic effects of antiarrhythmic drugs) are also a consideration in this situation. Torsades de pointes is the most important example of this type of tachycardia.

As a solitary finding, first degree AV block is almost never the cause of syncope. When syncope does occur in this setting, there is usually no direct causal relationship. However, the presence of first degree AV block, especially in the absence of structural heart disease, may suggest hypervagotonia and thereby raise suspicion of neurally mediated syncope. Rarely, symptoms—typically presyncope, with true syncope occurring only in exceptional cases—may occur if the PR interval is sufficiently prolonged such that, during exercise, successive P waves are so far in front of the QRS complex as to be superimposed on preceding T waves (i.e., pseudopacemaker syndrome) (80,81).

Type I second degree AV block generally is considered to be a relatively innocent conduction disturbance when the QRS complex is narrow and there is no evidence of associated infranodal conduction system involvement. In this setting, bradycardia is rarely of sufficient severity to account for syncope. On the other hand, when Type I second degree block occurs in the setting of evident infranodal conduction system disease (e.g., wide QRS), the delay is often within the intraventricular specialized conduction system, and the risk of progression to higher grades of AV block is great. Additionally, when Type I second degree block occurs in elderly patients (>70

years), the prognosis may be more worrisome, and pacing should be considered. Type II second degree AV block generally is agreed to carry a worrisome prognosis and to cause a predilection for syncopal attacks, as well as the development of higher grades of AV block (Fig. 71.4). Type II block is most often seen in conjunction with bundle branch block and is indicative of severe disease of the infranodal specialized conduction system.

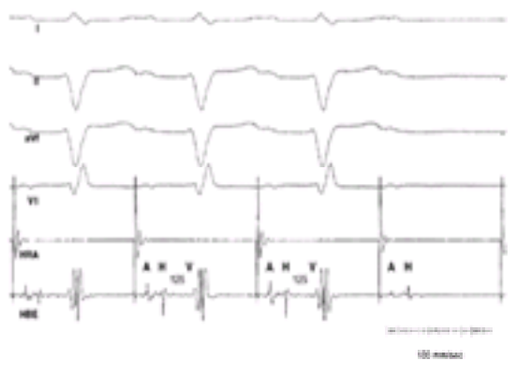

FIGURE 71.4 Electrocardiogram and intracardiac recordings illustrating a prolonged HV interval and infra-His block (Mobitz II) in a patient undergoing electrophysiologic evaluation for recurrent syncope of unknown cause. HBE, bundle of His electrogram; HRA, high rate atrium.

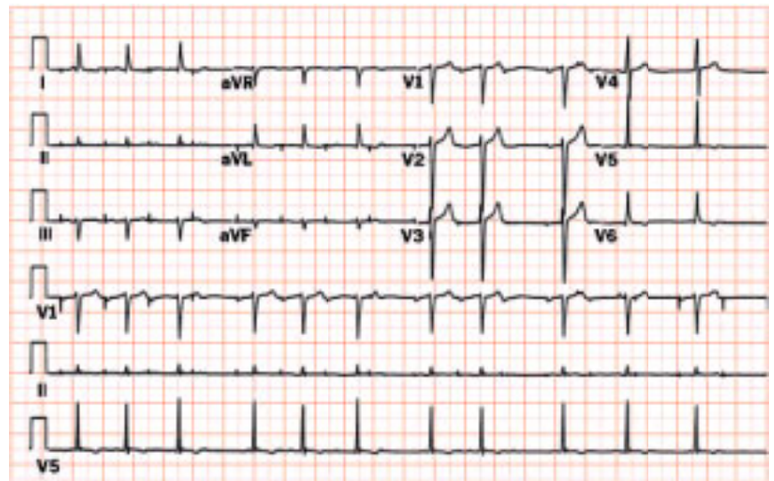
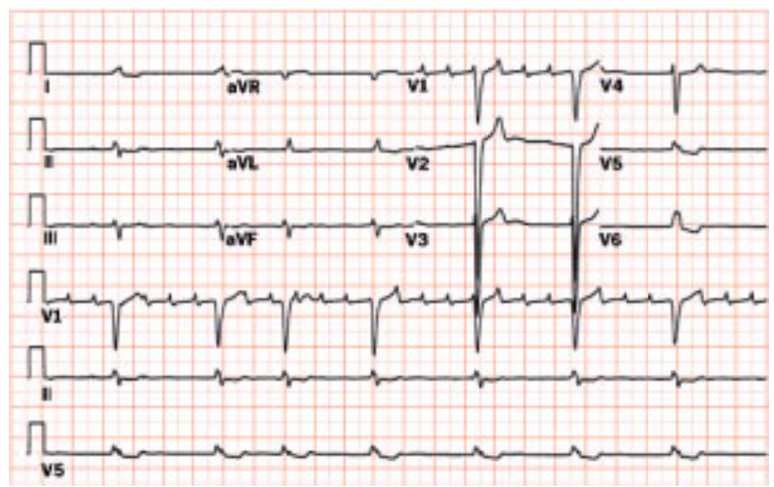


Mobitz I second-degree atrioventricular block. Note electronic atrial pacemaker with progressive PR segment prolongation before dropped QRS complex.

Third degree AV block may be high-grade (i.e., in which multiple P waves are blocked) or complete. In either case, the cardiac rhythm depends on subsidiary pacemakers located within the proximal portions of the specialized conduction system (e.g., bundle of His) that may result in relatively narrow QRS complexes, or within more distal aspects of the His-Purkinje system, resulting in wide QRS complexes. Syncope is a common feature in these cases [reported in 38% to 61% (82,83)], because the back-up pacemakers are usually relatively slow and often unreliable.



High-grade atrioventricular block. Note marked discrepancy between atrial and ventricular heart rates.

In general, the risk for syncope or dizziness is greatest at onset of AV block, before “warm-up” of a subsidiary rhythm (Fig. 71.4). Thereafter, the ventricular rhythm often stabilizes and may average 35 to 40 beats/min in acquired third degree AV block. In fixed complete AV block, syncope may occur as a result of the unreliability of subsidiary pacemakers or of the inability of the heart-rate–limited circulation to provide sufficient cerebral blood flow during periods of exercise or stress. In both cases, the close association with severe underlying heart disease also raises concern regarding tachyarrhythmia-induced syncope, including increased proarrhythmia risk in patients treated with antiarrhythmic drugs.

Traditionally, congenital complete AV block has been accorded a more benign prognosis than that accorded to acquired AV block (84,85). The site of block in patients with congenital AV block is typically at the level of the AV node. Generally, the QRS complexes are narrow, and the block usually is associated with a reasonable subsidiary rhythm, which tends to increase in rate with exercise. Recently, however, concern has been raised regarding the supposedly benign natural history of congenital AV block (86), and further evaluation of this issue is needed. In the meantime, syncope and dizziness, along with exertional intolerance, are accepted indications for pacing in these patients.

Bifascicular conduction system disease is a relatively common electrocardiographic finding. However, in most cases, progression to more severe forms of AV block is slow. Susceptibility to higher-grade block (i.e., blocks that may be long enough to cause syncope) increases the longer the HV interval is, particularly for HV ³100 ms (87,88 and 89). However, once again, it should be borne in mind that syncope in patients with evident conduction system disease may not be solely the result of bradyarrhythmias. VT is a concern in these cases because of the usual presence of significant underlying heart disease.

Supraventricular and Ventricular Tachyarrhythmias

Supraventricular tachyarrhythmias have been reported to be the causes of syncope in approximately 15% of patients referred for electrophysiologic evaluation (6). When syncope does occur, it is typically at the onset of an arrhythmic episode and before adequate peripheral vascular compensation can occur. A number of factors determine whether syncope or dizziness occurs in patients with SVT, including the tachycardia rate, the volume status and posture of the patient at onset of the arrhythmia, the presence of associated valvular, left ventricular, or pulmonary vascular disease, the mechanism of the arrhythmia, and the integrity of reflex peripheral vascular compensation. Additionally, it has come to be recognized that neural reflex responsiveness may be less efficient in individuals susceptible to syncope with SVT (90).

Electrophysiologic testing in SVT patients offers the possibility of obtaining direct evidence of the role played by the arrhythmia in the patient’s symptoms. However, to document symptomatic hypotension, it may be necessary to induce the arrhythmia with the patient in the head-up posture on a tilt table.

Sustained VT has been reported to be the cause of syncope in up to 20% of syncope patients referred for electrophysiologic testing (6). This diagnosis is of particular concern in the setting of underlying structural heart disease or long-QT syndrome (congenital or acquired). In regard to VT susceptibility, a detailed medical history should be supplemented with assessment of the status of underlying cardiac disease. In this regard, an echocardiographic study is adequate in most cases, but other imaging modalities—including angiography—may be required as well. Although the utility of a signal-averaged electrocardiogram (ECG) is controversial, it may be an appropriate consideration in individuals with ischemic heart disease in whom VT is a concern. If the signal-averaged ECG is normal, the likelihood that VT is the cause

of syncope is low (91,92).

Nonsustained ventricular tachycardia (NSVT) remains a difficult dilemma for physicians evaluating syncope patients. NSVT is a common finding during ambulatory electrocardiographic monitoring in patients with structural heart disease. Consequently, finding NSVT in a syncope patient usually is not helpful in the absence of concomitant symptoms (Fig. 71.2). Similarly, induced NSVT during electrophysiologic testing, especially if polymorphic, is not a reliable diagnostic finding. However, if reproducible periods of hypotensive NSVT are easily inducible, and there is no other apparent explanation for syncope, it is probably prudent to proceed with pharmacologic or device prophylaxis. The Multicenter Unsustained Tachycardia Trial data, although not directly focused on a syncope population, seem to provide additional support for this argument (93).

Particularly perplexing is the appropriate approach to be taken in the setting of syncope in patients with severe underlying left ventricular dysfunction (e.g., dilated cardiomyopathy) but without evident NSVT or inducible sustained VT. In such cases, evidence suggests that there is high risk for symptom recurrence and sudden death (94,95 and 96). As a result, prophylactic placement of an implantable cardioverter-defibrillator is often recommended. Whether this approach is justifiable awaits prospective evaluation.

Structural Cardiovascular or Cardiopulmonary Disease

Apart from cardiac arrhythmias, the most common cause of syncope attributable to left ventricular disease is acute myocardial ischemia or infarction. Other relatively common acute medical conditions associated with syncope include pulmonary embolism and pericardial tamponade. The basis of syncope in all of these conditions is multifactorial, including the hemodynamic impact of the specific lesion and neurally mediated reflex effects.

Syncope may also occur in conditions in which there is fixed or dynamic obstruction to left ventricular outflow (e.g., aortic stenosis, HOCM). In such cases, symptoms often are provoked by physical exertion but may also develop if an otherwise benign arrhythmia should occur (e.g., atrial fibrillation). In part, the basis for the faint may be inadequate blood flow due to the mechanical obstruction. However, especially in the case of valvular aortic stenosis, ventricular mechanoreceptor-mediated bradycardia and vasodilatation are thought to be important contributors (38).

Subclavian steal syndrome is an uncommon cause of syncope. In this setting, narrowing of the subclavian artery at its origin results in syncope or dizziness in conjunction with ipsilateral upper extremity exercise as blood is shunted from the brain to the exercising limb via the vertebral artery system. Other, even less common, conditions in this category include left ventricular inflow obstruction in patients with mitral stenosis or atrial myxoma. Similarly, right ventricular outflow obstruction and right-to-left shunting secondary to pulmonic stenosis or pulmonary hypertension may be associated with syncope.

Cerebrovascular Causes of Syncope

Cerebrovascular disease, including severe carotid artery disease, rarely causes syncope. Occasionally, however, transient disturbances of cerebrovascular blood flow may initiate a true syncopal spell. For example, arterial entrapment with intermittent obstruction of posterior circulation vessels can occur in conjunction with cervical spine disease. In such cases, any concomitant problems with the anterior circulatory supply may result in syncope.

Migraine may be associated with syncope. In such cases, extracranial vascular spasm may trigger neural reflex syncope, although cerebrovascular spasm might also occur. In any case, historical features of migraine and migraine susceptibility usually are sufficient to distinguish the diagnosis. Finally, symptoms secondary to cerebrovascular disease may be referred for evaluation as a syncopal episode. In particular, transient ischemic attacks due to vertebrobasilar disease may mimic syncope (41,59). In such cases, there are usually concomitant findings (e.g., vertiginous complaints, ocular disturbances, or speech problems) not typically encountered in the syncope patient.

Miscellaneous Causes of Impaired Consciousness: Syncope Mimics

Metabolic and Endocrine Disturbances

Metabolic and endocrine disturbances are more often responsible for confusional states or behavioral disturbances, rather than true syncope. However, it may be difficult to make a clear-cut distinction between such symptoms and syncope by medical history alone. One potentially useful distinguishing feature is that, unlike true syncope, conditions such as diabetic coma and severe hypoxia or hypercapnia do not resolve without active therapeutic intervention. In the case of syncope due to psychogenic hyperventilation, tilt-table testing may prove helpful for reproducing the event and permitting its documentation by blood gas analysis of arterial samples obtained from a previously placed indwelling catheter.

Psychiatric Disorders

Syncope may be mimicked by anxiety attacks, hysteria, or other psychiatric disturbances. Anxiety attacks are frequently associated with hyperventilation and hypocapnia. Hysteria, however, tends to be characterized by its “drama” because it can occur in the presence of onlookers and is not associated with marked alterations of heart rate, systemic pressure, or skin color.

Central Nervous System Causes

In Kapoor’s extensive review of more than 400 patients presenting with syncope, only a few were found to have abnormal neurologic studies (9). Typically, any diagnostic confusion is due to the fact that these conditions may result in a clinical picture, at least from a lay viewpoint, that may be mistaken for syncope. However, the differences are usually clearly distinguishable by careful history taking and neurologic physical examination.

Seizures may be mistaken for syncope, and vice versa (7,9,41,59,97). In some patients, temporal lobe seizures may so closely mimic or induce neurally mediated reflex bradycardia and hypotension, that differentiation from true syncope is difficult. Astatic or akinetic seizures are characterized by the patient slumping to the ground—or, if the patient is supine, by a period of muscular hypotonia—combined with unresponsiveness (41,59). However, these conditions are uncommon. More often, a careful history permits differentiation of seizures from true syncope.

Seizures tend to be positionally independent, whereas true syncope is most commonly associated with upright posture. Furthermore, seizures often are preceded by an aura and, occasionally, sensory hallucinations, whereas true syncope is not. Seizures are often associated with convulsive activity and loss of bowel or urinary continence, whereas any abnormal motor activity in true syncope is less severe, and incontinence is unusual (97). Finally, seizures are typically followed by a confusional state, whereas true syncope is typically followed by prompt restoration of mental state, although fatigue may persist.

Cataplexy, an uncommon condition characterized by abrupt onset of generalized muscle weakness, can be confused with syncope. As in the case of vasovagal syncope, symptoms may be triggered by emotional reactions or surprise. A narcoleptic sleep may follow. Cataplexy generally can be distinguished from syncope because the patient can be aroused. Electroencephalographic findings compatible with rapid eye movement sleep differentiate the narcoleptic state from a postictal event.

Drop attacks refer to a poorly defined condition in which abrupt loss of postural tone occurs but consciousness is generally preserved. The etiology of these attacks is unknown. In certain cases, drop attacks appear to be associated with atherosclerotic cerebrovascular disease, especially within the vertebrobasilar system, and are presumed to be the result of transient nutrient insufficiency to corticospinal tracts, which results in sudden atonia in the lower extremities (41). The dramatic clinical presentation of a fall often leads to syncope being the initial diagnosis.

MANAGEMENT: DIAGNOSIS AND TREATMENT

Strategy for Diagnostic Evaluation of the Syncope Patient

The goal of diagnostic testing in syncope patients is to obtain a sufficiently strong correlation between syncopal symptoms and detected abnormalities to permit confident statement of the cause of the faint, an accurate assessment of prognosis, and initiation of an appropriate treatment plan.

A detailed medical history—with particular attention to bystander observations—and a thorough physical examination may lead the physician to suspect the basis for syncope. However, unless these findings are classic, it is usually necessary to undertake selected diagnostic studies to establish the etiology with a greater degree of

certainty. In all cases, testing should be carefully targeted. The ordering of routine hematologic and biochemical screens is not productive. Similarly, routine application of specialized neurologic tudies (e.g., computed tomography, magnetic resonance imaging) has a low yield (9). A practicable strategy for the syncope evaluation is depicted in Fig. 71.5. As a rule, the first step—apart from excluding a history of seizure disorder—is differentiation of individuals with normal cardiovascular status from those with evident cardiac or cardiovascular disease. Usually, physical examination and echocardiographic assessment is sufficient for this purpose, although exercise testing should also be undertaken if syncope occurred with exertion or if ischemic heart disease is suspected.

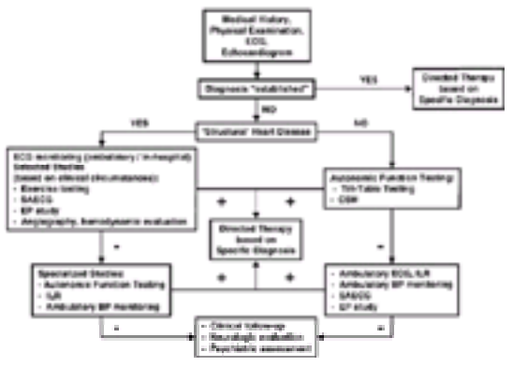


FIGURE 71.5 A proposed strategy for syncope evaluation. BP, blood pressure; CSM, carotid sinus massage; ECG, electrocardiogram; EP, electrophysiologic; ILR, implantable loop recorder; SAECG, signal-averaged electrocardiogram.

In the absence of structural heart disease, tilt-table testing is usually the next diagnostic step. On the other hand, in patients with abnormal cardiac findings, functional studies of the structural disturbance (e.g., hemodynamic, angiographic) and evaluation of susceptibility to tachyarrhythmias and bradyarrhythmias by conventional electrophysiologic testing is appropriate. In patients with demonstrable vascular disease, appropriate studies to assess the hemodynamic significance of observed arrhythmias (e.g., ultrasound) are needed. Thereafter, tilt-table testing should follow if the diagnosis remains in doubt. In only a few instances should special neurologic studies be elected as an initial step.

Specific Diagnostic Testing

Electrocardiographic Recordings

Electrocardiographic documentation during a spontaneous syncopal event is usually a high priority, because cardiac arrhythmias are so frequently the cause of syncope. In this regard, the 12-lead ECG is usually too brief to identify or exclude an arrhythmic cause. However, on occasion, findings such as ventricular preexcitation (e.g., Wolff-Parkinson-White syndrome) or QT interval prolongation suggest a potential mechanism. Other relatively common findings such as sinus bradycardia, ventricular ectopic beats, bundle branch block, or even NSVT often are not particularly helpful. Similarly, exercise testing is usually of limited utility in the evaluation of syncope, unless the events are clearly exertionally related by history. Only in rare instances does exercise testing uncover certain helpful findings [e.g., rate-dependent AV block, exertionally related tachyarrhythmias, severe degrees of chronotropic incompetence, excessively rapid heart rate deceleration after exercise, or the exercise-associated variant of neurally mediated syncope (98,99 and 100)]. For the most part, obtaining ECG documentation during spontaneous symptoms—if feasible at all—necessitates an extended period of cardiac monitoring using Holter monitors or event recorders. The latter systems can be used in a continuous-loop mode for patients whose symptoms preclude responding appropriately when the episode begins. Recently, the introduction of implantable loop recorders (Reveal, Medtronic, Inc., Minneapolis, MN) has added a powerful new diagnostic tool. The ability of these devices to be programmed for automatic storage of rhythm strips in which heart rates fall outside a predetermined range is particularly advantageous (101).

As a rule, if ambulatory ECG monitoring is successful in providing a symptom-arrhythmia correlation, the need for additional diagnostic testing may be diminished but not necessarily eliminated. For example, documentation of symptomatic bradycardia does not exclude the possibility of a neurally mediated etiology in which a concomitant vasodepressor element could complicate treatment.

Echocardiography and Vascular Ultrasound

Echocardiography rarely provides a definitive basis for syncope. Nevertheless, the echocardiogram has become essential for assessment of underlying structural heart disease. Furthermore, echocardiographic findings may be suggestive of a basis for syncope if evidence is obtained for HOCM, atrial myxoma, severe valvular aortic stenosis, or anomalous origin of one or more coronary arteries. Ultrasound techniques also are appropriately used to assess vascular disturbances detected on physical examination when these disturbances are deemed potential contributors to syncope. Thus, assessment of the carotid and subclavian systems may be an appropriate step in selected individuals.

Invasive Electrophysiologic Testing

In general, invasive electrophysiologic testing is useful for defining potential arrhythmic causes of syncope in individuals with underlying structural heart disease, including conduction system disturbances and the various forms of preexcitation syndromes. This is especially true when tachyarrhythmias are at fault. On the other hand, such testing is less successful among patients without apparent structural substrate for arrhythmia (5,6,102,103 and 104). For example, in one report (6), electrophysiologic testing was deemed to provide a diagnosis in 56% of all patients. However, the testing was clearly more successful in patients with evident structural cardiac disease (71%) than in patients without such disease (36%).

As with any test, care must be taken in interpreting findings of invasive electrophysiologic studies. This seems to be particularly a concern when evaluating potential bradyarrhythmic causes of syncope. In this regard, Fujimura et al. (105) undertook such studies in patients in whom bradyarrhythmias were known to be the cause of syncope; there were 21 syncopal patients with known symptomatic AV block or sinus pauses. Electrophysiologic testing only correctly identified three of eight patients with documented sinus pauses (sensitivity 37.5%) and 2 of 13 patients with documented AV block (sensitivity 15.4%). On the other hand, other abnormalities not known to have occurred spontaneously were often induced during electrophysiologic study. Tilt-table testing was not carried out in these patients; had it been undertaken, the additional findings may have been helpful in placing the apparently “false positive” electrophysiologic findings in perspective.

Head-Up Tilt-Table Testing

The importance of identifying susceptibility to vasovagal reactions in syncope patients is readily evident, given the frequency with which vasovagal syncope appears to be responsible for patient symptoms. To date, the head-up tilt-table test is the only diagnostic tool subjected to sufficient clinical scrutiny to assess its effectiveness in this setting.

Several reports have provided strong evidence that the symptomatic hypotension-bradycardia associated with a positive head-up tilt-table test is comparable to the spontaneous neurally mediated vasovagal syncope (106,107,108,109,110 and 111). Furthermore, tilt-table testing, especially when undertaken in the absence of provocative pharmacologic agents, appears to discriminate between symptomatic patients and asymptomatic control subjects with a level of precision considered acceptable for other clinically useful medical testing procedures (51,52,53 and 54).

de Mey and Enterling (112) reported only 8 instances of hypotension-bradycardia among 40 apparently normal subjects (20%). In a follow-up report, these investigators noted abnormal responses in 7 of 35 individuals (20%). Similarly, Fitzpatrick et al. (51,113) indicated that 60-degree upright tilt for 45 minutes was accompanied by development of syncope in only 7% of 27 subjects without a history of syncope (mean time to syncope, 35 ± 5 minutes). Finally, in regard to the potential impact of pharmacologic agents on the specificity of tilt-table testing, Natale et al. (114) examined the outcome of tilt-table testing at various angles and with various doses of isoproterenol provocation in 150 volunteers with no history of syncope or presyncope. These investigators found tilt-table testing at 60, 70, and 80 degrees to exhibit specificities of 92%, 92%, and 80%, respectively, when low doses of isoproterenol were used. In summary, most studies suggest that tilt-table testing at angles of 60 to 70 degrees and in the absence of pharmacologic provocation exhibits a specificity of approximately 90%. In the presence of pharmacologic provocation, test specificity may be reduced, although the magnitude of this reduction is unclear.

The response to upright tilt-table testing in patients with suspected neurally mediated syncope differs from the response observed in syncope patients in whom other diagnostic studies have provided a firm basis for symptoms. For example, Fitzpatrick et al. (113) found that 60-degree upright tilt reproduced symptoms in 53 of 71

patients (75%) with unexplained syncope; 40 patients exhibited both hypotension and bradycardia, whereas 13 subjects manifested primarily a vasodepressor response. As a result of this and many other studies, head-up tilt-table testing has become a key component of the diagnostic strategy in patients suspected of having neurally mediated syncope.

Combined Electrophysiologic and Tilt-Table Studies in Syncope

The addition of tilt-table testing to electrophysiologic testing has substantially enhanced diagnostic capabilities in syncope patients. For example, Sra et al. (102) reported results of electrophysiologic testing in conjunction with head-up tilt-table testing in 86 consecutive patients referred for evaluation of unexplained syncope. Electrophysiologic testing was abnormal in 29 patients (34%), with the majority of these (21 patients) having inducible sustained monomorphic VT. The remainder comprised inducible SVTs (five patients), sinus node dysfunction (one patient), and conduction system disease (two patients). Among the remaining patients, head-up tilt-table testing proved positive in 34 cases (40%), whereas 23 patients (26%) remained undiagnosed. During follow-up, syncope recurrence occurred in approximately 13% of patients. Importantly, however, syncope recurrence in patients in whom treatment was directed by electrophysiologic testing or tilt-table testing seemed to be highly associated with discontinuation of recommended therapies.

A further evaluation of the combined use of electrophysiologic testing and head-up tilt-table testing in the assessment of syncope is provided in the report by Fitzpatrick et al. (51). Among 322 syncope patients evaluated between 1984 and 1988, conventional electrophysiologic testing provided a basis for syncope in 229 of 322 cases (71%), with 93 patients having a normal electrophysiologic study. In terms of abnormal electrophysiologic findings, AV conduction disease was diagnosed in 34% of patients, sinus node dysfunction in 21%, carotid sinus syndrome in 10%, and inducible sustained tachyarrhythmias in 6%. As noted above, in the 93 patients with normal conventional electrophysiologic studies, tilt-table testing was undertaken in 71 cases; the testing reproduced syncope consistent with a vasovagal mechanism in 53 of these cases (75%).

Carotid Sinus Massage

The technique for undertaking carotid sinus massage and the interpretation of the test has been previously discussed. In general, the test has proved very safe; however, care should be exercised in using this test in patients with carotid bruits or prior strokes.

Neurologic Studies

Conventional neurologic laboratory studies (e.g., electroencephalogram, computed tomography of the head, and magnetic resonance imaging) have had a relatively low yield in the syncope patient. Consequently, these studies should be restricted to situations in which other clinical observations suggest organic nervous system disease (see the section Central Nervous System Causes). On the other hand, given the importance of orthostatic causes of syncope, tilt-table testing and other tests of autonomic function play an increasingly important role.

Treatment

Neurally Mediated Syncopal Syndromes

In the case of neurally mediated syncopal syndromes, treatment strategies remain in evolution. Specific treatment should, when possible, be directed at relieving apparent trigger factors. Thus, alleviating or suppressing the cause of cough in cough syncope or treating esophageal abnormalities in swallow syncope are desirable approaches. However, in conditions such as carotid sinus syncope and vasovagal syncope, comparable approaches usually are not available. Therefore, in carotid sinus syncope, cardiac pacing has become a primary treatment modality—recognizing that, in many instances, additional consideration must be given to the concomitant vasodepressor element of the syndrome.

In the case of vasovagal syncope, the mainstay in treatment is education and reassurance. This approach proves most effective when there is a prodrome of sufficient duration to permit the patient to take suitable evasive action. Patients whose symptoms demand more than mere reassurance are those whose attacks have minimal or no prodrome (especially if they have had resulting injury), those who cannot be taught to abort attacks, and those whose attacks are complicated by seizure-like activity or incontinence. Of particular concern are patients with high-risk occupations or avocations in which syncope might lead to injury to themselves or others (e.g., pilots, commercial drivers, window washers, swimmers).

In patients in whom a more aggressive treatment strategy is needed, volume expanders (e.g., increased dietary salt and electrolyte intake with salt tablets or fluids such as sports drinks) or moderate exercise training appear to be among the safest initial approaches. Additionally, in highly motivated patients with recurrent vasovagal symptoms, the prescription of progressively prolonged periods of exposure to still upright posture (i.e., tilt training) may be beneficial (115,116). Beyond these measures, a variety of pharmacologic approaches have been proposed, but few randomized clinical studies are available to confirm their utility. In this regard, beta-adrenergic blocking drugs, disopyramide, and vasoconstrictor agents [e.g., midodrine (117,118)] are the principal agents. Other drugs that appear to be useful in selected cases are serotonin-reuptake inhibitors (119,120).

Cardiac pacing has proved highly successful in carotid sinus syndrome when bradycardia has been documented (121). Currently, dual-chamber pacing is widely acknowledged to be the treatment of choice in all but the mildest forms of carotid sinus syndrome. Single-chamber atrial pacing is contraindicated due to the propensity for these patients to exhibit paroxysmal high-grade AV block during the episodes. Clinical experience with pacing in vasovagal syncope and other forms of neurally mediated syncope has been more limited than in carotid sinus syncope (122,123,124,125 and 126). However, the effectiveness of pacing in selected highly symptomatic patients with recurrent vasovagal faints has been supported by findings of two important multicenter randomized controlled trials (124,125).

In the two multicenter randomized trials examining the effectiveness of pacing in vasovagal fainters, the focus was treatment of individuals who appeared to demonstrate predominantly cardioinhibitory faints. In the case of the North American Trial (124), there was an actuarial first-year rate of recurrent syncope of 18% for pacemaker patients and 60% for controls. The results of the pacing arm of the European Vasovagal Syncope International Study (VASIS) (125) were similar but with a longer follow-up in less severely affected—thus, perhaps more typical—patients. Thus, in vasovagal syncope, pacing may play a useful role when reserved for severe cases in which cardioinhibition appears to be responsible for symptoms. In this setting, only a dual-chamber system is capable of slowing the fall of cardiac output in the face of diminishing venous return.

Orthostatic Syncope

In orthostatic syncope, the mainstay of treatment is avoidance or removal (to the extent possible) of drugs that aggravate volume status (e.g., diuretics) and vasoconstriction (e.g., vasodilators). The desire is to favor expansion of central circulating volume. To this end, certain pharmacologic approaches are well accepted; specifically, administration of increased salt in the diet or use of salt-retaining steroids (e.g., principally fludrocortisone) is usually the first step (117,118,119 and 120). Additional benefit has been reported with the use of erythropoietin, but it is not widely used for this indication. A second element in the treatment strategy of orthostatic syncope is reduction of the tendency for central volume to be displaced to the lower extremities with upright posture. To this end, physical training (e.g., tilt training, aerobic exercise) and directly and indirectly acting vasoconstrictors have been used. In regard to drugs, clonidine has been reported to be helpful, but there appears to be little ongoing enthusiasm for its use. Of greatest current interest is midodrine—an agent that has prominent venoconstrictive properties (117,118). Physical maneuvers such as the use of counter-pressure clothing (e.g., fitted stockings, abdominal compression devices) can be helpful. Unfortunately, fitted clothing is often uncomfortable, especially in hot climates, and exposes the patient to even worse symptoms when removed. In some cases, support stockings contain latex, thereby opening the door to latex allergy.

Apart from drug-induced orthostatic hypotension, in recent years, there has been increased recognition of patients with symptomatic autonomic disturbances. Treatment of these patients remains unsatisfactory. Indeed, apart from placement of greater emphasis on physical maneuvers [e.g., tilt training, counter-pressure clothing, leg-crossing, sleeping with the head of the bed elevated (115,116,127,128 and 129)], the treatment of orthostatic syncope is, in many respects, similar to that of neurally mediated syncopal syndromes.

Primary Cardiac Arrhythmias

The appropriate treatment of patients in whom tachyarrhythmias or bradyarrhythmias are the cause of syncope is relatively well understood. Patients in whom the correlation between syncope and bradycardia is well defined do well with cardiac pacemaker therapy (130,131,132,133,134,135,136,137,138,139,140,141,142,143,144,145,146,147,148 and 149). However, other factors are often important in the treatment decision process. For instance, in the case of individuals with sinus node dysfunction, optimal selection of treatment necessitates consideration of not only the culprit arrhythmic disturbance, but also the effects of drugs on sinus node and AV conduction properties and on ventricular function and proarrhythmic tendency. Additionally, current indications for and available modes of cardiac pacing and the role of anticoagulation must be incorporated into the overall treatment strategy. Finally, bundle of His

ablation with placement of a permanent cardiac pacemaker remains an important tool in treatment of selected sinus node dysfunction patients who are symptomatic due to rapid ventricular rates during atrial fibrillation (131).

Pacing techniques that endeavor to maintain a normal AV relationship are generally preferred in sinus node dysfunction and AV block patients. These pacing modes are more effective than ventricular pacing for diminishing bradycardia-related symptoms; at the same time, these modes tend to diminish the likelihood of later development of atrial fibrillation and its consequent risk of thromboembolism (132,133,134 and 135). In regard to the latter, stroke risk reduction by anticoagulation is an important element in the treatment of individuals with paroxysmal or persistent atrial fibrillation. In this regard, there is solid evidence supporting the use of warfarin therapy (for review, see reference 136).

In patients with syncope resulting from paroxysmal SVTs, drug and transcatheter ablation treatment options can be highly effective, although the former is often preferable, if available.

Many paroxysmal supraventricular tachyarrhythmias can be adequately controlled by conventional antiarrhythmic drug treatment. Beta-adrenergic blockers or calcium-channel blockers may be effective alone or, if necessary, in combination with class I antiarrhythmics—particularly class IC drugs such as flecainide and propafenone. Sotalol may also be used effectively, although there is greater concern regarding QT interval prolongation and its potential proarrhythmic consequences. However, long-term drug treatment is not readily maintained in many patients due to side-effects, issues of compliance, and, occasionally, expense. Transcatheter ablation has become a reasonable and highly effective treatment option (137,138). In the case of paroxysmal reentrant SVT associated with syncope, transcatheter ablation is probably the treatment of choice. For the most part, implantable devices for treatment of SVTs recently have been out of favor. However, the role of devices in difficult-to-control conditions may be making a resurgence with the availability of atrial implantable defibrillators and improved antitachycardia pacing systems (e.g., AT500, Medtronic, Inc., Minneapolis, MN).

Currently, surgical and transcatheter techniques for ablation of atrial fibrillation remain in early development. However, in patients with recurrent syncope associated with onset of atrial fibrillation, the application of these techniques may be warranted. Surgical methods for direct treatment of atrial fibrillation currently are confined to a selected small number of patients who are undergoing heart surgery for other reasons (139,140). However, transcatheter techniques for altering atrial electrophysiologic milieu and reducing susceptibility to atrial fibrillation are developing quickly, and the potential for such procedures to be of benefit to patients with recurrent syncope is an exciting possibility (141,142 and 143). Transcatheter ablation for control of atrial flutter is highly effective, but in the setting of recurrent syncope, ablation is best reserved for patients in whom atrial flutter is the primary atrial tachycardia causing syncope, or for situations in which atrial flutter seems to trigger deterioration to symptomatic atrial fibrillation.

In the case of syncope due to VT, underlying heart disease—especially left ventricular dysfunction—of varying severity is usually present. The latter also increases the proarrhythmic risk associated with antiarrhythmic drug therapy, especially with class I agents. Consequently, pharmacologic therapeutic strategies often involve early consideration of class III agents, principally sotalol or amiodarone, but also dofetilide to an increasing extent. However, given the difficulty of assuring effective prophylaxis in this apparently high-risk patient population (94,95 and 96,104), in many cases, the use of implantable cardioverter-defibrillators (ICDs) has become an important element of the overall treatment plan. In this context, Middlekauff et al. (95) noted that among patients with severe left ventricular dysfunction, the presence of a history of syncope was accompanied by a worrisome 1-year mortality (65% vs. 25% in comparable patients without syncope) and a greater tendency to sudden death (45% of deaths vs. 12% in comparable patients).

Currently, ablation techniques are appropriate first choices in patients with right ventricular outflow tract tachycardia and bundle branch reentry tachycardia. The future may bring more extensive use of such techniques into the treatment of a broader range of VT patients (144,145 and 146).

Structural Cardiovascular or Cardiopulmonary Disease

In cases of structural cardiovascular or cardiopulmonary disease, syncope is often only one of several possible types of symptoms being experienced by the patient with underlying structural disease. In such cases, treatment is best directed at amelioration of the specific structural lesion or its consequences. Thus, in syncope associated with myocardial ischemia, pharmacologic therapy or revascularization is clearly the appropriate strategy. If successful, syncope susceptibility—whether the result of tachyarrhythmias, bradyarrhythmias, or neural reflex effects—is reduced. Similarly, when syncope is closely associated with surgically addressable lesions (e.g., valvular aortic stenosis, pericardial disease, atrial myxoma, congenital cardiac anomaly), a direct, corrective approach is often feasible. On the other hand, when syncope is caused by certain difficult-to-treat conditions (e.g., primary pulmonary hypertension or restrictive cardiomyopathy), it is often impossible to ameliorate the underlying problem adequately. Even modifying outflow gradients in HOCM is not readily achieved surgically. In HOCM, the effectiveness of standard pharmacologic therapies remain uncertain (147,148); consequently, despite ongoing controversy, recent success with cardiac pacing techniques offers considerable promise to symptomatic individuals (149).

Cerebrovascular Causes

Treatment of cerebrovascular causes of syncope are critically dependent on an accurate diagnosis. Imaging studies and neurologic or neurosurgical consultation assistance should be sought. For the most part, cerebrovascular disease rarely accounts for syncope; consequently, its evaluation is generally a low priority in the absence of new neurologic signs or other nervous system symptoms. On the other hand, the possibility of such a cause should not be completely ignored. For example, arterial entrapment in conjunction with cervical spine disease is correctable but so rare that it is almost never considered.

Miscellaneous Disturbances

Syncope-like states occurring in the setting of conditions such as diabetic coma or severe hypoxia or hypercapnia obviously require addressing the underlying problem. True syncope is rarely, if ever, solely caused by these conditions. Syncope due to psychogenic hyperventilation is the most important to consider and, over the long haul, challenging to treat. Psychiatric assistance is essential in such cases. Pharmacotherapy, counseling, and biofeedback may be needed in combination.

Recognition of temporal lobe seizures, akinetic seizures, and drop attacks requires considerable clinical acumen, appropriate laboratory testing, and expert neurologic consultation. The first two conditions are controllable with antiepileptic medications, whereas drop attacks have proven difficult to control. Migraine is far more common, and, while an infrequent cause of syncope, pharmacologic treatment is highly effective.

Syncope accompanying anxiety attacks and hysteria can prove to be a chronically recurring problem. A psychiatric diagnosis for symptoms has to be considered carefully before the “label” is applied. Subtle disturbances of autonomic control may be overlooked in this setting.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Despite the strides that have been taken in the assessment of the syncope patient, many aspects of this multifaceted problem remain to be settled. This is particularly true in the management of patients with neurally mediated syncope. For example, although tilt-table testing is generally accepted as the “gold standard” in terms of confirming susceptibility to vasovagal syncope, its role in the assessment of treatment effectiveness continues to be controversial. In my view, the effectiveness of pharmacologic management of syncope patients cannot be reliably predicted by tilt-table testing. However, other treatment techniques such as tilt training may be able to take advantage of the laboratory’s ability to assess tolerance to upright posture. Why there should be a difference between the usefulness of tilt-table testing in assessing physical maneuvers as opposed to that of pharmacologic interventions is certainly not obvious, and I cannot claim any scientific basis for this opinion; time will tell whether it is valid.

In regard to treatment of neurally mediated syncopal syndromes, progress has been made since publication of the last edition of this book. Specifically, tilt training has become an important addition to the armamentarium and should be used in preference to drug treatments in most vasovagal fainters. Furthermore, there are now two multicenter randomized trials supporting the value of cardiac pacing in patients with frequently recurrent vasovagal syncope. On the other hand, the evaluation of pharmacologic therapies remains generally disappointing. There are as yet no large randomized drug treatment trials to report.

Still uncertain is the point at which patients with syncope should be referred for specialty evaluation. It continues to be my view that this referral is warranted if any of the following are present: (a) episodes are recurrent (i.e., >2 within a 1-year period); (b) there is evidence of underlying structural heart or cardiovascular disease; (c) physical injury has occurred; (d) the patient is at risk of economic loss (e.g., job loss); (e) the public is at risk due to his or her occupation (e.g., pilot, bus driver); or (f) the patient or his or her family indicates alarm regarding possible recurrences. The establishment of practice guidelines addressing these and related issues is essential in assuring that all syncope patients receive optimal care.

Recently, trends in medical care reimbursement in the United States and other countries have not been favorable to the introduction and study of new technologies. In the case of the syncope evaluation, large insurers (e.g., Medicare, Blue Cross–Blue Shield) continue to attempt to save money in the short-term by denying payment or

compensating at miniscule levels for techniques such as tilt-table testing, despite substantial literature documenting its value. The ability to clarify diagnoses and address new therapies is a long-term economic saving that these insurers have tended to ignore. Hopefully, concerted efforts by physician-investigators, practitioners, and professional organizations ultimately will overcome this shortsightedness.

Finally, a recent “crisis” in the United States has surrounded the disappearance of isoproterenol from the marketplace. This drug has multiple uses in the electrophysiologic laboratory, but it has been particularly important in tilt-table testing. It appears that the principal supplier has had manufacturing problems, and the relatively limited income derived from the drug does not seem to merit the supplier’s making the necessary investment to clear this up. Despite the fact that this may be a sound, if somewhat ruthless, business decision, physicians—and especially electrophysiologists—should make every effort to encourage the development of means by which “niche” agents can be made available to the marketplace. In the meantime, perhaps we can avoid the use of other products from suppliers who place their economic advantage ahead of patient needs.

SUMMARY

Prevention of recurrent syncope is critically dependent on establishing the basis for symptoms in each patient. The principal diagnostic step is differentiation of individuals with normal cardiovascular status from those with evident structural disease. In the former, assuming that the medical history or physical examination has not identified another system problem, tilt-table testing should be undertaken. In the latter group of patients, a functional assessment of the suspected structural disturbance and evaluation of susceptibility to tachyarrhythmias and bradyarrhythmias by conventional electrophysiologic testing are appropriate at an early stage. Tilt-table testing should follow if the diagnosis remains in doubt. In only a few instances should special neurologic studies be selected as an initial step. In all cases, the ultimate objective is to obtain a sufficiently strong correlation between the syncopal symptoms and detected abnormalities to permit an accurate assessment of prognosis and initiation of an appropriate treatment plan.

In cases in which structural cardiac or vascular disturbances or primary cardiac arrhythmias are determined to have caused syncope, therapy is relatively well defined. On the other hand, whereas considerable progress is being made, the treatment of neurally mediated reflex syncope, orthostatic syncope, and various neurologic and psychiatric conditions that can mimic syncope is less well established.

THE FUTURE

In recent years, considerable progress has been made in understanding the causes of syncope and the relative frequency with which each class of causes occurs. However, important diagnostic dilemmas remain. Most important, we continue to be limited in our ability to undertake long-term diagnostic monitoring in syncope patients. In this regard, the development of easy-to-use implantable electrocardiographic loop recorders (e.g., Reveal Plus, Medtronic, Inc., Minneapolis, MN) has been important. However, documenting electrocardiography is only part of the problem. Next-generation devices must focus on some assessment of systemic pressure recording. Furthermore, by using wireless communication from implantable devices, it should be possible to effect more rapid recognition of symptomatic rhythm and blood pressure problems, thereby permitting more efficient resolution of potentially hazardous conditions.

Syncope is a multifaceted disorder involving many organ systems. The most important and least understood of these systems is the CNS. In particular, the role of the CNS in neurally mediated syncope, syncope associated with orthostatic hypotension, and the dysautonomias remains a mystery. Future studies need to be directed at better understanding the multiple neurotransmitters and neural pathways associated with these disorders. Studies should address the molecular and genetic factors leading to the apparent increased susceptibility certain individuals exhibit with respect to these forms of syncope. Development of an understanding of these topics will have important implications in terms of the treatment of individuals and, in the most severe cases, the appropriate direction for advice regarding prognosis and family counseling.

ACKNOWLEDGMENTS

The author would like to thank Wendy Markuson and Barry L. S. Detloff for assistance in preparation of the manuscript.

OVERVIEW

It is increasingly recognized that drugs used for treating cardiac arrhythmias may not be completely effective and carry substantial risks for adverse effects. These adverse effects can be grouped into three broad categories.

1. *Noncardiovascular adverse effects*. Examples are (a) diarrhea with quinidine, (b) pulmonary toxicity with amiodarone, or (c) tinnitus with lidocaine. Some of these effects are related to high plasma concentrations, and others are not. The expected incidence of these noncardiovascular side effects frequently determines the choice of specific drugs in specific patients.
2. *Proarrhythmia*. Specific syndromes of proarrhythmia can be recognized and associated with specific mechanisms of drug action. These syndromes include (a) torsades de pointes, (b) atrial flutter with 1:1 atrioventricular (AV) conduction, (c) exacerbation of sustained ventricular tachycardia (VT), and (d) an increased incidence of sudden cardiac death (SCD) during long-term antiarrhythmic therapy.
3. *Other cardiovascular adverse effects*. These include (a) bradyarrhythmias and (b) exacerbation of congestive heart failure (CHF).

Despite these shortcomings, antiarrhythmic drugs retain a place in the treatment of cardiac arrhythmias. A solid understanding of the mechanisms that underlie these adverse effects and of the drugs' pharmacokinetics can help minimize the likelihood of adverse effects during long-term treatment.

HISTORICAL PERSPECTIVE

The use of drugs to treat cardiac arrhythmias dates to the mid-eighteenth century, with the initial description of digitalis therapy for "rebellious palpitations," presumably atrial fibrillation (AF) (1). In the early twentieth century, Wenckebach (2) described a Dutch sailor who found he could revert episodes of paroxysmal AF by taking an antimalarial agent derived from the bark of the *Cinchona* plant. Quinidine was found to be the most potent of a series of compounds isolated from this plant, and it became part of the antiarrhythmic armamentarium in the 1920s. Local anesthetic drugs and their derivatives, notably procainamide and lidocaine, began to be used as antiarrhythmics in the 1950s.

From these empiric beginnings, many of the subsequent developments in antiarrhythmic drug therapy have focused on developing better-tolerated compounds that mimic one or more of the important electrophysiologic actions of quinidine, procainamide, or lidocaine. Such focus resulted in the marketing of a number of new compounds in the late 1970s and 1980s.

1. Flecainide and encainide emerged from a search for more potent sodium channel–blocking analogs of procainamide.
2. Disopyramide emerged from a search for drugs that would mimic the effects of quinidine.
3. Mexiletine and tocainide were developed as lidocaine analogs.

Cardiac Arrhythmia Suppression Trial

Although antiarrhythmic drugs have diverse electrophysiologic and other pharmacologic properties, they all block cardiac sodium channels. In 1989, the Cardiac Arrhythmia Suppression Trial (CAST) investigators (3) reported that therapy with encainide and flecainide unexpectedly increased mortality in patients who were recovering from myocardial infarction (MI). This finding, along with an evaluation of a third sodium channel blocker, moricizine, by the CAST investigators (4) and other large but less well-controlled trials (5,6) that reported nevertheless suggestive data, raised serious concerns about the safety of sodium channel–blocking drugs.

Action Potential Prolongation

As a consequence of CAST, drug development moved rapidly away from sodium channel blockade and toward action potential (AP) prolongation as an antiarrhythmic intervention. In animal models (7,8,9 and 10), drugs that prolong cardiac APs have been shown to prevent ischemic ventricular fibrillation (VF), lower defibrillation energy requirements, and improve cardiac contractility. These are all desirable antiarrhythmic drug effects and are in direct contrast to the effects of sodium channel blockers (9,11). As described in more detail in this chapter, virtually all available drugs that prolong cardiac AP do so by blocking one specific cardiac ion current, termed I_{Kr}. An apparent class action of I_{Kr} blockers is the occasional development of marked QT prolongation and polymorphic VT called *torsades de pointes*. In 1995, the gene that encodes the protein responsible for I_{Kr} was identified, and mutations in the gene were found to be one cause of the congenital long QT syndrome (LQTS),

also associated with a high incidence of torsades de pointes (12,13). These molecular data suggest that if AP prolongation is to be successful as an antiarrhythmic mode of drug action, I_{Kr} blockade may not be the safest means of achieving this goal.

Calcium Channel Blockers

In the mid-1970s, calcium current was identified as playing a crucial role in mediating conduction under normal circumstances in some tissues, such as the sinus node and AV node (see Chapter 58, Chapter 65, and Chapter 66). Thus, drugs such as verapamil or diltiazem that block cardiac calcium channels at clinically useful dosages exert antiarrhythmic effects that slow ventricular response in AF or flutter and terminate or prevent reentrant arrhythmias that include the AV node as part of their circuit. Other calcium channel blockers such as nifedipine and other dihydropyridines target vascular tissue and do not exert antiarrhythmic properties. In fact, the sympathetic activation that may occur with dihydropyridine-mediated vasodilation can precipitate arrhythmias. In some animal models (14), calcium channel blockade can prevent ischemic VF. However, large clinical trials (15) have generally failed to demonstrate substantial effects of calcium channel blockade on mortality after MI. In fact, calcium channel blockers may increase mortality when used in patients with advanced ventricular dysfunction (16).

Beta-Blockers

The one drug effect that has repeatedly been shown to reduce mortality in patients who are recovering from MI is beta-blockade. In the early 1980s, three large trials (17,18 and 19) that used metoprolol, timolol, and propranolol demonstrated reduction in mortality with beta-blockade, and data from these and other studies (20) suggest that such blockade is mediated at least in part by a reduction in ischemic VF. Whether drugs with intrinsic sympathomimetic activity exert this mortality-sparing effect is the subject of some controversy. In addition, it cannot be assumed that drugs that produce beta-blockade and other important pharmacologic actions necessarily exert the same mortality-sparing effect. The mechanism by which beta-blockers reduce mortality after MI remains unclear. Studies using animal models (20) have found that beta-blockers usually exert only modest effects on the electrophysiology of the normal ventricle but that they produce a potent suppressant effect on ischemic VF. It is also possible that beta-blockers reduce mortality by some mechanism not directly related to an electrophysiologic effect; prevention of plaque rupture due to reduced intracoronary shear is one possibility.

Amiodarone

Amiodarone is a thyroid hormone analog that was developed in the 1960s to interfere with the actions of thyroid hormone on the heart, thereby decreasing angina (21). Indeed, amiodarone exerts coronary vasodilatory properties. Subsequently, amiodarone was found to prolong cardiac AP (22) and to be an effective antiarrhythmic in a number of clinical settings (23). The mechanisms by which amiodarone exerts its arrhythmia-suppressing effects are not known, and the drug has many pharmacologic properties including antiadrenergic effects that may explain its antiarrhythmic actions. The effects of amiodarone have also been evaluated in patients who are recovering from MI. Two large trials, the European Myocardial Infarction Amiodarone Trial (EMIAT) and the Canadian Myocardial Infarction Amiodarone Trial (CAMIAT), have studied amiodarone versus placebo in patients with recent MI (24,25). These trials had some differences in study design. CAMIAT randomized patients with recent MI and premature ventricular complexes [regardless of ejection fraction (EF)], whereas EMIAT randomized those with recent MI and an EF of less than 40% (regardless of premature ventricular complexes). CAMIAT was powered to detect a 50% reduction in arrhythmic mortality, whereas in EMIAT the primary end point was a 35% decrease in total mortality. In neither trial was the primary end point reached, although survival was no worse with amiodarone. Also, a high incidence of dropout occurred in both studies (e.g., 42% dropout rate on amiodarone vs. 29% dropout rate on placebo in CAMIAT). The main reason for study dropout was hypothyroidism (10%) and pulmonary infiltrates (3%). Thus, amiodarone is safer than sodium channel blockers in post-MI patients who require antiarrhythmic therapy for other reasons. It does not appear to be as effective as beta-blockers in reducing mortality, although head-to-head comparisons have not been performed, and some patients with reduced ventricular function tolerate amiodarone but not beta-blockers. Retrospective analyses of these trials have also indicated that combined therapy with amiodarone and beta-blockers, if tolerated, may be superior to either drug alone (26).

Changing Indications

A historical perspective on antiarrhythmic drugs includes not only the chronology in which drugs were developed and became available to practicing physicians but also a consideration of evolving concepts on which patients are or are not appropriate candidates for antiarrhythmic drugs. A major shift in philosophies has occurred since the late 1980s because of the increasing awareness of the risks of long-term antiarrhythmic therapy (i.e., notably an increase in mortality as exemplified in CAST and the increasingly appreciated risk for torsades de pointes with some QT-prolonging drugs) as well as the availability of new therapies, such as ablation or implanted devices, for long-term management of some arrhythmia syndromes. Although in the mid-1980s it was common practice to use drugs to suppress minimally symptomatic, or even asymptomatic, nonsustained arrhythmias detected incidentally (e.g., by Holter monitoring), this is no longer the case due to the increasing appreciation of the risks of such therapy. CAST found that suppressing asymptomatic ventricular ectopic activity did not reduce long-term mortality. However, CAST findings do not alter the fact that patients with nonsustained VT and depressed left ventricular (LV) performance are at high risk for SCD. Prospective identification of even asymptomatic patients at very high risk may allow effective therapies to be implemented. Indeed, the Multicenter Autonomic Defibrillator Implantation Trial (MADIT) (27), which studied a small group of high-risk individuals (n = 196), suggested that patients benefited from an implantable cardioverter-defibrillator (ICD). In Antiarrhythmics versus Implanted Devices (AVID), patients who were resuscitated from SCD did better with ICD therapy than with antiarrhythmics (28). In the Multicenter Unsustained Tachycardia Trial (MUSTT), asymptomatic “high-risk” (low EF, ventricular premature contractions, coronary disease) patients with sustained ventricular arrhythmias induced by programmed stimulation had improved survival with antiarrhythmic therapy (as opposed to no specific therapy for arrhythmias), but benefit was confined to patients who received ICDs, and in fact patients with inducible arrhythmias who received antiarrhythmic drugs fared slightly worse than individuals receiving no specific antiarrhythmic therapy (29).

For many patients with paroxysms of regular tachycardia (i.e., atrial tachycardia, AV nodal reentrant tachycardia, AV reentrant tachycardia, or VT), ablative therapy or antitachycardia pacing approaches are gaining wider acceptance for long-term management. Thus, the major indications for long-term antiarrhythmic drug therapy are AF, prevention of recurrent VF or rapid VT (often in conjunction with an ICD), and management of other arrhythmic syndromes that for some specific reason (e.g., ablation failure, general infirmity) make nonpharmacologic therapy less attractive. These considerations do not apply to therapy that is designed to terminate an ongoing tachycardia acutely, in which case drug therapy and direct current cardioversion continue to play a primary role.

Treatment of cardiac arrhythmias has moved from the completely empiric basis of the mid-eighteenth century to an increasing appreciation of the diverse mechanisms that may underlie cardiac arrhythmias and of the molecular mechanisms of action of older as well as newly available compounds. It seems entirely likely that as this knowledge continues to expand, new compounds devoid of serious toxicity that target specific arrhythmic mechanisms may well develop, supplanting the highly nonspecific and poorly tolerated drugs currently available.

PATHOPHYSIOLOGY

The three major mechanisms that underlie cardiac arrhythmias—enhanced automaticity, triggered activity, and reentry—are discussed in detail elsewhere (see Chapter 58). In most cases, choosing an antiarrhythmic drug for terminating ongoing arrhythmias or for suppressing recurrent episodes is based not on an understanding of specific mechanism(s) but on clinical experience. This experience includes not only determining what drug is likely to be effective against a particular arrhythmia but also estimating the risk for serious cardiac side effects from a particular drug in a particular patient, as well as estimating the risk for noncardiac side effects. This approach has proved effective because the drugs that are available are quite nonspecific (i.e., they produce a multiplicity of cardiac and noncardiac effects) and detailed characterization of the mechanisms underlying individual arrhythmic syndromes has not been considered part of routine clinical care until recently. The underlying mechanisms of individual arrhythmic syndromes have increasingly been characterized. As such information becomes available, it may be possible to choose antiarrhythmic therapy on the underlying basis of the mechanisms of individual arrhythmias and on the likelihood that an individual drug will disrupt a weak link in those mechanisms, restoring normal rhythm. This approach, popularized as the Sicilian Gambit in the early 1990s (30), seems self-evident. However, for many arrhythmias, there is insufficient information detailing the mechanisms, or in other cases appropriate drugs are not yet available to target weak links in individual arrhythmias. Conversely, an understanding of the putative mechanism underlying an individual arrhythmia in a particular patient may help the clinician avoid using drugs that are likely to prove ineffective or to exacerbate an individual arrhythmia. eTable 72.0.1 lists the mechanisms of the specific arrhythmias and provides clinical examples of arrhythmias caused by those mechanisms as well as drug effects that may be antiarrhythmic (or are contraindicated) in those mechanisms.

***e*TABLE 72.0.1** ANTIARRHYTHMIC DRUG THERAPIES, TARGETED TO AN UNDERSTANDING OF UNDERLYING MECHANISMS[a,b]

		Drug actions that may be antiarrhythmic

	VF						
	Acute termination	✔	✔			✔	
	Prevent recurrences	✔	✔	✔		✔	

✔, indicated; ✘, contraindicated; [], approaches that are not widely used clinically or that are theoretical but as yet unproven; APD, action potential duration; AV, atrioventricular; DAD, delayed afterdepolarization; EAD, early afterdepolarization; LV, left ventricular; MI, myocardial infarction; RVOT, right ventricular outflow tract; VF, ventricular fibrillation; VT, ventricular tachycardia.

[a]For further discussion of the choice of drugs in individual arrhythmias, see specific chapters.

[b]For some arrhythmias, nonpharmacologic approaches may be the acute or long-term treatment of choice; see text and specific chapters for a fuller discussion. In addition, the mechanisms underlying isolated ectopic beats, in the atrium or ventricle, have not been established and may be multifactorial; these generally require no therapy.

[c]Lidocaine congeners: mexiletine, tocainide.

[d]Includes disopyramide, flecainide, moricizine, procainamide, propafenone, and quinidine.

[e]Includes drugs such as amiodarone, bretylium, disopyramide, procainamide, quinidine, and sotalol that produce other important effects, as well as ibutilide.

[f]Acute termination is generally accomplished with adenosine or verapamil; prevention of recurrences with verapamil (in the absence of preexcitation) or flecainide.

[g]Contraindications specifically include flecainide and moricizine (see text).

Basic electrophysiologists have identified multiple ion currents in individual cardiac cells. This information allows not only identification of specific currents that are blocked by the drugs described in this chapter but also of factors such as rate and hypokalemia that can modulate this block. As described in this chapter, these data have direct implications for the clinical use of antiarrhythmic drugs. More recently, a combination of cellular electrophysiologic and molecular biologic techniques has enabled the cloning of individual genes whose protein products are responsible for individual ion currents. Studies (31,32) have identified specific regions on these proteins, and occasionally even specific amino acids, at which drug binding occurs. This information may ultimately prove useful in designing new antiarrhythmic molecules. It should be pointed out that virtually no data are available attesting to the long-term safety of any drug whose primary mode of action is to block an ion channel. Thus, another implication of such advanced molecular information is that entirely new targets may be identified at which new drugs may act to modify cardiac electrophysiology in clinically effective and safe manners.

CLINICAL PROFILES

Schemes that classify antiarrhythmic drugs by their major ionic mechanisms of action are commonly used. Their usefulness lies in the fact that they may allow clinicians to predict the therapeutic outcome of one drug based on the outcome of another. However, as mentioned previously, a major limitation of many currently available drugs is the likelihood of noncardiac side effects, which do not track with classification schemes. Moreover, members of the same drug class or subclass may exert subtle, or sometimes not so subtle, differences in pharmacologic actions, leading to different outcomes.

Sodium Channel Blockade

Although many antiarrhythmic drugs block cardiac sodium channels (eTable 72.0.2), their clinical electrophysiologic effects vary. A major factor that underlies this variability is the rate at which a drug dissociates from the sodium channel (33). During each AP, drug associates with the channel, and with each diastolic period, drug dissociates. If this dissociation rate is rapid [e.g., a time constant (t) <1 second], no channels are blocked with the next AP (eFig. 72.0.1). Thus, substantial sodium channel blockade only occurs with a rapidly dissociating drug such as lidocaine at fast rates (*shorter diastole*) or under conditions in which dissociation is slowed (e.g., ischemia). On the other hand, with flecainide, dissociation is so slow that substantial sodium channel blockade occurs even at slow rates. If sodium channel blockade accumulates (with lidocaine, at fast rates; with flecainide, at any rate), the most important electrophysiologic effect in cardiac tissue is to slow conduction; this is manifested by widening of the QRS interval. Thus, drug-induced sodium channel blockade is greater at fast rates, and hence QRS prolongation is exaggerated at more rapid rates. With rapidly dissociating drugs, such as lidocaine, no widening of the QRS interval manifests at usual rates. With other drugs, such as flecainide or quinidine, QRS prolongation is the rule at therapeutic dosages. Sodium channel blockade can also alter pacing and defibrillation energy requirements; the latter has become less of a problem with the implementation of biphasic waveforms in ICDs. Conduction slowing is actually a *pro*arrhythmic effect in reentrant arrhythmias (see Chapter 58). The mechanisms by which sodium channel blockade suppresses arrhythmias are not completely understood but may include a bidirectional block in reentrant circuits (by effects on impulse propagation or on refractoriness) or suppression of abnormal automaticity.

***e*TABLE 72.0.2** MAJOR PHARMACOLOGIC EFFECTS OF ANTIARRHYTHMIC DRUGS

	Na^+ channel block[a]				Autonomic effects		
	t <1 sec	**t >1 sec**	**↑ APD**	**Ca^{2+} channel block**	**Beta-blockade**	**Other**	**Comments/other actions**

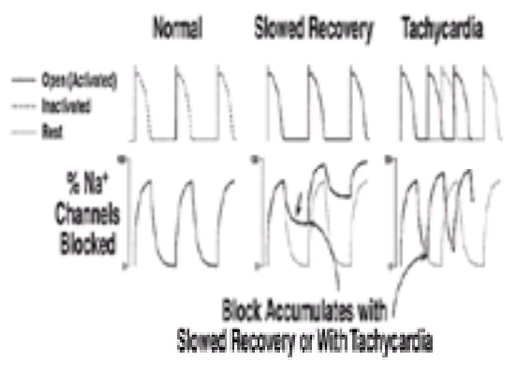
APD, action potential duration; NAPA, *N*-acetylprocainamide; [ ], minor effects that may not be clinically important.
[a]The clinical effects of sodium channel blockers depend in part on the time constant for recovery from block (t), as described in the text (*e*Fig. 72.0.1).
[b]The antiadrenergic effect produced by amiodarone resembles that of beta-blockers, but it is "noncompetitive"—that is, it cannot be overcome by increasing doses of an agonist such as isoproterenol.
[c]QT interval prolongation is not prominent with bretylium; the major effect appears to be reduction in dispersion of repolarization times.



***e*FIGURE 72.0.1** Rate dependence sodium channel blockade. The left panel shows a series of action potentials (APs), along with the extent of sodium channel blockade (*bottom panel*). The sodium channel shuttles among three states during the AP: open, inactivated, and rest, as indicated in the top APs. Most sodium channel blockers that are used clinically bind to open or inactivated channels, or both. Therefore, sodium channel blockade increases during the AP and decreases during each diastolic (rest) interval. A rapidly dissociating drug, such as lidocaine, is shown here. If the dissociation rate of the drug from the channel is decreased (*middle*), the extent of drug blockade can increase even in the absence of a change in rate. This is the case with lidocaine during ischemia or with flecainide. The right panel shows that even with a rapidly dissociating drug such as lidocaine, sodium channel blockade can develop if the rate is accelerated. In the middle and right panels, the dotted lines indicate the data presented in the left panel. (From Roden DM, Echt, DS, Murray KT, Lee JT. Clinical pharmacology of antiarrhythmic agents. In: Josephson ME, ed. *Sudden cardiac death*. Malden, MA: Blackwell Science, 1993:163–210, with permission.)

Proarrhythmic Effects of Sodium Channel Blockers

Therapy using sodium channel blockers such as flecainide has been associated with suppression of nonsustained ventricular arrhythmias and of paroxysmal AF. However, conduction slowing in patients with known atrial flutter and in some patients with atrial flutter or AF with no history of atrial flutter may sometimes lead to a marked slowing, but not termination, of the atrial flutter rate. With sufficient slowing, 1:1 AV conduction may ensue. To complicate the clinical picture further, because drugs such as flecainide block sodium channels more extensively at rapid than at slow rates, the ventricular complexes broaden and occasionally may even become aberrant. Thus, the clinical picture of this form of arrhythmia exacerbation is a patient with AF in whom wide, complex regular tachycardia then develops; it is not a surprise, therefore, that this arrhythmia is frequently misdiagnosed as VT (34,35). Management of this arrhythmia consists of acknowledging the possibility of its occurrence, withdrawing the potentially offending antiarrhythmic agent, and using AV nodal blocking drugs. Adenosine may be useful in establishing the diagnosis.

Conduction slowing in the ventricle usually only results in QRS prolongation. However, when a reentrant circuit due to ventricular scarring is present (e.g., in the post-MI patient), conduction slowing by sodium channel blockers can increase the frequency of VT while often slowing its rate. Such drug-facilitated VTs may be very resistant to cardioversion and may prove fatal (36). Some animal and a limited number of human studies (37,38) have suggested that sodium boluses may be effective in this setting.

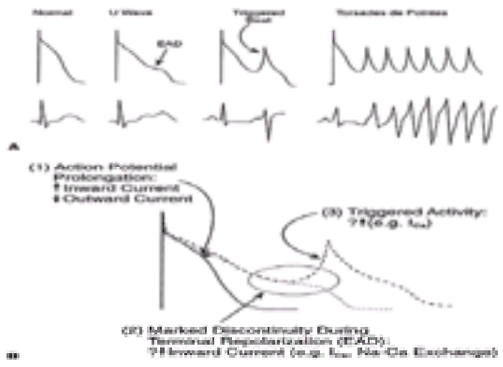
Another proarrhythmic effect of sodium channel blockers is the increase in mortality observed in CAST. The mechanism(s) responsible for this finding remain(s) unclear. However, evidence from animal studies and the CAST database (39,40 and 41) strongly suggests that in the presence of sodium channel blockade, recurrent myocardial ischemia may enhance the likelihood of fatal ventricular arrhythmias such as VF. For example, pretreatment with the sodium channel blocker aprindine in dogs before coronary occlusion was found to increase the incidence of VF following occlusion (42). In CAST, the relative risk of encainide or flecainide therapy in patients with transmural MI was 1.7 compared with those given placebo. However, among those patients with non–Q-wave MIs, a group thought to be at much higher risk for subsequent ischemic events, the relative risk was much higher, 8.7 (39).

Action Potential Prolongation

The hallmark of AP prolongation, a so-called class III effect, is QT prolongation. Drugs that produce this effect share a number of desirable features, including decreased defibrillation energy requirement, efficacy in models of ischemic VF, and increased contractility. Their major antiarrhythmic action is probably attributable to the prolongation of refractoriness that accompanies increased AP; this, in turn, is thought to suppress reentrant arrhythmias by decreasing the likelihood of unidirectional block (see Chapter 58).

Mechanisms of QT Prolongation Drug-Induced Torsades de Pointes

Although most drugs that prolong cardiac AP have the potential to cause torsades de pointes, amiodarone is an exception (43). Important clinical features of this syndrome include hypokalemia and a typical series of cycle-length changes (i.e., short-long-short), leading to an apparent bradycardia—or pause—dependence. Studies have shown that exposure of AP from the canine conducting system that is exposed to analogous clinical conditions (i.e., the presence of QT-prolonging antiarrhythmic, low extracellular potassium is slow drive rate) results in discontinuities in terminal repolarization, known as early *after-depolarizations* (*EADs*). Occasionally, *de novo* upstrokes can develop from EADs, and it is thought that these triggered beats are the likely initiators of torsades de pointes (*e*Fig. 72.0.2). The mechanisms that underlie the maintenance of the arrhythmia, and its frequent spontaneous termination, are speculative, but either repetitive triggered activity or reentry across the ventricular wall, perhaps dependent on heterogeneity of AP durations across the wall, have been suggested (44). Current thinking suggests that multiple cellular electrophysiologic changes are required to initiate EADs and triggered upstrokes (*e*Fig. 72.0.2). The first is a change in the balance between inward (*depolarizing*) currents, such as the sodium or calcium current, and outward (*repolarizing*) currents, generally potassium or chloride currents. Most antiarrhythmic drugs that prolong the QT interval do so by blocking outward currents and, in particular, by blocking one component of outward current known as I_{Kr} (45). Enhancement of inward current has been suggested for at least one available drug, ibutilide (46), but this remains controversial (47,48). However, enhanced inward current or decreased outward current cannot explain EADs and triggered activity. Rather, it seems likely that with sufficiently delayed repolarization, a normally functioning calcium current or the sodium-calcium exchanger provides a secondary source of inward current, accounting for the EAD and the upstroke (49,50,51 and 52). Torsades de pointes can occur not only with exposure to QT-prolonging antiarrhythmic drugs but also with the congenital LQTS. Identification of mutations in the genes that encode I_{Kr} or other K^+ channels [I_{Ks}] (to decrease outward current) or the cardiac sodium channel (to increase inward current) provides an explanation for the striking similarities between the congenital and the drug-induced syndromes (12,53).

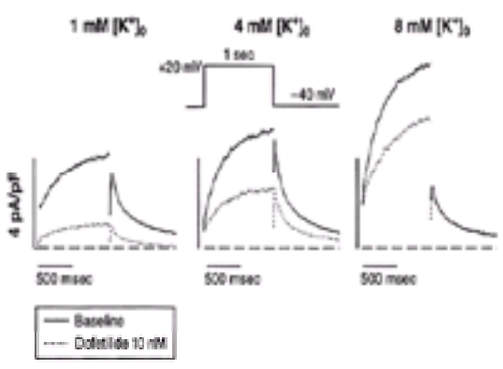


***e*FIGURE 72.0.2** Electrophysiologic mechanisms underlying torsades de pointes. Shown in **A** is one relationship between action potential (AP; *top*) and electrocardiographic complexes (*bottom*). It is thought that triggered beats arising from early after-depolarizations (EADs) produce single-triggered beats and torsades de pointes. The mechanism whereby triggered activity results in torsades de pointes remains speculative. Shown in **B** are electrophysiologic abnormalities resulting in EADs and triggered activity. At least three abnormalities are present. I_{Ca}, calcium current. (From Roden DM. Early afterdepolarizations and torsades de pointes: implications for the control of cardiac arrhythmias by controlling repolarization. *Eur Heart J* 1993;14:56–61, with permission; and Roden DM, Lazzara R, Rosen MR, et al., for the SADS Foundation Task Force on LQTS. Multiple mechanisms in the long QT syndrome: current knowledge, gaps, and future directions. *Circulation* 1996;94:1996–2012, with permission.)

A 51-year-old female patient with torsades de pointes.

Therapies for QT Prolongation Drug-Induced Torsades de Pointes

An understanding of these mechanisms can lead directly to an appreciation of therapies that are effective in torsades de pointes. The clinician should recognize torsades de pointes not simply by the presence of polymorphic VT; a markedly prolonged QT interval, often with prominent U waves, and the bradycardia-dependent onset of the tachycardia should also be present. The presence of polymorphic VT in the absence of QT changes before or after the arrhythmia suggests that other mechanisms, often acute myocardial ischemia, may be operative. Therapies such as isoproterenol infusion that are useful in torsades de pointes can be devastating in other forms of polymorphic tachycardia. Withdrawal of any QT-prolonging drugs and correction of serum potassium are the next steps in management. *In vitro* studies (54,55) have suggested that elevating extracellular potassium has two important effects in torsades de pointes: (a) It increases the magnitude of activating I_{Kr} (and thereby shortens the QT interval), and (b) it appears to reduce the potency of I_{Kr} blockers (*e*Fig. 72.0.3), another antiarrhythmic effect in this setting.



***e*FIGURE 72.0.3** Tracings of the outward (rectifier) potassium current (I_{Kr}) are shown at baseline (*solid lines*) and after exposure to the specific I_{Kr} blocker, dofetilide (*dotted lines*). The zero current level is indicated by the dashed line in each panel. The currents were elicited by 1-second depolarization to +20 mV, followed by repolarization to –40 mV, as indicated in the middle panel. In the absence of the drug, outward current during the step to +20 mV was greatest when extracellular potassium was elevated (*right panel*). In contrast, the extent to which the drug blocked the current was greatest with low extracellular potassium (*left panel*). These data help explain the clinical findings that action potentials and the QT interval are prolonged in hypokalemia and that hypokalemia appears to markedly potentiate the QT-prolonging effects of drugs such as dofetilide and quinidine. pA/pF, current per unit cell surface area.

Strong, albeit anecdotal, evidence (56) indicates that magnesium therapy can prevent recurrences of torsades de pointes. The likely mechanism is a block of the secondary inward current (e.g., the L-type calcium current) because magnesium therapy does not generally shorten the QT interval. The mainstay of therapy for recurrent torsades de pointes is to increase the heart rate, either with isoproterenol infusion or with external or transvenous pacing. In patients with congenital LQTS, long-term therapy with beta-blockers or other antiadrenergic interventions can be quite effective, presumably by reducing L-type calcium current. The description of specific mutations in ion channel genes in congenital LQTS has led to identification of specific subsets of patients with the condition. For example, among patients with lesions that interfere with normal sodium channel inactivation, torsades de pointes commonly occurs at rest or during sleep, the QT interval shortens normally (or even supernormally) with exercise, and the QT interval can be shortened by sodium channel blocking drugs such as mexiletine or flecainide (57,58). Whether such therapy reduces the incidence of SCD remains to be determined.

Continue or Discontinue QT-Prolonging Therapy in Drug-Induced Torsades de Pointes?

A vexing question in the management of patients with drug-induced torsades de pointes is whether they should ever be exposed again to QT-prolonging drugs. Often, a triggering factor such as bradycardia or hypokalemia is present at the time of the arrhythmia, which has been corrected. Most clinicians, however, are somewhat reluctant to continue QT-prolonging therapy in such individuals because a risk factor(s) of which we are not yet aware or which is not readily correctable may still be present and confer an increased risk for subsequent torsades de pointes. Unfortunately, there are no solid data addressing this point. Other risk factors for torsades de pointes may include AF [in which cases torsades de pointes frequently occurs after conversion to normal rhythm (59)], left ventricular hypertrophy, and female gender (60). For most drugs that may induce torsades de pointes, higher doses or higher plasma concentrations elevate the risk; quinidine is an exception. Subclinical mutations in genes such as those that encode K^+ channels or the sodium channel have been identified in some patients with drug-induced torsades de pointes, although the extent to which the development of torsades de pointes is genetically determined is not yet established (61,62).

PRINCIPLES OF DRUG USE

The fundamental principles of using antiarrhythmic drugs are no different from those applied when using any other drug.

1. Define a benefit for therapy.
2. Define an end point for therapy.

3. Minimize the risks (and ensure that these do not outweigh the expected benefits).
4. Define the need for therapy.
5. Consider alternative therapies.

Because the risks of antiarrhythmic therapy, particularly with long-term treatment, are relatively high and the benefits of treatment in many cases are at least partially illusory, it is important to adhere closely to these principles (63).

In acutely terminating ongoing sustained arrhythmias, there is little doubt that intravenous (i.v.) antiarrhythmic drugs can be highly effective.

1. Adenosine or verapamil is highly effective for AV-nodal reentrant tachycardia.
2. Lidocaine, procainamide, amiodarone, or sotalol (in Europe) is effective for sustained VT.
3. Ibutilide is effective for AF or flutter.
4. Procainamide, bretylium, lidocaine, or amiodarone is effective for recurrent VT or VF.

In each setting, risks are well recognized, but because the patient is being continuously monitored, these risks can be identified early and prevented or treated. With long-term antiarrhythmic therapy, it has been much more difficult to establish a clear benefit for treatment; risks, including proarrhythmia, other cardiovascular side effects such as CHF or bradyarrhythmias, and noncardiovascular toxicities, become a much greater concern.

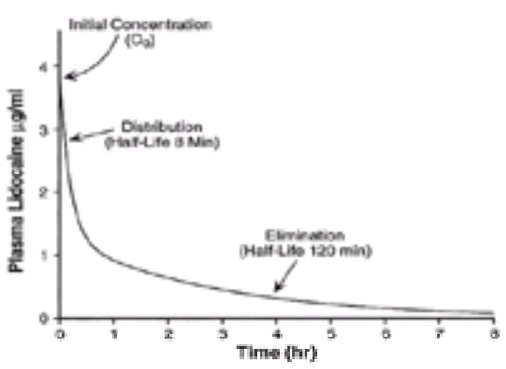
A specific arrhythmia diagnosis should be established before therapy is initiated. For example, verapamil may be an effective drug for treating VT that arises in the right ventricular outflow tract in patients with a structurally normal heart, whereas it is dangerous to use in reentrant VT in patients with remote MI (64).

For long-term therapy of paroxysmal arrhythmias, it is important to recognize the phenomenon of ascertainment bias. Patients with symptomatic arrhythmias, such as paroxysmal AF or frequent ICD discharges due to sustained VT, frequently display spontaneous unexplained variability in arrhythmia events. Such symptomatic patients are most likely to present to a physician during a period of high arrhythmia event frequency. Thus, institution of even ineffective therapy can appear to lower the frequency of arrhythmic events. In the case of AF, it is useful to establish some sense of the frequency of the arrhythmic episodes before initiating therapy. This approach is not usually possible for patients with very frequent ICD discharges that cannot be controlled in other ways (e.g., device reprogramming). However, even here, the physician should remain vigilant to the possibility that apparently effective antiarrhythmic therapy may, in fact, play very little role in reducing the frequency of arrhythmic episodes, and if drug side effects develop, discontinuation of the antiarrhythmic can still be considered.

Pharmacokinetic Principles

Because there is a small margin between dosages of antiarrhythmic drugs that may suppress arrhythmias and dosages that can produce serious or even life-threatening toxicities, an understanding of the principles that determine drug disposition is useful in guiding therapy. The processes that determine drug disposition, absorption, distribution, metabolism, and elimination are generally first order; that is, the rate of each process is determined by the amount of drug present. A characteristic of any first-order process is that it occurs exponentially as a function of time and is therefore conveniently described using half-lives. In one half-life, 50% of a given process is complete; in two half-lives, 75%; in three half-lives, 87.5%; in four half-lives, 93.75%; and so forth. Thus, any first-order process is near complete in four to five half-lives.

When drugs are administered intravenously, the time course of drug disappearance from plasma is often biexponential (eFig. 72.0.4). The usual explanation is that distribution occurs rapidly (accounting for a first exponential term), whereas elimination occurs more slowly (accounting for the slower exponential terms). For example, when a bolus of lidocaine is administered intravenously, plasma concentrations drop precipitously, with a half-life of 8 minutes. This reflects distribution of lidocaine into peripheral site(s). As one drug is distributed, elimination, a second slower process that occurs with a half-life of 2 hours, becomes more important (eFig. 72.0.4).



***e*FIGURE 72.0.4** Plasma concentration-time profile following a rapid bolus of lidocaine. Plasma concentrations decline biexponentially. The first phase of very rapid decreases in plasma lidocaine corresponds to distribution, with a half-life of 8 minutes. The terminal phase corresponds to elimination by metabolism, with a half-life of 2 hours. The plasma concentration directly after the bolus (C_0) can be used to estimate the central volume of distribution (dose $\neq C_0$).

Absorption and Metabolism

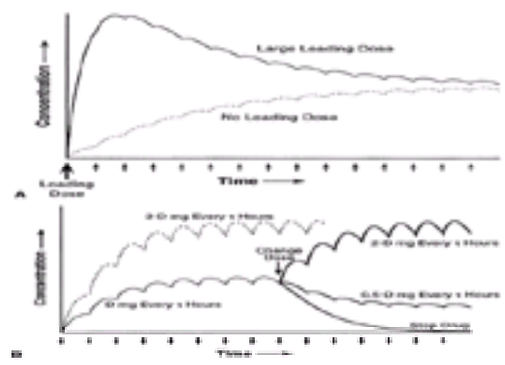
Distribution processes are generally most apparent with intravenously administered drugs. When a drug is given orally, absorption usually occurs sufficiently slowly so as to mask any rapid distribution. The amount of drug that actually reaches the systemic circulation, expressed as a percentage of total administered dose, is referred to as *bioavailability*. Bioavailability is commonly less than 100% following administration of a drug for two major reasons. First, the physicochemical characteristics of some drugs may not permit the gastrointestinal (GI) tract to absorb 100% of the drug. Amiodarone is only 30% to 50% bioavailable (65), probably for this reason. Second, some drugs are completely absorbed but undergo extensive metabolism, usually in the liver (or gut wall), before reaching the systemic circulation (66). The extent of this first-pass metabolism can be quite large and accounts for the fact that for some drugs much greater dosages must be given orally rather than intravenously to achieve therapeutic effects. Verapamil and propranolol are excellent examples; several hundred milligrams must be given orally to achieve the same plasma concentrations as less than 10 mg i.v.

Protein Binding

Another factor that can determine drug effect is protein binding. Many drugs are bound to plasma proteins, usually albumin. Another common ligand for many antiarrhythmic drugs is $alpha_1$-acid glycoprotein, an acute-phase reactant whose plasma concentrations are elevated with stresses such as acute MI or trauma. When $alpha_1$-acid glycoprotein is elevated, the amount of unbound drug that is available to exert pharmacologic effects is reduced. Thus, for example, some patients require (and tolerate) higher than usual lidocaine or quinidine concentrations to suppress arrhythmias shortly after MI (67).

Elimination Half-Life

Loading doses can be used to achieve a desired therapeutic drug effect rapidly. The magnitude of a loading dose can be estimated from the central volume of distribution (eFig. 72.0.4). However, the eventual steady-state plasma concentration that is achieved is determined by the elimination rate: Steady state is approached in four to five elimination half-lives, and this time is not abbreviated by the use of loading regimens (eFig. 72.0.5). Therefore, loading regimens are appropriate when a rapid drug effect is desired (e.g., to terminate an arrhythmia acutely) or when the elimination half-life of the drug is so long that no therapeutic effect would occur in a reasonable time with the institution of maintenance dosages only (e.g., amiodarone). In the absence of these two situations, the use of loading dosages carries some increased risk for side effects (and little added benefit) and therefore is not recommended.



***e*FIGURE 72.0.5** Effect of loading doses and of dose changes during chronic oral therapy. **A:** Hypothetical plasma concentrations are plotted as a function of time during long-term oral therapy. The arrows on the abscissa indicate the times at which a dose is administered, and the heavy arrow at the intercept indicates a loading dose. The administration of a loading dose does not abbreviate the time required to achieve steady-state concentrations, and it does not alter the steady state achieved. **B:** Concentration-time profiles in the absence of a loading dose. The tracings (*left*) show the time course of drug accumulation to steady state. The steady state achieved is twice as great when the dosage is doubled (*dashed line*), but the time course of accumulation to steady state remains the same. Following a change in dosing regimen (or discontinuation of the drug), the time required to achieve the new steady state is similarly four to five elimination half-lives. (From Roden DM, Echt DS, Murray KT, Lee JT. Clinical pharmacology of antiarrhythmia agents. In: Josephson ME, ed. *Sudden cardiac death*. Malden, MA: Blackwell Science, 1993:163–210, with permission.)

Clearance

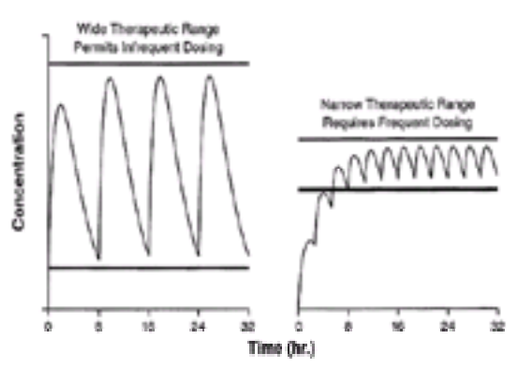
Although the time to steady state is determined by the elimination half-life, the actual steady state achieved is determined by the dose administered (eFig. 72.0.5) and by clearance, most readily defined as dose divided by mean plasma concentration. Clearance and elimination half-life are not synonymous, because elimination half-life is determined not only by clearance but also by volume of distribution. For example, in the case of lidocaine, volume of distribution and clearance are reduced in CHF, leaving elimination half-life unchanged (68). Therefore, loading regimens must be reduced in CHF (*volume of distribution effect*), and maintenance infusions should be reduced to avoid toxicity (*clearance effect*). However, the time required to achieve steady state, four to five elimination half-lives (8 to 10 hours), remains the same in CHF.

Drug Elimination in the Face of Organ Dysfunction

It is self-evident that if there is dysfunction (due to disease or by administration of other drugs) of a route of drug elimination, such as hepatic metabolism or renal excretion, the drug may accumulate in plasma and tissues, and toxicity may ensue. The greatest risk for such adverse events occurs when a drug has only a single major route of elimination. Specific hepatic enzymes are responsible for the biotransformation of antiarrhythmic (and other) drugs. It is increasingly well recognized that these enzymes are not expressed in a uniform fashion in all individuals and that such variability in expression can account for some of the clinically observed variability in response to therapy. The examples of propafenone and procainamide are discussed in this chapter. This variability in enzyme activity can be genetically determined or can be the result of coadministration of enzyme inhibitors. A particularly dangerous situation can arise when a drug is metabolized by a single pathway. In this case, administration of an inhibitor can result in marked increases in parent drug concentrations, with attendant toxicity. Torsades de pointes following administration of terfenadine, astemizole, or cisapride is determined by just this mechanism (69). Each drug is an I_{Kr} blocker that is eliminated by a specific enzyme, CYP 3A4. Therapy with CYP 3A4 inhibitors, such as erythromycin or ketoconazole, is now well recognized as the cause of most cases of torsades de pointes with these agents; indeed, these agents were withdrawn from the market because of the continuing occurrence of these interactions. Many drug interactions that elevate digoxin plasma concentrations and cause digoxin toxicity are also attributable to the problem of a single route of drug elimination. Digoxin is eliminated not by metabolism but by renal and biliary excretion mediated by a specific drug transport molecule, P-glycoprotein. The inhibition of P-glycoprotein–mediated digoxin transport by drugs such as amiodarone, quinidine, cyclosporine, verapamil, and erythromycin likely underlies their clinical effects to cause digoxin toxicity (70).

Monitoring Plasma Drug Concentrations

For some drugs, monitoring plasma drug concentrations and maintaining these in a “therapeutic range” are useful adjuncts to minimizing the risk for adverse effects and maximizing potential benefits of therapy; lidocaine, digoxin, and procainamide are examples. Unfortunately, many adverse reactions to antiarrhythmic therapy are not clearly related to high plasma drug concentrations but rather occur at usual drug concentrations in patients with advanced underlying heart disease or other predisposing factors (e.g., hypokalemia). In addition, the elimination of some drugs is highly variable, with an additional variable contribution to clinical effects by active metabolites (e.g., propafenone); plasma concentration measurements are virtually impossible to interpret under these conditions. Monitoring plasma drug concentrations can be especially useful when adjusting dosages in the face of fluctuating renal or hepatic function and to establish whether a patient is compliant with therapy. It is a common misconception that long-term drug therapy should be administered once every half-life. In fact, the minimum time between doses is determined by the rate of drug elimination and by the margin between maximally tolerated and minimally effective plasma concentrations (eFig. 72.0.6). If this margin is small and the drug is eliminated rapidly, frequent dosing is required. If, on the other hand, the margin is large, infrequent dosing may suffice even for a rapidly eliminated drug.



***e*FIGURE 72.0.6** The width of the therapeutic range of plasma concentrations, not the elimination half-life, determines frequency of dosing. Two therapeutic ranges, one wide (*left panel*) and one narrow (*right panel*), are shown. Plasma concentrations during administration of the same drug are illustrated. With a wide therapeutic range, dosing every 8 hours allows plasma concentrations to remain within the therapeutic range. In contrast, dosing every 2.7 hours is required to maintain plasma concentrations within the narrow therapeutic range (*right panel*). (From Roden DM, Echt DS, Murray KT, Lee JT. Clinical pharmacology of antiarrhythmia agents. In: Josephson ME, ed. *Sudden cardiac death*. Malden, MA: Blackwell Science, 1993:163–210, with permission.)

INDIVIDUAL ANTIARRHYTHMIC DRUGS

The relevant clinical pharmacokinetics and pharmacologic actions of individual antiarrhythmic drugs are presented in eTable 72.0.2 and eTable 72.0.3. A brief summary of issues that are important in the clinical use of individual antiarrhythmics is given in this section. The drugs are presented in alphabetical order.

***e*TABLE 72.0.3** DISPOSITION CHARACTERISTICS OF ANTIARRHYTHMIC DRUGS

	Elimination half-life			Elimination route			Dosage adjustments	Drug interactions			
Drug	**Seconds-minutes**	**Hour**	**>12 h**	**Hepatic**	**Renal**	**Other**	**Heart failure**	**Decreased antiarrhythmic dose**	**Increased antiarrhythmic dose**	**Impairing the disposition of other drugs**	**Therapeutic plasma concentrations[a]**
Adenosine	<10 sec					✔		Dipyridamole	Methylxanthines		

Amiodarone		wk–mo	✔					Digoxin, flecainide, procainamide, warfarin	0.5–2 µg/mL
Beta-blockers									
Esmolol	5–10 min				✔			Lidocaine	
Propranolol		4–6	✔					Lidocaine	
Bretylium		7–15		✔					
Digoxin		36 h		✔			Amiodarone, cyclosporine, quinidine, verapamil		0.5–2 ng/mL
Diltiazem		4	✔						
Disopyramide		4–10	✔	✔	✘				2–5 µg/mL
Dofetilide		8–10		✔			Verapamil (?), cimetidine (?)		
Flecainide		10–18 h	✔	✔	✘		Amiodarone		<1 µg/mL
Ibutilide		6[a]	✔[b]						
Lidocaine	120 min		✔		↓Load ↓ Maintenance rate		Beta-blockers, cimetidine		1.5–5 µg/mL
Magnesium				✔					
Mexiletine		11–15 h	✔				Phenytoin		0.5–2 µg/mL
Moricizine		2–3 (?)	✔						
Procainamide		3–4	✔	✔	↓Dose (i.v.)		Amiodarone		4–10 µg/mL
N-acetylprocainamide		6–8		✔					10–20 µg/mL
Propafenone		2–32	✔		✘		Fluoxetine, quinidine, tricyclics		<1 µg/mL
Quinidine		4–10	✔				Amiodarone	Phenytoin	Propafenone	2–5 µg/mL
Sotalol		8		✔	✘				<3 µg/mL
Tocainide		15 h		✔					3–11 µg/mL
Verapamil		6–12	✔		✘				

✘, avoid or use with caution; ✔, yes.

[a]As discussed in the text, monitoring plasma drug concentrations and maintaining them in a therapeutic range may be a useful adjunct to managing therapy with some drugs. Where no therapeutic range is presented, plasma concentration monitoring is of no value.

[b]The arrhythmia-terminating actions of ibutilide depend on transient achievement of high concentrations; the dissipation of pharmacologic effects may result from rapid distribution rather than drug elimination.

Adenosine

Adenosine is used for the acute termination of supraventricular tachycardias that use the AV node as part of their circuit (e.g., AV nodal reentry, AV reentry; see Chapter 65 and Chapter 66) (71). Adenosine can also be used to deliberately create transient AV block to diagnose arrhythmias such as VT. Unlike virtually any other drug, adenosine must be administered in as rapid a fashion as possible, because the drug undergoes very rapid elimination from the circulation, primarily by cellular uptake. Uptake is inhibited by dipyridamole, which, therefore, potentiates effects of the adenosine. Adenosine receptors are blocked by methylxanthines, such as caffeine and theophylline, which can therefore inhibit adenosine action. Most patients who receive adenosine complain of an uncomfortable feeling of chest tightness, the mechanism for which is not entirely explained. The absence of such symptoms with an adenosine bolus suggests that under these circumstances the drug may have been given too slowly or that a receptor blocker is present.

Intravenous Amiodarone

Amiodarone given i.v. can be effective in patients with recurrent episodes of life-threatening ventricular tachyarrhythmia (sustained VT or VF) (72,73). Because placebo-controlled trials are virtually impossible to conduct in this setting, clinical efficacy was demonstrated in trials showing that higher doses were more effective than lower doses and that the drug was somewhat more effective than bretylium. In these trials, the mortality remained high (approximately 20% at 48 hours), presumably reflecting the severity of illness in patients being tested. Because i.v. amiodarone is administered for short periods of time, the toxicity that can characterize long-term oral therapy (see the section Oral Amiodarone) is not a problem. Rather, hypotension, exacerbation of CHF, bradyarrhythmias, and phlebitis (if the drug is not given by central line) can occur. The mechanism whereby i.v. but not oral amiodarone exerts a prompt antiarrhythmic effect is not well understood but may involve a prominent sympatholytic action. A large placebo-controlled trial in patients with out-of-hospital cardiac arrest and refractory ventricular tachyarrhythmias showed improved survival to the hospital but no change in hospital discharge rates with i.v. amiodarone (74). Nevertheless, i.v. amiodarone is now considered first-line therapy in this setting (75). In Europe, i.v. amiodarone has been used to control ventricular response in AF; it is not very effective to convert AF to sinus rhythm.

Oral Amiodarone

One of the most important pharmacologic features of amiodarone is its very long elimination half-life (76). This necessitates the use of oral loading regimens to abbreviate the time from initiation of therapy to achievement of an antiarrhythmic effect. Another result of the slow elimination is that the minimum dose required to maintain an antiarrhythmic effect during long-term therapy is poorly defined. An advantage of very slow elimination is that missing a dose does not generally result in arrhythmia recurrence.

Efficacy of (Oral) Amiodarone

Amiodarone's efficacy has been evaluated in a number of clinical settings. In the Cardiac Arrest in Seattle: Conventional versus Amiodarone Drug Evaluation (CASCADE) trial (77), empiric therapy with oral amiodarone was found to be superior to treatment with conventional drugs (quinidine, procainamide), selected by response to programmed stimulation, in patients resuscitated from cardiac arrest. However, rates of recurrence with amiodarone in CASCADE were relatively high (e.g., 18% in 2 years). In addition, side effects necessitating discontinuation of drug therapy were common, with 10% of patients being taken off one drug by 2 years for pulmonary symptoms and a total side effect rate of 25% at 2 years.

In patients who are recovering from MI (as assessed in CAMIAT and EMIAT), amiodarone produces a slight, statistically insignificant survival benefit when the end point is total (and not arrhythmic) mortality and an intention-to-treat analysis is used (78). In patients with CHF and arrhythmias, clinical trials have provided conflicting results. In one study [Congestive Heart Failure Survival Trial of Antiarrhythmic Therapy (CHF-STAT)] (79), there was no survival benefit for amiodarone versus placebo, whereas in another study [Grupo de Estudio de la Sobrevida en la Insuficiencia Cardiaca en Argentina (GESICA)] (80), amiodarone-treated patients had significantly lower mortality. In both studies, amiodarone-treated patients tended to have improvement in EF compared with placebo-treated patients. The difference may reflect a greater proportion of patients with nonischemic cardiomyopathy in GESICA. These findings suggest that in patients with sustained symptomatic arrhythmias in the setting of advanced CHF, amiodarone is a reasonable treatment option.

In the Canadian Trial of Atrial Fibrillation (CTAF), there were significantly fewer recurrences of symptomatic AF with oral amiodarone (approximately 35% over 16 months) compared to sotalol or propafenone (approximately 70%) (81). Amiodarone therapy before bypass surgery reduced the incidence of postoperative AF (82).

Long-Term Use of Amiodarone: Side Effects

Side effects can be a major problem during long-term therapy with amiodarone, with dropout rates in large trials approaching 40% in 2 years (25,77,81). The most serious side effect during long-term amiodarone therapy is pulmonary fibrosis. The incidence appears higher with longer duration of therapy, higher dosages (especially more than 400 mg per day during chronic therapy), and the presence of pulmonary disease (83). With total daily dosages of 200 mg per day or less, pulmonary fibrosis is unusual. Routine surveillance chest x-rays or pulmonary function studies have been advocated to detect incipient pulmonary toxicity, but their utility remains to be determined; some patients present with fulminant respiratory failure. Monitoring plasma concentrations of amiodarone during chronic therapy has not been useful in

either limiting toxicity or increasing efficacy.

Amiodarone can cause a number of relatively common adverse effects that may not be life threatening but of which the patient should be aware. Photosensitivity is frequent, and patients should be warned to use sunscreens. Corneal microdeposits are routinely detectable after 3 months of therapy but are rarely symptomatic; the major symptom is visual halos. Hypo- and hyperthyroidism, proximal muscle weakness, and hepatic dysfunction (usually asymptomatic but rarely proceeding to cirrhosis) can occur. Unlike other drugs that prolong the QT interval, torsades de pointes is rare with amiodarone therapy. The mechanism is unknown but may relate to the drug's sympatholytic or direct calcium channel–blocking actions. Drug interactions are also frequent with amiodarone: Warfarin and digoxin requirements should be monitored closely because they may require downward adjustments in dosages.

Bretylium

Bretylium is useful in the management of recurrent VF or sustained VT (84). The drug has prominent effects on the sympathetic nervous system, with initial norepinephrine release (which may not be clinically obvious), followed by inhibition of norepinephrine reuptake in presynaptic neurons. As a result, hypotension is a characteristic feature of bretylium therapy. This does not usually indicate myocardial depression but is generally due to peripheral vasodilation. Evidence indicates that these sympatholytic effects are not required to produce the drug's antiarrhythmic effects, which presumably reflect a direct drug effect on myocardial cells (85). Because of its hypotensive effects, bretylium should be avoided in patients in whom vasodilation would be particularly hazardous (e.g., those with hypertrophic cardiomyopathy, aortic stenosis).

Digoxin and Other Digitalis Glycosides

Digoxin and other digitalis glycosides are used to control ventricular response in AF or flutter. Rate control can generally be achieved while the patient is at rest but is frequently lost during even modest exertion. The symptoms of digoxin toxicity include confusion, visual scotomas, and arrhythmias. The latter include atrial arrhythmias (often with AV block), bigeminy, bidirectional VT, and bradyarrhythmias due to suppression of sinus node function and AV block. With suicidal digoxin overdose, poisoning with sodium-potassium adenosine triphosphatase can result in extraordinary degrees of hyperkalemia. A number of regimens have been proposed to treat arrhythmias related to digitalis intoxication. When arrhythmias that are sufficiently serious to warrant specific therapy are present, the treatment of choice is antidigoxin antibodies. Lesser degrees of arrhythmias (e.g., asymptomatic slow ventricular rates in patients with AF) can be treated with discontinuation of the drug and monitoring.

Disopyramide

Disopyramide exerts quinidine-like electrophysiologic effects (sodium channel block, AP prolongation). However, it lacks quinidine's alpha-blocking actions and instead produces prominent anticholinergic effects (86). These account for many of disopyramide's adverse effects, including constipation, urinary retention (more common among men with prostatism), glaucoma, and dry mouth. In addition, disopyramide depresses myocardial contractility, and exacerbation of symptoms of CHF is common, especially among those with underlying LV dysfunction.

Dofetilide

Dofetilide is a high-potency blocker of I_{Kr} and does not exert significant other pharmacologic effects. Double-blind placebo-controlled trials have shown that it is effective in preventing recurrences of AF after cardioversion, but no significant effect was demonstrated in patients with paroxysmal AF or with VT. In two large placebo-controlled trials in patients with advanced heart failure or recent MI, dofetilide did not alter mortality, and a trend to decreased hospitalization for recurrent heart failure was found, possibly due to decreased AF (87). Torsades de pointes is the major toxicity of dofetilide. In all clinical trials, dofetilide was initiated in monitored in-patients because of the concern for this proarrhythmia. The incidence was 0.8% to 3.3% and was highest in patients with heart failure. In the United States, dofetilide is currently only available to practitioners who have taken a short course in the drug's use, and the labeling mandates in-patient initiation. Because of the drug's specificity of action, other side effects are unusual (88).

Flecainide

Flecainide defined the "class Ic" drug: It is a potent suppressor of chronic ventricular ectopic activity, it routinely prolongs PR and QRS intervals by approximately 25% during chronic oral therapy, and it produces remarkably few "nuisance" side effects during chronic treatment (unlike drugs such as quinidine or procainamide) (89). In patients with advanced LV dysfunction, especially among those with regional wall motion abnormalities and recurrent sustained VT, flecainide commonly exacerbates the underlying arrhythmia. It increased mortality in CAST. Atrial flutter with 1:1 AV conduction can occur, and flecainide can exacerbate CHF. On the other hand, among patients with no structural heart disease and supraventricular arrhythmias (including AF, atrial flutter, and reentrant supraventricular tachycardias), mortality during flecainide therapy is virtually unheard of (90). From a practical point of view, it is only in the latter group of patients that flecainide is currently used.

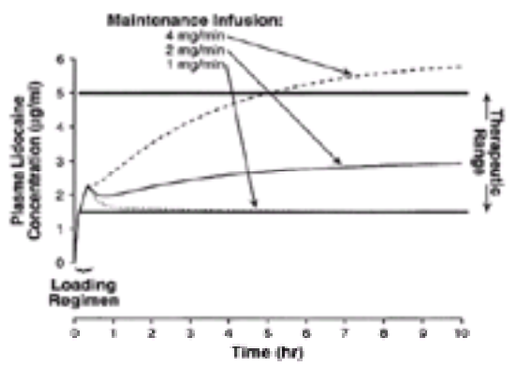
Ibutilide

Ibutilide is used for acute termination of AF or flutter. It is somewhat more effective in terminating atrial flutter (~60% of cases) versus AF (~30%). In AF, it is more effective if the arrhythmia has not been long-standing (e.g., months) and if the left atrium is not dilated. Ibutilide pretreatment can enhance the efficacy of direct current cardioversion in AF (91). Ibutilide acts by prolonging AP, and torsades de pointes occurs in 3% to 8% of patients. Other side effects are unusual (92).

Lidocaine

Lidocaine is useful for the acute suppression of recurrent VF or sustained VT, although amiodarone is increasingly viewed as the drug of first choice in these settings (75). Its efficacy, especially in sustained VT that is unrelated to ongoing myocardial ischemia, is not well established. In a head-to-head comparison, it was less effective than i.v. sotalol for sustained monomorphic VT (93).

Understanding the pharmacokinetics of lidocaine is helpful in minimizing toxicity and maximizing efficacy with the drug. After a bolus of lidocaine, plasma concentrations of the drug (which correlate with its antiarrhythmic activity) drop precipitously, not as a result of elimination but as a result of distribution. Therefore, an appropriate loading regimen of lidocaine administers approximately 3 to 4 mg per kg (200 to 300 mg total in an adult), either as a series of divided boluses or a rapid infusion over 20 to 30 minutes. Reduction in the size of this loading regimen is required in patients with advanced CHF (68). After loading, plasma concentrations approach true steady state in four to five elimination half-lives: Lidocaine elimination half-life is approximately 2 hours in normal individuals and in subjects with CHF and longer in those with liver disease. Thus, steady-state concentrations of lidocaine are achieved only many hours (³8 to 10 hours) after the initiation of therapy (eFig. 72.0.7). If the maintenance dosage is too low, the steady state may be subtherapeutic, with a late recurrence of arrhythmia. If, on the other hand, the rate of the maintenance infusion is too high, plasma concentrations rise slowly into the toxic range hours after initiation of apparently successful therapy. Under these circumstances, lidocaine toxicity is frequently characterized by relatively nonspecific symptoms such as dysarthria or disorientation (common among patients in intensive care units). Plasma lidocaine concentrations should be measured when steady state is approached, when arrhythmia recurs, or with suspected toxicity. Doses should be adjusted to maintain concentrations in the therapeutic range of 1.5 to 5.0 µg per mL.



***e*FIGURE 72.0.7** Plasma lidocaine concentrations during maintenance infusions. After administration of a loading regimen, plasma concentration-time profiles during approach to steady state over four to five elimination half-lives (8 to 10 hours) are shown. If the maintenance infusion is excessive, high plasma concentrations can develop many hours after institution of effective therapy (*dashed line*). On the other hand, if the maintenance infusion chosen is insufficient, plasma concentrations of lidocaine may drop to subtherapeutic levels many hours after institution of what was anticipated to be effective therapy. (From Roden DM. Treatment of cardiovascular disorders: arrhythmias. In: Melamine KL, Morrelli HF, Hoffman BB, Nierenberg DW, eds. *Clinical pharmacology: basic principles in therapeutics*. New York:

McGraw-Hill, 1992:151–185, with permission.)

Magnesium

Magnesium has assumed an increasingly prominent role in the therapy of recurrent or ongoing sustained ventricular tachyarrhythmias despite lack of data documenting that it is effective. Poorly controlled trials (56,94) suggest that it may have a role in suppressing torsades de pointes and atrial arrhythmias characteristic of digoxin toxicity. When it is used to treat long QT-related arrhythmias, the arrhythmia may resolve without marked shortening of the QT interval. No evidence has been found that magnesium is useful in treating other arrhythmias.

Mexiletine and Tocainide

P>Mexiletine (95) and tocainide (96) are structural analogs of lidocaine that were developed to permit long-term oral therapy. They are occasionally useful in the treatment of ventricular arrhythmias, especially in combination with sotalol or quinidine. Tocainide has a relatively high incidence of agranulocytosis, and for this reason, it is not widely used.

Moricizine

Moricizine was evaluated in CAST (4), and although it did not appear to increase mortality to the same extent as did flecainide, the mortality was definitely increased early during treatment. Thus, moricizine is rarely used in treating ventricular arrhythmias. Anecdotal evidence suggests some efficacy in supraventricular arrhythmias, including AF.

Procainamide

Procainamide produces electrophysiologic effects that are similar to those of quinidine and disopyramide. It lacks quinidine's alpha-blocking actions, but when it is administered intravenously, it exerts ganglionic blocking effects that may result in hypotension. When procainamide is used for long-term oral therapy, most patients develop antinuclear antibodies and a minority develop symptoms such as arthralgia or rash indicating the lupus syndrome; this reaction is commoner among patients who are genetically slow acetylators (~50% of patients) (97). Newer formulations allow administration of procainamide two to four times a day. Nevertheless, because of the problem of lupus as well as frequent GI intolerance, the drug is not widely used as primary therapy for atrial or ventricular arrhythmias. Torsades de pointes can occur during procainamide therapy and is most often due to accumulation of the AP-prolonging (non–sodium channel–blocking) metabolite *N*-acetylprocainamide (NAPA). Procainamide is eliminated by hepatic metabolism to NAPA and by direct renal excretion, whereas NAPA is eliminated by renal excretion alone. Thus, the most frequent setting in which NAPA accumulation occurs is renal failure.

Monitoring plasma procainamide and NAPA concentrations during long-term therapy can be useful to prevent toxicity. At concentrations of 8 to 10 µg per mL or greater, procainamide frequently produces GI upset, whereas NAPA concentrations associated with torsades de pointes are frequently 30 µg per mL or greater. It is common practice to add procainamide and NAPA concentrations together to develop a single plasma drug concentration for monitoring purposes. However, because the drugs exert different electrophysiologic effects, produce different toxicities, and use different elimination mechanisms, this approach is inappropriate. Rather, concentrations of the compounds should be considered individually with regard to their potential toxicity. Bone marrow aplasia may occur in 0.2% of patients and does not appear to be related to high plasma concentrations.

Propafenone

Propafenone (98) has sodium channel–blocking properties that are similar to those of flecainide and quinidine *in vitro*. Propafenone can exacerbate VT and produces electrocardiographic changes similar to those of flecainide; therefore, although it was not evaluated in CAST, most clinicians avoid its use in ventricular arrhythmias because its effects so closely resemble those of flecainide.

The major route of propafenone elimination is catalyzed by CYP 2D6, a hepatic enzyme that oxidizes the drug to an active metabolite, 5-hydroxy-propafenone (98). Propafenone exerts beta-blocking activity *in vitro*, whereas its metabolite does not. In patients who are genetically deficient in this elimination pathway (~7% of the white and black populations), propafenone elimination is impaired, and high plasma concentrations of the drug can be measured. It is in these patients that symptoms referable to beta-blockade can occur (99). CHF and bradycardia can also occur during propafenone therapy and are notably more common in poor metabolizers. In addition, some drugs, notably quinidine, tricyclic antidepressants, and selective serotonin reuptake inhibitors such as fluoxetine, can inhibit propafenone biotransformation, elevate its plasma concentrations, and thus increase the risk for adverse effects.

At present, propafenone is most frequently used in the suppression of AF or flutter. In this setting, propafenone, like flecainide and quinidine, can cause atrial flutter with 1:1 conduction and wide complexes, which can be misdiagnosed as VT.

Quinidine

Quinidine has been used for antiarrhythmic therapy since the 1920s. Side effects, including proarrhythmia, are a major concern with quinidine therapy. Very high concentrations generated by aggressive quinidine dosing regimens that were formerly used to convert AF can result in sustained VT similar to that seen with flecainide intoxication. Even low concentrations of quinidine can produce torsades de pointes (100). Although the mechanisms by which "subtherapeutic" plasma concentrations of quinidine produce torsades de pointes are not completely understood, it is now known that the drug blocks I_{Kr} at very low concentrations (55). Because blockade (or mutations in the channel responsible for I_{Kr}) is known to produce torsades de pointes, it seems likely that this can explain why marked QT prolongation and torsades de pointes may develop in some patients at even very low plasma quinidine concentrations. Some analyses (101,102) have suggested that mortality may be increased with long-term use of quinidine in patients with atrial arrhythmias, perhaps due to torsades de pointes, which has been reported in 2% to 10% of patients treated with quinidine for AF. Other side effects, notably diarrhea, are very common. With high plasma quinidine concentrations, a syndrome known as *cinchonism*, which includes tinnitus and headache, can occur. Immunologic reactions have also been reported with quinidine and include thrombocytopenia and, occasionally, the lupus syndrome. Most side effects from quinidine therapy, with the exception of cinchonism, are unrelated to high drug concentrations or any known metabolites.

Drug interactions can also occur during quinidine therapy. Quinidine is an inhibitor of CYP 2D6, responsible for the metabolism of propafenone (and of other drugs, such as beta-blockers, that use the same enzyme for their elimination). In addition, digoxin and digitoxin concentrations predictably double during quinidine therapy, with a corresponding rise in symptoms of digitalis toxicity. This likely reflects inhibition of P-glycoprotein–mediated digoxin excretion (70).

At the beginning of the 1990s, quinidine was the most widely prescribed antiarrhythmic in North America. Because side effects are so common and the awareness of torsades de pointes is increasing, quinidine has assumed an increasingly minor role in antiarrhythmic therapy. Currently, it is probably best reserved for patients with depressed LV performance and recurrent symptomatic arrhythmias (e.g., AF or frequent ICD shocks for VT) in whom other therapies such as amiodarone are deemed undesirable.

Sotalol

Sotalol is a nonselective beta-blocker with prominent AP-prolonging characteristics (103). It is useful in the treatment of ventricular and supraventricular arrhythmias. Side effects are confined to those related to beta-blockade and to torsades de pointes. The incidence of the latter is unknown, although comparative trials suggest it as approximately equivalent to (or perhaps somewhat less than) that seen with quinidine. Because the incidence of torsades de pointes during sotalol therapy appears to be dose related (in contrast to quinidine), most clinicians would avoid using high dosages (e.g., >160 mg twice a day). Unlike other beta-blockers, sotalol has not been shown to reduce the incidence of mortality among patients who are recovering from MI. However, the major trial (104) in which it was studied used a dose of 320 mg once a day. Thus, it is conceivable that the lack of a significant effect on mortality reflects a tradeoff between a mortality-sparing effect due to beta-blockade and a torsades de pointes–inducing effect. In support of this idea, the use of sotalol in patients with ICDs has been shown to reduce the incidence of device discharges or death (105).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Antiarrhythmic drug use is declining because effective nonpharmacologic therapies are becoming more widely available and because of an increasing recognition of

the limited efficacy and the potential for serious side effects during antiarrhythmic therapy, particularly during long-term treatments. Much of the long-term antiarrhythmic therapy has now devolved to amiodarone, a drug that the author believes is neither as effective nor as safe as its most ardent proponents believe. Nevertheless, among therapies that are available for long-term antiarrhythmic treatment, amiodarone has been demonstrated to be more effective and probably no more dangerous than drugs such as quinidine or procainamide, which heretofore have been considered conventional. Similarly, a number of studies suggest that sotalol is better tolerated and as effective as (if not more effective than) conventional drugs. Thus, it is now appropriate to relabel amiodarone and sotalol as conventional therapies and to reserve other drugs, such as quinidine or procainamide, for those unusual situations in which conventional drugs are contraindicated or ineffective and alternative therapies are not available.

All available antiarrhythmic drugs were developed at a time when the mechanisms that underlie the target arrhythmias and the antiarrhythmic drug effects were incompletely defined at best; indeed, this is still the case. Catheter ablation is a superb example of a therapy that has evolved to become an effective modality from an understanding of the underlying disease mechanisms. During the past decade, our understanding of the molecular and cellular events that underlie arrhythmogenesis has grown tremendously. Thus, we are in the paradoxical position of understanding better the mechanisms underlying the proarrhythmic effects of antiarrhythmic drugs than those that underlie the antiarrhythmic effects of these same agents. It seems clear that the molecular entities targeted by many of the antiarrhythmic drugs, notably the sodium channel and the rapidly activating component of the cardiac-delayed rectifier, I_{Kr}, may not be the best targets for suppressing atrial or ventricular arrhythmias. The author remains hopeful that better understanding of the mechanisms of arrhythmias may well allow identification of molecular and cellular targets for new antiarrhythmic entities that may prove to be highly effective and safe in treating common arrhythmia scenarios such as AF or patients at risk for VT or VF.

THE FUTURE

Use of antiarrhythmic drugs will continue to decline because of their recognized limited efficacy and serious side effects, especially during long-term therapy. Continuing research resulting in an improved understanding of the mechanisms of arrhythmias will allow identification of molecular and cellular targets for new antiarrhythmic entities. Such new entities may well provide highly effective and safe treatment of common arrhythmias.

OVERVIEW

The rationale behind ablative therapy is that, for any arrhythmia, there exists a critical anatomic substrate that allows propagation of that arrhythmia. If that substrate is irreversibly damaged or destroyed, then the arrhythmia should no longer occur spontaneously or with provocation.

A number of methods of catheter ablation have been attempted experimentally and clinically, but radiofrequency catheter ablation has emerged as the safest and most effective modality.

Radiofrequency energy heats myocardium by the passage of the radiofrequency electrical current through the tissue, resulting in resistive tissue heating.

Deeper tissue heating results in larger lesions. Larger electrodes, higher temperatures, and very high-power deliveries coupled with irrigated or cooled tip catheters increase lesion size.

Radiofrequency ablative lesions are thermally mediated. Temperatures exceeding 50°C result in breakdown of the sarcolemmal membrane and cell death.

The mechanisms of paroxysmal supraventricular tachycardia are varied and include atrioventricular (AV) reciprocating tachycardia, AV nodal reentrant tachycardia, atrial fibrillation, atrial flutter, and atrial tachycardia of focal automatic or reentrant mechanisms.

Catheter ablation of accessory pathways responsible for the Wolff-Parkinson-White syndrome and AV reciprocating tachycardias may be accomplished at either the atrial or ventricular insertion sites of the pathway with a high (greater than 95% at experienced centers) success rate.

Catheter modification of the AV node is highly successful in eliminating AV nodal reentrant tachycardia. In most cases, ablation in the low septal region results in elimination or marked modification of the slow AV nodal pathway and prevents tachycardia recurrence.

Atrial flutter is a macroreentrant rhythm that travels around the tricuspid valve annulus and through the isthmus between the valve and the inferior vena caval inlet. A linear ablative lesion placed across this isthmus results in successful ablation of the atrial flutter. However, concomitant atrial fibrillation is not altered by this ablation and will likely recur unless additional therapy is prescribed.

Atrial fibrillation may have a reentrant mechanism or, particularly in patients with frequent paroxysmal atrial fibrillation and normal atrial size, may originate from rapid firing from a pulmonary vein focus.

Ablation of focal origins of atrial fibrillation initiation is moderately successful in eliminating this arrhythmia in highly selected patients.

Common atrial fibrillation has a reentrant mechanism. Cure with ablation usually requires successful creation of long transmural continuous linear lesions in left and right atria. This has been difficult to achieve with catheter-based technologies.

Ventricular tachycardia may be idiopathic or caused by the presence of underlying structural heart disease.

Idiopathic ventricular tachycardia from the right ventricle is usually focal in origin, with a likely mechanism of abnormal automaticity or triggered activity. It may be ablated with a high likelihood of success.

Ventricular tachycardia in the setting of structural heart disease is usually caused by a reentrant mechanism in regions of patchy fibrosis. Ablation may be accomplished at sites within the zone of slowed electrical conduction that is identified with techniques such as activation and entrainment mapping.

GLOSSARY

Accessory pathway: An anomalous bridge of electrically conducting tissue between the atrium and ventricle, which is responsible for Wolff-Parkinson-White syndrome and AV reciprocating tachycardias, also known as a *bundle of Kent* or *bypass tract*.

Activation mapping: Multipoint electrogram acquisition during ongoing tachycardia demonstrates sites where the local electrical activity precedes the onset of the surface QRS complex. These sites represent exit points from the slow conduction zone for reentrant tachycardias or sites of arrhythmia origin for automatic or triggered tachycardias.

AV nodal modification: (a) Ablation of the slow AV nodal pathway to treat AV nodal reentrant tachycardia; (b) nonspecific ablation of the AV node to impair anterograde conduction and decrease the ventricular response rate to atrial fibrillation.

Coagulum: When boiling occurs at the electrode tip, coagulated protein from tissue and blood adhere to the tip of the electrode.

Convective cooling: The process by which thermal energy is removed by circulating blood flow through the heart.

Dispersive electrode: An electrode with a large surface area that is placed in contact with the patient's skin (usually with electrically conductive gel) to complete the electrical circuit during ablation with radiofrequency electrical current.

Electrical impedance: The resistance and capacitance of the radiofrequency electrical circuit, including the electronic components, conducting wires, point of conduction between the ablation electrode and the heart, tissue between the heart and the skin, and junction between the skin and the dispersive electrode.

Entrainment mapping: Pacing slightly faster than ongoing reentrant ventricular tachycardia from various sites in the ventricle. When one is in or near the slow conduction zone, the morphology of the resulting complex matches the tachycardia morphology exactly, and the time from the stimulus to the QRS complex is prolonged (concealed entrainment).

Impedance rise: If boiling and coagulum adherence occur, the available surface area for radiofrequency current conduction decreases, resulting in a sudden increase in system impedance.

Pace mapping: During sinus rhythm, pacing is performed from a variety of ventricular sites. For ventricular tachycardias of focal origin, the electrocardiograms during pacing should be almost identical to those during tachycardia if the pacing site is in close proximity to the arrhythmia origin.

Radiofrequency energy: High-frequency alternating electrical current; when passed through a resistive medium, it creates heat.

Slow and fast AV nodal pathways: The AV node has multiple atrial inputs that have varying properties, including conduction time. In typical AV nodal reentrant tachycardia, electrical activation travels anterograde down a slowly conducting AV nodal pathway and retrograde up a fast conducting pathway.

Tricuspid-inferior vena cava isthmus: The narrow anatomic region between the tricuspid annulus and the inferior vena caval orifice in the right atrium through which atrial flutter reentrant circuits conduct. This is the usual site targeted for atrial flutter ablation.

Ventricular preexcitation: Pattern seen on surface electrocardiograms characterized by delta waves (slurred QRS upstrokes) and resulting from the presence of an accessory pathway that conducts in an anterograde fashion. Wolff-Parkinson-White syndrome is the most common form of preexcitation syndrome.

Ventricular tachycardia slow conduction zone: Region in the border zone of scar in the ventricle bounded by areas of anatomic or physiologic conduction block, which has a slow conduction velocity. Conduction through this region accounts for the diastolic period of electrical silence on the surface electrocardiogram during ongoing reentrant ventricular tachycardia.

Volume heating: Heating from radiofrequency energy or other energy source that is direct and not a result of heat conduction from a contiguous region of heated tissue.

INTRODUCTION

Ablative therapy for the management of arrhythmias is based on the observation that most arrhythmias arise from a focal origin or are critically dependent on conduction through a defined anatomic structure. If those critical regions are irreversibly damaged or destroyed, then the arrhythmia should no longer occur spontaneously or with provocation. Traditionally, ablation was performed with open surgical techniques. It was discovered, however, that focal endocardial injury could also be achieved by a controlled delivery of destructive energy through a catheter. In the past decade, catheter designs have evolved to improve site access dramatically, and our knowledge and understanding of the anatomy of the heart and the sources of arrhythmia origin have significantly expanded. In response to this progress, the indications for catheter ablation have continued to broaden, and it is now the therapy of choice for a number of arrhythmias.

HISTORY OF CATHETER ABLATION

The concept of ablative therapy for the treatment of arrhythmias was well established in the surgical literature throughout the 1970s. Since the original description of the surgical division of an accessory pathway by Sealy et al. in 1969 (1), there have been several reports of surgical treatment of the Wolff-Parkinson-White syndrome (2,3) and ventricular tachycardia (4,5). In these series, the concept of curative ablative therapy was proved. However, the obvious limitation to this approach was that an open thoracotomy and, in most cases, cardiopulmonary bypass were required. Although researchers were pursuing a variety of approaches to decrease surgical morbidity and mortality, it was not thought possible to eliminate these arrhythmic substrates without direct visualization.

In 1979, a complication of transthoracic cardioversion was reported. Catheters had been placed for recording in the bundle of His position, and multiple direct current (DC) shocks were administered transthoracically to terminate an episode of ventricular tachycardia. At the conclusion of the cardioversion, complete heart block was observed. It was hypothesized that shunting of defibrillator current through the His bundle catheter caused irreversible damage to the AV conduction system (6). After this report, Scheinman et al. (7) and Gallagher et al. (8) published the first series of catheter ablation of the AV junction in patients with atrial fibrillation and a rapid ventricular response rate that could not be controlled with drugs. In these cases, high-voltage DC electrical energy was intentionally delivered between the tip of an electrode catheter placed contiguous to the bundle of His and a dispersive patch electrode placed on the skin. The field of catheter ablation was born. Subsequently, investigators reported successful catheter ablation of accessory pathways (9,10 and 11) and ventricular tachycardia (12,13) with this approach. Unfortunately, a relatively high complication rate was also reported, including pericardial tamponade, cardiogenic shock, and death (14).

The technique of high-energy DC shock catheter ablation was effective, but it was extremely difficult to control. The high voltage delivered to the tissue and surrounding blood routinely resulted in formation of an expanding gas bubble with subsequent dielectric breakdown and electrical arcing. The barotrauma created by the rapid gas expansion was uncontrolled and could lead to cardiac perforation. Additionally, the high voltage field was associated with transient or sometimes permanent depression of myocardial contractility. An alternative energy source for controlled ablation of myocardium was needed. A variety of different energy sources had to be employed to heat or ablate targeted tissues in the fields of neurosurgery and oncology. In 1985, Huang et al. described their use of radiofrequency electrical energy for controlled catheter ablation of the AV junction in dogs. Radiofrequency catheter ablation resulted in controllable, well-circumscribed endocardial lesions (15). It was discovered that lesion formation could be nicely controlled by either titrating power (16) or temperature measured at the catheter tip (17). Efficacy of radiofrequency catheter ablation in the clinical setting was unacceptably low, however. The next major advance in the field came with two improvements in the catheter design. First, it was recognized that a larger ablation electrode might increase lesion size (18). With an increase in the electrode tip size from 2 to 4 mm, an appreciable increase in procedure efficacy was realized (19). Second, catheter design pioneers such as Will Webster constructed catheters that had a distal segment that could be deflected by manipulation of the control handle. This greatly improved site access and catheter stability.

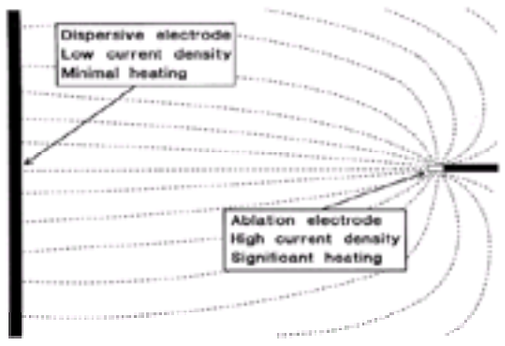
The modern era of radiofrequency catheter ablation was entered with the first report of successful catheter ablation of an accessory pathway with high-frequency alternating (radiofrequency) electrical current by Borggrefe et al. (20). Based on the important work of Jackman, Kuck, Haissaguerre, Morady, and others, the correlations between electrographic patterns, anatomic locations of accessory pathways, and access to those sites with ablation catheters were elucidated (21,22 and 23). Success rates exceeding 90% were reported by investigators in the treatment of paroxysmal supraventricular tachycardia (24,25 and 26). In the present day, experienced operators achieve greater than 95% success rates in the ablation of these patients. The indications for radiofrequency catheter ablation continue to expand, and it has become a dominant therapeutic modality for many varieties of symptomatic tachycardia.

BIOPHYSICS OF RADIOFREQUENCY CATHETER ABLATION

Radiofrequency electrical energy is employed to create thermal lesions in the heart. The frequencies generally employed are 300 to 1,000 kHz. It is important to note that, although this energy is similar to that employed for broadcast radio, the radiofrequency energy is electrically conducted, not radiated, during catheter ablation. The radiofrequency current is similar to low-frequency alternating current or DC with regard to its ability to heat tissue and create a lesion, but it oscillates so rapidly that cardiac and skeletal muscles are not stimulated, thereby avoiding induction of arrhythmias and decreasing the pain perceived by the patient. As the electrical current passes through the myocardium, the energy dissipates as heat. Direct resistive myocardial heating (volume heating) is proportional to the radiofrequency power density (or the square of the current density) that decreases in proportion to the fourth power of the distance from the electrode. Therefore, most of the volume heating occurs within the first 2 mm of depth from the electrode (17). Heating to deeper tissue layers occurs by heat conduction from the region of volume heating.

The radiofrequency current is generally delivered in a unipolar fashion between the tip of the ablation electrode and a dispersive electrode applied to the patient's

skin. Because the surface area of the ablation electrode is much smaller than that of the dispersive electrode, the current density is higher at the ablation site, and heating occurs preferentially at that site (eFig. 73.0.1). If, however, ablation is performed with a high-amplitude current and skin contact by the dispersive electrode is poor, it is possible to cause skin burns. The geometry of the radiofrequency current field is defined by the geometry of the ablation electrode and is relatively uniform in the region of volume heating. Thus, the position of the dispersive electrode has little effect on the geometry of the resulting lesion. Sometimes it is advantageous to increase the surface area of the dispersive electrode. The system impedance comprises the impedance of the generator, transmission lines, catheter, electrode-tissue interface, dispersive electrode-skin interface, and the interposed tissues. The energy dissipated at the tip of the ablation electrode (which is converted from electrical to thermal energy) is proportional to the square of the current density, the local impedance, and the time. If an ablation is power-limited, heat production at the catheter tip will therefore vary with the proportion of the local electrode-tissue interface impedance to the overall system impedance. If the impedance at the skin-dispersive electrode interface is high, then a smaller amount of energy is available for tissue heating at the electrode tip. Nath et al. (27) demonstrated that the tissue temperatures achieved during catheter ablation were similar, whether the dispersive electrode was placed on the patient's back between the scapulae or placed on the thigh. In patients who had a baseline system impedance of greater than 100 W, using two dispersive electrodes resulted in more effective heating than using a single electrode.



***e*FIGURE 73.0.1** Schematic representation of a catheter ablation electrode and a skin dispersive electrode during radiofrequency energy delivery. The dashed lines represent the electrical field. Note that because the available electrode surface area of the ablation electrode is much smaller than that of the dispersive skin electrode, the current density and its associated tissue heating of the former are much greater. In addition, the electrical field around the ablation electrode is relatively uniform, irrespective of the location of the dispersive electrode.

It has been demonstrated *in vitro* that, at steady state, the tissue temperature decreases radially in proportion to the distance from the ablation electrode and that, at steady state, the lesion size is proportional to the temperature measured at the interface between the tissue and the electrode (28). In addition, lesion size has also been shown to be proportional to the radiofrequency power amplitude (28,29). By using higher powers and achieving higher tissue temperatures, lesion size may be increased. However, once the peak tissue temperature exceeds the threshold of 100°C, boiling at the electrode-tissue interface may ensue (29). When boiling occurs, denatured serum proteins and charred tissue adhere to the electrode, forming an electrically insulating *coagulum* (30), which is accompanied by a sudden increase in electrical impedance preventing further current flow into the tissue and further heating. The consequences of this adverse event could include char embolism or excess disruption of the endocardium with subsequent thrombus formation and associated risk of thromboembolism. Conventional electrode catheters with temperature monitoring only report the temperature from the center of the electrode mass with one design or from the apex of the tip of the catheter with another design, and it is likely that the measured temperature underestimates the peak tissue temperature. Therefore, it is best if target temperatures not exceeding 70° to 80°C are selected in the clinical setting. Because the rate of temperature rise at deeper sites within the myocardium is slow (31), a continuous energy delivery of at least 60 seconds is often warranted to maximize depth of lesion formation. Tissue temperatures continue to rise somewhat after termination of radiofrequency energy delivery (32). This thermal latency effect can account for the observation that patients undergoing AV modification procedures who demonstrate transient heart block during radiofrequency energy delivery may progress to persisting complete heart block even if radiofrequency energy delivery is terminated immediately.

The dominant factor opposing effective heating of myocardium is the convective cooling from the circulating blood pool. If the catheter position is not stable, or if it is positioned in a region of high blood flow, the magnitude of convective cooling is increased (33). Efficiency of energy delivery to the tissue may vary from approximately 70% to 10% *in vivo.* The effects of convective cooling have been exploited to increase the size of catheter ablative lesions. To eliminate the risk of overheating at the electrode-tissue contact point but increase the magnitude of power delivery and the depth of volume heating, investigators have employed porous-tipped electrodes for open irrigation of the electrode tip (34) or closed irrigation systems for electrode tip cooling (Fig. 73.1) (35). Nakagawa et al. achieved temperatures of 95° ± 9°C at depths of 3.5 mm and lesion dimensions of 10 ± 1 mm depth by 14 ± 2 mm diameter with ablation through an irrigated-tip electrode in a superfused canine thigh muscle preparation. However, superheating within the tissue with a resulting sudden explosive release of the expanding steam to the surface (the so-called pop lesion) was observed in 7.5% of the ablations (34). Thus, increasing power delivery and convective cooling may create large lesions, but lesion production is somewhat difficult to control.

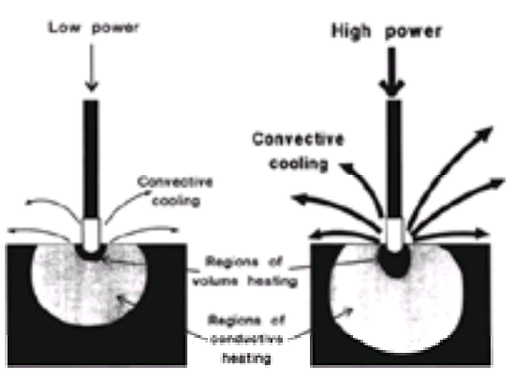


FIGURE 73.1 Schematic representation of two conditions during radiofrequency catheter ablation. The left panel depicts conventional conditions with a moderate degree of convective cooling. A low magnitude of radiofrequency power is applied to achieve heating at the electrode-tissue interface. This results in a small depth of volume heating and a moderate depth of conductive heating that create the final pathologic lesion. The right panel depicts radiofrequency ablation in the setting of increased convective cooling, either by active tip cooling with perfused or circulating saline or by unstable catheter-tissue contact. A high magnitude of radiofrequency power is applied, but the electrode-tissue interface does not exceed 100°C because of convective dissipation of heat at the tissue surface. The higher-applied power results in a greater depth of volume heating and a larger overall lesion size.

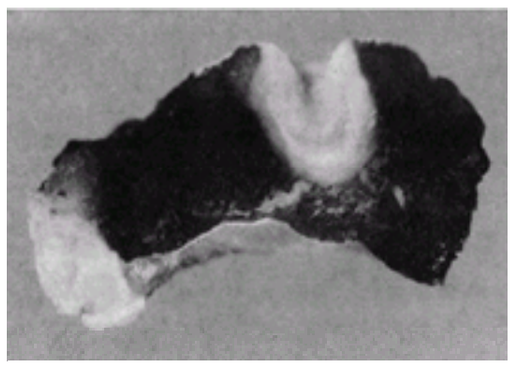
Because the success of radiofrequency catheter ablation in the clinical setting is sometimes limited by the relatively small size of the lesion, attempts have been made to increase the size of those lesions reliably and safely. One approach to this end is to increase the size and surface area of the electrode. The radiofrequency power needs to be increased comparably in order to achieve a similar current density and temperature at the electrode-tissue interface, and the result is a greater depth of volume heating and a larger lesion (18). The introduction of the larger 4-mm ablation electrode was an important factor in the improved success rates of present-day catheter ablation (35). Investigators are continuing to pursue novel electrode geometries for special applications of radiofrequency catheter ablation (36).

MECHANISMS OF MYOCARDIAL INJURY CAUSED BY RADIOFREQUENCY CATHETER ABLATION

It is likely that the major mechanism of tissue injury from radiofrequency catheter ablation is thermal. Heating of the myocardium occurs reproducibly during radiofrequency energy delivery, and the association of clinical effect and temperature measured at the electrode-catheter interface has been established. Experimentally, lesions created from a radiofrequency or microwave source have a reliable isotherm of irreversible tissue injury of 52° to 55°C (37). In the clinical setting, successful ablations were associated with a mean temperature measured at the electrode-tissue interface of 62° ± 15°C (38). During ablation of the AV junction, the reversible physiologic effect of an accelerated junctional rhythm was observed at temperatures of 51° ± 4°C, whereas temperatures of 58° ± 6°C were required to achieve heart block (39). Clinical effects of radiofrequency ablation have been observed with electrode tip temperatures of less than 40°C (40), indicating that the electrical effects of radiofrequency current may alter tissue properties as well.

Tissue Effects of Radiofrequency Catheter Ablation

Changes in myocardial tissue are apparent immediately on completion of the radiofrequency lesion. Pallor of the central zone of the lesion is attributable to myoglobin denaturation with an associated color change. Some volume loss in the central region of lesion formation is apparent as evidenced by a slight deformation at the point of catheter contact. Fibrin usually adheres to the endocardial surface and, if a temperature of 100°C has been exceeded, adherent char and thrombus are often apparent. On sectioning, the central portion of the lesion shows desiccation, with a surrounding region of hemorrhagic tissue, then normal appearing tissue (eFig. 73.1.1) (41,42). The histology of an acute lesion shows typical coagulation necrosis with basophilic stippling consistent with intracellular calcium overload. Immediately surrounding the central lesion is a region of hemorrhage and acute monocellular and neutrophilic inflammation. The progressive changes seen in the evolution of a radiofrequency lesion are typical of healing after any acute injury. Within 2 months of the ablation, the lesions show fibrosis, granulation tissue, chronic inflammatory infiltrates, and significant volume contraction (41). The lesion border is well demarcated from the surrounding viable myocardium without evidence of patchy fibrosis. This likely accounts for the absence of proarrhythmia side effects of radiofrequency catheter ablation. Because of the high-velocity blood flow within the epicardial coronary arteries, these vessels are continuously cooled and are spared from injury despite nearby delivery of radiofrequency energy (43). However, high radiofrequency power delivery in small hearts, such as in pediatric patients, may potentially cause coronary arterial injury, so caution is warranted (44).



***e*FIGURE 73.1.1** Example of a typical radiofrequency lesion created in an experimental preparation and stained with the histochemical dye nitro blue tetrazolium. The electrode-tissue contact point shows volume loss and dimpling. The viable myocardium (*dark stain*) is sharply demarcated from the nonviable lesion (*light stain*). The lesion width is narrower at the endocardial surface than at a 2-mm depth because of surface convective cooling from endocardial blood flow.

The border zone around the acute pathologic lesion is a region that can demonstrate initial stunning and then early or late recovery of function, or show late progression of physiologic block resulting in a “delayed cure” in some cases (45). Significant diminution in microvascular blood flow is observed in this region. Electron microscopic examination of the border zone has demonstrated marked ultrastructural abnormalities in tissue that appears to be viable by routine histologic examination. The microvessels appear severely damaged with loss of the basement membrane, disruption of the endothelial cell plasma membrane, and erythrocyte stasis (46). The myocytes show significant ultrastructural injury of the plasma membrane, mitochondria, sarcomeres, sarcoplasmic reticulum, and gap junctions. The most thermally sensitive structures appear to be the plasma membrane and gap junctions, which show morphologic changes as far as 6 mm from the edge of the pathologic lesion (47). It has, therefore, been documented that the effects of radiofrequency lesion formation extend well beyond the acute pathologic lesion and are characterized by marked ultrastructural abnormalities of the microvascular and myocytes acutely, and a typical inflammatory response later. Therefore, the recovery of electrophysiologic function after successful catheter ablation in the clinical setting may be caused by healing of the damaged, but surviving, myocardium. The progression of the electrophysiologic effects after completion of the ablation procedure may be caused by further inflammatory injury and necrosis in the border zone region.

Cellular Effects of Radiofrequency Ablation

Hyperthermic injury to the cell is both time and temperature dependent. This injury to the myocyte may be caused by changes in the membrane, protein inactivation, cytoskeletal disruption, nuclear degeneration, or a number of other potential mechanisms.

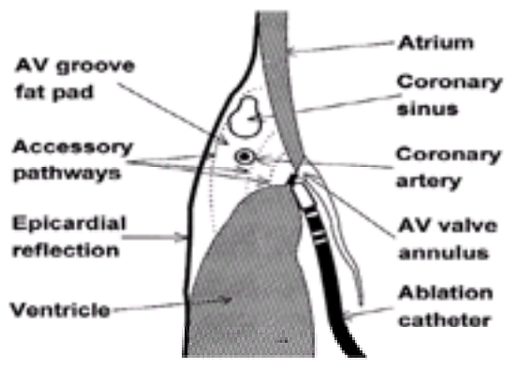
Experimentally, brief exposure to heat results in prominent changes in the electrophysiology of the myocyte. In one study, guinea pig papillary muscles were exposed to temperatures between 37° and 55°C, and transmembrane potentials were measured. In the low hyperthermic range (37° to 45°C), a minor change was seen in the resting membrane potential and action potential amplitude, and the action potential duration shortened significantly. In the intermediate hyperthermic range (45° to 50°C), progressive depolarization of the resting membrane potential, loss of action potential amplitude, abnormal automaticity, and reversible loss of excitability were seen. In the high temperature ranges (greater than 50°C), marked depolarization of the resting membrane potential, permanent loss of excitability, and contracture of the preparation were observed (48). Another study examined the effects of hyperthermia on conduction velocity of a preparation of epicardial shavings from canine left ventricular free walls. Conduction velocity was greater than at baseline between 38.5° and 45.4°C, but above 45.4°C, a progressive decrease in conduction velocity was seen, followed by temporary (49.5° to 51.5°C) then permanent (51.7° to 54.4°C) conduction block (49). It is hypothesized that these electrophysiologic changes may be caused by nonspecific ion transit through thermally induced transmembrane pores. In particular, intracellular calcium levels increase at temperatures above 45°C and result in cellular contracture as temperatures approach 50°C. Blockade of the intracellular calcium buffering system by the sarcoplasmic reticulum results in increased thermosensitivity, suggesting that acute calcium overload may be the mechanism of myocyte death with catheter ablation (50).

In addition to the thermal effects of radiofrequency catheter ablation, some of the cellular injury may be caused by a direct electrical effect. Electroporation is a technique of forming temporary pores in the phospholipid membrane with high-intensity electrical fields. Radiofrequency field stimulation has been used for the introduction of genetic material into a variety of host cells (51). Jones et al. have demonstrated that tested high-intensity DC fields created sarcolemmal microlesions in cultured chick myocytes (52). Although the amplitude of the electrical fields at which physiologic effects have been reported are higher than those associated with radiofrequency catheter ablation, it is hypothesized that a synergistic effect of electrical field stimulation and membrane heating may occur, resulting in membrane pore formation, cellular depolarization, calcium overload, and cell death.

ABLATION OF SPECIFIC SUPRAVENTRICULAR ARRHYTHMIAS

Accessory Pathway–Mediated Arrhythmias

A giant step forward was achieved with the first successful catheter ablations of accessory pathways (20). Before the catheter ablation era, patients with Wolff-Parkinson-White syndrome and concealed accessory pathways frequently required open surgical ablation of their extranodal pathways. The ability to map precisely the location of accessory pathways and deliver a precise ablative lesion with radiofrequency energy not only proved to be a valuable therapeutic modality, but also greatly enhanced the understanding of the physiologic and anatomic correlates of this relatively common abnormality. Important preliminary work by Jackman et al. identified electrogram patterns that correlated precisely with accessory pathway insertions in the atria and ventricles (21). The ultimate validation of the origin of these potentials arrived when small, discrete radiofrequency lesions placed at those locations resulted in elimination of both anterograde and retrograde accessory pathway conduction (*e*Fig. 73.1.2) (24,25 and 26,53). It has been proposed that the pathways frequently follow a slanting course with separation of atrial and ventricular insertion points by 4 ± 30 mm, and that they may be composed of multiple closely spaced fibers (21). The majority of accessory pathways has a discrete and narrow ventricular and atrial insertion. The presence of occasional branching accessory pathway insertions may be assumed in cases in which accessory pathway conduction is modified but not blocked by one lesion, and then is blocked by a second application of energy at a second discrete site. The high success rate of radiofrequency catheter ablation delivered from the endocardial approach implies that most pathways are situated closely to the endocardial surface. However, a small proportion of left free wall accessory pathways (1% to 4%) can only be ablated successfully from the epicardial approach via the coronary sinus and probably represent true epicardial pathways (54).



***e*FIGURE 73.1.2** Schematic representation of a cross section of the left atrioventricular (AV) groove with the position of a typical ablation catheter relative to the anatomic structures in this region. The possible courses of three accessory pathways are diagrammed. One accessory pathway follows a subepicardial course and can only be successfully ablated via the coronary sinus. Another pathway passes close to the coronary artery. The convective cooling of intracoronary blood flow protects the vascular endothelium from thermal injury by endocardial ablation with conventional ablation catheters.

The successful catheter ablation of accessory pathways is directly related to the skill and experience of the operator (55). Careful mapping of the accessory pathway atrial and ventricular insertion points before any radiofrequency energy delivery greatly enhances the efficiency of the ablation procedure and minimizes the risk of distortion of local electrograms by poorly placed ablative lesions. In patients with manifest ventricular preexcitation (Wolff-Parkinson-White syndrome), mapping is best performed in the anterograde direction during sinus or atrial-paced rhythm. The local ventricular activation recorded from the mapping and ablation catheter should precede the onset of the delta wave on the surface electrocardiogram by at least 10 ms (optimally an interval of at least 20 ms should be pursued), and the electrographic pattern should be stable, indicating stable catheter-tissue contact (Fig. 73.2). An excellent ablation site shows the presence of a high-frequency accessory pathway potential immediately preceding the local ventricular activation and a relatively short atrial-to-ventricular electrographic interval (56,57). This latter finding, however, should not be used to guide ablation catheter positioning, because parallel activation of atrium and ventricle distal to the insertion point of the accessory pathway may result in short AV times, but late ventricular electrogram timing relative to the delta wave onset.

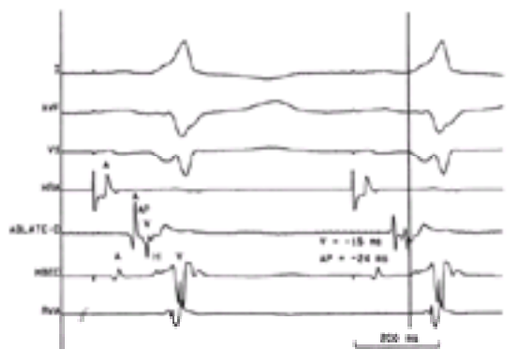


FIGURE 73.2 Surface electrocardiogram tracings I, aVF, and V_1, and intracardiac recordings from the high right atrium (HRA), distal ablation catheter bipole (ABLATE-D), the distal bundle of His bipole (HBED), and the right ventricular apex (RVA) in a patient with the Wolff-Parkinson-White syndrome. The vertical line indicates the onset of the delta wave on the surface electrocardiogram. The recording from the ablation electrode shows a discrete atrial (A) and ventricular (V) potential with an interposed high-frequency negative deflection that arises from the accessory pathway (AP). The local AP activation precedes the delta wave onset by 24 ms, and the local ventricular activation precedes the delta wave by 15 ms. H, bundle of His.

In cases in which the accessory pathway is concealed (absent anterograde but intact retrograde conduction), mapping of retrograde activation during ventricular pacing or ongoing orthodromic AV reciprocating tachycardia must be pursued. Some patients do not tolerate the prolonged periods of sustained tachycardia necessary for complete mapping, and the former approach must be employed. Discrimination between retrograde AV nodal conduction and conduction up the accessory pathway may be enhanced by pacing near the pathway's ventricular insertion site. The atrial insertion of the accessory pathway is determined by identifying the site with the shortest interval between the reference ventricular electrogram and the local atrial activation from the mapping and ablation electrode. One must be cautious not to confuse late components of the local ventricular electrogram as early atrial signals. As with anterograde mapping, the presence of a local high-frequency accessory pathway potential is an excellent marker for successful ablation sites.

Using electrogram criteria as described previously, Jackman et al. reported an initial accessory pathway catheter ablation success rate of 99% using a median of three radiofrequency energy deliveries (24). In a comparison of the electrograms from 49 successful versus 462 failed ablation sites, an interval of the local ventricular electrogram to delta wave onset of greater than 10 ms had a sensitivity of 98% for successful ablation, but only a positive predictive value of 11% (57). The low specificity of this finding may have been caused, in part, by inadequate tissue heating by the ablation catheter despite optimal site selection. The presence of ongoing atrial fibrillation can complicate and prolong mapping of accessory pathways because of the absence of consistent atrial electrograms and inability to measure the AV times. However, if the same criteria of local ventricular electrogram to delta wave interval and presence of accessory pathway potentials are employed, a high (95%) success rate can still be achieved (58). The characteristic of the local unipolar electrogram is also useful in identifying successful ablation sites. If the recording electrode is placed directly on the accessory pathway insertion site, all conduction into the ventricle (during anterograde mapping) or atrium (during retrograde mapping) follows a vector away from the electrode. Thus, a QS unipolar electrogram pattern should be more favorable than an electrogram pattern with any initial positive deflection. The positive predictive values of this feature reviewing 186 separate ablation sites in 56 patients were 86% and 92% for ventricular and atrial mapping, respectively. The negative predictive value overall was 92% (59).

Catheter placement for ablation of accessory pathways on the left free wall may be accomplished by two approaches. The catheter may be passed across a small puncture hole in the fossa ovalis (transseptal) (60) or may be prolapsed across the aortic valve and manipulated in the left ventricle back to the mitral annulus (retrograde) (24,25). Direct comparisons of the two techniques have yielded similar success rates (61), although in children and patients older than 65 years, complication and failure rates may be higher with retrograde versus transseptal catheter placement (62). Catheter ablation of right free wall pathways is technically challenging and has a lower success rate than ablation of left free wall pathways (55). It is difficult to stabilize the catheter position on the tricuspid annulus. Because the catheter is relatively fixed with regard to translational movement as it enters the right atrium, the catheter naturally tracks toward the septum and away from the free wall, and the normal movement of the heart in the mediastinum throughout the cardiac cycle causes the catheter tip to slide on the endocardial surface. Multiple accessory pathways are more frequently found in association with right free wall pathways than other locations (up to 10% of cases). A subset of patients with Ebstein's anomaly has a high prevalence of Wolff-Parkinson-White syndrome, often with multiple accessory pathways. Catheter ablation in this group of patients is made more difficult by the fact that the tricuspid valve (the normal anatomic landmark for catheter placement) is displaced downward from the true anatomic annulus where the accessory pathways are located. Septal accessory pathways may be divided into anteroseptal, midseptal, and posteroseptal locations. Anteroseptal and midseptal pathways are located in close contiguity to the normal AV conduction system. Therefore, catheter ablation in these regions may be associated with a higher than normal risk of complete heart block. However, with careful mapping and limited application of radiofrequency energy, successful ablation may be accomplished safely (63,64 and 65). The posteroseptal space is a complex anatomic region characterized by a broad region where the AV valve annuli are offset and diverge, resulting in a region of fatty and connective tissue that is not immediately accessible from endocardial ablation electrode positions and frequently requires ablation from within the coronary sinus (24,54,66).

The anatomic courses of slowly and decrementally conducting accessory pathways that activate the ventricle with a left bundle branch block configuration (previously referred to as *Mahaim's pathways*) have been demonstrated to commonly originate from the right atrial free wall. Discrete pathway potentials may be mapped from the tricuspid annulus, along the right ventricular endocardial surface to arborized insertions into the right bundle branch. Application of radiofrequency energy along this course successfully ablates the pathways and prevents further AV reciprocating tachycardia (64,67,68).

A number of large clinical series of radiofrequency catheter ablations of accessory pathways have been published with excellent overall results (Table 73.1). Presently, experienced electrophysiology laboratories routinely achieve acute procedure success rates in the ablation of accessory pathways of greater than 95%, with recurrence rates of less than 5%. The procedure duration and fluoroscopic exposure have shortened dramatically with increasing knowledge and experience in this field. Accordingly, the indications for catheter ablation of accessory pathways have broadened to include all patients with symptomatic arrhythmias who are refractory to

suppressive drug therapy or who prefer a drug-free lifestyle (69). Although there is little rationale for performing catheter ablation on patients with asymptomatic ventricular preexcitation, this may be pursued on occasion in patients with high-risk or special occupations (such as commercial airline pilots) in whom a single arrhythmic occurrence could have serious consequences.

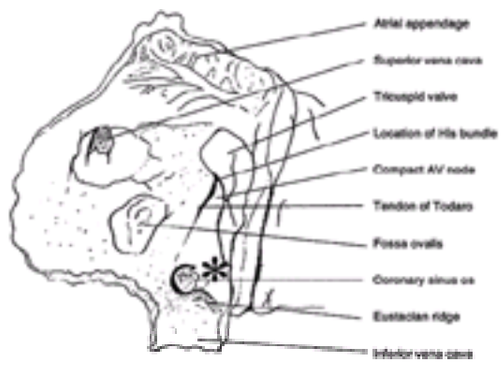
Atrioventricular Nodal Reentry

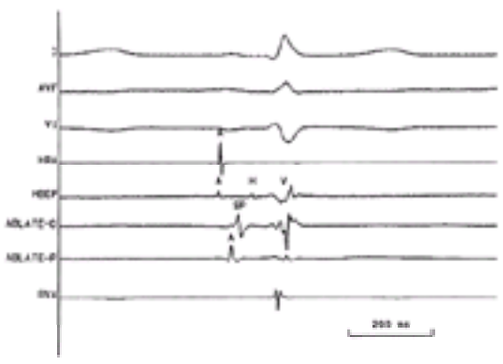
The AV node is located anatomically within the triangle of Koch, which is bounded by the tricuspid annulus, the tendon of Todaro, and the coronary sinus os. The compact AV node is located at the apex of the triangle and makes its transition with nodal-His cells to the common bundle of His. Spreading throughout the remainder of Koch's triangle are atrial transitional cells (atrial-nodal cells) and atrial myocytes. The mechanism of AV nodal reentrant tachycardia is reentrant, using a slowly conducting and a fast conducting pathway in the AV node. The typical form of this arrhythmia has anterograde slow and retrograde fast conduction, whereas the atypical form has the opposite conduction sequence or employs two separate slow pathways for the two limbs of the reentrant circuit. Before the era of catheter ablation, it was commonly hypothesized that the entire reentry circuit was within the compact AV node. However, that notion was challenged by the observation that surgical dissection of the perinodal region successfully eliminated the tachycardia (70). Anatomic study of the AV nodal region has demonstrated the presence of multiple anatomic insertions of atrial myocardium into the transitional cells of the AV nodal region (71). It is currently proposed that these pathways participate as separate pathways in AV nodal reentrant tachycardia. Typically, the atrial insertion of the slowly conducting pathway is located at the inferior-posterior extent of the triangle of Koch, near the coronary sinus os (72). The fast conducting pathway (which is thought to account for "normal" anterograde AV nodal conduction in most cases) is located in the anterior-superior region of the triangle, close to the compact node (eFig. 73.2.1). It is likely that part of the atrium participates in the reentrant circuit, but this point is unproved and somewhat controversial.



***e*FIGURE 73.2.1** Drawing of the right atrium from a right anterior oblique projection with the anterolateral atrial wall cut away. The triangle of Koch is bounded by the tricuspid annulus anteriorly, the tendon of Todaro posteriorly, and the coronary sinus inferiorly. The bundle of His is located at the apex of the triangle. The typical site for mapping and ablation of the slow atrioventricular (AV) nodal pathway is indicated by the asterisk.

Attempts have been made to map the slow pathway region and develop electrophysiologic criteria to identify the optimal site for selective slow pathway ablation. A pattern of double atrial potentials and late atrial activity is often observed along the tricuspid annulus at the base of the triangle of Koch from sites at which the slow pathway may be successfully ablated. It has been suggested that the late atrial potentials may represent slow pathway activation (73). Careful studies comparing the local electrophysiology and histopathology of canine and porcine hearts indicate that late atrial potentials may be attributed to asynchronous activation of the coronary sinus septum and the atrial tissue between the os and tricuspid valve, or to simultaneous activation of superficial transitional AV nodal tissue and a contiguous layer of atrial tissue along the tricuspid annulus (74). Microelectrode impalements in the region of slow potentials have demonstrated action potentials with AV node characteristics (75). This electrographic pattern may represent conduction through the slowly conducting AV nodal pathway but more likely originates from the distal extent of the compact AV node.

Initially, the fast pathway was targeted for ablation, but lower success rates and high rates of symptomatic heart block have led most operators away from this approach and toward slow pathway ablation (76). The technique for slow pathway ablation involves positioning the catheter in the inferior-posterior position of the triangle of Koch at a site where a typical pattern of slow pathway potentials is observed (eFig. 73.2.2). Subsequent catheter movement can be anatomically (77) or map guided (73). Similar success rates and complication rates between the two approaches have been observed (78). During radiofrequency energy delivery at successful sites, one may observe an accelerated junctional rhythm and 1:1 junctional to atrial conduction. The earliest site of retrograde atrial activation in this setting is superior to the tendon of Todaro, suggesting that the automaticity arises distal to the ablation site with conduction through the compact AV node and retrograde up the fast pathway (79).



***e*FIGURE 73.2.2** Surface electrocardiogram tracings I, aVF, and V_1, and intracardiac recordings from the high right atrium (HRA), the proximal bundle of His bipole (HBEP), distal and proximal ablation catheter bipoles (ABLATE-D, ABLATE-P), and the right ventricular apex (RVA) in a patient with typical atrioventricular nodal reentrant tachycardia. The atrial (A), bundle of His (H), and ventricular (V) deflections are labeled. On the distal bipolar tracing from the ablation electrode, a discrete high-frequency potential is observed 25 ms after the contiguous atrial potential measured on the proximal bipole. This electrogram pattern is a marker for local slow pathway (SP) activation.

The clinical success rates for catheter ablation of AV nodal reentrant tachycardia that have been generally reported are high (greater than 95%), and the complication rates low (less than 2%). The results of more recent clinical series are shown in Table 73.2. The major complication that has been reported in conjunction with this procedure is symptomatic heart block, with a prevalence of 0% to 4%. The lower prevalence of heart block in later clinical series compared with earlier may be attributable to an increased use of the posterior (slow pathway) approach, an increased understanding of the electrophysiology and anatomy of the AV nodal region, and improved skills of the individual operators (80). Aside from careful stepwise manipulation and positioning of the catheter, the most useful approach to prevent anterograde heart block is to terminate power delivery if there is evidence of loss of retrograde 1:1 conduction from a junctional tachycardia to the atrium via the fast pathway, because this implies that there is evolving injury to the compact AV node (80). Faster rates of junctional tachycardia have been observed in patients with anterograde heart block versus those without it (cycle length 363 ± 44 ms vs. 558 ± 116 ms, respectively) (81), because accelerated junctional rhythm implies proximity to the compact AV node (82). Some patients show evidence of impaired anterograde conduction before the ablation procedure. Although this may suggest the presence of fast pathway pathology, slow pathway ablation may still be pursued with a low risk of complete heart block (83). The reported recurrence rates of AV nodal reentrant tachycardia after initial successful AV nodal modification procedures are 2% to 15%. The majority of recurrences are reported within the first 2 months of the procedure. Some authors have found an association between persisting dual AV nodal physiology (presence of single AV nodal echo beats or evidence of a shift in anterograde conduction from a fast to a slow pathway) and late clinical recurrence of tachycardia (84), but this is in contrast to the experience of other operators who have not observed that association (85,86). The common practice among most operators is to terminate the ablation procedure once tachycardia can no longer be initiated at baseline or during infusion of isoproterenol and to accept the presence of persisting but impaired slow pathway function.

TABLE 73.2 CLINICAL RESULTS OF RADIOFREQUENCY CATHETER ABLATION OF PATIENTS WITH ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

Atrial Flutter

It has been observed that the dominant activation wavefront during atrial flutter is cranial to caudal along the lateral atrial wall, and caudal to cranial up the septum. Cosio et al. originally determined that the mechanism of this rhythm was macroreentry using the tricuspid annulus as an anatomic barrier. It was hypothesized that the difference between “typical” type I atrial flutter and “atypical” type I atrial flutter was that the former had reentrant activation sequence in a counterclockwise direction around the tricuspid valve in the frontal plane (viewed from apex to base), whereas the latter had a clockwise activation pattern (Fig. 73.3). Cosio et al. also observed that the necessary prerequisite for this arrhythmia was a region of physiologic conduction block between the posterior and lateral atrial walls (90). Without this region of block, the reentrant wavefront would conduct rapidly from the septum around the posterior wall of the atrium and render the lateral wall of the atrium refractory, thus preventing propagation of the subsequent reentrant wavefront. Subsequent mapping studies in humans using intracardiac ultrasound and careful entrainment mapping techniques have demonstrated physiologic conduction block in the posteromedial (sinus venosa) region of the right atrium during atrial flutter (91).

FIGURE 73.3 Surface electrocardiogram tracings I, aVF, and V_1, and intracardiac recordings from ten bipolar recording pairs (RA1 to RA10) positioned around the tricuspid annulus. RA1 is located on the low interatrial septum, RA3 is on the high septum, RA7 is on the high lateral wall, and RA10 is on the low atrial wall. The distal bipole of the ablation catheter (ABLATE-D) is positioned at the tricuspid-inferior vena cava isthmus. The arrows demonstrate the pattern of activation during ongoing atrial flutter. This is an example of typical “counterclockwise” atrial flutter in that the pattern of activation (viewing the heart from apex to base) rotates in that direction.

Understanding the path of reentry of atrial flutter led researchers to identify critical sites of conduction that would be amenable to catheter ablation in order to cure this arrhythmia (92,93). Cosio et al. pioneered the present-day approach of anatomically guided catheter ablation of atrial flutter. They reasoned that the reentrant circuit should always uses the subeustachian isthmus between the inferior vena cava orifice and the tricuspid annulus as a requisite limb of the reentrant circuit. They then demonstrated that a line of radiofrequency ablative lesions traversing this isthmus was successful in terminating atrial flutter (94).

The anatomically guided techniques that are currently used in radiofrequency ablation of typical atrial flutter typically employ an ablation catheter with a large tip electrode placed via the inferior vena cava across the tricuspid valve. The catheter is positioned across the subeustachian isthmus on the tricuspid valve, radiofrequency power is turned on, and the electrode is pulled back in a line until the catheter crosses the eustachian valve. Continued conduction across the subeustachian isthmus can be discerned by identification of a site where double potential (indicating electrical activation on either side of a line of conduction block) merges to a single breakthrough potential (95). Useful end points indicating conduction block include a reversal of activation sequence through the isthmus or change in bipolar electrographic polarity beyond the line of ablation (96,97). If conduction across the isthmus persists, further radiofrequency applications may be made to those sites. Wide variability of the anatomy of the subeustachian isthmus among patients has been observed, including width of the isthmus and its position and angle relative to the inferior vena cava (98). Thus, patients with significant right atrial hypertrophy or enlargement have thicker, wider, or more angled geometries in the isthmus region, have arrhythmia recurrence (99), and require a greater number of ablative applications to achieve procedure success (98).

The results of clinical series are presented in Table 73.3. The acute success rate of this procedure now exceeds 90% when performed by experienced operators, and the late atrial flutter recurrence rate is 10% to 20%. Confirmation of bidirectional block of electrical conduction through the isthmus between the tricuspid valve and inferior vena cava has been demonstrated to be an important criterion for the procedure’s success. Despite successful termination and prevention of reinduction of atrial flutter by ablative lesions, some patients still have residual conduction through the isthmus that can result in clinical arrhythmia recurrence (eFig. 73.3.1) (99,100). Success rates may also be improved with the use of irrigated-tip ablation catheters (101). Despite successful ablation of atrial flutter, the patient will likely have clinical recurrence of atrial fibrillation or type II atrial flutter if these arrhythmias were observed clinically before the ablation procedure (98,102,103 and 104). After initiation of antiarrhythmic drugs, particularly type 1C agents, some patients with atrial fibrillation or a combination of atrial fibrillation and atrial flutter convert to pure type I atrial flutter. In these cases, a combination of drug and atrial flutter ablation therapy may be effective in preventing arrhythmia recurrence (105).

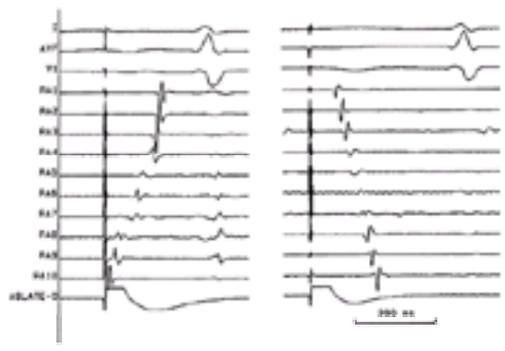
[a]Isthmus block confirmed in a subgroup of 10 patients.

TABLE 73.3 CLINICAL RESULTS OF RADIOFREQUENCY CATHETER ABLATION OF PATIENTS WITH ATRIAL FLUTTER

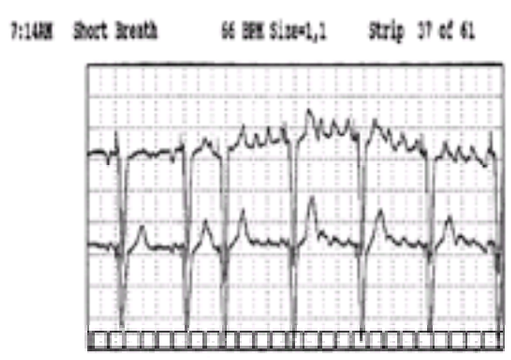


***e*FIGURE 73.3.1** Surface electrocardiogram tracings I, aVF, and V_1, and intracardiac recordings from ten bipolar recording pairs (RA1 to RA10) positioned around the tricuspid annulus as described in Figure 73.3. The roving ablation and pacing catheter (ABLATE-D) is used for pacing after completion of a linear ablation in the isthmus between the tricuspid valve annulus and the inferior vena cava. The left panel demonstrates pacing from a site that is lateral to the line of block. The atrial activation sequence is in a clockwise direction, up the lateral wall and down the interatrial septum. The right panel shows pacing on the low interatrial septum, with the opposite (counterclockwise) atrial activation sequence. These sequences indicate complete bidirectional conduction block at the line of ablation.

Atrial Fibrillation: Palliative Therapy

Atrial fibrillation is the most common sustained arrhythmia in the world, with a reported prevalence of 1.9% for patients under 65 years of age, and 5% to 6% for the population of patients over age 65 (107). The morbidity and mortality of this arrhythmia may be attributed primarily to three factors: the propensity of the fibrillating atria for thrombus formation with the sequelae of systemic thromboembolism including stroke; the loss of atrial systolic function as a contributor to ventricular filling; and the irregular and rapid ventricular rate response leading to symptoms of palpitations and reduction of diastolic filling time. Therefore, the two main strategies for management of patients with atrial fibrillation are maintenance of sinus rhythm with suppressive antiarrhythmic agents or rate control and anticoagulation. If the latter strategy is pursued, warfarin anticoagulation can significantly reduce (but not eliminate) the risk of thromboembolism. Symptomatic palpitations may be reduced with appropriate use of digitalis, beta-sympathetic blockers, or calcium channel blockers. Unfortunately, these drugs are often poorly tolerated, and because the AV nodal blocking action of digitalis is mediated through central vagotonic effects, the ventricular response rate to atrial fibrillation increases dramatically in settings of spontaneous vagolysis (such as exercise). Frequently, adequate doses of AV nodal blocking agents result in symptomatic bradycardia, requiring pacemaker implantation. Therefore, nonpharmacologic means of rate control are sometimes required.

The palliative ablative procedures that are available for the treatment of atrial fibrillation are AV junctional ablation and AV nodal modification. The goal of AV junctional ablation is to interrupt completely the AV conduction with an ablative lesion placed in the vicinity of the compact AV node. In most cases, the patient has a slow but tolerable junctional escape rhythm after AV junctional ablation, which arises from the low compact AV node or high bundle of His region, immediately distal to the site of ablation. This escape rhythm is usually adequate to prevent hemodynamic embarrassment, but not adequate to maintain a normal heart rate at rest or with activity. Therefore, permanent pacemaker implantation is always required. Selection of a single-chamber rate-responsive ventricular pacemaker is appropriate for patients who are in chronic atrial fibrillation. Patients with paroxysmal atrial fibrillation benefit most from implantation of a dual-chamber rate-responsive pacemaker with mode-switching capabilities. These devices maintain AV synchrony when the patient is in sinus rhythm, thus avoiding symptoms of pacemaker syndrome. After atrial fibrillation onset, the device automatically recognizes the atrial tachycardia and effectively converts from a dual-chamber to a single-chamber pacing mode, which prevents the pacemaker from tracking the atrium and pacing the ventricle at a high rate (*e*Fig. 73.3.2).



***e*FIGURE 73.3.2** A monitor strip is shown from a patient with paroxysmal atrial fibrillation and flutter, complete heart block after catheter ablation of the atrioventricular junction, and implantation of a mode-switching dual-chamber pacemaker. The initial rhythm is normal sinus with appropriate atrial sensing and ventricular pacing by the pacemaker (DDD mode). There is onset of atrial flutter, but after 1 second of tachycardia, mode-switching criteria are met, and the pacemaker switches to single-chamber pacing (VVI), maintaining a regular rhythm at 60 beats/min.

The goal of AV nodal *modification* procedures is to damage but not destroy all AV nodal conduction. In the ideal case, the patient has adequate basal rates, but the rapid heart-rate acceleration exercise is prevented. It is important to note that the atria continue to fibrillate after AV junctional ablation or modification despite excellent heart-rate control and resolution of the patient's symptoms. Therefore, the patient is still at risk for thromboembolic events, and ongoing treatment with warfarin is recommended.

One successful technique of AV junctional ablation employs a temporary backup pacing catheter that is placed in the right ventricular apex, and an ablation catheter that is positioned across the high septal portion of the tricuspid annulus, where the maximal His deflection is observed. The catheter is then withdrawn 5 to 10 mm to the atrial side of the annulus such that the atrial and ventricular electrogram amplitudes are equal, and the bundle of His deflection is low amplitude. In a small minority of cases, it is not possible to achieve AV block with ablation from the right septal approach because of anatomic variation or technical reasons. In these cases, the proximal bundle of His may be approached by advancing the ablation catheter retrograde across the aortic valve and positioning it on the high septum at a site with a large His deflection (108). A marker of successful site selection and ablation is the occurrence of an accelerated junctional rhythm at electrode-tissue interface temperatures above 51°C. Complete AV block is reliably observed at temperatures greater than 58°C (109). If an accelerated junctional rhythm is not observed despite adequate heating, then the catheter should be repositioned and ablation attempted again. When the goal of catheter ablation is modification, not complete ablation of AV conduction, the operator positions the catheter inferior and posterior to the site of maximal bundle of His deflection. Initial ablation attempts should employ low powers or temperatures, which should gradually be increased until the desired effect is achieved. The end point of this procedure is reached when a significant

diminution of ventricular rate response to ongoing atrial fibrillation is observed.

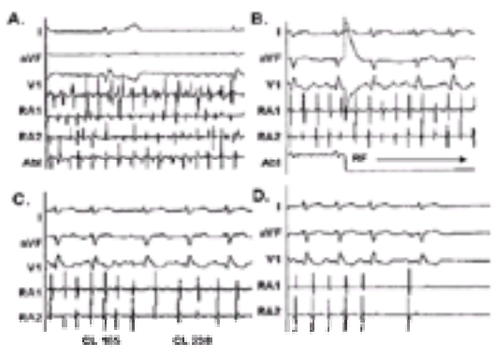
The technical success rate of AV junctional ablation is excellent, ranging from 95% to 100%, when performed by experienced operators (26,108,109 and 110). In appropriately selected patients, marked improvement in symptoms can be anticipated, with decreases in palpitations and effort dyspnea, asthenia, and exertional intolerance. Improvements in exercise time and ventricular function have been measured 3 months postablation (111). In one study of patients with atrial fibrillation and reduced left ventricular function, 90% of patients had improvement in their left ventricular ejection fractions and a decrease in left ventricular and atrial dimensions (112).

The acute success rate of AV nodal modification procedures is approximately 70% (113,114). Because the injury to the AV node is nonspecific, there is a high prevalence of complete heart block with this procedure. Clinical outcome has been favorable in patients with an initial successful response over short-term follow-up, although one late sudden death in a patient with dilated cardiomyopathy has been reported. Even with successful heart-rate control, patients treated with AV nodal modification continue to have an irregular ventricular response to their atrial fibrillation and may have persistent symptomatic palpitations. For this reason, AV junctional ablation and pacemaker implantation is the procedure of choice in most cases.

Atrial Fibrillation: Curative Therapy

The understanding of the pathophysiology of atrial fibrillation has advanced considerably in recent years. The long-standing hypothesis of atrial fibrillation has been that multiple wavelets of reentrant atrial activity conduct throughout both atria, and that reactivation of new wavelets of reentry perpetuate this arrhythmia. Factors that promote the formation and increase the number of wavelets have been associated with clinical atrial fibrillation propagation (115,116). An alternative hypothesis of reentrant atrial fibrillation propagation is that a dominant rotor of atrial reentrant activation drives the arrhythmia and the remaining atrium is passively activated (117). The regions of dominant periodic electrical activity measured in experimental atrial fibrillation have a characteristic frequency of 7 to 10 Hz, corresponding to atrial rates of 400 to 600 beats/min. In 1997, Jais et al. made the groundbreaking observation that some patients had atrial fibrillation on the basis of rapid firing of arrhythmogenic foci (118). These foci were found to arise predominantly from the pulmonary veins, and some patients had two or more focal sources of arrhythmia origin (119,120). Patients with atrial fibrillation of focal origin tend to be younger, have multiple brief paroxysms of arrhythmia, and most commonly have normal hearts. However, a continuum probably exists between these patients and those with persistent atrial fibrillation, structural heart disease, and a reentrant mechanism of atrial fibrillation. It is likely that patients with minimal to moderate heart disease and recurrent episodes of atrial fibrillation that are prolonged or persistent have focal initiation of their arrhythmia with reentrant propagation.

Atrial fibrillation that is dependent on reentrant propagation requires a minimal geographic region for the maintenance of the driving wavelets or rotor. If lines of anatomic conduction block are placed such that this critical circuit size cannot be achieved, then the fibrillation cannot propagate. This was the theoretical basis of the surgical maze procedure (121). It was hypothesized that similar long linear atrial lesions could be achieved by catheter ablation. Experimental studies have demonstrated that multiple linear lesions in the right and left atria can prolong atrial fibrillation cycle length and, ultimately, terminate this ongoing arrhythmia (eFig. 73.3.3) (122). The first cases of linear atrial fibrillation ablation in patients were reported by Swartz et al., who employed a technique of dragging a typical 4-mm tip ablation electrode on multiple lines along the atrial wall during ongoing radiofrequency energy delivery. Chronic atrial fibrillation could be successfully terminated in the majority of cases, but over one-half of the patients had arrhythmia recurrence and required at least a second ablation session. In addition, significant complications including stroke were observed (123). Haissaguerre et al. employed a multiple-ring electrode catheter that, when positioned tangentially to the atrial walls, allowed sequential multiple electrode radiofrequency energy delivery and achieved long linear lesions. In his series of 45 patients with drug-refractory paroxysmal atrial fibrillation, a staged procedure was performed with linear ablation, focal atrial tachycardia ablation, or both in the right, left, or both atria. Success, defined as less than one symptomatic episode of 6 hours' duration in 3 months with or without additional suppressive antiarrhythmic drug therapy, was achieved in 21 patients (47%) (124).



***e*FIGURE 73.3.3** Surface leads I, II, and aVF and intracardiac tracings from two right atrial (RA) sites and an ablation catheter (Abl) during linear atrial ablation for persistent atrial fibrillation. **A:** The rhythm at baseline before any linear ablations. The atrial fibrillation is disorganized and rapid. **B:** The onset of radiofrequency energy delivery (RF) after completion of a partial set of linear atrial ablations. The atrial fibrillation has been organized to a type II atrial flutter by the previous lesions. **C:** A transition from fast to slower atrial reentrant tachycardia during ongoing radiofrequency energy delivery. This suggests that the remaining reentrant circuit size was suddenly increased as conduction through a residual gap in the linear lesions was blocked and the reentrant circuit increased in length. **D:** With ongoing radiofrequency energy delivery, the slower tachycardia is ultimately terminated.

Linear atrial ablation can be accomplished by a point-to-point technique, a "drag" approach, or with multiple electrode side-contact catheters. At this time, the lines that are targeted are anatomically determined. Most investigators agree that some approach to isolate the pulmonary veins and a tricuspid-caval isthmus lesion is important for procedure success. Other lesion locations that are of potential value include a lesion that connects the encircling pulmonary vein lesions to the mitral annulus, a lesion extending anteriorly from the pulmonary vein lesions to Bachmann's bundle, a vertical intercaval lesion in the right atrium, and a vertical right or left septal lesion. Although a pattern of transition from disorganized to organized atrial fibrillation has been described as a favorable observation in the modification of atrial fibrillation wavelet conduction, most present-day linear ablation procedures are anatomically guided, not map guided. Because the relationship of the linear lesions to anatomic structures and the contact between the catheter and tissue are important factors in procedure success, advanced imaging modalities such as intracardiac echocardiography have been useful tools in this procedure (125).

Reported series of linear atrial ablation have employed a variety of techniques and tools to achieve continuous and transmural linear lesions (Table 73.4). Comparison among trials is difficult for a variety of reasons. The patients studied likely include a mix of both focal and reentrant mechanisms. The ablation targets vary among right atrial, left atrial, and biatrial procedures. The definitions of procedure success may or may not include concomitant suppressive antiarrhythmic drug therapy. Finally, the follow-up durations of all the studies are relatively short. Some common themes in linear ablation are emerging. Many investigators have concluded that ablation in the right atrium alone has a low success rate, and in most cases left atrial or biatrial ablation is required. A consequence of creation of incomplete lesions is arrhythmia exacerbation (proarrhythmia) caused by the production of scar-related left atrial "flutter" (126). The complexity and long duration of these procedures may increase their complication rate relative to standard catheter ablation procedures. The field of linear atrial ablation is still evolving, but available data suggest that transcatheter approaches achieve a far lower success rate than that observed with open surgical procedures such as the maze operation. This outcome is most likely caused by residual gaps in linear ablation lines from the catheter-based approaches that allow for the continued propagation of reentrant atrial fibrillation wavelets (127). As the technology of catheter-based linear ablation improves, success rates may ultimately approach those of the open surgical procedure. Alternatively, minimally invasive surgical maze procedures may supplant the catheter approaches if high success rates can be achieved with minimal surgical morbidity.

TABLE 73.4 CLINICAL RESULTS OF LINEAR ATRIAL ABLATION OF PATIENTS WITH ATRIAL FIBRILLATION

Identification of a focal mechanism of atrial fibrillation initiation led to advances in curative therapy for atrial fibrillation in selected patients. It was initially described by Jais et al. that foci of rapid electrical firing could trigger atrial fibrillation (118). Follow-up studies from the same group in a larger series (119), as well as studies from Chen et al. (120), confirmed that focal atrial fibrillation is a significant clinical entity and is very treatable by limited catheter ablation techniques. The majority of triggering foci for atrial fibrillation arises from the sleeve of muscular tissue that extends from the left atrial body into the pulmonary veins. The average extension of these muscle fibers into the vein is greater for the superior pulmonary veins (30 to 40 mm) than the inferior pulmonary veins (15 to 20 mm) (120). Although mapping studies indicate that they are truly focal in nature (135), the precise mechanism of these beats (microreentrant, automatic, or triggered) has not been clearly defined. In many cases, the focal activity is increased by adrenergic stimulation or rapid pacing and blocked by beta-adrenergic blocking drugs and calcium channel blockers (120), suggesting triggered activity as the most likely arrhythmia mechanism. The reason for the clustering of triggering foci in the pulmonary veins is unknown at this time. Other less prevalent sites of origin of triggering foci include the ligament of Marshall (a remnant of the left superior vena cava on the posterior left atrium) (136), the crista terminalis in the right atrium, and the superior vena cava (137).

The techniques of focal atrial fibrillation ablation are still in evolution. However, most investigators perform extensive pulmonary vein mapping via a single- or double-transseptal catheterization technique to attempt to identify the site(s) of arrhythmia origin. Advanced technologies such as multielectrode basket catheters, noncontact mapping, electroanatomic mapping, and intracardiac echocardiographic imaging have all been useful adjuncts toward successful ablation of the arrhythmogenic substrate. Some investigators have proposed using an anatomically derived procedure, with ablation of the bases of all pulmonary veins, foregoing the requirement for mapping (138). Because approximately 90% of the sites of arrhythmia origin seem to arise from the pulmonary veins, the anatomically guided ablation approach may ultimately be the most effective and time efficient. Unfortunately, the limitations of current ablation catheter technology coupled with the significant anatomic variability of pulmonary veins have curtailed the success of this approach.

VIDEO

Video 73.1 An isopotential activation map recorded from a 64-pole multielectrode basket mapping catheter placed in the left superior pulmonary vein in a patient with atrial fibrillation of focal origin. Two sequential atrial activation sequences are shown. The first beat shows activation of a sinus beat from the left atrium to the base of the pulmonary vein (*bottom*) and into the body of the vein (*top*). The second beat shows activation of a premature atrial beat initiating atrial fibrillation. The origin of activation is within the vein at site H3 with conduction around the vein body to the opposite wall. Of note: techniques may evolve, but it is likely that the overall outcome statistics will not change significantly. The main frontiers remaining in catheter ablation are curative therapy from atrial fibrillation and reentrant ventricular tachycardia. A wide variety of ablation tools are being developed for atrial fibrillation. But more importantly, selective linear atrial ablation will help us understand the pathophysiology of this complex arrhythmia, and direct us to the optimal ablation targets to achieve arrhythmia cure. Reentrant ventricular tachycardia is often hemodynamically unstable precluding prolonged periods of mapping. New mapping tools will allow for rapid ablation site section. Because ablation targets are frequently mid-myocardial or subepicardial, larger and deeper lesions that can be created with conventional radiofrequency energy ablation will be required for procedure success. Future innovative catheter designs and new ablation energy sources may solve this present limitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The early clinical series of pulmonary vein ablation are listed in Table 73.5. Acute success rates of this procedure are high (greater than 95%), but overall success rates are much lower (60% to 86%). There are several possible explanations for the high recurrence rate of atrial fibrillation observed after this procedure. First, the sensitivity of provocative maneuvers for initiating focal trigger activity is limited in some patients. Thus, despite successful ablation of all apparent triggering foci at the time of the procedure, some quiescent foci may emerge later. The more focal sites of origin identified, the lower the procedural success rates (140). Second, the triggering foci can be variable in their activity and can “turn off” coincident with catheter manipulation. Thus, the appearance of successful ablation can be achieved acutely with late recurrence due to reactivation of the focus. Finally, if a pulmonary vein isolation technique is employed, the line of ablation required to isolate the vein may range from 1 to 4 cm in length. Any recovery of conduction along the line of ablation results in conduction of the rapid atrial impulses from the targeted vein. Complications in focal atrial fibrillation ablation include all those related to all catheter ablation procedures. In addition, the unique complication of pulmonary vein stenosis may occur if ablation powers and temperatures are not limited (120,141). Also, the risk of systemic thromboembolism is probably higher than that observed with other left-sided ablation procedures because of the increased instrumentation and longer procedure duration, but the exact prevalence of this complication is not known.

TABLE 73.5 CLINICAL RESULTS OF FOCAL ATRIAL ABLATION OF PATIENTS WITH PAROXYSMAL ATRIAL FIBRILLATION

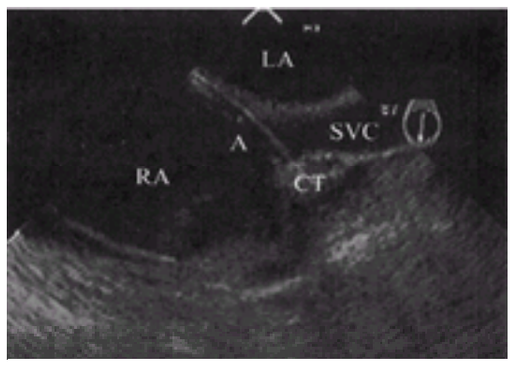
The ultimate success of atrial fibrillation ablation will rest with the development of the ablation tools and further understanding of the pathophysiology of this arrhythmia in different patient subsets. Ultimately, the proof of its value will depend on its ability to eliminate symptoms, restore normal left atrial mechanical activity, and prevent late thromboembolic complications.

Other Atrial Arrhythmias

Tachycardias that arise from the sinus node region include sinoatrial reentrant tachycardia and “inappropriate” sinus tachycardia. The former is characterized by its paroxysmal nature, the ability to initiate and terminate the rhythm with programmed atrial stimulation, and a P-wave morphology and intraatrial activation sequence that are indistinguishable from normal sinus rhythm. This is an uncommon arrhythmia and therefore the experience with ablative therapy is somewhat limited. It typically has its origin in the high atrial region at the junction between the atrium and superior vena cava in the classical sinus node anatomic region. The optimal site of ablation may be identified by searching for the earliest site of atrial activation relative to the P-wave onset. Ablation in this region results in termination of the tachycardia and frequently results in a slight shift of sinus node activation to a lower site along the crista terminalis (142,143). Although most patients have normal sinus node function postablation, sinus node dysfunction requiring pacemaker implantation is a potential risk. The reported clinical series are limited, but include one description of 11 patients who were identified out of a cohort of 343 consecutive patients referred for electrophysiologic evaluation of supraventricular tachycardia. Nine of the 11 patients had additional tachycardia mechanisms identified. Radiofrequency catheter ablation was successful in all ten patients in whom it was attempted, and no complications were noted (143).

Inappropriate sinus tachycardia is similar in P-wave morphology and atrial activation sequence to sinoatrial reentry and normal sinus rhythm, but does not follow a paroxysmal pattern and sometimes occurs incessantly. Patients with this arrhythmia have an exaggerated heart-rate response to minor physiologic stresses and often have heart rates greater than 100 beats/min at rest. It is important to confirm that patients presenting with apparent inappropriate sinus tachycardia do not have the postural orthostatic tachycardia syndrome (144). These patients have a marked compensatory sinus tachycardia because of failure of peripheral autonomic vascular response to orthostatic stress. “Successful” sinus node ablation in these patients may result in crippling hypotension. For patients with true inappropriate sinus tachycardia, catheter ablation has been successfully performed by targeting a relatively broad region of the superior crista terminalis for radiofrequency energy delivery (*e*Fig. 73.3.4). Lee et al. used intracardiac echocardiography to assist catheter positioning and were able to achieve complete sinus node ablation in four of four

patients, and successful arrhythmia modification (defined as a 25% reduction in sinus rate) in 12 of 12 patients (145). However, permanent atrial pacing was required in two patients, arrhythmias recurred in short-term follow-up in two patients, and two patients had significant procedural complications (transient superior vena cava syndrome and phrenic nerve injury). Thus, catheter ablation for inappropriate sinus tachycardia may be useful in the management of these challenging patients, but it should not be considered as first-line therapy.



***e*FIGURE 73.3.4** Transesophageal echocardiogram of a patient undergoing modification of the sinoatrial node. The image is oriented as follows: superior to the right; inferior to the left; posterior on the top; and anterior on the bottom. A longitudinal sector through the left atrium (LA), right atrium (RA), and superior vena cava (SVC) is seen. The ablation catheter (A) is positioned in contact with the superior aspect of the crista terminalis (CT). Earliest atrial activations during episodes of inappropriate sinus tachycardia were mapped to this site.

Atrial tachycardia is a rhythm that may originate from either the left or right atrium and may be caused by reentry or triggered or abnormal automaticity. In the right atrium, it commonly arises from the crista terminalis, although its origin may also be low atrial septum or right atrial appendage. In the left atrium, the arrhythmia origin is most often from the origins of the pulmonary veins. Surface electrocardiography can be useful to determine the arrhythmia site of origin. A positive or biphasic P wave in surface lead aVL suggests a right atrial origin, whereas a positive P wave in V_1 and a negative P wave in aVL imply a left atrial arrhythmia origin (146).

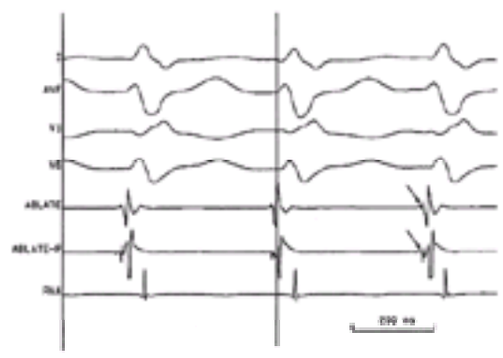
Because the right pulmonary veins are located posterior and rightward from the right atrial septum, the surface P-wave morphology can sometimes be inaccurate in predicting the arrhythmia site of origin. Mapping of atrial tachycardia is best achieved with activation mapping to identify local atrial activity before onset of the surface P wave, pace mapping to identify a site where the paced P wave is identical to the spontaneous tachycardia P wave, and paced activation sequence mapping where the relative activation timing from multiple atrial recording sites is identical between pacing and spontaneous tachycardia. Using this approach, Tracy et al. successfully ablated eight of ten patients, one of whom had multiple foci. Two patients had clinical recurrence, and one was successfully reablated (147).

ABLATION OF SPECIFIC VENTRICULAR ARRHYTHMIAS

Idiopathic Ventricular Tachycardia

Patients with structurally normal hearts may have ventricular tachycardia with a variety of underlying arrhythmia mechanisms. Idiopathic ventricular tachycardia most commonly arises from the right ventricle in the outflow tract below the pulmonic valve. These arrhythmias tend to fall into two main categories. Repetitive monomorphic ventricular tachycardia is characterized by multiple repeating bursts of nonsustained ventricular tachycardia and high-density premature ventricular beats. These arrhythmias may be increased in the setting of catecholamine stress, but frequently are suppressed in the setting of catecholamine-induced increases in sinus rate. It is hypothesized that the mechanism for repetitive monomorphic ventricular tachycardia is abnormal automaticity (148). Catecholamine-sensitive ventricular tachycardia may be nonsustained or sustained. Because these arrhythmias are catecholamine sensitive, they are frequently exercise induced. They should terminate in response to intravenous adenosine or verapamil bolus infusions. It is hypothesized that the mechanism for these arrhythmias is triggered automaticity. The typical features of these arrhythmias on 12-lead electrocardiograms include a left bundle branch block morphology, an inferior frontal plane axis, and a relatively isoelectric complex in surface lead (149,150). Idiopathic ventricular tachycardia of left ventricular origin is typically a reentrant tachycardia that uses Purkinje's network as part of its reentrant circuit. The site of slowed conduction in the reentry circuit has not been well characterized, but it is typically sensitive to verapamil and not to adenosine (151,152). This feature allows for differentiation of this arrhythmia from the rare left ventricular form of adenosine-sensitive left ventricular tachycardia that has a presumed triggered automatic mechanism (45). As anticipated, idiopathic left ventricular tachycardias have a right bundle branch block morphology on the surface 12-lead electrocardiography.

The mapping techniques used to ablate idiopathic ventricular tachycardias of focal origin include activation mapping, pace mapping, electroanatomic mapping, and body surface electrocardiographic mapping. Episodes of sustained or nonsustained ventricular tachycardia should be initiated with rapid ventricular pacing, isoproterenol infusion, or both. During ongoing tachycardia, the local ventricular activation should precede the onset of the surface QRS complex by 20 to 80 ms. Pacing from that site should result in a 12-lead electrocardiogram or body surface electrocardiogram that is identical in all leads to that recorded during tachycardia (149,153,154,155,156,157,158 and 159). Since these tachycardias are focal in origin, unipolar mapping at optimal ablation sites yields rapid negative deflections that precede the QRS onset, indicating that all local activations are emanating from, and conducting away from, those locations (160). Because these arrhythmias are autonomically sensitive and sometimes cannot be initiated in the artificial setting of the electrophysiology laboratory, precise mapping of the site of origin is not possible. Some patients, however, have unifocal premature ventricular contractions that are identical in morphology to those of ventricular tachycardia and presumably share the same origin and mechanism. In these cases, it is appropriate to map the unifocal premature beats as a guide to catheter ablation. A marker for successful site selection for catheter ablation is immediate acceleration then termination of the ventricular tachycardia coincident with the delivery of radiofrequency current. The site of origin of idiopathic verapamil-sensitive left ventricular tachycardia may be best identified by activation mapping during ongoing tachycardia. Discrete high-frequency Purkinje's potentials precede the site of earliest ventricular activation during tachycardia by 15 to 42 ms. These potentials are identified in the mid- or distal inferior septum or free wall and also precede local ventricular activation during sinus rhythm (155). In the same anatomic region, late diastolic potentials may be identified preceding Purkinje's potential activation by a mean of 35 ms. During entrainment, the interval between the late diastolic potentials and Purkinje's potentials shows decremental conduction properties (161). Catheter ablation at the site of fusion of the Purkinje's potential into the early ventricular potential yields a high success rate of arrhythmia termination and cure (eFig. 73.3.5) (155).



***e*FIGURE 73.3.5** Surface electrocardiographic leads I, aVF, and V_1 and intracardiac electrograms from the distal (ABLATE) and proximal (ABLATE-P) poles of the mapping and ablation catheter, and the right ventricular apex (RVA). The rhythm is idiopathic left ventricular tachycardia. The vertical line corresponds to the onset of the surface QRS complex and is preceded by local ventricular activity recorded by the ablation electrode. The arrows represent Purkinje's potentials, which precede local ventricular activation at this site. Catheter ablation at this location terminated this ventricular tachycardia.

The reported clinical success rate of catheter ablation of idiopathic ventricular tachycardia is 76% to 100% and generally greater than 90% for those arrhythmias arising from the right ventricular outflow tract (Table 73.6). The reported complications with this procedure have been infrequent. Two cases of pericardial effusion (one requiring pericardiocentesis) were observed in a series of 44 patients undergoing radiofrequency ablation of ventricular tachycardia in the right and left ventricles (161). One case of catheter-induced mitral regurgitation has been reported as a consequence of catheter manipulation in the left ventricle (155).

TABLE 73.6 CLINICAL RESULTS OF RADIOFREQUENCY CATHETER ABLATION OF PATIENTS WITH IDIOPATHIC VENTRICULAR TACHYCARDIA

Reentrant Ventricular Tachycardia with Structural Heart Disease

Patients with structural heart disease have varying degrees of fibrosis interspersed among bundles of surviving myocardial bundles. The most common arrhythmogenic substrate among patients with reentrant ventricular tachycardia is chronic ischemic heart disease. The central portion of a complete transmural scar from prior infarction is commonly electrically inactive, but some broad wavefronts of slowed conduction can occur across this region in a thin surviving endocardial layer (162). The border zone of the scar is extremely heterogeneous, making it an ideal substrate for reentry. A typical reentrant circuit uses these small myocardial bundles at the scar border zone as regions of slowed conduction (163). Conduction through these regions accounts for the isoelectric period between QRS complexes on surface electrocardiography, particularly with slower tachycardias. The return circuit is complex and uses the surrounding myocardium on one or both sides of the central conduction zone, thereby creating a circular or a figure-eight conduction pattern (164,165). In patients with posterior scars, the central conduction zone is often the isthmus between the scar and the mitral valve annulus (166). The slow conduction zone is characterized by a zigzag activation sequence through regions of patchy fibrosis. Most of the conduction delay is seen at the site of conduction from one fiber to another perpendicular to the fiber orientation (167).

The precise courses of the reentrant wavefronts in the ventricular tachycardias of patients with nonischemic myopathies are not well understood. Diffuse regions of fibrosis mingling with normal or hypertrophied myocytes are typically observed and create a substrate for reentrant rhythms (168). However, the diffuse nature of the structural abnormalities allows for dynamic changes in the reentrant circuits beat to beat and makes these patients more prone to polymorphic ventricular tachycardias. An interesting variant of ventricular tachycardia found predominantly in patients with dilated cardiomyopathy is bundle branch reentrant tachycardia. This is a macroreentrant tachycardia that uses one limb of the bundle branches in an anterograde fashion and another limb in a retrograde fashion (167). It is important to recognize this arrhythmia mechanism because bundle branch reentrant tachycardia is easily treated by ablation of the right or left bundle branch (170,171). Unfortunately, many of these patients have concomitant ventricular tachycardias of myocardial origin that require treatment despite elimination of the bundle branch reentry.

The critical zone for propagation of ventricular tachycardia is located in the septum or left ventricular free wall in most patients with reentrant ventricular tachycardia and structural heart disease. The one notable exception is ventricular tachycardia in patients with arrhythmogenic right ventricular dysplasia. A clinical presentation of a patient with normal left ventricular size and function and a tachycardia with a left bundle branch block morphology might suggest the diagnosis of idiopathic ventricular tachycardia. Careful evaluation of these patients with high-quality echocardiography of the right ventricle or contrast cine right ventriculography is necessary to identify those rare cases of right ventricular dysplasia (172). Mapping and entrainment studies of ventricular tachycardia in these patients have demonstrated that the common locations of the reentrant circuit sites were around the tricuspid annulus and in the right ventricular outflow tract (173). Of interest, a cohort of patients undergoing repeated attempted ablation of ventricular tachycardia arising from the right ventricular outflow tract underwent magnetic resonance imaging scanning. Despite normal right ventricular size and function and the presumptive diagnosis of idiopathic focal ventricular tachycardia, 65% of these selected patients had evidence of fatty deposition, wall thinning, or dyskinesis (174).

Mapping and ablation of reentrant ventricular tachycardia is challenging, associated with a lower overall success rate than those of other tachycardias, and currently limited to a highly selected subset of patients. Identification of the optimal ablation site is time-consuming and is usually performed while the patient is in ongoing tachycardia. Therefore, only patients with slower, monomorphic, hemodynamically tolerated tachycardias are good ablation candidates. A nonfluoroscopic mapping system relies on point-to-point mapping, but has the unique feature of precise spatial localization of the catheter tip within a low-level magnetic field. This allows the operator to map without using fluoroscopy and builds an anatomic as well as an electrical map of the ventricle (175). Multielectrode basket catheters with up to 64 recording electrodes or multielectrode balloon catheters that create a high-resolution endocardial map by employing a mathematical technique called the *inverse solution* may allow for rapid localization of the tachycardia site of origin with acquisition of complete mapping data from only two or three beats of tachycardia, thereby allowing mapping in some patients with tachycardias that are poorly tolerated hemodynamically (176,177). The ultimate clinical utility of these and other advanced mapping tools remains to be demonstrated.

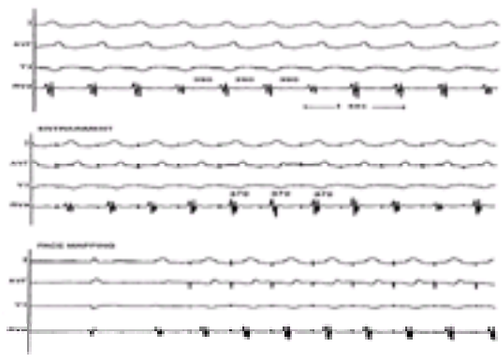
VIDEO

Video 73.2 An isopotential activation map during sustained monomorphic ventricular tachycardia is shown. Electrograms are recorded from a 64-pole multielectrode basket mapping catheter placed in the left ventricle and replayed in a global three-dimensional looping format at slow speed. Electrograms from seven bipoles from one recording spline are shown in the left window. The bottom window shows surface electrogram lead II. The right window shows that basket electrode in a right anterior oblique orientation. The base of the catheter emanates from the aortic valve. The earliest ventricular activation, representing the exit site from the slow conduction zone of the tachycardia, is observed on the high basal interventricular septum. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The critical slow or central conduction zones of reentrant ventricular tachycardias are often found in the midmyocardial or subepicardial planes (178). Conventional radiofrequency catheter ablation produces a relatively small and shallow lesion that may not be adequate to disrupt deeper arrhythmogenic substrates. New technologies, including the chilled tip (35) and the perfused tip (34) radiofrequency catheters and microwave (37), laser (179), or ultrasound (180) catheter ablation, may ultimately achieve reliable transmural ventricular lesions and improve ablation success rates.

The techniques routinely employed for mapping reentrant ventricular tachycardias include activation mapping and entrainment mapping. Activation mapping entails identification of sites with local electrograms that precede the onset of the surface QRS complex during ongoing tachycardia. These sites, which manifest presystolic activation, represent the exit sites of the reentrant rhythm from the central or slow conduction zone. Pace mapping from these locations often results in surface 12-lead electrocardiograms that closely match the ventricular tachycardia morphology. The anatomic substrate of this arrhythmia is complex, however, and a number of potential exit sites probably exist. Radiofrequency ablation at exit sites may change the tachycardia morphology, but unfortunately, it is rarely completely eliminated.

Entrainment mapping appears to be the best method for identification of the optimal site for ventricular tachycardia ablation. Pacing is performed at a rate that is slightly faster than the ongoing tachycardia from a mapping catheter positioned on or near the reentry circuit. In this case, each paced beat advances the tachycardia slightly by entering the excitable gap between the depolarizing wavefront of reentry and the tail of refractoriness of the previous beat, and the tachycardia becomes *entrained.* If pacing is performed directly on a critical part of the circuit that is isolated from conduction to the remainder of the heart with the exception of the tachycardia exit site, then the surface QRS complex during entrainment exactly matches that of the tachycardia. These sites of *concealed entrainment* correspond to the zone of slowed conduction and are optimal sites for attempted catheter ablation (eFig. 73.3.6). Stevenson et al. reported that sites of successful ventricular tachycardia termination by radiofrequency energy were more likely to fulfill criteria for concealed entrainment than unsuccessful sites. Optimal sites also had intervals measured from the last paced beat to the next tachycardia, which were nearly identical to the tachycardia cycle lengths when measured at the pacing site. This finding indicates that the pacing site is likely to be within the reentry circuit, rather than in a “blind alley.” Success of catheter ablation was also highest when radiofrequency ablation was performed near the middle of the slow conduction zone (defined by a stimulus to QRS interval during entrainment pacing of greater than 60 ms and less than 70% of the ventricular tachycardia cycle length) or when isolated diastolic potentials, continuous electrical activity, or both were recorded from the ablation catheter (181). Other criteria for successful ablation site selection include an exact QRS match between entrained and spontaneous ventricular tachycardia, and an activation time between the local electrogram to the onset of the surface QRS almost identical to the stimulus to QRS interval during spontaneous ventricular tachycardia (182,183).



***e*FIGURE 73.3.6** Surface electrocardiographic leads I, aVF, and V_1 and intracardiac electrograms from the right ventricular apex (RVA) in a patient with sustained ventricular tachycardia and a history of prior myocardial infarction. Ongoing tachycardia with a cycle length of 390 ms (*top panel*). Entrainment pacing at a cycle length of 370 ms during ongoing tachycardia (*middle panel*). Note that the QRS morphology during pacing is identical to that of ventricular tachycardia (concealed entrainment), and that there is a delay between the pacing artifact and the QRS onset, indicating that the pacing site is within the zone of slow conduction in the reentrant circuit. Pace mapping during sinus rhythm from the same site (*bottom panel*). The similar QRS morphology to that of ventricular tachycardia suggests that this site is near the exit point of the slow conduction zone, thereby resulting in a similar spread of ventricular activation during pace mapping as seen during tachycardia.

The clinical series of radiofrequency catheter ablation of reentrant ventricular tachycardia are small and comprise a highly selected subset of patients. Because patients must be able to tolerate their tachycardia hemodynamically to allow for mapping, patients with rapid, life-threatening tachycardias are not included in these series. The mean cycle lengths of the tachycardias in the reported clinical series of ablations were greater than 350 ms (less than 171 beats/min), and the patients undergoing ablative therapy made up only 10% to 20% of the overall ventricular tachycardia population. The results of the largest clinical series are summarized in Table 73.7. The reported success rates on the suppression of “clinical” tachycardias with radiofrequency catheter ablation range from 64% to 81%. Patients frequently have “nonclinical” tachycardias, defined as sustained monomorphic ventricular tachycardias with morphologies that have never been observed to occur spontaneously in the clinical setting but that can be induced by programmed ventricular stimulation. In these cases, adjunctive therapy with an implantable defibrillator is usually warranted. An expanding indication for ventricular tachycardia ablation is for patients in whom an implantable defibrillator has been previously implanted, but who are now suffering frequent or incessant runs of slower ventricular tachycardia, resulting in multiple device discharges. Radiofrequency catheter ablation can successfully palliate a significant number of these patients (187,190).

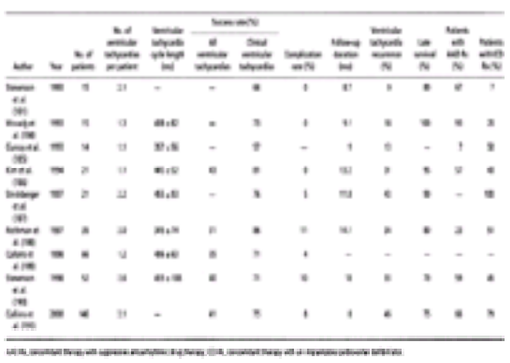


TABLE 73.7 CLINICAL RESULTS OF RADIOFREQUENCY CATHETER ABLATION OF PATIENTS WITH VENTRICULAR TACHYCARDIA IN PATIENTS WITH STRUCTURAL HEART DISEASE

An uncommon but important subset of patients with ventricular tachycardia are those with bundle branch reentrant tachycardia. This is a macroreentrant rhythm most commonly found in patients with dilated cardiomyopathy and conduction system disease. The reentrant wavefront uses one bundle branch in an anterograde fashion and one bundle branch for retrograde conduction. It is a rapid, potentially life-threatening rhythm found in as many as 5% of patients with ventricular tachycardia (192) and is readily treatable with catheter ablation. Bundle branch reentrant tachycardia may be identified by the presence of a bundle of His deflection that precedes each ventricular depolarization and shows identical beat-to-beat variability as the subsequent ventricular beats. In typical cases in which the right bundle branch is one limb of the circuit, the ablation catheter is positioned across the tricuspid valve beyond the common bundle of His, and the right bundle branch is selectively ablated. Using this approach, bundle branch reentrant tachycardia was successfully ablated in 42 of 42 patients in one clinical series (193). However, the presence of other concomitant ventricular tachycardias and underlying myopathic disease portends a poor prognosis even with successful ablation. In the previously mentioned studies, 23 of 42 patients died during the 16-month follow-up, and 13 of these died suddenly.

COMPLICATIONS OF CATHETER ABLATION

The field of radiofrequency catheter ablation has been met with tremendous enthusiasm by physicians and patients alike and had tremendous growth in its first decade in both numbers of procedures performed and in indications for the procedure (194). A natural consequence of this phenomenon is that the number of interventional electrophysiologists has also dramatically increased. The time and intensity of training required to become proficient in this field are considerable. It is necessary that the ablating physician have a detailed understanding of electrophysiologic mechanisms of arrhythmias, an excellent three-dimensional conceptualization of the anatomy of the cardiac chambers in which the ablation catheters are manipulated, and exceptional technical skill in catheter manipulation. For these reasons, success rates and complication rates of catheter ablation are first and foremost related to the skill and experience of the primary operator (195,196).

The overall reported complication rate from radiofrequency catheter ablation (excluding risks associated with outmoded techniques or tools) is low, ranging from 1.8% to 4.0% (197). The risk of major, irreversible complications is approximately 0.5% to 1.0% and includes events such as complete heart block, myocardial infarction, valvular injury, irreversible stroke, and death. The Multicentre European Radiofrequency Survey documented complications from a total of 4,398 catheter ablation procedures from 68 European institutions between 1987 and 1992. In patients undergoing catheter ablation for treatment of supraventricular tachycardia, the potential complications and their rates were complete heart block (fast pathway ablations excluded), 0.66%; significant vascular injury, 0.63%; pericardial tamponade, 0.60%; clinically significant pericardial effusion, 0.53%; pulmonary embolism, 0.13%; systemic embolism, 0.44%; irreversible stroke, 0.06%; and death, 0.06%. The complications among the 320 patients undergoing catheter ablation for ventricular tachycardia showed similar rates (198). Because this study was characterized by data from a large number of centers near the beginning of their experience with this procedure, the complication rates may be lower now than those initially reported. The data, however, depended on voluntary reporting, and 21% of the institutions solicited for participation did not report data, so there was a possibility of underreporting of events.

Another large study reported data from 1,400 patients who underwent radiofrequency catheter ablation at a single institution. In this large experience, the total prevalence of complications was 3.1%. There were no deaths. The complications reported included systemic embolism, 0.21%; stroke, 0.14%; valve trauma, 0.07%; tamponade, 0.21%; vascular injury, 0.62%; and complete heart block, 0.05%. The risk of complications was significantly higher in patients undergoing radiofrequency catheter ablation than in those undergoing routine diagnostic electrophysiologic study (3.1% vs. 1.1%). Predictors of complicated procedures by multiple logistical analysis included older age and the presence of comorbid systemic disease (199). The overall low risk of complications in this study may be attributable, in part, to the fact that it was performed in a high-volume center with experienced operators.

The final risk assumed by the patient and laboratory staff during catheter ablation procedures is the radiation exposure. Unlike diagnostic procedures in which the total fluoroscopy time is usually under 10 minutes, exposures of greater than 30 minutes occur frequently with ablation procedures. Manipulation of catheters within the cardiac chambers to difficult ablation sites often requires extensive fluoroscopic guidance, and maximum fluoroscopic exposure to the patient and operator can exceed 2 hours. Calkins et al. examined the degree of fluoroscopic exposure during radiofrequency catheter ablation in 31 unselected patients and found that median radiation doses to the thyroid, the ninth vertebral body, and to the iliac crest were 0.46, 7.26, and 2.43 rem, respectively. This translated into a lifetime risk of radiation-induced fatal malignancy of 0.1% for every hour of fluoroscopic exposure, and a risk of genetic defects of 20 per 1 million births (200). New fluoroscopy units that use pulsed energy delivery and improved ablation tools that decrease the time of ablation site access have significantly decreased radiation exposure in recent years, but it still

remains a point of significant concern.

CONTROVERSIES AND PERSONAL PERSPECTIVES

In the last 15 years, radiofrequency catheter ablation has become a dominant modality in the treatment of a number of symptomatic arrhythmias. The popularity of catheter ablation is due in large part to the extremely low complication rate observed by practitioners. The major factor that has limited the number and severity of complications is that the volume of injury produced by radiofrequency catheter ablation is small. Thus, small lesions are associated with minimal endocardial disruption, a low prevalence of significant thrombus formation, a low rate of transmural injury with left ventricular lesions (which eliminates the risk of free wall rupture and significant ablation-induced ventricular dysfunction), and rare prevalence of coronary arterial injury, even though most accessory pathway ablations are performed in close proximity to the epicardial coronary arteries. However, with small lesions come higher skill requirements for target selection. In addition, some targets are inaccessible because of their location deep within the myocardium away from the endocardial plane. For these reasons, investigators have been working to increase dramatically the size of ablative lesions by using novel catheter designs and new energy sources. As the depth and volume of myocardial injury increase with catheter ablation, it is likely that the complications will increase as well. The lingering effects of this injury in young people may not be realized for decades when they present with premature coronary artery disease. Intramural superheating and sudden “popping” result in crater-like lesions with a small but real risk of free wall perforation.

The popularity of catheter ablation therapy may be attributed to the observation that it has been curative in the majority of cases, and the procedure-related morbidity and mortality have been extremely low. Thus, the indications for catheter ablation have continued to broaden. In fact, the majority of patients presenting for catheter ablation of paroxysmal supraventricular tachycardia at the University of Virginia has never failed drug therapy but simply desires a drug-free lifestyle. Although it is often an appropriate decision to subject an otherwise healthy patient to the risk of an invasive procedure if one can eliminate the requirement of lifelong drug therapy, not all patients with arrhythmias amenable to catheter ablation should undergo this therapy. It is still appropriate to pursue vagal maneuvers and medical therapy with AV nodal blocking drugs before performing interventional therapy. Although a supraventricular tachycardia may cause significant symptoms, it is not a life-threatening arrhythmia.

Most arrhythmia experts will agree that symptomatic patients with the Wolff-Parkinson-White syndrome should undergo diagnostic electrophysiologic testing to determine if they have an increased risk of fatal arrhythmias. Because the main morbidity of catheter ablation is caused by the placement of multiple diagnostic catheters in the heart, it is common practice to proceed with ablation of the accessory pathway even if it is determined to be low risk. The approach toward asymptomatic patients with evidence of ventricular preexcitation on the electrocardiogram is somewhat variable. The natural history of these patients suggests that no evaluation or therapy is needed until and unless they develop symptoms. However, a potential for dangerous arrhythmias may exist in pediatric patients who have yet to present with clinical arrhythmias. Thus, there is some rationale for studying and ablating pediatric Wolff-Parkinson-White patients.

The field of curative atrial fibrillation ablation is advancing rapidly. The outcomes of catheter ablation for atrial fibrillation with a focal mechanism are good enough that many practitioners are offering this as a clinically indicated procedure. Presently, there is significant variability among laboratories as to the techniques employed and the patient selection criteria. Thus, determining the best approach to employ has been difficult. It is clear that this procedure is becoming more anatomically guided. It is hoped that with development of the tools for this procedure, procedure times will decrease and success rates will increase. Presently, patients with frequent bursts of self-terminating atrial fibrillation and atrial tachycardia and normal hearts should be strongly considered for ablative therapy. Patients with structural heart disease and longer, less frequent atrial fibrillation episodes should probably only be considered for curative catheter ablation as a final alternative to AV junctional ablation and pacemaker implantation. Linear ablation is presently investigational only and should not be considered as an alternative to drug therapy. Highly motivated patients who have failed multiple drug trials are appropriate candidates for this procedure, but it must be acknowledged that the risks of the procedure may ultimately outweigh its benefits.

Catheter ablation for the treatment of ventricular tachycardia in patients with structural heart disease has not emerged as a dominant modality. In fact, most practitioners employ catheter ablation as a palliative therapy only, because almost all patients with ventricular tachycardia and ischemic cardiomyopathy have multiple tachycardia morphologies. Therefore, although one can often modify or eliminate the clinical tachycardia, a number of different (usually faster) tachycardias with morphologies not previously seen can be induced with programmed ventricular stimulation. Each investigator and practitioner may choose to define clinically significant tachycardia and procedure success differently. Therefore, it is not clear when, if ever, it is appropriate to leave a patient without any antiarrhythmic therapy after a successful catheter ablation when one or more nonclinical tachycardias could still be induced. In these cases, patients at the University of Virginia almost uniformly receive an implantable cardioverter defibrillator if one is not already in place. Similarly, catheter ablation is rarely offered as first-line therapy for patients with reentrant ventricular tachycardia and structural heart disease.

Advanced mapping systems and more extensive ablation techniques may improve ablation results over time for a variety of arrhythmias. Clearly, many of the mapping systems can recreate the anatomic relationships and create improved electroanatomic correlations. Some systems provide global mapping information on individual beats, whereas others require point-to-point data acquisition from multiple points. One feature is common among all mapping systems: Procedure cost is increased. In addition, some systems require placement of additional large-diameter mapping catheters into the chamber being mapped, increasing the potential for catheter-related complications. The risk-benefit relationship for advanced mapping systems and the impact of the added procedural cost have not been fully explored, but their use is probably of benefit in select cases.

The number of catheter ablation procedures increased exponentially in the years for which survey data are available. This has been associated with a dramatic growth in the number of practitioners who perform catheter ablation procedures. Curative catheter ablation is cost-effective, and expansion of case numbers has not been held in check by financial disincentives, because reimbursement by third-party payers has not been restricted. The proliferation of catheter ablation procedures may be associated with some undesirable phenomena, including inappropriate self-referral for invasive catheter ablation procedures and performance of catheter ablation procedures by inadequately trained and inexperienced operators. The number of catheter ablation procedures required for adequate training and maintenance of skills has not been determined, but it is proposed that trainees have experience with at least 75 cases as primary operators, and practitioners maintain a volume of at least 50 cases per year in order to be certified to perform catheter ablation procedures. These numerical guidelines will undoubtedly trigger outraged cries of “restraint of trade,” but ultimately the patients and the field of interventional electrophysiology will benefit. The most important criteria for selecting a physician and laboratory to whom a patient should be referred are the chronologic and numerical experience of the primary operator and laboratory staff in catheter ablation procedures. Operators with limited experience may achieve excellent outcomes through careful patient selection, but may be inadequately prepared to diagnose and treat unusual arrhythmia variants.

Catheter ablation of supraventricular and ventricular arrhythmias has advanced rapidly and is now a widely accepted modality of therapy for symptomatic arrhythmias, along with drugs and devices. The tools for ablation are continuing to improve, thereby increasing procedure efficacy and decreasing the risk of complications. This has resulted and will continue to result in expanding indications for ablative therapy. Although the opportunity to cure a patient suffering from an arrhythmia is extremely attractive, one must be vigilant to present all aspects of the risks and benefits to the patient. It is inappropriate to treat an electrocardiographic abnormality in an asymptomatic patient with a potentially morbid intervention. Similarly, if easy, well-tolerated medical therapy is effective in suppressing an arrhythmia, one should not be compelled to send the patient for catheter ablation. More intensive catheter ablative therapies such as curative atrial fibrillation ablation have lower success rates, higher complication rates, and unclear long-term benefits. Patients need to be well informed of these issues before undergoing these interventions. Ultimately, if the patient understands and is willing to accept the small but real risks associated with the procedure in order to achieve improved arrhythmia control or arrhythmia cure, then catheter ablation should be pursued.

THE FUTURE

Curative catheter ablation of common forms of supraventricular tachycardia has exceeded most expectations with regard to both safety and efficacy. Although catheter designs and ablation techniques may evolve, it is likely that the overall outcome statistics will not change significantly. The main frontiers remaining in catheter ablation are curative therapy for atrial fibrillation and reentrant ventricular tachycardia. A wide variety of ablation tools are being developed for atrial fibrillation ablation. More important, selective linear atrial ablation will help us understand the pathophysiology of this complex arrhythmia and direct us to the optimal ablation targets to achieve arrhythmia cure. Reentrant ventricular tachycardia is often hemodynamically unstable, precluding prolonged periods of mapping. New mapping tools will allow for rapid ablation site selection. Because ablation targets are frequently midmyocardial or subepicardial, larger and deeper lesions than can be created with conventional radiofrequency energy ablation will be required for procedure success. Future innovative catheter designs and new ablation energy sources may solve this present limitation.

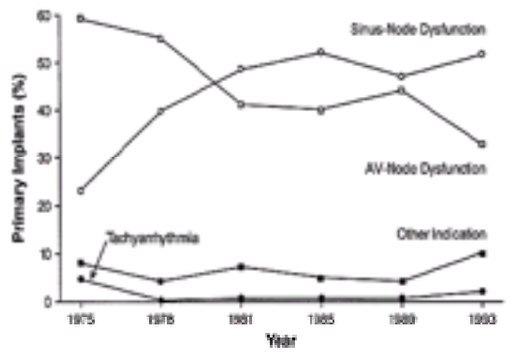
OVERVIEW

When pacemaker implantation is being considered, the clinician should be able to document that implantation is justified and the pacemaker will benefit the patient clinically. This is valuable for long-term care of the patient and subsequent pacing needs as well as for purposes of reimbursement.

The selection of the pacing mode should be based on the immediate needs of the patient and the potential long-term benefit of specific pacing modes. When determining the most appropriate pacing mode for a patient, the clinician should consider the patient's activity level, need for atrioventricular (AV) synchrony, need for chronotropic support, and associated medical conditions. When choosing a pacemaker, remember that rate-adaptive pacing technology allows, for most patients, restoration of a near normal chronotropic response.

Potential interference from outside electrical sources is always of concern to both the patient with a pacemaker and referring physicians. The most common sources of electromagnetic interference for permanent pacemakers are found in a hospital environment (e.g., electrocautery, cardioversion, and magnetic resonance imaging).

The utilization and sophistication of permanent pacemakers have increased steadily since the first pacemaker implantation in 1958 (eFig. 74.0.1) (1,2). Initially, pacemakers were indicated only for the prevention of Stokes-Adams attacks, but the indications have broadened as the technology has advanced. According to the estimates of four manufacturers, there were 152,909 primary pacemaker implantations (571 per million population) in 1997 and 37,946 pacemaker pulse generator replacements (3). Despite the continued sophistication and, at times, complexities of permanent pacemakers, they have become such a mainstay of therapy that it is imperative for clinical cardiologists to have a working knowledge of these devices.



***e*FIGURE 74.0.1** Trends in pacemaker indications in the United States, 1975 to 1993. AV, atrioventricular. (From Bernstein AD, Parsonnet V. Survey of cardiac pacing and defibrillation in the United States in 1993. *Am J Cardiol* 1996;78:187–196, with permission of Excerpta Medica.)

GLOSSARY

AAI/AAIR: Single-chamber atrial pacing modes, with *R* noting the capability of rate adaptation.

Blanking period: Temporary disabling of pacemaker-sensing amplifiers following the delivery of an output pulse. This prevents inappropriate sensing of residual energy from the pacemaker output pulse and, in dual-chamber pacemakers, prevents sensing of pacemaker output pulses or intrinsic events in the chamber other than that in which the event occurs.

DDD/DDDR: Dual-chamber pacing modes, with *R* noting the capability of rate adaptation.

Electromagnetic interference: Any strong source of electromagnetic interference potentially could interfere with the pacemaker and alter its function.

Functional pacing abnormalities (e.g., functional undersensing or functional failure to capture): Failure to sense or capture that is appropriate because of imposed pacemaker refractory periods or myocardial refractoriness due to a previous intrinsic atrial or ventricular event.

Mode switch: Capability of a dual-chamber pacemaker to switch automatically from an atrial-tracking (P synchronous) mode to a non–atrial-tracking mode in the presence of an atrial rhythm that the pacemaker determines to be pathologic. When the atrial rhythm meets the criteria for a physiologic rhythm, the mode switches back to an atrial-tracking mode.

Postventricular atrial refractory period: The period during which the atrial-sensing circuit is refractory following a sensed ventricular event. The purpose of this is to avoid sensing retrograde atrial activity that could initiate an endless-loop tachycardia.

Total atrial refractory period: The period during which the atrial channel of a dual-chamber or VDD pacemaker ignores intrinsic atrial activity or other activity sensed on the atrial-sensing circuit.

Ventricular safety pacing: Delivery of a ventricular output pulse, following atrial pacing, if a signal is sensed by the ventricular channel during the early portion of the AV interval (AVI). This is used to ensure that ventricular depolarization occurs if the sensed event was something other than an intrinsic ventricular depolarization.

VVI/VVIR: Single-chamber ventricular pacing modes, with *R* noting the capability of rate adaptation.

HISTORICAL PERSPECTIVE

Since the first totally implantable pacing system was used by Senning in 1958 (4), the evolution of pacemaker technology has been rapid. Senning's epicardial pacing system was followed by the first transvenous system by Furman and Schwedel (5), also in 1958. Sophistication of sensing circuitry led to the introduction of single-chamber demand pacing systems in 1963 (6). Although atrial-synchronous systems and dual-chamber systems were described in the 1950s (7,8), these devices were not used clinically for many years. The 1970s were significant for the introduction of lithium batteries and programmability (9). Milestones of the 1980s included greater acceptance of dual-chamber pacing systems and the introduction of rate-adaptive pacing systems. The 1990s witnessed continued sophistication of sensor technology as well as increasing automaticity of many programmable features. Also, newer applications for pacing, including pacing for hypertrophic and dilated cardiomyopathy and for the prevention of atrial fibrillation, began in the 1990s and continues.

PACEMAKER NOMENCLATURE

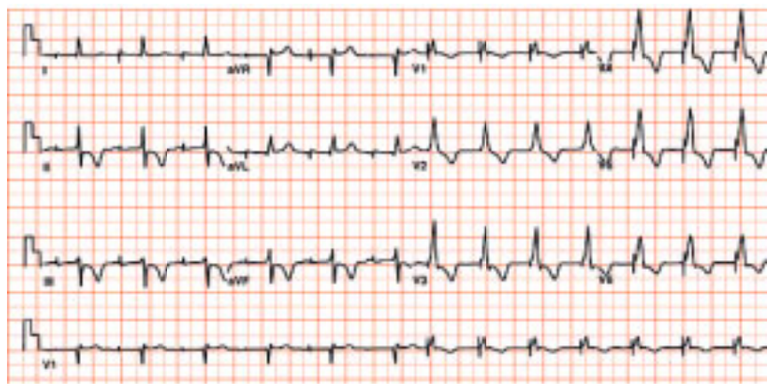
A three-letter code describing the basic function of the various pacing systems was first proposed in 1974 by a combined task force from the American College of Cardiology and the American Heart Association (ACC/AHA) (10). Since then, the responsibility for periodically updating the code has been assumed by the North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group. The code is designated by the NBG code for pacing nomenclature (11) (Table 74.1). The code has five positions, but the fifth position is rarely used. It is a generic code and does not describe specific or unique functional characteristics of each device.

Position[a]	I	II	III	IV	V
Category	Chamber(s) paced	Chamber(s) sensed	Response to sensing	Programmability, rate modulation	Antitachyarrhythmia function(s)
	O = None A = Atrium V = Ventricle D = Dual (A + V) S = Single (A or V)	O = None A = Atrium V = Ventricle D = Dual (A + V) S = Single (A or V)	O = None T = Triggered I = Inhibited D = Dual (T + I)	O = None P = Simple programmable M = Multiprogrammable C = Communicating R = Rate modulation	O = None P = Pacing (antitachyarrhythmia) S = Shock D = Dual (P + S)
Manufacturer's designation only					

[a]Positions I through III are used exclusively for antibradyarrhythmia function.
From Bernstein AD, Camm AJ, Fletcher RD, et al. The NASPE/BPEG generic pacemaker code for antibradyarrhythmia and adaptive-rate pacing and antitachyarrhythmia devices. Pacing Clin Electrophysiol 1987;10:794–799, with permission of Futura.

TABLE 74.1 NBG CODE

The first position reflects the chamber or chambers in which stimulation occurs: A, atrium; V, ventricle; and D, dual chamber; or both A and V.



A 72-year-old patient with atrial pacing with transition to ventricular pacing.

The second position refers to the chamber or chambers in which sensing occurs. The letters are the same as those for the first position. (Manufacturers also use *S* in both the first and second positions to indicate that the device is capable of pacing only a single cardiac chamber.)

A 67-year-old male patient with atrial fibrillation and intermittent demand ventricular pacing.

The third position refers to the mode of sensing, or how the pacemaker responds to a sensed event. An *I* indicates that a sensed event inhibits the output pulse and causes the pacemaker to recycle for one or more timing cycles. *T* means that an output pulse is triggered in response to a sensed event. *D* means that both T and I responses may occur. This designation is restricted to dual-chamber systems. An event sensed in the atrium inhibits the atrial output but triggers a ventricular output. Unlike a single-chamber–triggered mode (VVT or AAT), in which an output pulse is triggered immediately on sensing, there is a delay between the sensed atrial event and the triggered ventricular output to mimic the normal PR interval. If a native ventricular signal or R wave is sensed, it inhibits the ventricular output and possibly even the atrial output, depending on where sensing occurs.

The fourth position of the code reflects both programmability and rate modulation. An *R* in the fourth position indicates that the pacemaker incorporates a sensor to control the rate independently of intrinsic cardiac activity. From a practical standpoint, R is the only indicator commonly used in the fourth position. Other indicators are described in Table 74.1.

The fifth position is restricted to antitachycardia functions and is rarely used.

INDICATIONS FOR CARDIAC PACING

According to the criteria established by a joint committee of the ACC/AHA, the indications for pacing are divided into three categories: generally indicated, may be indicated, and not indicated (12,13). The clinician prescribing permanent pacing systems should be aware of the published indications and the controversies regarding the indications. Although some indications for permanent pacing are relatively certain or unambiguous, others require considerable expertise and judgment.

The clinical need for pacing and appropriate objective data, such as electrocardiographic tracings, must be documented clearly in the patient's medical record to ensure reimbursement by Medicare or third-party payers.

Indications are considered here for the categories of acquired AV block, congenital AV block, chronic bifascicular and trifascicular block, sinus node dysfunction, and neurocardiogenic syndromes. Potential hemodynamic indications for permanent pacing are discussed separately.

Acquired Atrioventricular Block

Traditionally, AV block is classified into first-, second-, and third-degree (or complete) heart block. Alternatively, it can be defined anatomically as supra-, intra-, or infra-Hisian. If the QRS is wide, there is a greater probability that the conduction disturbance is infra-Hisian. Most commonly, acquired AV block is idiopathic and related to aging, but it has many potential causes (Table 74.2). The indications for permanent pacing in acquired AV block are listed in Table 74.3.

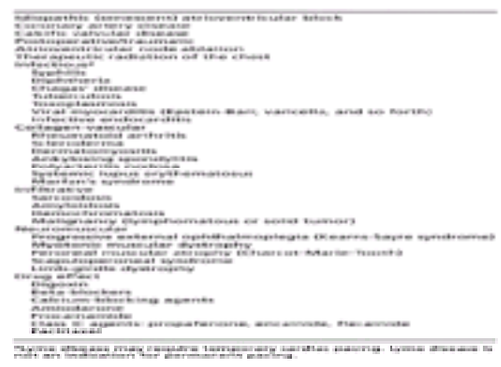


TABLE 74.2 ACQUIRED ATRIOVENTRICULAR BLOCK: DIFFERENTIAL DIAGNOSIS

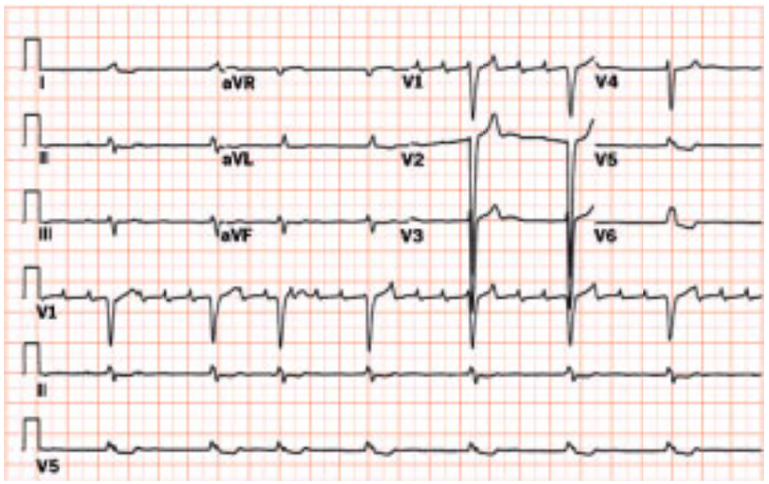
Degree	Pacemaker necessary	Pacemaker probably necessary	Pacemaker not necessary
Third	Symptomatic congenital CHB		
	Acquired symptomatic CHB		
	Atrial fibrillation with CHB		
	Acquired asymptomatic CHB		
Second	Symptomatic type I	Asymptomatic type II	Asymptomatic type I at supra-His
	Symptomatic type II	Asymptomatic type I at intra-His or infra-His levels*	(atrioventricular nodal) level
First			Asymptomatic or symptomatic*

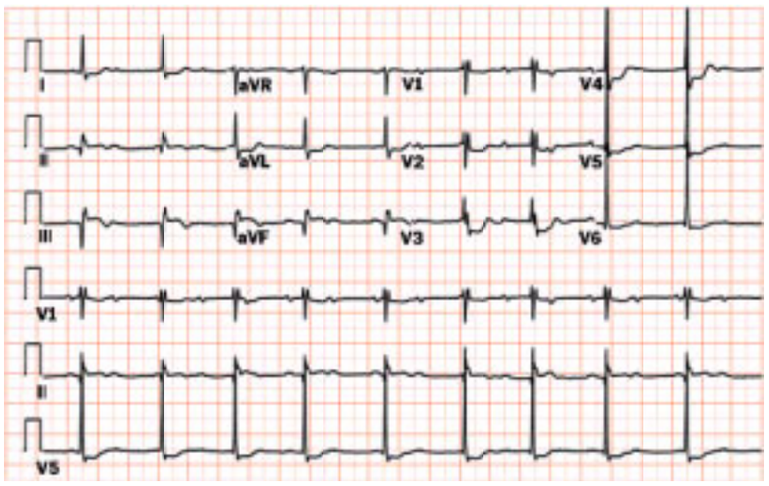
CHB, complete heart block.
*Data from Campbell RW. Chronic Wenckebach type I second degree atrioventricular block. Has its importance been underestimated? [Editorial]. Br Heart J 1980;53:585-588.

TABLE 74.3 INDICATIONS IN ATRIOVENTRICULAR BLOCK

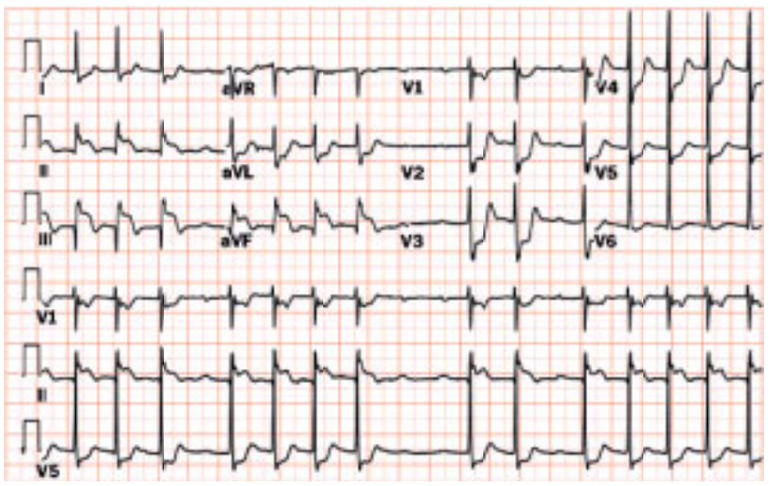


High-grade atrioventricular block. Note marked discrepancy between atrial and ventricular heart rates.

Indications for permanent pacing for AV block that occurs with myocardial infarction are more controversial. Generally, a pacemaker is considered to be indicated if complete AV block, Mobitz II block, or bilateral or alternating bundle branch block persists longer than 72 hours after the acute event. Some clinicians would consider new and persistent bifascicular block an indication for pacing, and others would consider pacing for a new left anterior or left posterior hemiblock alone.



Complicated acute inferior myocardial infarction. Note inferior ST-segment elevation as well as atrioventricular dissociation secondary to complete heart block.



Acute inferior myocardial infarction with Mobitz II atrioventricular block. Note ST-segment elevation in the inferior leads as well as intermittently dropped QRS complexes.

An 83-year-old patient with complete heart block, junctional escape rhythm, left anterior hemiblock, and complete right bundle branch block.

Congenital Complete Heart Block

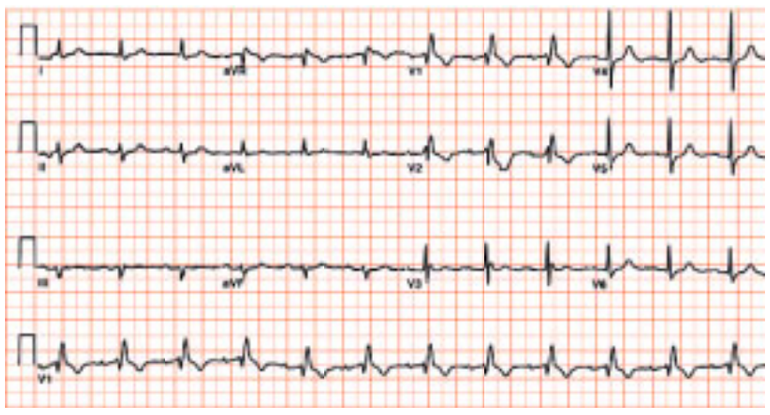
Although some controversy remains about when patients with congenital complete heart block should have pacing, the tendency now is to provide pacing to these patients earlier.

In pediatric patients, pacemaker implantation is recommended for the following indications: congestive heart failure, average heart rate less than 50 beats/min in an awake infant, history of syncope or presyncope, significant ventricular ectopy, or exercise intolerance (14). Prophylactic pacemaker implantation is generally considered appropriate in adults, even if asymptomatic, because of a high incidence of unpredictable syncope with significant mortality from initial attacks, a gradual decrease in heart rate, and a high incidence of acquired mitral insufficiency (15). This author recommends permanent pacing in all adults with congenital complete heart block.

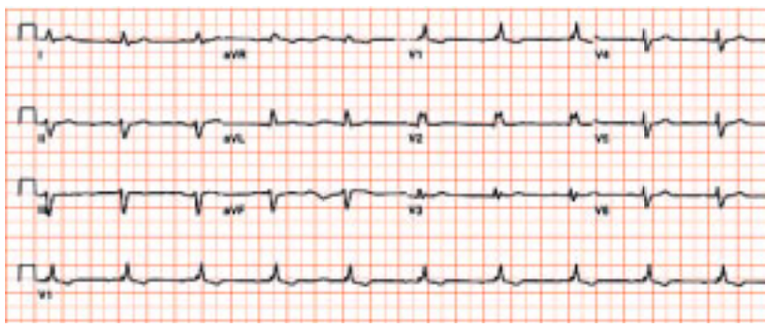
Chronic Bifascicular or Trifascicular Block

If the bifascicular or trifascicular block is associated with symptoms or transient complete heart block, pacing is clearly indicated. If the bifascicular or trifascicular block is associated with high-grade AV block without symptoms, pacing is also indicated. An important class II ACC/AHA indication is the probable necessity for pacing in a patient with bifascicular or trifascicular block and syncope that cannot be attributed to any other cause. If fascicular block is noted in an asymptomatic patient, pacing is not indicated (16).

Trifascicular block. Note right bundle branch block, left anterior hemiblock, and associated first-degree atrioventricular block.



A 93-year-old male patient with trifascicular block.



A 75-year-old male patient with trifascicular block.

Sinus Node Dysfunction

Tachycardia-bradycardia syndrome, sick sinus syndrome, symptomatic sinus bradycardia, sinus arrest and sinus pauses, and chronotropic incompetence are all variants of sinus node dysfunction and the terms are often used synonymously. The definition of bradycardia varies, but it generally is accepted to be rates less than 40 beats/min during waking hours. There is disagreement about the absolute cycle length at which treatment should be required. Although every patient needs to be considered individually, most clinicians would agree that sinus pauses of 3 seconds during waking hours should be considered abnormal and may warrant pacing. Pauses that occur during sleep are more difficult to categorize. Because of vagal influences, many healthy persons may have pauses significantly longer than 3 seconds during sleep and, in the absence of symptoms or rhythm disturbances during waking hours, should not require treatment. Permanent pacing should be considered for any patient who has symptomatic bradyarrhythmias when the cause of the bradyarrhythmia is not reversible (Table 74.4).

Pacemaker necessary	Pacemaker probably necessary	Pacemaker not necessary
Symptomatic bradycardia Symptomatic sinus bradycardia due to long-term drug therapy of a type and dose for which there is no accepted alternative	Symptomatic patients with sinus node dysfunction with documented rates of <40 bpm/min without a clear-cut association between significant symptoms and the bradycardia	Asymptomatic sinus node dysfunction

TABLE 74.4 INDICATIONS FOR PERMANENT PACING IN SINUS NODE DYSFUNCTION

Permanent pacing for patients with sinus node dysfunction after myocardial infarction is reserved for those who have symptoms. If drug therapy results in symptomatic bradycardia, criteria for permanent pacing should follow the guidelines given for sinus node dysfunction in Table 74.4.

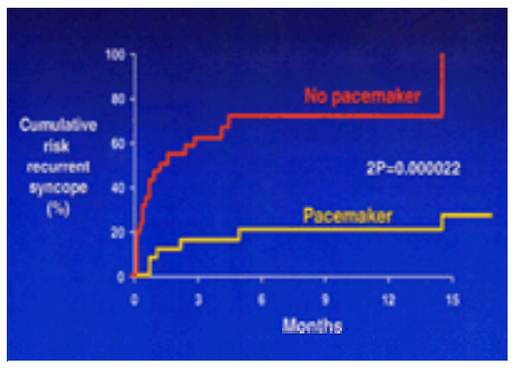
Neurocardiogenic Syncope

Permanent pacing may be indicated for some of the several types of neurally mediated syncope. Understanding the physiology involved is crucial to understanding the clinical manifestations (17,18 and 19). The carotid sinus reflex is the physiologic response to pressure exerted on the carotid sinus. Stimulation activates the baroreceptors within the wall of the carotid sinus. Vagal efferents then result in cardiac slowing. Although this reflex is physiologic, some persons have an exaggerated or even pathologic response. The reflex has two components: a cardioinhibitory response and a vasodepressor response. A cardioinhibitory response results from increased parasympathetic tone and may be manifested by any or all of the following conditions: sinus bradycardia, PR prolongation, and advanced AV block. The vasodepressor response is due to decreased sympathetic activity and secondary hypotension. Although a pure cardioinhibitory or pure vasodepressor response may occur, a mixed response is most common.

Tilt testing can provide the physiologic environment to reproduce malignant vasovagal syncope (20). With head-up tilt, susceptible patients have decreased venous return and a subsequent decrease in left ventricular filling, which may result in efferent vagal discharge. Stimulation of baroreceptors and adrenergic discharge may also result in efferent vagal discharge. Vasodilatation and hypotension as well as cardiac slowing may result from efferent vagal discharge. It is important to document whether the predominant cause of symptoms is cardioinhibitory or vasodepressor in origin, because therapy differs. Tilt-table testing is often helpful in determining the predominant cause.

This abnormality is difficult to categorize by the ACC/AHA classification because of the controversy about treatment. Historically, some studies have strongly supported initial treatment with beta-blockers (6) and others have advocated permanent pacing (21). In the more recent randomized North American Vasovagal Pacemaker Study (22), 46 patients with recurrent syncope and positive findings on the tilt test were randomly assigned to either dual-chamber pacemaker with a special feature known as *rate drop* or no pacemaker therapy. (The rate drop algorithm allows the pacemaker to pace at a faster rate if bradycardia suddenly occurs.) Although Vasovagal

Pacemaker Study 1 was stopped prematurely because of the benefit observed with pacemaker therapy, it showed that only 17% of patients with pacing had recurrent syncope compared with 59% of those without pacing (i.e., an 85% risk reduction) (eFig. 74.0.2). Another study randomly assigned 60 patients with carotid sinus hypersensitivity to pacing or no pacing (23). At a mean follow-up of 36 months, syncope recurred in 9% of the pacing group compared with 57% of the group without pacing. Although pacing may not be required in the majority of patients with neurally mediated syncope, a specific subset of patients with drug-resistant syncope and a predominant bradycardic component definitely benefit from permanent dual-chamber pacing (24,25).



***e*FIGURE 74.0.2** In the North American Vasovagal Pacemaker Study-I, there was an 85% risk reduction of syncope in the group of patients who received a pacemaker. [From Connolly SJ, Sheldon R, Roberts RS, et al. The North American Vasovagal Pacemaker Study (VPS). A randomized trial of permanent cardiac pacing for the prevention of vasovagal syncope. *J Am Coll Cardiol* 1999;33:16–20, with permission of the American College of Cardiology.]

Additional trials, Vasovagal Pacemaker Study 2, Vasovagal Syncope International Study (26), and SAFE PACE2 (Syncope and Falls in the Elderly Pacing and Carotid Sinus Evaluation), are under way to assess pacing therapy in both neurocardiogenic syncope and carotid sinus hypersensitivity.

NONBRADYARRHYTHMIC INDICATIONS FOR PACING

Hypertrophic Obstructive Cardiomyopathy

Dual-chamber pacing has been proposed as a therapeutic modality for patients with severe, symptomatic hypertrophic obstructive cardiomyopathy (27,28,29 and 30). Several investigators have reported a significant decrease in the left ventricular outflow tract gradient and symptomatic improvement in patients with hypertrophic obstructive cardiomyopathy after implantation of a dual-chamber pacemaker (Fig. 74.1).

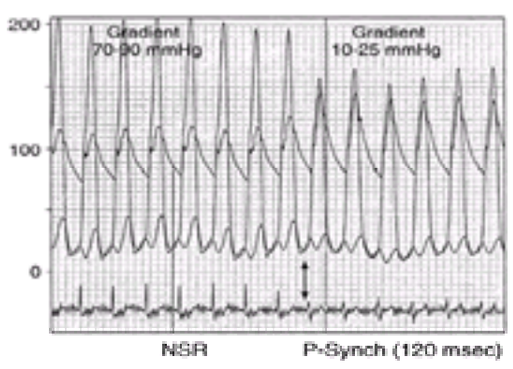


FIGURE 74.1 Hemodynamic tracing demonstrating left ventricular outflow gradient reduction during a temporary pacing study. During normal sinus rhythm (NSR), the patient exhibits marked left ventricular outflow obstruction, with a gradient of 70 to 90 mm Hg. With initiation of P-synchronous pacing at an AV interval of 120 ms, the gradient is decreased to 10 to 25 mm Hg. (From Symanski JD, Nishimura RA. The use of pacemakers in the treatment of cardiomyopathies. *Curr Probl Cardiol* 1996;21:385–443, with permission of Mosby.)

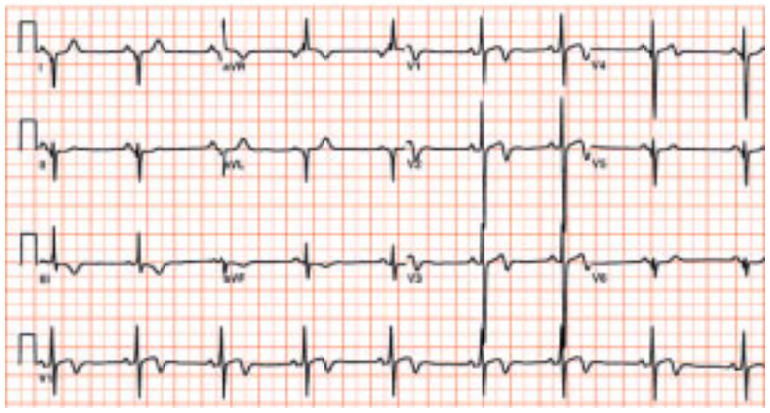
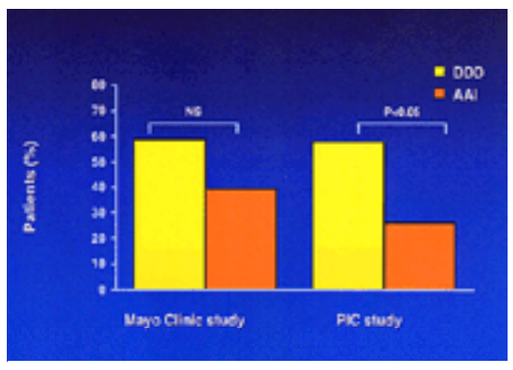


A 28-year-old Caucasian male patient with hypertrophic obstructive cardiomyopathy.

It has been recognized that AV timing is critical if optimal hemodynamic improvement is to be achieved (31). Although some patients with hypertrophic obstructive cardiomyopathy have optimal improvement with a very short AVI, others may have hemodynamic deterioration if the AVI is too short. Also, it has been recognized that depolarization of the ventricle must occur via the pacemaker. Some have advocated AV nodal ablation to ensure paced ventricular depolarization if rapid intrinsic AV nodal conduction prevents total ventricular depolarization via the pacing stimulus (32).

In the Pacing in Cardiomyopathy study, a multicenter, randomized, cross-over study, dual-chamber pacing resulted in a 50% decrease of the left ventricular outflow tract gradient, a 21% increase in exercise duration, and improvement in New York Heart Association (NYHA) functional class compared with baseline status (33). When clinical variables, including chest pain, dyspnea, and subjective health status, were compared between DDD and backup AAI pacing, the difference was not significant, again suggesting an important placebo effect (eFig. 74.1.1).



***e*FIGURE 74.1.1** Two trials have demonstrated significant placebo effect from pacemaker placement in patients with hypertrophic cardiomyopathy. The yellow bars depict symptom improvement when paced in the DDD pacing mode, and the orange bars depict symptom improvement when paced in a backup AAI mode (i.e., no

effective pacing). Despite the lack of pacing in the AAI pacing mode, a significant subset of the study population in both studies reported symptomatic improvement. NS, not significant. (From Sorajja P, Elliott PM, McKenna WJ. Pacing in hypertrophic cardiomyopathy. *Cardiol Clin* 2000;18:67–79, with permission of WB Saunders.)

In another randomized, double-blinded, cross-over study, the Multicenter Study of Pacing Therapy for Hypertrophic Cardiomyopathy trial, no significant differences were evident with randomization between pacing and no pacing, either subjectively or objectively, when exercise capacity, quality-of-life score, treadmill exercise time, and peak oxygen consumption were compared (34). The investigators concluded that pacing should not be regarded as a primary treatment for hypertrophic obstructive cardiomyopathy, and subjective benefit without objective evidence of improvement should be interpreted cautiously.

Currently, pacing for the treatment of medically refractory hypertrophic obstructive cardiomyopathy is a class IIb indication by the ACC/AHA guidelines (2).

Dilated Cardiomyopathy

Dual-chamber pacing has been reported to be effective in the treatment of selected patients with dilated cardiomyopathy of idiopathic or ischemic cause (35).

Treatment of idiopathic dilated cardiomyopathy with short AVI DDD pacing was first reported by Hochleitner et al. (36). They treated 16 patients with idiopathic dilated cardiomyopathy refractory to pharmacologic therapy who were in NYHA functional class III or IV. These authors reported marked improvement in NYHA functional class and a decrease in mortality over that expected at 1 year.

Hochleitner et al. (37) subsequently published long-term follow-up results of their original patient cohort. Excluding four patients who received transplants, median survival in this critically ill population was 22 months. Improvements in hemodynamic function continued throughout the follow-up period for the five patients with disease of known cause; except for one death due to cancer, all deaths were caused by embolic events and not from continued deterioration in ventricular function. No patient needed rehospitalization because of worsening heart failure after pacemaker implantation.

The mechanism by which standard dual-chamber permanent pacing may produce improvement probably is due to optimization of AV synchrony (38). However, standard dual-chamber pacing resulted in improvement in only a limited number of patients (39,40 and 41). Subsequently, it was hypothesized that, in addition to the need for optimization of AV synchrony, the correction of intraventricular conduction disturbances might result in clinical improvement. Ventricular dyssynchrony is common among the heart failure population and has been associated with paradoxical septal wall motion, decreased left ventricular pressure, prolonged duration of mitral regurgitation, and decreased diastolic filling times in patients with left bundle branch block.

Biventricular or left ventricular pacing may counter the decreased septal contribution to stroke volume caused by late left ventricular activation occurring as the septum has begun repolarizing and help to increase the ejection fraction (Fig. 74.2).

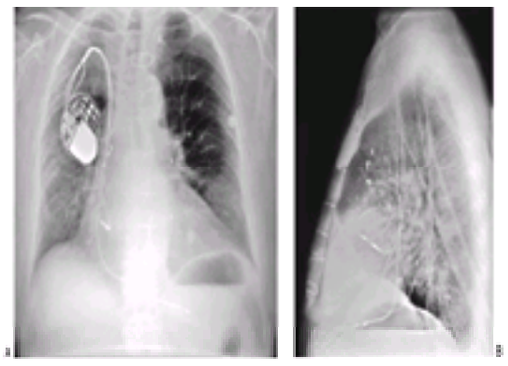


FIGURE 74.2 Postero-anterior **(A)** and lateral **(B)** chest radiographs demonstrating a ventricular lead that courses posteriorly in the coronary sinus and into a cardiac vein, probably a tributary of the posterior cardiac vein. From the postero-anterior view alone, this determination cannot be made. (From Hayes DL, Zipes DP. Cardiac pacemakers and cardioverter-defibrillators. In: Braunwald E, Zipes DP, Libby P, eds. *Heart disease: a textbook of cardiovascular medicine*, 6th ed. Philadelphia: WB Saunders, 2001:775–814, with permission.)

To date, the data have been promising (42), but randomized prospective trials are needed to prove the efficacy and safety of cardiac resynchronization. An early nonrandomized trial, InSync, demonstrated improvement in 6-minute walking, quality of life, and NYHA functional class. Randomized trials that have demonstrated similar outcomes include Pacing Therapy in Congestive Heart Failure (43) and MUSTIC (Multisite Stimulation in Cardiomyopathies) (44).

Pacing for the Prevention of Atrial Fibrillation

There is considerable interest in the potential prevention of recurrent atrial tachyarrhythmias by dual-site or alternate-site atrial pacing (45,46 and 47). The proposed mechanism of this technique is to decrease the refractoriness of dispersion of the atrium by simultaneously depolarizing both left and right atria. Early applications of dual-site atrial pacing have had some success, and this has significant promise.

The optimal method of pacing for prevention of atrial fibrillation has not been established, but it should be determined by the numerous trials that are being conducted. Techniques include dual-site or alternate-site pacing, with the alternate site usually being an atrial septal position.

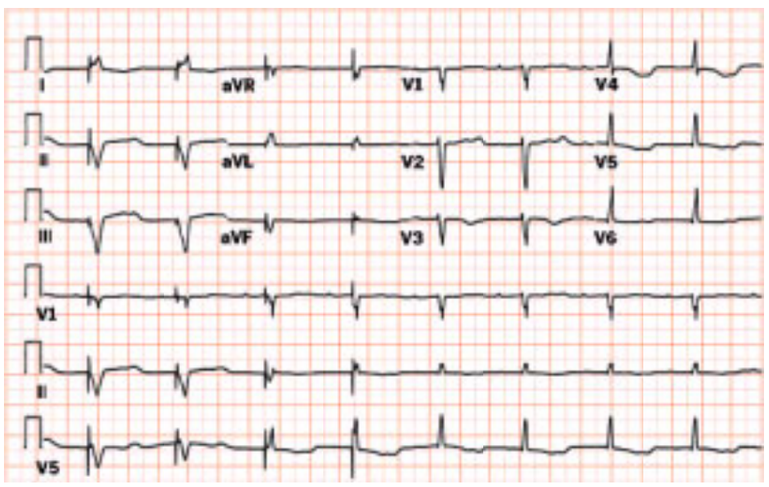
SELECTION OF THE APPROPRIATE PACING MODE

In selecting the optimal pacing mode, the patient's overall physical condition, associated medical problems, exercise capacity, and chronotropic response to exercise must be considered in conjunction with the underlying rhythm disturbance (48). Table 74.5 describes clinical applications of various pacing modes in three classifications: conduction disorders for which a given pacing mode is indicated, those for which a given pacing mode is controversial, and those for which a given pacing mode is contraindicated.

TABLE 74.5 INDICATIONS FOR VARIOUS PACING MODES

It is difficult to comprehend completely the advantages and disadvantages of each of the pacing modes unless the timing cycle of each mode is also understood.

Single-chamber–triggered pacing (AAT and VVT) releases an output pulse every time a native event is sensed. This feature increases the current drain on the battery, which accelerates its rate of depletion, and deforms the native signal, thus compromising interpretation of the electrocardiogram. However, it can serve as an excellent marker for the site of sensing within an intrinsic complex and can prevent inappropriate inhibition from oversensing when the patient does not have a stable native escape rhythm. Also, it can be used for noninvasive electrophysiologic studies, with the already implanted pacemaker tracking chest wall stimuli created by a programmable stimulator.



Demand ventricular pacemaker. As sinus rhythm accelerates, ventricular pacing is inhibited.

A 50-year-old female patient with atrial pacing during an acute inferior myocardial infarction.

Ventricular-inhibited (VVI) pacing incorporates sensing on the ventricular channel, and pacemaker output is inhibited by a sensed ventricular event (Fig. 74.3). VVI pacemakers are refractory for a period after a paced or sensed ventricular event, the *ventricular refractory period*. Any ventricular event occurring within this period is not sensed and does not reset the ventricular timer.

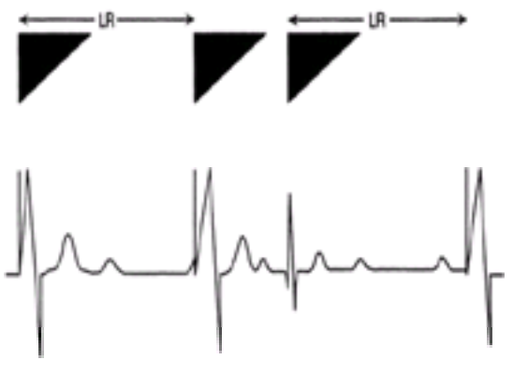


FIGURE 74.3 The VVI timing cycle consists of a defined lower rate (LR) limit and a ventricular refractory period (*black triangle*). When the LR limit timer is complete, a pacing artifact is delivered in the absence of a sensed intrinsic ventricular event. If an intrinsic QRS occurs, the LR limit timer is started from that point. A ventricular refractory period begins with any sensed or paced ventricular activity. (From Hayes DL, Levine PA. Pacemaker timing cycles. In: Ellenbogen KA, ed. *Cardiac pacing*. Boston: Blackwell Scientific, 1992:263–308, with permission.)

Worldwide, VVI pacing is the most commonly used pacing mode. Although VVI pacing protects the patient from lethal bradycardias, it has significant limitations in that it does not restore or maintain AV synchrony or provide rate responsiveness in patients with chronotropic incompetence. Also, some patients with VVI pacing experience symptomatic hemodynamic deterioration with ventricular pacing (49,50). Adverse hemodynamics associated with a normally functioning pacing system that result in overt symptoms or limit the patient's ability to achieve optimal functional status are referred to as *pacemaker syndrome* (Fig. 74.4). Pacemaker syndrome was recognized initially with ventricular (VVI) pacing, but it may occur with any pacing mode if there is AV dissociation. The incidence of pacemaker syndrome is difficult to determine and depends on how the syndrome is defined. If the definition is restricted to patients with clinical limitations during any pacing mode that results in AV dissociation, the incidence, as estimated in an older review by Ausubel and Furman (49), is probably in the range of 7% to 10% of patients with VVI pacing. In a study by Heldman et al. (50), patients with DDD pacemakers who were randomly assigned to DDD or VVI pacing mode for 1 week and subsequently to the alternate mode completed questionnaires comparing 16 symptoms experienced during each pacing mode. Some degree of pacemaker syndrome was thought to be present in 83% of those studied. The most common symptoms reported were shortness of breath, dizziness, fatigue, pulsations in the neck or abdomen, cough, and apprehension. It can be concluded from this study that if patients with VVI pacing have some basis for comparison, they may be more aware of symptoms with VVI pacing.

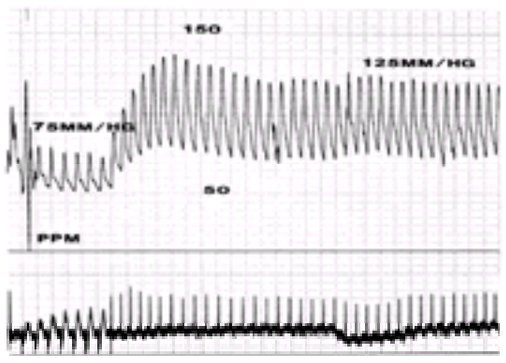

FIGURE 74.4 Hemodynamic tracing of a patient with pacemaker syndrome. In the initial portion of the tracing, there is ventricular pacing, with a systolic arterial pressure of approximately 75 mm Hg. The patient's intrinsic sinus rhythm inhibits ventricular pacing, and the arterial systolic pressure increases to approximately 125 mm Hg. PPM, pulses per minute. (From Hayes DL, Holmes DR Jr. Hemodynamics of cardiac pacing. In: Furman S, Hayes DL, Holmes DR Jr. *A practice of cardiac pacing*, 3rd ed. Mount Kisco, NY: Futura, 1993:195–218, with permission.)

Atrial-inhibited (AAI) pacing incorporates the same timing cycles, with the obvious difference that pacing and sensing occur from the atrium, and pacemaker output is

inhibited by a sensed atrial event (Fig. 74.5). An atrial-paced or sensed event initiates a refractory period during which nothing is sensed by the pacemaker. Confusion can arise when multiple ventricular events occur while there is atrial pacing. For example, in addition to the intrinsic QRS that occurs in response to the paced atrial beat, if a premature ventricular beat follows, it does not inhibit an atrial pacing artifact from being delivered. When the atrial timing cycle ends, the atrial pacing artifact is delivered regardless of ventricular events, because an AAI pacemaker should not sense anything in the ventricle. The single exception to this rule is far-field sensing; that is, the ventricular signal is large enough to be sensed inappropriately by the atrial lead. In this situation, the atrial timing cycle is reset. Sometimes, this anomaly can be corrected by making the atrial channel less sensitive or by lengthening the refractory period.

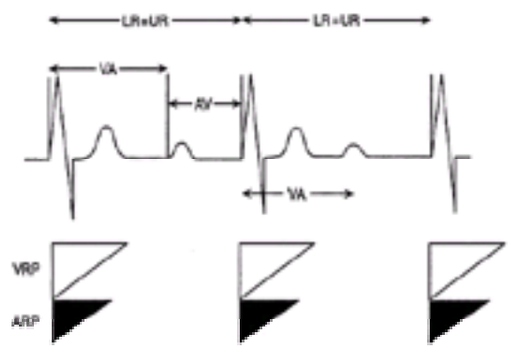
FIGURE 74.5 The AAI timing cycle consists of a defined lower rate (LR) limit and an atrial refractory period. When the LR limit timer is complete, a pacing artifact is delivered in the atrium in the absence of a sensed atrial event. If an intrinsic P wave occurs, the LR limit timer is started from that point. An atrial refractory period begins with any sensed or paced atrial activity. (From Hayes DL, Levine PA. Pacemaker timing cycles. In: Ellenbogen KA, ed. *Cardiac pacing*. Boston: Blackwell Scientific, 1992:263–308, with permission.)

AAI pacing is appropriate for patients with sinus node dysfunction. The obvious disadvantage of atrial pacing is lack of ventricular support should AV block occur. If the patient with sinus node dysfunction is evaluated carefully for the presence of AV nodal disease at the time of pacemaker implantation, the occurrence of clinically significant AV nodal disease is low, 2% per year (51). The evaluation before the use of an AAI system should include incremental atrial pacing at the time of pacemaker implant. Although criteria vary among institutions and implanting physicians, adult patients should be capable of one-to-one AV nodal conduction to rates of 120 to 140 beats/min.

AV sequential, ventricular-inhibited pacing (DVI) is rarely used as the preimplantation pacing mode of choice. By definition, DVI provides pacing in both the atrium and the ventricle (D), but provides sensing only in the ventricle (V). The pacemaker is inhibited and reset by sensed ventricular activity, but it ignores all intrinsic atrial complexes.

At one time, DVI pacemakers were implanted in a large number of patients, often with a satisfactory outcome. However, DVI pacing is limited by the absence of atrial sensing, which prevents atrial tracking. In addition, lack of atrial sensing may lead to competitive atrial pacing and initiation of atrial rhythm disturbances. For these reasons, DVI pacing is rarely selected as the mode of choice at the time of implantation, but it is still a programmable option in many dual-chamber pacemakers.

AV sequential, non–P-synchronous pacing with dual-chamber sensing (DDI) incorporates atrial sensing as well as ventricular sensing, which prevents competitive atrial pacing that can occur with DVI pacing (*e*Fig. 74.5.1). The DDI mode of response is inhibition only (i.e., no tracking of P waves can occur). Therefore, the programmed rate, which by definition is the lower rate since only a single rate exists, is the fastest paced rate that can occur.



***e*FIGURE 74.5.1** The timing cycle in DDI consists of a lower rate (LR) limit, an atrioventricular (AV) interval, a ventricular refractory period (VRP), and an atrial refractory period (ARP). The VRP is initiated by any sensed or paced ventricular activity, and the ARP is initiated by any sensed or paced atrial activity. DDI can be thought of as DDD pacing without the capability of P-wave tracking or DVI without the potential for atrial competition by virtue of atrial sensing. The LR limit cannot be violated even if the sinus rate is occurring at a faster rate. For example, the LR limit is 1,000 ms, or 60 pulses per minute, and the AV interval is 200 ms. If a P wave occurs 500 ms after a paced ventricular complex, the AV interval is initiated, but at the end of this interval, 700 ms from the previous paced ventricular activity, a ventricular pacing artifact cannot be delivered because it would violate the LR limit. UR, upper rate; VA, ventriculoatrial. (From Hayes DL, Levine PA. Pacemaker timing cycles. In: Ellenbogen KA, ed. *Cardiac pacing*. Boston: Blackwell Scientific, 1992:263–308, with permission.)

DDI is rarely the preimplantation mode of choice, but it remains a programmable option in most dual-chamber pacemakers (52).

Atrial synchronous (P-tracking) pacemakers (VDD) pace only in the ventricle, sense in both the atrium and ventricle, and respond both by inhibition of ventricular output by intrinsic ventricular activity and by ventricular tracking of P waves. The VDD mode also has become increasingly available as a single-lead pacing system. In this system, a single lead is capable of pacing in the ventricle in response to sensing atrial activity by way of a remote electrode situated on the intraatrial portion of the ventricular pacing lead (53).

A sensed atrial event initiates the AVI. If an intrinsic ventricular event occurs before the termination of the AVI, ventricular output is inhibited and the lower rate timing cycle is reset (Fig. 74.6). If a paced ventricular beat occurs at the end of the AVI, this beat resets the lower rate. If no atrial event occurs, the pacemaker escapes with a paced ventricular event at the lower rate limit (i.e., the pacemaker displays VVI activity in the absence of a sensed atrial event).

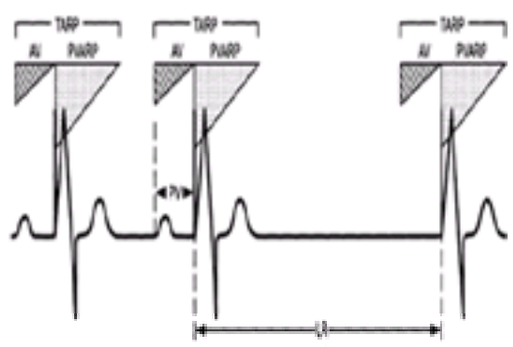


FIGURE 74.6 The timing cycle of VDD consists of a lower rate (LR) limit, an atrioventricular (AV) interval, a ventricular refractory period, a postventricular atrial refractory period (PVARP), and an upper rate limit. A sensed P wave initiates the AV interval (during this interval, the atrial-sensing channel is refractory). At the end of the AV interval, a ventricular pacing artifact is delivered if no intrinsic ventricular activity has been sensed (i.e., P-wave tracking). Ventricular activity, paced or sensed,

initiates the PVARP and the ventriculoatrial interval (the LR limit interval minus the AV interval). If no P-wave activity occurs, the pacemaker escapes with a ventricular pacing artifact at the LR limit. PV, postventricular; TARP, total atrial refractory period. (From Hayes DL, Zipes DP. Cardiac pacemakers and cardioverter-defibrillators. In: Braunwald E, Zipes DP, Libby P, eds. *Heart disease: a textbook of cardiovascular medicine*, 6th ed. Philadelphia: WB Saunders, 2001:775–814, with permission.)

VDD pacing may be appropriate for patients who have normal sinus node function and conduction disease of the AV node.

Dual-chamber pacing and sensing with inhibition and tracking (DDD) are reasonably easy to comprehend. The basic timing circuit associated with lower rate pacing is divided into two sections: the ventriculoatrial (VA) interval and the AVI. The AVI may be defined by AV sequential pacing, initiated (a) by pacing, with subsequent intrinsic ventricular conduction, or (b) by a native P wave, with subsequent ventricular pacing (Fig. 74.7). The total atrial refractory period, which consists of the AVI and the postventricular atrial refractory period (PVARP), defines the maximal tracking rate of the pacemaker.

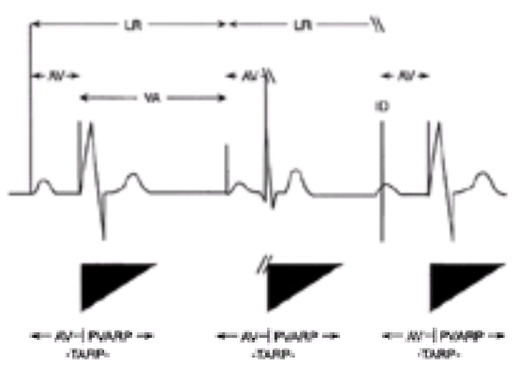

FIGURE 74.7 The timing cycle in DDD consists of a lower rate (LR) limit, an atrioventricular (AV) interval, a postventricular atrial refractory period (PVARP), and an upper rate limit. The AV interval and PVARP together constitute the total atrial refractory period (TARP). There are four variations of the DDD timing cycle. If intrinsic atrial and ventricular activity occurs before the LR limit times out, both channels are inhibited and no pacing occurs. If no intrinsic atrial or ventricular activity occurs, there is AV sequential pacing (first sequence). If no atrial activity is sensed before the ventriculoatrial (VA) interval is completed, an atrial pacing artifact is delivered, which initiates the AV interval. If intrinsic ventricular activity occurs before the termination of the AV interval, the ventricular output from the pacemaker is inhibited [i.e., atrial pacing (second sequence)]. If a P wave is sensed before the VA interval is completed, output from the atrial channel is inhibited. The AV interval is initiated, and if no ventricular activity is sensed before the AV interval terminates, a ventricular pacing artifact is delivered [i.e., P-synchronous pacing (third sequence)]. ID, intrinsic deflection. (From Hayes DL, Levine PA. Pacemaker timing cycles. In: Ellenbogen KA, ed. *Cardiac pacing*. Boston: Blackwell Scientific, 1992:263–308, with permission.)

In summary, four different rhythms can occur as a result of normal DDD function: (a) normal sinus rhythm, (b) atrial pacing, (c) AV sequential pacing, and (d) P-synchronous pacing. The DDD pacing mode is most appropriate for patients with normal sinus node function and AV block. Some consider DDD pacing the mode of choice in neurocardiogenic syndromes with symptomatic cardioinhibition.

DDD pacing has limitations in patients with sinus node dysfunction. P-synchronous pacing is not possible in the presence of chronic atrial fibrillation or in patients with a paralyzed or nonexcitable atrium. Also, DDD pacing is not able to restore rate response in a patient with chronotropic incompetence (a patient in whom atrial rate is unable to increase appropriately with exercise). In a patient with chronotropic incompetence, DDD pacing is suboptimal because rate responsiveness is not restored.

INDICATIONS FOR RATE-ADAPTIVE PACEMAKERS

Single-chamber rate-adaptive pacing modes (AAIR, VVIR) have timing cycles that are not significantly different from those of their non–rate-adaptive counterparts. The difference lies in the potential variability of the paced rate (Fig. 74.8). Depending on the sensor incorporated and the level of exertion of the patient, the basic interval is shorter than the programmed lower rate limit. Shortening requires that an upper rate limit be programmed to define the absolute shortest cycle length allowable.

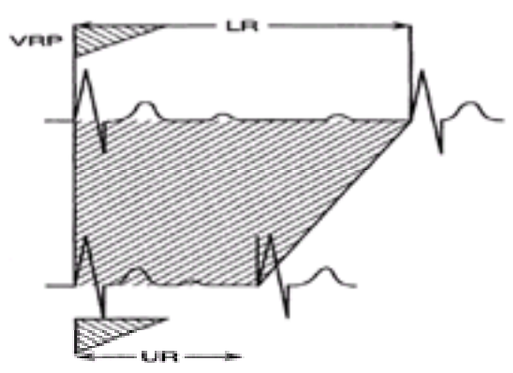

FIGURE 74.8 The VVIR timing cycle consists of a lower rate (LR) limit, an upper rate (UR) limit, and a ventricular refractory period (VRP) (*triangle*). As indicated by sensor activity, the VV cycle length shortens accordingly. (The striped area represents the range of sensor-driven VV cycle lengths.) In most VVIR pacemakers, the VRP remains fixed despite the changing VV cycle length. In selected VVIR pacemakers, the VRP shortens as the cycle length shortens. (From Hayes DL, Levine PA. Pacemaker timing cycles. In: Ellenbogen KA, ed. *Cardiac pacing*. Boston: Blackwell Scientific, 1992:263–308, with permission.)

VVIR pacing, like VVI, is contraindicated if ventricular pacing results in retrograde (VA) conduction, a decrease in blood pressure, or both. VVIR pacing should not be used as an excuse to forego attempts at placing an atrial lead in a patient who is undergoing pacemaker implantation, has normal sinus node function, and would benefit from rate-adaptive pacing. If the sinus node is intact, P-synchronous pacing should still be considered the optimal rate-adaptive parameter and be used when possible.

AAIR pacing can be considered in patients with sinus node dysfunction and normal AV node function, because this mode restores rate responsiveness and maintains AV synchrony. If AAIR pacing is contemplated, normal AV node conduction must first be determined as discussed previously for AAI pacing.

AV sequential, non–P-synchronous, rate-adaptive pacing with dual-chamber sensing (DDIR) is the same as DDI pacing except that paced rates can exceed the programmed lower rate limit through sensor-driven activity. An upper rate limit must be programmed to define the shortest cycle length allowable.

At one time, DDIR pacing was popular for patients requiring permanent pacing who had associated paroxysmal supraventricular tachyarrhythmias. Now, DDDR pacing with mode switching is considered the optimal pacing mode for such patients.

Dual-chamber rate-adaptive (DDDR) pacemakers are capable of all the variations described for DDD pacemakers. In addition to using P-synchronous pacing as a method for increasing heart rate, the sensor incorporated in the pacemaker may also drive heart rate. The resulting rhythm may be sinus-driven (alternatively called *atrial-driven* or *P-synchronous*) or sensor-driven.

The patient ideal for DDDR pacing has combined sinus node and AV node dysfunction, allowing restoration of rate responsiveness and AV synchrony.

Algorithms for determining the appropriate pacing mode for patients with sinus node disease and AV node disease are given in eFigure 74.8.1 and eFigure 74.8.2. eFigure 74.8.1, a more complex algorithm, considers most of the available pacing modes. The algorithm in eFigure 74.8.2 is simpler and assumes that a pacemaker

capable of rate adaptation will be used.

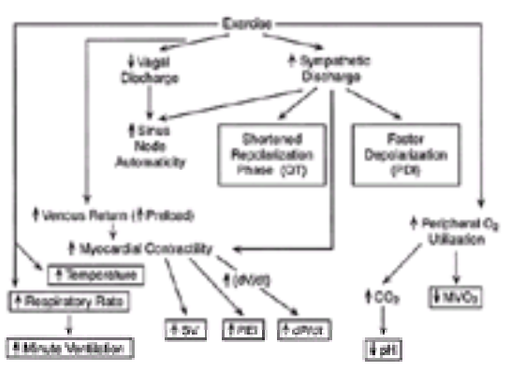
CHOOSING THE PACEMAKER SYSTEM HARDWARE

After the appropriate pacing mode has been selected, the actual pacemaker must be selected. The advising physician or the one performing the implantation should select a pacemaker that provides the specific features needed for the patient. It is imperative that the physician responsible for following the patient be completely familiar with the pacemaker implanted.

Lead selection should also be individualized. This requires a thorough knowledge of the available leads as well as the performance records of specific models (54,55).

Selecting the Appropriate Sensor for Rate-Adaptive Pacing

To classify sensors on the basis of their response to physiologic variables, Rossi (56) divided them into five orders (*e*Table 74.5.1). A variety of sensors appropriate for rate-adaptive pacing have been developed and are shown in *e*Figure 74.8.3 as end points of some physiologic response.



***e*FIGURE 74.8.3** Physiologic responses that have been investigated or used clinically for rate adaptation of permanent pacemakers. The boxed terms represent the end points used for rate adaptation. MVO_2, mixed venous oxygen; PEI, pre-ejection interval; SV, stroke volume.

*e*TABLE 74.5.1 CLASSIFICATION OF SENSORS BY RESPONSE TO PHYSIOLOGIC VARIABLES

Order	Physiologic variable
First: Sensor that directly measures O_2 consumption or energy expenditure	Oxygen uptake
Second: Sensor with a linear relationship to sensors of the first order	Cardiac output, minute ventilation,[a] atrioventricular O_2 difference
Third: Sensor with a linear relationship to sensors of the second order	Heart rate,[a] stroke volume,[b] mixed O_2 saturation,[b] respiratory rate, tidal volume
Fourth: Sensor that relies on changes in sympathetic activity and circulating catecholamines	QT interval,[a] right ventricular dP/dT,[b] preejection interval,[b] ventricular depolarization gradient[b]
Fifth: Sensor that responds to physiologic feedback mechanisms in terms of metabolic activity or receptor reflexes	Central venous pH, central venous temperature,[a] right atrial pressure,[b] mixed venous lactate and bicarbonate levels

[a]Available clinically in the United States or Europe.
[b]Under investigation.

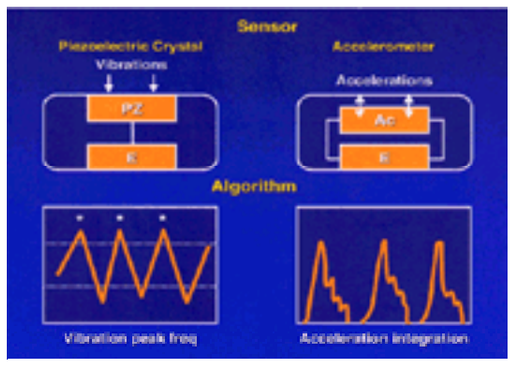
Activity Sensors

Currently, activity-controlled pacing with vibration detection (piezoelectric crystal or accelerometer) is the most widely used form of rate adaptation, because it is simple, easy to apply clinically, and rapid in onset of rate response (57,58).

The main difference between the piezoelectric crystal sensor and the accelerometer is that the crystal senses vibration from up and down motion and the accelerometer also senses anterior and posterior motion (*e*Fig. 74.8.4). Some investigators (57,58) have shown that with accelerometer-based pacemakers, heart-rate response tends to be more physiologic and less responsive to local pressure and tapping than with piezoelectric crystal-based pacemakers.



***e*FIGURE 74.8.4** Comparison of piezoelectric crystal and accelerometer. (Data from Wilkoff BL. Cardiac chronotropic responsiveness. In: Ellenbogen KA, Kay GN, Wilkoff BL, eds. *Clinical cardiac pacing*. Philadelphia: WB Saunders, 1995:432–446, with permission.)

Subsequent variations of activity sensors have included a gravitational sensor able to discriminate changes in vertical gravitational acceleration (59) and to measure electrical signals from a moving magnetic ball (60).

Minute-Ventilation Sensors

Minute volume (respiratory rate multiplied by tidal volume) has an excellent correlation with metabolic demand. In a rate-adaptive pacing system, minute volume is measured by emitting a small charge of known current from the pacemaker and measuring the resulting voltage at the lead tip (61) (Fig. 74.9). When both current and voltage are known, transthoracic impedance can be measured between the ring electrode and the pacemaker can. Because transthoracic impedance varies with respiration and its amplitude varies with tidal volume, the impedance measurement can be used to determine respiratory rate and tidal volume. A pacing algorithm uses the minute-volume measurements to alter pacing rate (62). Long-term reliability of the minute-volume sensor has been excellent (63), and this sensor is increasingly being used.

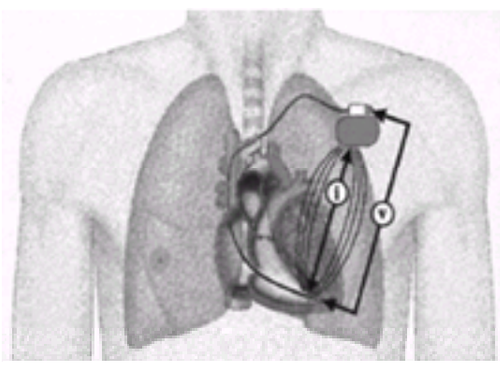


FIGURE 74.9 The mV sensor signal for rate change is derived by measuring the changes in transthoracic impedance. Ohm's law, R = V/I. (Courtesy of Guidant Inc., St. Paul, MN.)

Stimulus-T or QT-Sensing Pacemaker

The interval from the onset of a paced QRS complex to the end of the T wave has been used for rate adaptation for many years (64,65). This *stimulus-T interval* is affected by autonomic activity and heart rate. This relationship allows measurement of the stimulus-T interval to be used for rate adaptation. The QT-sensing rate-adaptive pacing system has been successful clinically. Response characteristics of this sensor make it a reasonable partner for activity sensors in dual-sensor systems.

Many other sensors have been incorporated, with varied success, in rate-adaptive pacing sensors. Other variables that have been used for rate-adaptive pacing include temperature, preejection interval, dP/dT, paced depolarization integral, and mixed venous oxygen saturation. These are discussed in the accompanying CD-ROM and in the online version of this text.

Temperature Sensors

Because central venous temperature increases with exercise, it is reasonable to consider this variable as the basis for a physiologic sensor. The increase in temperature can be measured with a thermistor contained within the right ventricular portion of the pacing lead (66). At the onset of exercise, core body temperature decreases as cooler peripheral blood is returned to the central circulation. Temperature-sensing rate-adaptive pacemakers have been available for many years but have never gained widespread acceptance, in part because a special pacing lead is required and rate response is less adequate at low workloads owing to the relatively slow response of central venous temperature (64).

Other Sensors

The *preejection interval* is the systolic time interval from the onset of electrical ventricular depolarization to the onset of ventricular ejection. In terms of ventricular pacing, the preejection interval is the interval between a right ventricular pacing stimulus and the onset of contraction determined by an impedance catheter (67,68). The preejection interval shortens as exercise workload increases, and this can be used as a signal to increase the pacing rate. An increase in heart rate does not appreciably affect the preejection interval (i.e., no significant positive feedback occurs). Stroke volume, also measured by an impedance catheter in the right ventricle, can be used for rate-adaptive pacing by incorporation of a pacing algorithm that alters the pacing rate to keep the right ventricular stroke volume relatively constant and within physiologic values (68).

Change in right ventricular pressure, dP/dT, has been used for rate-adaptive pacing. It is measured by incorporating a pressure transducer in the right ventricular portion of the pacing lead (69,70). In clinical investigations and in follow-up, the sensor has performed well.

Mixed venous oxygen saturation, measured with hemoreflectance oximetry, varies with physical activity and changes rapidly with the onset of exercise. For a rate-adaptive pacing system, the oximeter is incorporated in the right ventricular portion of the pacing lead. The greatest challenge has been to find a stable sensor. The results of the initial studies in animals and humans are encouraging (71).

Paced depolarization integral is a less well-known physiologic sensor (72,73). The concept of paced depolarization integral refers to the vector integral of the paced QRS, or ventricular depolarization gradient. Lau (74) explained the clinical response of this gradient as follows: During fixed-rate ventricular pacing, exercise and the effect of circulating catecholamines decrease the ventricular depolarization gradient. An increase in pacing rate increases the gradient.

Dual-Sensor Combinations

The overall performance of market-approved, single-sensor, rate-adaptive systems has been excellent. However, the perfect sensor would mimic the response of the normal sinus node at all levels of activity and during emotional stress.

Clinical problems with available rate-adaptive pacing systems have been minimal. Both activity-sensing and minute-ventilation devices may respond to nonphysiologic stimuli. For example, with activity-sensing systems, rate acceleration may occur when the pacemaker is tapped or the patient rolls over on the pacemaker. A

paradoxical rate response has also been shown (e.g., sensor-driven rate response is often faster during descent of stairs than during ascent). Although response to nonphysiologic stimuli represents less than perfect specificity of the sensor response, both activity sensing and minute ventilation have served patients very well.

The perfect sensor also would be resistant to nonphysiologic stimuli. A multisensor rate-adaptive pacing system could improve specificity by having one sensor verify or cross-check the other (75). For example, if one sensor indicated a rate increase and the other did not, a rate increase would not occur. Both sensors would have to indicate a rate increase before it would be allowed. Sensor combinations that are in use include QT interval/activity and activity/minute ventilation.

EFFECT OF PACING MODE ON MORBIDITY AND MORTALITY

An early study by Rosenqvist and colleagues stimulated much of the current interest in the effect of pacing mode on survival (76,77 and 78). Although their study is not without criticism, the 4-year analysis of the data remains impressive. At 4 years of follow-up, atrial fibrillation had occurred in 47% of the VVI group versus 7% of the AAI group (p = .0005), congestive heart failure in 37% of the VVI group versus 15% of the AAI group (p = .005), and mortality of 23% in the VVI group versus 8% of the AAI group (p = .025).

The Swedish study of Rosenqvist et al. (78) prompted many other investigators to perform retrospective reviews to assess the effect of pacing mode on mortality (*e*Table 74.5.2). Despite the retrospective nature of all the studies [except for that of Rosenqvist et al. (78)] and all the inherent weaknesses of retrospective analyses, the similar outcome of all the studies listed in *e*Table 74.5.2 (79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96 and 97) cannot be dismissed easily. This subject has been reviewed extensively and critiqued by Barold and Santini (98).

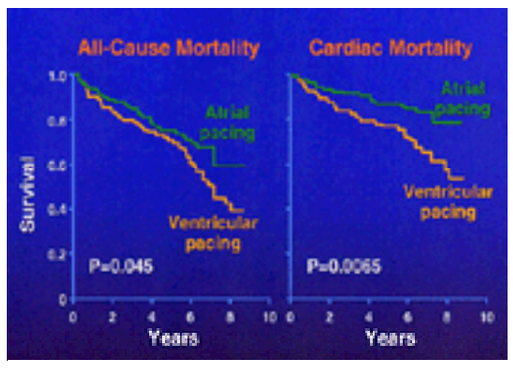
Adapted from Hesselson AB, Parsonnet V, Bernstein AD, et al. Deleterious effects of long-term single-chamber ventricular pacing in patients with sick sinus syndrome: the hidden benefits of dual-chamber pacing. *J Am Coll Cardiol* 1992;19:1542–1549.

Lamas et al. (99) reported survival in a large population (n = 20,948) of patients with sinus node dysfunction. The population was a random sample of the complete U.S. cohort of Medicare patients who had pacing for sinus node dysfunction from 1988 through 1990. DDD/DDDR pacing mode was an independent correlate of survival.

In a 1992 review and critique of the retrospective literature on the effect of pacing mode on the development of atrial fibrillation and survival, Lamas et al. (100) recommended a prospective randomized controlled trial, because the retrospective data did not allow definitive recommendations to be made regarding atrial pacing to prevent atrial fibrillation in patients with sick sinus syndrome.

Andersen et al. (101) published the first prospective data on pacing mode and survival. Of the 225 patients (mean age, 76 years) with sinus node dysfunction randomly assigned to AAI or VVI pacing, the VVI group had a higher incidence of atrial fibrillation (23% of the VVI group vs. 14% of the AAI group, $p = .12$) and thromboembolism ($p = .0083$) than the AAI group. Although no difference in mortality could be detected at the initial analysis at 3.3 years, a subsequent analysis at 5.5 years showed improved survival and less heart failure in the AAI group (102). In addition, there was a persistent reduction in the incidences of atrial fibrillation and thromboembolic events (eFig. 74.9.1 and eFig. 74.9.2).



***e*FIGURE 74.9.1** All-cause (*left*) and cardiac mortality (*right*) in a Danish pacing trial contrasting atrial and ventricular pacing. (From Andersen HR, Nielsen JC, Thomsen PEB, et al. The Pacemaker Selection in the Elderly trial, a prospective, randomized, multicenter trial, entered a total of 400 patients and assessed quality of life as a primary end point in patients with pacemakers programmed to DDDR and VVIR pacing modes (103). Secondary end points included all causes of mortality; hospitalization for congestive heart failure, cerebrovascular accidents, or both; and atrial fibrillation. No significant difference was noted between DDDR and VVIR pacing for quality of life or any of the secondary end points. There was a trend toward superiority of DDDR pacing in the sinus node dysfunction group, but it was not statistically significant.

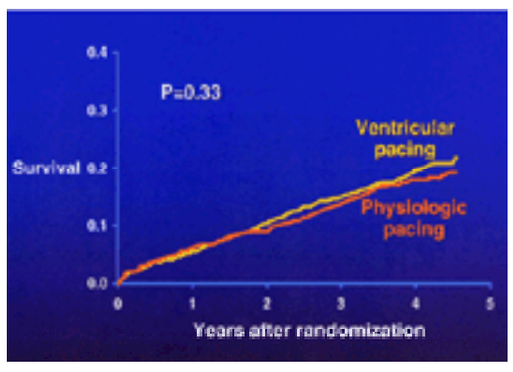
The Pacemaker Selection in the Elderly study was the template for the Mode Selection Trial. In this study, 2,000 patients with sinus node dysfunction will be randomly assigned to either VVI or DDD pacing. Primary end points will be all causes of mortality as well as cerebrovascular accidents.

The Canadian Trial of Physiologic Pacing (CTOPP) compared VVIR with DDDR or AAIR and had primary end points of overall mortality and cerebrovascular accidents (eFig. 74.9.3) and secondary end points of atrial fibrillation (eFig. 74.9.4), hospitalizations for congestive heart failure, and death due to a cardiac cause (104). CTOPP demonstrated that physiologic pacing (DDD/AAI) was associated with a decreased rate in the development of chronic atrial fibrillation, from 3.78% to 2.87% per year at the 3-year analysis. However, no difference in quality of life or mortality was demonstrated.



***e*FIGURE 74.9.3** From the Canadian Trial of Physiologic Pacing, the cumulative risk of stroke or death from a cardiovascular cause. (From Connolly SJ, Kerr CR, Gent M, et al. ***e*FIGURE 74.9.4** From the Canadian Trial of Physiologic Pacing, the incidence of atrial fibrillation was greater with VVI than physiologic pacing modes. (From Connolly SJ, Kerr CR, Gent M, et al. Effects of physiologic pacing versus ventricular pacing on the risk of stroke and death due to cardiovascular causes. *N Engl J Med* 2000;342:1385–1391, with permission of the Massachusetts Medical Society.)

A prospective randomized British trial (UK PACE) is comparing DDD with VVI pacing modes in 2,000 patients 70 years and older requiring permanent pacing for second- or third-degree AV block.

PACEMAKER IMPLANTATION

Guidelines for appropriate training for pacemaker implantation and follow-up have been established by the North American Society of Pacing and Electrophysiology as well as the American College of Cardiology (105,106). These guidelines are summarized in *e*Table 74.5.3.

*e*TABLE 74.5.3 RECOMMENDED TRAINING REQUIREMENTS FOR PACEMAKER IMPLANTATION

Core knowledge base for pacemaker follow-up
Participate in at least 100 pacemaker follow-up visits
Participate in at least 50 initial transvenous pacemaker implantations as the primary operator (recommended that at least one-half of these be dual-chamber)
Participate in at least 20 revisions of pacing systems
Exposure to lead extraction techniques (suggested)
Thorough knowledge of recognition and treatment of pacemaker and surgical complications and emergencies

Data from Hayes DL, Naccarelli GV, Furman S, et al. Report of the NASPE Policy Conference training requirements for permanent pacemaker selection, implantation, and follow-up. North American Society of Pacing and Electrophysiology. *Pacing Clin Electrophysiol* 1994;17:6–12; and Josephson ME, Maloney JD, Barold SS, et al. Guidelines for training in adult cardiovascular medicine. Core Cardiology Training Symposium (COCATS). Task Force 6: training in specialized electrophysiology, cardiac pacing and arrhythmia management. *J Am Coll Cardiol* 1995;25:23–26.

Actual implantation techniques are described in many textbooks, and interested readers should consult these sources (107). However, because a physician not participating in implantation may be involved in follow-up care of the patient, it is important for the physician to recognize and understand measurements made at the time of implantation and how they affect long-term management and the potential complications of implantation (see Pacemaker Complications, later in this chapter).

Also, a newer consideration in implantation technique is the effect of lead placement on hemodynamics. The ventricular pacing lead traditionally has been positioned in the right ventricular apex. However, more recent investigations have suggested that cardiac output may be improved by placing the ventricular lead in other portions of the right ventricle (108,109 and 110). More work is necessary to determine optimal lead site(s).

For the purpose of optimizing hemodynamics, reports of trichambered pacing (biventricular and right atrial) and four-chambered pacing are encouraging (111,112). Additional investigations are also necessary to determine the optimal number of chambers to be paced and optimal site(s) of lead placement.

Implantation Measurements

The position of the pacing leads must be tested acutely to establish that myocardial stimulation and sensing of intrinsic cardiac electrical activity are adequate and reliable. Stimulation threshold may be defined as the smallest amount of electrical activity that produces consistent myocardial capture outside the refractory period. The threshold may be affected by several factors, including the duration of the stimulus (pulse width), type of electrode and its age, site of stimulation, electrolyte status, and state of the myocardium.

The threshold, acute or chronic, is described in terms of voltage or current (milliampere) requirements for capture. Acceptable values for ventricular stimulation thresholds should be 1.0 V or less at a pulse width of 0.5 ms. The acceptable values for atrial pacing thresholds should certainly be less than 1.5 V at a pulse width of 0.5 ms, and with the atrial leads available currently, the threshold usually should be less than 1.0 V. Acute impedance measurements can range from 300 to 1,500 W, depending on the type of lead used.

The thresholds increase shortly after implantation and then usually decrease, reaching a stable value at approximately 6 weeks after implantation (113). The early increase in threshold is thought to be due to an inflammatory reaction at the electrode–myocardial interface. This reaction is minimized with leads capable of steroid elution (114,115).

Although the threshold for stimulation is described in terms of voltage and current, it is equally important that the pulse duration (the amount of time a given amount of energy is delivered) is also known. The shortest duration of an electrical impulse that produces consistent capture (at a constant pulse amplitude) represents the threshold of stimulation as a function of pulse duration. The strength-duration curve can be generated by comparing stimulation thresholds at various pulse widths (Fig. 74.10). This measurement is particularly important because the proper adjustment of pulse duration and output voltage allows long-term pacing with maximal conservation of energy.

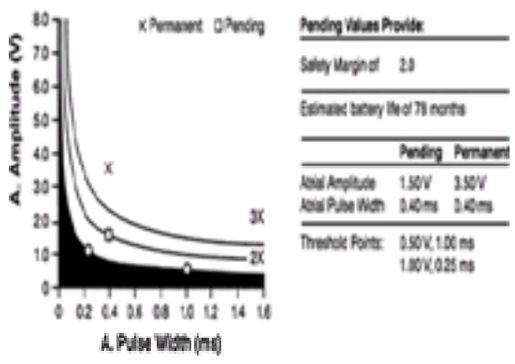

FIGURE 74.10 Atrial strength-duration threshold curve generated by the pacemaker programmer. The voltage amplitude is represented on the *y*-axis and the pulse width in milliseconds on the *x*-axis. The shaded area of the graph represents amplitude/pulse width combinations that would not allow successful capture or depolarization. The upper two curves represent output combinations that would result in two times and three times safety margin (i.e., areas above the capture threshold), which is represented by the lowermost of the three curves. The X is the pacemaker-derived suggested point of permanent programming, in this example, 3.5 V and 0.4-ms pulse width.

The lead impedance, or resistance to current flow, is determined by Ohm's law: $R = E/I$, in which E is voltage, I is current in milliamperes, and R is resistance in ohms. By simultaneously measuring voltage and the resultant current, the resistance can easily be calculated by transposing the equation. Average impedance tends to decrease slightly after initial implantation of the lead and then stabilizes. In the absence of lead complications or myocardial abnormalities, the long-term values for impedance tend to remain constant and do not differ significantly from the original value. Measurement of lead impedance is equally important at the time of pacemaker replacement in determining the integrity of the pacing lead.

Postimplantation Management

The length of time the patient is kept in the hospital after pacemaker implantation varies considerably among institutions. Many physicians who perform implantation allow patients who are not pacemaker dependent to ambulate the evening of the procedure, with dismissal the following morning. The patient's condition is usually monitored to assess normalcy of pacing in the immediate postimplantation period. Before dismissal, thresholds are documented and the pacemaker is programmed to its final settings. If a rate-adaptive pacemaker has been implanted, informal exercise is performed the morning after implantation and the rate-responsive parameters are adjusted to the needs of the patient. Pacemaker-dependent patients may be kept in the hospital one night. When the patient's pacemaker reaches battery depletion indicators, replacement is performed as an outpatient procedure.

Many physicians now perform initial pacemaker implantation as an outpatient procedure. Some perform outpatient implantation only in non–pacemaker-dependent patients, whereas others do not consider dependency status. Possibly, ambulatory pacemaker implantation with outpatient follow-up the next day may become the more usual approach (116).

PACEMAKER PROGRAMMING

All currently available pacemakers have some degree of programmability. In most markets, the simplest single-chamber pacemaker available is capable of rate, pulse width, voltage amplitude, sensitivity, refractory period, and polarity programmability. An attempt is being made to automatize many programmable features to allow optimal programming at all times. Programmable options that are available in many current pacemakers are listed in Table 74.6.

TABLE 74.6 POTENTIAL PROGRAMMABLE OPTIONS

Programming of Energy (Pulse Width and Voltage Amplitude)

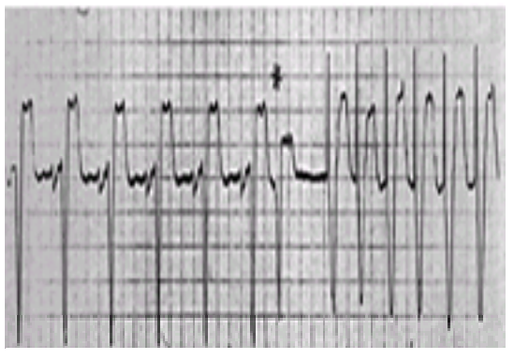
Output programming is probably the most important aspect of programming that should be accomplished routinely. The output must be high enough to allow an adequate pacing margin of safety but should also be programmed with the intent of maximizing pacemaker longevity.

One manufacturer has pacemakers capable of calculating and graphically displaying a strength-duration curve as well as suggesting optimal output parameters (Fig. 74.10).

Automatic programming of output functions has been investigated actively for more than a decade, but only recently have manufacturers developed this as a reliable option.

Refractory Periods

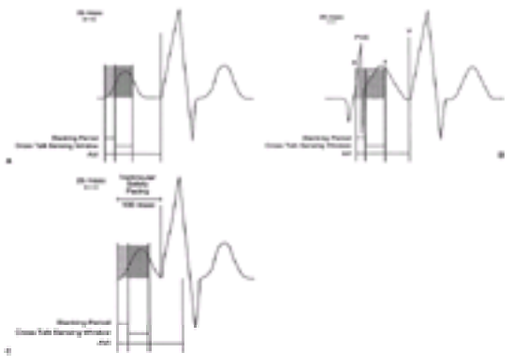
Every pacemaker capable of sensing must include a refractory period in its basic timing cycle. Refractory periods prevent the sensing of early inappropriate signals, such as the evoked potential and repolarization (T wave). The *PVARP* is the period after a sensed or paced ventricular event during which the atrial sensing circuit is refractory. Any atrial event occurring during the PVARP is not sensed by the atrial-sensing circuit. If a P wave occurs after the PVARP and is sensed, no atrial pacing artifact is delivered at the end of the VA interval. Because the maximal tracking rate of the pacemaker is determined by the total atrial refractory period, the PVARP is a significant determinant of the upper rate limit. The PVARP is especially important for the prevention of endless-loop or pacemaker-mediated tachycardia. In the presence of intact VA conduction, any event that uncouples AV synchrony may allow retrograde atrial activation. (The most common stimulus for VA conduction is a premature ventricular contraction.) If the atrium is refractory at the time of VA conduction, the atrium will be depolarized and the atrial depolarization will initiate the AVI. Paced ventricular depolarization may once again result in VA conduction, establishing a reentrant or endless-loop tachycardia (eFig. 74.10.1) (117). This often symptomatic tachyarrhythmia can be prevented by extending the PVARP so that the retrograde P wave is not sensed and, thus, does not initiate the AVI. In an effort to avoid a long PVARP, which in turn would limit the upper rate limit, most dual-chamber pacemakers have the option of PVARP extension. With this feature, the pacemaker extends the PVARP, usually for one cycle, if the pacemaker recognizes an event as a premature ventricular contraction. Most pacemakers define a premature ventricular contraction as occurring when there are two consecutively sensed ventricular events without an intervening atrial event. Most dual-chamber pacemakers also have algorithms capable of interrupting an established pacemaker-mediated tachycardia. The pacemaker usually recognizes a pacemaker-mediated tachycardia as a paced ventricular rate at the programmed maximum tracking rate. The algorithms usually require that a predefined number of VV cycles at the maximum tracking rate occur to meet the definition of pacemaker-mediated tachycardia.



***e*FIGURE 74.10.1** Electrocardiographic example of a pacemaker-mediated tachycardia in a patient programmed to the VDD pacing mode. A premature ventricular contraction (*asterisk*) results in retrograde atrial activation. The retrograde P wave must occur in the postventricular atrial refractory period and does not result in ventricular pacing. In the absence of another intrinsic atrial event, a paced ventricular event occurs at the lower rate limit. The resulting retrograde P wave is sensed, with ventricular pacing occurring at a cycle length of approximately 500 ms, which corresponds to the programmed upper rate limit of 120 beats/min. (From Hayes DL, Osborn MJ. Pacing. A. Antibradycardia devices. In: Giuliani ER, Gersh BJ, McGoon MD, et al., eds. *Mayo Clinic practice of cardiology*, 3rd ed. St. Louis: Mosby, 1996:909–976, with permission of Mayo Foundation.)

Atrioventricular Interval

To properly program the AVI, the components of a normal AVI have to be understood (eFig. 74.10.2A).



***e*FIGURE 74.10.2 A:** The atrioventricular interval (AVI) should be considered a single interval with two subportions. The entire AVI corresponds to the programmed value (i.e., the interval after a paced or sensed atrial beat allowed before a ventricular pacing artifact is delivered). The initial portion of the AVI is the blanking period.

This interval is followed by the cross talk–sensing window. **B:** The initial portion of the AVI in most dual-chamber pacemakers is designated as the *blanking period*. During this portion of the AVI, sensing is suspended. The primary purpose of this interval is to prevent ventricular sensing of the leading edge of the atrial pacing artifact. Any event that occurs during the blanking period, even if it is an intrinsic ventricular event, as shown in this figure, is not sensed. In this example, the premature ventricular beat (PVC) that is not sensed is followed by a ventricular pacing artifact delivered at the programmed AVI and occurring in the terminal portion of the T wave. **C:** If the ventricular sensing circuit senses activity during the cross talk–sensing window, a ventricular pacing artifact is delivered early, usually 100 to 110 ms after the atrial event. This has been referred to as *ventricular safety pacing*, *110-ms phenomenon*, and *nonphysiologic AV delay*. (From Hayes DL, Levine PA. Pacemaker timing cycles. In: Ellenbogen KA, ed. *Cardiac pacing*. Boston: Blackwell Scientific, 1992:263–308, with permission.)

Ventricular Safety Pacing

Cross talk is the sensing of the pacemaker output in the unintended chamber (i.e., sensing the atrial pacing output on the ventricular sensing circuit). (Other noise sensed on the ventricular lead could also result in the appearance of cross talk.) The major concern is the sensing of an atrial stimulus in the ventricular sensing circuit. To prevent ventricular inhibition by cross talk, a blanking period begins in the ventricular channel simultaneously with the atrial stimulus. During this period, the sensing circuits are insensitive. This interval most commonly is in the range of 12 to 50 ms, depending on the pacemaker, and is programmable in many pacemakers. If the blanking period is too long, a spontaneous R wave, occurring soon after the atrial stimulus, is not sensed and a competitive ventricular stimulus is emitted (eFig. 74.10.2B). If the blanking period is too short, the possibility exists that cross talk and ventricular inhibition may result. Cross talk occurs more frequently as the voltage output of the atrial stimulus increases or, less commonly, as pulse duration increases. The potential for cross talk should be evaluated carefully and the blanking period appropriately lengthened if necessary.

In an effort to create the safest situation possible while retaining a relatively short blanking period, this period is followed in most dual-chamber pacemakers by another portion of the AVI, during which activity sensed in the ventricular channel results in forced early ventricular pacing (eFig. 74.10.2C). This occurrence has been referred to as *ventricular safety pacing* or the *nonphysiologic AV delay*. Both terms are descriptive, because the paced interval is often shorter than the programmed AVI and is present to ensure ventricular pacing when cross talk or other noise is sensed in the early portion of the AVI. Because the safety stimulus occurs at a fixed delay after the beginning of the safety pacing interval, the total AVI is likely to be abbreviated. Because several early pacemakers had a ventricular safety pacing interval of 110 ms, the designation *110-ms phenomenon* has also been used.

Differential Atrioventricular Interval

An option of a differential AVI is an attempt to provide a PR interval (i.e., the hemodynamic interval) of equal duration whether the atrial contraction is paced or sensed. The AVI following a sensed atrial event is shorter than that following a paced atrial event. In some pacemakers, the differential is programmable, and in others, a preset differential is used when this feature is programmed *on*.

Rate-Variable or Rate-Adaptive Atrioventricular Interval

Some DDDR pacemakers have the capability of shortening the AVI during AV sequential sensor-driven pacing. Rate-adaptive or rate-variable AVI is intended to optimize the cardiac output by mimicking the normal physiologic decrease in the PR interval that occurs in the normal heart as the atrial rate increases (118,119). There is ongoing investigative work to automatize the AVI (120).

Mode Switching

Mode switching refers to the ability of the pacemaker to change automatically from one mode to another in response to an inappropriately rapid atrial rhythm (121,122). Mode switching is particularly useful for patients with paroxysmal supraventricular rhythm disturbances. In the DDD or DDDR pacing modes, if a supraventricular rhythm disturbance occurs and the pathologic atrial rhythm is sensed by the pacemaker, rapid ventricular pacing may occur. Any pacing mode that eliminates tracking of the pathologic rhythm (i.e., DDI, DDIR, DVI, DVIR) also eliminates the ability to track normal sinus rhythm, which is usually the predominant rhythm. Mode switching avoids this limitation.

Current mode switching combinations include DDDR to VVIR, DDDR to DDIR, DDD to VVI, DDD to VVIR, and VDDR to VDD.

PROGRAMMING GOALS OF RATE ADAPTATION

The most important aspect of programming rate-adaptive pacemakers is optimization of the patient's chronotropic response. It is negligent to implant a rate-modulating pacemaker and program the sensor to on without assessing rate response. To date, all pacemakers capable of rate modulation are packaged with the sensor off. To effect rate modulation, the sensor must actively be programmed on. Although the manufacturer usually states nominal values for rate-response parameters, the nominal values are not appropriate for all patients. Some form of exercise is necessary. It is not necessary to use formal exercise testing routinely.

For patients who are limited to activities of daily living, we perform informal exercise testing (e.g., walking at a casual and brisk pace in the hospital corridor or in the outpatient facility). Alternatively, rate adaptation can be assessed with diagnostic tools incorporated within the pacemaker. There are many variations, including histograms of rate response and ambulatory monitoring capabilities.

If formal exercise testing is performed, the chronotropic exercise assessment protocol (123), as developed at The Cleveland Clinic, or a low-intensity exercise protocol may be preferable to a standard Bruce protocol. The chronotropic exercise assessment protocol allows for a gradual increase in speed and grade and thus mimics more levels of exercise that are apt to occur during activities of daily living. In determining appropriate heart-rate response, the patient's age and usual activities must be considered (124).

If the pacemaker is capable of automatically programming rate response parameters, the patient still must be evaluated to determine whether the automatically programmed parameters result in the appropriate rate response for the patient.

PACEMAKER COMPLICATIONS

Complications can occur directly from the implantation technique or from failure of a component of the pacing system (125). Many complications are related directly to the experience of the physician performing the implantation.

Implant-Related Complications

Most patients undergoing pacemaker implantation have some discomfort at the site of the incision in the early postoperative period, and mild analgesics may be required. Mild ecchymoses around the incision are common.

Access to the subclavian vein, commonly used for implantation of an endocardial pacemaker lead, is usually accomplished by subclavian vein puncture with a modified Seldinger technique. Because of the relationship of the subclavian vein with the apex of the lung, traumatic pneumothorax and hemopneumothorax are always possible when a subclavian puncture technique is used. Hemothorax can be caused by laceration of the subclavian artery and hemopneumothorax by laceration of the lung and subclavian artery.

The anatomy of the area must be considered before subclavian puncture is undertaken. In a patient with unusual anatomic relationships, specifically, concern that the subclavian vein may be displaced, peripheral injection of contrast media and fluoroscopic guidance of the subclavian puncture help minimize complications (126).

Other potential complications of subclavian puncture include inadvertent arterial puncture, air embolism, arteriovenous fistula, thoracic duct injury, subcutaneous emphysema, and brachial plexus injury. These risks are minimized by careful technique and contrast-guided puncture.

Hematoma Formation

Because local ecchymoses are common after pacemaker implantation, a small or large ecchymosis that is not expanding is treated with observation only. Discrete hematoma formation at the site must be managed on the basis of its secondary consequences. Aspiration or evacuation of the hematoma should be considered only if there is continued bleeding or potential compromise of the suture line or skin integrity or if pain from the hematoma cannot be managed with analgesics.

To avoid hematoma formation, patients should have a normal prothrombin time before pacemaker implantation, and heparin administration should have been discontinued long enough to allow a normal partial thromboplastin time. Ideally, the patient should not recently have taken aspirin or other platelet-inhibitory drugs. For patients who have been receiving platelet-inhibitory drugs, hemostasis during implantation is often quite difficult. Careful attention to hemostasis before closure of the incision should prevent complications in most patients taking platelet-inhibitory drugs.

For patients who require therapeutic anticoagulation, a 48-hour delay after implantation is ideal before resuming full heparinization. If heparinization is started in less than 48 hours, bleeding may be minimized by avoiding a bolus dose and beginning with a maintenance dose only. Warfarin (Coumadin) usually can be administered safely 24 hours after implantation, but 48 hours is preferable if it does not compromise the patient's condition. Warfarin treatment should be started at the patient's maintenance dose and not at the higher doses that would be used to initiate therapy. The absolute timing for reinstitution of anticoagulant therapy varies from patient to patient. Anticoagulation at greater than therapeutic levels can result in late hematoma formation.

Arterial Lead Puncture and Cannulation

Introduction of the lead(s) into the subclavian artery, the aorta, and the left ventricle usually is readily recognized because of the pulsatile flow of saturated blood. If this is recognized promptly and the needle removed, it is unlikely that a problem will occur. Hemothorax may occur if the artery is lacerated, but this is an extremely rare complication. However, entry into the artery may not be recognized because of desaturation of the arterial blood, making it appear venous, or because of loss of pulsatile arterial flow due to hypotension or diminution of the arterial pulse pressure. Once the lead is within the great arteries, its passage into the left ventricle is as easy as passage into the right ventricle via the venous system.

Usually, entry into the artery can be recognized fluoroscopically as passage into the left ventricle, as viewed in the anteroposterior projection, and is significantly medial to the entry into the right ventricle. If a lateral view is used, a right ventricular lead will be anterior (i.e., posterior to the sternum), and a left ventricular lead will be in the posterior aspect of the heart.

In right ventricular pacing, the electrocardiogram shows a left bundle branch block pattern, and during left ventricular pacing, it shows a right bundle branch block pattern.

A pacing lead may also be placed in the left ventricle by passing it across an unsuspected atrial or ventricular septal defect. In patients with a ventricular septal defect, endocardial pacing should be avoided because small emboli potentially could cross the ventricular septal defect, causing symptoms in the arterial circulation.

Although left ventricular pacing may be permanently secure, it has been associated with thrombus formation, embolization, and, consequently, stroke. Reports of long-term uncomplicated left ventricular endocardial pacing exist, but the risk of embolization continues. The left ventricular lead should be removed if left ventricular placement is recognized early after implantation. If it is recognized after long-term uncomplicated pacing and anticoagulation can be performed, it may be best to leave the endocardial lead in place.

Lead Perforation

Ventricular perforation may be asymptomatic. The only sign may be a rising stimulation threshold. In other patients, the signs may include (a) right bundle branch block pattern from a lead placed in the left ventricle (depending on lead position, it is also possible to see this pattern when the lead is within the right ventricular cavity); (b) contraction of intercostal muscle or the diaphragm; (c) friction rub after implantation; and (d) pericarditis, pericardial effusion, or cardiac tamponade.

Ventricular perforation may be suggested by radiographic, electrocardiographic, and echocardiographic findings. After the perforation has been identified, lead withdrawal and repositioning usually are uncomplicated and rarely result in pericardial bleeding or tamponade.

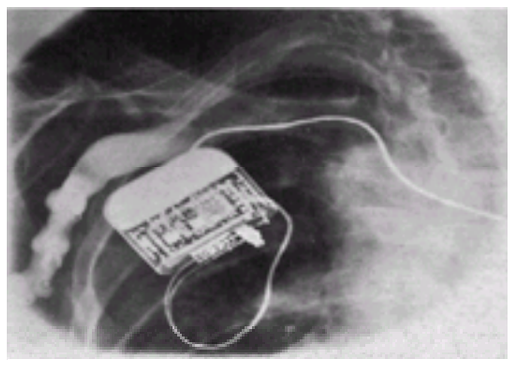
If the patient has mild symptoms or signs compatible with lead perforation (e.g., pericardial pain, friction rub) but a persistent perforation cannot be identified, it is reasonable to observe the patient. If the symptoms or signs resolve over 24 to 48 hours, it probably will not be necessary to reposition the lead. If an echocardiogram shows a small pericardial effusion but no definite perforation, serial echocardiograms should be performed to confirm that the effusion is not hemodynamically significant or enlarging.

Lead Damage

Leads may be damaged acutely by sharp instruments or by the stylets. Such damage is infrequently recognized, and the true frequency with which it occurs is unknown.

Venous Thrombosis

Partial or silent inconsequential thrombosis following transvenous lead placement is not uncommon and usually is clinically insignificant. Such partial or silent thrombosis may limit venous access at the time of pacing system revision (*e*Fig. 74.10.3) (127).



***e*FIGURE 74.10.3** Peripheral dye injection reveals contrast media in a dilated axillary/subclavian vein that subsequently is occluded at or near the lead entry site. (From Hayes DL, Holmes DR Jr, Furman S. Permanent pacemaker implantation. In: Furman S, Hayes DL, Holmes DR Jr, eds. *A practice of cardiac pacing,* 3rd ed. Mount Kisco, NY: Futura, 1993:261–307, with permission.)

If thrombosis involves the superior vena cava, axillary vein, or area around the pacemaker lead in the right atrium or right ventricle, several problems can develop, including occlusion of the superior vena cava and superior vena cava syndrome; thrombosis of the superior vena cava, right atrium, or right ventricle, with hemodynamic compromise or pulmonary embolism; or symptomatic thrombosis of the subclavian vein, with an edematous, painful upper extremity.

Lead Fracture

Lead fractures most often occur adjacent to the pacemaker or near the site of venous access (i.e., at a stress point). Although uncommon, direct trauma may damage the pacing lead. If a bipolar lead fractures and the pacemaker is polarity programmable, it may be possible to restore pacing by reprogramming to the unipolar

configuration. This is a short-term solution and should not be a substitute for replacing the lead.

Lead Insulation Defect

Insulation defects and conductor fractures may be caused by crush injury, specifically at the costoclavicular space, when the lead is placed via the subclavian puncture technique. In bipolar coaxial leads, the insulation defect often occurs internally (i.e., the layer of insulation between coils) as opposed to an external, outer surface insulation defect.

Thresholds, lead impedance, and electrograms are helpful in distinguishing insulation defect from conductor fracture. This information may be obtained with measurements made during implantation or with the telemetric capabilities of many pacemakers (*e*Table 74.6.1).

*e*TABLE 74.6.1 INTRAOPERATIVE EVALUATION OF PACING SYSTEM

Defect	Voltage threshold	Current threshold	Lead impedance
Wire fracture	High	High, normal, or low	High
Insulation break	Low	High	Low
Lead dislodgment	High	High	Normal
Exit block	High	High	Normal

Exit Block

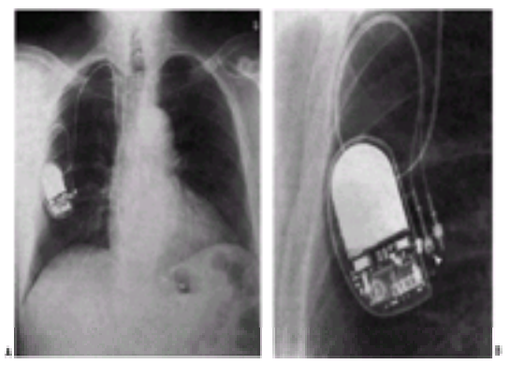
The most commonly accepted clinical definition of exit block is high pacing thresholds, often progressive, that cannot be explained on the basis of radiographic dislodgment or perforation. (If normal thresholds are achieved and maintained after the lead has been repositioned, then the term *exit block* does not apply.) Exit block is uncommon and appears to represent an abnormality at the interface of myocardial tissue and the electrode. Steroid-eluting leads are often effective in preventing exit block.

Lead Dislodgment

Active and passive fixation mechanisms common to current pacing leads have significantly decreased the incidence of lead dislodgment. Dislodgment has been classified by some as *macrodislodgment* and *microdislodgment*. Macrodislodgment is evident radiographically, and microdislodgment is not. Adequate lead position is assessed by postero-anterior and lateral chest radiographs. It must be remembered that on chest radiographs, lead placement may appear excellent in patients with microdislodgment.

Loose Set-Screw Connection

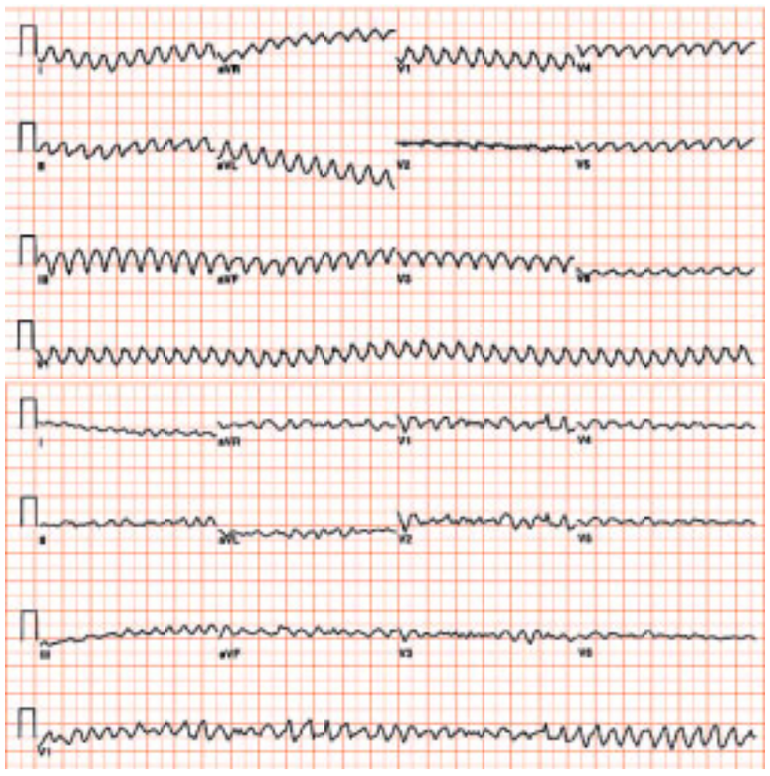
Intermittent or complete failure of output can occur because of a loose connection at the pacing lead–connector block interface (*e*Fig. 74.10.4). This usually occurs because the lead was secured inadequately at the time of implantation. When a connection is loose, manipulating the pacemaker may reproduce the problem. The poor connection may be evident radiographically.



***e*FIGURE 74.10.4 A:** Postero-anterior chest radiograph of a patient with a VVI pacemaker and a bifurcated bipolar ventricular lead. The patient presented with recurrent near syncope and intermittent failure to output. **B:** Close-up of the pacemaker reveals that the lower connector pin is not securely in the connector block (*arrowhead*). (From Hayes DL. Pacemaker complications. In: Furman S, Hayes DL, Holmes DR Jr, eds. *A practice of cardiac pacing*, 3rd ed. Mount Kisco, NY: Futura, 1993:537–569, with permission.)

Pacemaker-Related Arrhythmias

Supraventricular and ventricular arrhythmias are often encountered during pacemaker implantation and are usually inconsequential.



Ventricular flutter (A). Same patient with degeneration into ventricular fibrillation (B).

*Tip extrasystol*es may be seen in the early postimplantation period. These are ventricular complexes with morphology similar to that of the paced beats, because they originate at the same site as the paced beats but are not preceded by a pacemaker stimulus (Fig. 74.11). Tip extrasystoles occur most often during the first 24 to 48 hours after implantation and usually resolve spontaneously. Rarely is it necessary to suppress tip extrasystoles pharmacologically.

FIGURE 74.11 Electrocardiographic tracing from a patient with a newly implanted dual-chamber pacemaker. The paced beats are followed by ventricular complexes of similar morphology. The patient had not displayed ventricular ectopy before implantation, and the tip extrasystoles had resolved the morning after implantation.

Runaway pacemaker describes a sudden increase in pacing rate caused by circuit malfunction. This phenomenon is rare with current pacemakers. In more recent years, the rare reports of runaway pacemaker have usually described it as a complication of pacemaker exposure to therapeutic radiation, with subsequent circuit damage (128).

Pacing either cardiac chamber could induce rhythm disturbances if pacing occurred during a vulnerable portion of the cardiac cycle. This could happen with asynchronous pacing (VOO, AOO, DOO) if a pacing stimulus occurred during the vulnerable portion following intrinsic depolarization. From a practical standpoint, induction of atrial or ventricular arrhythmias during asynchronous pacing is uncommon. Historically, the induction of atrial rhythm disturbances was seen with DVI pacing, which allowed atrial pacing but not atrial sensing, and ventricular rhythm disturbances were described with VAT pacing, which allowed ventricular pacing but not ventricular sensing.

Endless-loop tachycardia is another well-recognized pacemaker-related rhythm disturbance (see previous discussion). In the presence of intact VA conduction, any event that uncouples AV synchrony may allow retrograde atrial activation. (The most common stimulus for VA conduction is a premature ventricular contraction.) If the atrium is refractory at the time of VA conduction, the atrium will be depolarized and the atrial depolarization will initiate the AVI. Paced ventricular depolarization may once again result in VA conduction, establishing a reentrant or endless-loop tachycardia (117).

Extracardiac Stimulation

Extracardiac stimulation usually involves the diaphragm or pectoral muscle. Diaphragmatic stimulation may be due to direct stimulation of the diaphragm (usually stimulation of the left hemidiaphragm) or stimulation of the phrenic nerve (usually stimulation of the right hemidiaphragm). At the time of implantation, if any extracardiac stimulation is noted when pacing at 10 V, the pacing lead should be repositioned. Because this usually is tested with the patient supine, it does not eliminate the possibility of diaphragmatic stimulation when the patient is upright. Diaphragmatic stimulation occurring during the early postimplantation period may be due to either microdislodgment or macrodislodgment of the pacing lead. (Although perforation of the myocardium by the pacing lead may result in diaphragmatic pacing, perforation is uncommon.) Stimulation may be minimized or alleviated by decreasing the voltage output or pulse width, or both. (An adequate pacing margin of safety must be maintained after decreasing the output parameters.) Local muscle stimulation occurs more often with unipolar than with bipolar pacemakers and usually is noted in the early postimplantation period.

Pectoral muscle stimulation may also be due to an insulation defect of the pacing lead, current leakage from the connector or sealing plugs, or erosion of the pacemaker's protective coating. If the problem is due to an insulation defect on either a unipolar pacemaker or the pacemaker lead, the stimulation may be minimized by decreasing the voltage output or pulse width or both, but it may be necessary to replace the defective portion of the system. If pectoral muscle stimulation occurs in a polarity-programmable pacemaker that is programmed unipolar, reprogramming to the bipolar configuration may alleviate the problem.

Erosion

Erosion is an uncommon complication that usually occurs because of an indolent infection. With the small size of current pacemakers, it is unlikely that erosion is due to insufficient pocket size, but this is possible.

If the patient seeks medical attention before the pacemaker has eroded through the skin, it may be possible to revise the pocket and reimplant the pacemaker (129). Impending erosion (i.e., skin thinned to the point of transparency) should be managed as an emergency. When any portion of the pacemaker has eroded through the skin, the only choice is surgical revision of the pacemaker site. If associated with infection, the entire system (both the pacemaker and the lead) probably will need to be removed and a completely new pacing system implanted at a clean site. In rare situations, it may be possible to revise the pacer site, enlarge the pocket, and fashion a satisfactory skin flap. Revision can be undertaken only in the absence of infection. Because infection may be present even if there is no purulent material, the pocket should be cultured and proven negative before pocket revision. Adherence of the pacemaker to the skin strongly suggests the presence of an infection, and salvage of the site may not be possible.

Pacemaker System Infection

The incidence of infection after pacemaker implantation should be less than 2% and, in most series, has been less than 1%. Careful attention to surgical details and sterile procedures are paramount in avoiding infection of the pacemaker site. Prophylactic antibiotic therapy before implantation and in the immediate postoperative period is controversial (130). Most studies have not shown any significant difference in the rate of infection between patients who have had prophylactic antibiotic treatment and those who have not. Irrigation of the pacemaker pocket with an antibiotic solution at the time of implantation probably is more important in preventing infection.

VIDEO

Video 74.1 Pacemaker vegetation. In this transesophageal echocardiogram, a huge mass is seen attached to the pacemaker wire as it passes through the right atrium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Pacemaker infection must be recognized and treated properly. It may appear as local inflammation and abscess formation in the area of the pacemaker pocket, as erosion of part of the pacing system through the skin with secondary infection, or as fever associated with positive findings on blood culture, with or without a focus of infection elsewhere. The most common clinical presentation is infection around the generator; septicemia is an uncommon mode of presentation. Early infections usually are caused by *Staphylococcus aureus*, are aggressive, and are often associated with fever and systemic symptoms. Late infections commonly are caused by *Staphylococcus epidermidis* and usually are more indolent, without fever or systemic manifestation. Treatment for both organisms requires removal of the entire infected pacing system, pacemaker and leads. Many other organisms have been reported in pacemaker system infections.

There is controversy about how to proceed after the infected system has been removed (131). In the absence of septicemia, a one-stage surgical approach involves implantation of a new pacing system at a distant clean site after explantation of the infected pacing system. In the presence of septicemia, or as a preferred approach (regardless of sepsis), others favor removal of the infected system, an interim period of temporary pacing (if required), and antibiotic management in the interim, with implantation of a new system at a later date.

Retained Lead Fragments

Multiple leads usually can safely be left in place as long as none of them has been part of an infected system (132). If the pacing system is infected, it is essential that

all the hardware be removed.

Lead Extraction

A detailed description of extraction techniques is beyond the scope of this textbook, but these techniques include various approaches: simple traction, locking stylet/telescoping sheaths with countertraction, laser-assisted extraction, electrodessication-assisted extraction, and open surgical techniques (133,134).

Pacemaker Allergy

Pacemaker allergy is a rare but reported complication (135). Usually, the allergy is to the pacemaker can, but the patient may be allergic to any exposed portion of the pacing system. The most common materials used in a pacing system that may be responsible for an allergy include titanium, epoxy, silicone rubber, and polyurethane. Proof of such an allergy requires sophisticated allergy testing, and correction of the problem may require changing to another type of system. Some of the cases of allergy, in fact, are low-grade *S. epidermidis* infections, which should be treated as infections rather than as allergies. No diagnosis of allergy should be made until infection has been ruled out thoroughly.

TROUBLESHOOTING ELECTROCARDIOGRAPHIC ABNORMALITIES

Electrocardiographic abnormalities in a patient with pacing can be grouped broadly into failure to capture, failure to output, undersensing, oversensing, and inappropriate rate change (136,137).

Failure to capture indicates that a pacing artifact is present without subsequent cardiac depolarization (Fig. 74.12). The differential diagnosis for failure to capture includes the following items:

FIGURE 74.12 Electrocardiographic tracing from a patient with a DDD pacemaker. The second ventricular pacing artifact fails to result in ventricular depolarization, failure to capture, and is followed by an intrinsic ventricular escape beat after a PR interval of approximately 300 ms. AP, atrial-paced event; AS, atrial-sensed event; VP, ventricular-paced event; VS, ventricular-sensed event.

- High thresholds with an inadequately programmed output
- Partial conductor coil fracture
- Insulation defect
- Lead dislodgment or perforation
- Impending total battery depletion
- Functional noncapture
- Poor or incompatible connection at connector block
- Circuit failure
- Air in pocket (unipolar pacemaker)
- Increased thresholds due to drugs or metabolic abnormality

Failure to output is sometimes used synonymously with *failure to capture*, but this is not appropriate. Failure to output is often due to oversensing and inhibition of output, but it also can be due to true failure to output from the pacemaker or circuit interruption such that the electrical signal cannot reach the heart (Fig. 74.13). The differential diagnosis for failure to output includes the following items:

FIGURE 74.13 Electrocardiographic tracing from a patient with a DDD pacemaker with a lower rate of 55 beats/min. The tracing begins with atrioventricular (AV) sequential pacing for two cycles. The next atrial pacing artifact results in atrial capture but is not followed by a ventricular pacing artifact at the programmed AV interval. (The programmed AV interval can be determined from the two initial paced cycles.) Following the intrinsic ventricular beat is a pause of 1,520 ms, which is greater than the programmed lower rate of 55 beats/min, or 1,090 ms. The first event that is recognized by the pacemaker is a P wave, which is designated as an atrial beat that occurs within a refractory period (AR). Whatever extrinsic, noncardiac event that has been oversensed has initiated a refractory period(s), because there is no evidence of any intrinsic cardiac event that has initiated the refractory period. AP, atrial-paced event; VP, ventricular-paced event; VS, ventricular-sensed event.

- Circuit failure
- Complete or intermittent conductor coil fracture
- Intermittently or permanently loose set screw
- Internal insulation failure (bipolar lead)
- Oversensing any noncardiac activity
- Total battery depletion
- Lack of anodal connector contact (examples include unipolar lead in bipolar generator, bipolar lead in a pacemaker programmed unipolar, air in the pocket of a unipolar device, unipolar pacemaker not in the pocket)
- Cross talk

The differential diagnoses of failure to capture and failure to output overlap. For example, electrocardiographic manifestations of a conductor coil fracture may include failure to capture due to significant leakage of current at the incomplete fracture site, leaving inadequate current to result in stimulation. Nonetheless, the pacemaker stimuli may appear. Alternatively, escaping current may be sensed by the pacemaker and inhibit pacemaker output. If the conductor coil is completely fractured, rendering the circuit incomplete, no pacemaker output will be detected on the electrocardiogram. Also, secondary sensing abnormalities may be noted.

Insulation defects may also present with oversensing and failure to output or with failure to capture, although the most common presentation of insulation failure is sensing abnormalities.

As the pacemaker battery reaches the end stages of depletion, either failure to capture due to dropping voltage output or failure to output due to total battery depletion may be seen. This degree of battery depletion could and should be avoided with appropriate pacemaker follow-up.

Apparent failure to capture will be noted if a pacemaker stimulus occurs during the refractory period of a spontaneous beat. This is referred to as *functional noncapture*.

Sensing abnormalities can be divided into true abnormalities, including undersensing (failure to recognize normal intrinsic cardiac activity; Fig. 74.14), oversensing (see Fig. 74.13), unexpected sensing of intrinsic or extrinsic electrical signals, and functional sensing abnormalities. The differential diagnosis for undersensing includes the following items:

FIGURE 74.14 Electrocardiographic tracing from a patient with a DDD pacemaker programmed to a lower rate of 85 beats/min. There is atrial failure to sense throughout the tracing. The arrow indicates an atrial-paced event (AP) that occurs immediately after an intrinsic atrial event and does not represent failure to capture but functional noncapture. When atrioventricular sequential pacing does occur, the atrioventricular interval is approximately 100 ms. This represents ventricular safety pacing that occurs because the intrinsic ventricular beat is occurring in the cross talk–sensing window. VS, ventricular-sensed event.

- Morphology of intrinsic event different from that measured at implantation
- Lead dislodgment or poor lead positioning
- Lead insulation failure
- Circuit failure
- Magnet application
- Malfunction of reed switch
- Electromagnetic interference
- Battery depletion

Most commonly, true undersensing is due to lead dislodgment or inadequate initial lead placement. Sensing abnormalities commonly are due to insulation defects and uncommonly to intermittent conductor fracture.

Occasionally, a normally functioning pacing system fails to detect atrial or ventricular extrasystoles. The intrinsic events measured at the time of implantation generate an electrogram at the electrode tip. If an extrasystole is occurring elsewhere in the heart, the sensing vector would be different from that of the normal intrinsic beat and the resulting voltage generated may not be great enough to be sensed by the pacemaker. This cannot be anticipated unless extrasystoles of the same morphology occur during implantation and can be measured. It is reasonable to attempt reprogramming the sensitivity to allow sensing of extrasystoles, but if this is unsuccessful, it is rarely, if ever, necessary to reposition the lead for this abnormality.

Functional undersensing is present when an intrinsic cardiac event is not sensed because it falls within a programmed refractory period (136). For example, if an intrinsic atrial event occurs within the PVARP, the event will not and should not be sensed. However, if the timing cycle is not understood thoroughly, it may appear as though there is true undersensing.

Fusion and *pseudofusion* beats occur as a result of superimposition of an ineffective pacemaker stimulus on a spontaneously occurring P wave or QRS complex (Fig. 75.15). Fusion is present when the morphology of the cardiac event is a hybrid of the intrinsic morphology and the paced morphology. Pseudofusion is present when the pacemaker artifact occurs late enough that the intrinsic morphology is not deformed. It usually is the consequence of pacemaker discharge during the refractory period of atrial or ventricular activity before sufficient intracardiac voltage is generated to activate the sensing circuit. This would be expected to occur when the pacing rate and the intrinsic rate are similar. Pseudofusion beats also may be the result of the delayed arrival of ventricular activity in a VVI system because of intraventricular conduction abnormalities at the site of the sensing electrodes.

FIGURE 74.15 Electrocardiographic tracing from a patient with a VVI pacemaker. The first two complexes represent fully paced ventricular depolarizations. The third and fourth events result in different paced morphology and represent fusion beats. This is followed by failure to capture and a single ventricular escape. VP, ventricular-paced event.

Every pacing mode has a defined lower rate limit, and dual-chamber pacemakers, as well as rate-adaptive pacemakers, also require a defined upper rate limit. One must be familiar with the timing cycle of a particular pacing mode as well as any idiosyncrasies of the specific pacemaker to determine whether the paced rate is appropriate. There are multiple causes of a paced rate that appear to be different from the programmed rate. The differential diagnosis includes the following items:

- Circuit failure
- Battery failure
- Magnet application
- Hysteresis (Fig. 74.16)
- Cross talk
- Undocumented reprogramming of the pacemaker
- Oversensing
- Runaway
- Malfunction of the electrocardiographic recording equipment, alteration in paper speed

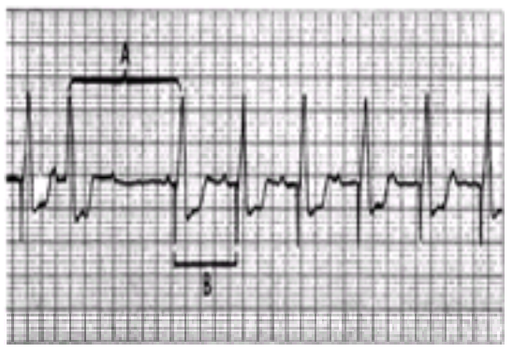


FIGURE 74.16 Electrocardiographic tracing from a patient with a VVI pacemaker programmed to a lower rate of 60 beats/min and hysteresis rate of 40 beats/min. The longer cycle **(A)** follows an intrinsic ventricular beat. The shorter cycle **(B)** represents the programmed lower rate of 60 beats/min (1,000 ms). (From Hayes DL. Pacemaker electrocardiography. In: Furman S, Hayes DL, Holmes DR Jr, eds. *A practice of cardiac pacing*, 3rd ed. Mount Kisco, NY: Futura, 1993:309–359, with permission.)

Drugs may affect sensing and pacing thresholds and result in electrocardiographic abnormalities (136). Although many drugs have been reported to affect pacing thresholds, the class IC agents are the only drugs that commonly cause a problem. Encainide, flecainide, propafenone, and moricizine have the potential to increase pacing thresholds. If these drugs are administered to a patient with a pacemaker, treatment should be monitored for an increase in pacing threshold. Class IC agents also have been reported to cause sensing abnormalities.

Electrolyte and metabolic abnormalities may also affect pacing and sensing thresholds. Hyperkalemia is the electrolyte abnormality that most commonly causes clinically significant problems, but severe acidosis or alkalosis, hypercarbia, severe hyperglycemia, hypoxemia, and myxedema should also be considered (136).

PACEMAKER DIAGNOSTICS

Various diagnostic functions are available in many current generation pacemakers and can be extremely helpful during pacemaker troubleshooting. Diagnostic capabilities vary widely from pacemaker to pacemaker (e.g., real-time telemetry of programmed parameters and battery status, lead impedance, electrograms, annotated electrocardiograms, histograms, or long-term recordings of rate variations, or a combination of these). A full discussion of this topic is beyond the scope of this textbook, but outstanding summaries of pacemaker diagnostics are available (138).

ELECTROMAGNETIC INTERFERENCE

Electromagnetic interference can be defined as any signal, biologic or nonbiologic, occurring within a frequency spectrum that may be detected by the sensing circuitry of the pacemaker. Electromagnetic interference can result in rate alteration, sensing abnormalities, magnet mode response, or reprogramming.

Biologic signals that may be responsible for oversensing include T waves, myopotential interference, afterpotential delay, and P waves. Isoelectric extrasystoles may give the appearance of oversensing (136,137).

Although there are many potential nonbiologic sources of electromagnetic interference, few sources of electromagnetic interference are truly a threat to patients with a pacemaker. Hospital sources of potentially significant electromagnetic interference are listed in Table 74.7. The effects of electrocautery and guidelines for cardioversion and defibrillation in the patient with a pacemaker are given in Table 74.8. There are additional potential nonbiologic sources of electromagnetic interference and oversensing that are listed in *e*Table 74.8.1 (139).

Electrocautery/cardiovascular/defibrillation
Magnetic resonance imaging
Lithotripsy
Radiofrequency ablation
Electroshock therapy
Diathermy

TABLE 74.7 SOURCES OF ELECTROMAGNETIC INTERFERENCE IN THE HOSPITAL ENVIRONMENT

Reprogramming
Permanent damage to the pulse generator
Pacemaker inhibition
Reversion to a fall-back mode, noise reversion mode, or electrical reset
Myocardial thermal damage
Cardioversion/defibrillation of the pacemaker patient
Ideally place paddles in the anterior-posterior position
Try to keep paddles at least 4 in. from the pulse generator
Have the appropriate pacemaker programmer available
Interrogate the pacemaker following the procedure

[c]Remote potential for interference.
[d]DDD mode only.
Modified from Telectronics: electromagnetic interference and the pacemaker patient. *Technical Notes* May 1991;110.

Electromagnetic interference during the last portion of the refractory period of a pacemaker, the *noise-sampling period*, can disable the demand function of the pacemaker and cause reversion to a fixed-rate mode for one cycle, creating the impression of undersensing.

Currently, there is considerable interest in cellular telephones (140) and antitheft devices (141) as potential sources of electromagnetic interference. The information available suggests that analog cellular telephones are safe for patients with pacemakers. Digital cellular telephones have a greater potential for electromagnetic interference, and pacemaker-dependent patients who use a telephone with digital technology should exercise caution. If the patient avoids having the telephone over the pacemaker, either from random motion of the telephone or from carrying the activated telephone in a breast pocket over the pacemaker, it is unlikely that any adverse clinical event will occur; however, research is being conducted on this question.

Antitheft devices also potentially can interfere with pacemakers (142,143 and 144). Patients with a pacemaker or an implantable cardioverter defibrillator (ICD) should be aware of electronic equipment for surveillance of articles and should avoid leaning on or lingering near such devices. If the patient passes through the equipment at a normal pace, adverse effects are unlikely. Any patient who feels unusual in any way when near electronic surveillance equipment should move away.

Hospital sources of potentially significant electromagnetic interference are electrocautery, cardioversion, defibrillation, magnetic resonance imaging, lithotripsy, radiofrequency ablation, electroshock therapy, and diathermy. The most important aspect of pacemaker or ICD care after exposure to any of these sources of electromagnetic interference is to reassess the device to be certain that the programmed parameters have not been changed.

Frequently, the question is asked about how to manage a patient with a pacemaker or ICD during a surgical procedure, given the potential effects of electrocautery and guidelines for cardioversion and defibrillation. Routine interrogation of the device and deactivation of ICD therapy should be performed before the operation. After the operation, the device should be reinterrogated and ICD therapy reinitiated. (During the time ICD therapy is off, the patient must be monitored.) For pacemaker-dependent patients, it is reasonable to program the pacemaker to an asynchronous pacing mode, VOO or DOO, or to achieve the same effect by placing a magnet over the pacemaker throughout the procedure. The potential effects of electrocautery are myocardial thermal damage, reprogramming, permanent damage to the pulse generator, pacemaker inhibition, and reversion to a fall-back mode, noise reversion mode, or electrical reset.

LIMITATIONS FOLLOWING PACEMAKER IMPLANTATION

In the early postimplantation period, it is reasonable to limit motion of the ipsilateral shoulder and arm. However, complete immobilization may result in a frozen shoulder and should be discouraged. Complete range of motion can be resumed in 2 to 4 weeks.

Although most patients with a pacemaker should be able to resume driving, reasonable advice is to wait 1 or 2 weeks after pacemaker implantation, for medicolegal reasons.

Few, if any, activities are totally contraindicated after implantation. Currently, magnetic resonance imaging is usually denied to patients with a pacemaker.

Any activity with the potential for creating a significant electromagnetic field near patients with a pacemaker should be approached with caution. The classic warnings given to these patients include avoidance of arc welding and working directly over combustion engines. Although pacemakers progressively have become more resistant to electromagnetic interference, caution is still warranted. If the livelihood or hobby of a pacemaker-dependent patient involves strong electromagnetic fields, pacemaker function should be monitored during exposure to the electromagnetic interference. The initial exposure should be controlled, with an assistant present to prevent sustained exposure should the electromagnetic interference result in sustained inhibition of the pacemaker. During exposure to electromagnetic interference, pacemaker function may be monitored with an ambulatory electrocardiogram or by monitoring capabilities incorporated within the pacemaker.

Younger patients with a pacemaker should be cautioned about contact sports. Although not absolutely contraindicated, the patient needs to understand that the system, especially the pacing lead(s), can be damaged by direct trauma.

FOLLOW-UP OF PATIENTS WITH PACEMAKERS

After the pacemaker has been implanted, the physician who performed the procedure or the institution where it was performed should assume responsibility for or arrange follow-up. Follow-up may be performed at the institution or at several commercial pacemaker follow-up centers.

There are several follow-up requirements (16,145). Although many centers have specific follow-up routines, the exact timing and location of follow-up, as well as programming routines, need to be established by the individual center to best meet its needs and institutional capabilities. The following requirements are included:

- Initial programming and optimization of rate response for all rate-adaptive pacemakers should be done.
- In-clinic follow-up should be done at 2 to 4 months to reassess energy output needs: Increase output if safety margin is inadequate, and decrease output to increase pacemaker longevity when appropriate. At the same follow-up visit, rate-adaptive parameters should be reassessed. Special attention also should be given to the incision and pacemaker pocket.
- Routine follow-up should assess battery status. In the United States, most patients have transtelephonic follow-up. The approved Medicare schedule for transtelephonic monitoring is more frequent than that followed by some centers. Regular transtelephonic follow-up should occur every 3 months until the first sign of battery depletion indicators (i.e., change in magnet rate or widening of pulse width), at which time the patient begins calling monthly until elective replacement indicators are reached; this has been shown to be an effective and safe follow-up schedule. Routine transtelephonic transmissions should include electrocardiographic monitoring with and without a magnet. Ideally, these records should be stored and available for retrieval for subsequent comparison should questions arise about change in pacemaker function.
- All patients should be reevaluated in the clinic setting at least once annually. Depending on the individual center's transtelephonic schedule, the center may prefer to have the patient assessed in the clinic more frequently.

Ideally, the pacemaker center will have all of the patient data in a computer database. This allows the nurse or technician who receives a transtelephonic call or the health care specialist evaluating the patient in the clinic to retrieve data about the last follow-up, the most recent measured pacing parameters, appropriate magnet

response of the pacemaker, age of the pacemaker and lead, programmed settings, and so forth.

TEMPORARY PACING

Familiarity with temporary cardiac pacing is essential for those involved in permanent cardiac pacing and the treatment of patients in coronary care units and postoperative units. Knowledge of the indications, techniques, and routes of implantation, postinsertion management, and risk-benefit ratio for each patient is required for safe, reliable pacing.

Temporary pacing may be used for diagnostic or therapeutic purposes (146). Most commonly, it is used for short-term management of symptomatic bradycardias, either as a bridge to permanent pacing or for self-limited bradycardias (e.g., bradyarrhythmias associated with Lyme disease).

The indications for temporary pacing include both bradycardia and tachycardia (Table 74.9). There are two general categories: (a) patients with symptomatic bradycardia, and (b) patients with asymptomatic bradycardia or conduction defects. The decision to proceed with temporary pacing depends on assessment of the risk of development of symptomatic bradycardia. With the advent of reliable and readily available external temporary pacing, it is less common to place a temporary transvenous pacemaker in patients with asymptomatic conduction disturbances.

Third-degree atrioventricular block
Symptomatic congenital complete heart block
Symptomatic acquired complete heart block
Postoperative symptomatic complete heart block
Symptomatic second-degree atrioventricular block
Acute myocardial infarction with:
Symptomatic bradycardia
Complete heart block
New bundle branch block with transient complete heart block*
Alternating bundle branch block*
Sinus node dysfunction
Symptomatic bradyarrhythmias
Tachycardia, prevention or treatment
Bradycardia-dependent arrhythmias
Long QT syndrome with ventricular arrhythmias

*If asymptomatic, could consider observation and readily available external pacing. Transvenous temporary pacing only if external pacing is required.

TABLE 74.9 INDICATIONS FOR TEMPORARY PACING

Temporary Pacemaker Placement

Temporary pacing usually is performed by a transvenous approach. The clinical setting determines the urgency with which pacing is required and, to a certain extent, the venous access chosen. The basic equipment required for temporary transvenous pacing includes a surgical pack with instruments to obtain venous access, a pacing catheter, an external pulse generator, and, under usual circumstances, a procedure room for placement.

Various temporary pacing catheters are available. Although dual-chamber temporary pacing can readily be accomplished, single-chamber ventricular pacing is the most common approach.

Management of Temporary Pacemakers

Patients with transvenous temporary pacemakers must have continuous electrocardiographic monitoring to ensure continued reliable pacing and to detect any other significant arrhythmias.

Pacing and sensing thresholds should be checked daily. Changing thresholds may be the first manifestation of lead dislodgment. Chest radiographs and electrocardiograms should be obtained periodically, and physical examination should be performed daily to identify any complications or change in pacing function.

If the patient's intrinsic rate is dominant, the pacemaker rate is increased to approximately 10 beats above the intrinsic rate so that the paced activity can be evaluated. The stimulation current then is decreased slowly until capture is lost. The point at which capture is lost is recorded in the medical record. Next, the output is increased to at least three times the threshold value, usually at least 3 to 5 mA.

Meticulous nursing care is essential for patients with temporary transvenous pacemakers. Rhythms should be recorded regularly, and connections between the pacing lead and the external generator should be checked daily to ensure that they are secure.

The entry site should be assessed regularly, with the area covered with a self-adhesive semipermeable transparent dressing. Careful attention to site care significantly reduces the potential for infection. The pacing catheter should be immobilized as much as possible at the skin entry site.

Esophageal Pacing

The esophagus can be used as a route for obtaining cardiac electrograms as well as for cardiac pacing (147). A conventional coronary sinus lead can be placed through the nares, or a small French quadripolar catheter or a pill electrode catheter can be used. The catheter is advanced and positioned to record the largest and most distinct atrial electrogram. Fluoroscopy is not required. Recording the electrogram is helpful in the diagnosis of the mechanism of arrhythmias (e.g., atrial flutter when flutter waves are not seen on the standard electrocardiogram).

In addition, the timing of the relationship of atrial and ventricular potentials can be helpful in analyzing the underlying electrophysiologic substrate. The same catheter can also be used for stimulation for attempts at inducing or terminating supraventricular tachycardia to assess antiarrhythmic therapy. Complications with transesophageal pacing are uncommon, but they may produce some discomfort for patients.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Controversies regarding the effect of pacing mode on morbidity and mortality continue. It was hoped that the publication of the CTOPP trial would bring some closure to the controversy, but it did not (104). With CTOPP failing to show a difference in mortality but a decreased incidence of atrial fibrillation with physiologic pacing, we now need to wait for longer follow-up of this population and for other trials that are under way.

Biventricular or left ventricular pacing for subjective and objective improvement in patients with congestive heart failure remains controversial but is becoming less so. With the publication of several randomized trials that have demonstrated clinical improvement, the controversy is no longer about whether pacing may be of benefit in a subset of this patient population but about the selection of patients and the optimal pacing site(s).

ICD therapy is discussed in Chapter 75. However, ICDs with extensive dual-chamber pacing capabilities are gaining widespread acceptance, and increasingly the clinical disciplines of cardiac pacing and cardiac defibrillation overlap.

Continued automaticity of permanent pacemakers undoubtedly will lead to better optimization of implanted devices and provide patients greater benefit from devices that previously may not have been tailored optimally to their needs.

Overall, permanent pacing was one of the remarkable success stories of the twentieth century. Having entered the twenty-first century, there are no signs that continued improvements in pacing therapy are slowing.

THE FUTURE

With the next decade, permanent pacemakers will continue to become more sophisticated, with automatic functions being the most prominent refinement. Also, dual-sensor rate-adaptive pacemakers will increasingly be accepted.

Prospective information is still limited about the effect of pacing mode on survival, but this information will become available within the next 2 to 3 years. The results of these prospective studies likely will support the results of retrospective studies, which consistently have shown lower morbidity and mortality with atrial-based pacing systems.

Biventricular and left ventricular pacing will gain increasing acceptance for the treatment of congestive heart failure, but it is too early to speculate whether either one may be used for patients with asymptomatic left ventricular dysfunction and an intraventricular conduction delay. If coronary lead placement becomes increasingly easier and reliable with the development of better leads and placement techniques, it could replace standard right ventricular apical pacing if a hemodynamic advantage can be shown. Pacing for the prevention of atrial fibrillation will also gain acceptance. A combination of alternate atrial pacing sites, either septal or left atrial pacing via the coronary sinus, with pacing algorithms that respond to premature atrial contraction will be the most likely successful application.

OVERVIEW

Randomized controlled trials have demonstrated the superiority of the implantable cardioverter-defibrillator (ICD) over antiarrhythmic drug treatment in patients with serious ventricular arrhythmias. At the same time, technological advances have made ICDs small, easy to implant, and very versatile. The surgical mortality rate has dropped to less than 1%. Antitachycardia pacing allows for the painless termination of many episodes of sustained monomorphic ventricular tachycardia (VT), whereas defibrillation shocks are needed for more rapid or polymorphic VT or for ventricular fibrillation (VF). However, complications including lead failure, infection, spurious shocks for supraventricular tachyarrhythmias, and psychological morbidity still occur. In the next few years, ongoing randomized studies will clarify the role of ICDs in the management of larger populations at risk for sudden cardiac death. These trials will assess not only the impact of ICDs on overall survival, but also their effects on quality of life and their cost-effectiveness. If these studies show positive results, ICDs will become the preeminent clinical tool for the prevention of sudden cardiac death. Future technological developments will continue to improve the performance of ICDs, expand their therapeutic capabilities for treatment of heart failure and supraventricular arrhythmias, and reduce complications associated with their use.

GLOSSARY

Biphasic waveform: Shock waveform that consists of two phases of opposite polarity.

Dedicated bipolar: Defibrillator lead in which sensing of the depolarization signal and pacing are delivered between a distal-tip electrode and a closely positioned ring electrode, neither of which participates in the defibrillation pathway.

Defibrillation threshold: Minimal shock strength that terminates induced VF during implant or follow-up testing.

Detection enhancements: Optional programmable criteria (e.g., sudden onset or rate stability) used to increase the specificity of detection algorithms for VT.

Integrated bipolar: Defibrillator lead in which sensing of the depolarization signal and pacing are delivered between a distal-tip electrode and a more proximal defibrillation coil that is part of the defibrillation pathway.

Upper limit of vulnerability: Shock strength at and above which VF is not induced, even when the shock is delivered during the ventricular vulnerable period.

HISTORICAL PERSPECTIVE

The ICD was conceived and developed by Mirowski and colleagues during the 1970s (1,2). It was inspired by the success of prompt external defibrillation in terminating VF complicating acute myocardial infarction in the coronary care unit and by the high recurrence rate in patients resuscitated from out-of-hospital cardiac arrest. Initially, the concept of an ICD met strong resistance in the academic community (3). After prolonged preclinical investigation, the first human implant was performed in 1980 (4). Early ICDs were primitive by current standards. The generators were bulky, nonprogrammable, and lacked shock synchronization capability. A thoracotomy was required to position at least one defibrillation patch epicardially.

The next generation of devices allowed programming of the rate and duration for arrhythmia detection, as well as of the initial shock energy. Several different manufacturers joined the first in researching, developing, and marketing ICD systems, accelerating the technological progress. In the early 1990s, the advent of transvenous-subcutaneous defibrillation leads obviated the need for thoracotomy (5). The adoption of biphasic shock waveforms improved defibrillation efficiency, and the addition of extensive telemetric and diagnostic capabilities refined patient follow-up.

Current ICDs deliver not only high-energy defibrillation shocks, but also low-energy shocks, antitachycardia pacing for VT, and pacing for bradyarrhythmias. They are £40 mL in size and are implanted transvenously with techniques similar to those used for implantation of standard pacemakers. As with other therapeutic modalities, technological advances preceded progress in the elucidation of the role of the ICD in different patient populations. More recently, randomized controlled trials have clarified the indications for ICD therapy.

CURRENT STATUS OF IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR TECHNOLOGY

ICD systems consist of two main components: the pulse generator, which harbors the electronic circuitry, power sources, and memory; and the lead electrode system that interfaces with the heart (6). Among the important components of ICD generators, the microprocessor orchestrates the interplay between the various subsections of the system. The read-only memory contains instructions that determine the general functional characteristics of the device, and individualized programming and diagnostic information are stored in random access memory. Lithium/silver vanadium oxide batteries provide the power source. The predicted longevity of current generators varies between 5 and 9 years, depending on the model and the frequency of activation. The pacing and high-output sections convert the 3 to 10 V provided by the batteries into device discharges that range from less than 1 V (for pacing) to 750 V (for defibrillation). The circuitry for delivering pacing pulses is similar to that found in standard bradycardia pacemakers, and high-voltage pulses are provided by capacitors. Batteries and capacitors consume two-thirds of the volume of current devices. The sense amplifier section adapts continually to the intracardiac ventricular depolarization signal, which may vary dramatically in amplitude (i.e., from sinus rhythm to VF) while avoiding significant signal drop and oversensing of T waves or extracardiac interference. This adaptation is achieved by adjusting either the gain or the sensing threshold. The communications section allows the ICD to exchange information with the dedicated programmer.

Transvenous defibrillation leads have complex multielectrode designs because of the need for combined pacing, sensing, and shocking capabilities (7). Fixation to the endocardium is achieved with tines (passive fixation) or screws (active fixation). Detection of low-amplitude signals in VT requires bipolar sensing, which is accomplished between a dedicated pacing/sensing electrode pair (dedicated bipolar) or between a single pacing/sensing electrode and a shocking coil electrode in close proximity (integrated bipolar). Integrated bipolar systems are convenient, because they permit two defibrillating coils in the same lead, and they may be more efficient, because they minimize the distance between the defibrillating coil and the endocardium. However, they also may be more susceptible than dedicated bipolar systems to oversensing of endogenous or exogenous interference (8).

ELECTROPHYSIOLOGIC MECHANISMS

Ventricular Fibrillation

During the last quarter of the nineteenth century and the first half of the twentieth century, work by MacWilliam, Prevost, Batelli, King, Wiggers, Kouwenhoven, and Beck established the effects of the application of electrical currents to the heart and the possibility of terminating VF by a timely electrical countershock (9). Active research on the mechanisms of VF and defibrillation during the last two decades has provided a rational basis for the development of ICD technology.

VF has been extensively studied in models of ischemia and reperfusion and after induction by a large premature stimulus during the vulnerable period of the cardiac cycle. Depending on the model, both reentrant and nonreentrant mechanisms can be responsible for the initiation of VF, but its maintenance depends mainly on reentrant mechanisms. Cinematographic (10) and computerized mapping studies demonstrate four stages of VF. In the early undulatory stage, the transition from sinus rhythm to VF is often briefly preceded by organized epicardial activation that represents functional reentry around a single circuit (11,12). A second premature stimulus given to the same site at a critical coupling interval (the protective zone) may terminate this functional reentry (12). The second stage, convulsive incoordination, lasts for 15 to 40 seconds and is characterized by more frequent, asynchronous waves of activation that have complicated patterns (13). Complete reentrant wavefronts are uncommon and, when present, have a small and unstable core, a short life span, and a short cycle length. Most of the time, multiple disorganized wandering wavelets that follow constantly changing pathways are present. The third stage, tremulous incoordination, lasts for 2 to 3 minutes. The final stage is atonic fibrillation. Timely ICD shocks are delivered during the first two stages.

Ventricular Defibrillation

Defibrillation is best described as a dose-response phenomenon that can be depicted with a sigmoidal curve of energy versus probability of success (14). Construction of a probability-of-success curve in patients is impractical, because it requires at least 20 to 30 fibrillation-defibrillation trials. Determination of the defibrillation threshold (i.e., the lowest energy that successfully terminates VF) is clinically more applicable (15). The defibrillation threshold determined by clinical protocols generally identifies energies with 50% to 75% probability of success (Fig. 75.1).

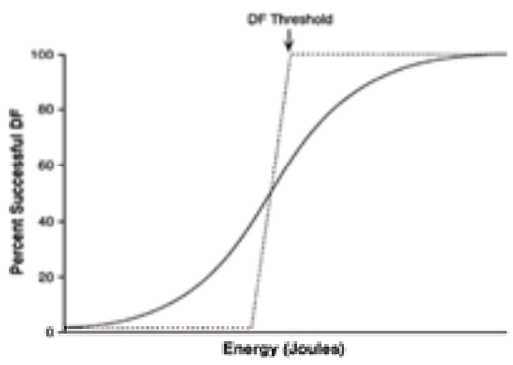

FIGURE 75.1 Comparison of defibrillation (DF) probability-of-success curve and DF threshold concepts. A probability-of-success curve implies a dose-response relationship in which increasing energies are associated with a higher percentage of success, whereas a DF threshold implies a clear-cut distinction between effective and ineffective energies. (Reproduced from Davy JM, Fain ES, Dorian P, et al. The relationship between successful defibrillation and delivered energy in open-chest dogs: reappraisal of the “defibrillation threshold” concept. *Am Heart J* 1987;113:77–84, with permission from Mosby–Year Book.)

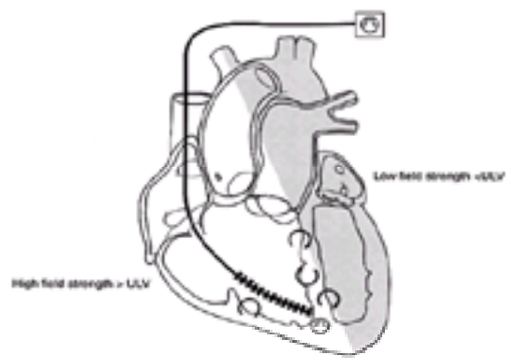
A defibrillation shock generates uneven potential gradients and current densities through the myocardium. The potential gradient is a measure of how quickly the electrical field changes over space, typically expressed in volts per centimeter. High-gradient areas are produced close to the electrodes, and low-gradient areas exist at distant sites (16). These extracellular potential gradients result in changes in the transmembrane potential of myocytes that are ultimately responsible for the process of defibrillation. The exact nature of the relationship between the distribution of extracellular potential gradients and the transmembrane potential is a topic of active research (17). Shock-induced prolongation and homogenization of refractoriness seem to be important determinants of the defibrillation process (18). Recent optical mapping studies showed that electrical shocks can induce areas of negative polarization (i.e., hyperpolarization) known as *virtual electrodes*, whose effects on membrane potential might last beyond the end of the shock. Negative polarization can “deexcite” cardiac cells, creating regions of excitable tissue through which wavefronts can propagate. These wavefronts can result in new reentrant circuits, inducing fibrillation or causing defibrillation to fail. In addition, deexcitation can lead to rapid propagation through newly excitable regions, resulting in the elimination of excitable gaps soon after the shock and causing defibrillation to succeed (19).

Mapping the electrical activity immediately before and after successful and failed shocks in animal models has provided valuable information about the mechanism of defibrillation. Successful defibrillation shocks halt all existing fibrillatory wavefronts without creating new wavefronts that reinduce fibrillation (20,21). Unsuccessful shocks may also halt fibrillatory wavefronts, but at the same time they induce new wavefronts (generally originating in a low-gradient area) that reinitiate the fibrillation (22). Preshock intervals at the sites activated early after these failed shocks are not distributed randomly, which suggests the presence of a vulnerable period in VT activations (23).

These observations tend to rule out the critical mass hypothesis as the mechanism of ventricular defibrillation. According to this hypothesis, successful defibrillation depends on the depolarization of a critical mass of myocardium: a shock could fail to halt the fibrillatory wavefronts in a region of myocardium smaller than the “critical mass” and still defibrillate the heart (24). The upper limit of vulnerability hypothesis better accounts for experimental findings (25). The upper limit of vulnerability is a shock strength at and above which VF is not induced, even when the shock falls in the vulnerable period of the cardiac cycle (26). This shock strength correlates well with the defibrillation threshold in animals (26) and patients (27).

The critical potential gradient that leads to the induction of VF during the vulnerable period of regular rhythm is very similar to the potential present in low-gradient areas that are responsible for reinitiation of fibrillation after a failed shock. Therefore, to defibrillate consistently, a shock must be strong enough to create fields above the upper limit of vulnerability throughout the myocardium. For example, with a transvenous electrode in the right ventricular apex, a shock may generate a low-gradient field in distant areas, such as the base of the ventricles, while the field is above the upper limit of vulnerability in the remainder of the ventricles (eFig. 75.1.1). In this latter area, all fibrillation wavefronts are eliminated and none can be reinitiated, resulting in cessation of fibrillation activation. In the low-gradient area, the results depend on the timing of the shock with regard to the local activation. A weak shock may terminate fibrillation only if it falls in the protective zone (28). This may explain the probabilistic nature of defibrillation. The critical potential at the low-gradient areas cannot be achieved by simply delivering shocks of very high strength, because such shocks produce functional and cellular damage in the high-gradient areas close to the electrodes (29).



***e*FIGURE 75.1.1** Mechanism of ventricular defibrillation. This figure shows a pectorally implanted implantable cardioverter-defibrillator in which shocks are delivered between a single coil positioned into the right ventricular apex and the case of the generator. A defibrillation shock resulted in a high-gradient field [higher than the upper limit of vulnerability (ULV)] in the right ventricle. The field strength of the left ventricle was low (lower than the ULV). In the area in which field strength was high, the shock terminated all reentrant wavefronts without initiating new ones. However, in the area in which field strength was low, the effect of the shock followed a probability function and was determined by whether the reentrant wavefronts were n the protective zone.

The type of defibrillation waveform and the surface area, impedance, and geometry of the defibrillation electrodes are crucial determinants of the energy requirements for defibrillation; clinical variables are less important (30). The ICDs currently in use deliver biphasic shocks (i.e., the pulse has two phases of opposite polarity). This waveform markedly decreases the energy requirements for defibrillation in comparison with the earlier monophasic waveform (31). However, identification of the optimal waveform remains elusive. Variables that influence the efficiency of the biphasic waveform are the duration and relative amplitude of each phase (32), and capacitance (32,33). With current ICD systems, a high defibrillation threshold (i.e., 23 J) is more likely to occur in patients with idiopathic dilated cardiomyopathy (as opposed to coronary artery disease) and in patients taking amiodarone or other antiarrhythmic drugs with sodium channel blockade activity (34).

CLINICAL TRIALS OF THE IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

Recent trials have examined the role of the ICD in secondary prevention of sudden cardiac death (i.e., in patients who have already had a clinical episode of life-threatening ventricular arrhythmia) and primary prevention of sudden cardiac death (i.e., in patients at high risk for this outcome who have not yet experienced a serious arrhythmic event) (Table 75.1 and Fig. 75.2).

Study	Control intervention	Population	Findings
Antiarrhythmics versus Implantable Defibrillator Trial (AVID)	Amiodarone or sotalol	Cardiac arrest survivor or syncopal ventricular tachycardia or symptomatic sustained ventricular tachycardia with left ventricular ejection fraction ≤0.40	Significant improvement in overall survival with ICDs.
Canadian Implantable Defibrillator Study (CIDS)	Amiodarone	Cardiac arrest survivor or syncopal ventricular tachycardia or symptomatic sustained ventricular tachycardia with left ventricular ejection fraction ≤0.35 or syncope and inducible ventricular tachycardia	Nonsignificant improvement in overall survival with ICDs.
Cardiac Arrest Study—Hamburg (CASH)	Propafenone, metoprolol, or amiodarone	Cardiac arrest survivor	Nonsignificant improvement in overall survival with ICDs.
Multicenter Automatic Implantable Defibrillator Trial (MADIT)	Conventional therapy	Prior myocardial infarction and left ventricular ejection fraction ≤0.35 and nonsustained ventricular tachycardia and inducible ventricular tachycardia and not suppressible with intravenous procainamide	Significant improvement in overall survival with ICDs.
Coronary Artery Bypass Graft–Implantable Cardioverter-Defibrillator Study (CABG Patch)	None	Coronary bypass surgery and left ventricular ejection fraction ≤0.35 and positive signal-averaged electrocardiogram	No difference in overall survival
Multicenter Unsustained Tachycardia Trial (MUSTT)	None	Previous myocardial infarction and left ventricular ejection fraction ≤0.40 and asymptomatic, unsustained ventricular tachycardia and inducible ventricular tachycardia	Significant improvement in overall survival in patients randomly assigned to electrophysiologically guided therapy. All the benefit in this arm occurred in patients who received ICDs.
Amiodarone versus Implantable Cardioverter-Defibrillator Randomized Trial (AMIO/VHT)	Amiodarone	Nonischemic cardiomyopathy and left ventricular ejection fraction ≤0.35 and nonsymptomatic nonsustained ventricular tachycardia	No difference in overall survival

Secondary Prevention of Sudden Death

Despite the unquestionable efficacy of the ICD in terminating VF and preventing sudden death, competing causes of death in ICD recipients (e.g., heart failure) may limit the overall survival benefit (35). Early nonrandomized studies suggested the superiority of the ICD over antiarrhythmic drugs in patients who had life-threatening ventricular arrhythmias (36), but the presence of selection bias, the use of controversial end points, and a lack of adequate controls limited the applicability of their implications. After controlled studies demonstrated an increase in the mortality rate with class I or pure class III antiarrhythmic drugs, only amiodarone (37) and sotalol (38) remained viable alternative therapies for ventricular arrhythmias. Well-powered randomized controlled trials were needed to assess the impact of the ICD on survival of patients with life-threatening ventricular arrhythmias.

The Antiarrhythmics versus Implantable Defibrillators Trial (AVID) (39) studied 1,016 patients with VF, sustained VT with syncope, or sustained VT with serious symptoms and left ventricular ejection fraction £0.40 that was not believed to be secondary to correctable or reversible causes. Patients were randomly assigned to receive an ICD or antiarrhythmic drugs (empiric amiodarone or guided sotalol). The study essentially compared the ICD to amiodarone, because only 2.6% of patients randomized to the antiarrhythmic drug limb were discharged on sotalol. ICD patients had better survival throughout the course of the study (unadjusted survival at 1 year, 89% among patients with ICD vs. 82% among patients treated with amiodarone, and at 3 years, 75% vs. 61%; $p < .02$). The corresponding reductions in mortality rates in the ICD group were 39% and 31% at 1 and 3 years, respectively. The ICD significantly decreased the incidence of cardiac arrhythmic death but had no effect on nonarrhythmic deaths (40). No significant differences were seen in the benefit conferred by ICD therapy among prespecified subgroups categorized according to age, degree of left ventricular dysfunction, presence of coronary artery disease, or presenting rhythm. More patients in the ICD group were treated with beta-blockers, but adjusting for this imbalance did not change the estimate of the mortality rate reduction attributable to the ICD. Several design features of this study, including the enrollment of a wide spectrum of patients with little evidence of selection biases [as supported by a concomitant comprehensive registry (41)], the almost exclusive use of transvenous defibrillators, and the comparison of ICD use against the best available antiarrhythmic drug therapy, make extrapolation of its findings to clinical practice valid.

The Cardiac Arrest Study—Hamburg (CASH) (42) randomly assigned cardiac arrest survivors to ICD implantation or treatment with propafenone, metoprolol, or

amiodarone. The propafenone limb was prematurely concluded when interim analyses suggested that the mortality rate in that limb was higher than in the ICD limb. The trial continued its comparison of ICDs, metoprolol, and amiodarone in 288 patients. Nearly one-half of the ICDs were implanted by thoracotomy. Over the course of a mean follow-up period of 57 ± 34 months, the crude mortality rates were 36.4% (95% confidence interval, 26.9% to 46.6%) in the group who received ICDs and 44.4% (95% confidence interval, 37.2% to 51.8%) in the groups receiving amiodarone or metoprolol. Overall survival was higher, though not significantly so, in patients assigned to ICD than in those assigned to drug therapy (one-sided p = .081; hazard ratio, 0.76). In ICD patients, the percentages of reduction in all-cause mortality were 42% at 1 year, 28% at 3 years, and 9% at 7 years of follow-up. No statistically significant differences were seen in global or sudden death rates between patients receiving amiodarone and patients receiving metoprolol.

The Canadian Implantable Defibrillator Study (CIDS) (43) included 659 patients who had been resuscitated after cardiac arrest or who had syncopal VT, presyncopal VT with a heart rate <150 beats/min or accompanied by left ventricular ejection fraction <0.36, or unmonitored syncope with subsequent spontaneous or inducible VT. Patients were randomly assigned to receive ICD implantation or treatment with empiric amiodarone. The 3-year mortality rate was 25% in the group who received ICD and 30% in the group being treated with amiodarone. A nonsignificant reduction in the risk of death was observed with the ICD, from 10.2% per year to 8.3% per year (relative risk reduction, 19.7%; 95% confidence interval, –7.7% to 40%; p = .142). A nonsignificant reduction in the risk of arrhythmic death was observed, from 4.5% per year to 3.0% per year (relative risk reduction, 32.8%; 95% confidence interval, –7.2% to 57.8%; p = .094).

A pooled analysis of AVID, CIDS, and CASH (44) showed that the estimates of ICD benefit from the three studies were consistent. A 28% reduction in the relative risk of death was seen with use of ICDs that was owed almost entirely to a 50% reduction in arrhythmic death. Survival was extended by a mean of 4.4 months by use of ICDs during a follow-up period of 6 years. Subgroup analysis showed that patients with left ventricular ejection fraction £0.35 derived significantly more benefit from ICD therapy than patients with better-preserved left ventricular function.

Primary Prevention of Sudden Death

Sudden cardiac death represents a major public health challenge that requires continuing development of new, multifaceted approaches for primary prevention. Use of the ICD is a potentially useful intervention, but the expense and invasiveness involved make accurate identification of candidates imperative. Efficient interventions require methods of identifying higher-risk clusters within the lower-risk subgroups (45). Target populations considered for prophylactic ICD implantation include patients with various combinations of left ventricular dysfunction, congestive heart failure, complex ventricular ectopy, late potentials on signal-averaged electrocardiography, depressed heart-rate variability, exercise-induced microvoltage T-wave alternans, and inducibility of VT at electrophysiologic study.

The Multicenter Automatic Defibrillator Implantation Trial (MADIT) (46) examined the efficacy of the ICD versus conventional therapy for prolonging survival in 196 patients with prior myocardial infarction, left ventricular ejection fraction £0.35, spontaneous nonsustained VT, and inducible VT not suppressed by intravenous procainamide at electrophysiologic study. Amiodarone was the most frequently used therapy in the group of patients receiving conventional therapy. ICD patients had better survival throughout the course of the study (actuarial survival at 1 year, 97% among patients who had ICDs vs. 77% among patients receiving conventional therapy; at 3 years: 83% vs. 56%; p <.009). This translated into a 54% reduction in death from all causes. More patients in the ICD group were treated with beta-blockers (26% vs. 8% 1 month after enrollment; 27% vs. 5% at last contact). Separate analyses revealed no evidence that antiarrhythmic medications, including amiodarone and beta-blockers, other cardiac medications being given 1 month after enrollment, or any of 11 preselected baseline variables had a meaningful influence on the magnitude of the ICD effect.

The Multicenter Unsustained Tachycardia Trial (47) was a randomized, controlled trial that tested the hypothesis that electrophysiologically guided antiarrhythmic therapy would reduce the risk of sudden death among patients with coronary artery disease, a left ventricular ejection fraction £0.40, and asymptomatic, unsustained VT. A total of 704 such patients in whom sustained ventricular tachyarrhythmias were induced by programmed stimulation were randomly assigned to receive either antiarrhythmic therapy, including drugs or use of ICDs (as indicated by the results of electrophysiologic testing), or no antiarrhythmic therapy. The 5-year incidence of the primary end point of cardiac arrest or death from arrhythmia was 25% among patients who received electrophysiologically guided therapy and 32% among those assigned to receive no antiarrhythmic therapy (relative risk, 0.73; 95% confidence interval, 0.53–0.99; relative risk reduction, 27%). The 5-year estimates of overall mortality rates were 42% and 48%, respectively (relative risk, 0.80; 95% confidence interval, 0.64–1.01). All the observed benefit occurred in patients who were given ICDs before discharge after failure to identify an effective drug during serial electropharmacologic testing. The risk of cardiac arrest or death from arrhythmia among the patients who received treatment with ICDs was significantly lower than that among the patients discharged without ICDs (relative risk, 0.24; 95% confidence interval, 0.13–0.45; p <.001). Neither the rate of cardiac arrest or death from arrhythmia nor the overall mortality rate was lower among patients who were assigned to electrophysiologically guided therapy and treated with antiarrhythmic drugs than among the patients who were assigned to no antiarrhythmic therapy.

The Coronary Artery Bypass Graft–Implantable Cardioverter-Defibrillator Study (CABG Patch) (48) randomly assigned 900 patients with left ventricular ejection fraction £0.35 and late-potentials on signal-averaged electrocardiography who were scheduled for coronary bypass surgery to treatment with ICD (implanted at the time of bypass surgery) or to no antiarrhythmic treatment. The study was halted prematurely after an average follow-up of 32 months when interim analysis showed no difference between the treatment groups (hazard ratio, 1.07; 95% confidence interval, 0.81–1.42).

The Amiodarone versus Implantable Cardioverter-Defibrillator Randomized Trial (49) randomly assigned 103 patients with nonischemic dilated cardiomyopathy and nonsustained VT to receive treatment with an ICD or with amiodarone. During a mean 21-month follow-up, no significant difference was seen in mortality rate between the groups, and the trial was stopped early because it met the futility criteria.

The divergent results of CABG Patch, MADIT, and the Multicenter Unsustained Tachycardia Trial highlight the importance of selecting populations at high risk for sudden death as targets for ICD therapy. In CABG Patch, most of the deaths were perioperative and not potentially preventable by an effective antiarrhythmic strategy. Only 29% of the deaths in the control group were classified as arrhythmic. Therefore, the 45% decrease in arrhythmic death that was seen in patients who were treated with use of ICDs did not translate into a significant reduction in the overall mortality rate (50). Other ongoing, large-scale, multicenter trials are evaluating the role of prophylactic ICDs in various high-risk populations, including patients with coronary artery disease and left ventricular dysfunction (51), patients with recent myocardial infarction and high-risk markers (52,53), patients with heart failure (54,55), and patients with nonischemic dilated cardiomyopathy (56) (*e*Table 75.1.1). It has been estimated that, depending on the definitions of the targeted populations, up to 1,000,000 patients could become candidates for ICD therapy in the United States in the next few years. At current costs, this would represent between $20 billion and $25 billion in hardware alone. Given the fiscal impact of such a radical change in indications, solid scientific backing for the move is needed.

***e*TABLE 75.1.1** ONGOING RANDOMIZED TRIALS OF THE IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

Study	Control intervention	Population	Status
Second Multicenter Automatic Implantable Defibrillator Trial (MADIT II)	Conventional therapy	Prior myocardial infarction *and* left ventricular ejection fraction £0.30	Ongoing; plans to recruit 700 patients
Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT)	Placebo or amiodarone	Congestive heart failure class II or III *and* left ventricular ejection fraction <0.35	Ongoing; plans to recruit 2,500 patients
Comparison of Medical Therapy, Pacing, and Defibrillation in Chronic Heart Failure (COMPANION) trial	Conventional therapy *or* biventricular pacing	Congestive heart failure class III or IV *and* left ventricular ejection fraction <0.35 *and* QRS duration ³120 ms	Ongoing; plans to recruit 2,200 patients
Defibrillator in Acute Myocardial Infarction Trial (DINAMIT)	None	Recent myocardial infarction *and* left ventricular ejection fraction <0.35 *and* mean 24-hour heart rate >80 beats/min *or* depressed heart-rate variability	Ongoing; plans to recruit 525 patients
Defibrillators in Nonischemic Cardiomyopathy Treatment Evaluation (DEFINITE)	Heart failure medications plus beta-blocker	Nonischemic cardiomyopathy *and* left ventricular ejection fraction <0.35 *and* symptomatic heart failure *and* nonsustained ventricular tachycardia *or* >10 ventricular premature depolarizations per hour	Ongoing; plans to recruit 408 patients

INDICATIONS AND CONTRAINDICATIONS FOR USE OF THE IMPLANTED CARDIOVERTER-DEFIBRILLATOR

Indications for ICDs are evolving as technology improves and results from clinical trials are incorporated into clinical practice (Table 75.2) (57). ICDs should be considered first-line therapy for patients who have survived episodes of cardiac arrest or hemodynamically significant sustained VT that is not caused by reversible causes and for patients who have coronary artery disease, left ventricular dysfunction, and nonsustained VT and in whom sustained ventricular tachyarrhythmias can be induced during electrophysiologic testing.

Secondary prevention
Patients with at least one clinical episode of ventricular fibrillation or hemodynamically significant ventricular tachycardia without reversible, correctable cause
Patients with unexplained syncope and inducible sustained ventricular tachycardia on electrophysiologic study
Patients with structural heart disease and sustained monomorphic ventricular tachycardia, regardless of hemodynamic tolerance[b]
Patients with idiopathic dilated cardiomyopathy and unexplained syncope despite electrophysiologic testing[b]
Primary prevention
Patients with coronary artery disease, at least moderate left ventricular dysfunction, spontaneous nonsustained ventricular tachycardia, and inducible sustained ventricular tachycardia
Patients with familial or inherited conditions who have a high risk for life-threatening ventricular tachyarrhythmias such as long QT syndrome or hypertrophic cardiomyopathy[b]

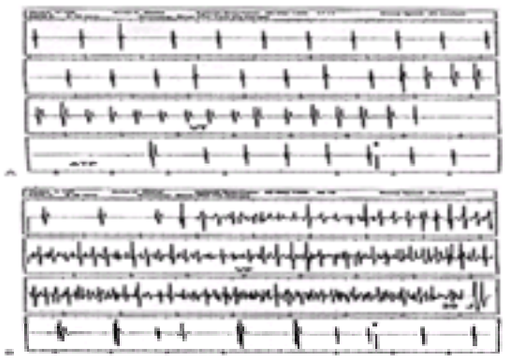
[a]Several other indications are being evaluated in ongoing randomized studies.
[b]Experts may differ regarding the appropriateness of implantable cardioverter-defibrillator therapy in these patients.

TABLE 75.2 CURRENT INDICATIONS FOR IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR IMPLANTATION[a]

Although most ICD recipients involved in clinical trials had coronary artery disease or idiopathic dilated cardiomyopathy, growing evidence from nonrandomized trials suggests that patients with other forms of cardiomyopathy and primary electrical disorders may benefit from use of ICDs. In a retrospective multicenter study of 128 patients with hypertrophic cardiomyopathy who were judged to be at high risk for sudden death, the rate of appropriate ICD discharge was 7% per year. The study suggested that VT or VF is the principal mechanism of sudden death in patients with hypertrophic cardiomyopathy, and that the ICD has an important role in its prevention (58). Some experts recommend ICD implantation (in conjunction with treatment with beta-blockers) as a fail-safe back-up therapy in high-risk patients who have congenital long-QT syndrome, especially those who have experienced an aborted cardiac arrest (59). Use of the ICD is also indicated in patients with idiopathic VF, including those with Brugada syndrome (60). Children who have life-threatening ventricular arrhythmia can also be successfully treated with ICDs (61).

Patients with syncope of undetermined origin and inducible sustained VT have a high incidence of appropriate defibrillator discharge (62,63) and also appear to benefit from ICD implantation. Patients with unexplained syncope, nonischemic dilated cardiomyopathy, and negative results of electrophysiologic examination have also been considered as candidates for ICD implantation because of the difficulties in risk-stratification. In a small series of 14 such patients, the incidence of appropriate shocks was high (50%) and similar to the rate observed in patients with idiopathic cardiomyopathy who were resuscitated from cardiac arrest (64). Other series have reported a lower (but not negligible) incidence of appropriate ICD intervention (65). Another retrospective analysis reported improved survival in patients who had nonischemic cardiomyopathy and unexplained syncope and were treated with ICDs (66). On the basis of this observational evidence, ICD implantation appears reasonable in this group of patients after other causes of syncope have been ruled out.

The role of the ICD in patients who have structural heart disease and present with nonsyncopal sustained monomorphic VT is unclear. Such patients had a low risk of sudden death in nonrandomized observational studies of antiarrhythmic drug therapy (67). On the other hand, a relatively high incidence of shocks for rapid, potentially life-threatening ventricular arrhythmias has been reported in a selected population of patients with stable VT who were treated with ICDs (68) (*e*Fig. 75.2.1). Furthermore, among 3,559 patients enrolled in the AVID registry who had documented sustained ventricular tachyarrhythmias, the hemodynamic impact of the index arrhythmia did not influence overall survival (69). Until more information is gathered, we believe that use of the ICD should be strongly considered in all patients who have structural heart disease and sustained VT. Catheter ablation of the tachycardia circuit(s) is another potentially curative option in these patients (70), but we believe it should, for now, be reserved as adjunctive therapy in patients who have ICDs and frequently recurring VT (71).



***e*FIGURE 75.2.1** Unexpected ventricular fibrillation (VF) in a patient with recurrent sustained monomorphic ventricular tachycardia (VT). The patient was being treated with amiodarone, 300 mg/day. The implantable cardioverter-defibrillator was programmed to treat tachyarrhythmias in two “zones.” Two electrograms (EGMs; 32 seconds each) were retrieved from device memory. **A:** Monomorphic VT initiated by a late-coupled ventricular pacing device on 6 March 1996, which is terminated by the first burst on antitachycardia pacing (ATP). Such episodes occurred on at least a monthly basis. **B:** An episode of VF initiated by an earlier-coupled ventricular pacing device (2 May 1996). The device detected it correctly and terminated it with a 20-J shock. There was no clear trigger for this episode. Arrows mark the redetection of sinus rhythm by the implantable cardioverter-defibrillator.

ICDs should not be implanted in patients whose ventricular tachyarrhythmias have been triggered by acute ischemia or infarction, correctable toxic or metabolic factors, or atrial fibrillation in the Wolff-Parkinson-White syndrome. The assessment of the reversibility of ventricular tachyarrhythmias in patients who have myocardial ischemia or severe coronary disease but not acute infarction is difficult and often inaccurate. Coronary artery disease was present in 81.5% of 270 patients in the AVID Registry who were thought to have VT or VF due to transient or correctable causes. Revascularization was performed in approximately one-half of the patients, and most of them were discharged without specific antiarrhythmic treatment. Actuarial 3-year survival was only 71% (lower than the 73% observed in patients in the same registry who had VT thought to be from uncorrectable causes) (41). The decision to perform surgical or percutaneous revascularization in patients with life-threatening ventricular arrhythmias should be based on grounds similar to those used in other clinical settings (e.g., presence of large areas of viable, ischemic myocardium). Observational studies suggest that the prognosis is good with revascularization alone in patients who have VF and normal left ventricular function, but arrhythmias frequently recur in patients who have left ventricular dysfunction or who present with VT. The value of using programmed ventricular stimulation after the revascularization procedure has been debated (72,73).

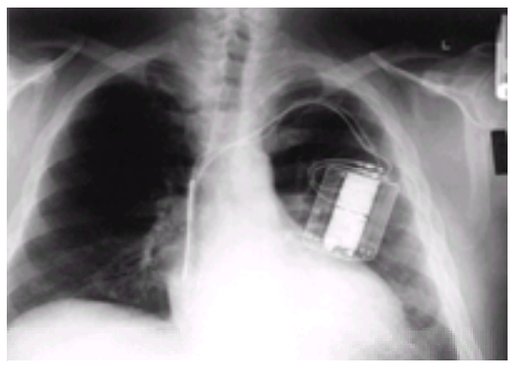
Patients with very frequent VT or VF that is not responsive to drugs, ablation, or antitachycardia pacing should not receive ICDs, because such arrhythmias would trigger frequent shock therapy. The low morbidity of current ICD implant techniques has made surgical or medical contraindications less relevant than in the past. However, patients who have terminal illness or a life expectancy of less than 6 to 12 months are not good candidates for ICD implantation. Patients awaiting cardiac transplantation have a high incidence of sudden death, but the use of the ICD as a “bridge” to transplantation remains controversial (74).

CLINICAL MANAGEMENT OF PATIENTS WITH IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

Implantation

Implantation of transvenous ICDs by clinical electrophysiologists is safe and efficient (75). Similarly high rates of success and acceptable complication rates are achieved when the implant is performed in the electrophysiology laboratory as when it is performed in the operating room (76). In most institutions, cost considerations favor the use of the electrophysiology laboratory. Shortened procedure times and reduced tissue dissection have essentially eliminated the need for general anesthesia. Implantation can be safely performed under local anesthesia, supplemented with intravenous sedation, administered by nonanesthesiologists (77,78).

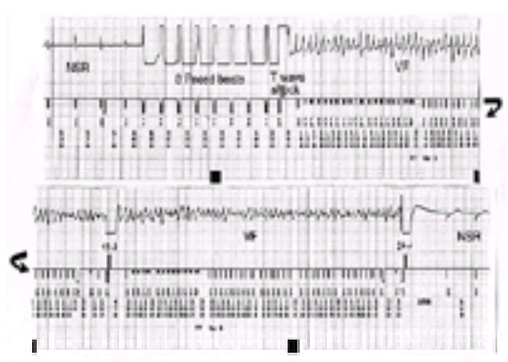
ICDs are implanted via the subclavian, axillary, or cephalic veins. A right ventricular lead is used for sensing and pacing. Shocks are delivered between a coil in this lead and the case of the generator. Leads incorporating a second coil at the level of the superior vena cava are often preferred, because the resulting bidirectional shocking vector improves the efficiency of defibrillation (79). Defibrillators capable of dual-chamber pacing require an additional pacing lead in the right atrium (*e*Fig. 75.2.2). Some ICDs can also deliver electrical therapy for atrial tachyarrhythmias, including cardioversion shocks for atrial fibrillation (80). This can be achieved with conventional systems that include a coil electrode in the superior vena cava (81). However, the lowest atrial fibrillation cardioversion thresholds are achieved when a coil electrode is added in the coronary sinus (82). Newer units that provide resynchronization therapy for heart failure (i.e., biventricular pacing) require insertion of an additional lead into a coronary vein to achieve left ventricular capture (83) (Fig. 75.3).



***e*FIGURE 75.2.2** Posteroanterior chest radiograph after implantation of a dual-chamber implantable cardioverter-defibrillator. An active-fixation bipolar pacing lead was positioned in the right atrial appendage. A dual-coil active-fixation defibrillation lead was positioned in the right ventricular apex.

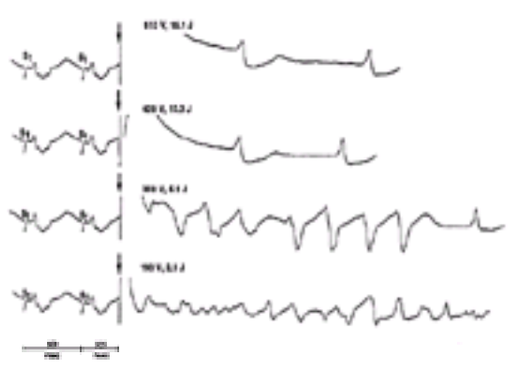
FIGURE 75.3 Posteroanterior chest radiograph after implantation of a triple-chamber implantable cardioverter-defibrillator capable of biventricular pacing. In addition to the atrial and defibrillation leads, a unipolar pacing lead was advanced via the coronary sinus into the middle segment of the anterior interventricular coronary vein.

The generator is implanted in a subcutaneous pocket in the pectoral area, although a submuscular plane is of value in patients who have a thin layer of subcutaneous tissue (84). The left side is preferred because of the smoother venous route to the heart and the more favorable shocking vector (85). Intraoperative testing is performed to establish appropriate pacing thresholds and adequate sensing during sinus rhythm and VF (86). The system's defibrillation capabilities are also tested, and the shocking lead configuration is optimized. In many institutions, this is accomplished by determining the ventricular defibrillation threshold (i.e., the minimal energy that terminates induced VF) (15), which is usually between 5 and 15 J. This ensures an adequate safety margin for defibrillation in most cases, because the maximum output of currently available ICDs ranges between 26 and 38 J (*e*Fig. 75.3.1). A safety margin can also be established by step-down protocols that do not require a failed shock.



***e*FIGURE 75.3.1** Assessment of the defibrillation threshold during implantable cardioverter-defibrillator implantation. Intracardiac electrograms and markers during an induction of ventricular fibrillation (VF) show initial normal sinus rhythm (NSR). VF is induced by a low-energy shock delivered during the vulnerable period (T-wave shock) after eight paced beats. VF is promptly detected. The first shock (15 J) does not terminate the arrhythmia. The device promptly recharges and restores NSR with a 24-J shock.

Defibrillation threshold testing requires the repetitive induction of VF. Although it is generally well tolerated, this procedure can result in myocardial depression in some patients (87). Alternatively, the upper limit of vulnerability is determined. Shocks of progressively smaller energy are delivered around the apex of the T wave during a paced or spontaneous rhythm until VF is induced (*e*Fig. 75.3.2). The last energy level that does not induce fibrillation is the upper limit of vulnerability. Accurate determination of the upper limit of vulnerability requires delivery of three shocks at the peak of the T wave and 20 and 40 ms before the peak (88). The upper limit of vulnerability predicts the energy level associated with a high rate of successful ventricular defibrillation and appears to be a convenient and reproducible method of determining defibrillation energy requirements without the need to induce multiple episodes of VF.



***e*FIGURE 75.3.2** Determination of the upper limit of vulnerability during implantable cardioverter-defibrillator implantation. Recordings on electrocardiographic lead II during baseline (S_1) pacing at 500 ms and S_1–S_2 interval of 325 ms. Shocks of 510 V (15.1 J) and 420 V (10.3 J) did not induce ventricular tachycardia or fibrillation. A 300-V (5.1-J) shock induced nonsustained ventricular tachycardia, which spontaneously converted to sinus rhythm. A 190-V (2.1-J) shock induced ventricular fibrillation. (Reproduced from Chen P-S, Feld GK, Kriett JM, et al. Relation between upper limit of vulnerability and defibrillation threshold in humans. *Circulation* 1993;88:186–192, with permission from the American Heart Association.)

The operative mortality rate after implantation of ICDs is less than 1% (89). Most patients can be discharged to their homes on the same day or the next day after surgery. Complications are similar to those accompanying pacemaker implantation and include pneumothorax, hemothorax, cardiac perforation, pericardial tamponade,

pocket hematoma (90), lead dislodgment, skin erosion, venous thrombosis, and frozen shoulder (91). Infection occurs in up to 2% of patients (92). Complete system removal and intravenous antibiotic therapy are generally needed to cure infection (93). Percutaneous extraction of chronic defibrillator leads is technically challenging, but it can be performed at low risk by trained operators equipped with specially designed tools (94). A large-bore (16 French) excimer laser sheath is particularly useful (95).

A thoracotomy approach using epicardial defibrillation patches is reserved for the rare patient who cannot be successfully defibrillated with a transvenous system and for patients with mechanical tricuspid valve prostheses. Implantation of an ICD via thoracotomy during concomitant cardiac surgery is rarely indicated, because it is associated with increased morbidity and death (96). Implantation of a transvenous system soon after recovery from the initial surgery is recommended instead.

Programming

The therapeutic target of ICD therapy should be the complete prevention of sudden death and syncope due to ventricular tachyarrhythmias using only sporadic delivery of high-energy shocks. Antitachycardia pacing is useful mostly for monomorphic VTs with rates lower than 200 beats/min (97). For these tachycardias, pacing and low-energy cardioversion both have a success rate of approximately 80% and have a similar risk of tachycardia acceleration (98). Antitachycardia pacing has the advantages of much better patient tolerance, lower energy consumption, and lack of atrial proarrhythmia (Fig. 75.4 and *e*Fig. 75.4.1).

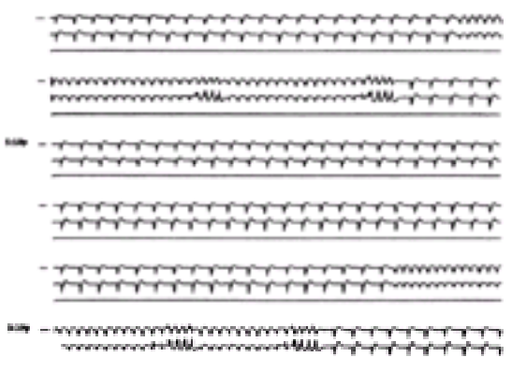


FIGURE 75.4 Antitachycardia pacing. Holter monitor shows that during a 2-minute period, two episodes of monomorphic ventricular tachycardia were converted by the scanning antitachycardia pacing algorithm (both in the second attempt). The patient remained asymptomatic. (Reproduced from Pinski SL, Simmons TW, Maloney JD. Troubleshooting antitachycardia pacing in patients with defibrillators. In: Estes NAM, Wang P, Manolis A, eds. *Implantable cardioverter-defibrillators: a comprehensive textbook*. New York: Marcel Dekker, 1994:445–477, with permission.)

***e*FIGURE 75.4.1** Stored atrial and ventricular electrograms (EGMs) and markers of an episode of ventricular tachycardia (VT) terminated by antitachycardia pacing (ATP) in a patient with a dual-chamber implantable cardioverter-defibrillator. Normal sinus rhythm (NSR) is interrupted by VT at a cycle length of approximately 320 ms with two-to-one ventriculoatrial conduction. A six-beat “ramp” of ATP restores NSR.

VF can be successfully treated only with a defibrillation shock. Charging to approximately 30 J (700 V) takes 5 to 13 seconds, depending on the model and battery status of the ICD (99). A first shock energy ³30 J, however, is not universally necessary. Programming of the initial energy at 5 J above the upper limit of vulnerability (100) or at twice the defibrillation threshold when it is <15 J (101) still results in almost 100% successful conversion of spontaneous arrhythmia episodes during follow-up. The shorter charge time decreases the risk of arrhythmia-induced syncope. If the first shock fails, the device will recharge and deliver up to five additional high-output shocks. Spontaneous episodes of de novo VF are not common, even in patients with a history of this arrhythmia (102). Most episodes begin as fast monomorphic VT, which the ICD detects and cardioverts before it has an opportunity to spontaneously degenerate into fibrillation.

ICDs recognize ventricular tachyarrhythmias based on programmable rate and duration criteria. Assuming correct sensing of the cardiac depolarization signal, this ensures 100% sensitivity for tachycardias above the programmed cutoff rate, but the specificity may be poor (103). Underdetection of tachycardias is uncommon when adequate sensing has been demonstrated during implantation. With some integrated bipolar leads, underdetection of VF has occurred after a failed shock. Increasing the distance between the distal tip and coil has largely averted this problem (104).

Failure to discriminate between supraventricular and ventricular tachyarrhythmias results in clinically inappropriate ICD interventions. Many of these spurious interventions can be avoided by adequate device programming. The cutoff rate for tachycardia detection should ideally be programmed to be higher than the patient’s maximal exercise-induced sinus rate. However, in many patients (more frequently in those on antiarrhythmic drugs), the sinus and VT rates overlap. Detection enhancements can be programmed that will improve the accuracy of arrhythmia diagnosis. The sudden onset criterion helps to discriminate between sinus tachycardia and VT, and the rate stability criterion is useful in rejecting atrial fibrillation with a rapid ventricular response (105). Morphology criteria assess the differences (e.g., width) in the intracardiac QRS electrogram between beats of supraventricular and ventricular origin. The incorporation of these enhancements into the detection algorithms represents a trade-off between sensitivity and specificity; a perfectly specific algorithm may fail to detect some episodes of hemodynamically significant VT (106,107). However, empiric enabling of conservative discrimination criteria is safe and effective in reducing the occurrence of inappropriate shocks (108). In some devices, a programmable sustained high rate criterion overrides the other enhancement criteria and allows therapy delivery for persistent tachycardia episodes that did not fulfill enhancement criteria. Dual-chamber ICDs can achieve better discrimination between ventricular and supraventricular arrhythmias by incorporating information that originates in the atrium into the detection algorithms (109) (Fig. 75.5 and *e*Fig. 75.5.1). However, the diagnostic performance of these devices is algorithm dependent, and in some cases, it may not surpass that of single-chamber devices with optimal programming (110).

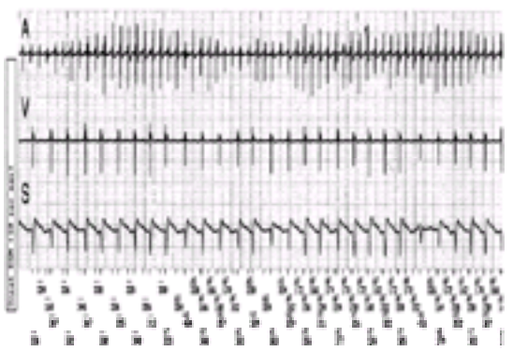

FIGURE 75.5 Accurate rejection of atrial fibrillation with rapid ventricular response by a dual-chamber implantable cardioverter-defibrillator. Stored atrial (A), ventricular (V), and shocking lead (S) electrograms (EGMs) show a very rapid atrial rate (approximately 350 beats per minute) and an irregular ventricular rate of approximately 165 beats per minute. Despite the fact that the ventricular rate was within the programmed ventricular tachycardia detection window, the device interpreted the fast

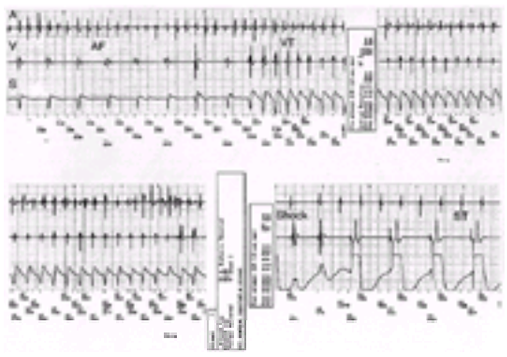
atrial rate and the slower and irregular ventricular rate as representing atrial fibrillation and appropriately withheld intervention.



***e*FIGURE 75.5.1** Appropriate detection of “dual” tachycardias by a dual-chamber implantable cardioverter-defibrillator. Atrial (A), ventricular (V), and shocking leads (S) stored electrograms (EGMs) show initial atrial fibrillation (AF) with paced ventricular rhythm followed by the sudden onset of fast ventricular tachycardia (VT). The VT is detected and a 31-J shock terminates both arrhythmias. A sinus (or atrial) tachycardia (ST) that is faster than the upper tracking rate ensues. The device initiates atrial-synchronous ventricular pacing with a two-to-one response.

The VVI(R) antibradycardia pacing in single-chamber ICDs is useful in patients who have intermittent or shock-induced bradyarrhythmias, but it has a more limited role in patients who need permanent pacing. It has been estimated that up to 55% of patients could benefit from use of a dual-chamber ICD (111). Widely accepted indications for dual-chamber pacing may be present in as many as 30% of patients who require ICD implantation (111,112). The frequent need to add drugs that have negative chronotropic effects (e.g., amiodarone or sotalol) in patients in whom ICDs have been implanted for control of VT may justify use of a dual-chamber ICD system in some patients who do not have documented bradycardia (113). Industry surveys estimate that in 1999, 50% of the ICDs implanted in the United States and 30% of those implanted in Europe had dual-chamber pacing capabilities (113).

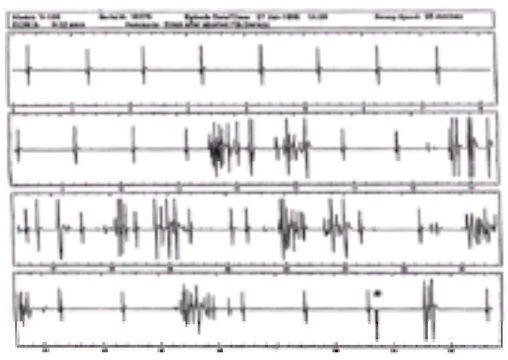
ICDs capable of dual-chamber, rate-responsive pacing have nearly eliminated the need for separate pacemakers while increasing the clinical importance of recognizing ICD pacing malfunction, especially in pacemaker-dependent patients (114). ICDs can display the same causes of pacing malfunctions seen in permanent pacemakers, including oversensing of interference, lead dislodgment or failure, exit block, premature battery depletion, random component failure, and software error. It is recommended that higher pacing outputs be programmed for approximately 1 minute to prevent failure to capture immediately after a defibrillation shock. Because of their higher sensitivity, ICDs are more likely than pacemakers to oversense extracardiac (e.g., myopotentials or electromagnetic fields) or intracardiac (e.g., T waves) interference. The lack of magnet-triggered or programmable asynchronous pacing modes makes the management of pacing-dependent ICD patients difficult during procedures that involve sources of electromagnetic interference.

ICD interventions can have proarrhythmic effects, which are rarely fatal but increase the morbidity associated with device therapy (115). ICD-induced proarrhythmia often results from inadequate programming. Prevention of proarrhythmia triggered by appropriate device interventions (e.g., tachycardia acceleration) is based on tailoring of antitachycardia therapies to the individual patient. When acceleration of VT occurs, prompt delivery of a high-output shock will generally prevent syncope (116) (*e*Fig. 75.5.2). Prevention of proarrhythmia resulting from the delivery of inappropriate therapies depends on the optimization of sensing parameters and detection algorithms, the suppression of the triggering rhythms, or both.

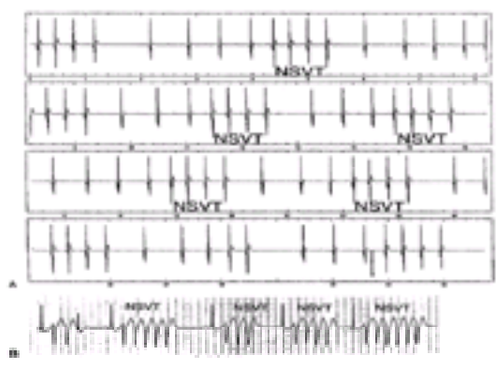
***e*FIGURE 75.5.2** Acceleration of ventricular tachycardia (VT) by antitachycardia pacing (ATP). Stored ventricular electrogram and marker show initial VT with a cycle length of approximately 310 ms. A seven-beat “ramp” of ATP accelerates the VT to a cycle length of approximately 250 ms. The faster tachycardia is detected in the ventricular fibrillation “zone” and promptly terminated with a 19.9-J shock. The patient felt lightheaded but had no syncope. NSR, normal sinus rhythm.

Follow-Up and Long-Term Complications

Follow-up of ICD patients is best carried out in a focused device clinic (117). Routine follow-up should include taking a careful history with regard to interim symptoms of tachyarrhythmias and ICD discharges; device interrogation (including real-time telemetry of battery status and retrieval of diagnostic data from the memory) (*e*Fig. 75.5.3 and *e*Fig. 75.5.4); and determination of pacing and sensing thresholds. Radiologic examination can demonstrate lead displacement or migration but is less useful for the identification of lead fractures (118). Routine predischarge noninvasive arrhythmia induction in the electrophysiology laboratory is no longer recommended (119). It should be selectively performed when satisfactory testing is not achieved during implantation or when treatment with antiarrhythmic drugs that can decrease defibrillation efficacy is added during follow-up (120). The relative merits of empiric programming of detection and therapeutic algorithms (121) for VT versus fine-tuning based on the results of noninvasive arrhythmia induction are not clear (122).



***e*FIGURE 75.5.3** Stored electrograms (EGMs) from a patient with lead fracture. The breakdown produced “make-and-break” signals that were recognized as a ventricular tachyarrhythmia. Because the signals were present intermittently, the device could not “reconfirm” the arrhythmia, and the shock was not delivered. The lead was replaced. Early identification of the problem prevented premature battery depletion.



***e*FIGURE 75.5.4** Value of stored electrograms (EGMs) in patients with aborted shocks. Stored EGM **(A)** of a patient who has multiple aborted shocks caused by frequent nonsustained runs of ventricular tachycardia (NSVT). The diagnosis was confirmed with electrocardiographic monitoring **(B)**, and the arrhythmia was suppressed pharmacologically.

Approximately 40% of patients receive appropriate discharges during the first year of follow-up after implantation of an ICD. The rate of new first shock drops by 10% each year after the first (123,124). Appropriate device activation occurs sooner and more often in patients with spontaneous (123) or inducible sustained monomorphic VT (124). There is a morning peak in device activation for rapid ventricular tachyarrhythmias, which is observable in patients with and without ischemic heart disease (125). Some studies have found a similar prognosis in patients whose devices did or did not fire (124), whereas other studies have demonstrated worse outcome in patients who present with ventricular arrhythmias that trigger shocks, especially in patients in whom more than one shock is necessary for termination of arrhythmia (126). The occurrence of clusters of VT that require multiple shocks is also associated with a poor outcome (127,128).

Complete withdrawal of antiarrhythmic drugs is a desirable (but not always attainable) goal in patients with ICDs (129). Indications for concomitant antiarrhythmic drug therapy include suppression of frequently recurring ventricular arrhythmias that trigger device intervention, suppression of supraventricular arrhythmias, and slowing of VT to avoid syncope and facilitate pace termination. In a double-blind, placebo-controlled study of 302 patients, sotalol was significantly effective in reducing the incidence of death from any cause or the delivery of a first shock for any reason (including appropriate and inappropriate shocks) (130). In a smaller study of 70 patients with ICDs, metoprolol was significantly more effective than sotalol in preventing recurrences of ventricular tachyarrhythmias (131). Amiodarone is also used often to decrease the incidence of shocks, although definitive controlled data regarding its efficacy for this indication are lacking. Treatment with amiodarone seems to decrease the incidence of shocks compared with treatment with class I drugs (124,132). Potentially significant interactions between antiarrhythmic drugs and ICD systems include dose-dependent increases in defibrillation [lidocaine (133), procainamide, flecainide, and amiodarone (134)] or pacing (flecainide) energy requirements; slowing of VT rate below the programmed cutoff (135); and increases in latency or conduction time leading to double counting, reduced efficacy of antitachycardia pacing, and proarrhythmic effects.

Long-term complications are not uncommon during ICD therapy. Transvenous defibrillator leads have a relatively high structural failure rate (e.g., conductor fracture or insulation cracking) causing spurious shocks (delivered or aborted), undersensing, or loss of pacing capture and requiring operative lead replacement (91,136). The incidence of lead failure may be higher when subclavian puncture is used for venous access (137). Rarer hardware problems include inadvertent device inactivation by electromagnetic fields, premature battery depletion, random component failure, and twiddler's syndrome.

Even with dual-chamber discrimination algorithms, some supraventricular tachyarrhythmias are detected as ventricular, resulting in spurious shocks (138). The incidence of spurious shocks is higher (>20% of patients) with single-chamber ICDs, especially when they are left at nominal programming settings (89). In patients with spurious shocks, reprogramming of detection criteria to increase specificity should be attempted first. It is often necessary to add pharmacologic therapy to reduce the sinus rate, prevent recurrences of paroxysmal atrial tachyarrhythmias, or slow AV conduction. Catheter ablation may also be considered.

Quality of Life

Most patients adapt well to living with the ICD, in a process described as "securing life through technology acceptance" (139). Studies examining quality of life measured before and after ICD implantation have showed unchanged or improved quality-of-life scores after implantation (140,141). Common concerns in ICD patients include fear of shocks, fear of device malfunction, fear of public shocks and embarrassment, and altered body image (142). Younger patients worry about the need for repeat surgeries, the cosmetic appearance of the device and the scar, and risks during pregnancy (143). However, ICD implantation is compatible with subsequent normal pregnancy and delivery (144).

Experiencing an ICD shock can be frightening. Most patients perceive ICD shocks as quite uncomfortable, comparing them with a jolt from an electric socket or a kick in the chest. Fewer than 15% of patients lose consciousness during the lag between arrhythmia onset and device discharge (145). Patients who receive multiple shocks have higher levels of anxiety, anger, and depression (146,147). A few patients develop adjustment disorders specific to the ICD, such as anticipatory anxiety with secondary panic reaction and phobia, imaginary shocks, and defibrillator dependence, abuse or withdrawal (148). Patient support groups provide a valuable opportunity for dissemination of relevant information, alleviation of anxiety, and promotion of a positive attitude toward device therapy (149). Psychotherapeutic counseling, behavioral therapies (150), and psychotropic medication may be required. Some antidepressant and antipsychotic drugs have proarrhythmic effects similar to those of antiarrhythmic drugs and should be used with caution in patients with ICDs.

Safety issues arise frequently during the follow-up of patients with ICDs. Most of these patients are able to exercise safely when appropriate clinical guidelines are provided (151). The ability to drive is an important determinant of quality of life; however, although prohibition from driving is a major inconvenience, safety must be the most important consideration. Arrhythmia-induced impairment of consciousness during driving could harm the patient or others.

The risks associated with noncommercial driving by ICD patients appears to be low. Using an equation incorporating the time the patient spends driving, the type of vehicle driven, the risk of sudden death or incapacity, and the probability that sudden death or incapacity that occurs while the patient is driving will result in death or injury to others, it can be estimated that the annual risk of harm to others is 1 in 45,000 for noncommercial drivers with ICDs. The annual risk for commercial drivers is unacceptably high, at 1 in 2,100 (152). A survey of U.S. physicians reported 30 motor vehicle accidents (nine of which were fatal) involving ICD patients over a 12-year follow-up period (153). Eight patients, one passenger in a car driven by a patient with an ICD, and no bystanders were killed. Based on these data, the fatality and injury rates for patients with ICDs were estimated to be significantly lower than in the general population.

Most U.S. states do not have specific laws governing driving by ICD patients. A joint statement by the American Heart Association and the North American Society of Pacing and Electrophysiology (154) advised that patients who had ICDs implanted for sustained ventricular tachyarrhythmias refrain from private driving for 6 months after implantation and for 6 months after each subsequent shock. [In survivors of VT or VF, the risk of arrhythmia recurrence is higher soon after an index event and decreases to <0.7% per month after the seventh month (155).] Noncommercial driving should not be restricted in patients who receive ICDs for prophylactic indications. Commercial driving should be prohibited entirely in ICD patients. Slightly different recommendations have been issued by the Working Groups on Cardiac Pacing and Arrhythmias of the European Society of Cardiology (156). These restrictions could represent a hardship, especially for patients with sporadic nonsyncopal arrhythmias that trigger single shocks that do not warrant pharmacologic suppression, who may display low compliance (157). Many ICD patients resume driving early, against physician recommendations, but they tend to drive only when absolutely necessary, avoiding rush hour, highways, and night driving (158).

Because many patients who receive ICDs are of advanced age and have severe heart disease, they often retire before ICD implantation. For those who are still working, the type of work and the effect of the index event on physical or mental performance influences whether they return to work (159). Approximately 60% of patients do return to work, a figure similar to that seen after coronary bypass surgery (160). Ability to work may be transiently or permanently hindered by the need to restrict motion of the ipsilateral arm for several weeks after implantation, by private driving limitations, by the risk of syncope during operation of machinery, by the risks associated with electromagnetic radiation in the workplace (e.g., arc welders), and by prohibition of commercial driving.

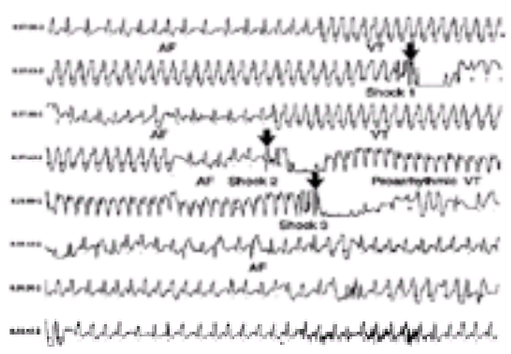
Patients frequently ask about the risks of electromagnetic radiation sources they may encounter during daily life (161). Microwave ovens represent no hazard. When traveling, patients should notify airport security personnel that they have an ICD. It is not dangerous to walk through the security gate as instructed, although it may detect the metal device. A quick pass of the hand-held weapon detector is innocuous, but prolonged exposure to its magnetic field should be avoided. Cellular telephones are unlikely to interact deleteriously with ICDs. However, it has been recommended that patients not carry or place cellular telephones within 15 cm (6 in.) of an ICD, to minimize risks. Walking through electronic antitheft devices at a normal pace has no consequences, but prolonged exposure can result in pacing inhibition, spurious shocks, or both (162).

Management of Emergencies

Guidelines for the management of medical emergencies in ICD patients have been published (163,164). Patients with ICDs should carry identification cards with information about the manufacturer, model, and lead system of the ICD and a 24-hour emergency contact telephone number. An overpenetrated radiograph including the generator permits identification of the model by a radiopaque identifier. During emergencies, placement of a magnet on top of the device when the specific programmer is not readily available can temporarily disable recognition and treatment of tachyarrhythmias. The magnetic field closes a reed switch in the generator circuit, triggering a response that differs among models. In general, tachyarrhythmia recognition and treatment is disabled as long as the magnet remains close to the generator. Pacing is not affected.

The presence of an ICD should not deter standard resuscitation techniques. If VF is documented, it should be assumed that the device is inoperative, and external defibrillation should be administered promptly. Transvenous ICD systems do not affect the energy requirements for external defibrillation. Anyone administering cardiopulmonary resuscitation might feel a mild electric shock on the patient's body surface from an ICD discharge. Although these shocks do not pose a risk to people (165) or to monitoring equipment, it is advisable, when possible, to deactivate the ICD during cardiopulmonary resuscitation. Supraventricular tachycardias with adequate perfusion are common during resuscitation maneuvers and can trigger ICD discharges that may reinduce VT or VF (115).

Multiple defibrillator discharges within a short period require prompt attention (eFig. 75.5.5). Multiple shocks can be a manifestation of ICD system failure; can result in significant battery drainage, leading to premature depletion; and may produce psychological morbidity. Accurate diagnosis is needed for correct management (eTable 75.2.1). Initial evaluation of patients with multiple ICD shocks should be performed in a setting in which electrocardiographic monitoring and advanced cardiac resuscitation are possible. The device should be interrogated as soon as possible. Detailed event logging and storage of interval-by-interval cycle length data and intracardiac electrograms of detected tachyarrhythmias facilitate the diagnosis. Electrical storm (i.e., frequently recurring VT or VF) occurs in 10% of patients (166). Patients with electrical storm should be admitted to an intensive care unit. Sympathetic blockade and intravenous amiodarone are often effective in treating this condition (167). If spurious firing is documented, the ICD should be deactivated and the patient placed under continuous electrocardiographic monitoring. Consultation with the cardiac electrophysiologist is required for definitive treatment (reprogramming or hardware revision). The ICD should be reactivated only after the condition that triggered the spurious shocks is controlled.



***e*FIGURE 75.5.5** Multiple appropriate and inappropriate shocks. Monitor lead shows atrial fibrillation (AF), followed by ventricular tachycardia (VT). A first shock terminates VT, but VT reinitiates before the device algorithms can declare the "end" of the arrhythmia episode. This second run of VT self-terminates, but a second shock is nevertheless delivered during AF because of idiosyncrasy in the arrhythmia confirmation algorithm. This "committed" shock is proarrhythmic, triggering a faster VT, which is finally terminated by a third shock. AF persists afterwards.

***e*TABLE 75.2.1** MANAGEMENT OF PATIENTS WITH MULTIPLE IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR SHOCKS

Cause for implantable cardioverter-defibrillator shocks	Acute management	Definitive management
Appropriate discharges for sustained ventricular tachyarrhythmias		
Frequently recurring VT or VF (electric storm)	Treatment of reversible triggering causes	Optimization of oral AADs
	Sedation	Antitachycardia pacing
	Sympathetic blockade	Surgical or catheter ablation of VT
	i.v. AADs (especially, i.v. amiodarone)	
	Consider temporary device inactivation	
Multiple shocks required for termination of VT or VF	External cardioversion/defibrillation	Optimization of oral AADs
Acute ischemia	Treatment of reversible triggering cause	Device reprogramming
Programming of inappropriately low shock output	Avoid class I AADs	Surgical revision of the system
Antiarrhythmic drug effect		
Shocking lead dislodgment or failure		
Inappropriate (spurious) discharges		
"Committed" shocks for nonsustained ventricular arrhythmias	i.v. AADs	Device reprogramming
	Consider temporary device inactivation	Optimization of oral AADs
Supraventricular tachyarrhythmias	Temporary device inactivation	Device reprogramming
	AV nodal–blocking drugs	Optimization of oral AADs
	Pharmacologic or electrical cardioversion	Catheter ablation of arrhythmia circuit
		Catheter ablation of AV junction
Oversensing during sinus (or paced) rhythm	Temporary device inactivation	Device reprogramming
Oversensing of intracardiac (e.g., T waves) or extracardiac (e.g., myopotentials) signals		Surgical revision of the system
Sensing of external electromagnetic interference		

AADs, antiarrhythmic drugs; AV, atrioventricular; VF, ventricular fibrillation; VT, ventricular tachycardia.

Many diagnostic and therapeutic procedures involve sources of electromagnetic radiation that could affect ICD function (161). Possible effects include cessation or intermittent delivery of antibradycardia pacing, inadvertent delivery of antitachycardia therapy, resetting of programmed parameters, and damage to the pulse generator, the tissues interfacing with the electrodes, or both. Most diagnostic and therapeutic maneuvers, including electrosurgery, shock wave lithotripsy (168), electroconvulsive therapy (169), and most imaging methods, can be safely performed under continuous electrocardiographic monitoring in ICD patients. Trained personnel should be readily available to deactivate the device before the procedure and to reactivate it and confirm that it is operating appropriately afterward. Magnetic resonance imaging is contraindicated in ICD patients because of the very strong electromagnetic fields involved.

COST-EFFECTIVENESS OF THE IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

ICD hardware is expensive. In the United States, the cost to the hospital of a modern ICD system ranges between $20,000 and $25,000. In comparison, a rate-responsive dual-chamber pacemaker system costs approximately $7,000, and the retail cost of a 1-year supply of 400 mg of amiodarone daily is $2,200. So far, competition among ICD manufacturers has not resulted in the substantial decreases in hardware price that could be expected in an economically efficient market.

Appraisal of the cost-effectiveness of ICD therapy is difficult, because continuous technological advances and changes in practice patterns make analyses obsolete rapidly (170). The cost-effectiveness of the ICD has been estimated in mathematical models and from empirical data prospectively collected during randomized studies. Both approaches have limitations. The conclusions of cost-effectiveness models differ greatly according to the many assumptions that are introduced. In a detailed analysis, Owens and colleagues (171) estimated that to become economically "attractive" (i.e., cost less than $50,000 per quality-adjusted life year gained), the ICD would have to reduce total mortality by at least 30% relative to amiodarone (a magnitude of benefit observed in some, but not all, randomized studies). When a reduction in the total mortality rate of 40% was assumed, the cost of one quality-adjusted life year afforded by treatment with the ICD was $37,300. Sensitivity analysis showed that reductions in perioperative death and implantation costs and prolongation of battery longevity (already realized in current practice) would significantly improve the cost-effectiveness of the ICD.

Measurement of costs (or charges) has been an integral part of randomized studies comparing the ICD and pharmacologic therapy of ventricular tachyarrhythmias. These analyses depend critically on the relevance of the control maneuver and the treatment effect observed in the study. Furthermore, changes in ICD technology

and practice patterns tend to make results less relevant by the time they become available.

An early, small study by Wever and associates (172) involving survivors of cardiac arrest with prior myocardial infarction compared early ICD implantation to the (then more conventional) strategy of serial electropharmacologic testing, followed by direct arrhythmia surgery or ICD implantation in case of drug failure. The study was terminated prematurely after the enrollment of 60 patients because of a survival advantage in the ICD group. After a follow-up period of 24 months, 13% of patients in the early implantation ICD group died versus 35% in the conventional strategy group ($p = .07$). The costs per patient per day alive were $63 and $94 for ICD and electrophysiology-guided strategies, respectively. This amounted to a net cost-effectiveness of $11,315 per life-year saved by early ICD implantation. The ICD group also underwent fewer invasive procedures and spent fewer days in the hospital. Although in this small study, early ICD implantation was dominant (i.e., more effective and cheaper), the results are difficult to extrapolate because the control group did not reflect current optimal management.

In MADIT, the cost per life-year gained with ICD treatment was $27,000 (173). Sensitivity analyses highlighted the impact of technological advances and hardware price in the cost-effectiveness of ICD therapy. Exclusive use of transvenous systems (in MADIT, approximately one-half of the patients received thoracotomy defibrillators) would decrease the cost per life-year gained to $22,800; a 25% decrease in device cost would reduce the cost per life-year gained to $13,100. This very favorable cost-effectiveness ratio was partially driven by the impressive survival benefit (54%) conferred by the ICD, which appears to be at the upper end of plausible results. Furthermore, the costs of screening for eligible patients were not factored.

The economic analysis in CIDS included the first 430 patients enrolled in the study (174). Costs were provided in 1999 Canadian dollars (C$1 ~ U.S.$0.65). Over 6.3 years, mean cost per patient in the ICD group was C$87,715 versus C$38,600 in the amiodarone group (difference, C$49,115; 95% confidence interval, C$25,502 to C$69,508). Life expectancy for the ICD group was 4.58 years versus 4.35 years for amiodarone (difference, 0.23; 95% confidence interval, –0.09 to 0.55), for incremental cost-effectiveness of ICD therapy of C$213,543 per life-year gained. ICD benefit was greater in patients with low left ventricular ejection fraction (<35%), and cost-effectiveness in this group was more attractive (C$108,484). Alternative extrapolations of survival benefit and costs to 12 years indicated cost-effectiveness in the range of C$100,000 to C$150,000 per life-year gained. The results of the economic analysis in AVID are eagerly awaited.

Streamlining of clinical practices will result in improved cost-efficiency. For example, ICD implantation after a major arrhythmic event without extensive electrophysiologic evaluation may decrease costs without compromising outcome (175). Modeling in AVID suggested that for every 1-day differential reduction in the initial length of the hospital stay, the cost-effectiveness ratio of the ICD would improve by $6,300 (174). Likewise, a reduction in hospitalizations for multiple appropriate or inappropriate shocks [a prominent source of health care expenditures in ICD patients (176)] that is achievable with improved device diagnostic and therapeutic algorithms should also make the ICD more cost-effective.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Knowledge about basic electrophysiologic mechanisms is accumulating rapidly. However, despite advances in the understanding of the structure and function of cardiac ion channels (177), the electrophysiologic heterogeneity of myocardial cells (178), and the fundamental mechanisms of reentry (179), clinical applications remain scarce (180,181). The development of widely effective and safe gene (182), pharmacologic, or ablative therapies for ventricular arrhythmias is not likely in the foreseeable future. In the long run, the best strategy for preventing sudden cardiac death will be the prevention of coronary artery disease and its sequelae. We believe that, in the meantime, ICDs will become a key clinical tool in the fight against sudden death.

During the next decade, progress in ICD therapy will occur on both the clinical and technological fronts. Primary prevention trials will identify additional populations who will benefit from ICD implantation. Current validated indications restrict prophylactic use to patients with previous myocardial infarction and are based on inducibility of VT at invasive electrophysiologic study. Identification of ICD candidates with other substrates and with noninvasive methods could greatly expand the application of this therapy. If that is the case, the cost-effectiveness of ICDs will be very carefully scrutinized. In view of the potential allocation of scarce resources to diverse therapies and populations, society will have to decide the extent to which ICDs should be used.

Two avenues have been proposed to improve cost-effectiveness: more refined risk-stratification (183) (cost-effectiveness should be most favorable in patients at high risk for sudden death but at low risk of dying from competing causes) and reduced costs. It is quite apparent that not all patients with ventricular tachyarrhythmias have the same prognosis (69). The pooled AVID/CIDS/CASH analysis showed significantly higher benefit in patients with severe left ventricular dysfunction (44). The CIDS investigators devised a clinical prediction rule to identify patients likely to benefit from ICD therapy that included two or three of the following: age ³70 years, left ventricular ejection fraction £0.35, and New York Heart Association class III or IV (184). However, post hoc prediction rules should not be accepted without prospective validation. When the same rule was applied to the AVID population, it lacked discriminatory power (185). It is likely that the relationship between severity of heart disease and benefit from ICD has an inverted U shape. Patients with severe (but not end-stage) heart disease should benefit the most, but patients with severe heart failure and those with almost normal heart function will benefit less. However, specific thresholds for identifying patients who will not benefit are unlikely. Furthermore, patients who have life-threatening ventricular arrhythmias but mild structural heart disease have a low risk of dying from competing causes, and a survival benefit should be apparent with longer follow-up.

It has been speculated that manufacturers could make prophylactic ICD therapy more cost-attractive by making stripped-down devices available (i.e., single-chamber shock-only units capable of delivering only a limited number of shocks and with shorter longevity) at a significant discount. However, we foresee strong resistance from clinicians in the United States to implanting suboptimal hardware that could require premature replacement in at least some patients. The approach may be more viable in countries with centralized financing of health care.

Paradoxically, the ICD may help to develop safe and effective pharmacologic therapies by providing a safety net in randomized clinical trials of new antiarrhythmic drugs (186). Advances in storage, retrieval, and accurate interpretation of ICD electrograms may allow the use of an ICD end point as a clinical surrogate for sudden death. However, the extent to which the results of data on antiarrhythmic drug efficacy and safety acquired in the context of an ICD endpoint trial might be extrapolated to patients not using the device is controversial.

The debate over whether surgical or medical practitioners should be providers of ICD therapy has been largely settled, and, at least in the United States, cardiac electrophysiologists now perform most implants (187). However, because of the broadly accepted indications and the ease of implantation, the debate has now shifted within the cardiology community as cardiologists without specific electrophysiology training have begun to indicate ICD treatment, implant the devices, and follow up after implantation in some institutions (188). The body of knowledge and the experience for such practices have been promulgated by professional organizations, and the implementation of ICD therapy by unqualified practitioners should be viewed with great concern. For example, training guidelines for ICD implantation from the American College of Cardiology require that a clinician perform 20 procedures as the primary operator, and they also consider the maintenance of established competence critical (189). For pacemaker implantation, inexperience (e.g., performance of fewer than 12 implants per year) is the main determinant of surgical complications (190), and a similar association can be expected for ICDs. The availability of systems with very different capabilities, from the simple single-chamber unit to the complex combined atrioventricular defibrillators or triple-chamber units that provide resynchronization therapy, makes understanding the value and limitations of these devices in relation to the individual patient's needs crucial.

The increasing versatility of the devices has made programming and troubleshooting complicated and time-consuming. The untrained physician who is a "casual" follower of ICDs may rely excessively on the expertise of manufacturer representatives to determine appropriate device function. This practice is questionable on both medical and ethical grounds and cannot guarantee optimal results (191). As stated by professional organizations, cardiac electrophysiologists should prescribe the type of ICD, be involved in the implant, and provide follow-up care of ICD patients (57).

THE FUTURE

ICD technology will continue to evolve. The next generation of devices will be smaller, owing to improvements in battery and capacitor technology and optimization of shock waveforms and electrodes. Emphasis will be placed on decreasing the complexity of programming, device interrogation, and patient monitoring during routine patient follow-up. The addition of sensors to assess the hemodynamic impact of tachyarrhythmias will further refine therapy delivery and eradicate spurious device interventions. Continuous monitoring for myocardial ischemia (192), subtle hemodynamic decompensation (193), and electrical instability (194) will be feasible. The device could warn the patient, automatically transmit data to a Web-based server accessible by authorized health care staff, and then initiate corrective action. The capability to intervene before an arrhythmia occurs is particularly desirable (195). Future research should produce reliable methods of predicting impending VT or VF. VF may be a form of deterministic chaos whose development is compatible with the quasiperiodic route seen in fluid dynamics (196). Potential preventive interventions include multisite pacing (197,198), pacing algorithms aimed at the suppression of long-short cardiac cycle sequences (199), subthreshold stimulation of arrhythmogenic tissues exploiting the phenomenon of cardiac inhibition (200), and the timely infusion of antiarrhythmic or antiadrenergic agents via a venous port. Specific pacing algorithms also have the potential to prevent atrial fibrillation. During the next decade, we will witness the culmination of the evolution of the ICD from a "shock-box" to a smart, multimodal monitoring, communications, and therapeutic unit.

OVERVIEW

Few therapies are more dramatic or more decisive to patient outcome than electrical defibrillation of ventricular fibrillation (VF). Untreated VF is invariably fatal within minutes. The sooner that electrical defibrillation shocks are delivered, the greater the likelihood of survival. Transthoracic electrical defibrillation is accomplished by passing an adequate current density of appropriate waveform through the fibrillating myocardium. Evidence is increasing that biphasic waveforms are more effective and safer than the monophasic damped sine waveform (MDS) that has been in use over the past four decades.

To assure success, the operator needs to know how to operate the external defibrillator, the proper electrode position, and, unless the defibrillator is automated, the appropriate shock strength. The operator also needs to know the factors that determine transthoracic resistance or impedance to defibrillator shock so as to assure adequate current delivery and the factors to consider and the actions to take if the patient fails to defibrillate.

The optimal approach to electrical cardioversion of reentrant-type supraventricular arrhythmias requires proper placement. Disposable electrode pads are commonly used and work most of the time, but in larger adults, metal electrodes, gels with excellent conductance characteristics, and other techniques that assure the lowest transthoracic impedance may be necessary.

GLOSSARY

Amps: A measurement of electrical current.

Cardiac arrest, primary: Cardiac arrest in a patient without severe heart failure or cardiogenic shock.

Cardiac arrest, secondary: Cardiac arrest in a patient with severe heart failure or cardiogenic shock.

Cardioversion: The termination of tachycardia or fibrillation by an electrical shock.

Current: The flow of electricity.

Defibrillation: The termination of ventricular fibrillation, irrespective of the resulting rhythm.

Energy: The exertion of power; the capacity to do work.

Impedance: The opposition to changing electrical flow or current.

Joule (J): One joule is equal to 1 watt-second.

Resistance: The opposition to steady electrical flow or current.

Threshold, defibrillation: The minimal energy level at which defibrillating shocks produce defibrillation.

Volt: Unit of electrical pressure or electromotive force.

Voltage: Electromotive force, electrical pressure, or potential expressed in volts.

Watt: A unit of electrical power. One watt is the power available when the current is 1 A and the electromotive force is 1 V.

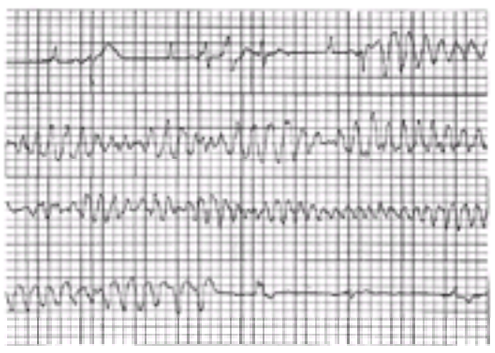
Waveform, defibrillation: The shape of the current, voltage, or power wave from a defibrillator discharge.

INTRODUCTION

The dictionary defines *defibrillation* as the arrest of fibrillation of the cardiac muscle (atrial or ventricular) with the restoration of normal rhythm (1) and *cardioversion* as the restoration of the heart's rhythm to normal by electrical countershock (1). Thus defined, these terms have significant overlap. Practically, however, the medical community uses the term *defibrillation* to mean the termination of VF, irrespective of the resulting rhythm, and *cardioversion* to mean the termination of a tachycardia or fibrillation by drugs, pacing, or electrical shock. Defibrillation and termination of reentrant tachycardias can be accomplished by electrical, mechanical, or pharmacologic means. This chapter addresses transthoracic electrical defibrillation and cardioversion. Implantable cardioverter-defibrillators are the subject of Chapter 75.

Defibrillation

Within minutes, untreated VF is invariably fatal. Accordingly, few therapies are more dramatic or more decisive to patient outcome than electrical defibrillation. In rare instances, spontaneous reversion of VF occurs, but many of these are in fact instances of polymorphic ventricular tachycardia (*e*Fig. 76.0.1) that is incorrectly assumed to be VF.



***e*FIGURE 76.0.1** Electrocardiographic monitor lead showing torsades de pointes in a 78-year-old man who had recurrent syncope. Note the spontaneous conversion to a perfusing rhythm.

The shock of electrical defibrillation is designed to depolarize a critical mass of the ventricles. Provided the factors that initiated the VF are no longer present, this shock depolarizes the ventricles and allows the development of a potentially perfusing rhythm. The exact mechanism of defibrillation by the shock is unknown but is thought to prolong the action potential duration of a significant number of myocytes, blocking the reentrant circuit. However, if the shock is delayed, there are longer periods of nondepolarization of the action potentials, and defibrillation success decreases (2). With further delays, prolonged underperfusion of the contracting myocytes results in depletion of their energy stores. Delayed defibrillation in effect allows the ventricles to "autoinfarct." In this situation, even if VF is terminated, the resulting rhythm is most likely to be idioventricular or asystole.

This chapter reviews transthoracic electrical defibrillation and cardioversion and updates previous authored and coauthored chapters and reviews (3,4,5 and 6).

Cardiac Arrest

The most common cause of cardiac arrest is VF. This is fortunate, because this arrhythmia responds to therapy more often than does asystole or pulseless electrical activity, the other major causes of cardiac arrest.

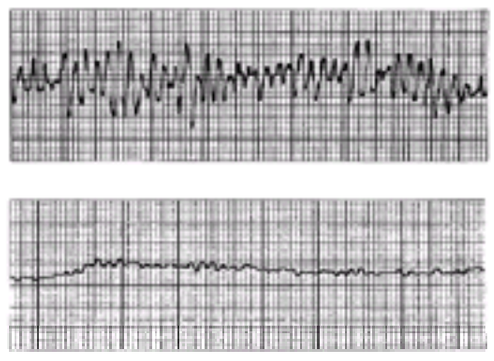
Cardiac arrest from VF has been divided into primary and secondary causes. Patients with primary electrical disturbances have a better prognosis than do those with VF secondary to periods of prolonged myocardial hypoperfusion from severe hypotension or shock.

It is well recognized that the more important determinant of survival from unexpected or primary cardiac arrest is the interval between the onset of VF and defibrillation (7). If defibrillation is delayed, the speed with which basic life support is initiated becomes the second most important determinant.

VENTRICULAR FIBRILLATION

Etiology

VF (*e*Fig. 76.0.2) results from the chaotic electrical excitation of the ventricles (2,3,6,8). It is best explained by reentrant depolarization of the myocardium, initially in waves that then take more circuitous routes and degenerate into smaller reentry circuits (3,8,9). The hemodynamic consequence is the loss of coordinated contractions of the myocytes, resulting in the loss of the rhythmic contractile function of the ventricles, which is so essential to life.



***e*FIGURE 76.0.2** Electrocardiographic recordings of subjects in ventricular fibrillation. **Top:** Coarse ventricular fibrillation. **Bottom:** Fine ventricular fibrillation.

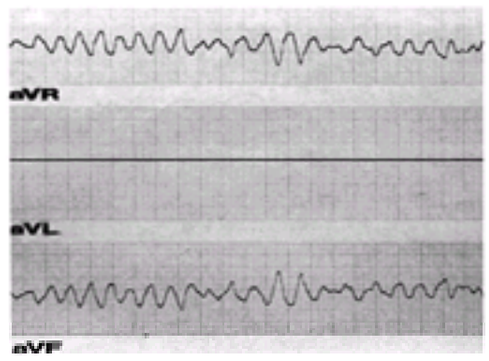
The larger and more diseased the heart, the easier it is to fibrillate. Small hearts are difficult to fibrillate. It is difficult to kill a rodent by VF, as once the 60-Hz fibrillating current is removed, the heart often returns to sinus rhythm. If a fibrillating heart of a larger animal is cut in two, both halves continue to fibrillate, but when cut again and again fibrillation stops when the remaining ventricular muscle size is too small to sustain the reentrant circuits of VF (4). It is difficult to fibrillate a puppy's heart but easy to fibrillate an adult dog heart. These facts have immense clinical importance, as cardiac arrest in neonates and children is most commonly due to asystole from respiratory arrest or prolonged periods of inadequate myocardial perfusion and not due to VF. In contrast, the diseased, dilated, or hypertrophied adult heart is prone to VF.

VF is most frequently the result of deterioration of ventricular tachycardia or is from myocardial ischemia or infarction. The most common cause of ventricular

tachycardia is scarring from an old myocardial infarction. It is of extreme interest, however, that in patients who have an open coronary artery to the infarcted area after myocardial infarction, the incidence of sudden cardiac death is less, suggesting that the incidence of VF is less (10). Thus, the scarring or remodeling process, or both, after myocardial infarction must predispose to reentrant ventricular arrhythmias. Another important cause of VF is heart failure, because more than one-third of patients with severe heart failure die of sudden death. VF has many other causes, including right ventricular dysplasia, hypertrophic cardiomyopathy, and atrial fibrillation in patients with preexcitation syndromes, to list just a few.

Ventricular Fibrillation Masquerading as Asystole

The electrocardiographic reflection of VF is characteristically a chaotic irregular pattern that frequently passes through but spends no time at the isoelectric point (*e*Fig. 76.0.2). Although VF is easy to recognize, in some subjects and in some leads, it can appear as a very fine VF or even as a straight line (9) (*e*Fig. 76.0.3).



***e*FIGURE 76.0.3** Simultaneously recorded electrocardiographic leads aVR, aVL, and aVF from a subject in ventricular fibrillation. This type of recording illustrates that ventricular fibrillation can appear as asystole if only one lead is monitored.

Soon after we described VF masquerading as asystole (9), McDonald (11) published a case report of this phenomenon in humans. A few years later, Ornato and associates (12) studied the effectiveness of countershocks for asystole. They found that during the course of resuscitation, countershock appeared to be effective in treating asystole, “suggesting that the rhythm diagnosed as asystole may actually be VF in many cases” (12). VF disguised as asystole has been identified by echocardiography (13). Nevertheless, most instances of fine fibrillation and asystole are the result of prolonged untreated VF. Over time, the fibrillation waves get smaller and smaller and finally become a straight line.

Ventricular Fibrillation Depletes Myocardial Energy Stores

VF is not an innocuous rhythm, even when the circulation is supported by artificial means. The rapid asynchronous contraction of the muscles increases myocardial oxygen consumption to the level that it depletes adenosine triphosphate and other energy stores (14).

The longest duration of VF that the author has observed was approximately 2 weeks! The patient was in the intensive care unit with an implanted left ventricular assist device when VF developed. Several attempts at defibrillation were not successful, and the patient was left in VF. He was sitting in a chair reading the paper, but the electrocardiographic monitor showed VF. Each day the amplitude of the VF became less coarse; a week or so later, the fibrillatory waves became fine. As the patient became more hypotensive, his electrocardiogram became a straight line. A donor heart was not available for cardiac transplantation, and he died. VF results in a greater myocardial oxygen demand than can be supplied by the coronary perfusion pressure afforded by a left ventricular assist device or by external chest compression during attempted cardiopulmonary resuscitation (CPR).

In addition to the fall in myocardial adenosine triphosphate, VF results in a marked increase in the coronary sinus concentrations of adenosine, lactate, epinephrine, and norepinephrine (15). Adenosine levels increased more than 12-fold, whereas lactate levels increased by twofold (15). Increases were also seen in epinephrine and norepinephrine concentrations (15). Increased adenosine concentrations have been associated with an increased defibrillation threshold (see the section Defibrillation Threshold).

EXTERNAL ELECTRICAL DEFIBRILLATION

Historical Perspective

The era of clinical defibrillation was initiated a half-century ago, when Beck applied alternating current (AC) directly to the fibrillating human heart. The young man was successfully defibrillated and resuscitated (3). Because, at that time, an open chest was required, defibrillation was rarely used outside the surgical suite until the mid-1950s, when closed-chest ventricular defibrillation was reported. Even this method had limited clinical application, as survival was rare because defibrillation was rarely prompt. Kouwenhoven’s experimental studies found that if the shock was delivered within 30 seconds of VF, 98% of his animals survived; if the shock was delayed just 2 minutes, only 27% lived (3). This short window of opportunity was the major barrier to the successful application of electrical defibrillation. In 1960, this time window was extended by the discovery of the closed-chest compression technique for CPR (3). When this time limit became longer, there was increased enthusiasm for defibrillators and for the development of portable defibrillators. The ensuing decades witnessed a number of improvements in defibrillators, and their clinical use became commonplace. Authority for their use was extended first to the coronary care unit nurse-specialist, then to the paramedic, to the emergency medical technician, and, during the last decade with the development of the automated external defibrillator (AED), to nontraditional providers and even to the lay public.

The history of defibrillating waveforms is one of progression from AC, to the spike-like waveform of a pure capacitor discharge, to damped sinusoidal waveforms, to trapezoidal waveforms, to the biphasic waveforms.

Indications and Contraindications to Defibrillation

With rare exceptions, the presence of VF is an indication for defibrillation. Defibrillation is contraindicated when the patient’s desire not to be resuscitated is clearly documented in his or her medical record or other legal document (16,17), when continued resuscitation efforts are determined to be futile (18), or in the extremely rare situation in which there is significant danger to the rescuers due to the patient’s location or environment.

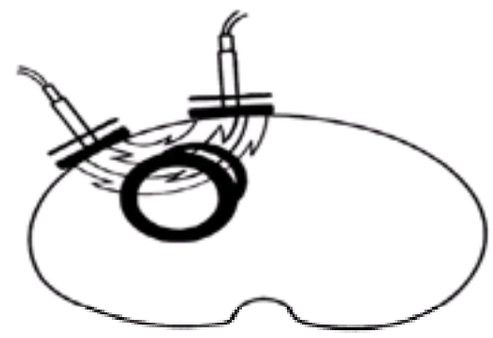
The operation of an AED is relatively easy. The electrodes are placed, and the patient is not touched until the AED analyzes the rhythm and either automatically delivers the shock or advises the operator to press a button, which causes the unit to deliver a shock. The major disadvantage of some AEDs is that, because they measure thoracic impedance, they delay defibrillation until gasping and all motion stop. The analysis takes time, and for each minute delay, resuscitation success is decreased by 10%. Although the early reports indicated that the overall time from power-on to first shock was 1.1 minutes, a post–market surveillance study found that the overall time from AED power-on to first shock was 39 ± 26 seconds and the time from pad placement to first shock was 21 ± 10 seconds (19). The arrival time in the latter report was greater than 8 minutes—a time when most spontaneous respirations would have ceased (19).

Following application of a defibrillation shock, the patient in cardiac arrest should be reassessed, clinically and electrocardiographically. If after three shocks there is still no pulse, chest compression should be initiated. If the patient remains in VF, repeated shocks or antiarrhythmic medications, or both, may be necessary. When repeated shocks fail to defibrillate, a reevaluation of the techniques used is necessary.

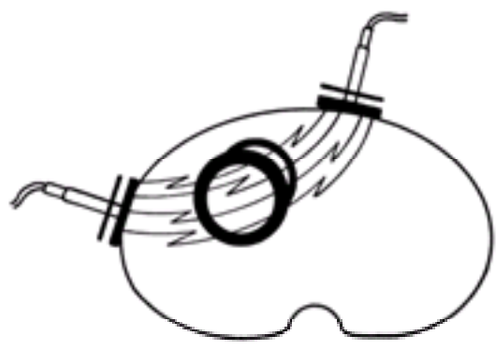
Electrode Position

Electrical defibrillation is accomplished by passing an adequate current density of appropriate waveform through the fibrillating myocardium. Because it takes a critical mass of muscle to sustain fibrillation, it is not necessary to “defibrillate” every myofibril. However, it appears that most of the myocardial mass must be defibrillated. This requires, among other things, appropriate electrode size and placement. The electrodes cannot be placed just anywhere on the chest. If they are too close together, the current tends to shunt between the electrodes and does not depolarize enough of the left ventricular mass (*e*Fig. 76.0.4). For most emergency defibrillation, the recommended electrode position is the so-called anterior-apical position. One paddle electrode is placed anteriorly under the right clavicle just to the right of the

sternum and the other above the bottom of the ribcage, in the left mid-axillary line (eFig. 76.0.5).



***e*FIGURE 76.0.4** Illustration of current flow with defibrillation paddle electrodes that are too close together.

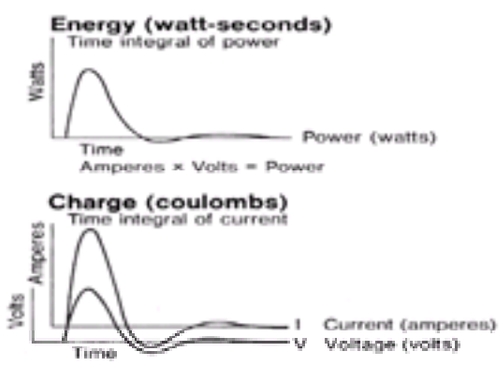


***e*FIGURE 76.0.5** Illustration of current flow with defibrillator paddle electrodes in a more optimal position.

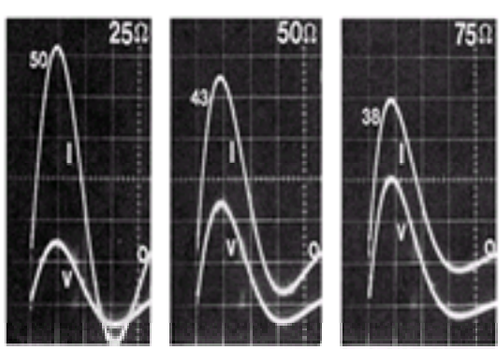
Others and we have found that the same principles of electrode size and placement held true for transcatheter or catheter electrode to subcutaneous electrode defibrillation. To be effective the current path had to be through the major ventricular muscle mass (20,21).

Defibrillation Energy, Current, and Voltage

When one selects the strength of the shock for defibrillation, one chooses an energy level in watt-seconds or joules. However, it is the current delivered to the myocardium that defibrillates. When the defibrillator capacitor discharges, the output can be measured in current, voltage, and energy. To help physicians understand current and voltage, an analogy can be made with the cardiovascular system. When the heart ejects blood, the result can be measured in terms of blood flow and blood pressure. The current is analogous to the flow and the voltage to the pressure. When the defibrillator capacitor is charged, this charge is measured only in volts, as there is no current flow. On discharge, if the instantaneous voltage is multiplied by the instantaneous current, the result is expressed in watts. The watt is a unit of power. If this multiplication is done at each point along the discharged current and voltage wave, a power wave can be constructed (eFig. 76.0.6). When the area under the power wave is integrated with time in seconds, one derives energy measured in watt-seconds or joules. One watt-second is equal to 1 J. Energy is the unit of strength that is indicated on almost all defibrillators. As shown in eFigure 76.0.7, when the simultaneous current and voltage waves from a defibrillator with the same stored energy are delivered into 25, 50, and 75 W of resistance or impedance the delivered peak current decreases with increasing resistance or impedance (2,3). Because it is the current that defibrillates, impedance is important. With constant energy selected, defibrillation effectiveness is related to the resistance between the defibrillator and the patient's heart. At a near threshold shock strength, the lower the resistance or impedance the higher the defibrillation success (22).



***e*FIGURE 76.0.6** Illustration of the power and of the current and voltage waves of a defibrillator discharge delivering damped half-sinusoidal waveforms.



***e*FIGURE 76.0.7** Simultaneous current (I) and voltage (v) waves from a defibrillator with the same stored energy delivered into 25, 50, and 75 W of impedance. Delivered peak current decreases with increasing impedance.

When using defibrillators that deliver monophasic shocks (damped sinusoidal or truncated exponential), impedance becomes critical to success (22,23). The design of the new defibrillators that deliver biphasic waveforms is such to minimize the importance of transthoracic impedance to defibrillator discharge. Some models (Zoll) maintain the same waveform over a wide range of transthoracic impedance. As discussed in the following section, others have some variations in waveform with higher impedances.

Factors Determining Transthoracic Impedance

Several factors influence transthoracic impedance to defibrillation or cardioversion discharge. One factor is the diameter of the electrode. As one increases the diameter of the electrodes, the impedance decreases. Therefore, with lower impedance, defibrillation effectiveness should improve, and in our canine cardiac arrest model this proved to be true. Standard 8-cm-diameter paddles applied within the first minutes of VF successfully defibrillated 71%. A larger paddle with a 12.8-cm diameter successfully defibrillated 88% (23). Kerber (24) showed lower impedance with larger (13-cm) paddles in human defibrillation and, when coupled with firm pressure to the chest, better current delivery. If very large electrodes are used, the impedance is even lower, but defibrillation effectiveness falls, as much of the current is wasted because it is not going through the heart. This demonstrates that it is not current but the current density through the heart that is the major factor in defibrillation (22,23,24,25,26,27,28 and 29). In studies of very small to very large animals, Geddes and associates (28) found that the optimal electrode size is approximately the same as the size of the animal's heart. Optimal paddle size in human defibrillation remains uncertain, but the author predicts that the optimal size might be close to 12-cm-diameter electrodes for human adults. Many electrodes in clinical use today are not this large.

A second factor that is known to affect transthoracic impedance, and thus defibrillation success, is the interface used between the skin of the chest wall and the electrode (29). Impedance is relatively high if the electrodes are applied directly to the skin without some form of conductive medium (29). The impedance is lower if appropriate electrode-skin interfaces are used (29).

We found a wide discrepancy in the impedance of commercially available creams, pastes, and gels used on metal electrodes. Of the 26 products tested, we found 4 to have the lowest impedance to defibrillator discharge (29,30). Of these, Redux Paste (Hewlett-Packard, Waltham, MA) is the only one that is still commercially available. One should avoid gels that have not been shown to have a low resistance. For example, the gels used for echocardiography are very poor conductors of electricity, and when used on metal electrodes for defibrillation or cardioversion, they result in a very high impedance (29,30 and 31). Hummel and associates (32) confirmed our findings and showed that repeated defibrillator shocks via high-impedance gels might produce sparking.

Alternatives to gels include saline-soaked gauze pads and commercially available disposable electrode pads. We compared the transthoracic impedance of metal electrodes using Redux Paste as the interface with saline-soaked gauze pads and with disposable electrodes and found that the impedance was lowest with the metal electrodes with Redux Paste (29). Kerber and his associates (33) also measured impedance to defibrillation discharge using R2 Corporation (Eagan, MN) electrode pads. They studied 80 patients who received 267 shocks. All but two patients achieved defibrillation or cardioversion at least once. The measured transthoracic impedance of the disposable pads was 75 ± 21 W, similar to previous results by these investigators with standard hand-held electrode paddles (67 ± 36 W) (33). More recently, Bissing and Kerber (34) reported transthoracic impedance in 11 nonhirsute individuals using self-adhesive defibrillation pads to be 103 ± 6 (standard error) W. They reported a transthoracic impedance of 162 + 11 W in hirsute subjects that decreased to 105 + 3 W after shaving the hirsute chest (34). In our study of impedance to the cardioversion shock in humans, we delivered an initial shock of 100 J via a research defibrillator-cardioverter. With hand-held paddles with metal electrodes placed in the anterior (8 cm)-posterior (12.8 cm) position and using Redux Gel as an interface, we found a mean impedance of 50 ± 12 W in those who successfully cardioverted and 59 ± 10 W in those not cardioverted with an initial 100-J shock (35). These resistance or impedance values from Redux Paste and metal electrodes are lower than those of the previous reports in which the disposable self-adhesive defibrillation electrode pads were used.

Although the self-adhesive, disposable electrode pads are effective for routine defibrillation and cardioversion and provide an advantage in certain circumstances such as in the electrophysiologic laboratory and in transportation of the high-risk patient with cardiac disease, because of the somewhat higher impedance with defibrillation shock (33,34) many of the presently available disposable electrodes are, in the author's opinion, not optimal for cardioversion or defibrillation in patients who are very large or have a barrel or hirsute chest.

Adequate pressure must be applied to the paddles to ensure a low-impedance electrode thoracic interface. Recommendations are for application of at least 25 lb of pressure (24). Another disadvantage of disposable self-adhesive electrodes is the lack of firm pressure during defibrillation or cardioversion. This can be overcome by folding a towel, placing it over the anterior electrode, and having a bystander apply firm pressure. The bystander does not feel the shock if he or she is not touching anything else.

Another determinant of transthoracic impedance to direct current (DC) shock is the phase of respiration. Our laboratory has demonstrated higher impedance and decreased defibrillation effectiveness when shocks are delivered at full inspiration (from bag-valve–induced ventilation) rather than in expiration (35). Likewise, defibrillation is rarely possible if there is a left-sided pneumothorax, one of the rare indications for open-chest defibrillation.

Other factors that have been shown to affect transthoracic impedance to defibrillation shocks include the number, strength, and time interval of previous shocks (24,36). The impedance drops slightly with repeated shocks. This may help to explain why in some patients it may take several maximal defibrillator shocks to defibrillate.

Kerber and associates (37) have shown that for at least 1 month after open-heart surgery, the transthoracic impedance remains lower. The impedance is higher with greater distance between the electrodes or if one of the electrodes is placed on a female breast (38). *e*Table 76.0.1 lists the determinants of transthoracic resistance (or trans-chest impedance) to defibrillator shocks.

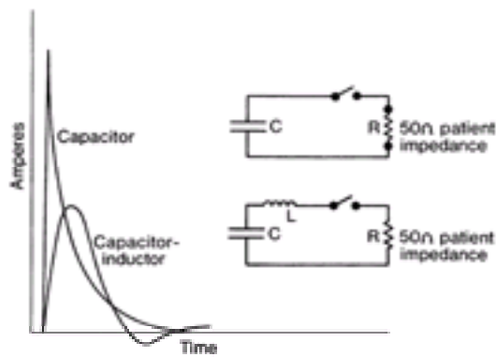
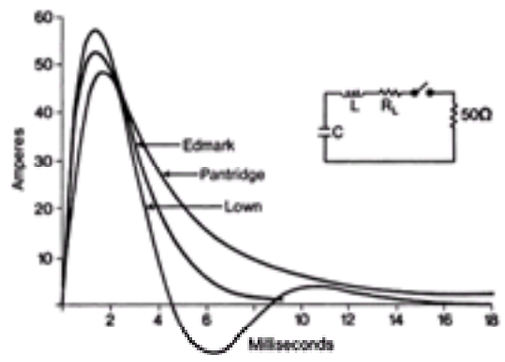
Defibrillation Waveform

The first waveform that was used for ventricular defibrillation was the 60-Hz AC, the same as is used as standard household current. Because of myocardial damage caused by AC current and the problem of the induction of VF from prolonged AC current, units were developed that used a pure capacitance discharge. The pure or undamped capacitor discharge with a short time constant is described mathematically by a curve called an undamped *exponential* (*e*Fig. 76.0.8), and therefore the waveform was given this name (21). These pure DC defibrillators also caused significant cardiac damage. This led to the addition of an inductance coil (*e*Fig. 76.0.8), which rounded the initial, sharp, high-voltage peak that is thought to be responsible for the dysfunction. It is this "damped exponential" waveform that has been in clinical use for transthoracic defibrillation for nearly four decades (21). Depending on the capacitance, inductance, and resistance of a particular model of defibrillator and the impedance of the subject, the waveform is either "critically damped" (Edmark or Pantridge waveform), so that it does not oscillate below the baseline, or "underdamped" (Gurvich or Lown waveform), so that with low impedance it oscillates and has a negative component (*e*Fig. 76.0.7 and *e*Fig. 76.0.9).

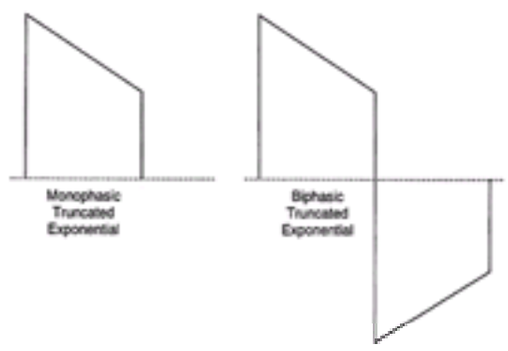


***e*FIGURE 76.0.8** Illustration of an undamped and a damped sinusoidal (capacitor-inductor) waveform from direct current capacitor (C) discharge. L, inductance coil; R, resistance.



***e*FIGURE 76.0.9** Sinusoidal waveforms illustrating a critically damped capacitor (C) discharge (Edmark and Pantridge) and an underdamped C discharge (Gurvich or Lown) waveform. L, inductance coil; R_L, resistance of inductance coil.

With the advent of internal defibrillators, new waveforms were required because the large induction coils that are used for transthoracic defibrillation initially could not be made small enough for implanted devices. To avoid the high-voltage, sharp peaks associated with the underdamped capacitor discharge, the internal defibrillators used underdamped discharges with long time constants that were then truncated so that they were near square wave (low-tilt or trapezoidal) (21) (*e*Fig. 76.0.10).



***e*FIGURE 76.0.10** Monophasic and biphasic square or trapezoidal (truncated exponential) waveforms from defibrillator discharge.

The development of transvenous lead systems prompted the search for more effective defibrillator waveforms. Another stimulus for the development of new waveforms was a new theory of defibrillation (21,39). These hypotheses led to the trial of newer waveforms. Jones (21) confirmed in tissue culture Schuder's findings in animals, that the biphasic waveforms were more effective than monophasic waveforms. This finding was then confirmed in humans. Consequently, modern implantable defibrillators deliver biphasic waveforms (see Chapter 75).

In 1995, it was shown that truncated biphasic pulses of low energy (115 J) were as effective as 200-J damped sine-wave shocks for standard transthoracic defibrillation (40). The mechanisms of electrical defibrillation by the newer defibrillator waveform have been reviewed by Blanchard and Ideker (41).

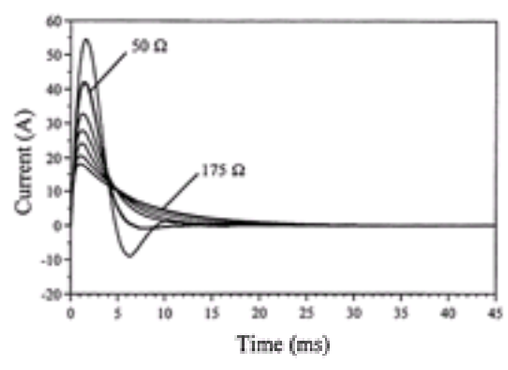
The finding that biphasic waveforms were more effective than monophasic waveforms prompted a reevaluation of the effectiveness of the different sinusoidal waveforms that are used for transthoracic defibrillation. A study of the defibrillation effectiveness of the critically damped capacitor discharge (Edmark) versus the underdamped capacitor discharge (Lown) waveforms revealed that the underdamped sinusoidal waveform (Lown) that more closely resembled the biphasic waveform was more effective. As noted above, with a defibrillator that delivers an underdamped capacitor discharge, the lower the resistance, the more the delivered current becomes more biphasic; the higher the resistance, the more the delivered current becomes more monophasic (*e*Fig. 76.0.7).

The newer biphasic waveforms are probably more effective than monophasic damped sine waves for transthoracic defibrillation. In 2000, Schneider and associates (42) reported a comparison of a monophasic (200–360 J) and a biphasic (150 J) AED for out-of-hospital cardiac arrest. Their study included 115 patients who presented with VF as their initial monitored rhythm (42). The time from the emergency call to first shock was 8.9 ± 3.0 minutes. Defibrillation with three or fewer shocks occurred in 69% of patients who received monophasic shocks and 98% of patients receiving biphasic shocks. Return of spontaneous circulation occurred in 54% of patients who received monophasic shocks and 76% of those receiving biphasic shocks. The study was not powered to show differences in patient survival, and indeed survival to hospital discharge was not different (31% vs. 28%). However, neurologic outcome appeared better in patients who received the biphasic shock, as 21% of those receiving monophasic shocks were in a coma on hospital discharge compared with none of the patients who received biphasic shocks (42).

Mittal and associates compared 200-J damped sine-wave monophasic shocks and 120-J rectilinear biphasic shocks of the Zoll defibrillator in 184 patients in whom VF was induced in the electrophysiology laboratory (43). First shock success was 93% with the monophasic and 99% with the biphasic shock (43). The major difference in defibrillation success was in patients who had high transthoracic impedance. Those with transthoracic impedance of greater than 90 W had a defibrillation success rate of less than 65% with the monophasic shock and near 100% with the biphasic shock (43).

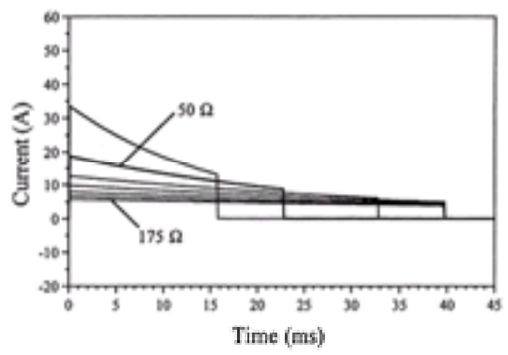
Tang and associates (44) reported better defibrillation effectiveness and less postresuscitation myocardial dysfunction with up to three 150-J shocks with biphasic waveform compared to the conventional sequence of 200-, 300-, or 360-J monophasic waveform shocks. Niemann and associates (45), using a similar protocol, concluded that monophasic and biphasic waveforms were equally effective in terminating prolonged VF with the first shock and that there was no apparent clinical disadvantage of subsequent low-energy biphasic shocks compared with progressive-energy monophasic shocks.

*e*Figure 76.0.11 represents "current plots" of traditional MDSs, and *e*Figure 76.0.12 represents current plots of monophasic, truncated exponential waveforms as a function of load impedance from 25 to 175 W in 25-W increments (46). *e*Figure 76.0.11 illustrates that the shape of the monophasic current waveform changes passively as a function of the impedance (46). With defibrillators that deliver the MDS, the peak delivered current decreases dramatically with increasing impedances. In contrast, with defibrillators that deliver the monophasic truncated exponential waveform, increasing load impedance not only decreases the peak delivered current of the delivered current wave but also prolongs the waveform length (46). Animal studies show that the effectiveness of a monophasic truncated exponential waveform decreases for waveform durations greater than 20 ms (47,48 and 49). Because lower peak current and longer-length monophasic waveforms are not as effective, impedances to defibrillator discharge using defibrillators that deliver MDSs or monophasic waveforms are not as effective at high transthoracic impedances. Increasing impedance distorts sinusoidal monophasic (*e*Fig. 76.0.11) and square-wave monophasic (*e*Fig. 76.0.12) waveforms.



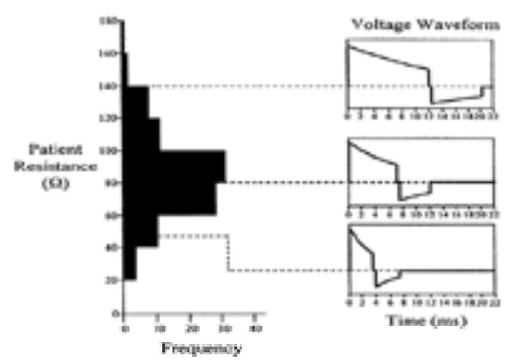
***e*FIGURE 76.0.11** Representative current plots of traditional monophasic damped sine waveforms as a function of load impedance from 25 to 175 W in 25-W increments. (From Gliner BE, Jorgenson DB, Poole JE, et al. Treatment of out-of-hospital cardiac arrest with a low-energy impedance-compensating biphasic

waveform automatic external defibrillator. *Biomed Instrum Tech* 1998;32:631–644, with permission.)



***e*FIGURE 76.0.12** Representative current plots of traditional monophasic truncated exponential waveforms as a function of load impedance from 25 to 175 W in 25-W increments. (From Gliner BE, Jorgenson DB, Poole JE, et al. Treatment of out-of-hospital cardiac arrest with a low-energy impedance-compensating biphasic waveform automatic external defibrillator. *Biomed Instrum Tech* 1998;32:631–644, with permission.)

Will the transthoracic load impedance to defibrillator discharge distort the biphasic waveform as it does the monophasic waveforms? In some commercially available units, the answer is yes. However, they have been engineered so that the changes are not as dramatic. Some of the clinically available biphasic waveform defibrillators are single capacitor. As such, the voltage and width of the second or phase 2 part of a biphasic waveform are dependent on phase 1 pulse characteristics (*e*Fig. 76.0.13). The Heartstream AED is designed with low-energy impedance-compensating biphasic-voltage waveforms that vary the duration of phase 1 and phase 2 so that the total duration is 5.66 ms at an impedance of 25 W and 20 ms at an impedance of 125 W or greater (*e*Fig. 76.0.13). To keep the biphasic waveform more optimal, the tilt of the two phases is decreased at lower impedance, because animal studies have shown higher energy requirements when total tilt is greater than 80%. The use of two separate output capacitors avoids these limitations. Studies of Yamanouchi and associates (50) using two separate output capacitors to produce tailored biphasic waveforms have shown higher defibrillation efficacy. The Zoll biphasic defibrillator has a constant waveform over a wide range of load impedances.



***e*FIGURE 76.0.13 Left:** Distribution of shock resistances (impedances) for 100 patients presenting in ventricular fibrillation. **Right:** Voltage waveforms of the Fore Runner AED, SMART Biphasic defibrillator at 140, 80, and 45 W. (From Gliner BE, Jorgenson DB, Poole JE, et al. Treatment of out-of-hospital cardiac arrest with a low-energy impedance-compensating biphasic waveform automatic external defibrillator. *Biomed Instrum Tech* 1998;32:631–644, with permission.)

It is not known whether one of these newer biphasic defibrillators is more effective than the other. The impedance-compensating biphasic waveform would be significantly longer than the Zoll biphasic waveform at high impedance and in theory might be less effective. Encouraging, however, is a post–market surveillance study of AEDs incorporating 150-J impedance-compensating biphasic truncated exponential waveforms (ForeRunner AED, SMART Biphasic, Heartstream, Inc., Seattle, WA) that failed to show decreased effectiveness at transthoracic impedance over 100 W versus that of patients with an impedance of less than 100 W (19).

New experimental evidence has shown that the triphasic or small shock before the biphasic shock is the most effective waveform for ventricular defibrillation (51,52).

Current Density

The importance of electrode size to transthoracic resistance or impedance is discussed in the section Factors Determining Transthoracic Impedance. If shock strength and resistance are held constant, the major determinant of current density is the electrode size. If the shock strength is high and the electrode size is too small, the current density is high and myocardial damage is more likely (53). If the electrode size is too large, the current density will be too diffuse and the amount of current delivered to the heart may not be adequate for defibrillation (22,28).

Defibrillation Threshold

Irrespective of the theories of defibrillation, there is a defibrillation threshold. Shock strength below this threshold does not defibrillate and must be above the defibrillation threshold to defibrillate. Several factors affect the defibrillation threshold. For example, the defibrillation threshold increases with durations of VF of more than 30 to 60 seconds (54). Metabolic mechanisms have been proposed for this increase. One mechanism may be the intracellular accumulation of potassium (21). Neither hypoxia, metabolic acidosis, nor alkalosis appears to affect the defibrillation threshold adversely (54,55). Catecholamine levels are markedly elevated during VF, but catecholamines are known to decrease the defibrillation threshold (15,56).

Lerman and Engelstein (15) postulated that adenosine mediated this phenomenon. In their experimental study these investigators showed that the increase in defibrillation threshold was blocked before treatment with the adenosine A_1 receptor antagonist 8-cyclopentyl theophylline. They further postulated that these effects are mediated through an antiadrenergic mechanism, because the effect of adenosine on the defibrillation threshold was blocked by denervation (propranolol, 0.2 mg per kg, plus bilateral vagotomy) (15).

Some antiarrhythmic drugs, including lidocaine, encainide, and flecainide and perhaps high doses of the class I antiarrhythmics, increase the defibrillation threshold. If the patient has an implanted cardioverter-defibrillator, these drugs must be added to the medical regimen with caution.

Defibrillation Shock Strength and Cardiac Damage

Shock strength must be adequate for defibrillation (3,28). Shocks delivered below the defibrillation threshold are of insufficient strength to defibrillate. Shock strength in excess of this threshold causes myocardial damage or may reinitiate fibrillation, or both (53,57).

Geddes et al. (28) showed that over a wide range of body size, the smaller the animal, the less energy was needed for defibrillation. Larger animals require higher shock strength to defibrillate. Less energy is needed to defibrillate small children than is needed to defibrillate large adults.

In the 1970s, shock strengths of 6 J per kg body weight were recommended. At about this time, Ewy and others demonstrated myocardial damage at very high shock strengths (53,57). Adgey and associates found that many patients could be defibrillated with energies as low as 100 to 200 J (58,59).

In 1982, Weaver and associates (60) demonstrated in an out-of-hospital study that a 175-J MDS shock defibrillated as well as a 320-J shock but without the negative side effects of an increased postshock incidence of atrioventricular block. Defibrillation rates were not different, and the proportion of patients who were successfully

resuscitated and discharged from the hospital was also similar (60). In 1996, Bardy et al. (61) showed in an in-hospital electrophysiology study that a 200-J MDS shock defibrillated as well as a 360-J MDS shock but with less electrocardiographic evidence of myocardial injury from the shock.

In 1983, Kerber and colleagues (62) reported a prospective in-hospital study of 183 patients who required defibrillation. They found no difference in first shock or accumulative success rates in patients who received initial monophasic countershocks of either 200 J or 300 to 400 J (62).

As reviewed above, biphasic waveform defibrillation shocks at lower energies appear to be more effective than monophasic shocks. Evidence also shows that the biphasic defibrillation shocks produce less myocardial damage and postshock myocardial dysfunction (61). Reddy and associates (43) found that biphasic transthoracic defibrillation causes less electrocardiographic ST-segment elevation after a defibrillation shock than does monophasic transthoracic defibrillation shock. Studies in animals have demonstrated that defibrillation waveform and energy dose affect postresuscitation myocardial function (63,64 and 65).

Transthoracic impedance declines with repeated shocks (36,63). Such a decline in transthoracic impedance results in greater current delivery to the myocardium using the same energy of shock and should enhance the possibility of achieving successful defibrillation. However, the decrease in trans-chest impedance with rapidly delivered shocks is small, and therefore, the present recommendation that the second monophasic shock strength be 300 J is reasonable. If VF continues after the second attempt of 200 or 300 J, higher energy level (360-J) monophasic should be used for the third and subsequent shocks. As noted above, if repeated 360-J shocks do not defibrillate, sequential monophasic shocks, using two defibrillators, or biphasic defibrillator shocks should be considered. The energy level for defibrillation with biphasic waveform shocks is less and ranges from 120 to 180 J.

VF may recur after successful defibrillation. In such circumstances, it is reasonable to use energy levels similar to those that were previously effective. Particularly in the cases in which VF reoccurs frequently, shock strength should be kept as low as possible to minimize myocardial damage. Myocardial injury associated with defibrillation corresponds not only with total joules used (energy) but also with the time interval between the defibrillation shocks (53). Ideally, defibrillation shocks should be of sufficient strength to stop fibrillation but not so strong that they decrease cardiac function, cause myocardial necrosis, or reinitiate fibrillation.

Sequential Shocks from Two Defibrillators

Sequential shocks from two defibrillators have been shown to be more effective than repeated shocks from a single defibrillator. VF that is refractory to transthoracic shocks can occur in up to 0.1% of electrophysiologic studies (64). Hoch and associates (64) reported that 5 of 2,990 consecutive patients experienced refractory VF during routine electrophysiologic studies. Multiple shocks were delivered by means of a single defibrillator. Double sequential shocks were delivered externally 0.5 to 4.5 seconds apart by means of two defibrillators with separate pairs of electrodes. The five patients in whom repeated standard defibrillation shocks were unsuccessful were all successfully defibrillated using the two sequential shocks (64).

Another approach is to use a defibrillator that delivers a biphasic waveform shock, because these units have been shown to be more effective than defibrillators that deliver the monophasic sine waveform.

TIMING OF DEFIBRILLATION

Importance of Early Defibrillation

The time between an arrest due to VF and the application of defibrillation shocks is a major determinant of survival from cardiac arrest (65,66,67,68,69 and 70). This fact is now well appreciated. Each minute that defibrillation is delayed after the first minute, survival decreases an average of 10%. This fact was a major determinant in the paradigm to develop the internal cardiac defibrillator and the development of the AED that can be used with minimal training.

Automated External Defibrillators

The development of automatic and semiautomatic external defibrillators has allowed some communities to staff many first-responding units with the ability to defibrillate early (71,72 and 73). AEDs have algorithms that are specific and sensitive for the identification of VF (46,71,73). Once placed and activated, the automatic device advises a shock if VF is present. In others, the advice to shock is withheld until absence of respiration is documented, usually by the lack of impedance change between the electrodes. Several studies have shown improvement in survival rates for out-of-hospital cardiac arrest with the use of AEDs (73,74,75,76,77,78,79 and 80). Interest in the wider use of the devices continues, particularly where there is a large public gathering (79,80,81,82,83 and 84) and in airplanes (80).

Valenzuela and associates (79) reported the best out-of-hospital survival rates to date by supplying AEDs and training security guards in casinos. Overall, 56 of 105 (53%) patients whose initial rhythm was VF survived to hospital discharge. The mean time from collapse to first shock was 4.4 ± 2.9 minutes. The mean time of arrival of the paramedics was 9.8 ± 4.3 minutes. Survival was 74% in the patients who received their first shock within 3 minutes. Survival was 49% in patients who received their first shock after 3 minutes. The authors concluded that intervals of no more than 3 minutes from collapse to defibrillation are necessary to achieve the highest survival rates (79).

In summary, rapid electrical countershock of patients in VF by emergency medical technicians who are trained to defibrillate has been shown to save lives in urban (77,85), suburban (86), and rural (87) settings and by nontraditional providers, such as security guards in gambling casinos (79). The following questions should now be asked: In what specific setting will the AEDs be cost effective? Should they become more readily available to the general public, much like fire extinguishers, or should they be placed in areas where there is a high likelihood of cardiac arrest? The recommendations of the Guidelines 2000 for Cardiopulmonary Resuscitation and Emergency Cardiac Care International Consensus (88) are (a) that public access defibrillation programs should be in locations where the frequency of cardiac arrest events is such that there is a reasonable probability of one AED use in 5 years, or one sudden cardiac arrest per 1,000 patient-years; and (b) that the emergency medical system's call-to-shock time interval of less than 5 minutes cannot be reliably achieved (88). However, emotional considerations may lead to the placement of AEDs in schools and in many other locations. Identifying these venues will be one of the challenges of the next few years.

Defibrillating Shocks after Prolonged Arrest

In view of the evidence supporting the effectiveness of early defibrillation in improving cardiac arrest survival, the International Guidelines Committee for Emergency Cardiac Care recommends that patients with cardiac arrest who are in VF undergo three attempts at external defibrillation as the initial step to resuscitation (88). These recommendations for immediate defibrillation are not without some controversy. Yakaitis et al. (89) confirmed that when defibrillation was performed within minutes of the onset of cardiac arrest, no CPR or drug therapy was needed. However, we found that if cardiac arrest continued for more than 5 minutes before defibrillation was attempted, administration of epinephrine and a number of external chest compressions before defibrillation shocks helped restore a perfusing rhythm (89). Neimann et al. (90), using an animal model of VF cardiac arrest, found that after 7.5 minutes of untreated VF, animals that were initially given epinephrine and manual closed-chest CPR before defibrillation attempts had a higher resuscitation rate (9 of 14) than those treated with initial countershock (3 of 14). These findings suggested that, after prolonged VF, a brief period of enhanced myocardial perfusion before countershock may improve successful resuscitation.

The relevance of these early animal studies was confirmed in humans by the study by Cobb and associates (91). They noted a decrease in the out-of-hospital survival of cardiac arrest in the Seattle paramedic system once they had changed from standard defibrillators to AEDs. They noted that, before this change, the paramedics had been instructed to perform a short period of chest compression and assisted ventilation before they attempted defibrillation. They instituted a new protocol in which 90 seconds of CPR was performed before defibrillation (91). They compared the outcome of 639 patients before the change and 478 patients after the change. Overall survival improved from 24% to 30%. Survival in the group in whom paramedic arrival was longer than 4 minutes improved from 17% to 27%. Favorable neurologic function at hospital discharge improved from 71% to 79% (91).

OTHER METHODS OF DEFIBRILLATION

Precordial Thump

The precordial thump is the easiest, although least effective, form of defibrillation. First reported in the early 1960s as being capable of defibrillating VF as well as converting ventricular tachycardia, it became apparent that precordial thumps could also convert ventricular tachycardia to VF (92). Because of that concern, the American Heart Association Guidelines Committee recommended in 1986 that a precordial thump be used only in patients with "monitored VF or in witnessed cardiac arrest if a defibrillator is unavailable" (93). Precordial thumps defibrillate only 2% of patients with very recent onset of VF (94). Nevertheless, in individuals with witnessed hemodynamic collapse, precordial thump appears justified because of its rapidity and ease of delivery. However, a defibrillator should be available before application of precordial thump in patients with ventricular tachycardia who have a pulse, because the mechanical stimulus can induce VF (93).

Open-Chest Defibrillation

The most common use of open-chest defibrillation is during cardiac surgery. Although presently very rare, VF can result from a variety of circumstances in the operating room. During induction of anesthesia, cardiac surgery patients occasionally fibrillate and are treated with external defibrillation in the usual fashion. Even when the chest has been opened, it is possible to defibrillate by external means (95,96 and 97), but internal defibrillation is usually used once the chest is opened. The most common scenario for VF requiring internal defibrillation is at the conclusion of a cardiac surgical procedure. On rewarming and unclamping of the aorta, approximately 40% to 50% of the patients experience VF (98).

Several studies have examined the optimal dose for open-chest defibrillation. Tacker and associates (99) reported that 93% of patients required 10 J or less for successful defibrillation; 48% required 5 J or less. Lake and colleagues (100) found that approximately 90% of 150 cardiac surgical patients could be defibrillated successfully with 10 J or less. Pugsley et al. (101) found similar results in a study of 168 patients showing that 98% could be defibrillated internally with less than 10 J energy.

Another less common use for open-chest defibrillation occurs during emergent circumstances in which closed-chest resuscitation efforts have failed and more aggressive open-chest measures have been used. Open-chest CPR and subsequent internal defibrillation have been shown to be more effective than closed-chest techniques in a number of circumstances (102,103). Myocardial and cerebral perfusion with open-chest CPR techniques are significantly better than those obtained with closed-chest efforts (104,105 and 106). Short-and long-term survival, in animal models, has been substantially better with open-chest resuscitation (107,108 and 109). The most difficult decision in using open-chest techniques is when to use such invasive techniques (emergent thoracotomy and open-chest resuscitation).

The University of Arizona Cardiopulmonary Resuscitation Research Group studied the time course feasibility of instituting open-chest CPR and direct defibrillation after various periods of unsuccessful closed-chest efforts and found that after a 15-minute period of ineffective closed-chest efforts, open-chest CPR resulted in improved survival (110). However, after a period of 25 or 30 minutes of ineffective closed-chest efforts, the institution of open-chest invasive resuscitation did not result in long-term benefits (109). Hence, the decision to use invasive techniques must be made relatively early, probably within 15 minutes of cardiac arrest and failed closed-chest efforts.

RISK OF DEFIBRILLATION TO THE RESCUER

Performed in an appropriate manner, defibrillation poses almost no risk to the would-be rescuer. However, precautions must be taken to assure that the procedure is safe. Gibbs et al. (111) reported on the severity of injuries to pre-hospital emergency personnel in King County, Washington. Questionnaires mailed to the paramedics in the King County emergency medical system documented only eight cases of injury to paramedics or emergency medical technicians over a 9-year period. The actual incidence was 1 in 1,700 defibrillation attempts among paramedics and 1 in 1,000 defibrillation attempts among emergency medical technicians who were trained to defibrillate. Most of the incidences resulted from contact with the cardiac arrest patient during the defibrillation shock, producing localized transmission of a portion of electrical current that culminated in extremity tingling or soreness. One equipment failure, a crack in the defibrillator paddle, resulted in a more significant shock delivered to a paramedic, resulting in frequent premature ventricular ectopic beats and localized muscle spasms that required admission to the hospital. No deaths have been reported from accidental injury to the individuals who administered the defibrillation shock. The incidence and consequences of defibrillator-associated injuries to pre-hospital emergency personnel appear to be low and the nature of the injuries minimal. However, safety must continue to be stressed and efforts made to eliminate all such injuries (111).

Cases of defibrillation hazards associated with placing defibrillating paddle electrodes over nitroglycerin patches have been reported. Wrenn (112) described a small explosion in a nitroglycerin patch during a defibrillation attempt when a paddle was placed directly on such a patch. Although no adverse effects occurred in this patient, the dangers of “arcing” during defibrillation and ineffective delivery of current in reference to patches or ointments, particularly nitroglycerin, should be considered (112).

Hummel and associates (32) reported a fire started by a defibrillation shock in an oxygen-rich environment. This occurred on the sixth defibrillation attempt in an unsuccessful 40-minute resuscitation effort. A spark generated the fire during defibrillation and ignited the bed sheets, quickly engulfing the patient’s bed. It is likely that the fire spread rapidly because of an oxygen-enriched environment created by the continued discharge of the patient’s volume-cycled ventilator, which had been disconnected from the endotracheal tube to permit manual bag-valve ventilation at the onset of the resuscitation. The patient died from his terminal illness, not as a result of the fire. However, the fire destroyed the ventilator and the bed mattress, caused minor smoke damage to the cardiac monitor attached to the patient, and forced evacuation of the remaining 11 patients in the intensive care unit (32). The major problem appeared to be that these investigators were using an electrode gel interface with high resistance (32). They reported on the spark-generating properties of electrode gels used during defibrillation. They found that low-resistance gels, such as Redux Paste or Signagel (Parker Laboratories, Inc., Orange, NJ), had little spark-generating potential, whereas high-resistance gels, such as those used for echocardiography, had high spark-generating properties (32).

CARDIOVERSION

Ventricular Tachycardia

The techniques used for cardioversion of hemodynamically stable ventricular tachycardia are the same as those advocated for elective cardioversion, except that the energy required is lower. Shock strength of 30 to 50 J can frequently cardiovert hemodynamically stable ventricular tachycardia. The exception to this rule is that the cardioversion threshold for multiform ventricular tachycardia is higher than that of monomorphic ventricular tachycardia (113).

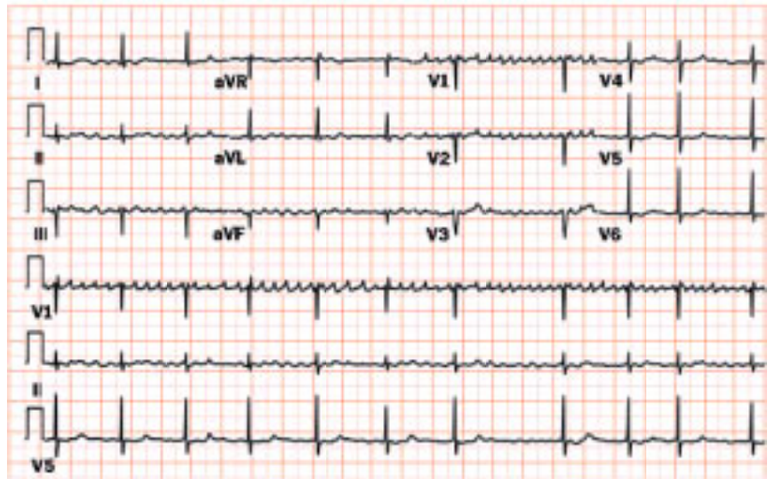
An 81-year-old male patient with ventricular tachycardia.

In hemodynamically unstable patients and perhaps in those with polymorphic ventricular tachycardia, a 200-J monophasic or 120- to 150-J biphasic shock should be given. If the initial shock is not successful, the strength of the second and third shocks, for defibrillators that deliver the monophasic sine waveform, should be 300 J and 360 J, respectively. In patients with recurrent ventricular tachycardia, shock strength on subsequent shocks should be the lowest effective dose to prevent potential cardiac damage from repeated shocks. In patients with recurrent ventricular tachycardia, consideration should be given to the placement of a temporary pacemaker for overdrive suppression or burst pace termination of the arrhythmia until an effective antiarrhythmic drug regimen has been established.

In stable patients with slower rates of ventricular tachycardia, synchronization of the cardioversion shock with the QRS complex is recommended. However, with faster rates, it is often difficult to distinguish the QRS complex from the T wave. In this situation, nonsynchronized shocks are also recommended.

Atrial Fibrillation

Lown and associates (114) developed the technique of transthoracic DC electrical cardioversion from atrial fibrillation four decades ago. Perfecting the technique, Lown reported that sinus rhythm was reinstated in 94% of the 456 episodes of atrial fibrillation (114,115). External cardioversion success rates vary (116), and as recently as 1992, a series reported only 67% success using external delivery of shocks (117). Why have cardioversion success rates been so different? One explanation is that in some series, many of the patients were in chronic atrial fibrillation for over 1 year and had failed previous pharmacologic attempts at cardioversion (117). Another possible explanation for the different success rates is the difference in techniques of external cardioversion (114,115,116,117,118,119,120 and 121).

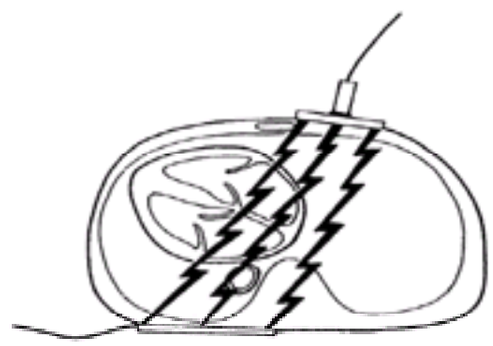


Atrial fibrillation. Narrow complex QRS with irregular RR intervals. Ventricular rate is controlled.

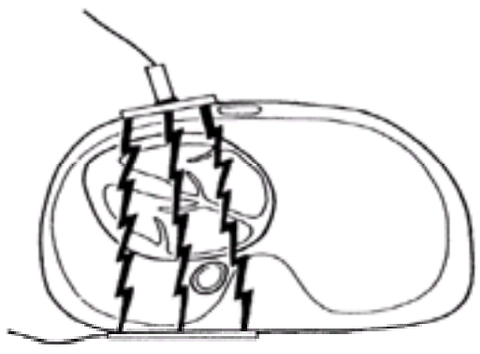
As with ventricular defibrillation, successful cardioversion of atrial fibrillation requires the delivery of adequate current density through the fibrillating chamber. The same considerations of electrode size and transthoracic impedance (see the section Factors Determining Transthoracic Impedance) apply for cardioversion as for defibrillation. However, electrode positioning should be significantly different for cardioversion of atrial fibrillation than for electrical ventricular defibrillation (see the section Electrode Positions).

Electrode Positions

Electrode position is decisive, because the current of the shock must traverse a critical mass of the atrial muscle for cardioversion to occur. Lown reported that the antero-posterior electrode position was more effective for cardioversion of atrial fibrillation than the anterior-anterior electrode position (115,116). He wrote, “The anterior paddle is held with pressure over the upper sternum at the level of the third intercostal space. . . . This antero-posterior position, compared with the previously employed antero-lateral placement, shortens the pathway between the electrodes and augments the density of the electrical field which traverses the heart, thereby diminishing by about 50% the energy required for reversion” (115). In contrast, Kerber and associates (120) reported that the electrode position or size made little difference in cardioversion success. However, in their study, the 111 patients with atrial fibrillation were divided into four groups, each with high success rates, making a statistical beta error so likely that the study is not definitive. In addition, in a study of electrode position by Kerber et al., the electrode positions recommended by Lown et al. (sternal or right parasternal anterior–left posterior) (14) (*e*Fig. 76.0.14) or Ewy (left parasternal antero-posterior) (121) (*e*Fig. 76.0.15) for cardioversion of atrial fibrillation were not tested.



***e*FIGURE 76.0.14** Right anterior-posterior electrode position for cardioversion of atrial tachycardias. (Copyrighted and reprinted with the permission of Clinical Cardiology Publishing Company, Inc., and/or Foundation for Advances in Medicine and Science, Inc., PO Box 832, Mahwah, NJ 07430.)



***e*FIGURE 76.0.15** Left anterior-posterior electrode position for cardioversion of atrial tachycardias. (Copyrighted and reprinted with the permission of Clinical Cardiology Publishing Company, Inc., and/or Foundation for Advances in Medicine and Science, Inc., PO Box 832, Mahwah, NJ 07430.)

Cardioversion requires that the current traverse a critical mass of the atrial muscle. Analysis of computed tomographic scans of the thorax at the level of the heart provides insight into appropriate electrode positions for defibrillation of the atria. The antero-posterior positions (*e*Fig. 76.0.14 and *e*Fig. 76.0.15) fulfill this criterion the best. The right anterior–left posterior position (*e*Fig. 76.0.14) or Lown’s sternal-posterior is the position of choice if the pathology involves both atria (i.e., atrial fibrillation due to atrial septal defect or diffuse cardiomyopathy). This position has more of the right atria between the electrodes. The right antero-posterior electrode position (*e*Fig. 76.0.14) has the disadvantage of a greater interelectrode distance and more lung tissue between the electrode and the heart in the unoperated or emphysematous chest. The left parasternal antero-posterior electrode position has the advantage of smaller interelectrode distance and less lung between the electrodes (*e*Fig. 76.0.15). It is not known whether the right parasternal anterior–left posterior position (*e*Fig. 76.0.14) is better than the left parasternal antero-posterior paddle electrode position (*e*Fig. 76.0.15) that Ewy et al. (123) advocate in patients whose major pathology is left atrial enlargement. The antero-anterior (*e*Fig. 76.0.16) and the apical–left posterior position (*e*Fig. 76.0.17) are not recommended for electrical cardioversion of atrial fibrillation, as these positions probably do not provide optimal current flow through the atria.

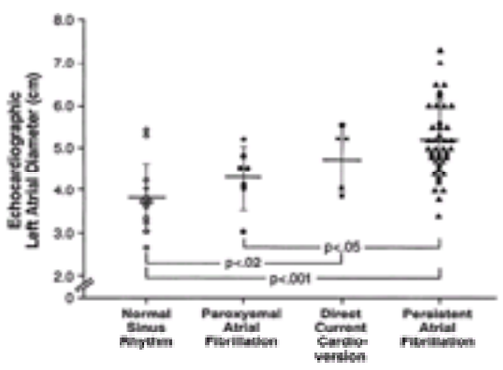
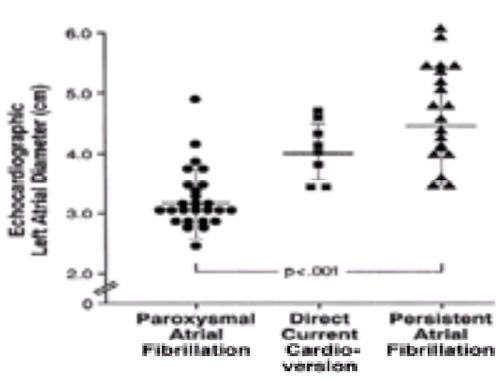
With antero-posterior electrode placement, the greater the antero-posterior chest diameter, the greater the impedance and the less likely that cardioversion will be successful (121). In a 1992 study, the only determinant of successful cardioversion was body weight (117), which usually correlates with chest diameter. Geddes and associates (28) clearly showed that the electrical dose for VF was related to body size and weight. When the impedance is low and the current delivery is high, the relationship between shock strength and body weight is difficult to show and is not clinically important in adults. However, if current delivery is marginal, this relationship is evident (117).

Predictors of Long-Term Success

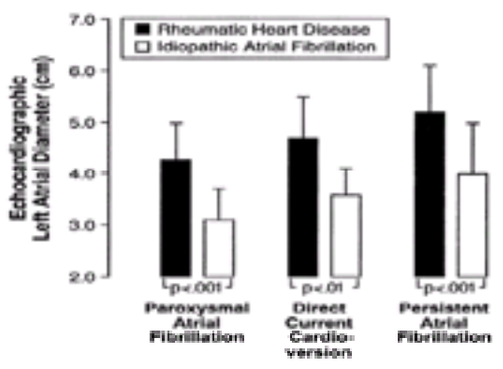
The initial enthusiasm for elective cardioversion of all patients in atrial fibrillation was somewhat dampened by the high recurrence rate in some subsets of patients. As Lown emphasized, the initiating mechanism and the sustaining mechanism of atrial fibrillation are different (114,115 and 116). If the initiating mechanism is no longer present, cardioversion should have lasting success. If, however, the initiating mechanism is still present, atrial fibrillation is very likely to recur. Some patients are not suitable candidates for cardioversion because the initiating mechanism is still present. Untreated thyrotoxicosis, significant untreated mitral valve disease, and congestive heart failure are obvious examples of situations in which the initiating mechanism is still present. Atrial fibrillation of more than 1 year's duration, first-degree heart block greater than 0.24 second before the onset of atrial fibrillation, and significant left atrial enlargement are markers that the initiating pathology is still present, because these factors predict early recurrence. Some studies have not shown a relation between left atrial size and postcardioversion atrial fibrillation recurrence rate. However, studies that looked at cardioversion success rates and recurrence rates within disease states (i.e., mitral disease, hypertrophic cardiomyopathy, idiopathic atrial fibrillation) have shown that a larger left atrium is one of the contributing factors to cardioversion failure or high recurrence rates after cardioversion (108,109,122) (*e*Fig. 76.0.18, *e*Fig. 76.0.19, and *e*Fig. 76.0.20).



***e*FIGURE 76.0.18** Relation between left atrial diameter obtained by M-mode echocardiography and the response of atrial fibrillation to therapy in patients with rheumatic mitral valve disease. The paroxysmal atrial fibrillation group converted spontaneously or with antiarrhythmic drug therapy and remained in sinus rhythm during the 3 months of follow-up. The direct current cardioversion group required electrical cardioversion and were in sinus rhythm 3 months after cardioversion. The persistent atrial fibrillation group all had electrical cardioversion but had reverted to atrial fibrillation at 3 months of follow-up. Left atrial diameter plotted as individual patients with mean ±1 standard deviation and statistical differences. (From Ewy GA, Ulfers L, Hager WD, et al. Direct current shock and transcardiac impedance. *J Electrocardiol* 1980;13:119–124, with permission.)



***e*FIGURE 76.0.19** Relation between left atrial diameter obtained by M-mode echocardiography and the response of atrial fibrillation to therapy in patients with nonvalvular atrial fibrillation. The paroxysmal atrial fibrillation group converted spontaneously or with antiarrhythmic drug therapy and remained in sinus rhythm during the 3 months of follow-up. The direct current cardioversion group required electrical cardioversion and were in sinus rhythm 3 months after cardioversion. The persistent atrial fibrillation group all had electrical cardioversion but were back in atrial fibrillation at 3 months of follow-up. Left atrial diameter plotted as individual patients with mean ± 1 standard deviation and statistical differences. (From Ewy GA, Ulfers L, Hager WD, et al. Direct current shock and transcardiac impedance. *J Electrocardiol* 1980;13:119–124, with permission.)



***e*FIGURE 76.0.20** Relation between left atrial diameter obtained by M-mode echocardiography and the response of atrial fibrillation to therapy in patients with rheumatic and “idiopathic” atrial fibrillation. In this study, patients with nonvalvular atrial fibrillation, even if they had a history of hypertension, were classified as idiopathic. The paroxysmal atrial fibrillation group converted spontaneously or with antiarrhythmic drug therapy and remained in sinus rhythm during the 3 months of follow-up. The direct current cardioversion group required electrical cardioversion and were in sinus rhythm 3 months after cardioversion. The persistent atrial fibrillation group all had electrical cardioversion but were found to have reverted to atrial fibrillation at 3 months of follow-up. Left atrial diameter plotted as individual patients with mean ±1 standard deviation and statistical differences. (From Ewy GA, Ulfers L, Hager WD, et al. Direct current shock and transcardiac impedance. *J Electrocardiol* 1980;13:119–124, with permission.)

Anticoagulation

Hemodynamically unstable patients or patients with marked ischemia secondary to recent-onset atrial fibrillation may need urgent cardioversion. In this setting, there may be no time for anticoagulation.

Otherwise, patients who are undergoing electrical cardioversion should be anticoagulated, either with heparin or with 3 weeks of warfarin (124,125,126,127,128,129,130,131,132,133,134,135 and 136). The recommendation for heparin therapy before electrical cardioversion—even if the transesophageal echocardiogram (TEE) shows no evidence of thrombus—is based in part on the observation of Fatkin et al. (131), who reported 66 patients who underwent TEE before cardioversion and 15 patients in whom TEE was performed during the cardioversion procedure. Thromboembolism occurred in four patients, none of whom had prior evidence of left atrial thrombus by TEE (131). Surprisingly, within 10 seconds of cardioversion shock, spontaneous echo contrast appeared in the left atrium in five of the patients, increased in one, and was unchanged in nine (131). These investigators concluded that transient atrial dysfunction (stunning) caused by the electrical shock of cardioversion promoted new thrombus formation (131). Grimm and associates (132) have also demonstrated the development of spontaneous echoes in the left atrium and left atrial appendage in approximately 35% of patients undergoing electrical cardioversion. These authors, in reviewing the role of TEE before electrical cardioversion for atrial fibrillation, concluded that TEE can identify left atrial clot. If clot is identified, anticoagulation for 6 weeks is indicated (132). If no clot is identified, the patient is anticoagulated with heparin and started on warfarin before the cardioversion. Heparin is continued until the international normalized ratio is therapeutic (2.0–3.0). They recommend that the warfarin anticoagulation be continued for at least 6 weeks.

Another issue is the effect of the duration of atrial fibrillation on the time of the return of atrial contractile function following cardioversion. The longer the duration of atrial fibrillation, the longer it takes for normal atrial contractile function to return (133). Manning and associates (113) found that patients with duration of atrial fibrillation of less than 6 weeks had near complete return of atrial function by 1 week. This fact argues in favor of a TEE evaluation in hospitalized patients with recent-onset atrial fibrillation and 2 days of intravenous heparin followed by cardioversion. If pharmacologic therapy does not result in cardioversion, one can proceed with electrical cardioversion. At the same time that the heparin is initiated, the patient is started on oral anticoagulation. On the other hand, the fact that it takes much longer for atrial contractions to return in atrial fibrillation of longer duration argues for longer duration of anticoagulation after cardioversion.

Cardioversion and Antiarrhythmic Drug Therapy

Lown (115) instituted quinidine therapy 1 or more days before attempted electrical reversion, stating that this antiarrhythmic (a) improves the chances of the patient who remains in normal sinus rhythm immediately after cardioversion, (b) decreases by approximately 40% the energy required for cardioversion, (c) diminishes the incidence of postcardioversion arrhythmias, and (d) helps to “obtain a small dividend of reversions which results in about 10% of patients.” Digoxin is also given to counteract the vagolytic effect of quinidine. Therapeutic digoxin dose should be halved before this antiarrhythmic is begun, as quinidine doubles the serum digoxin level. Procainamide infusion and other antiarrhythmic agents such as sotalol and propafenone have also been advocated for pharmacologic cardioversion.

A major unanswered question is the role of antiarrhythmic drugs pre- and postcardioversion. The most important drug(s) that are to be used before and after cardioversion is (are) the one(s) that treat the factor(s) predisposing to the atrial fibrillation. If the etiologic mechanism, for example, thyrotoxicosis, has been corrected, antiarrhythmic drugs may not be necessary.

Lown gave quinidine before electrical cardioversion. He thought that patients on quinidine required less energy for cardioversion (114,115 and 116). In an evaluation of antiarrhythmic drug therapy and cardiac mortality in atrial fibrillation, patients in the Stroke Prevention in Atrial Fibrillation (SPAF) study were analyzed (137). Of the 1,330 patients in the study, 189 were taking antiarrhythmic drugs; the majority (127/189) were taking quinidine (137). No increased risk was found in patients without congestive heart failure or a history of congestive heart failure. However, with or with a history of heart failure, there was a 4.7 (1.9–11.6)-fold increase in the risk of cardiac death (137).

In the Cardiac Arrhythmia Suppression Trial (CAST), mortality was increased in patients with ventricular arrhythmias who were treated with antiarrhythmic drugs (138). The results of these studies should occasion concern about the wisdom of long-term antiarrhythmic therapy after cardioversion in patients who have congestive heart failure or a history of heart failure or who have had a previous myocardial infarction.

Beta-adrenergic blocking drugs have been used. Kuhlkamp et al. (140) reported a relapse rate of 48.7% in patients treated with beta-blocker after electrical cardioversion, compared to 59.9% in those who received placebo.

Propafenone and sotalol have both been used for cardioversion and maintenance of sinus rhythm after electrical cardioversion. De Simone and colleagues (139) reported that pretreatment with verapamil for 3 days before and 3 days after electrical cardioversion, combined with oral propafenone begun 3 days before electrical cardioversion and continued, reduced the incidence of early (3-month) recurrence of atrial fibrillation compared with propafenone therapy alone.

In the Canadian Trial of Atrial Fibrillation (CTAF), amiodarone has been reported to be twice as effective as either propafenone or sotalol in preventing recurrent atrial fibrillation (141). The recurrence of atrial fibrillation was 35% with amiodarone, 63% with propafenone, and 63% with sotalol (141).

Atrial pacing may also be important to the maintenance of sinus rhythm in those patients with the sick sinus syndrome.

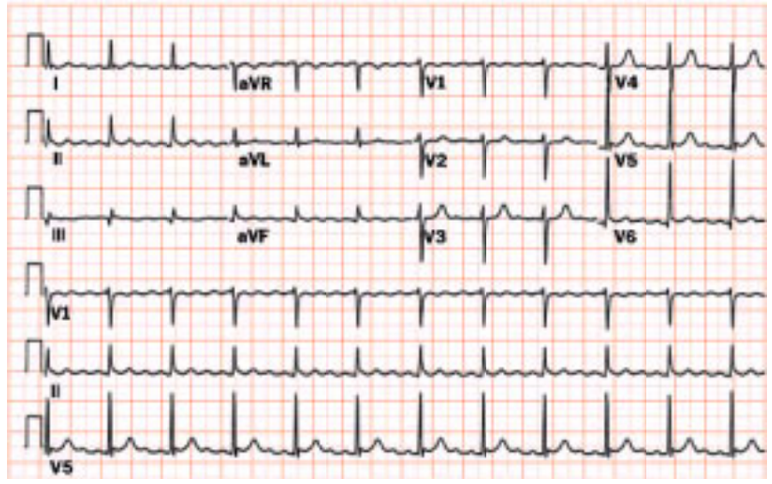
Shock Strength

The strength of the initial shock to cardiovert hemodynamically stable atrial fibrillation when one is using the monophasic waveform should be 200 J (stored energy), because only 50% of patients are cardioverted with 100 J (114,115 and 116). Approximately 85% of those who electrically cardiovert do so at 200 J (114,115 and 116). The monophasic shock should be 360 J, because almost all patients who cardiovert electrically via the external technique do so at the maximal setting (114,115 and 116). If the first 360-J shock is not successful, one should assess electrode position. If the electrode positions are to be unchanged, one should wait a full 3 minutes before delivering a final 360-J shock. This wait allows a greater decrease in transthoracic impedance from the previous DC shock than occurs with shocks delivered at 15-second or 1-minute intervals (36,63). In addition, a number of patients do not revert to sinus rhythm immediately after the shock but do so a few seconds or minutes later. This phenomenon is thought to represent depolarization of a major portion, but not all, of the atrium. The remaining rhythm does not have a large enough area for continued reentry and dies out. This “delayed” cardioversion is thought to occur in approximately 4% of electrical cardioversions.

Shock strength of biphasic waveform defibrillation is less, but the ideal shock strength for biphasic waveform cardioversion is yet to be determined.

Atrial Flutter

Multiple modalities have been used for cardioversion of atrial flutter, including antiarrhythmic drugs, atrial pacing, DC cardioversion, and catheter ablation. Although atrial flutter is usually associated with organic heart or lung disease, nearly one-third of patients have no apparent etiology. Atrial flutter with a persistently rapid ventricular response may result in the myopathy of tachycardia. These patients present with atrial flutter with a rapid ventricular response and poor ventricular function and thus are often classified as having flutter secondary to heart disease rather than having heart disease secondary to flutter (myopathy of tachycardia). This group of patients may have a marked improvement in their ventricular function after catheter ablation of their chronic atrial flutter. This same sequence of events occurs in patients with any persistent supraventricular arrhythmia, including atrial fibrillation.



Atrial flutter. Atrial rate of 300 beats/min with upright P waves inferiorly. This is consistent with atypical atrial flutter.

Atrial flutter. Inverted "saw-tooth" waves in the inferior leads suggest typical atrial flutter.

When considering cardioversion of atrial flutter, two issues are potentially different from those of atrial fibrillation. The first is the question of anticoagulation, and the second is shock strength.

Until recently, most authors and most studies recommended cardioversion of atrial flutter without anticoagulation (125). Because the incidence of systemic emboli following cardioversion of atrial flutter is small, thousands of patients would have to be studied to be sure of this approach. One is influenced by the literature, but also by one's own experience. The only fatal emboli that the author has seen after electrical cardioversion has been in a patient with hypertrophic cardiomyopathy and atrial flutter. Because of this experience, some 20 years ago, I have routinely anticoagulated patients with either atrial fibrillation or flutter of 48 or more hours in duration before elective cardioversion. Support for this approach has been published. Irani and associates (142) found atrial thrombus or spontaneous echocardiographic contrast, or both, in 34% of patients with atrial flutter. Pagadala et al. (143) studied 85 patients referred for cardioversion of chronic atrial flutter. Embolism occurred in 1 of 39 nonanticoagulated patients compared with none of 46 anticoagulated patients.

Atrial flutter can occasionally be cardioverted with very-low-energy, for example, 15- to 35-J, shocks. However, low-energy monophasic shocks often change the rhythm from flutter to atrial fibrillation, requiring a higher-energy shock. Accordingly, it is recommended that the first monophasic shock be at least 50 J (approximately 38 J delivered) for elective cardioversion of atrial flutter (118). Lower-energy shocks might be effective if biphasic shocks are delivered.

CONTROVERSIES AND PERSONAL PERSPECTIVES

It is well recognized that two of the more important determinants of survival from unexpected cardiac arrest are the speed with which basic life support is started and the interval between the onset of VF and defibrillation. Therefore, the improvement and implementation of "public access defibrillation" is critical to the success of out-of-hospital defibrillation. However, a major problem with the present AEDs is the fact that the patient cannot receive CPR while the AED is analyzing his or her rhythm. Even though the initial shock is delivered within 30 seconds, it takes 90 seconds to deliver the first three-shock cycle. This 90 seconds without CPR after a long arrest markedly increases mortality, and this delay is unacceptable.

A detailed discussion of bystander-initiated CPR is outside the context of this chapter. Nevertheless, it needs to be emphasized that presently only approximately 20% of out-of-hospital cardiac arrests are afforded bystander CPR, mainly because of the fear of infection from, or an aversion to, mouth-to-mouth resuscitation (144,145). Our experimental studies have clearly demonstrated that chest-compression-only CPR is much better than doing nothing or performing no bystander CPR (146). In the author's opinion, the other significant advance in out-of-hospital cardiac arrest, a new protocol recommending that the lay public call 911 and initiate uninterrupted chest compression CPR without pausing for assisted ventilation, is critical. Calling 911 and waiting for the emergency medical technicians or paramedics to arrive result in extremely low survival rates.

In the author's opinion, the transthoracic impedance of the majority of disposable defibrillation electrodes is too high. Therefore, one area in which my personal recommendations differ from currently accepted practice is the recommendation to use metal electrodes with Redux Paste for elective cardioversion as well as defibrillation. For elective cardioversion one needs to order special metal antero-posterior paddle electrodes so that the current passes through the atrium. After cardioversion of patients with atrial fibrillation, the author recommends anticoagulation for 3 to 6 months rather than 4 weeks because of the high incidence of asymptomatic recurrence.

Finally, this author recommends anticoagulation before cardioversion of atrial flutter as well as atrial fibrillation. The incidence of emboli with or following cardioversion of atrial flutter is rare, but it occurs.

THE FUTURE

More defibrillators will be designed to deliver biphasic or triphasic waveform shocks. AEDs will be developed that can analyze and detect VF while chest compression is in progress. Defibrillators will become lighter weight. Mass production should result in more economical defibrillators and disposable one-use AEDs. They will be used by a wide variety of individuals, including the lay public. The problem of litigation risk is being addressed by appropriate legislation.

OVERVIEW

Disturbances of autonomic nervous system function are thought to contribute significantly to risk of ventricular arrhythmias and sudden death in patients with coronary heart disease and other cardiac diseases.

Excessive activity of the sympathetic nervous system promotes malignant ventricular arrhythmias.

The parasympathetic nervous system antagonizes sympathetically mediated malignant ventricular arrhythmias and therefore is considered to have a major protective effect against sudden death.

The autonomic nervous system can be assessed in humans by measuring RR variability, baroreflex sensitivity (BRS), or heart-rate changes during and immediately after exercise.

High-frequency (HF) cyclic fluctuations of RR intervals reflect vagal modulation of RR intervals linked to breathing.

Low-frequency (LF) cyclic fluctuations of RR intervals reflect modulation of RR intervals by baroreflexes and other cardiovascular control mechanisms.

The physiologic mechanisms responsible for ultra-low-frequency fluctuations in RR intervals are not established, but the renin-angiotensin system may be partly responsible.

Low BRS indicates inadequate vagal response to fluctuations in arterial blood pressure and results in sympathetic dominance.

Low values of RR-interval variability or BRS predict cardiac death and sustained ventricular arrhythmias.

LF or ultra-low-frequency fluctuations are the best measures of RR variability for predicting cardiac death or arrhythmic events.

RR-interval variability or BRS has a strong and independent relationship with cardiac death, sudden cardiac death, and sustained ventricular arrhythmias in coronary heart disease.

RR variability and BRS can be combined with other risk predictors [e.g., left ventricular ejection fraction (LVEF) or ventricular arrhythmias] to improve predictive accuracy for cardiac death or arrhythmic events.

Beta-blockers may improve autonomic balance; it is conceivable that in this way they improve survival in patients with coronary heart disease and chronic heart failure.

Abnormalities of autonomic nervous system function can be easily detected by measuring heart rates during and after exercise. A failure of heart rate to rise appropriately during exercise ("chronotropic incompetence") as well as a failure of heart rate to fall quickly after exercise ("impaired heart-rate recovery") are powerful, independent, and easily measured predictors of all-cause mortality.

GLOSSARY

Autoregression: A parametric statistical algorithm for resolving a complex signal into its component frequencies.

Baroreflex sensitivity: The magnitude of increase in RR intervals when systolic blood pressure increases.

Chronotropic incompetence: A failure of heart rate to rise appropriately during exercise. Chronotropic incompetence is predictive of increased mortality.

Chronotropic index: A marker of chronotropic response to exercise calculated as [(exercise heart rate) – (resting heart rate)]/[(220 – age) – (resting heart rate)]. It can also be considered as the proportion of heart-rate reserve used at peak exercise. A chronotropic index less than 0.8 at peak exercise is abnormal.

E:I ratio: Ratio of maximum RR interval during expiration to the minimum RR interval during inspiration.

Fourier transform: A nonparametric mathematical algorithm for resolving a complex signal into its component frequencies.

Heart-rate recovery (HRR): The parasympathetically mediated return toward baseline of heart rate immediately after exercise. An abnormal 1-minute HRR is less than 12. An abnormal HRR is a powerful predictor of all-cause mortality.

Heart-rate variability (HRV): Periodic fluctuations of heart rate. See *RR-interval variability*.

NN interval: Difference between adjacent normal QRS complexes.

Power spectrum: Plot of power (energy) versus frequency of a complex signal composed of oscillations at multiple frequencies.

RR interval: Difference between adjacent QRS complexes.

RR-interval variability: The periodic fluctuations of RR intervals. Information about the general health of the heart, the prognosis, and the propensity toward malignant ventricular arrhythmias may be determined from analysis of these fluctuations.

INTRODUCTION

A large body of clinical and experimental evidence indicates an important role for the autonomic nervous system in the triggering or sustaining of malignant ventricular arrhythmias. Experimentally, sympathetic stimulation reduces ventricular refractoriness and fibrillation threshold and promotes arrhythmias; it also promotes afterdepolarizations and triggered activity. Vagal stimulation opposes these effects, prolonging ventricular refractoriness and reducing the effects of adrenergic stimulation. The antiarrhythmic effects of vagal activity are much more pronounced when adrenergic activity is increased. Normally, afferent nerve impulses from the arterial baroreceptors to the brain cause inhibition of the sympathetic outflow, while increasing efferent parasympathetic activity. Lowered BRS can lead to increased sympathetic drive with decreased vagal activity, a situation promoting ventricular arrhythmias, particularly during myocardial ischemia.

There are several noninvasive or minimally invasive ways to evaluate the autonomic nervous system in intact humans. This chapter discusses three of these approaches: RR-interval variability from continuous electrocardiographic (ECG) recordings, BRS, and heart-rate changes during and immediately after exercise. RR variability measurements provide a low-cost, widely available method for assessing the status of the parasympathetic nervous system in humans and for predicting cardiovascular events, especially cardiac death and sustained ventricular arrhythmias in coronary heart disease patients. BRS also is useful for predicting cardiac death and sustained ventricular arrhythmias after myocardial infarction and adds prognostic information to RR variability.

Chronotropic incompetence during exercise and HRR immediately after exercise are important and easily obtained autonomic markers. Chronotropic incompetence may reflect excess resting sympathetic activity, and HRR reflects parasympathetic reactivation after exercise. Both have been shown to be predictive of cardiac and all-cause mortality. This chapter focuses on the mechanistic association between changes in autonomic function and sustained ventricular arrhythmias or death, and on the clinical use of the RR variability, BRS, and exercise heart-rate responses.

HISTORICAL PERSPECTIVE

In the mid-nineteenth century, Carl Ludwig recognized that the vagus nerve mediated sinus arrhythmia and that vagotomy or atropine treatment would abolish sinus arrhythmia (1). In the 1930s, Anrep determined that a direct interaction of respiratory and cardiovascular medullary centers and reflex mechanisms contributes to respiratory sinus arrhythmia (2,3). In 1970, Katona et al. (4) published direct recordings of vagus nerve activity showing that, during normal ventilation in dogs, respiratory sinus arrhythmia is due to a marked decrease of efferent vagal nerve activity during inspiration, an effect that is evident over a wide range of vagal tone. In a series of ingenious experiments on dogs, Katona and Jih (5) demonstrated that the degree of sinus arrhythmia can be used as a noninvasive, quantitative measure of parasympathetically mediated heart-rate control. They showed that the difference in the maximum and minimum RR intervals in a respiratory cycle was proportional to the average vagal activity in the cycle. When the vagus nerves were temporarily cooled, the average RR interval decreased and respiratory sinus arrhythmia was abolished; both average RR interval and sinus arrhythmia returned to control values when the vagus nerves were rewarmed. They called the change in average RR interval during cooling of the vagus nerves *parasympathetic control*. A similar result was obtained when arterial blood pressure was increased or decreased to alter vagal tone. The relationship between vagal activity and variation in RR intervals was not altered by cardiac beta-adrenergic blockade, but was abolished by atropine treatment. In 1984, Fouad et al. adapted the methods of Katona and Jih to measure parasympathetic cardiac control in humans (6).

In 1981, Hirsch and Bishop (7) reported that, in healthy human subjects, sinus arrhythmia decreased with increasing frequency of breathing and increased with increasing tidal volume. The effect of breathing frequency on respiratory sinus arrhythmia was large. At breathing frequencies of seven breaths per minute or less, respiratory sinus arrhythmia was large and constant. As breathing frequency increased above seven breaths per minute, the amplitude of respiratory sinus arrhythmia showed a steep log-linear decrease (7). In contrast to the frequency of breathing, tidal volume had a small effect; a 50% increase in tidal volume caused only a 15% increase in respiratory sinus arrhythmia (8).

Since the late 1970s, the ratio of maximum RR interval during expiration to the minimum RR interval during inspiration (E:I ratio) has been used to evaluate the autonomic nervous system in patients with diabetes mellitus (9). Smith (10) computed the E:I ratio in 174 healthy subjects aged 16 to 89 years and found no significant relation between E:I ratio and resting heart rate, but a substantial decrease in the ratio with age. Therefore, Smith recommended that age-adjusted normal values should be used to interpret the E:I ratio (10). He used the confidence intervals of the regression of E:I ratio on age to detect parasympathetic dysfunction in diabetics. The difference between maximum and minimum RR interval during a single breath or during a period of controlled deep breathing has been used extensively in humans to evaluate parasympathetic nervous system function, especially as part of a battery of autonomic function tests in patients with diabetes mellitus (11,12). The E:I ratio has not been used extensively to evaluate risk or parasympathetic nervous system function in cardiovascular diseases.

It was not until the 1980s that variability of RR intervals was evaluated with power spectral methods. Cohen's group at the Massachusetts Institute of Technology and Malliani's group in Milan performed landmark studies to define the effects of autonomic maneuvers on HRV in dogs and healthy human subjects (13,14 and 15). These workers demonstrated that noninvasive measurement of heart-rate or RR-interval variability could quantify autonomic nervous system activity in intact animals or human subjects. This methodologic advance not only made autonomic assessment easier and more precise, but also more available and less expensive. Once these tools were available, clinicians were eager to apply them in cardiovascular medicine.

The first substantial finding indicating prognostic significance for RR variability in coronary heart disease was the 1978 report by Wolf et al. in Australia (16). The definitive report in 1987 by Kleiger et al. that RR-interval variability predicted mortality after myocardial infarction catapulted RR variability into cardiovascular medicine (17). In the years since that report, there have been more than 1,000 papers on the clinical use of RR variability.

Interest in the use of heart-rate response to exercise as a prognostic marker began in the 1970s. Hinkle et al. followed 301 men for 7 years after exercise testing and noted that those men who failed to reach an expected heart rate uring exercise had an increased number of cardiac events (18). They termed the syndrome *sustained relative bradycardia*. Ellestad became interested in this area after exercise testing a 51-year-old man who had a good exercise tolerance and no ST-segment depression or pain but with maximum heart-rate response of only 110. Shortly after testing, the patient died suddenly, and an autopsy revealed significant coronary artery disease with 80% narrowing in both the anterior descending and circumflex arteries (19). Ellestad went on to examine 2,700 patients and found that a slow heart-rate response to exercise predicted an increased risk of cardiac events (20). He coined the term *chronotropic incompetence* to describe reduced heart-rate response to exercise.

In the 1980s, interest in chronotropic incompetence moved away from its prognostic properties and rather toward its adverse effect on the sensitivity of stress imaging studies (21). This led to tests showing chronotropic incompetence being labeled as *nondiagnostic*, suggesting that there was something wrong with the test, but not the patient. Beginning in the mid-1990s, however, chronotropic incompetence was rediscovered as a powerful and independent predictor of outcome in its own right (22,23,24 and 25).

HRR after exercise has been used as a marker of physical fitness since the 1940s (26,27 and 28). Several different ways of quantifying HRR have been explored. One simple method is to measure the time it takes for the heart rate to return to baseline after exercise (28). Johnson et al. were the first to notice a first-order exponential decay pattern to HRR and to calculate the time constant (T) for this equation (27). This measure was impractical due to the cumbersome calculations required until Cardus and Spencer used newly emerging computer technology to determine T (29). They demonstrated a correlation between $T_{0.63}$ and an individual's age and physical condition (29). More recently, T has been used in the correlation of HRR with parasympathetic reactivation after exercise (30,31).

The concept of HRR as a marker of physical fitness was incorporated into the Harvard Step Test (32) and later the YMCA Step Test (33). These tests prescribe physical exertion for a specified period followed by a recovery period during which the decrease in heart rate is measured. The decrease in heart rate is then compared with tables of standards (33), which provide a reference for the physical fitness of an individual. Step tests are still used today, particularly in measuring the fitness of children (34). Only relatively recently has HRR been described as a prognostic marker (35).

PHYSIOLOGIC AND PATHOPHYSIOLOGIC EFFECTS OF THE AUTONOMIC NERVOUS SYSTEM ON THE HEART

Autonomic Modulation of Heart Rate

The autonomic nervous system is the primary system for regulating heart rate in healthy persons. The intrinsic sinus node rate at rest (the rate after pharmacologic or surgical denervation of the sinus node) is 95 to 110 per minute (36). In healthy persons at rest, substantial efferent traffic on the vagus nerves suppresses the sinus node rate to 60 to 70 per minute. At rest, there is little efferent traffic on sympathetic nerves, and the concentration of circulating catecholamines is low (37). In healthy persons under resting conditions, the RR intervals fluctuate substantially to produce the familiar sinus arrhythmia. Sinus arrhythmia is caused by rhythmic fluctuations in the rate of firing on vagus nerves as modulated by the rate and depth of breathing (5,7,8). When mental or physical activity perturbs the resting state, the number of factors that modulate RR intervals increases. In particular, the average frequency of impulses on the vagus nerves decreases with mental stress (38,39,40 and 41) or physical activity (42,43,44 and 45). And, as effort increases, the sympathetic nervous system comes into play more and more intensively (37,42). During the phase immediately after cessation of exertion, HRR is almost completely driven by parasympathetic reactivation (31,45,46,47 and 48). As recovery progresses, the withdrawal of sympathetic activity plays more of a role (31).

Sympathetic Nervous System and Cardiac Arrhythmias

There is a vast literature that documents an important role for the sympathetic nervous system in the genesis of cardiac arrhythmias (49,50,51,52,53 and 54). Some of the proarrhythmic effects of increased cardiac sympathetic nervous activity can be attributed to adverse effects of tachycardia and some to heterogeneity of ventricular repolarization during intense sympathetic nervous activity. Stimulation of the hypothalamus and other areas that increase sympathetic nervous system activity cause cardiac arrhythmias, including ventricular fibrillation (VF) in healthy animals (55). Also, interruption of central pathways that inhibit sympathetic nervous system activity causes cardiac arrhythmias (56,57). Experimental situations that evoke anger or fear also can evoke cardiac arrhythmias in intact animals (58). In all of these settings, cardiac arrhythmias can be prevented by pretreatment with beta-adrenergic blockade. When the myocardium is “sensitized” to cardiac arrhythmias by acute myocardial ischemia or drug toxicity (e.g., digitalis toxicity, cocaine, or certain anesthetics), the probability of VF during increased sympathetic nervous system activity is increased substantially.

The interaction between myocardial ischemia or infarction and sympathetic nervous system activity is complex. Myocardial ischemia, especially of the anterior wall, increases the activity on afferent cardiac sympathetic nerves (59,60). The increased afferent nerve activity triggers reflexes that increase efferent cardiac sympathetic nerve activity and that decrease efferent activity on the vagus nerves (59). High extracellular K^+ concentration in the ischemic region can cause release of norepinephrine from epicardial sympathetic nerves (61). Not only is the regional concentration of norepinephrine heterogeneous, but also the response of normal and ischemic myocardial cells to norepinephrine is heterogeneous. Regional heterogeneity of depolarization and repolarization caused by acute ischemia increases the likelihood of reentrant electrical activity in the ventricles, especially VF. Damage to the epicardial sympathetic nerve by myocardial infarction can cause regional sympathetic denervation of the myocardium apical to the infarct (62). Sympathetic nerve traffic to and from denervated areas can be interrupted. Ordinarily, stimulation of cardiac sympathetic nerves causes a decrease in the effective refractory period of the ventricular myocardium, and vagal stimulation causes an increase in the ventricular effective refractory period. After experimental anterior infarction, stimulation of cardiac sympathetic or vagus nerves fails to produce these changes in the effective refractory period at epicardial sites apical to the infarct (62). The regional heterogeneity of repolarization caused by regional sympathetic denervation promotes reentrant ventricular arrhythmias for days to weeks after myocardial infarction. Preliminary studies in humans show that the extent of regional damage to cardiac sympathetic nerves 2 to 4 weeks after myocardial infarction quantified by radiolabeled meta-iodobenzylguanidine was related to the magnitude of reduction of two time domain measures of RR variability, standard deviation of normal to normal (NN) intervals over a 24-hour period (SDNN), and square root of the mean squared successive differences of NN intervals (r-MSSD) (63). Denervation of the myocardium as a consequence of infarction may be arrhythmogenic in several different ways: Areas of myocardium may become supersensitive to catecholamines, and the destruction of afferent neural fibers and receptors may result in impairment or loss of protective cardiac reflexes that promote electrical stability. Lowered BRS causes increased sympathetic drive and decreased vagal activity, promoting ventricular arrhythmias, particularly in the setting of myocardial ischemia.

Sympathetic nerves in the epicardium of the ventricle carry afferent signals to the brain when they are activated by mechanical or chemical stimuli (59,60). Epicardial application of bradykinin is used experimentally to evaluate the functional integrity of sympathetic nerves in the cardiac ventricles. Application of bradykinin to the epicardium of a dog activates afferent sympathetic nerve activity, causing a reflex increase in arterial blood pressure (64,65). Regional denervation using epicardial application of phenol blocks afferent impulses on cardiac sympathetic nerves and prevents the increase in arterial pressure. Epicardial application of bradykinin in dogs with experimental myocardial infarction has demonstrated regional epicardial denervation (65).

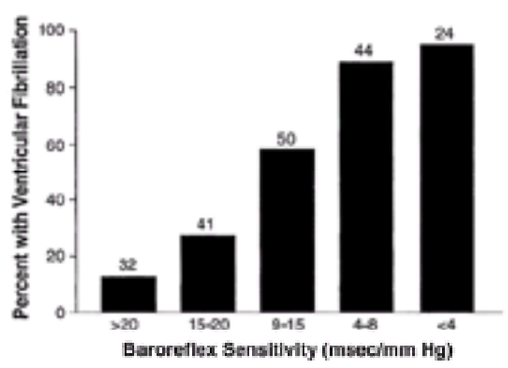
Antiarrhythmic Effects of the Parasympathetic Nervous System

The parasympathetic nervous system has pronounced antiarrhythmic properties by reducing heart rate and by counteracting the proarrhythmic effects of sympathetic nervous system activity (66). The antiarrhythmic benefit of increased parasympathetic activity is especially evident when the sympathetic nervous system plays a role in the arrhythmic activity. There are three clinical methods for quantifying parasympathetic nervous system modulation of cardiac activity: BRS, RR variability, and HRR. A number of experimental studies have attempted to define the value of these markers for assessing parasympathetic activity and for evaluating the risk of VF.

Baroreflex Sensitivity Predicts Ischemic Ventricular Fibrillation

The predictive value of BRS for ischemic VF was suggested by a series of elegant studies in an experimental model of sudden cardiac death (67,68,69 and 70). Thirty days after left anterior descending coronary artery ligation, conscious dogs with healed anterior myocardial infarctions were subjected to transient circumflex coronary artery occlusions while running on a treadmill to increase heart rate and sympathetic nervous system activity. Of 192 dogs subjected to transient ischemia during exercise, 55% developed VF during exercise and ischemia and 45% did not (69). Dogs susceptible to VF showed a substantial increase in heart rate during ischemia before the onset of VF, whereas dogs resistant to VF showed a decrease in heart rate.

In this model of sudden cardiac death, ischemic VF can be predicted with considerable accuracy by measuring BRS (69). Dogs with a lower BRS had a much higher chance of VF during the exercise ischemia challenge (eFig. 77.0.1). Unexpectedly, dogs susceptible to VF during exercise ischemia after experimental myocardial infarction already had a lower BRS before coronary artery ligation. There were large differences in BRS among healthy dogs, and those with the lowest values of BRS before myocardial infarction were most susceptible to VF after myocardial infarction when challenged with myocardial ischemia and sympathetic activation (69). This finding suggests that individuals at high risk of arrhythmic events after myocardial infarction can be identified and treated before infarction occurs. In dogs, 6 weeks of daily exercise training substantially increased BRS and markedly reduced the likelihood of VF during exercise ischemia (68). Exercise also might benefit coronary heart disease patients at high risk of VF.



***e*FIGURE 77.0.1** The probability of developing ventricular fibrillation during exercise and ischemia in dogs with previous myocardial infarction is inversely related to baroreflex sensitivity. The *x*-axis gives the categories for baroreflex sensitivity; the *y*-axis is the percent of dogs that develop ventricular fibrillation during exercise and ischemia. The numbers over the bars indicate the number of dogs in each group. (Adapted from Schwartz PJ, Vanoli E, Stramba-Badiale M, et al. Autonomic mechanisms and sudden death: new insights from the analysis of baroreceptor reflexes in conscious dogs with and without a myocardial infarction. *Circulation* 1988;78:969–973. This figure was first published as Figure 19.1 in Bigger JT Jr, Rottman JN. Spectral analysis of RR variability. In: Podrid PJ, Kowey PR, eds. *Cardiac arrhythmia. Mechanisms, diagnosis, and management*. Baltimore: Williams & Wilkins, 1995:280–298, with permission.)

Vagal stimulation prevented susceptible dogs from developing VF during the exercise ischemia test (71). Part of the vagal protection was due to the decrease in heart rate and part to other factors.

RR-Interval Variability Predicts Ischemic Ventricular Fibrillation

RR variability has been studied in the same dog model of sudden cardiac death that showed the value of BRS as a predictor of arrhythmic events. The study was done on dogs to test the hypothesis that low values of RR variability would predict which dogs would develop VF when challenged by exercise ischemia 1 month after myocardial infarction (72).

Immediately after infarction, RR variability decreased substantially in all dogs, but the time course of recovery of RR variability was different for dogs that were resistant and those that were susceptible to VF. In resistant dogs, RR variability recovered to pre–myocardial infarction levels within 10 days, whereas susceptible dogs had persistent attenuation of RR variability throughout the 30 days after myocardial infarction (73). Decreased RR variability 30 days after myocardial infarction had 88% sensitivity and 80% specificity for predicting VF. No sham-operated animals developed VF (72).

Chronotropic Incompetence May Reflect Baseline Sympathetic Overload

The heart-rate response to exercise can yield important prognostic information for the clinician. In the healthy individual, heart rate increases during exercise to an age-related maximum heart rate. There is a wide individual variation in peak heart rates obtained, but the maximum heart rate declines uniformly with advancing age. Age-predicted peak heart rate is commonly estimated using the formula 220 minus age. A commonly used definition of chronotropic incompetence is failure to reach 85% of the age-predicted peak heart rate, but other investigators have suggested the use of the chronotropic index as a better marker of chronotropic incompetence (22,23).

A major limitation of using a percentage of age-predicted maximum heart rate as a marker of chronotropic response is that the estimated peak heart rate has a high standard deviation and therefore may be difficult to apply to individuals, as opposed to populations (74). There are other problems with using ability to reach 85% of the age-predicted maximum heart rate as a measure of chronotropic incompetence. In addition to age, other important predictors of the heart-rate response to exercise are resting heart rate and physical fitness, both factors that themselves are predictive of coronary heart disease risk (74,75,76,77 and 78). Data from the Framingham Heart Study have shown that ability to reach a target heart rate is influenced by these two variables and even by age itself (22). Therefore, any effort to relate chronotropic incompetence of prognosis or diagnosis suffers an inherent risk of serious confounding.

Wilkoff and Miller have described a method for describing the exercise heart-rate response that takes advantage of the linear relation between exercise heart-rate increase and metabolic work (79). Before exercise, a person has a certain metabolic reserve, which is the difference between the peak oxygen consumption (or exercise capacity) and the rest oxygen consumption, which is typically 3.5 mL per kg per minute, or 1 metabolic equivalent (MET). As exercise progresses, that metabolic reserve is used up. Analogously, at rest there is a potential heart-rate reserve, which is the difference between the peak attainable heart rate (as estimated, for example, by 220 minus age) and the resting heart rate. As exercise progresses, heart-rate reserve, like the metabolic reserve, is used up as well. Wilkoff and Miller described a metabolic chronotropic relation, which we have termed the *chronotropic response index*, which is based on the long-known linear association between use of heart-rate reserve and metabolic reserve during exercise.

The mathematical derivation of the chronotropic response index is as follows: During any given stage of exercise, the percent metabolic reserve (MR) used can be expressed as

$$\%\text{MR used} = [(\text{METs}_{stage} - \text{METs}_{rest})/(\text{METs}_{peak} - \text{METs}_{rest})] \times 100$$

Similarly the percent HR reserve used at any given stage of exercise can be expressed as

$$\%\text{HR reserve used} = [(\text{HR}_{stage} - \text{HR}_{rest})/(220 - \text{age} - \text{HR}_{rest})] \times 100$$

Wilkoff and Miller have shown that among healthy adults the ratio of heart-rate reserve used to metabolic reserve used at any stage of exercise has a value of one with a 95% confidence interval of 0.8 to 1.3 (79). This ratio is the chronotropic response index (22,23) and is independent of stage of exercise considered. Thus, chronotropic incompetence can be defined as a percent heart-rate reserve used to percent metabolic reserve used ratio of less than 0.8; this is referred to as a *low chronotropic index*. The advantage of using this approach to assess chronotropic response is that it accounts for age, functional capacity, and resting heart rate; it is in fact a measure largely independent of functional capacity (22).

One problem with this method is that during routine exercise testing exercise capacity in METs is only estimated. Nonetheless, among patients who undergo symptom-limited testing, one can consider the ratio of heart-rate reserve used to metabolic reserve used at peak exercise, when by definition the proportion of metabolic reserve used has a value of one. Using this approach, the chronotropic index is based entirely on directly measured variables, namely, resting heart rate, peak heart rate, and age (80).

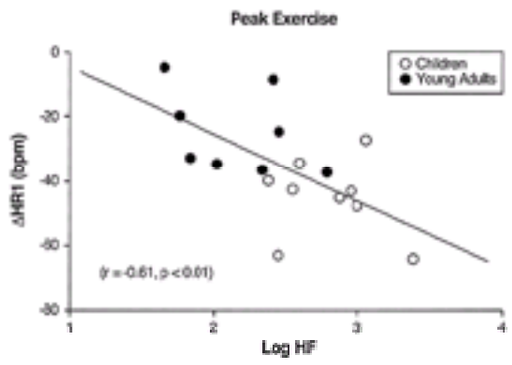
The chronotropic response to exercise has been demonstrated to be an important predictor of mortality (19,20,22,24,25,81,82). The mechanisms to explain this finding are not entirely clear, but it may be that a blunted chronotropic response is indicative of a baseline sympathetic overload (83). There is evidence to suggest that individuals with a blunted chronotropic response to exercise have a postsynaptic desensitization to beta-adrenergic receptor stimulation (83). Colucci et al. demonstrated that heart failure patients with blunted chronotropic responses had similar increments of change of norepinephrine levels from resting to peak exercise but much higher baseline levels when compared with healthy controls (83). When isoproterenol was infused the heart rate increased less in heart failure patients than in healthy controls. These data suggest that although individuals with chronotropic incompetence have an increase in sympathetic activity to maximum levels, they are unable to attain higher heart rates due to an increased baseline sympathetic level along with a decreased sensitivity to further sympathetic stimulation, leading to a blunting of the heart-rate response. This situation is analogous to an automobile that is “out of tune.” Gasoline use during idling is increased, but the car is unable to increase speed by much in response to increased gasoline delivery.

Heart-Rate Recovery Reflects Parasympathetic Reactivation

The increase in heart rate during exercise is due to the combination of parasympathetic withdrawal and sympathetic activation, whereas the recovery of heart rate back toward baseline is due to the reverse (30,42,45,46,48,74,84,85 and 86). What is less well understood is the relative contributions and timing of parasympathetic and sympathetic activity during recovery. To address this question, Imai et al. (31) measured HRR in three groups of individuals: healthy controls, trained athletes, and heart failure patients. They studied postexercise HRR under two different conditions: after parasympathetic blockade with atropine and after sympathetic blockade with propranolol. Across all groups, the decrease in heart rate during the first 30 seconds of recovery was markedly prolonged following atropine administration but not with beta-blockade. This effect was less pronounced at 2 minutes. Crouse et al. (47), Maciel et al. (46), and Perini et al. (48) obtained similar results. These findings suggest that HRR during the first minute of recovery is due almost exclusively to parasympathetic activity.

Two additional observations provide evidence that early HRR is a marker of parasympathetic activity. First, Imai et al. (31) demonstrated that HRR was accentuated in athletes, but blunted in patients with heart failure. Other investigators have also noted an increased HRR in trained individuals (87) and a decreased HRR in poorly fit persons (88). The link between these findings and the autonomic nervous system may be established by nearly identical changes in RR variability. There are data that show RR variability is decreased in poorly fit individuals and those with heart failure (89) and may be increased through exercise training (90). Arai et al. (45) found an increase in the HF power, which reflects parasympathetic activity, during early recovery that was more pronounced in individuals with higher fitness levels. Based on these studies, it may be hypothesized that parasympathetic activity is the link between fitness level and HRR.

A second observation is that HRR is known to be faster in children than in adults (87,91). A study by Ohuchi et al. (92) may shed light on this finding. They measured both HRR and RR variability in children and adults after exercise. The children had significantly higher log HF power than adults during recovery, corresponding to increased parasympathetic activity. There was a strong correlation between HRR and log HF power (eFig. 77.0.2), thus linking the two together and providing additional evidence that HRR in early recovery is primarily a function of the parasympathetic nervous system.



***e*FIGURE 77.0.2** Relationship between log high-frequency heart-rate variability (log HF) and decrease in heart rate 1 minute after peak exercise (DHR1). (From Ohuchi H, Suzuki H, Yasuda K, et al. Heart rate recovery after exercise and cardiac autonomic nervous activity in children. *Pediatr Res* 2000;47:329–335, with permission.)

MEASUREMENT OF RR-INTERVAL VARIABILITY AND BAROREFLEX SENSITIVITY

Measurement of RR Variability

Variation in RR intervals can be measured by many methods; these methods can be categorized as time domain measures or frequency domain measures (93). Table 77.1 lists the commonly used measures of RR-interval variability. Every frequency domain measure of RR variability has an equivalent time domain measure (*e*Table 77.1.1). The physiologic correlates of RR variability are discussed later (see Frequency Domain Measures of RR Variability).

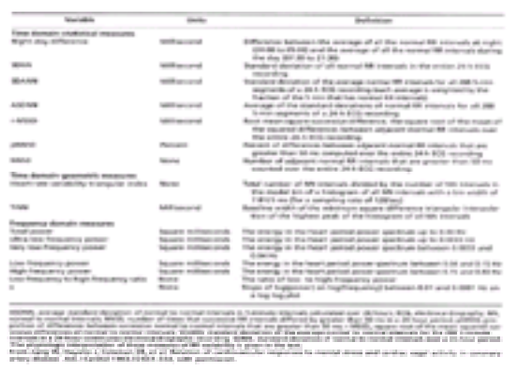


TABLE 77.1 DEFINITIONS FOR TIME AND FREQUENCY DOMAIN MEASURES OF HEART PERIOD VARIABILITY[a]

***e*TABLE 77.1.1** CORRELATIONS AMONG TIME AND FREQUENCY DOMAIN MEASURES OF RR VARIABILITY IN HEALTHY SUBJECTS (N = 274)

Ln (low frequency to high frequency ratio)	–0.08	–0.09	–0.09	–0.12	–0.12	–0.09	–0.03	–0.13	–0.04	–0.51	–0.46	–0.58	1.00

ASDNN, average standard deviation of normal to normal intervals in 5-minute intervals calculated over 24 hours; Ln, natural logarithm; pNN50, proportion of differences between successive normal to normal intervals that are greater than 50 ms; r-MSSD, square root of the mean squared successive differences of normal to normal intervals; SDANN, standard deviation of the average normal to normal intervals for the 288 5-minute intervals in a 24-hour continuous electrocardiographic recording; SDNN, standard deviation of normal to normal intervals over a 24-hour period.
Note: Numbers in boldface indicate variables with such high correlation that they are interchangeable.
From Bigger JT Jr, Fleiss JL, Steinman RC, et al. RR variability in healthy, middle-age persons compared with patients with chronic coronary heart disease or recent acute myocardial infarction. *Circulation* 1995;91:1936–1943, with permission.

Time Domain Measures of RR Variability

Time domain measures of RR variability can be used to summarize information about either short-term or long-term variation in RR intervals, and a large number of measures have been proposed. These measures attempt to estimate the influence of nervous and humoral influences on the sinus node so they usually exclude RR intervals caused by ectopic (nonsinus) beats. In a continuous ECG recording, each R wave (QRS complex) is detected and labeled as normal (N) or abnormal. The series of NN intervals is used to calculate time domain measures, which may be expressed directly as NN intervals or as instantaneous heart rate.

Statistical Measures

From a series of NN intervals, various statistical measures are calculated (93,94). Most often the NN series is recorded for an entire 24-hour period or for a short period, typically 5 minutes or 1 hour. Some of the commonly used time domain measures are summarized in Table 77.1. A commonly used and useful measure of RR variability is SDNN. This measure summarizes all sources of variation in NN intervals over the period of calculation. The longer the recording for an individual, the greater is the magnitude of SDNN. If the SDNN is calculated on an interval substantially different from 24 hours, this should always be stated clearly because the values cannot be compared with standard 24-hour values. A common time domain measure of long-term (slow) variation in NN intervals is the standard deviation of the average NN intervals for the 2885-minute intervals in a 24-hour continuous ECG recording (SDANN). A common time domain measure of short-term (fast) variation in NN intervals is the average standard deviation of NN intervals in 5-minute intervals calculated over 24 hours (ASDNN). SDANN measures fluctuations in NN intervals with cycles longer than 5 minutes, and ASDNN measures fluctuations with cycles shorter than 5 minutes.

Differences in Adjacent RR Intervals

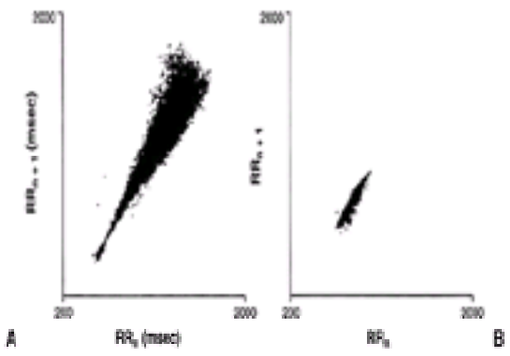
Measures calculated from differences in adjacent NN intervals measure fluctuations with very short cycles (i.e., measured in seconds). The r-MSSD and the proportion of differences between successive NN intervals that are greater than 50 ms (pNN50) are two measures that estimate HF variations in NN intervals caused by modulation of sinus node firing rate by the vagus nerves and, thus, are always highly correlated (*e*Table 77.1.1).

Geometric Methods

Geometric patterns have been used to quantify long-term RR variability (93,95). The 24-hour NN interval time series is plotted as a frequency distribution of NN intervals, and then summary measures are calculated to describe it. HRV triangular index and the triangular interpolation of NN intervals (TINN) are two geometric measures that have been used to describe the frequency histogram of NN intervals over a 24-hour period. These measures are determined by finding the length of the base of a triangle that best fits the frequency histogram (93).

The frequency histogram of NN intervals most commonly is tabulated in bins 7.8125 ms, reflecting the 128 per second sampling rate used by commercial Holter systems. The HRV triangular index is calculated by dividing the total number of NN intervals (the integral of the histogram) by the modal frequency (the number of NN intervals in the bin that contains the most NN intervals). TINN is the width of the base of the frequency histogram of NN intervals obtained by triangular interpolation and has the units of milliseconds. HRV triangular index and TINN are relatively free of errors in labeling of the RR intervals, so their values do not much depend on the quality of the recordings or the analysis.

The Lorenz or Poincaré plot is another geometric display that has been used to evaluate RR variability (95). Each RR interval is plotted as a function of RR-1, which gives a cigar-shaped distribution. The Lorenz plot for a healthy person is long and wide, and the width increases at the longer RR intervals (*e*Fig. 77.0.3A). In severe heart disease, the plot becomes short and narrow (*e*Fig. 77.0.3B). Errors in QRS detection produce characteristic patterns as well. Although certain patterns have been described and correlated with severity of disease, there are no standardized methods for quantifying Lorenz plots.



***e*FIGURE 77.0.3** Lorenz or Poincaré plots. The current RR interval (RR_n) is plotted on the *x*-axis, and the subsequent RR interval (RR_{n+1}) is plotted on the *y*-axis. Panel **A** is a plot from a healthy 52-year-old man that shows a wide range of RR intervals and shows greater dispersion of RR interval at longer RR intervals. Panel **B** is a plot from a 61-year-old man with heart failure that shows a decreased range of RR intervals and does not show greater dispersion of RR interval at longer RR intervals. (Adapted from Woo MA, Stevenson WG, Moser DK, et al. Complex heart rate variability and serum norepinephrine levels in patients with advanced heart failure. *J Am Coll Cardiol* 1994;23:565–569, with permission.)

Frequency Domain Measures of RR Variability

Analytic Methods

Both nonparametric (fast Fourier transforms; FFT) and parametric (autoregression) methods have been used to compute power spectral density of RR-interval time series (13,15,93,96). The nonparametric (FFT) method is simple, fast to compute, and does not require that a model be assumed. The parametric (autoregression) method produces a smoother spectrum and permits automatic estimation of HF and LF power and their center frequencies, but requires that the order of the model be specified (93,96). Unless there are differences in selection of beats for analysis or in signal-processing procedures, FFT and autoregression methods provide similar results.

Five-Minute Power Spectra

The Task Force on Heart Rate Variability of the European Society of Cardiology and the North American Society of Pacing and Electrophysiology recommended that power spectral analysis of 5-minute ECG recordings be used to assess autonomic physiology and pharmacology (93). Frequencies between 0.0033 and 0.40 Hz can be estimated from a 5-minute ECG recording. Figure 77.1A shows a 5-minute power spectrum in a healthy person lying supine. Two “peaks” are present in the 5-minute power spectrum: HF power in the frequency range 0.15 to 0.40 Hz and LF power in the frequency range 0.04 to 0.15 Hz. The power spectral density usually is expressed as absolute units of power (square milliseconds), but may be expressed in normalized units (Fig. 77.2). Normalized units can be used to emphasize the reciprocal action of the parasympathetic and sympathetic limbs of the autonomic nervous system and to minimize the effect of changes in total power on the values of LF and HF components (97). HF power reflects modulation of efferent parasympathetic (vagal) activity by ventilation (respiratory sinus arrhythmia). LF power reflects modulation of efferent parasympathetic (vagal) and efferent sympathetic nervous system activity by baroreflex activity. It should be emphasized that the amplitude of LF or HF power reflects modulation of sinus node firing rate, not the average level of parasympathetic or sympathetic tone (13,98). Note that the amplitude of LF power is greater than HF power in a healthy person resting in the supine position. The LF/HF ratio is used as an index of vagosympathetic balance (15).

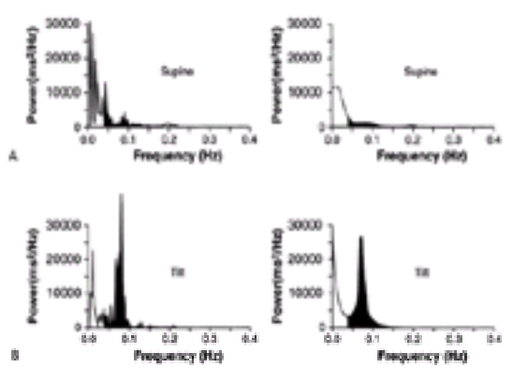


FIGURE 77.1 A,B: Power spectral analysis of RR-interval time series. The left panels show fast Fourier transform (FFT) analysis of two 5-minute recordings of RR intervals. The left panel of **A** shows the FFT of a recording made supine and resting; the left panel of **B** shows the FFT of a recording made during 60-degree head-up tilt. The right panels show the results of autoregression analysis of the same two 5-minute recordings. The autoregressive algorithm smooths the data, but gives almost identical areas under the curves as the FFT algorithm in the frequency bands of interest. In the supine recording, there is a peak at approximately 0.20 Hz in the high-frequency (HF) power band, and a peak at approximately 0.08 Hz in the low-frequency (LF) power band. More than one-half the power is in the very low-frequency power band. Both methods show a decrease in HF power and a marked increase in LF power during head-up tilt. (From Bigger JT Jr. RR variability to evaluate autonomic physiology and pharmacology and to predict cardiovascular outcomes in humans. In: Zipes DP, ed. *Cardiac arrhythmias: from cell to bedside.* Philadelphia: WB Saunders, 1995:1151–1170, with permission.)

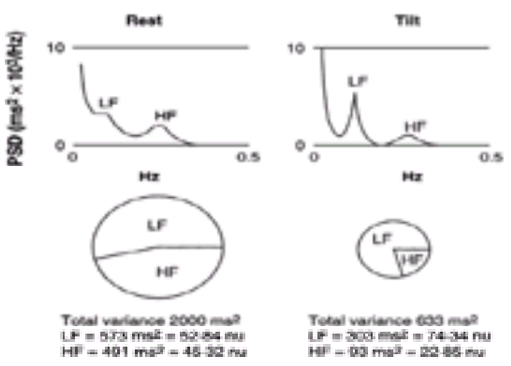

FIGURE 77.2 Use of normalized units to interpret spectral analysis (autoregressive model) of RR-interval variability in a healthy subject. The recording on the left was made while the subject was resting in the supine position; the recording on the right was made during 90-degree head-up tilt. At rest, low-frequency (LF) and high-frequency (HF) power have a similar magnitude, whereas during the head-up tilt, LF power is much greater than HF power. Total variance is markedly reduced

during tilting, so both LF power and HF power are diminished when expressed in absolute units. The use of normalized units (nu) clearly indicates the altered relation between the two spectral components induced by tilting. The pie charts show the absolute power of the two components (represented by the area of the circles) as well as the relative distribution of LF and HF power. The LF/HF ratio also quantifies the relative distribution of LF and HF power. These changes in the normalized units and LF/HF ratio are interpreted as a decrease in parasympathetic modulation and an increase in sympathetic modulation of RR intervals. PSD, power spectral density. (From Malliani A, Lombardi F, Pagani M. Power spectrum analysis of heart rate variability: a tool to explore neural regulatory mechanisms. *Br Heart J* 1994; 71:1–2, with permission.)

The energy between 0.0033 and 0.04 Hz is called *very low-frequency power*; the physiologic correlates of very low-frequency power are not known, but the power in this range can be influenced substantially by physical activity (99).

Dynamic Changes in the Five-Minute RR-Interval Power Spectrum

The RR-interval power spectrum is dynamic as a function of autonomic activity. For example, if breathing is synchronized to a metronome, the HF peak becomes narrow at its base and taller; if the beat of the metronome is changed, the HF peak moves to the new frequency of breathing (100). Figure 77.1B shows the dramatic changes in the NN interval power spectrum during head-up tilt to 60 degrees. HF power decreases, LF power increases, and the LF/HF ratio increases. These changes reflect the baroreflex, which causes a substantial decrease in efferent parasympathetic activity and an increase in efferent sympathetic activity.

Twenty-Four-Hour Power Spectra

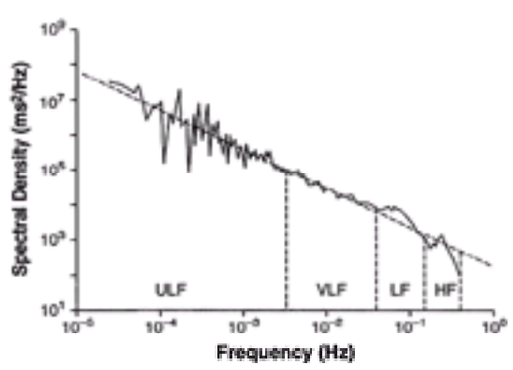
If power spectral density is calculated over a 24-hour interval, then power below 0.0033 Hz (down to approximately 0.00003 Hz) can be calculated (i.e., ultra low-frequency power) (96). Physiologic correlates of ultra low-frequency power are not established, but there is some evidence that it is modulated by activity of the renin-angiotensin system (13). Also, fluctuations of RR intervals at this very low frequency are powerful predictors of death in the years after acute myocardial infarction (101).

Power Law Behavior of RR-Interval Variability

If 24-hour power spectral density is plotted as a function of frequency on a log-log graph, the relationship is linear over a frequency range from 0.00003 to 0.04 Hz, with a slope approximately equal to –1 in healthy young people, indicating that power decreases approximately as the reciprocal of frequency, 1/*f* (102). The relationship between power and frequency is described by a power law:

$$P = Cf^{a},$$

where *P* is the power spectral density, *f* is frequency, a is a negative exponent, and *C* is a proportionality constant (eFig. 77.2.1) (103); a also corresponds to the slope of the log *P* versus log *f* relationship:



***e*FIGURE 77.2.1** The relationship between regression of the log of spectral power for RR-interval fluctuations on log frequency and traditional power spectral bands for a healthy subject. The computed power law regression line is superimposed on the data; the darkened portion of the lines is the segment between 10^{-4} and 10^{-2} Hz that is used to compute the regression line. In the region of the ultra-low-frequency (ULF) and very low-frequency (VLF) bands, the log-log graph of spectral power versus frequency is linear. In the region of the low-frequency (LF) and high-frequency (HF) bands, the log-log graph of spectral power versus frequency is nonlinear due to modulation by the autonomic nervous system. (From Bigger JT Jr, Steinman RC, Rolnitzky LM, et al. Power law behavior of RR-interval variability in healthy middle-aged persons, patients with recent myocardial infarction, and patients with heart transplants. *Circulation* 1996;93:2142–2151, with permission.)

$$\log P = \log C + a \log f.$$

a usually is computed over the two-decade band from 10^{-4} to 10^{-2} Hz and then extrapolated. The slope of log power on log frequency is a fundamentally different RR-interval power spectral measure than the standard power spectral bands (e.g., ultra low frequency, very low frequency, LF, or HF). In contrast to these power spectral bands, the slope reflects not the magnitude but rather the distribution of power in this two-decade region. The average slope is close to –1 for healthy persons. Saul et al. found that a averaged –1.02 ± 0.05 in five healthy young men (102), and Bigger et al. found that a averaged –1.06 ± 0.12 in 274 healthy middle-aged subjects (103). As the heart gets sicker, the slope of log power on log frequency gets steeper, finally approaching a limit of approximately –2 found in totally denervated hearts (e.g., transplanted hearts) (103).

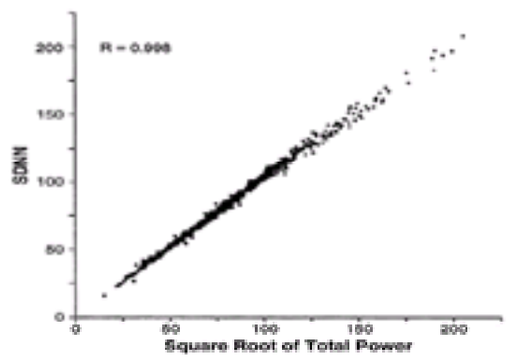
Because power is an inverse function of frequency, variance increases with the length of the ECG recording. Therefore, RR-interval variance, or its square root, SDNN, is meaningful only with respect to a particular duration of ECG recording. One implication of the power law relation between spectral power of RR-interval fluctuations and their frequency is the need to standardize the length of ECG recordings used to calculate SDNN or the need to correct SDNN for differences in the duration of Holter ECG recordings.

Nonlinear Dynamic Measures of RR Variability

RR-interval data have been analyzed using nonlinear dynamic methods, or “chaos theory” (104,105,106 and 107), which assume data are aperiodic, but not random. Nonlinear dynamic measures are less intuitive to interpret, but quantify the RR-interval time series in a different way than linear methods, including conventional power spectral analysis. Most nonlinear dynamic measures can be estimated from ECG recordings digitized at 128 samples per second, but Skinner’s correlation dimension (PD2) (106) is calculated from ECG recordings.

Correlations among the Measures of RR-Interval Variability

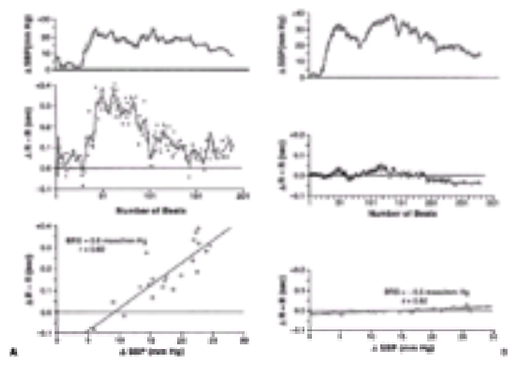
*e*Table 77.1.1 gives the correlations among the measures of RR-interval variability in 274 healthy middle-aged subjects (108). There are three natural clusters of high correlation among 10 of the 12 variables in *e*Table 77.1.1: (a) SDNN, SDANN, total power, and ultra-low-frequency power; (b) very low-frequency power, LF power, and ASDNN; and (c) HF power, r-MSSD, and pNN50. The ratio of the power in the LF band to the power in the HF band does not correlate strongly with any of the other measures of heart period variability, even those that are used to calculate the ratio. Power in each power spectral band correlates so strongly with a time domain variable (correlation coefficients approximately 0.90) that the two variables are essentially equivalent: ultra-low-frequency power with SDNN and SDANN, very low-frequency power and LF power with ASDNN, and HF power with r-MSSD and pNN50. As expected from theoretical considerations, SDNN and the square root of total power for a 24-hour interval are almost perfectly correlated (eFig. 77.2.2) (i.e., the regression line essentially has a slope of 1 and an intercept of 0). Although the absolute values of these measures of RR variability decrease markedly in patients with recent myocardial infarctions and other heart diseases, correlations between frequency and time domain measures of RR variability are preserved (94).



***e*FIGURE 77.2.2** The relationship between the standard deviation of the normal RR intervals (SDNN) and the square root of total power in the 24-hour heart period power spectrum. The unit for both variables is milliseconds. Note that the empirically observed relationship is close to the theoretically expected relationship (i.e., intercept of 0 and slope of 1). Also, the correlation coefficient is very close to 1. (From Bigger JT Jr, Fleiss JL, Steinman RC, et al. Correlations among time and frequency domain measures of heart period variability two weeks after acute myocardial infarction. *Am J Cardiol* 1992;69:891–898, with permission.)

Measurement of Baroreflex Sensitivity

Methodology to investigate the baroreflex control of heart rate was developed at Oxford University in the 1960s by measuring the reflex increase in RR intervals in response to a blood pressure increase produced by intravenous injection of an alpha-adrenergic agonist (109). Phenylephrine, a pure alpha-adrenergic receptor agonist that lacks direct effects on cardiac contractility and on the central nervous system, is most commonly used to measure BRS. Phenylephrine doses of 50 to 150 µg are injected to increase systolic arterial pressure by 20 to 30 mm Hg. In this range of blood pressure increase, a linear relationship is found between the increase in RR intervals and the initial increase in systolic blood pressure after phenylephrine injection (*e*Fig. 77.2.3). The slope of this regression line (expressed as milliseconds of increase in RR interval per 1 mm Hg rise in pressure) quantifies the sensitivity of the arterial baroreflex (eFig. 77.2.3A). Three to five injections are given at 5-minute intervals, and the individual slopes are averaged to estimate the mean slope. Variability among individual measurements can be attributed to (a) rate of the injection, (b) steepness of arterial pressure increase, and (c) selection of the time window for the analysis. The slope of RR-interval change on the increase in systolic blood pressure after phenylephrine injection is steep in healthy persons; the slope becomes less steep with increasing age and almost flat in patients with severe cardiovascular disorders (e.g., hypertension or heart failure) (eFig. 77.2.3B) (110,111). BRS is modulated by several physiologic conditions. BRS decreases whenever the autonomic balance shifts toward a sympathetic dominance and increases whenever the autonomic balance shifts toward a parasympathetic dominance. For example, BRS increases during sleep and rest (109).



***e*FIGURE 77.2.3 A:** The phenylephrine method for measuring baroreflex sensitivity (BRS). The top and middle panels show beat-to-beat changes in systolic blood pressure (SBP) and RR intervals after phenylephrine injection. Pairs of SBP and RR-interval values for regression analysis (*bottom panel*) were selected from the first major increase in blood pressure after the injection. In this patient with recent myocardial infarction, phenylephrine produced a 25-mm Hg increase in systolic blood pressure, which was accompanied by a marked increase in the RR intervals. Accordingly, the slope of the regression line reflecting BRS was steep (19 ms per mm Hg) and represents a normal response. **B:** In this patient with recent myocardial infarction, the RR intervals did not change significantly despite a clear-cut increase in SBP, indicating that BRS is extremely depressed –0.5 ms per mm Hg (*bottom panel*). (From La Rovere MT, Specchia G, Mortara A, et al. Baroreflex sensitivity, clinical correlates and cardiovascular mortality among patients with a first myocardial infarction: a prospective study. *Circulation* 1988;78:816–824, with permission.)

Two principal factors have limited the widespread clinical use of BRS by the phenylephrine method: (a) the need to cannulate an artery for beat-to-beat systolic blood pressure measurement and (b) the need for drug injection. More recently, noninvasive measurement of beat-to-beat systolic blood pressure has become practical using devices such as the FINAPRES (from *fin*ger *a*rterial *pres*sure) device. The accuracy of blood pressure measurement has been documented, in small groups of subjects, during several interventions such as Valsalva's maneuver, sustained handgrip, postural changes, and vasoactive drug administration (112,113) and in a large population of post–myocardial infarction patients as part of the Autonomic Tone and Reflexes after Myocardial Infarction (ATRAMI) study (114). More recently, BRS has been quantified using spectral techniques to analyze the relationship between spontaneous beat-to-beat oscillation of blood pressure and RR intervals to obviate the need for phenylephrine injection (112,115,116). These spectral methods are promising but have not been sufficiently validated for routine clinical use.

USE OF AUTONOMIC MARKERS TO PREDICT DEATH OR ARRHYTHMIC EVENTS

Clinical Use of RR Variability for Assessment of Risk

In the opinion of the Task Force on Heart Rate Variability, there were two proven clinical uses of RR variability: (a) to predict risk of cardiac death or arrhythmic events after acute myocardial infarction, and (b) to detect and quantify autonomic neuropathy in diabetes mellitus (93). In the following sections of this chapter, we review some of the studies that have established RR variability as a predictor of cardiac death after acute myocardial infarction and in chronic coronary heart disease. Both time and frequency domain measures have been used to predict mortality, and nonfatal arrhythmic events in coronary heart disease. The measures most often used for this purpose include SDNN, SDANN, HRV triangular index, total power, ultra-low-frequency power, LF power, and power law regression parameters (Table 77.1).

Prediction of Hospital Mortality after Myocardial Infarction Using the Variance of 30 RR Intervals

In 1978, Wolf et al. published the first report of an association between RR variability and prognosis (16). These workers studied 176 patients admitted to hospital for acute myocardial infarction to evaluate the relationship between RR variability and in-hospital mortality. A 60-second ECG recording was made on the day of admission to the coronary care unit, and the variance of 30 consecutive RR intervals was calculated for each patient. Wolf et al. arbitrarily dichotomized their group using a variance of 1,000 ms^2; 73 patients (42%) had a variance greater than or equal to 1,000 ms^2, and 103 patients (59%) had a variance less than 1,000 ms^2 (eTable 77.1.2). Patients with RR variance less than 1,000 ms^2 were more likely to have anterior myocardial infarction, a Norris index greater than or equal to 10, low values for average RR interval, and admission to hospital longer after onset of chest pain.

***e*TABLE 77.1.2** RR VARIANCE AND HOSPITAL MORTALITY[a]

	Hospital death		
Variance (ms^2)	Yes	No	Total
<1,000	16 (15.5%)	87	103
³1,000	3 (4.1%)	70	73
Total	19	157	176

[a]Relative risk, 3.8 (95% confidence interval, 1.1–12.5).

From Wolf MM, Varigos GA, Hunt D, et al. Sinus arrhythmia in acute myocardial infarction. *Med J Aust* 1978;2:52–53, with permission.

The study by Wolf et al. showed that RR variability, estimated from a short ECG recording on the day of myocardial infarction, predicted mortality over the next 9 to 14 days (16). The hospital mortality of patients with RR variance less than 1,000 ms^2 was 15.5% compared with 4.1% for patients with RR variance greater than or equal to 1,000 ms^2. After adjusting for average RR interval and location of the infarct, low RR variance was still significantly associated with higher mortality.

Prediction of Long-Term Mortality after Acute Myocardial Infarction Using Time Domain Measures of RR Variability

In 1987, Kleiger et al. (17) reported that SDNN, measured at the time of hospital discharge after myocardial infarction, predicted death during the subsequent 2 to 4 years. They performed baseline studies on a group of 808 patients with acute myocardial infarction and then followed them an average of 31 months. Twenty-four-hour ECG recordings were done 11 ± 3 days after acute myocardial infarction. SDNN was calculated for the 24-hour period, and a value of 50 ms was chosen arbitrarily to dichotomize their group into 125 patients (16%) with low values and 683 patients (84%) with high values. During 2 to 4 years of follow-up, 127 deaths occurred (Fig. 77.3). The mortality of patients with an SDNN less than 50 ms was 34% compared with a 12% mortality in patients with an SDNN greater than or equal to 50 ms, a relative risk of 2.8 (95% confidence interval, 2.0 to 3.8). SDNN predicted mortality independently of other risk predictors such as LVEF or ventricular arrhythmias.

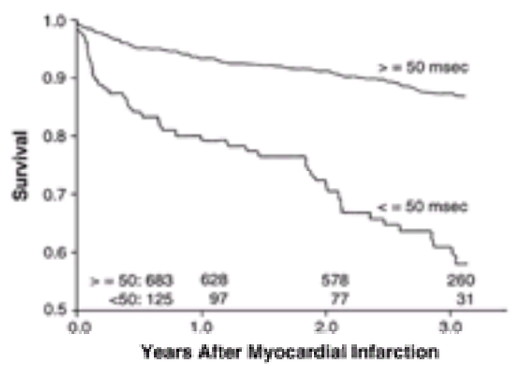


FIGURE 77.3 Survival as a function of the 24-hour standard deviation of normal RR intervals in 808 patients with myocardial infarction. Time after myocardial infarction is plotted on the *x*-axis; proportion surviving is plotted on the *y*-axis. (Adapted from data published in Kleiger RE, Miller JP, Bigger JT Jr, et al. Decreased heart rate variability and its association with increased mortality after acute myocardial infarction. *Am J Cardiol* 1987;59:256–262. This figure was first published as Figure 19.6 in Bigger JT Jr, Rottman JN. Spectral analysis of RR variability. In: Podrid PJ, Kowey PR, eds. *Cardiac arrhythmia. Mechanisms, diagnosis, and management.* Baltimore: Williams & Wilkins, 1995:280–298, with permission.)

This study was the first to show the predictive value of RR variability for all-cause mortality during long-term follow-up after myocardial infarction. Bigger et al. showed that SDANN was strongly associated with all-cause mortality. SDNN or SDANN were better predictors of mortality than ASDNN or time domain measures of HF fluctuations in NN intervals (e.g., r-MSSD or pNN50) (94).

Farrell et al. obtained similar results using a geometric time domain measure of RR variability, the HRV triangular index (117). Farrell et al. studied 416 patients 6 or 7 days after acute myocardial infarction, 48% of whom were treated with thrombolysis (117). RR variability was quantified by triangular interpolation of the frequency distribution of normal RR intervals (TINN), a measure that is strongly correlated with SDNN, SDANN, total power, and ultra-low-frequency power. Farrell et al. arbitrarily chose a value of 20 ms for TINN to dichotomize their group into 113 patients (27%) with low values and 348 patients (73%) with high values. During an average follow-up of 20 months, 47 cardiac deaths occurred. The risk of experiencing a cardiac death during 2 years of follow-up was seven times as high in the group with a TINN less than 20 ms as in the group with a value greater than or equal to 20 ms. TINN did not predict recurrent myocardial infarction. Also, it is notable that the results of Kleiger et al. and Farrell et al. are so similar, considering that the former sample was collected before and the latter after thrombolysis was commonly used.

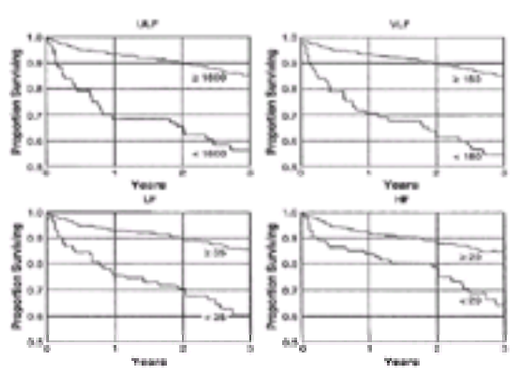
In an interesting more recent study, 185 consecutive patients who had experienced a first myocardial infarction underwent a simple deep breathing test (118). Approximately 5 days after the infarct, patients were asked to take six deep respirations during 1 minute. HRV was measured as the difference between the longest and shortest RR intervals; value difference of less than 10 beats/min was noted in 65 patients (35%). During 1 year of follow-up, decreased HRV was predictive of all-cause mortality (14% vs. 1%, p = .004) and a composite end point of death, recurrent myocardial infarction, angina, or heart failure (46% vs. 28%, p = .003).

Prediction of Long-Term Mortality after Acute Myocardial Infarction Using Frequency Domain Measures of RR Variability

Twenty-Four-Hour Power Spectral Analysis

Bigger et al. studied 715 patients with acute myocardial infarction to establish the associations between six frequency domain (power spectral) measures of RR period variability and mortality during 4 years of follow-up (101). Power was calculated for four frequency bands of the 24-hour periodogram: (a) ultra-low-frequency power; (b) very low-frequency power; (c) LF power; and (d) HF power. Also, they calculated total power and the LF/HF ratio. Calculated by this method, LF and HF power are averaged over 24 hours. Total power and all of the frequency bands were substantially reduced after acute myocardial infarction when compared with values found in healthy age- and sex-matched controls (108). The LF/HF ratio was lower early after myocardial infarction than in healthy persons, and the pattern of change suggested that the reduction in LF and HF power resulted more from reduced vagal modulation than from increased sympathetic modulation.

The six frequency domain measures of RR variability were associated with three mortality end points: death from all causes, cardiac death, and arrhythmic death (101). Each frequency domain measure of RR variability had a significant and relatively strong univariate association with all-cause mortality (eFig. 77.3.1), cardiac death, and arrhythmic death. Total power and ultra low-frequency power had the strongest associations with all three mortality end points.



***e*FIGURE 77.3.1** Kaplan-Meier survival curves. The charts show 715 patients in the high or low category for the four mutually exclusive frequency domain measures of 24-hour RR variability, ultra-low-frequency (ULF), very low-frequency (VLF), low-frequency (LF), and high-frequency (HF) power, using all-cause mortality as the end point. (From Bigger JT Jr, Fleiss JL, Steinman RC, et al. Frequency domain measures of heart period variability and mortality after myocardial infarction. *Circulation* 1992;85:164–171, with permission.)

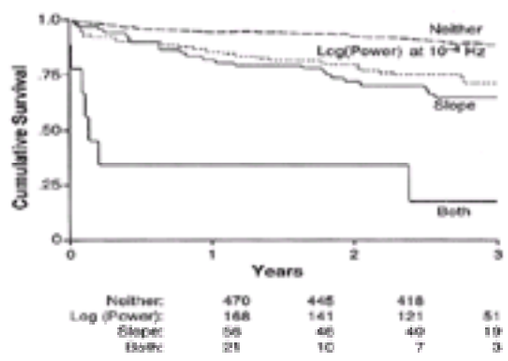
To determine how much predictive value frequency domain measures of RR variability add to previously established postinfarction risk predictors, the strength of the relationship between the RR variability measures and all-cause mortality, cardiac death, and arrhythmic death were evaluated before and after adjusting for five previously established postinfarction risk predictors: age, New York Heart Association functional class, rales in the coronary care unit, VEF, and ventricular arrhythmias quantified in a 24-hour Holter ECG recording (101). After adjustment for the five risk predictors, the association between mortality and total power, ultra low-frequency power, and very low-frequency power remained significant and strong, whereas LF power and HF power were only moderately strongly associated with mortality.

Power Spectral Measures of RR Variability Measured over a Five-Minute Interval

Bigger et al. studied 715 patients 2 weeks after myocardial infarction and showed that short-term power spectral measures of RR variability (calculated from 5 minutes of normal RR-interval data) predict all-cause mortality or arrhythmic death (119). From continuous 24-hour ECG recordings, two 5-minute segments were selected for analysis, one from the 8 a.m. to 4 p.m. interval, and one from the 12 midnight to 5 a.m. interval. The former corresponds to the time interval during which short-term measures of RR variability would most likely be obtained. The latter simulates the conditions that exist when patients have an ECG recorded while lying quietly in a laboratory. Four frequency domain measures were calculated from the daytime and nighttime 5-minute intervals: (a) very low-frequency power; (b) LF power; (c) HF power; and (d) LF/HF ratio. Mean power spectral values from 5-minute periods during the day and night were similar to 24-hour values, and the correlations between short segment values and 24-hour values were strong (most correlations were greater than or equal to 0.75). Power spectral measures of RR variability, obtained from 5-minute ECG recordings, were excellent predictors of all-cause, cardiac, and arrhythmic mortality. Patients with low values were two to four times as likely to die over an average follow-up of 31 months than were patients with high values.

Power Law Regression Parameters

In healthy persons, the slope of log(power) on log(frequency) (a) is approximately –1, and the log(power) at 10^{-4} Hz is approximately 6.90 (103). After myocardial infarction, a averages –1.15 and the log(power) at 10^{-4} Hz is 6.56. The combination of a and log(power) at 10^{-4} Hz measured soon after myocardial infarction is an outstanding predictor of death over the next 2 to 4 years (eFig. 77.3.2). Patients classified as high risk by a and log(power) at 10^{-4} Hz had a tenfold increased risk of dying during 2.5 years of follow-up compared with patients classified as low risk; the actuarial 3-year mortality was 79% for the high-risk group compared with 11% for the low-risk group. The power law regression parameters predict death of any cause or arrhythmic death better than any single power spectral band or any combination of power spectral variables (103).



***e*FIGURE 77.3.2** Predicting mortality after myocardial infarction using power law regression parameters. Kaplan-Meier survival curves for 715 myocardial infarction patients cross-classified by slope of the power law regression line (dichotomized at –1.372) and log(power) dichotomized at 10^{-4} Hz (dichotomized at 6.345). The 3-year survival rates were, for patients in neither high-risk category, labeled "Neither," 89%; for patients in the high-risk category for log(power) at 10^{-4} Hz only, labeled "Log(power) at 10^{-4} Hz," 70%; for patients in the high-risk category for slope only, labeled "Slope," 64%; for patients in the high-risk category for both variables, labeled "Both," 17%. The survival curve labeled "Log(power) at 10^{-4} Hz" is thinner than the other three curves to distinguish it from the survival curve labeled "Slope." For each of the four groups, the numbers of patients being followed at enrollment and at 1, 2, and 3 years is shown below the graph. (From Bigger JT Jr, Steinman RC, Rolnitzky LM, et al. Power law behavior of RR-interval variability in healthy middle-aged persons, patients with recent myocardial infarction, and patients with heart transplants. *Circulation* 1996;93:2142–2151, with permission.)

Short-Term Fractal Scaling Exponent (a_1) and Mortality after Myocardial Infarction

Huikuri et al. studied several nonlinear dynamic measures of RR variability in a 446-patient subgroup from the Danish Investigations of Arrhythmia and Mortality on Dofetilide in Survivors of Acute Myocardial Infarction (DIAMOND-MI) trial with acute myocardial infarction and LVEF less than 0.36 (120). Time, frequency, and fractal measures of RR-interval variability were related to deaths during 2 years of follow-up. The reduced short-term fractal scaling exponent, a_1, was the strongest predictor of total mortality (n = 114), arrhythmic death (n = 75), and nonarrhythmic cardiac death (n = 28) (relative risk, 3.0; 95% confidence interval, 2.5 to 4.2). The short-term scaling exponent, a_1, remained a significant predictor of death after statistical adjustment for age, New York Heart Association functional class, ejection fraction, and use of cardiac medications.

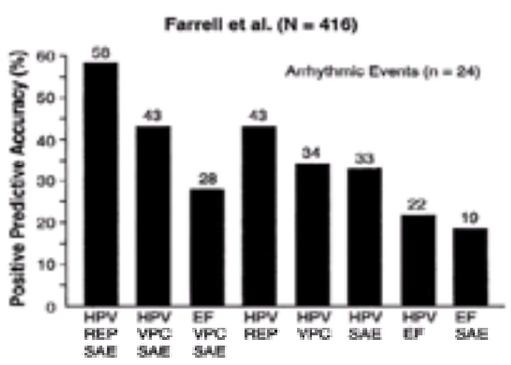
Improved Prediction of Death Using RR Variability Combined with Other Risk Predictors

All-Cause Mortality

Correlations between time or frequency domain measures of RR variability and previously identified postinfarction risk predictors, e.g., LVEF (r = 0.24) and ventricular arrhythmias (r = approximately 0.12) are remarkably weak (17). The lack of correlation between RR variability and previously established postinfarction risk predictors suggests that measures of RR variability will improve the identification of patients at high risk after myocardial infarction. Bigger et al. studied the ability of power spectral measures of RR variability to improve the accuracy of predicting all-cause mortality in 715 patients with recent myocardial infarctions (101). Adding power spectral measures of RR variability, measured approximately 10 days after myocardial infarction, to LVEF and ventricular arrhythmias quantified over a 24-hour interval, identified small subgroups with a 2.5-year mortality risk of approximately 50% (101). Total power or ultra low-frequency power increased positive predictive accuracy the most.

Arrhythmic Events

Farrell et al. studied the ability of the TINN to predict arrhythmic events (sustained ventricular arrhythmias or arrhythmic death) in 416 patients with acute myocardial infarction (117). eFigure 77.3.3 shows how combinations of risk predictors improve positive predictive accuracy for arrhythmic events during long-term follow-up after myocardial infarction. Adding the signal-averaged ECG to the TINN doubled positive predictive accuracy and adding repetitive ventricular premature complexes to the combination almost doubled positive predictive accuracy again. The best multivariate predictor for arrhythmic events was the combination of three variables: (a) TINN less than 20 ms, (b) a positive signal-averaged ECG, and (c) repetitive ventricular premature complexes quantified by 24-hour ECG recordings. The combination of these three variables had a positive predictive accuracy of 58% (113).



***e*FIGURE 77.3.3** Improving positive predictive accuracy using combinations of risk predictors after myocardial infarction. Although each risk predictor has modest (less than 20%) positive predictive accuracy for arrhythmic events when used alone, the positive predictive accuracy is 40% to 60% for some of the combinations. EF, left ventricular ejection fraction; HPV, heart period variability index; REP, repetitive ventricular premature complexes; SAE, signal-averaged electrocardiogram; VPC, ventricular premature complexes. ambulatory electrocardiographic variables and the signal-averaged electrocardiogram. *J Am Coll Cardiol* 1991;18:687–697. This figure was first published in Bigger JT Jr, Rottman JN. Spectral analysis of RR variability. In: Podrid PJ, Kowey PR, eds. *Cardiac arrhythmia. Mechanisms, diagnosis, and management.* Baltimore: Williams & Wilkins, 1995:280–298, with permission.)

RR Variability Identifies Patients with Left Ventricular Dysfunction Who Benefit from Amiodarone Treatment

A prospective substudy of the European Myocardial Infarction Amiodarone Trial (EMIAT) tested the hypothesis that patients with recent myocardial infarctions, LVEF less than 0.41, and reduced RR variability would benefit from amiodarone treatment (121). The rationale for this substudy was that RR variability predicts more specifically arrhythmic than nonarrhythmic death; therefore, such a group would benefit from amiodarone.

In EMIAT, 1,216 patients (82%) had RR variability index calculated from 24-hour Holter recordings. The substudy consisted of the 363 (30%) patients who had an HRV index less than 21 units. In placebo-treated patients, those with reduced RR variability had a substantially higher mortality than patients with preserved RR variability (22.8% vs. 9.5%, $p < .05$). In the substudy, there was a 23% reduction in all-cause mortality in those treated with amiodarone (22.8% vs. 17.5%, $p = .24$) and a 66% reduction in cardiac mortality (12.8% vs. 4.4%, $p < .01$). The efficacy of amiodarone in patients with reduced RR variability was further evaluated in a number of patient categories. The benefit of amiodarone was large in patients with reduced RR variability and a resting heart rate greater than or equal to 75 beats/min; this subgroup had 29.0% mortality when treated with placebo compared with 19.3% when treated with amiodarone, a 33.7% reduction in mortality ($p = .075$). The EMIAT substudy is the first to demonstrate that RR variability can select a group of patients with autonomic dysfunction that will benefit from prophylactic amiodarone therapy.

Effect of Myocardial Infarction on RR Variability

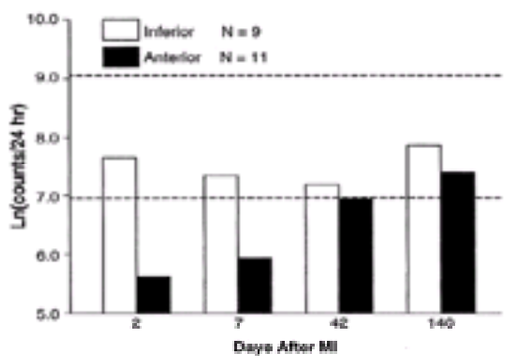
Bigger et al. showed that measures of RR variability are reduced to approximately 25% of normal 2 to 3 weeks after myocardial infarction (122). They explained the decrease in efferent cardiac vagal activity in anterior infarction by postulating an increase in afferent sympathetic nerve traffic, an effect that has been shown to decrease efferent vagal nerve traffic in experimental myocardial ischemia (123). It is not known to what extent RR variability is reduced before myocardial infarction in patients with coronary heart disease. It is known that experimental myocardial infarction created in the dog by coronary artery ligation is followed by an abrupt decrease in RR variability (72).

Recovery of RR Variability after Myocardial Infarction

Several small studies have investigated the recovery of RR variability after myocardial infarction. Both early and late phases of recovery have been studied.

Early Phase of Recovery

Flapan et al. studied 20 highly selected patients to define the time course of recovery of vagal modulation of RR intervals after a first myocardial infarction (124). This study excluded patients with previous infarction, age older than 70 years, history of diabetes, renal failure, alcohol abuse, hypertension, prior treatment with or contraindication to treatment with beta-adrenergic blocking drugs or with antihypertensive drugs. Patients with arrhythmias or heart failure on admission to the coronary care unit also were excluded. All patients were treated with streptokinase and aspirin on admission and were given atenolol and aspirin over the 3-month follow-up period. Continuous 24-hour ECG recordings were made at less than 1.5, 7.0, 42.0, and 140.0 days after myocardial infarction. Cardiac parasympathetic activity was estimated using counts of the number of times that successive RR intervals differed by greater than 50 ms in a 24-hour period (NN50). The pattern of recovery of NN50 differed depending on the site of infarction (eFig. 77.3.4). For 11 patients with anterior myocardial infarction, NN50 was 20% of normal at 1.5 days and recovered progressively to 67% of normal by 140.0 days. For nine patients with inferior myocardial infarction, NN50 was within normal limits for age at 1.5 days after infarction and did not change significantly over the 140-day follow-up. By 42 days, NN50 did not differ significantly between patients with anterior and inferior infarcts. These workers postulated that stimulation of vagal afferent nerves by ischemia and prostaglandins preserved the efferent vagal nervous activity in inferior myocardial infarction.

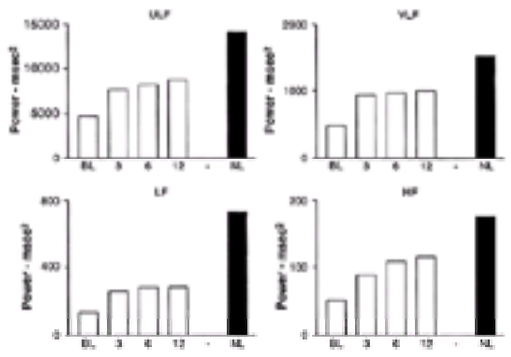


***e*FIGURE 77.3.4** Recovery of vagal modulation early after myocardial infarction (MI). The natural logarithm (Ln) of the number of times that successive normal RR intervals differ by more than 50 ms during a 24-hour period is plotted on the *x*-axis; time after MI is plotted on the *y*-axis. In this selected sample of 20 patients, vagal activity decreased markedly in patients with anterior MI, but not in those with inferior MI. By 42 days after MI, the counts had nearly recovered to a stable value. (Adapted from data in Flapan AD, Wright RA, Nolan J, et al. Differing patterns of cardiac parasympathetic activity and their evolution in selected patients with a first myocardial infarction. *J Am Coll Cardiol* 1993;21:926–931. This figure was first published in Bigger JT Jr, Rottman JN. Spectral analysis of RR variability. In: Podrid PJ, Kowey PR, eds. *Cardiac arrhythmia. Mechanisms, diagnosis, and management.* Baltimore: Williams & Wilkins, 1995:280–298, with permission.)

Late Phase of Recovery

Bigger et al. (122) studied recovery of RR variability in the placebo group of the Cardiac Arrhythmia Pilot Study (CAPS). The 68 placebo-treated patients who had 24-hour ECG recordings at baseline and at 3, 6, and 12 months after myocardial infarction were studied. The 24-hour power spectral density was computed using FFTs and divided into four components of the RR power spectrum: ultra low-frequency power, very low-frequency power, LF power, and HF power. Total power (power less than 0.40 Hz) also was calculated. The mean baseline values (25 days after myocardial infarction) for the five frequency domain measures of RR variability in the CAPS patients were similar to those found in 715 patients who participated in the Multicenter Post Infarction Program, indicating that the CAPS sample is generally representative of postinfarction patients with respect to these measures.

*e*Figure 77.3.5 shows the time course of recovery of RR variability over the year after myocardial infarction. There was a substantial increase in all measures of RR variability between 3 weeks and 3 months ($p < .001$). On average, recovery of RR variability is completed by 3 months after myocardial infarction (eFig. 77.3.5). Between 3 months and 12 months, the values were quite stable for the group as a whole, as well as for individual patients (intraclass correlation coefficients greater than or equal to 0.66). *e*Table 77.1.3 shows that, even at 12 months after infarction, the average full recovery values for the five measures of RR variability were only one-half to two-thirds the values found in the sample of 274 healthy age- and sex-matched controls (108). However, recovery of RR variability during the year after myocardial infarction is quite variable. Some patients recover to normal values of RR variability, whereas others have very little recovery or have a decrease.



***e*FIGURE 77.3.5** Recovery of RR variability during the year after myocardial infarction. Data are plotted for 68 patients in the placebo group of the Cardiac Arrhythmia Pilot Study who had a complete set of 24-hour electrocardiographic recordings. Because the distributions of RR variability measures are markedly skewed, the geometric means are plotted for baseline (BL), 3, 6, and 12 months after myocardial infarction (*white bars*). For comparison, the geometric means are plotted for a group of 95 healthy persons of similar age and sex (*black bars*). Recovery was complete by 3 months after infarction, but recovery values after infarction are lower than those found in healthy persons of similar age and sex. HF, high-frequency power; LF, low-frequency power; NL, normal; ULF, ultra-low-frequency power; VLF, very low-frequency power. (Adapted from data in Bigger JT Jr, Fleiss JL, Rolnitzky LM, et al. Time course of recovery of heart period variability after myocardial infarction. *J Am Coll Cardiol* 1991;18:1643–1649. This figure was first published in Bigger JT Jr. RR variability to evaluate autonomic physiology and pharmacology and to predict cardiovascular outcomes in humans. In: Zipes DP, ed. *Cardiac arrhythmias: from cell to bedside*. Philadelphia: WB Saunders, 1995:1151–1170, with permission.)

Predictive Value of Power Spectral Measures of RR Variability Late after Myocardial Infarction

The substantial recovery of RR variability in the 3 months after myocardial infarction raises the question whether recovery values for RR variability predict death. To answer this question, Bigger et al. (125) studied the 331 patients in the CAPS who survived for 1 year, had a 24-hour ECG recording made after the CAPS drug was washed out, and were discharged on no antiarrhythmic drug therapy. Thirty deaths occurred in the CAPS group between 1.0 and 2.2 years after myocardial infarction. Power spectra were calculated from 24-hour continuous ECG recordings, and six power spectral measures of RR variability were evaluated: (a) ultra low-frequency power; (b) very low-frequency power; (c) LF power; (d) HF power; (e) total power; and (f) the LF/HF ratio. Because of the large increase in RR variability that takes place during the first 3 months after myocardial infarction, the optimum cutpoints for measures of RR variability in the 1-year recordings were substantially higher than those previously determined for 24-hour ECG recordings made approximately 2 weeks after infarction (*e*Table 77.1.4). Each power spectral measure of RR variability calculated from the recordings made 1 year after infarction had a strong and significant univariate association with 2.5-year all-cause mortality; the relative risks for these variables ranged from 2.5 to 5.6.

***e*TABLE 77.1.4** OPTIMAL CUTPOINTS FOR PREDICTION OF ALL-CAUSE MORTALITY AFTER MYOCARDIAL INFARCTION BY FREQUENCY DOMAIN MEASURES OF HEART PERIOD VARIABILITY

	Optimal cutpoints	
Variable	At discharge 2 weeks after myocardial infarction	After recovery from myocardial infarction
Ultra-low-frequency power (ms^2)	1,600.00	5,000.0
Very low-frequency power (ms^2)	180.00	600.0
Low-frequency power (ms^2)	35.00	120.0
High-frequency power (ms^2)	20.00	35.0
Total power (ms^2)	2000.00	6000.0
Low frequency/high frequency ratio	0.95	1.6

From Bigger JT Jr. Spectral analysis of RR variability to evaluate autonomic physiology and pharmacology and to predict cardiovascular outcomes in humans. In: Zipes DP, Jalife J, eds. *Cardiac electrophysiology from cell to bedside*, 2nd ed. Philadelphia: WB Saunders, 1995:1151–1170, with permission.

The prediction of death from the measures of RR variability made 1 year after myocardial infarction was not improved when measures of RR variability made within a month of myocardial infarction were added to the survival model (125). After adjustment for age, New York Heart Association functional class, rales in the critical care unit, LVEF, and ventricular arrhythmias, measures of RR variability still had a strong and significant independent association with all-cause mortality. It is clear from this study that RR variability, measured after full recovery from myocardial infarction, predicts death independent of other important postinfarction risk predictors. The final recovery values for RR variability are the best predictors of subsequent events (i.e., knowledge of the recovery pattern does not improve prediction significantly).

In healthy persons, RR variability is influenced significantly by age, sex, physical fitness, and drugs (126), as well as heritability (127). This naturally raises the question whether these factors confound the use of RR variability to predict death and arrhythmic events in patients with coronary heart disease. Fortunately, these factors do not confound the predictive value of RR variability in coronary heart disease because the effect of coronary disease on RR variability is much larger than the effect of

factors such as age, sex, physical fitness, and drugs.

RR Variability to Assess Prognosis in Patients with Heart Failure

Patients with heart failure often have autonomic dysfunction. The United Kingdom Heart Failure Evaluation and Assessment of Risk Trial prospectively evaluated the predictive value of RR variability in 433 patients with heart failure followed for 482 ± 161 days (128). SDNN was only weakly related to LVEF (r = 0.12). SDNN was a strong predictor of mortality: 6% of the patients had an SDNN less than 50 ms with an annual mortality of 51%, 32% had an SDNN of 50 to 100 ms with an annual mortality of 13%, and 62% had an SDNN greater than 100 ms with an annual mortality of 6%.

Significance of Low RR Variability in the Elderly

In 1948, a sample of 5,209 residents of Framingham, MA, was selected to undergo biennial examinations in a prospective study (129). In the eighteenth examination cycle (1983 to 1985), 1,028 2-hour Holter recordings were made during routine clinic examinations of 1,825 surviving participants (130).

A total of 292 were excluded, leaving 736 persons in the study. The clinical characteristics of the participants in the Holter substudy were similar to those of the nonparticipants. The average age for the study sample was 72 ± 6 years, 40% were male subjects, 9% had a history of myocardial infarction, and 2% had a history of congestive heart failure. The average heart rate for the group was 74 ± 12 beats/min, and the average blood pressure was 142/76 mm Hg. During an average follow-up of 3.9 years, 74 of the 736 participants died. Where the cause of death was known, the most common causes were coronary heart disease and cancer.

For frequency domain analysis, 100-second blocks of data were sampled at 128 samples per second, and power spectral density was calculated using an FFT method. As previously found after myocardial infarction (119), LF power was the best of eight time and frequency domain measures of RR variability for predicting death of all causes (130).

A 1 SD decrement in natural log-transformed LF power was associated with a relative risk (hazard ratio) of 1.87 (95% confidence interval, 1.55 to 2.26). After statistical adjustment for age, sex, and clinical risk factors (history of myocardial infarction, heart failure, diuretic use, and frequent or complex ventricular premature complexes), the relative risk was 1.70. These results indicate that reduced RR variability predicts mortality in a population-based sample of elderly subjects.

Significance of Low RR Variability in Patients Referred for 24-Hour Holter Recordings

Algra et al. conducted a retrospective case control study to determine whether a disturbance of autonomic nervous system activity may play a role in sudden cardiac death (131). All 6,693 consecutive patients who had 24-hour Holter ECG recordings in four Rotterdam hospitals between August 1, 1980, and December 31, 1984, were included.

The indications for the 24-hour ECG recordings were evaluation of palpitations, dizziness, syncope, or angina pectoris, 65%; evaluation of risk after myocardial infarction, 10%; evaluation of antiarrhythmic therapy, 8%; and search for a cardiac cause of transient cerebral events, 7%. Seventy-five percent of the recordings were done in outpatients. Patients were excluded for unanalyzable Holter recordings and for frequent supraventricular arrhythmias, leaving approximately 5,500 patients. During a 2-year follow-up period, 193 sudden cardiac deaths (less than 1 hour) occurred.

Three time domain measures of RR variability were used in the Rotterdam study: (a) pNN50; (b) short-term variation (mean over 24 hours of per minute standard deviations of RR intervals); and (c) long-term variation (standard deviation over 24 hours of per minute means of RR intervals). Although the latter two measures are unorthodox, the measure of short-term variation is similar to ASDNN or LF power, and the measure of long-term variation is similar to SDANN or ultra low-frequency power. Patients with low values for these three measures of RR variability had a higher relative risk of experiencing sudden cardiac death in 2 years of follow-up. The relative risks were pNN50, 1.8; short-term variation, 3.0; and long-term variation, 2.7. This study showed that RR variability had predictive value in a consecutive, heterogeneous group of patients referred to a Holter laboratory.

How to Interpret and Use RR-Variability Reports from Commercial Holter Systems

Most commercial Holter systems provide some measures of RR variability. The calculation of statistical measures of RR variability is straightforward if ectopic complexes are correctly measured. For example, measurements of SDNN made by commercial systems are comparable with those made with research systems. Power spectral measures of RR variability in most commercial systems have not been validated against research systems that establish their predictive value for cardiac death or sustained arrhythmias. Beta-blocker therapy increases RR variability somewhat in patients with recent myocardial infarctions and is known to improve survival. A careful evaluation for the sources of risk is recommended for patients with low values for RR variability after myocardial infarction, and beta-blocker therapy should be instituted if there is no contraindication.

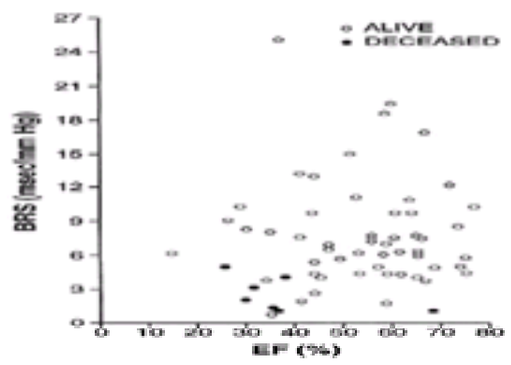
Summary of RR Variability in Coronary Heart Disease

RR variability has proven to be a remarkably effective predictor of death and arrhythmic events after acute myocardial infarction and in chronic coronary heart disease. RR variability is a better predictor than LVEF or ventricular arrhythmias. Both time and frequency domain measures of RR variability measured during 5-minute or 24-hour ECG recordings predict deaths after myocardial infarction. RR variability predicts death of all causes, cardiac death, arrhythmic death, and also nonfatal sustained arrhythmias. However, RR variability, measured soon after acute myocardial infarction, does not predict recurrent infarction. Combined with other risk predictors, RR variability has a positive predictive accuracy up to 50%. RR variability is readily available in commercial Holter equipment and is inexpensive. The EMIAT substudy indicates that patients with left ventricular dysfunction and low RR variability benefit from prophylactic amiodarone therapy.

Clinical Use of Baroreflex Sensitivity for Assessment of Risk in Coronary Heart Disease

Baroreflex Sensitivity Has a Weak Relationship with Infarct Size or Left Ventricular Ejection Fraction

To explore the correlations with other risk predictors and the predictive value of BRS in patients with recent myocardial infarction, La Rovere et al. studied 78 patients who had experienced their first infarction and were younger than age 65 years. BRS was measured with the phenylephrine method within 30 days of infarction, and patients were then followed for 24 months (132). BRS averaged 8.2 ± 4.8 ms per mm Hg in 71 patients who survived and 2.4 ± 1.5 ms per mm Hg (p = .004) in seven patients who died during follow-up. Mortality was 2.9% in the 68 patients with BRS greater than or equal to 3 ms per mm Hg compared with 40% in the ten patients with BRS less than 3 ms per mm Hg. BRS predicted total cardiac mortality as well as sudden cardiac death. The relationship between a depressed BRS and LVEF was explored in detail (eFig. 77.3.6). No association was found between the peak level of serum creatine kinase (r = 0.11) or between BRS and LVEF (r = 0.07) (132). It is clear that BRS is not just a reflection of ventricular function because there was a poor correlation between LVEF and BRS, and BRS increased the predictive accuracy for cardiovascular death after myocardial infarction. The correlation between BRS and RR variability was only modest, suggesting that BRS and RR variability might have independent predictive value for predicting death or nonfatal arrhythmic events after myocardial infarction (123).



***e*FIGURE 77.3.6** Relationships among baroreflex sensitivity (BRS), left ventricular ejection fraction (EF), and cardiovascular mortality in a group of 78 patients with a recent first myocardial infarction. All but one of the seven patients who died had a left ventricular EF below 0.50. The risk of death was 50% when left ventricular dysfunction and a BRS less than 3 ms per mm Hg were both present compared with 10% for patients with left ventricular EF less than 0.50 but BRS greater than or equal to 3 ms per mm Hg. (From La Rovere MT, Specchia G, Mortara A, et al. Baroreflex sensitivity, clinical correlates and cardiovascular mortality among patients

with a first myocardial infarction: a prospective study. *Circulation* 1988;78:816–824, with permission.)

Baroreflex Sensitivity Predicts Arrhythmic Events

Farrell et al. subsequently studied the predictive value of BRS in 122 patients with recent myocardial infarction (133). BRS, HRV, 24-hour continuous ECG recordings, exercise tests, and LVEF were measured between days 7 and 10 after myocardial infarction. During a 1-year follow-up period there were ten arrhythmic events (five sudden deaths and five admissions for sustained ventricular arrhythmias). BRS was appreciably reduced in the ten patients who experienced arrhythmic events (1.73 ± 1.49 compared with 7.83 ± 4.5 ms per mm Hg in the 112 patients who did not; p <.0001). A significant correlation was noted between BRS and age (r = –0.68, p <.001), but not with LVEF or the other tests done to identify risk. A BRS less than 3.0 ms per mm Hg carried the highest relative risk for arrhythmic events (23.1; 95% confidence interval, 7.7 to 69.2) and was similar to other prognostic variables, including LVEF (relative risk of 10.4; 95% confidence interval, 3.3 to 32.6), frequent ventricular complexes (relative risk of 20.6; 95% confidence interval, 11.0 to 37.1), or SDNN (relative risk 10.1; 95% confidence interval, 5.6 to 18.1). BRS had predictive value independent of other tests used for postinfarction risk stratification.

Baroreflex Sensitivity and Patency of the Infarct-Related Artery

Mortara et al. conducted a study to evaluate the association between patency of the infarct-related artery and BRS in 359 patients with a recent myocardial infarction who also had a coronary angiogram (134). Patients with occluded infarct-related arteries had lower values for BRS (p <.005) and LVEF (p <.001) compared with patients with patent infarct-related arteries. In different categories of LVEF, BRS was significantly lower among patients with occluded infarct-related arteries than in patients with patent infarct-related arteries. When clinical and angiographic variables were entered into a stepwise multiple regression model with BRS as the dependent variable, only age and patency of the infarct-related artery emerged as significant independent predictors of BRS (134). The correlation with age (r = –0.52) was similar in magnitude to that found by Farrell et al.

Two small studies have found that BRS was markedly reduced, whereas measures of RR variability showed only borderline reductions in patients who had arrhythmic events a year or more after myocardial infarction (135,136). These preliminary findings need to be confirmed with full-scale clinical studies. Bonaduce et al. studied a group of patients with single-vessel coronary disease who were having percutaneous transluminal coronary angioplasty (137). They measured RR variability before and 2 to 3 weeks after angioplasty. Before angioplasty, LF power and HF power were reduced only in those patients who had a regional wall motion abnormality in the distribution of the stenotic artery. Patients whose wall motion returned to normal after angioplasty showed a significant improvement in RR variability. This finding was explained by a reduction in sympathetic afferent nerve traffic when normal wall motion was restored.

Autonomic Tone and Reflexes after Myocardial Infarction Study

Based on the strong experimental evidence that BRS predicted ischemic VF, and encouraging evidence from small clinical studies, ATRAMI, a large epidemiologic study, was launched in 1991 (114). ATRAMI was designed to definitively assess the predictive value of BRS after myocardial infarction and to determine how the predictive value of BRS ranked with RR variability, LVEF, and ventricular premature complexes. A total of 1,284 patients were enrolled 6 to 28 days after myocardial infarction, had BRS measured, and were followed for greater than or equal to 12 months. The primary end point was cardiac death or nonfatal cardiac arrest.

The a priori hypotheses were that a BRS less than 3.0 ms per mm Hg would predict higher cardiac mortality and that it would add predictive power to that of SDNN less than 70 ms. The strength of association of BRS and SDNN with cardiac death and cardiac arrest with and without adjusting for LVEF and ventricular premature complexes was estimated using a Cox regression model.

The average age in ATRAMI was 57 ± 10 years and their risk was relatively low, as indicated by the mean LVEF of 0.49 ± 0.12. The average BRS for the group was 7.2 ± 4.6 ms per mm Hg and the average SDNN was 108 ± 35 ms; 17% of the patients had greater than or equal to 10 ventricular premature complexes per hour. Patients with depressed BRS or SDNN were older, were more frequently women, and had more ventricular premature complexes and lower LVEFs.

During a mean follow-up of 21 ± 8 months, cardiac death or cardiac arrest occurred in 49 patients (3.9%) (Fig. 77.4). Two-year mortality was 9% among patients with BRS less than 3 ms per mm Hg compared with 2% in patients with BRS less than or equal to 3.0 (vs. p <.0001), definitively establishing the predictive value of this autonomic marker. Similarly, patients with SDNN less than 70 ms had a 10% mortality compared with 2% in those with SDNN less than or equal to 70 ms (p <.0001), thus confirming the predictive value of SDNN. The relative risk of patients with BRS values less than 3.0 ms per mm Hg or SDNN values less than 70 ms remained strong even after adjusting for LVEF and ventricular premature complexes. BRS and SDNN both had relative risks of approximately 3.0 for cardiac death or cardiac arrest.

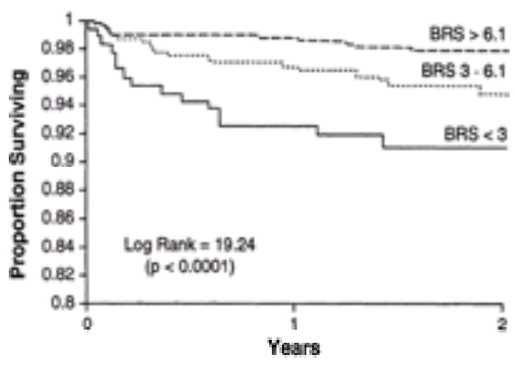


FIGURE 77.4 The ability of baroreflex sensitivity (BRS) to predict cardiac death (n = 44) or cardiac arrest (n = 5) after myocardial infarction in 1,182 patients who participated in the Autonomic Tone and Reflexes after Myocardial Infarction study and had BRS measured by the phenylephrine method. Patients were divided into three groups: 179 patients below the fifteenth percentile (BRS less than 3.0 ms per mm Hg), 414 patients from the fifteenth percentile to the median value (BRS 3.0 to 6.1 ms per mm Hg), and 589 patients above the median value (BRS greater than 6.1 ms per mm Hg). The p value refers to differences in the event rates among the three groups. [From La Rovere MT, Bigger JT Jr, Marcus FI, et al. Baroreflex sensitivity and heart rate variability in the prediction of total cardiac mortality after myocardial infarction. The results of ATRAMI (Autonomic Tone and Reflexes After Myocardial Infarction). *Lancet* 1998;351:478–484, with permission.]

Patients with depressed BRS and depressed SDNN had a 1-year mortality of 15% versus 1% (p <.0001), a relative risk of 10.9, indicating that BRS adds significantly to the predictive value of SDNN. Similarly, BRS or SDNN combined with LVEF improved predictive accuracy for cardiac mortality and cardiac arrest. When LVEF less than 0.35 was combined with an SDNN less than 70 ms, the relative risk was 7.4 (95% confidence interval, 3.1 to 17.8), and when it was combined with a BRS less than 3.0 ms per mm Hg, the relative risk was 11.9 (95% confidence interval, 5.1 to 27.4). This large prospective study provides definitive evidence that BRS is a strong and independent predictor of death after myocardial infarction. Moreover, BRS adds significantly to the predictive value of SDNN.

Clinical Use of Heart-Rate Responses to Exercise to Predict Death

Chronotropic Incompetence as a Prognostic Marker

Increase in heart-rate rise during exercise is a prognostic marker for coronary events and all-cause mortality (19,20,22,24,25,81,82). Lauer et al. examined 1,575 men from the Framingham Offspring Study who underwent exercise testing and classified their heart-rate response to exercise using three different criteria: (a) failure to reach 85% of the age-predicted maximum heart rate; (b) change in heart rate from rest to peak exercise; and (c) the percentage of the heart-rate reserve used during exercise (chronotropic response index) (22). After almost 8 years of follow-up, 55 deaths and 95 new cases of coronary artery disease accumulated. All three markers predicted total mortality and coronary artery disease. After adjustment for confounding factors, the chronotropic response index emerged as the strongest predictor of mortality.

Although chronotropic response is predictive of coronary artery disease (81), it is independent of ischemia (24,25) and coronary artery plaque burden (82). Lauer et al.

studied 2,953 patients undergoing stress thallium testing to assess the interaction between ischemic response and chronotropic response (25). Failure to achieve 85% of age-predicted maximum heart rate or a low chronotropic index was predictive of all-cause mortality outcomes even after adjusting for myocardial ischemia and other risk factors. The independence of chronotropic response from coronary artery disease was confirmed by Dresing et al. in an angiographic study (82). They looked at a cohort of patients who had undergone both exercise testing and angiography. Coronary artery plaque burden was assessed using the Duke Prognostic Weight Score. Chronotropic response remained predictive of death even after adjustment for severity of coronary artery disease. In fact, although angiographic severity of coronary disease was associated with risk of death in univariate analyses, once the chronotropic response to exercise was considered the angiographic findings had no independent predictive value.

Heart-Rate Recovery as a Prognostic Marker

Although used as a marker of physical fitness for many years, the use of HRR as a prognostic marker is a relatively recent development. In the first study to look at the predictive potential of HRR, Cole et al. (35) followed 2,428 adults who underwent symptom-limited exercise testing and single photon emission computed tomographic thallium imaging. Patients exercised to peak workload and then continued to walk at 2.4 km (1.5 miles) per hour at a grade of 2.5% for at least 2 minutes into recovery. HRR was defined as the decrease in heart rate from peak exercise to 1 minute of recovery.

$$\text{HRR} = \text{Heart rate}_{\text{Peak}} - \text{Heart rate}_{\text{1-Minute Recovery}}$$

An abnormal value for HRR was determined by finding the maximal value for the log-rank chi-square test statistic for all possible cutoff points between the tenth and ninetieth percentiles for the study cohort. This turned out to be less than 12 beats/min. The median value for HRR was 17 beats/min, with a range from the twenty-fifth to the seventy-fifth percentile of 12 to 23 beats/min. An abnormal value was found in 26% of the population.

During 6 years of follow-up, there were 213 deaths from all causes. A low value of HRR (less than 12 beats/min) was highly predictive of mortality, with a relative risk of 4.0 (mortality at 6 years, 19% vs. 5%, p <.001) (Fig. 77.5). Even after adjusting for age, fitness level, and thallium perfusion defects, HRR remained predictive of death. These data suggest that an abnormal HRR is independent of cardiac ischemia. When both an abnormal HRR and thallium perfusion defects were present, the mortality was markedly increased, with a relative risk of 7.8 (mortality at 6 years, 31% vs. 4%, p <.001). Abnormal HRR has also been demonstrated in a large population of healthy young adults undergoing routine submaximal exercise testing (138). More than 5,000 healthy adults enrolled in the Lipid Research Clinics Prevalence Study, with no known heart disease, were followed 12 years after near maximal exercise treadmill testing. Abnormal HRR was defined as less than a 42-beat fall in heart rate 2 minutes into recovery. Those with abnormal HRR were at increased risk for cardiac deaths (4% vs. 1%) and for all-cause mortality (10% vs. 4%).

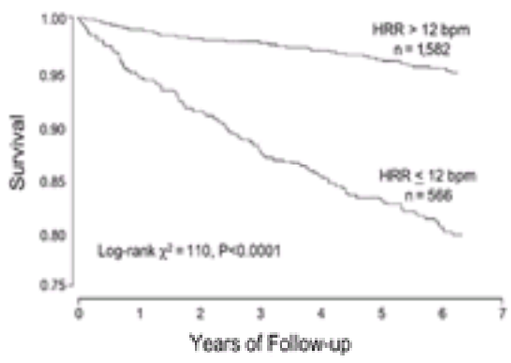

FIGURE 77.5 Kaplan-Meier plot relating heart-rate recovery (HRR) to all-cause mortality. (From Cole CR, Lauer MS. Exercise testing and risk assessment. In: Foody JM, ed. Preventive cardiology. Totowa, NJ: Humana Press, 2001, with permission. Based on data from Cole CR, Blackstone EH, Pashkow FJ, et al. Heart-rate recovery immediately after exercise as a predictor of mortality. *N Engl J Med* 1999;341:1351–1357.)

There were important similarities and differences between this study and the prior study. First, the population studied was younger and at lower risk for heart disease at baseline. Second, the tests were not true maximal exercise tests but were stopped when the subjects achieved 85% to 90% of age-predicted maximum heart rate. Third, there was no cool-down period, and the subjects went directly from maximum exercise to a seated position. Last, heart rate during recovery was not measured until 2 minutes had elapsed and thus could not be directly compared with the prior study. Despite these differences, HRR was a strong, independent predictor of mortality in both populations.

To better understand the interactions that HRR has with other exercise-derived predictors of outcome, we studied HRR and the Duke treadmill exercise score in a population of 9,454 patients who underwent symptom-limited exercise ECG testing (139). The Duke treadmill exercise score incorporates exercise duration and ST-segment deviation and symptoms and has been validated as a predictor of mortality (140). Patients were divided into low-, intermediate-, or high-risk groups based on their treadmill exercise scores. For HRR a cutoff value of 12 beats/min or less after 1 minute of recovery was called an abnormal response. The primary end point was all-cause mortality.

In 5 years of follow-up, there were 312 deaths. Either an abnormal HRR or an intermediate- or high-risk treadmill exercise score predicted a fourfold increase in mortality (Fig. 77.6). If both the treadmill exercise score and HRR were normal the 5-year mortality was only 2%, but if both were abnormal mortality increased to 14%. There was no interaction between the two predictors. These findings demonstrate that HRR adds important information to the interpretation of the exercise test in addition to standard predictors.

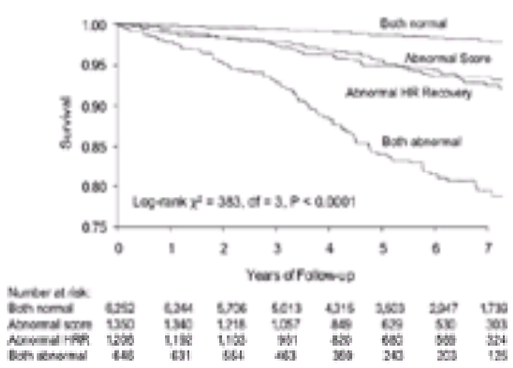

FIGURE 77.6 Kaplan-Meier survival curves according to heart rate (HR), heart-rate recovery (HRR), and treadmill exercise score. (From Nishime EO, Cole CR, Blackstone EH, et al. Heart rate recovery and treadmill exercise score as predictors of mortality in patients referred for exercise ECG. *JAMA* 2000;284:1392–1398, with permission.)

CONTROVERSIES AND PERSONAL PERSPECTIVES

There is little controversy about the value of RR variability or BRS for predicting cardiac death or arrhythmic events in coronary heart disease. This new knowledge should be put to use more frequently and incorporated into practice guidelines. RR variability and BRS have positive predictive accuracy as good as any other risk predictor in coronary heart disease. After myocardial infarction, patients who have values of RR variability and BRS below the critical high-risk cut points have double the risk of cardiac death or an arrhythmic event, even if they have a good ejection fraction and lack ventricular arrhythmias. Furthermore, when combined with LVEF, ventricular arrhythmia frequency, or both, they substantially improve positive predictive accuracy and identify groups at very high risk.

The controversies with respect to diagnostic use of RR variability and BRS are when to measure these variables and what to do for patients who have critically low values for RR variability or BRS. Given what we know about the role of the autonomic nervous system in the pathophysiology of coronary heart disease, it is reasonable to measure RR variability, BRS, or both in patients with previous myocardial infarction. RR variability and BRS are best measured 6 to 21 days or greater

than or equal to 3 months after myocardial infarction. Between 3 and 12 weeks, RR variability is increasing as recovery from infarction proceeds and the values are more difficult to interpret. Many commercial Holter systems provide measurements of RR variability, making these measurements easily accessible and inexpensive. Although the RR variability measures provided by various commercial Holter systems vary, many of the measures are equivalent and can be used interchangeably (eTable 77.1.1). Thus, nearly every commercial Holter system provides one or more useful measure(s) of RR variability. Equipment to measure BRS is not widely available at the present time. However, equipment is likely to become more widely available over the coming years now that measurement of BRS has been shown to be useful and safe.

Patients categorized as high risk based on their RR variability, BRS values, or both should be evaluated carefully for reversible risk. Also, these patients should be treated with drugs proven to decrease postinfarction risk (e.g., aspirin, statins, and beta-adrenergic blocking drugs). Beta-adrenergic blocking drugs are known to be safe and effective for preventing cardiac deaths after myocardial infarction. By blocking peripheral beta-receptors, beta-adrenergic blocking drugs decrease the adverse cardiovascular effects of the sympathetic nervous system. By blocking beta-receptors in the central nervous system, beta-adrenergic blocking drugs also increase parasympathetic activity. These effects of beta-adrenergic blocking drugs increase RR variability and BRS.

Many physicians do not prescribe beta-blockers for low-risk patients with recent myocardial infarctions (i.e., patients with good left ventricular function, no ventricular arrhythmias, and a negative exercise test result). However, among such “low-risk” patients, there are some whose risk is identified only by critically low values of RR variability or BRS. These patients also should be treated with beta-adrenergic blocking drugs. Patients who have an LVEF less than 0.41 and low RR variability should be considered for prophylactic amiodarone.

The recognition that heart-rate changes during and immediately after exercise are both correlated with autonomic function and with long-term mortality now means that the exercise stress laboratory is a venue for easy, inexpensive, and prognostically meaningful assessment of autonomic disturbances. As with HRV, it might be argued that since the pathophysiology and treatment of exercise heart-rate abnormalities are not known, no practical clinical value exists. We believe that this is not the case. By combining exercise heart-rate responses with other exercise test measures, it is simple to identify a large number of very low risk patients, for whom conservative management can be confidently recommended. Although the optimal treatment of patients with abnormal heart-rate dynamics is not known, these patients can be identified as being at increased risk and therefore it is reasonable to aggressively manage all correctable disturbances for which there is evidence of benefit, such as elevated low-density lipoprotein cholesterol in the setting of known coronary disease or aggressive reduction of elevated blood pressure.

Several questions remain to be answered about HRR. The optimal time to measure the recovery rate has not been well defined. One-minute recovery heart rate has been used successfully in two studies and is also routinely measured in most exercise laboratories. However, 2-minute recovery is also predictive of outcome and may be an alternative. It is also possible that a shorter HRR, such as 30-second recovery (31), may be a better predictor of death. A cool-down period following exercise is currently routinely used except in certain situations such as stress echocardiography. HRR for the use or nonuse of different cool-down periods still needs to be defined. Last, it is unclear if HRR is a modifiable risk factor. It is possible that exercise may increase HRR (141) as may pharmacologic intervention, but this currently is unknown.

Currently, we recommend that all individuals undergoing exercise testing have 1-minute HRR measured during a cool-down period and the findings reported in the results. For those individuals whose heart rates fail to decrease by more than 12 beats/min an abnormal HRR should be reported and they should be considered at higher risk for death. Their other risk factors should be optimized, but there is no need to proceed to heart catheterization based solely on an abnormal HRR. There are no current recommendations regarding exercise or medications for an abnormal HRR.

THE FUTURE

The future will bring a clearer understanding about the physiologic systems that determine cyclic fluctuations in RR intervals. This knowledge will increase our ability to interpret alterations in RR variability in disease states or during drug therapy and to react to them appropriately. Further research will provide information on the role that the autonomic nervous system plays in cardiac death and establish treatments that target the autonomic nervous system to decrease cardiac death in patients with coronary artery disease.

We still have much to learn about how physiologic control systems determine the fluctuations of heart rate that we quantify and use diagnostically. In the future, we will learn more about the physiologic systems that determine cyclic fluctuations in RR intervals and heart-rate changes. This knowledge will increase our ability to interpret these alterations in disease states or during drug therapy and to react to them appropriately.

The predictive value of RR variability and BRS is established for death and arrhythmic events in coronary heart disease. However, the predictive value of these measures of autonomic nervous system activity for death and other important cardiovascular outcomes is yet to be firmly established for other cardiac diseases. This is an important task for the future.

Sudden cardiac death remains one of our biggest public health problems. Most out-of-hospital cardiac arrests occur in persons with coronary heart disease and are due to VF. The low salvage rate for out-of-hospital cardiac arrest motivates attempts to predict this event and to prevent it. In the 1990s, the predictive value of RR variability and BRS was established for cardiac death in coronary heart disease. These findings suggest that the autonomic nervous system is intimately involved in the pathogenesis of cardiac deaths, presumably by arrhythmic mechanisms. However, it is possible that RR variability and BRS are not responsible for cardiac death, but reflect other factors that are. It remains to be proven that the autonomic nervous system plays a major causal role in cardiac death. To establish a causal role for the autonomic nervous system, a treatment that increases RR variability and BRS must be shown to decrease cardiac death in patients with coronary heart disease. The EMIAT substudy demonstrated that amiodarone prophylaxis in patients with recent myocardial infarction and LVEF less than 0.41 was beneficial for patients who had low RR variability, but not for patients with normal RR variability. Defibrillators in Acute Myocardial Infarction Trial (DINAMIT) is recruiting patients who have reduced LVEF and low RR variability and randomizing them to implantable cardioverter-defibrillator (ICD) prophylaxis or no antiarrhythmic therapy (121).

At the present time, ICDs are the dominant treatment for coronary heart disease patients who survive out-of-hospital cardiac arrest, and beta-adrenergic blocking drugs are the dominant therapy for those at risk, but who have not had a sustained ventricular tachyarrhythmia. The dominance of implantable defibrillator therapy for cardiac arrest survivors is based several randomized trials that show ICD therapy to be superior to amiodarone therapy in patients who have survived a spontaneous cardiac arrest. For patients at risk who have not yet had a sustained ventricular arrhythmia, it remains to be proven that RR variability or BRS will predict the deaths that can be prevented by ICDs. ICD prophylaxis should be restricted in clinical practice to groups that have been shown in randomized controlled trials to benefit. The value of RR variability and BRS for identifying patients who will benefit from ICD prophylaxis is being studied in ongoing trials (e.g., DINAMIT). Also, it will be possible to conduct randomized trials of drug prophylaxis to prevent sudden cardiac death in patients who have had an ICD implant (142); before ICDs, such trials would have been unethical.

ACKNOWLEDGMENTS

OVERVIEW

Coronary angiography remains the clinical gold standard for the diagnosis of coronary artery disease. Approximately 2 million procedures are performed annually in the United States. More than 60% of cardiologists in the United States perform coronary angiography as part of their practice (1). Because it is an invasive procedure with potentially serious risks, it should be performed only by well-trained individuals when an appropriate clinical indication exists. Physicians who perform coronary angiography must clearly understand its limitations and possess a firm grasp of the fundamental technical aspects of catheterization (2). From gaining arterial access to obtaining adequate images of the coronary arteries, angiographers must obtain and maintain a specific set of skills.

GLOSSARY

Caudal projection: Radiographic view with the image intensifier pointing to the inferior surface of the heart.

Conus artery: A branch that variably arises either from the right coronary artery or in close proximity to it and perfuses the right ventricular outflow tract.

VIDEO

Video 78.1 Inadvertent subselective cannulation of the conus branch of the right coronary artery. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Cranial projection: Radiographic view with the image intensifier pointing to the superior surface of the heart.

Crux: The intersection of the atrioventricular groove and the interatrial and interventricular septa on the inferior aspect of the heart.

Damping: Blunting of a recording of the arterial pressure waveform.

Diagonal artery: A branch of the left anterior descending artery that perfuses the left ventricular free wall.

Dominance: Refers to the vessel, either the right coronary artery or the left circumflex artery, that supplies the posterior part of the heart; codominance refers to the situation in which both arteries provide circulation to the posterior heart.

Image intensifier: The portion of the catheterization laboratory imaging equipment that increases the brightness of images produced by x-rays.

Internal mammary artery (IMA): An artery that runs from the subclavian artery down the chest wall, which can be harvested for use as a surgical conduit for bypass grafting; sometimes called the *internal thoracic artery*.

Left anterior descending (LAD) artery: The artery that supplies the anterior surface of the heart.

Left anterior oblique (LAO) projection: Radiographic view with the image intensifier on the left side of the patient.

Left circumflex artery (LCx): The artery that supplies blood to the lateral aspect of the heart.

Left main (LM) coronary artery: The short artery that divides into the left anterior descending artery and the left circumflex artery (and sometimes the ramus intermedius) and supplies most of the left side of the heart.

Marginal artery: A branch (acute marginal) of the right coronary artery that supplies the right ventricle; also, a branch (obtuse marginal) of the left circumflex, sometimes referred to as a *lateral branch*.

Posterior descending artery (PDA): The branch of the right coronary artery, or occasionally the left circumflex artery, that provides blood flow to the posterior aspect of the interventricular septum.

Ramus intermedius (RI): A branch of the left main artery that supplies the lateral wall of the left ventricle.

Right anterior oblique (RAO) projection: Radiographic view with the image intensifier on the right of the patient.

Right coronary artery (RCA): The artery that supplies blood to the right side of the heart and usually to the posterior aspect of the left ventricle.

Saphenous vein graft: A surgical conduit harvested from the legs, used to reroute blood from the aorta to the coronary arteries.

Scatter: Dispersion of radiation as it passes through the body; it is the source of most of the radiation exposure to the operator.

Ventricularization: Distortion of the recorded arterial pressure waveform such that the diastolic component is blunted, simulating a left ventricular pressure tracing.

GENERAL PRINCIPLES OF CORONARY ANGIOGRAPHY

Historical Perspective

The first selective coronary angiogram was performed in 1958 by Dr. F. Mason Sones, Jr., a cardiologist at The Cleveland Clinic Foundation (3). Quite accidentally, the catheter positioned in the aorta for an angiogram to assess aortic insufficiency dove into the RCA, and an image was obtained before it was fully realized what had occurred. Although the patient's heart rate slowed down transiently, there were no other untoward effects, and the era of selective coronary angiography was born. When Dr. Sones and Dr. Earl K. Shirey published their results of more than 1,000 procedures in 1962, interest in coronary angiography surged. Coronary angiography as a diagnostic tool blossomed with Dr. René Favaloro's description in 1968 of his pioneering work in performing saphenous vein coronary artery bypass grafting at The Cleveland Clinic.

Radiologists played an important role in the development of catheterization techniques in the early 1960s. New preformed catheter designs, such as those by Dr. Melvin Judkins and Dr. Kurt Amplatz, enabled selective angiography to be performed with greater ease than was previously possible with the Sones catheters. Additionally, percutaneous approaches were also now possible, and arterial cutdowns were no longer required. Improvements in radiographic imaging concomitantly led to better image quality. After Dr. Andreas Grüntzig introduced percutaneous coronary angioplasty in 1977, cardiologists were able to make the transition from being diagnosticians to becoming endovascular surgeons.

Coronary Artery Anatomy

Normal Anatomy

The LM coronary artery originates from the left sinus of Valsalva and usually bifurcates into the LAD, which supplies the left ventricle's anterior surface, and the LCx, which supplies the lateral aspect of the left ventricle (Fig. 78.1). The LAD traverses the anterior interventricular groove, giving rise to septal perforating branches to supply the interventricular septum and to diagonal branches that supply the anterolateral wall. It then bifurcates distally and tapers out as a "whale's tail" at the cardiac apex, although sometimes it "wraps around" the apex to supply part of the inferior wall. The LCx courses along the left atrioventricular groove and provides small atrial branches to the left atrium and marginal branches that supply the lateral wall of the left ventricle. The marginal branches are sometimes referred to as *lateral branches*, with the first marginal branch called the *high lateral* and subsequent lateral branches referred to as *lateral* or *posterolateral branches*. Occasionally, the LM coronary artery trifurcates to give rise also to a ramus intermedius branch that supplies the high lateral wall of the left ventricle.

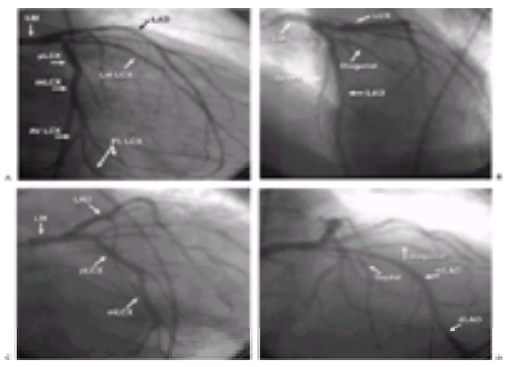

FIGURE 78.1 Normal left coronary artery with segments labeled. **A:** Shallow right anterior oblique (RAO) caudal projection. **B:** Left anterior oblique cranial projection. **C:** Posteroanterior caudal projection. **D:** RAO cranial projection. AV, atrioventricular continuation of the left circumflex artery; dLAD, distal left anterior descending artery; Lat LCX, lateral branch of the left circumflex artery; LM, left main coronary artery; mLAD, mid-left anterior descending artery; mLCX, mid-left circumflex artery; PL, posterolateral branch of the left circumflex artery; pLAD, proximal left anterior descending artery; pLCX, proximal left circumflex artery.

The RCA originates from the right sinus at a slightly more caudal level than the LM coronary artery and supplies the right ventricle and the inferior aspect of the left ventricle (Fig. 78.2). It traverses the right atrioventricular groove and provides small branches to the right atrium and marginal branches to the right ventricle. Approximately 60% of the time, the RCA atrial branches supply the sinus node; otherwise, the LCx atrial branches serve this function. Approximately 50% of the time, the first branch of the RCA is a conus branch, supplying the right ventricular outflow tract; the remainder of the time, the conus branch originates separately from an ostium near the RCA ostium. The dominant artery is generally defined as the one that provides the PDA to supply the posterior wall. In approximately 85% of patients, the RCA is dominant, with the remainder of patients having either a dominant LCx or a codominant RCA and LCx. The PDA of the RCA (or the LCx) courses along the inferior interventricular groove, providing septal perforators, a feature that may aid in its identification and differentiation from the posterolateral segment of the RCA (or LCx), which gives off branches to the posterior ventricle. More than 90% of the time, the artery to the atrioventricular node originates from the atrioventricular branch of the RCA as it passes through the crux.

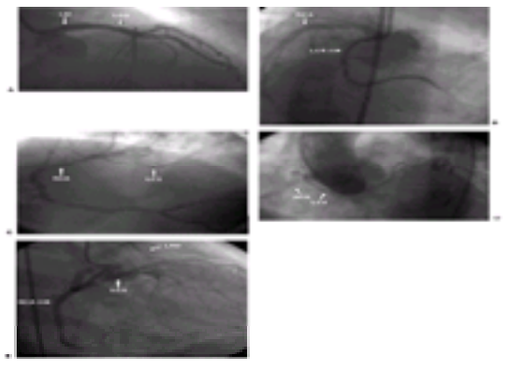
Coronary Anomalies

It is important for the angiographer to be alert for possible variations in normal coronary anatomy (*e*Fig. 78.2.1). In a series of 126,595 patients undergoing coronary angiography at The Cleveland Clinic Foundation, Yamanaka and Hobbs (4) found that coronary artery anomalies occur in 1.3% of patients. Of the anomalies identified, 87% involved anomalies of origin or distribution, and 13% involved the presence of coronary artery fistulae (*e*Table 78.0.1). Most coronary artery anomalies were discovered incidentally, and 81% were considered benign. Some anomalies may be potentially harmful, however, such as a coronary artery that originates from the pulmonary artery or the opposite aortic sinus. For example, most patients with an anomalous origin of the left coronary artery from the pulmonary artery (Bland-White-Garland syndrome) die as infants unless surgical repair is undertaken. In fact, surgical repair is recommended for ectopic origin of the coronary arteries from the pulmonary artery even in the asymptomatic patient.



***e*FIGURE 78.2.1** Coronary artery anomalies. **A:** Angiogram of the left main (LM) coronary artery and left anterior descending artery (LAD), with no left circumflex artery (LCX), raising the suspicion of an anomalous LCX. **B:** Anomalous LCX from the right sinus (same patient as in **A**). In this right anterior oblique projection, the right coronary artery (RCA) and anomalous LCX are seen to fill from the right cusp. (Courtesy of Dr. Mark A. Robbins and Dr. Eric J. Topol.) **C:** Left anterior oblique cranial view of an anomalous LCX originating from the very proximal RCA. (Courtesy of Dr. Keith Kruithoff.) **D:** Aortogram demonstrating anomalous origins of the LCX from the right sinus. **E:** RCA, LCX, and LAD all originating from the right sinus.

***e*TABLE 78.0.1** RELATIVE FREQUENCY OF CORONARY ARTERY ANOMALIES

Anomaly	% of total
Separate origin of the LAD and LCx	30.4
LCx from right sinus or RCA	27.7
RCA from aorta	11.2
Small coronary artery fistulae	9.7
RCA from left sinus[a]	8.1
Multiple or large fistulae[a]	3.7
LAD from right sinus[a]	2.3
Single left coronary artery[a]	1.85
Single right coronary artery[a]	1.46
LM from right sinus[a]	1.3
LM from aorta	0.95
LM from pulmonary artery[a]	0.59
Absent LCx (with very dominant RCA)	0.24
RCA from posterior sinus	0.24
Intercoronary communication	0.18
RCA from pulmonary artery	0.12
LAD from pulmonary artery[a]	0.06
LM from posterior sinus	0.06

LAD, left anterior descending artery; LCx, left circumflex artery; LM, left main coronary artery; RCA, right coronary artery.

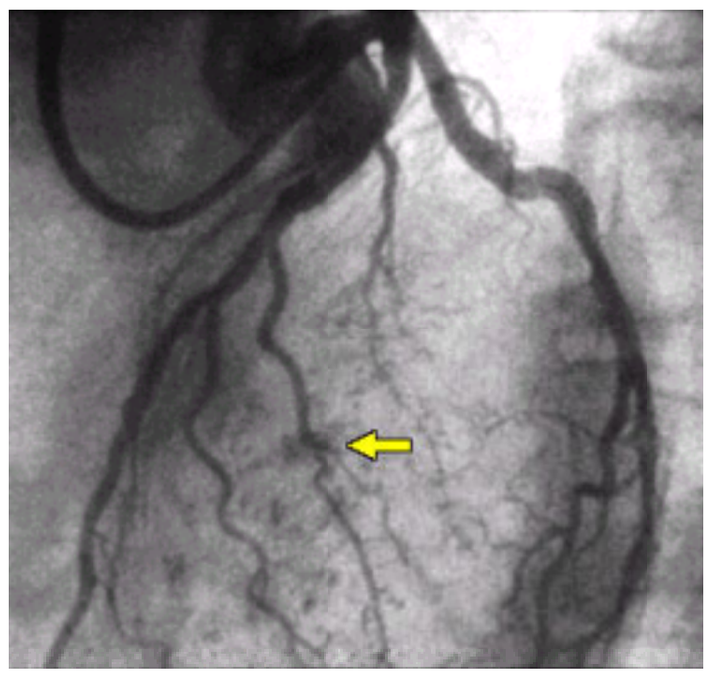
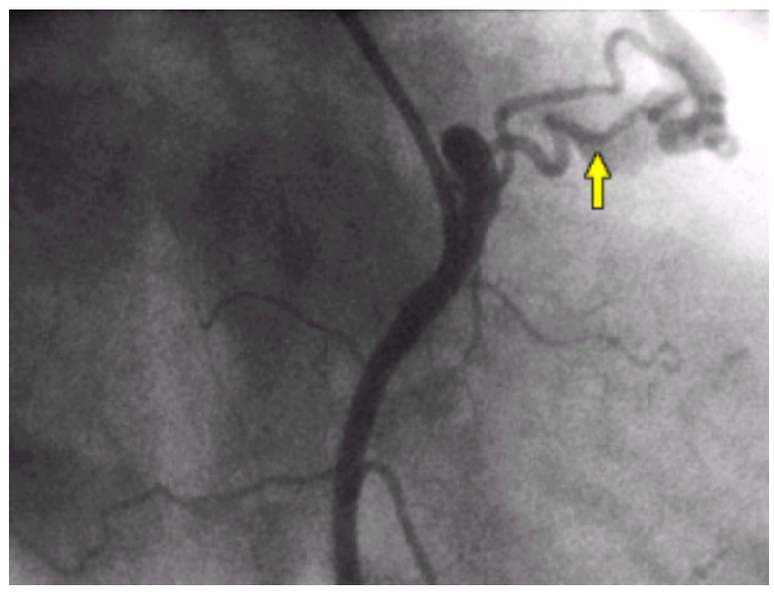
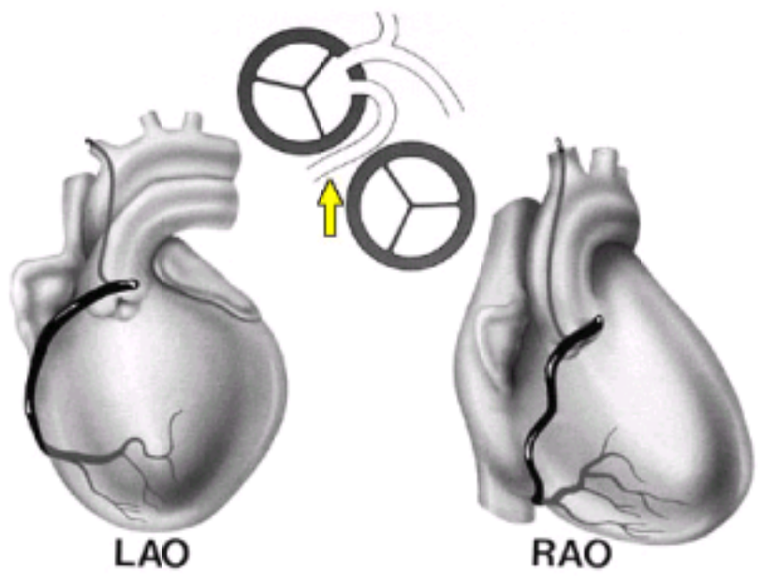
Left circumflex artery fistula to right atrium. There is a large serpiginous vessel arising from the circumflex (*yellow arrow*) that terminates in the right atrium (*white arrow*).



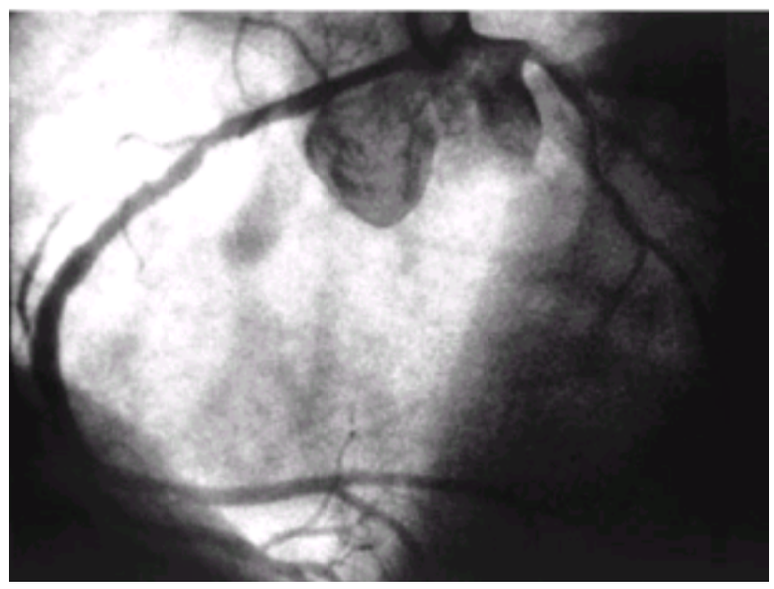
Diagonal artery fistula to the left ventricular cavity (*yellow arrow*). In this left anterior oblique projection, faint opacification of the left ventricular cavity is visible upon injection of the left coronary artery.



Fistula from the right coronary artery to the pulmonary artery (*yellow arrow*).



Fistula from the right coronary artery to the pulmonary artery (*yellow arrow*).



Angiogram showing anomalous origin of the right coronary artery. In this left anterior oblique cranial projection the right coronary artery originates from the left sinus of Valsalva and passes between the aorta and pulmonary artery.

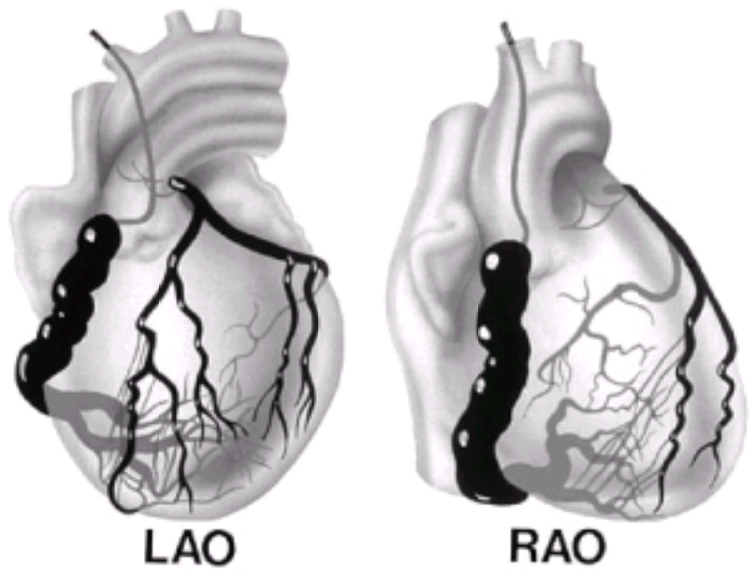


Diagram of the right coronary artery originating from the right sinus of Valsalva and providing collateral circulation to the left coronary artery, which drains directly into the pulmonary artery. This is described as the Bland-White-Garland anomaly. Left panel depicts a left anterior oblique projection of a injection of the right coronary artery arising from the right sinus of Valsalva which provides rich collateral circulation to the left anterior descending and left circumflex arteries, which fill in a retrograde fashion and drain into the pulmonary artery. The right panel depicts the right anterior oblique projection of the same.

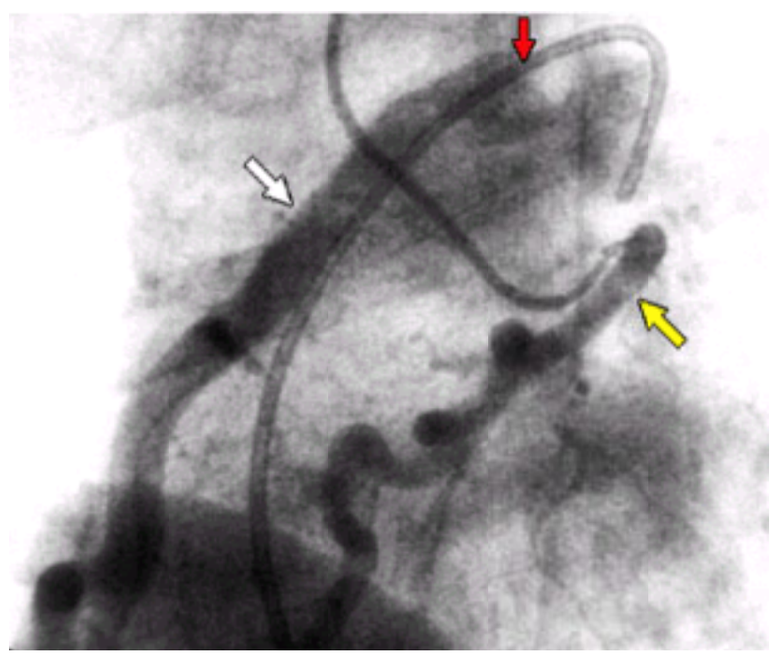
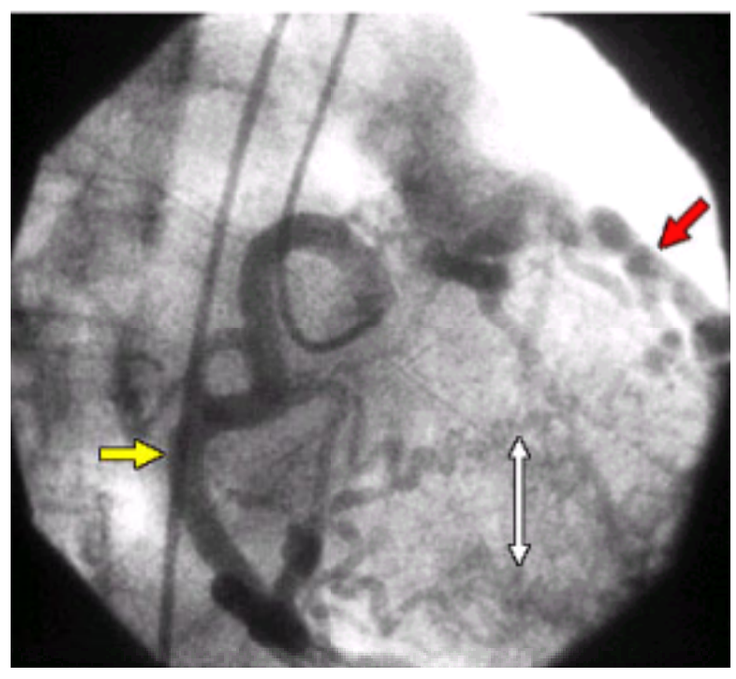


Bland-White-Garland anomaly. This left anterior oblique angiogram demonstrates injection of the right coronary artery (*yellow arrow*) originating from the right coronary sinus with return of contrast material from the left coronary artery (*white arrow*) into the pulmonary artery as demonstrated by the placement of the Swan-Ganz catheter (*red arrow*).



Bland-White-Garland anomaly. The right anterior oblique angiogram demonstrates injection a serpiginous and dilated right coronary artery (*yellow arrow*) that provides generous collateral circulation (*white arrow*) to the left coronary artery (*red arrow*), which originates from the pulmonary artery.

Origin of the left coronary artery from the right sinus may also lead to sudden death, depending in large part on the traversal of the anomalous artery. If the anomalous vessel travels intramyocardially through the septum (the most common variant of this anomaly), or anteriorly or posteriorly, symptoms of ischemia are less likely. If the anomalous artery courses between the pulmonary artery and aorta, however, exercise may lead to expansion of the aorta and compression of the anomalous LM coronary artery, potentially causing symptoms or leading to sudden death. In this latter variant, the LM coronary artery projects on end as a “dot” on the anterior surface of the aorta during a ventriculogram or aortogram in an RAO projection. Likewise, a single coronary artery or large coronary artery fistulae may be problematic (*e*Fig. 78.2.2). Large coronary artery fistulae may present with heart failure or ischemia, and they may also cause endocarditis; therefore, endocarditis prophylaxis is recommended (5). Small coronary artery fistulae, however, are rarely problematic. These fistulae typically originate from the LAD and drain into the pulmonary artery two-thirds of the time, with drainage into a cardiac chamber in the remainder of instances.

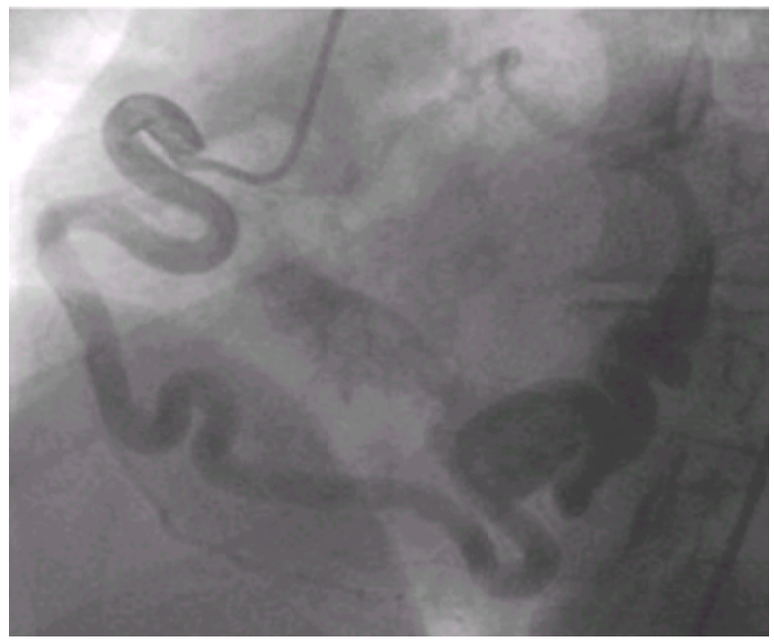
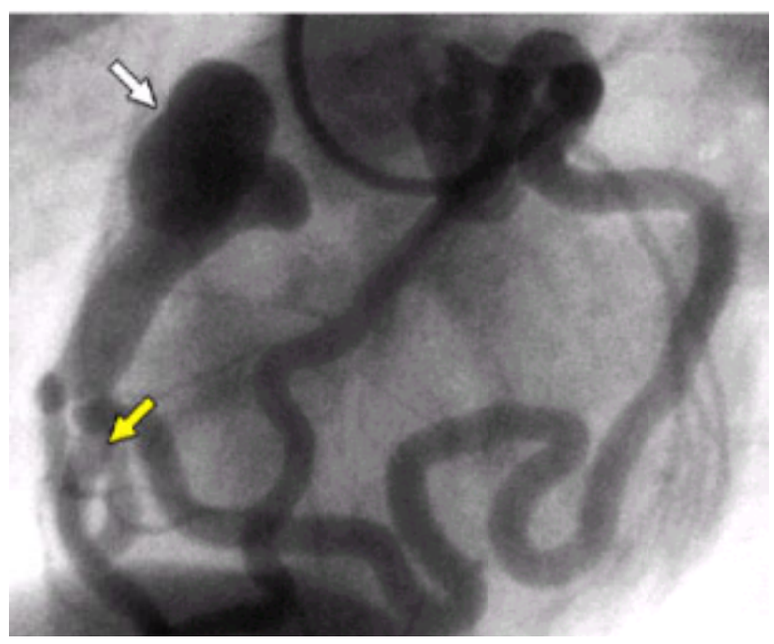
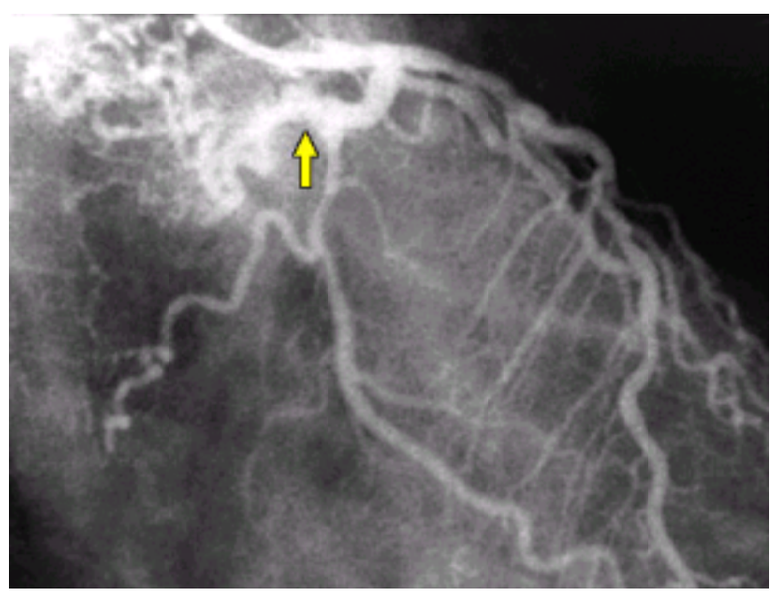
Single coronary artery originating from the left sinus of Valsalva. This left anterior oblique projection demonstrates injection of the left coronary artery that perfuses the entire heart.



A 46-year-old female patient with congestive heart failure. Coronary angiograms revealed large coronary arteriovenous fistula involving the right coronary artery. The patient underwent surgical ligation of the fistula with resolution of her symptoms.



Anomalous connection of the left coronary artery to the right coronary artery with fistula to the right atrium. This left anterior oblique projection demonstrates an anomalous connection of the left circumflex to the right coronary artery (*yellow arrow*) and a fistula from the right coronary artery to the right atrium (*white arrow*).



Left coronary artery fistula to the pulmonary artery. This right anterior oblique projection demonstrates a fistula from the left circumflex to the pulmonary artery (*yellow arrow*).

The association between coronary artery anomalies and congenital heart disease is noteworthy. Approximately 10% of patients with coronary artery anomalies have some form of congenital heart abnormality, such as a bicuspid aortic valve (6). In tetralogy of Fallot, for example, the LAD sometimes originates from the right sinus, crossing the right ventricular outflow tract. Although communication between cardiologist and cardiac surgeon is always important, it is especially critical to convey the presence of any anomalies that may have an impact on the surgical approach, so as to prevent any accidental transection or ligation of anomalous coronary arteries (7).

Myocardial Bridging

Systolic compression of a coronary artery is referred to as *bridging* (eFig. 78.2.3). Approximately 12% of normal angiograms demonstrate some degree of myocardial bridging, although only 1.7% show systolic narrowing of more than 50% (8). Bridging occurs in the mid-LAD when it courses through the septum. If this is the case, it is important to note this for the surgeon, as it makes grafting more technically challenging, especially from a minimally invasive approach. Myocardial bridging of septal perforating branches, also called *septal squeeze*, is commonly found in hypertrophic cardiomyopathy and aortic stenosis and occasionally with severe proximal LAD stenosis, but rarely in normal hearts (9). Other more unusual locations for bridging include the PDA. When a circumflex marginal branch is intramyocardial, ventricular systole usually produces little or no compression. The intramyocardial portion appears unusually straight rather than serpentine. Nitrate administration tends to make bridging more apparent angiographically. As the majority of coronary flow occurs in diastole, the systolic phenomenon of bridging rarely leads to ischemia (8). In the few instances in which it does lead to objective signs of ischemia, stenting has been performed successfully (10,11,12 and 13).

Collateral Circulation

When an occlusion or severe narrowing of a coronary artery develops, collateral channels may form from a nearby artery to supply blood to the hypoperfused area of myocardium (eFig. 78.2.4). Although it may be confusing on a two-dimensional image, as a general principle, collaterals form between arteries that are situated on the same area of the heart, and such connections cannot form if a cardiac chamber is superimposed in between. For example, collateral development via septal perforators is common between the LAD and PDA when one of these vessels is occluded. Occasionally, a separate conus branch arising near the RCA supplies collaterals to the LAD; identification is important if consideration is being given to bypass surgery targets. Kugel's artery is a small vessel that arises from the proximal RCA or LCx, or both, and traverses the interatrial septum; it commonly terminates near the crux, where it may act as a source of collaterals to the distal RCA or LCx via the atrioventricular nodal artery. Just as collaterals may develop between different coronary arteries, intracoronary collaterals, so-called bridging collaterals, may form from the same coronary artery across an area of total vessel occlusion. Identification of such bridging collaterals and recognition of an underlying chronic total occlusion are important. Although rare, pericardial or bronchial arteries may provide coronary collaterals (14). When collaterals are present from more than one source, competitive flow from both sources may occur, leading to inadequate opacification of the target vessel; this may produce the false appearance of a significant luminal obstruction at the point where the two collateral flows meet.

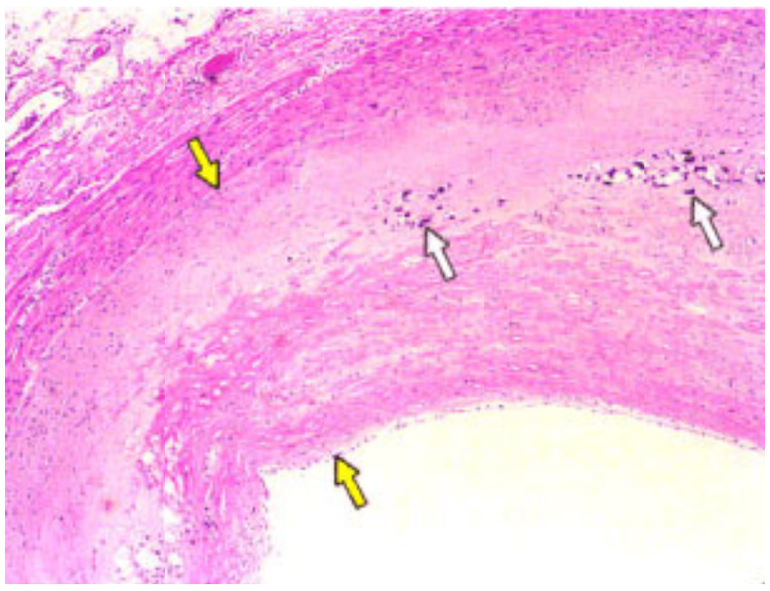
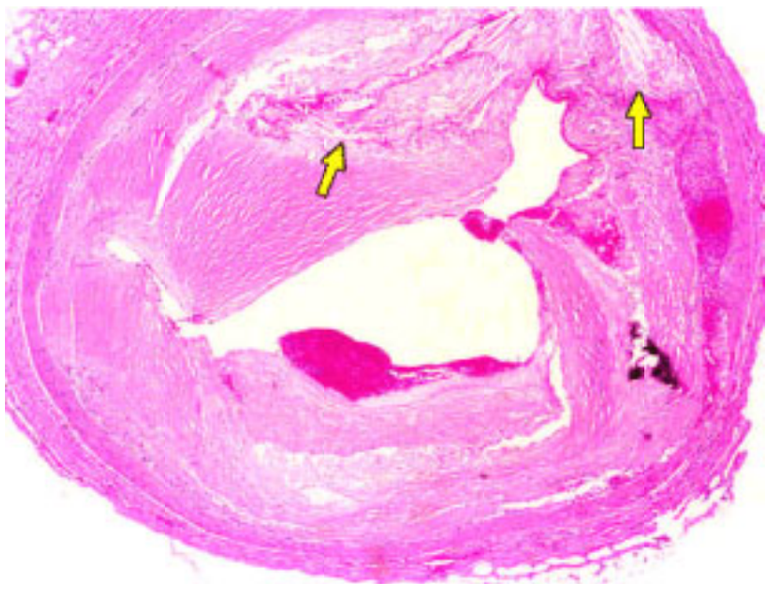
***e*FIGURE 78.2.4** Collateral circulation. **A:** Angiogram demonstrating collateral flow (*arrow*) from the right coronary artery supplying the area beyond occlusion of the left circumflex artery. (Courtesy of Dr. Mark A. Robbins.) **B,C:** Collaterals (*arrows*) from the atrioventricular left circumflex artery to the distal right coronary artery.

Lesion Assessment

An important component of coronary angiography is the description of coronary artery stenoses. Historically, lesions of at least 70% diameter stenosis of a coronary artery (50% diameter stenosis of the LM coronary artery) are considered hemodynamically significant. For the purposes of many research studies, 50% or greater stenosis constitutes significant coronary artery disease. However, the realization that the majority of myocardial infarctions are due to stenoses of less than 50% severity underscores the importance of the identification of milder degrees of atherosclerosis. Thus, the term *clean coronary arteries* is best avoided, because the absence of hemodynamically significant lesions does not preclude plaque rupture and a future ischemic event.



Advanced coronary atherosclerosis. There is fibrotic intimal thickening marked by the yellow arrows with small areas of intimal calcification (*white arrows*).

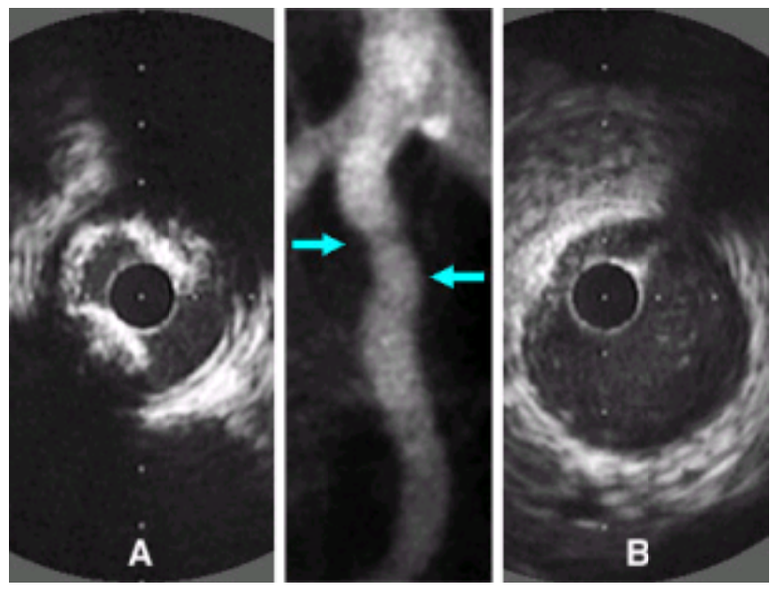


Severe fibrocalcific atherosclerosis. This is a hematoxylin-eosin stained specimen showing significant luminal narrowing with prominent cholesterol clefts within the atheromatous material (*yellow arrows*). The irregular lumen suggests remote thrombosis with recanalization.

Video 78.8 Ostial left main coronary artery disease. Contrast injection reveals severe narrowing of the ostium of the left main coronary artery. In this patient, after coronary artery bypass graft surgery there was rapid acceleration of the underlying coronary disease leading to this left main stenosis. *This video must be viewed with*

QuickTime. If you do not have QuickTime you may download it here.

Video 78.9 Left anterior oblique caudal view of the left main trunk showing severe ostial stenosis. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Limitations of angiography. Haziness in angiogram (*top arrow*) corresponds to lesional calcium (A). In comparison, a site just distal to the lesion (*bottom arrow*, B) remains within normal limits.

In addition to the percent diameter stenosis, the morphology and length of the lesion are important and should be described. The presence of calcification, angulation, eccentricity, or ulceration should be noted, because these characteristics may have an impact on the ability to perform percutaneous intervention (15) (eFig. 78.2.5). Any angiographically apparent thrombus should be mentioned (eFig. 78.2.6). However, the absence of thrombus on an angiogram does not mean that none is present, because angiography is a relatively crude method to detect thrombus (16). The size of the vessel should also be described, because lesions in vessels that are smaller than 1.5 mm usually do not warrant bypass surgery or angioplasty. Lesion size can be estimated by comparison with the size of the catheter. A 6-French (Fr) catheter is approximately 2 mm in external diameter (0.33 mm per Fr size). Automated quantitative coronary analysis is now commonly available and can be used to quantitate stenosis severity and length with more consistency than visual estimation (17).

The modified American College of Cardiology (ACC)/American Heart Association scoring system incorporates multiple angiographic features of coronary obstructions, which helps the cardiologist stratify the risk of angioplasty (18). Lesions that are categorized as *type A* are simple lesions, *type B1* refers to moderately complex lesions, and *B2* signifies a higher degree of complexity than B1. Type C refers to complex lesions, in which angioplasty is less likely to be technically successful and more likely to be associated with complications. Even in the era of stenting, this scoring system appears to be a useful mode of categorizing lesions (19,20). The degree of flow should also be described for acute lesions using the Thrombolysis in Myocardial Infarction (TIMI) flow grade (21). In this scheme, TIMI grade 0 flow refers to no flow past the culprit lesion, and TIMI grade 1 flow refers to penetration of contrast just beyond the lesion, but not into the distal vessel and vascular bed. TIMI grade 2 flow refers to flow that reaches the distal vasculature, but at a slower than normal rate compared with nonculprit arteries. TIMI 2 flow can be further categorized into TIMI 2A, in which dye reaches the distal bed within five systolic cycles; TIMI 2B in which dye reaches the distal bed in more than five cycles; and TIMI 2C, in which inflow is normal but dye washout is slowed (22). TIMI grade 3 refers to normal angiographic flow. The corrected TIMI frame count is a newer method to describe flow, which is more reproducible than the TIMI grading system and may have incremental value (23,24 and 25). Other refinements to angiographic assessment of perfusion such as the TIMI myocardial perfusion grade, which quantifies myocardial blush, are being developed (26).

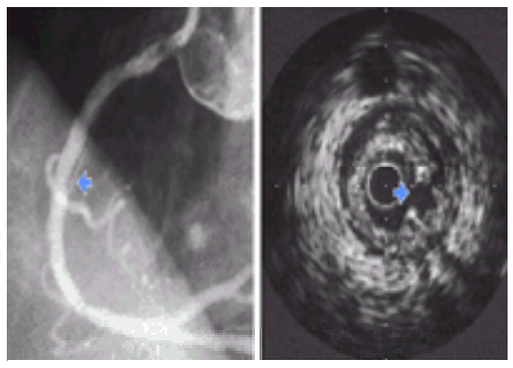
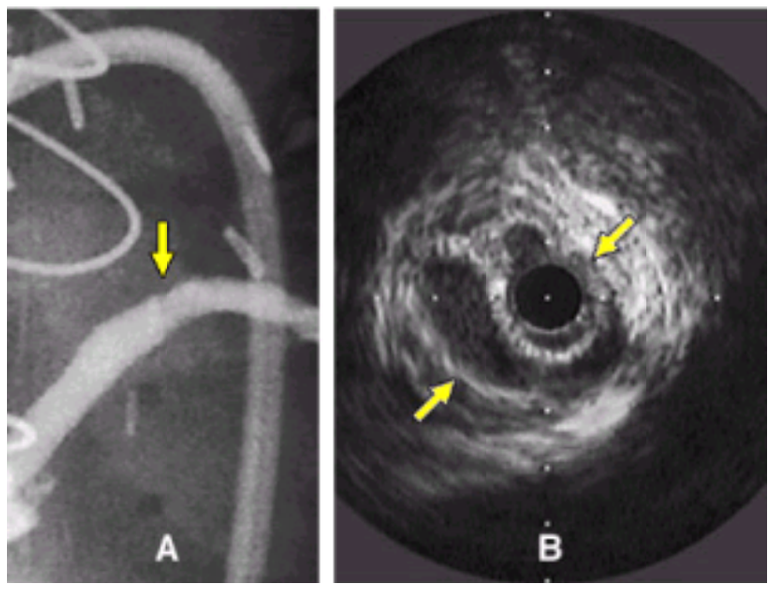
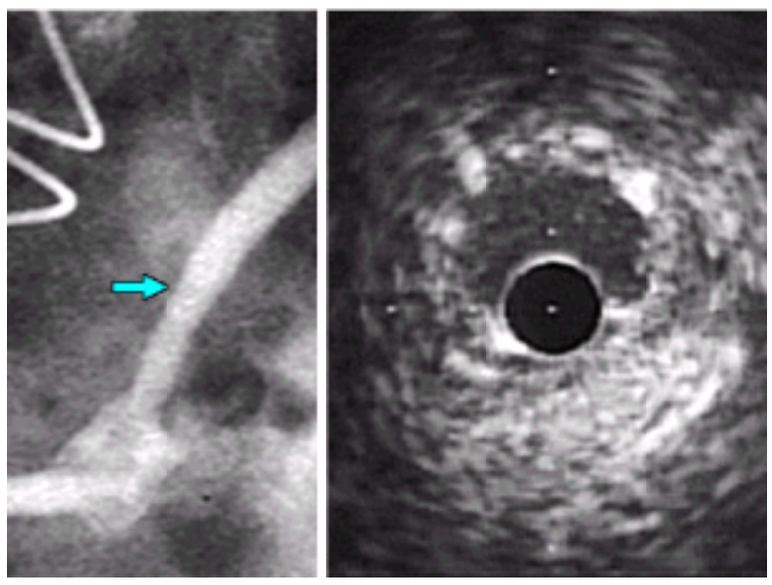
Adjunctive diagnostic modalities that should be considered for ambiguous or indeterminate coronary artery stenoses include intravascular ultrasound (IVUS) and fractional flow reserve (FFR) measurement. IVUS is able to provide a quantitative assessment of luminal dimensions in moderate angiographic lesions. Another insight that IVUS has provided is that the coronary angiogram is truly just a “luminogram” (27). Extensive atherosclerosis may be present with no obstruction detected on angiography (*e*Fig. 78.2.7). The phenomenon of outward remodeling may lead to preservation of the coronary lumen, despite significant plaque burden (28). IVUS enables the angiographer to determine whether remodeling has occurred. Although IVUS may provide better anatomic detail about coronary stenoses, the hemodynamic significance of a lesion may be better assessed by the FFR. Measurement of the FFR allows performance of stress testing in the catheterization laboratory with infusions of vasodilators such as adenosine.

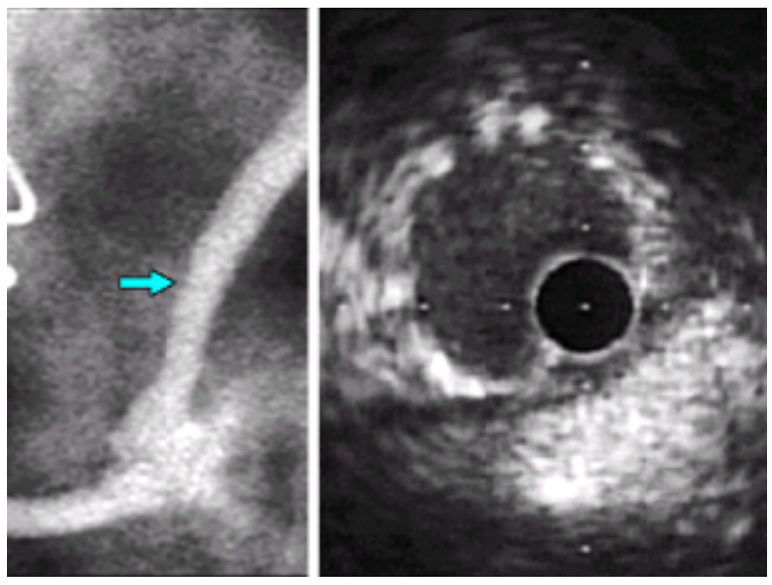


***e*FIGURE 78.2.7** Eccentric coronary artery stenosis (*arrows*). Because of the complex three-dimensional nature of this severe stenosis, single, or even multiple, two-dimensional angiograms may easily underestimate the true severity of the lesion.



Limitation of angiography: A minor angiographic luminal irregularity is present at the distal end of a stent (A, *arrow*) in a saphenous vein graft. IVUS (B) shows a dissection with two flow channels. The arrow at 2 o’clock shows the true lumen containing the imaging catheter, and the arrow at 7 o’clock indicates the false lumen.

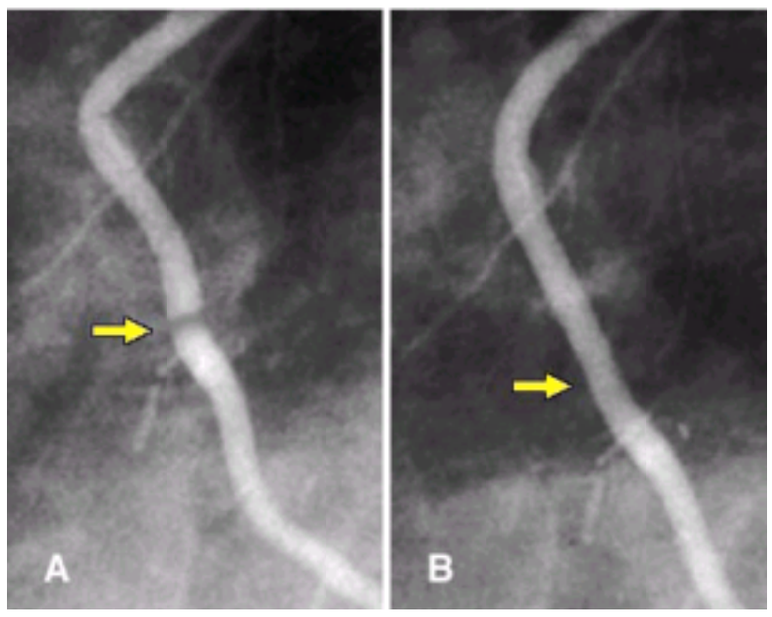




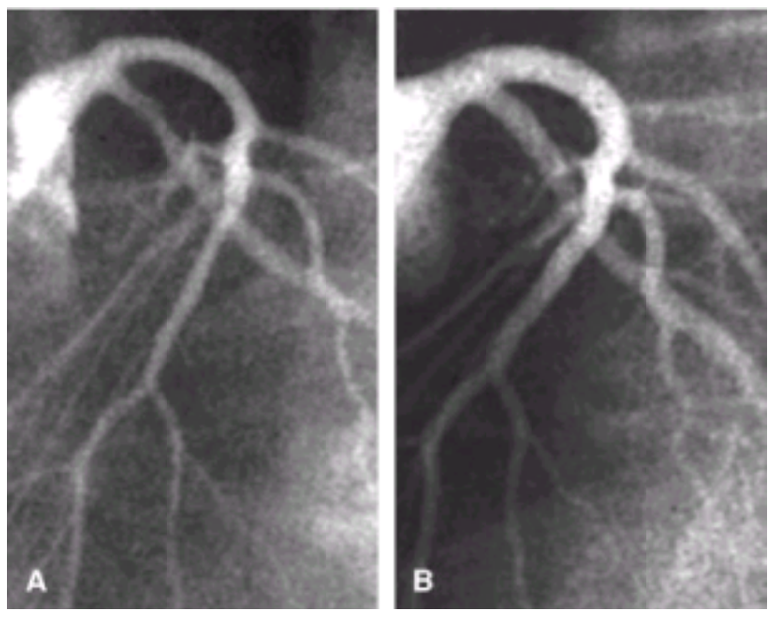
Role of intravascular ultrasound in optimizing stent deployment. Although the angiogram shows minimal residual stenosis (A), the intravascular ultrasound lumen size is small (<5 mm^2). After further dilatation (B), the lumen area increased to >7 mm^2.

Coronary Artery Spasm

Prinzmetal's angina or *variant angina* refers to the syndrome of coronary artery spasm that causes transient ST-segment elevation during angina (29,30). This may result in anginal chest pain at rest, often in the early morning, as well as syncope from heart block or ventricular arrhythmias. The coronary arteries of these patients are predisposed to spasm, often despite the absence of angiographically severe atherosclerosis. Prinzmetal's angina is rare, and it is recognized clinically even less often than in the past due to the advent of calcium channel blockers and long-acting nitrates (31). In patients with no significant atherosclerosis but a suspicion of spasm, Holter monitoring may reveal ST-segment shifts that verify the diagnosis. If angina occurs concurrent with ST-segment elevation in a patient with a "normal" catheterization, the diagnosis is made, with no need for confirmatory provocative testing.



Spasm of the left internal mammary artery after bypass surgery. In the left panel, a significant stenosis is evident that is completely resolved after administration of nitroglycerin. Spasm of the left internal mammary bypass graft can lead to ischemia in the perioperative period after coronary surgery.



Spasm of the left main coronary artery and proximal left anterior descending and left circumflex coronary arteries. The caliber of the left main, proximal left anterior descending, and circumflex arteries are smaller than the distal vessels. This can be better appreciated after administration of intracoronary nitroglycerin.

Provocative testing for coronary artery spasm is most likely to be clinically useful in the patient with no severe coronary artery obstructions, in whom it has been impossible to document the diagnosis. It is not likely to be useful in patients with fixed severe coronary obstructions, and the risk of testing is increased in these individuals. The major risk of provocative testing is unrelenting spasm, with subsequent myocardial infarction. Therefore, when this test is performed, intraarterial nitroglycerin and calcium channel blockers should be immediately available. The method to perform provocative testing involves administration of 0.05 mg intravenous (i.v.) methylergonovine while monitoring a complete electrocardiogram every minute (32,33). If typical chest pain or electrocardiographic changes develop, the coronary arteries should be reimaged immediately. The location of the ST elevation should guide which coronary artery to image first. If there is no ST elevation, the RCA should be catheterized first, because it is more likely to be the culprit. Five minutes after the methylergonovine has been administered, if there has been no chest pain or electrocardiographic changes, the coronary arteries should be reimaged. If there is no evidence of spasm, 0.2 mg methylergonovine should be administered and the above procedure repeated. Some operators prefer to omit the 0.05-mg dose to save time. If spasm does occur, 100 to 200 µg nitroglycerin should be administered intraarterially to relieve the spasm, and the diagnosis is made. Intracoronary acetylcholine is another provocative agent for coronary spasm, but it probably lacks the specificity of methylergonovine.

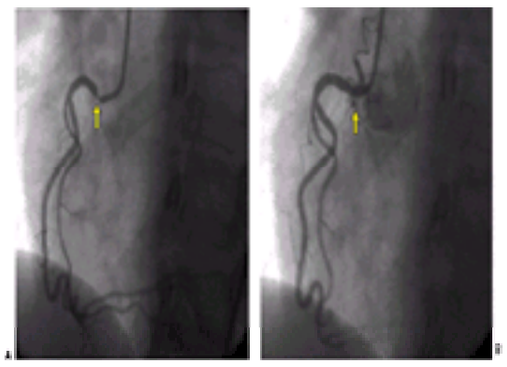
Diffuse spasm that occurs without angina or ST-segment changes may be physiologic and is not diagnostic of Prinzmetal's angina. Methylergonovine-induced severe coronary spasm may recur after immediate treatment because of the longer half-life of methylergonovine compared with nitroglycerin; therefore, the patient should be observed and treated with systemic long-acting nitrates and calcium channel blockers (34). Provocative testing should be avoided in patients with severe systemic or pulmonary hypertension, as well as in patients who may be pregnant. Spasm may also be an etiology of chest pain or myocardial infarction after acute alcohol ingestion or cocaine use, in which cases the clinical history is useful in making the diagnosis (35). Nonischemic, "catheter-induced" coronary spasm, especially ostial spasm, may be triggered by the catheter tip (eFig. 78.2.8).



***e*FIGURE 78.2.8** Catheter tip spasm of the ostium (*arrows*) of the right coronary artery **(A)** before and **(B)** after intracoronary nitroglycerin. (Courtesy of Dr. Marc S. Penn.)

Coronary Artery Dissection

Rarely, spontaneous coronary artery dissection produces an ischemic syndrome or sudden death (36). Much of what is known about this entity is from case reports in the literature, with no one center having enough experience to make definitive statements about its etiology or natural history. Predisposing factors include pregnancy, a burst of intense physical exertion, and cocaine use (37,38). Pregnant or postpartum women are the demographic group in which spontaneous coronary artery dissection is most commonly seen, and the LAD is the vessel that is most frequently involved (39). Severe hypertension may also predispose to spontaneous dissection (40). Although not exactly spontaneous, blunt trauma, such as from a motor vehicle accident, may also lead to dissection (41). Aortic dissection may also extend into the coronary arteries, particularly the RCA. Marfan's syndrome may be complicated by coronary dissection, as may connective tissue disorders such as Ehlers-Danlos syndrome. Arteritis, such as that due to polyarteritis nodosa, may lead to dissection (42). Additionally, dissection may occur as a result of catheter trauma. It is important to recognize this entity, which may appear as a radiolucent flap in the opacified artery or as a linear persistent stain in the arterial wall after the contrast material has cleared from the true lumen (*e*Fig. 78.2.9).

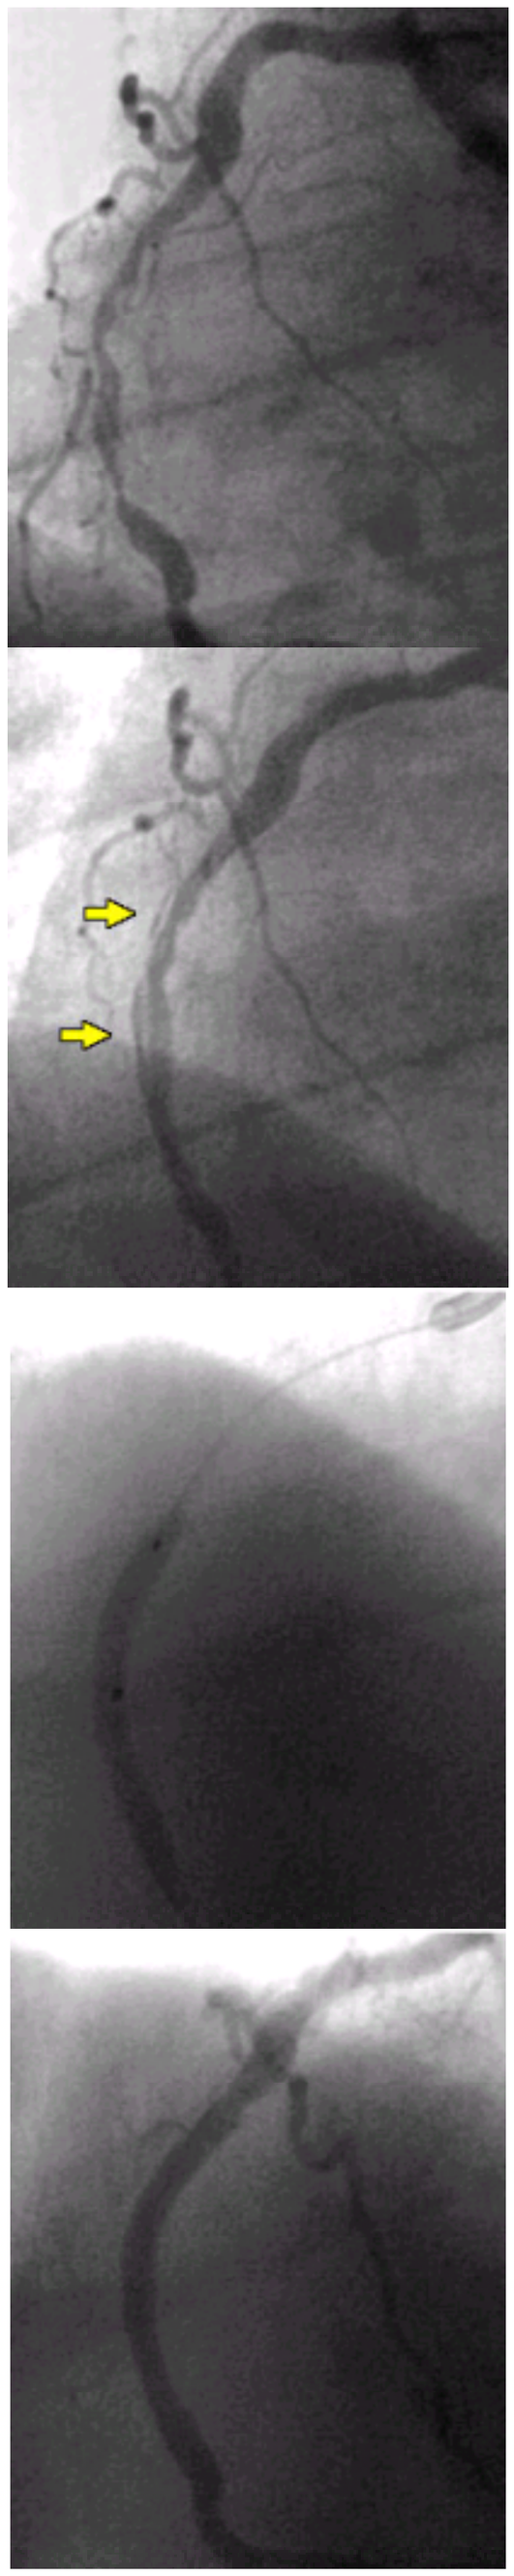
Regardless of the cause, dissection can often be treated percutaneously with stent deployment (43,44). Although healing of dissection with conservative treatment has been reported, this approach is less common in the interventional era (45). In some instances of postpartum dissection, immunosuppressive therapy has been used with success (46). Eosinophils appear to be present in the dissection plane in cases of peripartum dissection, similar to peripartum cardiomyopathy, suggesting an inflammatory etiology in at least some instances (47). The plane of dissection is often between the media and adventitia of the vessel, although in some cases, an

intimal tear is noted at autopsy. Some cases of spontaneous dissection, especially in older individuals at risk for atherosclerosis, are probably due to plaque rupture and intimal dissection (48).



“Bailout” stent placement for a long dissection complicating balloon angioplasty. After balloon angioplasty of a long lesion of the mid-right coronary artery (A), a long linear dissection flap is apparent (B, *arrows*). A 39-mm-long AVE stent is deployed across the area of dissection (C). No residual stenosis is present after stent placement (D).

Coronary Artery Ectasia and Aneurysm

Coronary artery ectasia refers to an abnormal enlargement of the coronary arteries (eFig. 78.2.10). Arteries that are ectatic appear to be prone to thrombus formation, dissection, and spasm (49). Additionally, prior percutaneous intervention occasionally leads to development of segments of ectasia. When the area of dilatation is more than 1.5 times the diameter of the normal portion of the artery, the enlarged portion is referred to as an *aneurysm* (50). The RCA is the vessel that is most frequently involved. Atherosclerosis is the most common cause of coronary ectasia and aneurysm (51). Kawaski’s disease may lead to formation of giant coronary artery aneurysms in approximately 20% of untreated patients (52,53,54 and 55). Mycotic aneurysms of the coronary arteries occur rarely (56). Historically, large coronary artery aneurysms have been treated conservatively with antiplatelet or anticoagulant therapy, or both, but, more recently, surgery as well as intracoronary stent graft

deployment have been used (57,58). When there is an associated stenosis, invasive treatment may be indicated.

Indications for Coronary Angiography

Coronary angiography is indicated when there is a need for delineation of coronary artery anatomy. The ACC has published guidelines to assist the clinician in appropriate use of this invasive procedure (59) (Table 78.1). Indications are listed as class I when there is general consensus that angiography is indicated, class II when there is a divergence of opinion, and class III when there is consensus that angiography should not be performed. The guidelines are useful as a starting point for discussion about evidence supporting angiography for specific indications. In a patient with anginal chest discomfort and evidence of ischemia on a functional study, coronary angiography may reveal a stenosis that is amenable to angioplasty or coronary artery bypass surgery (class I). In a patient with an acute coronary syndrome, angiography is given a class II indication. However, emerging evidence supports an invasive approach in the initial evaluation of patients with acute coronary syndromes (60,61). The development of pharmacologic adjuncts, such as the glycoprotein IIb/IIIa inhibitors, has enhanced the safety of percutaneous intervention and broadened the indications for cardiac catheterization. Thus, the ACC guidelines provide a framework for the practice of evidence-based medicine but do not substitute for clinical judgment, and they do not necessarily incorporate the most current research.

TABLE 78.1 INDICATIONS FOR CORONARY ANGIOGRAPHY

Contraindications o Coronary Angiography

The only absolute contraindication to coronary angiography is patient refusal. According to the ACC classification, indications that are labeled as class III are actually situations in which coronary angiography is contraindicated (Table 78.1). Common sense supports these recommendations. Additional relative contraindications are shown in Table 78.2. It should be emphasized that *relative* contraindications imply that in certain urgent clinical circumstances, proceeding with angiography may be appropriate, although caution must be exercised.

Renal insufficiency
Bleeding diathesis or active bleeding
Fever or active infection
Aortic valve vegetation
Anemia
Severe dye allergy
Metabolic abnormalities
Hyperkalemia
Hypokalemia
Digitalis toxicity
Uncontrolled hypertension
Decompensated heart failure
Uncontrolled tachyarrhythmia
Untreated high-grade heart block

TABLE 78.2 RELATIVE CONTRAINDICATIONS TO CORONARY ANGIOGRAPHY

Operator Proficiency

The ACC has set minimum training requirements for the performance of diagnostic angiography. During cardiology fellowship, each trainee must perform 300 diagnostic coronary angiograms while serving as the primary operator on 200. Operator and institutional procedure volumes are linked to outcomes in the catheterization laboratory (62). After training is completed, a minimum yearly volume of 150 diagnostic catheterizations per year for each angiographer has been recommended, although more recently the number has been revised to 100 (63). It is desirable to have cardiac surgical backup nearby (64). Although nonphysicians may assist in coronary angiography, they should not function as independent operators (65). Additionally, performance standards for cardiac catheterization laboratories have been established. Principally, this involves monitoring of procedural outcomes to ensure that some degree of internal review of complications occurs (66,67).

Informed Consent

The risks, benefits, and alternatives to coronary angiography should be discussed with the patient and also the family, if possible. Specifically, the risk of death, stroke, myocardial infarction, renal failure, or emergency coronary bypass surgery should be discussed. Notation of this discussion should be made in the medical record to satisfy the legal requirements for “informed consent.” In particular, consideration should be given for noninvasive assessment of coronary artery disease, if this can be substituted for initial diagnostic angiography. A discussion about percutaneous intervention and its greater level of risk should also occur at this time. Separate informed consent should be obtained for this procedure, because many patients who undergo diagnostic angiography proceed to angioplasty at the same setting.

Preprocedural Medication

Aspirin, 325 mg, should be given to eligible patients before the procedure in case an angioplasty is necessary. If the probability of percutaneous intervention seems high, a loading dose of clopidogrel, 300 mg, can also be given. Metformin (Glucophage) should be discontinued on the day of the procedure, because this medication may cause lactic acidosis if renal failure results from the procedure and if metformin is continued after the onset of renal failure (68). Warfarin should be stopped before the procedure if possible until the international normalized ratio is less than 1.8. If anticoagulation is essential, warfarin can be stopped several days before the anticipated procedure, and subcutaneous injections of the low-molecular-weight heparin, enoxaparin (1 mg per kg b.i.d.), can be substituted; the dose of enoxaparin can then be withheld the morning of the procedure.

Sedation

Conscious sedation is generally administered during cardiac catheterization procedures. Proper sedation increases the likelihood of the procedure going smoothly. This important part of the procedure is often overlooked. Lack of adequate sedation may lead to an uncooperative patient, as well as increases in blood pressure and a greater tendency to vagal reactions. Before the catheterization, the patient should be assessed for suitability for conscious sedation. Specifically, the airway should be examined. Certain patients, such as those with sleep apnea or a body habitus that suggests a predisposition to sleep apnea, should be sedated with caution. During the procedure, continuous pulse oximetry must be performed, with oxygen supplementation as necessary. Again, preprocedural assessment should include evaluation for pulmonary diseases that may predispose to hypopnea and elevations of carbon dioxide levels with oxygen supplementation. Similarly, continuous electrocardiographic monitoring and blood pressure measurement with an automated blood pressure cuff maximize the safety of conscious sedation.

A benzodiazepine or opiate can be used for initial sedation. Frequently, a combination achieves excellent patient comfort. The benzodiazepine may also provide some degree of retrograde amnesia such that the patient does not recollect any unpleasant aspect of the procedure. The benzodiazepine of choice is midazolam (Versed) because it has a rapid onset but is short-acting. An initial dose of 0.5 mg or 1.0 mg i.v., with repeat dosing every few minutes, may achieve sedation safely. Fentanyl, a short-acting agent, can be used for the opiate. A dose of 25 or 50 µg i.v. can be used initially. For more prolonged cases, morphine, at a dose of 1 to 3 mg i.v., can be substituted as the opiate if the patient has tolerated the initial fentanyl.

Radiation Principles and Safety

Most catheterization laboratories have already moved to digital image acquisition, distribution, and archiving. A major factor enabling this transition has been the widespread adoption of the Digital Imaging Communication in Medicine (DICOM) standard (69). In addition to improving image quality, digital imaging may lower radiation exposure to the operator by approximately 20%. Retrieval of angiographic information and transfer of data among physicians are also easier, because a typical catheterization study may easily fit on a single CD or be distributed rapidly on a high-bandwidth network.

Efforts to reduce radiation exposure to the angiographer and patient are important because the cumulative doses of radiation with repeated exposures can produce direct tissue injury (deterministic effects) and neoplasms (stochastic effects). Risk reduction efforts fall into two major categories: radiation protection (usually protection of the operator from radiation exposure) and radiation production. All efforts aimed at reducing radiation exposure must take into account their effects on the operator, patient, and image quality. These effects are often discordant—that is, maneuvers that decrease radiation exposure to operators and patients may degrade image quality. These effects are summarized in *e*Table 78.2.1.

***e*TABLE 78.2.1** FACTORS AFFECTING IMAGE QUALITY AND RADIATION EXPOSURE TO LABORATORY PERSONNEL AND PATIENT

Method	Operator dose	Patient dose	Image quality
Patient, operator protection			
Lead gown, thyroid collar	Lower	Same	Same
Leaded glasses	Lower	Same	Same
Lead shield above, below table	Lower	Same	Same
Increased distance from operator to table	Lower	Same	Same
Femoral vs. brachial approach	Lower	Same	Same
Operator’s fingers out of direct beam	Lower	Same	Same
Move patient’s arm out of field	Lower	Lower	Better
Radiation dose reduction			
Shorter fluoroscopy, cine times	Lower	Lower	Same
Pulsed fluoroscopy	Lower	Lower	Same
Fewer pulses/sec	Lower	Lower	Worse
Fewer cine frames/sec	Lower	Lower	Worse
Greater distance from source to patient	Variable	Lower	Better
Smaller distance from image intensifier to patient	Lower	Lower	Better
Electronic image magnification	Variable	Higher	Better
Smaller collimator opening	Lower	Variable	Better
Cranial, caudal angulation	Higher	Higher	Worse
Large patient, pleural effusion	Higher	Higher	Worse

Radiation protection for the operator is accomplished by a variety of shielding and positioning mechanisms. A thyroid collar and lead apron provide excellent protection

for the operator's thyroid (which decreases the likelihood of thyroid cancer) and trunk. Leaded glasses should be worn because radiation exposure increases the risks of cataracts; a headband may make these heavy glasses less uncomfortable. The catheterization table should be equipped with two lead shields: one for the lower body and an adjustable leaded glass shield to protect the operator's upper body and head. Doubling the distance of the operator from the x-ray entrance beam site reduces the operator's dose to one-fourth. The femoral approach, in which the operator is farther away from the site of radiation, is likely to decrease the operator's exposure compared to the brachial approach. Operators should never permit repeated or prolonged exposure of their fingers in the direct field of radiation, except for extreme emergencies.

Radiation protection for the patient can be provided by avoiding unnecessary radiation exposure to body parts that are not essential to the study. For instance, in angulated views, the patient's arm commonly enters the field of view. Displacing the arm decreases radiation dose to the patient and operator and improves image quality. If a female patient is pregnant, a lead shield placed between the x-ray source and the patient's pelvis may provide some protection, but it functions primarily as a reminder to the operator to avoid fluoroscopy in the vicinity of the pelvis. Protection of the fetus is limited because most of the radiation that the fetus receives is due to scatter radiation, and the lead shield serves only to increase the x-ray dosage to penetrate the shield if fluoroscopy is performed directly over the shielded part of the body.

Radiation production can be reduced by a variety of methods, but care must be taken to achieve adequate image quality. A trade-off is commonly made between radiation dose and image quality (eTable 78.2.1). The operator should manipulate radiation dosage to produce the minimum image quality that is required for the task at hand. For instance, high image quality is generally not needed for passage or placement of catheters, whereas it is usually required for recording of diagnostic information.

Radiation dosage to the patient and operator can be reduced with no change in image quality by shortening the fluoroscopy and cine times and by using pulsed fluoroscopy. The amount of dose reduction that is obtained with pulsed fluoroscopy depends on how the manufacturer configures the equipment. It is possible to achieve large dose reductions, but at the expense of reduced image quality. Reducing the number of fluoroscopy pulses per second and the number of cine frames per second by 50% reduces dose to the patient and operator, but the former produces flicker, and the latter reduces the information content of the study by 50%. Cineangiography leads to greater radiation exposure per second than fluoroscopy. Increasing the distance between the x-ray source and the patient not only improves image quality, but it also reduces the x-ray intensity at the patient's skin and the likelihood of skin injury. For this reason, federal regulations mandate a spacer device mounted on the x-ray tube to maintain a minimum distance of 38 cm between the x-ray source and the end of the spacing device.

Positioning the image intensifier as close as possible to the patient reduces radiation exposure to the patient and the operator, and it improves image quality. The farther the image intensifier is positioned from the patient, the larger the image becomes, because of geometric magnification, but image quality deteriorates as a result of blurring, and the dose increases with the square of the magnification. Electronic image magnification is achieved by decreasing the field-of-view size [e.g., changing from the 9-in. (23-cm) or 7-in. (17-cm) field to the 5-in. (13-cm) field]. Unless collimation is used in the larger field size, changing from the 7-in. mode to the 5-in. mode approximately doubles the entrance dose to the patient, has no major change on dose to the operator, and produces greater spatial resolution. The 5-in. mode is usually optimal for visualizing small coronary arteries.

Radiographic views obtained in LAO, lateral, or steeply angulated cranial or caudal projections result in decreased image quality and increased radiation exposure to the patient and operator. The same applies to any factor that increases the thickness or density of tissue being penetrated, such as obesity, large body size, cardiomegaly, and pleural effusion. If image quality is poor in any of these circumstances, the operator may wish to obtain most images in the RAO projection, switch from the 5-in. to the 7-in. mode, or perform a thoracentesis before the procedure. Use of shields to cover the bright areas of the lungs may decrease radiation exposure and enhance image quality. The use of collimators to minimize the field size improves image quality and decreases scatter radiation to the operator but produces a slight increase in entrance dose to the patient. However, the dose-area product (the entrance dose multiplied by the area of exposure) decreases with collimation, which reduces long-term (stochastic) effects for the patient.

The radiation exposure from a single catheterization is rarely of significance to the patient. After prolonged fluoroscopy (usually in conjunction with prolonged or multiple interventional procedures) radiation dermatitis may rarely occur. This may manifest several hours to days after the procedure as an area of erythema, although weeks or months may pass before other effects of radiation on the skin, such as dermal atrophy or telangiectasia, are manifest.

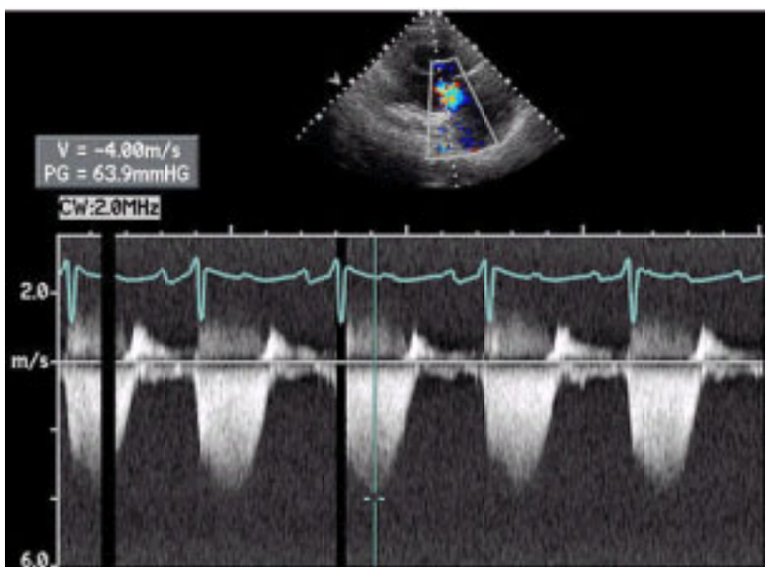
Angiographers must consider the "other side of the coin"—that is, image quality—as they reduce radiation dose. Subjective evaluation of angiographic image quality is unreliable. A new testing system has been introduced that permits standardized objective benchmarking of cardiovascular radiographic equipment performance (69a). This unique testing system permits evaluation of spatial and contrast resolution in relation to radiation dose in an anthropomorphic phantom. The clinical utility of this system remains to be validated.

Selection of Contrast Agents

Contrast agents are categorized based on their ionicity (either ionic or nonionic) and osmolality (high, low, or isosmolal). All intravascular radiopaque contrast agents contain iodine. Therefore, the iodine concentration of commonly used coronary angiographic contrast agents is within a similar range. Thus, an "allergy to iodine," likely an allergy to some other component of the contrast agent, should not influence the choice of contrast agent. The ionic, high-osmolal contrast agents include diatrizoate and metrizoate. Iogloxate is an ionic, low-osmolal agent. Iohexol, iopamidol, metrizamide, and ioversol are nonionic, low-osmolal agents. Iodixanol is a nonionic, isosmolal contrast agent. Several established factors should influence the choice of contrast agent. A major disadvantage of nonionic and low-osmolar contrast agents is their high cost. They may cost 10 to 20 times as much as ionic, high-osmolar agents, which may translate to an additional expense of a million dollars per year or more for a large-volume laboratory. There are numerous studies that contradict one another regarding purported benefits of specific contrast agents, making appropriate selection controversial in many circumstances. Complicating the issue further is the fact that many comparisons of newer contrast agents included older formulations of ionic, high-osmolal agents that are no longer in common clinical use.

Although nonionic contrast is more commonly selected by angiographers, high-osmolal, ionic contrast has been recommended as the first choice in the average patient (70). It is inexpensive and well tolerated by the majority of patients. Evidence suggests that nonionic contrast has less of an anticoagulant effect than ionic contrast and may thus be detrimental in patients with acute coronary syndromes (71,72). However, the COURT trial compared the isosmolar nonionic dye iodixanol with the low-osmolar ionic agent ioxaglate in patients with acute coronary syndromes and found a reduction in in-hospital adverse events with the nonionic agent (73). Thus, ongoing research may help determine optimal contrast agent selection.

Ionic contrast agents produce more myocardial depression than nonionic agents and also provide a greater osmotic volume load. High-osmolality ionic agents, especially in large volumes, may cause vasodilatation and hemodynamic deterioration in patients with LM coronary artery disease or aortic stenosis, and they may precipitate pulmonary edema in patients with significant left ventricular dysfunction. Thus, patients with LM coronary artery disease, severe aortic stenosis, or severe left ventricular dysfunction should receive as low a volume of nonionic contrast as possible (74). In addition to impairing contractility and affecting systolic function, contrast agents may impair ventricular relaxation, causing diastolic dysfunction and an increase in left ventricular end diastolic pressure (LVEDP). Unlike the deterioration in systolic function, which usually lasts only a few seconds to a few minutes, the diastolic dysfunction may last for more than an hour. Severe pulmonary hypertension is another situation in which nonionic agents would be preferred. Nonionic agents cause less bradycardia; therefore, the patient who experiences marked heart rate slowing with a high-osmolality ionic agent should be switched to a nonionic agent. Nonionic agents are also less likely to provoke arrhythmias such as ventricular fibrillation; however, this risk should be less than 1 in 1,000 during diagnostic angiography with high-osmolality ionic agents. Rarely, the iodine content in contrast agents may provoke thyroid storm in patients with hyperthyroidism due to thyroid nodules (75).



Continuous wave Doppler trace through the tricuspid valve of a patient with pulmonary hypertension. The maximal jet velocity of 4 m/sec corresponds to a pressure gradient of 64 mm Hg or a PA pressure of approximately 80 mm Hg.

Nonionic agents are less likely to cause minor reactions such as nausea or flushing (76). It is therefore reasonable to use them in a patient who previously had a great deal of discomfort with ionic agents. For cerebral or peripheral arterial angiography, nonionic agents are preferred for patient comfort. With cerebral angiography in particular, contrast agents may cause transient visual changes and, even more rarely, neurologic changes. This risk is greater for higher-osmolality dyes. When such changes occur, usually time and hydration result in full resolution of symptoms. Additionally, injections of the IMA may be painful if ionic agents are used; therefore, nonionic agents should be substituted.

Evidence is conflicting regarding the frequency of renal failure in relation to the type of contrast used (77,78). However, in a patient with preexisting renal insufficiency, with a serum creatinine of 2.0 mg per dL or greater before the procedure, it is reasonable to use a nonionic contrast agent. Intravenous hydration with normal saline or 0.45% saline and maintenance of adequate hydration (100 mL fluid per hour or more) during and after the procedure reduces the risk of worsening renal function in patients with baseline renal insufficiency, particularly diabetics at risk of renal failure (79). No convincing evidence has been found that mannitol, furosemide, or dopamine is useful in preventing renal dysfunction (80). Concomitant nephrotoxins should not be administered. When renal failure occurs, it may not manifest for 24 to 48 hours; hence, the creatinine measurement the morning after the procedure may be of limited value. The rise in creatinine may not occur until at least 24 hours after the procedure, peaking approximately 5 days after the procedure and, commonly, resolving by the tenth day. Acetylcysteine has been shown to reduce the occurrence of contrast nephropathy in small studies, but this approach has not yet gained widespread acceptance (81). It is important to limit the quantity of contrast agent used in patients with chronic renal insufficiency (82). Limiting the quantity of dye to less than 30 mL markedly decreases the need for subsequent dialysis (83).

Patients, such as asthmatics, with any history of atopy are at increased risk of an allergic reaction to contrast. Despite what is commonly believed, allergies to seafood, such as shellfish, are no more predictive of allergy to contrast than a history of atopy or other allergies. Previous contrast reactions increase the risk of a subsequent reaction. Anaphylactoid reaction may occur with contrast agents, although there is no difference in the incidence among agents. In patients with previous life-threatening contrast reactions, nonionic agents should be used. The patient should be premedicated with steroids and diphenhydramine. Steroids are most useful when begun the day before the procedure, preferably at least 12 hours before (84). In severe cases, premedication may include histamine (H_2) blockers such as famotidine (Pepcid), 20 mg i.v. When a life-threatening reaction has occurred in the past and catheterization is necessary, it is useful to give 1 or 2 mL contrast agent first, observe the patient for any reaction, and then proceed with the case. If a reaction to a contrast agent occurs, the treatment depends on the severity of the reaction (85). The first priority should be maintenance of the airway, ensuring ventilation, and hemodynamic resuscitation. Inhaled beta-agonists or racemic epinephrine may be useful to alleviate bronchospasm. If severe hypotension occurs, i.v. saline should be administered rapidly for volume expansion. Epinephrine should be given subcutaneously at a dose of 0.3 mL of the 1:1,000 concentration (0.3 mg), or, for severe hypotension, 10 µg per minute of the 1:10,000 concentration should be continuously infused i.v. until the patient's condition stabilizes. Diphenhydramine and steroids should also be administered, although the steroids will not produce any effect for hours. If the patient can be stabilized, it is reasonable to continue and complete the angiographic procedure (85). When severe anaphylactoid reactions to contrast agents develop, they usually occur during the procedure. Rarely, reactions occur hours to days after contrast administration (86). These more delayed contrast reactions, unlike contrast reactions in the catheterization laboratory, may be due to antibody formation (87).

Latex allergy rarely produces an anaphylactic reaction that is clinically indistinguishable from a reaction to iodinated contrast. Patients should be questioned before catheterization regarding an allergy to latex. If a latex allergy is present, the patient should be premedicated with corticosteroids, and the catheterization should be conducted in a latex-free environment, as the first case of the day before latex particles may accumulate in the catheterization suite. If latex allergy is questionable, the patient should undergo testing.

TECHNICAL ASPECTS OF CARDIAC CATHETERIZATION

Technique

Cardiac catheterization involves multiple sequential steps, each fraught with potential hazards. The first step is gaining arterial access. After this, coronary angiography is performed. Next, left ventriculography and measurement of left ventricular pressures can be done. Aortography and imaging of the cerebral or peripheral vasculature can also be performed. Sterile surgical technique should be maintained throughout the procedure (88). This includes proper preparation of the access site with hair removal and skin cleaning and sterile draping. The operator should wear a surgical cap, gown, shoe covers, and facial mask.

Anesthesia

After adequate sedation, the access site should be anesthetized with 2% lidocaine. The anesthetic should be administered slowly so as to minimize the discomfort of the injection. Once the maximum pulsation of the artery is identified, an initial skin wheal can be raised with 1 to 2 mL of 2% lidocaine administered through a 25-gauge needle. Anesthesia should be administered more deeply with a 22-gauge needle, through which an additional 4 to 8 mL can be given. In patients who are obese or in whom the pulse is difficult to locate, the volume of the local anesthetic may obliterate the pulse. In this situation, it may be useful to mark the pulse with a finger or straddle the artery with a finger on each side, administer the local anesthetic, and, without moving the finger(s), cannulate the artery. If a patient is allergic to lidocaine, which is an amide agent, procaine, which is an ester agent, can be used instead. Bupivacaine, a preservative-free amide agent, is another alternative, especially if the allergy is believed to be due to the preservative component of the local anesthetic.

Femoral Arterial Access

The most common form of arterial access for cardiac catheterization in the United States is femoral cannulation. Typically, an 18-gauge, hollow beveled needle is used. Fluoroscopy should be used to facilitate puncture of the common femoral artery at the appropriate level. Rupp et al. (89) identified the target site as 1 cm lateral to the most medial cortex of the femoral head as seen on an anteroposterior (AP) projection (Fig. 78.3). This increases the likelihood of infrainguinal puncture as well as the ability to compress the puncture site against the femoral head after sheath removal. Puncture of the artery more cranially may be associated with a greater risk of retroperitoneal hemorrhage, whereas a more caudal puncture is associated with arterial entry below the femoral artery bifurcation and with pseudoaneurysm formation (eFig. 78.3.1). Use of the skin crease to determine the arterial entry site may be misleading, especially in the obese, in whom the skin crease is often well below the desired point of entry.

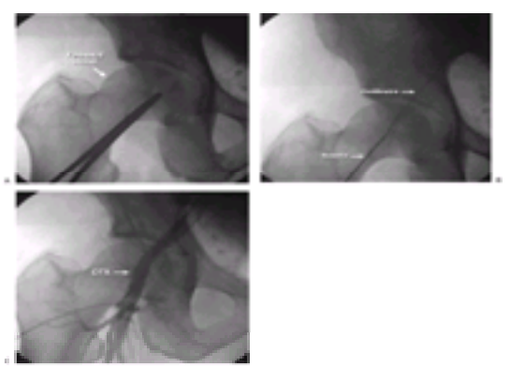


FIGURE 78.3 A: Fluoroscopic landmark for femoral artery cannulation in posteroanterior projection, marked with a hemostat. **B:** Cannulation of femoral artery and passage of guidewire. **C:** Angiogram shows the right common femoral artery and its relation to the femoral head in a posteroanterior projection. CFA, common femoral artery.

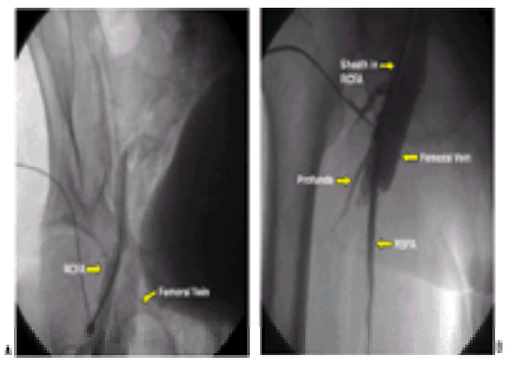

***e*FIGURE 78.3.1** Arteriovenous fistula of the femoral artery and vein, a potential complication of sheath placement. **A:** The sheath is in the right common femoral artery (RCFA). **B:** The right superficial femoral artery (RSFA) is also identified. (Courtesy of Dr. Albert W. Chan.)

The angle of entry of the needle is critical, with 30 to 45 degrees being the optimal range. A greater degree of angulation may cause problems during sheath insertion, leading to sheath kinking. Pulsatile blood flow should be obtained once the artery is effectively cannulated. Weaker degrees of blood flow could be due to subintimal position of the needle bevel or an awkward angle of the needle, with bevel abutting the vessel wall. In these situations, gentle manipulation of the needle backward or forward, or a slight change in angulation (usually a shallower angle), usually restores blood flow. In the presence of marked hypotension or severe peripheral vascular disease, blood return may not be brisk. In cases in which the pulse is not palpable, the Smart Needle, a flow needle attached to a Doppler probe, can be used to generate acoustic signals of arterial flow and facilitate puncture of the artery (90). It is helpful to use this device a few times in healthy arteries with a strong pulse before trying it for the first time on a nonpalpable one. It is relatively easy to puncture the posterior wall of the artery with this approach. Fluoroscopy can be used to locate the medial border of the femoral head, and this facilitates locating the artery. Often, with extensive peripheral vascular disease, fluoroscopic calcification is present in the vessel wall, further helping to identify the approximate location for needle entry. Old peripheral bypass grafts may also be calcified.

Once the artery is cannulated with the needle and pulsatile flow is obtained, a guidewire is passed through the needle. If resistance is encountered, fluoroscopy should be used to ensure that the wire tip is free, and undetected subintimal wire advancement is not occurring. The wire should follow a pathway to the anatomic left of the spine, unlike with venous cannulation, in which the wire follows the inferior vena cava to the right of the spine. With extensive vessel calcification or extensive scar tissue from previous procedures, resistance may be encountered during sheath advancement. Use of a small dilator, followed by progressively larger dilators, as well as a stiff wire, such as an Amplatz wire, may facilitate placement of the desired sheath size. This same technique can be used to enter Dacron grafts if they are at least 2 months old. After successful sheath placement, a blood pressure should be obtained and recorded from the sheath sidearm and correlated with the blood pressure cuff measurement. This allows detection of any aortoiliac disease, and it provides accurate documentation of the patient's arterial pressure.

Brachial or Radial Artery Access

Use of the radial artery for cardiac angiography has grown popular in certain European centers. Advantages of this technique include easy compressibility and shorter times to ambulation. Catheter manipulation may be slightly more difficult from the radial artery than from the femoral artery. Before cannulation of the radial artery, it is advisable to perform an Allen's test to ensure the adequacy of ulnar circulation to the hand. Another concern with radial artery cannulation is the possible need for this artery as a bypass graft conduit in the future.

Allen's test. To test the competence of the collateral circulation of the radial and ulnar arteries, a patient is asked to pump his or her hands after which both arteries are occluded (1). Then the pressure on one artery is released (2). Rapid return of blood flow signifies a normal response. The same steps are

repeated with the other artery (3). Final image is combined.

Although many operators attempt to cannulate the brachial artery at the level of the elbow crease, in approximately 10% of patients the brachial artery bifurcation is more proximal than this. Therefore, it is desirable to cannulate the brachial artery more proximally, a couple of centimeters above the skin crease. After sheath placement, approximately 2,000 to 3,000 units of intraarterial heparin can be given through the sheath if no pulse is palpable distal to the sheath. Some operators also give intraarterial nitroglycerin to prevent sheath spasm around the smaller-caliber radial artery. Specially designed micropuncture kits allow use of smaller equipment with the brachial or radial arteries.

Catheter Selection

The size of the catheter is largely a matter of physician choice and the size of the coronary arteries to be visualized; 6-Fr diagnostic catheters are commonly used. They provide good opacification, with easy manual injections of contrast. A 5-Fr system creates a smaller hole at the arterial access site, but adequate coronary artery opacification may be more challenging for the operator because “streaming” (incomplete mixing of contrast and blood) may occur, resulting in over- or underestimation of stenosis severity. A 4-Fr system can be used, in particular from the radial artery, but, again, coronary opacification and catheter manipulation may be problems. In certain circumstances, larger catheter sizes, up to 8 Fr, may be desirable, although this warrants a femoral approach or a brachial artery cutdown approach. If a patient has large coronary arteries or ectasia, it may be necessary to use one of the larger-bore catheters. This is also true of vein grafts, which may be quite large. Similarly, in any condition that leads to a state of increased coronary flow, such as aortic stenosis, aortic insufficiency, hypertrophic ventricular enlargement, dialysis, or tachycardia, better opacification may occur with a larger-bore catheter.

The initial catheter selected is the Judkins Left 4 (JL4) for the images of the left coronary system. The Judkins Right 4 (JR4) is next used to obtain images of the RCA. The size of the initial catheters selected depends on the aortic root. If there is a dilated aortic root or a large person, a JL5 or JR5 may be necessary. Similarly, if the aortic root is small, a JL3.5 or JR3.5 may be necessary. From the left brachial or radial artery, the standard Judkins catheters are usually adequate. However, from the right arm, multipurpose or Amplatz-type catheters are most useful. In an average-sized aorta, an AL2 is often the correct size for the LM, and an AL1 or AL2 is often appropriate for the RCA. Amplatz catheters are particularly useful if the origin of LM or RCA is more anterior, posterior, or superior than usual in the aorta. The multipurpose-A catheter is well suited for coronary artery ostia that have an inferiorly directed takeoff. Amplatz catheters are more likely than Judkins catheters to lead to ostial dissection due to their ability to engage the coronary arteries deeply. This risk can be minimized by rotating the catheter counterclockwise before disengaging from the artery.

Principles of Imaging

At least two orthogonal views should be obtained of each vessel (91). Adequate visualization of the left coronary artery commonly requires five or more views. Coronary artery visualization is commonly performed in the 5-in. (magnified) or 7-in. image intensifier mode. In the 7-in. mode, “panning” of the image intensifier is generally not necessary, but the spatial resolution of coronary arteries is less than that obtained in the 5-in. mode. Therefore, the 5-in. mode is usually preferred to obtain optimal spatial resolution, but the 7-in. mode may be preferred for the steeply angulated views and for obese patients. Use of the 5-in. mode usually requires panning of the image intensifier to visualize the distal vessels and collaterals. The process of panning is performed as follows. After waiting two or three systolic cycles after injection of contrast, the focus of the image should be moved from the proximal area, down the vessel of interest and then to the contralateral artery to observe for collaterals. If a stenosis is present, even a moderate one, multiple views may be necessary to delineate the severity of the stenosis, especially if it is eccentric.

Identification of coronary vessels and interpretation of angiograms may be difficult for the beginning practitioner (92). As a general principle, in RAO views the spine is on the left of the screen, whereas in LAO views the spine is on the right. The LCx and not the LAD is usually closer to the spine. In an RAO view, a diagonal branch of the LAD, as opposed to the LAD, forms the left heart border. However, in an LAO view, the LAD usually forms the right heart border, not the diagonal branches; it is important not to overlook an occluded LAD by mistaking a well-developed septal perforator for the true LAD.

Angulated views are generally required to prevent excessive vessel overlap that may obscure an area of interest (93). It may be helpful to use 1-mL “puffs” of dye to see if a particular view indeed adds information before filming. Cranial angulation tends to bring the shadow of the diaphragm into view at the bottom of the screen, and obtaining images while the patient takes a deep inspiration improves image quality by moving the diaphragm. Cranial angulation also tends to move posterior vessels such as the posterolateral branches of the RCA superiorly, whereas caudal angulation moves posterior vessels inferiorly.

The movement of coronary vessels provides clues to aid in differentiating them. The diagonal branches of the LAD and the marginal branches of the LCx tend to move in synchrony with cardiac contraction, as they supply the lateral aspect of the left ventricle. In the RAO projection, the LAD moves inward and the diagonal branches outward during systole if there is no anterior wall aneurysm. In patients in sinus rhythm, the portions of the RCA and LCx that lie in the atrioventricular groove move with an “atrial kick,” as do the atrial branches.

Obtaining views in different phases of respiration may also enhance image quality. An RAO cranial view performed with the patient in end expiration may help separate out the diagonal from the LAD. An RAO cranial view in end inspiration may help visualize the proximal LCx. The LAO caudal view is usually obtained in end expiration to facilitate viewing the LM coronary artery and ostial portion of the LAD, although it may be acquired at end inspiration if the objective is to view the LCx.

Historically, the frame rate for coronary cineangiographic acquisition has been 30 frames per second to minimize flicker. Many all-digital laboratories now acquire images at 15 frames per second. This practice results in a permanent 50% loss of information—a form of “lossy compression.” The clinical significance of this practice has not been established. In patients with tachycardia or high flow states such as aortic insufficiency, and in angiographic views with multiple overlapping vessels, a frame rate of at least 30 frames per second may be necessary to adequately visualize the coronary arteries.

Hand injections of contrast should be “ramped,” meaning that the injection should start slowly and increase in force; this minimizes the chance of the catheter disengaging from the artery. The injection of contrast must be of adequate force to produce reflux into the sinus of Valsalva to visualize the ostium of the coronary artery. The artery should remain completely opacified throughout the cardiac cycle to prevent “washout” and “streaming” of contrast material. Extreme care must be taken to avoid injection of air into the coronary circulation (*eFig. 78.3.2*). If this does occur, an immediate attempt should be made to aspirate the air out of the vessel with the same syringe that injected the air. Unless a very large quantity of air was injected, the patient usually has only transitory chest pain and ST-segment elevation. The patient should be monitored in the catheterization laboratory until the angina and electrocardiographic changes resolve.

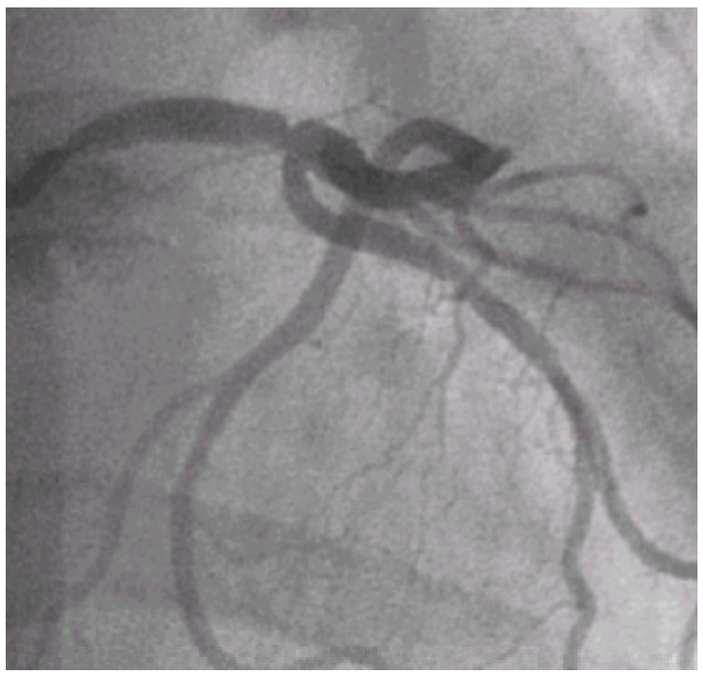
***e*FIGURE 78.3.2 A:** Inadvertent air embolus during injection of left internal mammary artery to left anterior descending (LAD) graft, shown in left anterior oblique projection. Air bubbles are seen in the left internal mammary artery, the anastomosis to the LAD, and even retrograde into the proximal LAD (*arrows*). The patient had transient, severe chest pain and ST-segment elevation but did not even develop a creatinine kinase elevation. **B:** Air bubble (*arrow*) injected down the LAD, producing transient chest discomfort without ST-segment deviation.

Coronary angiography involves integration of multiple visual cues that identify and differentiate coronary segments. With repetition, much of angiographic interpretation becomes pattern recognition. Nonetheless, a systematic approach to the evaluation of angiograms may prevent the angiographer from overlooking significant lesions that are not immediately apparent.

Left Coronary Artery

LM coronary artery disease is a serious finding that mandates proceeding with extreme caution. Clues to its presence include heavy calcification of the ostium. A stress test that demonstrates marked hypotension with exercise is another red flag. Damping or ventricularization of the pressure waveform on catheter engagement raises the possibility of LM coronary artery stenosis. Alternatively, the catheter may not be coaxial to the LM coronary artery, and slight withdrawal of the catheter tip should relieve damping in this situation; forceful contrast injection through a damped, noncoaxial catheter tip pointed upward into the LM coronary artery may lead to dissection. A contrast injection in the left coronary cusp is a reasonable first step to define the ostium of the LM coronary artery. An AP view or a shallow RAO caudal view may be useful to evaluate for mid- and distal LM coronary artery stenosis. A shallow LAO or LAO cranial view is usually best to visualize ostial LM stenosis. As soon as significant LM disease is identified, nonionic contrast should be used for the rest of the angiography. Limited injections of the left and right coronary arteries should be performed, sufficient to identify other stenoses and delineate surgical targets. A left ventriculogram should usually not be performed in the presence of severe LM coronary artery stenosis, because the contrast load and depression in cardiac contractility may prove fatal. If the patient is hemodynamically unstable, consideration should be given to intraaortic balloon pump placement.

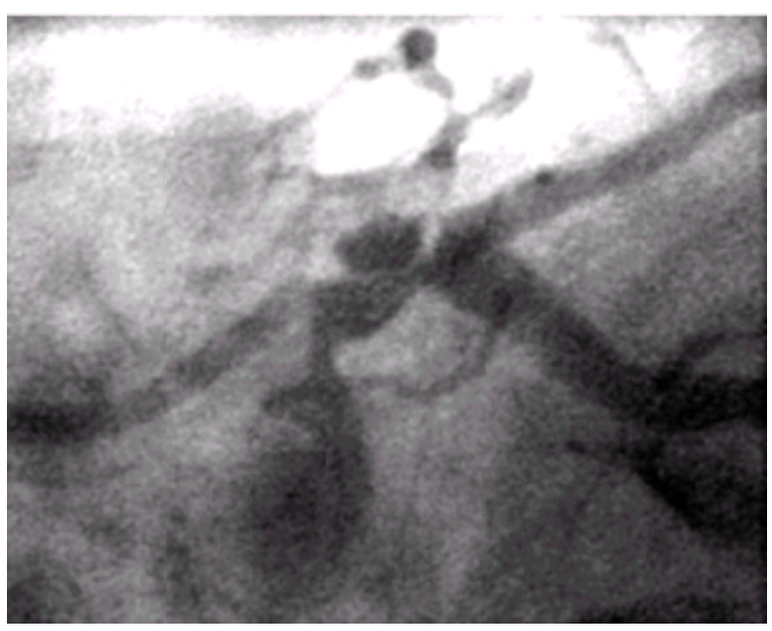


A 64-year-old male patient with severe ostial and moderate distal left main trunk stenosis.

Initial engagement of the LM coronary artery is performed in the 30-degree LAO position. If the JL4 catheter does not line up coaxially with the LM coronary artery, slight counterclockwise rotation should move the catheter tip anteriorly and engage it. If this does not work, gentle clockwise rotation, which moves the catheter posteriorly, can be applied. In a dilated aorta, the “elbow” of the JL4 catheter curve does not rest on the aortic wall, and clockwise rotation is necessary to move the catheter tip anteriorly in the aorta. Also, in the dilated aorta, larger-sized catheters such as a JL5 or JL6 may be necessary.

If Amplatz catheters are being used to engage the LM coronary artery, these are pushed down into the left cusp, with the catheter tip pointing upward until the engagement is accomplished. The catheter is then withdrawn slightly, which causes the catheter to advance into the LM coronary artery. To disengage, the catheter is advanced slightly and gently rotated counterclockwise out of the LM coronary artery. Although the JL catheters typically find the LM coronary artery with little manipulation, the Amplatz catheters are particularly useful when the orientation of this artery is unusual or anomalous. However, particular care must be used with Amplatz catheters, as the motions that are used to engage and disengage are the opposite of the Judkins catheters.

Isolated LM coronary artery disease occurs rarely (94). When there appears to be no other significant coronary artery disease, consideration should be given to LM coronary artery spasm, and intracoronary nitroglycerin should be administered before repeat angiography. Alternatively, the LM artery may just taper, and IVUS is particularly useful to document whether angiographic narrowing is due to vessel tapering or to atheroma. Additionally, whenever ostial LAD or ostial LCx stenosis, or both, are present, the index of suspicion for distal LM coronary artery stenosis should fall, and further views should be obtained to exclude this possibility.



Severe ulcerated plaque of the left main trunk discovered on diagnostic angiography.

Video 78.23 Coronary angiogram showing ostial and proximal left circumflex artery lesion. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

In the setting of separate ostia of the LAD and LCx, an LAO caudal view may be particularly helpful. If the catheter first engages the LAD, a larger catheter is often necessary for the engagement of the LCx, such as upsizing from a JL4 to a JL5, with clockwise rotation applied to the catheter. Alternatively, if the LCx is first engaged with the catheter, a shorter catheter is usually necessary to engage the LAD selectively, such as downsizing from a JL4 to a JL3.5, with counterclockwise rotation applied.

Several additional views of the left coronary artery should be obtained after the LM coronary artery has been evaluated. The AP cranial view is useful for evaluating the midportion of the LAD. Additional LAO or RAO cranial views may help further evaluate the mid-LAD, as well as separate the diagonal branches of the LAD, allowing the ostia to be imaged. The lateral view may further delineate the mid-LAD. The AP caudal view is useful for evaluating the body of the LCx, as well as the marginal-branch ostia. Added shallow LAO or RAO angulation may further maximize this view. For a ramus intermedius branch, an LAO caudal view is most useful to evaluate the ostium. An LAO cranial view is also useful for displaying a left-sided PDA.

Right Coronary Artery

In the 30-degree LAO projection, the JR4 is advanced to the aortic valve level and slowly withdrawn approximately 2 cm while clockwise rotation is applied to rotate the catheter anteriorly to the right sinus of Valsalva. Then the catheter should sit in the RCA ostium. If this maneuver does not work, the RCA ostium can be approached from slightly above its expected level, with clockwise rotation being applied to the catheter. With ostial disease of the RCA, if damping occurs with the catheter, it may sometimes be helpful to use a larger-sized catheter, which is less likely to engage the artery deeply. Usually, two or three views of the RCA are obtained. The LAO view is useful to evaluate the proximal and mid-RCA. The AP view with 30-degree cranial angulation is often the best for evaluating the RCA bifurcation and ostia of the PDA and posterolateral branches. A shallow RAO view is useful to lay out the entire PDA. In the RAO view, the marginal branches point to the patient's left, and the atrial branches point to the patient's right; thus, this view is useful in differentiating atrial and marginal branches that may be overlapped in an LAO view. The lateral view may be useful to evaluate the mid-RCA and the ostia of RV marginal branches. If significant LM coronary artery disease has been identified, a single view of the RCA, probably an LAO cranial to identify any needed surgical targets, may be sufficient for planning bypass surgery.

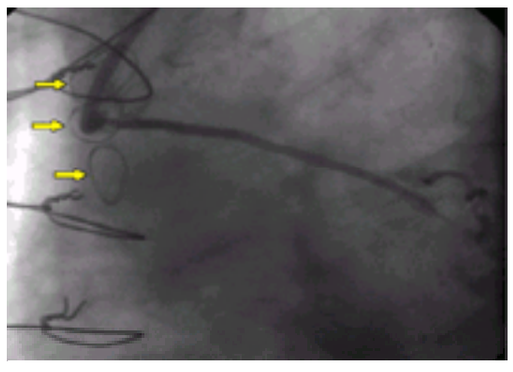
Surgical Bypass Grafts

When angiographers perform cardiac catheterization on patients with previous bypass surgery, they should obtain the operative report to know the number and types of grafts. For example, if an IMA graft has been used, is it *in situ* or is it freely anastomosed to the aorta? Are there any "Y grafts" with two limbs, or do any of the grafts have sequential anastomosis sites? The operative report may thus ensure a complete catheterization with a minimal amount of contrast expenditure. It is often helpful to review any previous postoperative angiograms. If all the vein grafts were clearly documented to be occluded on a previous study (not just the report), there would be no point in searching for them again. Additionally, any unusual anatomy of the innominate or subclavian artery could be appreciated. Furthermore, preoperative catheterization studies are also useful to ensure that all lesions were in fact bypassed. The relation of the patient's symptoms to the presence of lesions on consecutive angiograms may be revealing. For example, when a totally occluded bypass graft is detected in a patient with new-onset angina, knowledge that this vein graft was occluded 5 years ago would affect the management of this patient's current pain syndrome.

Video 78.24 A 73-year-old male patient status post coronary artery bypass grafting with right internal mammary artery (RIMA) graft to left anterior descending artery (LAD). Patient continued to have angina after coronary artery bypass grafting and stress thallium showed anterior wall ischemia. Angiography revealed arteriovenous fistula from the RIMA graft to the pulmonary artery. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Sometimes information regarding the operative anatomy is not available. If the cardiac catheterization procedure is urgent and an operative report cannot be obtained, the patient or family may remember how many grafts were used and whether the internal mammary arteries were used. Fluoroscopic identification of the surgical clips along the course of the left or right IMA may be clues that these conduits were used. Finally, a 30-degree LAO aortogram can be performed, although adequate opacification must be ensured. At least a 50- to 60-mL aortogram is generally required; otherwise it is possible to miss grafts that are, in fact, patent. Additionally, a long cine run is sometimes necessary to view a late-filling, diseased vein graft.

Left coronary artery bypass grafts are best visualized in an RAO projection, whereas grafts to the RCA are best engaged in the LAO projection. If a graft is occluded, an injection should still be performed to confirm the presence of a stump and ensure that it is not just the catheter abutting the aortic wall. In the presence of multiple grafts from more than one bypass operation, it may be useful to visualize the stump in an RAO and an LAO projection. This allows the area to be localized more clearly and avoids multiple cannulations of the same stump or confusion with another closely located stump. Some surgeons place marker rings on the outside of the aorta at the proximal anastomosis of the graft (eFig. 78.3.3). This facilitates engagement of the graft during subsequent catheterizations. The usual sequence of proximal anastomoses of aortocoronary bypass grafts to the left coronary, going from caudal to cranial, is LAD, diagonal, ramus, first obtuse marginal, and second obtuse marginal. Grafts to the RCA are more caudal and more anterior than grafts to the left coronary artery.



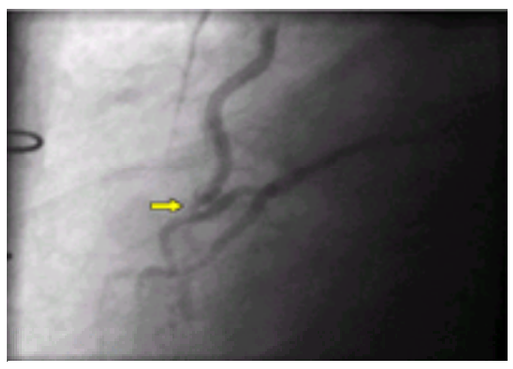
***e*FIGURE 78.3.3** Sequential marker rings (*arrows*), which denote the aortic anastomoses of saphenous vein grafts.

Before cannulating the IMA, the angiographer should visualize the proximal subclavian or innominate artery to provide a road map of the anatomy, to facilitate catheter manipulation. Importantly, the presence of a subclavian stenosis proximal to the IMA may be identified. The JR4 is well suited to cannulate the subclavian or innominate artery and is easier to use for this purpose than a preformed IMA catheter. Measurement of a pullback gradient, with a saline-filled catheter, confirms the hemodynamic significance of an angiographic stenosis.

The contralateral oblique view is useful to evaluate the ostia of the internal mammary arteries. Care must be taken on engagement of the ostia of the IMA, as dissection of an IMA–LAD conduit may be catastrophic. The IMA is more delicate in this regard than a saphenous vein graft. Although a JR4 is sometimes used to cannulate the

IMA, the curve on the catheter tip is often not sufficient to engage the IMA, which usually originates anteriorly from the subclavian artery. An IMA catheter has a more acute tip curve for selective IMA cannulation. One strategy is to use a JR4 to engage the subclavian artery, visualize this vessel, and then pass a 260-cm exchange-length J-wire or Glidewire into the distal subclavian artery and advance the IMA catheter over the exchange wire. In the presence of marked tortuosity, the Glidewire may be particularly useful, as may use of a Glide catheter; the hydrophilic coatings on these instruments may ease passage through curved vessels. Attempts to cannulate the IMA should be made while withdrawing the IMA catheter, not while advancing it, to prevent dissection. Counterclockwise torque is generally applied to turn the catheter anteriorly to engage the left IMA, or clockwise torque for the right IMA, while the catheter is withdrawn.

It is important to visualize precisely the distal anastomosis of the graft to the artery, as this is often the site of a culprit lesion. In the IMA grafts, in particular, a discrete lesion that is amenable to angioplasty may be found in this location. The lateral view is particularly useful if there is a question of a left IMA–LAD anastomosis lesion (*e*Fig. 78.3.4). The RAO and LAO cranial views are also useful. Otherwise, the views that are used to visualize grafts are similar to the views required for the native vessels. For example, the anastomosis of a graft to the distal RCA could be seen in an LAO cranial view.



***e*FIGURE 78.3.4** Lateral view of the left internal mammary artery to the left anterior descending artery anastomosis (*arrow*).

The gastroepiploic artery can be used as an *in situ* graft to the distal RCA. The gastroepiploic artery originates from the common hepatic artery, which arises from the celiac trunk in the abdominal aorta. It normally supplies the stomach but can be rerouted surgically to the inferior surface of the heart. Visualization of this graft involves cannulation of the celiac trunk with a curved catheter such as the Cobra catheter. If a selective injection is necessary for adequate opacification, a catheter can be advanced over a Glidewire into the origin of the gastroepiploic artery.

If left ventriculography is performed, opacification of vein grafts is sometimes observed. Perhaps more useful is observation of the contraction pattern of the left ventricle. For example, if the anterior wall is completely normal but the LAD is occluded and no patent graft has been found that supplies the LAD territory, it is highly likely that a graft has been overlooked.

Cerebral Angiography

A 30-degree LAO arch aortogram is performed to see the great vessels (95). A bovine arch, where the left common carotid artery arises from the innominate artery, is a relatively common anomaly. If the origins of the great vessels lie on a horizontal plane, a 5-Fr JR4 can be used to engage the great vessels. In general, 5-Fr catheters are less likely to traumatize vessels than are larger catheters. A Headhunter 1 has a shape similar to that of a JR4 and can be used to engage the common carotid arteries. If the origin of the great vessels lies in more of a vertical orientation, a curved catheter such as a Vitek is often necessary. The Simmons curved catheters may be extremely useful when the curve of the Vitek is not sufficient to engage the great vessels. However, this catheter is more difficult to use and has a tendency to jump into the vessel of interest, increasing the risk of vessel dissection. Additionally, the curved catheters by necessity scrape along the aorta, which raises the chance of embolic complications in a heavily diseased aorta. Use of these curved catheters is somewhat analogous to the use of Amplatz catheters in that the vessel is cannulated and the catheter is pulled back slightly to engage the vessel more deeply. To disengage, the catheter is not just pulled back but rather needs to be advanced and torqued. When curved catheters are used, it is easier to engage the great vessels going forward—that is, engaging the left subclavian, then the left common carotid, and then the innominate—whereas the opposite strategy is preferred when using the noncurved catheters such as the JR4.

For cerebral angiography, nonionic contrast should be used, and images should be acquired using digital subtraction angiography. The carotid arteries should be visualized in at least two views, the ipsilateral oblique and the cross-table lateral (90-degree LAO). The ostia of the vertebral arteries are best seen in the contralateral oblique. Often, a nonselective visualization of the vertebral arteries is sufficient, with the catheter tip pointed in the direction of the vertebral and a blood pressure cuff inflated above the systolic pressure in the ipsilateral arm. If selective engagement is necessary, great care must be taken with catheter manipulation so as to avoid dissection. Special vertebral artery catheters are available for selective cannulation.

Severe left internal carotid artery stenosis in a 67-year-old male patient with transient ischemic attacks (A) and after implantation of a self-expanding stent (B).

Renal Angiography

Although it is often possible to engage the left and right renal arteries with a JR4 catheter, an initial AP abdominal aortogram may be useful to identify the exact location of the renal arteries and allow visualization of accessory renal arteries. Philosophically, this sort of “drive-by” angiography, without clinical indications, is undesirable, because angiographic stenosis may be of little functional consequence to the patient in certain circumstances. However, in a patient with uncontrolled hypertension despite adequate doses of multiple antihypertensives, or when noninvasive imaging has suggested severe stenosis, renal angiography at the time of cardiac catheterization may be reasonable.

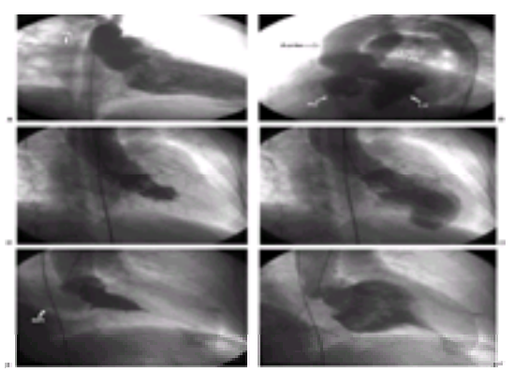
It is generally preferable to start with an abdominal aortogram. Identification of bony landmarks, such as the first lumbar vertebral body, may help position the pigtail catheter above the renal artery ostia. As the renal arteries tend to arise somewhat posteriorly, LAO or RAO angulation may help visualize the ostia. If an ostial stenosis is identified, recording of a pressure gradient may help assess the severity of the angiographic stenosis. Imaging should continue for a period of time sufficient to view the nephrograms. An abdominal aortic aneurysm may be noted on the abdominal angiogram. Even a small angiographic aneurysm may in fact be a much larger clot-filled sac, and an ultrasound or computed tomographic (CT) scan is warranted to document the exact dimensions of the aneurysm.

Left Ventriculography

Even with the refinement of several noninvasive measures, ventriculography remains a useful modality to assess left ventricular function. Before left ventriculography is performed, an assessment of LVEDP should be made with the pigtail catheter. If the pressure is markedly elevated, sublingual nitroglycerin should be administered until the pressure is reduced. If LVEDP remains elevated (e.g., LVEDP >30 mm Hg), consideration should be given to aborting the left ventriculogram.

Left ventricular hypertrophy secondary to chronic hypertension with secondary ectasia of the right ventricle.

The 30-degree RAO is the usual view for left ventriculography, although biplane ventriculography with an additional LAO or LAO cranial view may be preferable in some cases, if available. If mitral regurgitation is known to be present and an assessment of severity is required, 50 to 60 mL of dye should be used to opacify the left atrium (96). Care must be taken in positioning the catheter and ensuring that it is free, such that it does not trigger premature ventricular contractions or entwine the mitral valve apparatus, thereby artificially causing mitral regurgitation. The LAO cranial is the optimal view for a muscular ventricular septal defect, and the left lateral view is optimal for a membranous ventricular septal defect. The LAO cranial is also useful to assess for left ventricular outflow obstruction in patients with hypertrophic cardiomyopathy (eFig. 78.3.5).



***e*FIGURE 78.3.5** In addition to assessment of left ventricular function, ventriculography may diagnose several other conditions. **A:** Ventricular septal defect in a right anterior oblique (RAO) projection, showing opacification of the pulmonary artery (PA). **B:** Ventricular septal defect in a steep left anterior oblique projection, clearly showing opacification of the left ventricle (LV), right ventricle (RV), and PA. In addition to angiographic assessment, the information obtained from fluoroscopy should not be overlooked. Pericardial calcification may be a clue for the presence of constrictive pericarditis, although this was much more common in the era of widespread tuberculosis (eFig. 78.3.6). Additionally, tethering of the coronary arteries during angiography may be noted in constrictive pericarditis. Fluoroscopy may also show calcification of the aortic valve or mitral annulus, perhaps indicating the presence of valvular heart disease. Fluoroscopy can also be used to assess the function of mechanical heart valve prostheses.

Aortography

Aortography is usually performed in a 60-degree LAO projection to assess the aortic root and determine if aortic regurgitation is present (eFig. 78.3.7). Aortic coarctation is best seen in the lateral view. If there is a suspicion of aortic dissection (which there always should be in a patient with acute chest pain), care should be taken to attempt entry into the true lumen. With a femoral approach, the stronger pulse should be used, as this also increases the likelihood of entering the true lumen if the dissection extends to involve the iliofemoral system. Entry into the true lumen may be facilitated by using a pigtail catheter or a JR4 catheter to direct the guidewire toward the medial edge of the aorta, as this increases the likelihood of avoiding the false lumen, which typically arises from the outer aspect of the aorta. A soft-tip exchange length 260-cm J-wire should be used. Entry across the aortic valve into the left ventricle is desirable to confirm entry into the true lumen. Ventriculography followed by aortography can then be performed with a pigtail catheter. An aortogram at 60 degrees LAO can be performed to assess the great vessels and ensure that these arteries are not involved. Next, over the exchange length wire, a JL5 or 6 catheter can be used to engage the LM coronary artery in what is usually a dilatated aorta. The RCA can then be cannulated with a JR4 or 5, although the dilatated aorta may necessitate the use of AL3 or multipurpose catheters for either the LM coronary artery or RCA. The initial aortogram may help guide the selection of catheter shapes and sizes for coronary engagement. Despite the conventional belief that

coronary angiography is necessary before a patient goes to surgery for acute aortic dissection, the data indicate that there is probably no benefit to routine coronary angiography in this setting unless the patient has had previous coronary artery bypass surgery (97).

Postprocedural Care

The angiographic images should be reviewed and a plan formulated in the catheterization laboratory. Once it is certain that all necessary information has been obtained from the angiogram, the sheath can be pulled. If heparin was administered for a diagnostic coronary angiogram (e.g., when a radial/brachial approach was used or cerebral angiography was performed), an activated clotting time or activated partial thromboplastin time should be checked before the sheath is pulled. If the activated clotting time is less than 160 seconds or the activated partial thromboplastin time is under 45 seconds, the sheath can be pulled and manual pressure applied for several minutes until hemostasis is obtained. Direct compression of the artery a few fingerbreadths above the needle insertion site in the skin (above the estimated arterial entry site) with the pads of the fingertips is the most reliable method to obtain hemostasis and should be the initial approach if a closure device is not used. After a few minutes of direct manual pressure, a C-clamp can be positioned appropriately, although the patient must still be monitored. A FemoStop is an alternative to the C-clamp, but some care must be taken to ensure correct positioning over the artery. Use of smaller-sized sheaths may greatly decrease the time to ambulation. With the use of 5-Fr sheaths, ambulation has been demonstrated to be safe after 2 hours of bed rest.

Closure devices are increasingly used to obtain hemostasis. It is recommended that an oblique angiogram be performed through the sidearm of the sheath to determine the sheath insertion site. Additionally, vessel size and the presence of any plaque may be noted. If it appears that the sheath is in the bifurcation of the common femoral artery, manual pressure is best applied. If the sheath is placed in the profunda femoris or the superficial femoral artery, or if there is atherosclerotic plaque at the insertion site, it may be best not to use any closure device. Vessels of 4 mm or less in size are not well suited to current closure devices. If a slight degree of blood oozing from the skin occurs, a 10-mL solution of lidocaine hydrochloride 1% and epinephrine 1:100,000 can be injected into the skin tract.

A variety of closure devices are currently available. The Perclose is a percutaneous device used to suture the hole in the artery formed by the sheath (98). The device is placed over a wire after the sheath is removed. Then needles are deployed that pull sutures through the artery wall, and the sutures are tied to obtain hemostasis. Because the guidewire can be maintained in the artery for the entire procedure, a sheath can be reinserted if the device fails. Additionally, immediate leg movement and recannulation are possible, if necessary. The technique of “preclosing” the femoral artery involves placement of a Perclose over the guidewire after its initial placement through the cannulation needle. The sutures of the Perclose are kept to the side underneath a sterile towel until the conclusion of the procedure and the removal of the sheath. The Perclose device has been used to obtain hemostasis after brachial artery cannulation as well, although care must be taken because of the smaller caliber of the brachial artery (99).

The Angio-Seal is available in an 8-Fr device for 7- or 8-Fr sheaths and in a 6-Fr device for 5- or 6-Fr sheaths (100,101). Placement involves exchange of the sheath over a guidewire for the Angio-Seal device, which places a collagen plug external to the hole in the artery, with an anchor inside the artery to hold the plug in place. Movement of the leg should be restricted for 1 to 2 hours, and repuncture is not recommended for 3 months. The VasoSeal is an external collagen plug that is placed immediately outside the hole in the artery, as well as in the skin tract that leads to the arterial cannulation site (102). The Duett device is similar in concept to the VasoSeal except that it involves injection of thrombin external to the artery. Care must be taken to avoid intraarterial injection of thrombin. Although closure devices may decrease the time to ambulation and hasten discharge from the observation unit, there is no evidence that they decrease groin complications. Likewise, in well-trained operator hands, there is no evidence that closure devices increase groin complications, although when complications occur, they are more often immediately apparent than when manual pressure is used (103,104 and 105).

After radial artery catheterization, if the radial pulse is lost but the hand is otherwise asymptomatic (and the ulnar supply is adequate), there is no cause for action. With loss of the brachial or radial pulse after brachial artery catheterization, vascular surgical consultation ought to be obtained. Loss of distal pulses after femoral catheterization should also prompt surgical consultation or lower extremity angiography. In patients with extensive peripheral vascular disease, if pressure is being applied to the femoral catheterization site, particular care must be given to the distal extremity to ensure that ischemia is not occurring; this is best accomplished with direct visualization of the distal extremity (i.e., the foot should not be covered up with a sheet).

Elective diagnostic coronary angiography has been transformed into an outpatient procedure in most circumstances. This appears to be a safe development. However, there are patients for whom outpatient catheterization is not appropriate. Individuals with severe aortic stenosis or LM coronary artery disease should be monitored for a more extended period, as should patients who are at risk of developing renal failure. Similarly, patients with severely impaired left ventricular function or unstable coronary artery disease should remain for observation. Individuals who live alone and have no one to watch them should be monitored overnight.

Before discharge, patients should be told to notify their physician if they subsequently have any sudden drop-off in urine quantity. Any pain or swelling at the site of the catheterization should also prompt emergency care. Patients should be counseled to avoid driving for a day to allow sedation to wear off and heavy lifting for at least 2 days to allow the catheterization site to heal. Warfarin, if necessary, can be reinitiated the night of the procedure. If more immediate anticoagulation with heparin is desired, this can be started a few hours after the sheath is removed, or immediately if a closure device is used. If metformin was given, this can be resumed after 2 days if renal function appears stable.

Complications and Management

Major complications are unusual after cardiac catheterization, but the operator must be familiar with them. An analysis of 59,792 patients documented the frequency of major complications with cardiac catheterization and coronary angiography (Table 78.3) (106). Although that analysis is somewhat old, the numbers have not changed significantly, although older, sicker patients are being catheterized. Death occurs in approximately 1 in 1,000 cases. Patients with severe LM coronary artery stenosis or critical aortic stenosis are at particularly high risk. Myocardial infarction occurs in approximately 1 in 2,000 cases; stroke occurs in approximately 1 in 1,000 cases. Thus, a major complication of death, myocardial infarction, or stroke occurs in about 1 of 500 cases.

Complication	Percent
Death	0.11
Myocardial infarction	0.05
Stroke	0.07
Arrhythmia	0.38
Vascular complications	0.43
Contrast reaction	0.37
Hemodynamic complications	0.26
Perforation of cardiac chamber	0.03
Other complications	0.28
Total	**1.70**

Hypotension and Bradycardia

Vasovagal reactions may occur, especially with initial arterial access or sheath removal. Patients should be instructed not to hold their breath, because breath-holding may predispose to a vagal reaction. Hypotension in the catheterization laboratory may be catastrophic in certain circumstances, and prompt treatment may be lifesaving. Norepinephrine (Levophed) should be administered to reverse rapidly hypotension that is due to vasovagal reactions. Dopamine is often used in catheterization laboratories; however, this is not the ideal initial agent for serious hypotension, because it takes a period of time for blood levels to reach a level at which the pressor effect occurs. At the initial low serum concentrations, dopamine acts primarily as a renal and splanchnic vasodilator and may transiently decrease blood pressure. Therefore, norepinephrine, not dopamine, is the agent of choice for prompt treatment of hypotension. Epinephrine is the treatment of choice for hypotension secondary to an anaphylactoid reaction. For hypotension that is unresponsive to i.v. fluids and vasopressors, placement of a Swan-Ganz catheter and an intraaortic balloon pump should be considered. With the availability of the lower profile 8-Fr intraaortic balloon pump systems, a balloon pump can often be placed

through an existing sheath.

Atropine, 1.0 mg i.v., should be administered for symptomatic bradycardia. dditionally, if bradycardia occurs with injections of ionic contrast, nonionic contrast should be substituted. Furthermore, if the bradycardia occurs with RCA injection, the minimum amount of dye to ensure opacification should be used. For sustained and symptomatic bradycardia, a transvenous pacemaker should be placed.

Vascular Complications

Bleeding from the arterial cannulation site with development of a hematoma is a risk of angiography. Retroperitoneal bleeding can be particularly sinister due to the difficulty in making the diagnosis. Although symptoms such as inguinal or abdominal tenderness, femoral neuropathy, and back pain may be clues to retroperitoneal hemorrhage, hypotension with a falling hemoglobin may be the only manifestation and, if undetected, may lead to death. An abdominal CT scan can confirm the diagnosis (107). The risk of vascular complications is increased in patients who are receiving anticoagulation at the time of angiography (108). Female gender, obesity, and advanced age are other risk factors for groin complications. Color duplex ultrasound is the preferred mode of assessing groin complications (109). Pseudoaneurysm and arteriovenous fistula formation are additional risks. When pseudoaneurysms are less than 3 cm in size, conservative management usually results in spontaneous closure (110). Although ultrasound-guided compression of pseudoaneurysm and arteriovenous fistula has become commonly used, surgical therapy is still necessary in a significant minority of cases, especially when anticoagulation is being administered (111). A newer method of ultrasound-guided thrombin injection has been described for the management of pseudoaneurysms that develop after catheterization (112). The success rate with this method is high, even in patients who are receiving anticoagulation, and, in experienced hands, this should likely be the first approach tried before consideration of surgical repair. Endovascular techniques have also been used successfully to treat pseudoaneurysm and arteriovenous fistula (113).

Brachial artery hematoma. Hematoma complication after brachial artery catheterization and urokinase administration.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Numerous critics of coronary angiography decry the overuse of this invasive procedure. Certainly, overuse may be a problem, especially given patient demand in fee-for-service health-care systems. Improved noninvasive screening techniques may diminish the need for angiography as a diagnostic tool in the future. As magnetic resonance imaging continues to improve, it may one day replace coronary angiography as a diagnostic tool for suspected coronary artery disease. Alternatively, newer modalities such as CT scanning may identify a larger number of people who need coronary angiography for more definitive delineation of coronary anatomy. Furthermore, percutaneous coronary intervention continues to grow as a revascularization method, necessitating coronary angiography to define stenoses. The aging of the population will further increase the need for coronary angiography. Additionally, emerging evidence suggests that an invasive strategy incorporating angiography is the ideal approach to patients with acute coronary syndromes (60,61). Individuals with unstable angina who are treated with aggressive catheterization strategies in the United States fare better than their more conservatively treated counterparts in Canada (114). For patients with acute ST-segment elevation myocardial infarction, an invasive approach, including percutaneous intervention, where available, leads to better outcomes than pharmacologic therapy (115,116 and 117). If a patient with acute myocardial infarction is in cardiogenic shock, an initial invasive approach may be lifesaving (118). Thus, the prominence of coronary angiography is likely to grow, as a diagnostic tool and as a prelude to percutaneous intervention.

THE FUTURE

Although the future of coronary angiography remains bright, limitations will be placed on who actually performs it. As minimum volume standards become more widely accepted and separate certification examinations are developed, coronary angiography will become part of a discrete invasive subspecialty within cardiology. The evolution and refinement of arterial closure devices will continue, allowing an even greater proportion of cases to be performed on an outpatient basis. Older patients with a greater degree of medical comorbidities, as in the very elderly, will undergo coronary angiography at much higher rates. Further refinements in imaging, through magnetic resonance and CT, will likely reduce radiation exposure to the operator, enhance image quality, and ultimately yield “noninvasive” coronary angiography using an i.v. injection of a contrast agent. Real-time three-dimensional reconstruction of coronary arteries will become feasible. Potentially, hybrid imaging technologies will enable the identification of vulnerable atherosclerotic plaque, the veritable “holy grail” of diagnostic angiography. Thus, although coronary angiography will probably continue to evolve, it will remain central to the evaluation of coronary artery disease.

OVERVIEW

Diagnostic cardiac catheterization is performed to establish the presence and to assess the severity of cardiac disease. Catheterization of the right and left sides of the heart can be accomplished by the introduction of catheters via several approaches. During routine right-sided heart catheterization, measurements of pressures and oxygen saturations in the venae cavae, right atrium, right ventricle, pulmonary artery, and pulmonary capillary wedge position can be performed, and cardiac output (CO) can be quantified. The measurement of right-sided pressures helps one to evaluate the severity of tricuspid or pulmonic stenosis, to assess the presence and severity of pulmonary hypertension, and to calculate pulmonary vascular resistance. With left-sided heart catheterization, one can assess mitral and aortic valvular function, left ventricular pressures and function, systemic vascular resistance, and coronary arterial anatomy. Cardiac catheterization may be performed to assess the presence, site, and magnitude of intracardiac shunting, and injection of radiographic contrast material into various cardiac chambers (angiography) may be performed to evaluate their structure or function.

HISTORICAL PERSPECTIVE

Cardiac catheterization was first performed in the 1840s on experimental animals. In 1929, Werner Forssmann was the first to pass a catheter into the heart of a living person—himself. Guided by a fluoroscopic image projected onto a mirror, Forssmann introduced a thin urologic catheter into his left antecubital vein, advanced it to the right atrium, then climbed a flight of stairs to the radiology suite to document catheter position with a chest radiograph. Although he repeated this feat several times, concern about the utility and safety of cardiac catheterization limited its use and development until the 1940s, when Andre Cournand and Dickinson Richards systematically performed catheterization to investigate cardiac function in healthy subjects and in patients with heart disease (*e*Table 79.0.1). During its early years, catheterization was performed sparingly and with substantial risk. As time has elapsed, considerable advances have been made, and the associated morbidity and mortality have fallen precipitously. Today, diagnostic cardiac catheterization is performed with minimal risk, and therapeutic catheterization (i.e., coronary angioplasty and valvuloplasty) is performed without incident in most patients. Cardiac catheterization now plays a central role in the diagnostic evaluation of the patient with suspected or known cardiac disease, and it offers percutaneous therapeutic possibilities in many individuals.

***e*TABLE 79.0.1** HISTORICAL HIGHLIGHTS OF CARDIAC CATHETERIZATION

1929	First cardiac (right atrial) catheterization in man: Werner Forssmann
1930	Cardiac output measured by the Fick principle: O. Klein
1940s	Right-sided heart catheterization studies: Andre Cournand and Dickinson Richards
1947	Pulmonary capillary wedge measurements: Lewis Dexter
1950	Retrograde left-sided heart catheterization: H. Zimmerman, R. Limon-Lason
1953	Percutaneous catheterization technique: S. Seldinger
1956	Nobel prize awarded to Werner Forssmann, Andre Cournand, and Dickinson Richards for their work in cardiac catheterization
1959	Transseptal catheterization: John Ross, Constantin Cope
1959	Selective coronary angiography: Mason Sones
1968	Coronary artery bypass surgery: Rene Favalaro
1970	Balloon-tipped flow-directed right-sided heart catheterization: H. Jeremy Swan and William Ganz
1977	Percutaneous transluminal coronary angioplasty: Andreas Gruentzig

INDICATIONS AND CONTRAINDICATIONS

Diagnostic cardiac catheterization is appropriate in several circumstances. First, it is indicated to confirm or exclude the presence of a condition already suspected from the history, physical examination, or noninvasive evaluation. In such a circumstance, it allows one both to establish the presence and to assess the severity of cardiac disease. Second, catheterization is indicated to clarify a confusing or obscure clinical picture in a patient whose clinical findings and noninvasive data are inconclusive. Third, catheterization is performed in some patients for whom corrective cardiac surgery is contemplated to confirm the suspected abnormality and to exclude associated abnormalities that might require the surgeon's attention. Fourth, catheterization is occasionally performed purely as a research procedure.

Therapeutic catheterization is appropriate in several circumstances. Percutaneous coronary revascularization (e.g., angioplasty, directional or rotational atherectomy, or endovascular stenting) may be indicated in the patient with symptomatic atherosclerotic coronary artery disease whose coronary anatomy is suitable for the procedure. Valvuloplasty is indicated in the subject with symptomatic isolated pulmonic stenosis, and it is an acceptable alternative to surgery in the patient with mitral stenosis or aortic stenosis in whom valvular anatomy is suitable and surgery is believed to offer an unfavorable risk-benefit ratio, due, for example, to advanced age or comorbid medical conditions (i.e., chronic pulmonary, hepatic, or renal disease or an underlying malignancy).

Catheterization is absolutely contraindicated if a mentally competent individual does not consent. It is relatively contraindicated if an intercurrent condition exists that, if

corrected, would improve the safety of the procedure (*e*Table 79.0.2).

***e*TABLE 79.0.2** RELATIVE CONTRAINDICATIONS TO CARDIAC CATHETERIZATION
Decompensated heart failure (e.g., pulmonary edema)
Uncontrolled ventricular irritability
Uncontrolled systemic arterial hypertension
Acute or severe renal insufficiency
Difficulty with vascular access
Electrolyte imbalance (i.e., hypokalemia or hyperkalemia)
Digitalis intoxication
Active infection or febrile illness
Uncorrected bleeding diathesis
Severe anemia
Active bleeding from internal organ
Severe allergy to radiographic contrast material
Mental incompetence

RISKS AND COMPLICATIONS

As cardiac catheterization has been more frequently performed, the incidence of complications has diminished (*e*Table 79.0.3). However, even in skilled hands, the procedure is not without risk (1,2,3 and 4). The overall incidence of a major complication (death, myocardial infarction, or cerebrovascular accident) during or within 24 hours of diagnostic catheterization is 0.2% to 0.3%. Of these major complications, death during or within 24 hours of the procedure occurs in 0.1% to 0.2% of patients. Such deaths may be caused by perforation of the heart or great vessels, cardiac arrhythmias, acute myocardial infarction, or anaphylaxis to radiographic contrast material. Individuals with an increased risk of death include those with (a) advanced (older than 70 years) or very young (younger than 1 year) age, (b) marked functional impairment (class IV angina or heart failure), (c) severe left ventricular dysfunction or coronary artery disease (particularly left main disease), (d) severe valvular disease, (e) severe comorbid medical conditions (i.e., renal, hepatic, or pulmonary disease), or (f) history of an allergy to radiographic contrast material. Patients with significant left main coronary artery stenosis have a substantially greater risk of periprocedural death (2.8%) compared with those without left main coronary artery stenosis (0.1%) (5,6).

***e*TABLE 79.0.3** COMPLICATIONS ASSOCIATED WITH DIAGNOSTIC CARDIAC CATHETERIZATION

Complications	**Percent**
Major	
Death	0.1
Cerebrovascular accident	0.07
Myocardial infarction	0.07
Arrhythmia (life threatening)	0.5
Vascular compromise	0.5–1.5
Anaphylaxis (to contrast material)	0.007
Minor	
Hives	2.0–3.0
Nausea/vomiting	~5.0
Vasovagal reaction	3.0

Myocardial infarction during or immediately after diagnostic catheterization occurs in approximately 0.07% of patients, but most are small and uncomplicated. Cerebrovascular accidents in the pericatheterization period may be (a) embolic (from the arterial catheter, guidewire, left ventricular or atrial thrombus, or dislodged atherosclerotic plaque) or (b) thrombotic (i.e., existence of previous extensive cerebrovascular disease that, in association with the hemodynamic alterations induced by arteriography, leads to inadequate cerebral perfusion).

Numerous minor complications may cause morbidity but exert no effect on mortality. Local vascular complications occur in 0.5% to 1.5% of patients. The incidence is similar for the brachial and femoral approaches and somewhat higher for the radial approach. After arterial catheterization by the brachial or radial approach, thrombosis, dissection, intimal flap formation, or subintimal hemorrhage may compromise blood flow to the hand or arm, and the patient may require thrombectomy or surgical exploration after catheterization. With the percutaneous femoral approach, hemorrhage, hematoma formation, or both at the arterial puncture site are the most common problems and, if severe, may require limited surgical exploration. Arteriovenous (AV) fistulae or pseudoaneurysm formation may occur, especially if protracted bleeding at the puncture site occurs after sheath removal, as may result from inadequate compression of the femoral vessel, insertion of large sheaths, severe systemic arterial hypertension, prolonged heparinization, or administration of thrombolytic or antiplatelet agents. Less commonly, femoral arterial thrombosis occurs, which requires urgent thrombectomy. Compression by a large hematoma or groin clamp may cause local nerve damage. Local infection may occur at the site of catheter entrance and manipulation, but this can usually be treated effectively with meticulous wound care and antibiotics.

Atheroemboli. Embolization of cholesterol, fibrin, and platelet debris results in digital necrosis and gangrene (*yellow arrow*), as well as localized skin necrosis and livedo reticularis (*white arrows*).

Atheroemboli. Digital necrosis resulting from severe atheroemboli.

Livedo reticularis. Mottled reddish discoloration of the lower extremities with accompanying multiple ulcerations associated with atheroemboli.

The injection of radiographic contrast material commonly causes nausea and vomiting as well as a transient decrease in systemic arterial pressure. Occasionally, such injections are associated with allergic reactions of varying severity, and a rare individual has anaphylaxis. Only 15% of individuals with a known allergy to contrast material have another adverse reaction with repeat administration, and most of these are minor (urticaria, nausea, vomiting) (7). In the vast majority of patients with a history of contrast allergy, angiography can be performed safely; however, premedication with glucocorticosteroids and antihistamines as well as use of a nonionic contrast agent are usually recommended. The endocardial injection of contrast material during ventriculography (so-called endocardial staining) may cause ventricular irritability. Finally, use of excessive quantities of radiographic contrast material may result in renal insufficiency, which is usually transient. This is particularly likely to occur in patients with preexisting renal dysfunction and diabetes mellitus, and its occurrence can be minimized by (a) limiting the amount of contrast material used during catheterization based on the patient's body surface area and baseline serum creatinine (8), and (b) administering sufficient oral and intravenous fluids after catheterization to ensure that the osmotic diuresis caused by the hyperosmolar contrast material does not induce intravascular volume depletion.

TECHNIQUES OF CARDIAC CATHETERIZATION

Approaches

Catheterization of the right and left sides of the heart can be accomplished by the introduction of catheters (a) by direct vision (into the brachial vein and artery) (9) or (b) by percutaneous puncture (of the radial artery or femoral or brachial vein and artery) (10). The choice of approach (brachial, femoral, or radial) for venous and arterial catheterization is determined by the preference and experience of the operator as well as the anatomic and pathophysiologic abnormalities of the patient. In general, right-sided heart catheterization is easier via the brachial approach in the patient with right ventricular or right atrial dilatation. In contrast, in the patient with a secundum atrial septal defect, a right-sided heart catheter can be passed across the defect more easily via the femoral approach. Thus, in choosing the route for right-sided heart catheterization, it is necessary to be cognizant of anatomic abnormalities and specific disease entities. In most patients, left-sided heart catheterization can be performed by the radial, brachial, or femoral approach. However, the femoral approach offers several advantages. This approach can be performed quickly and repeatedly in the same patient, allows the use of larger lumen catheters, and has a low incidence of infection or vascular injury. Certain conditions, however, render left-sided heart catheterization by the femoral approach difficult, such as extensive peripheral vascular disease, marked obesity, severe systemic arterial hypertension, bleeding diatheses, and any disorder that results in a markedly augmented arterial pulse pressure (e.g., severe aortic regurgitation). In the patient with any of these conditions, the brachial or radial approach may be safer if performed by an operator experienced with this technique. In turn, the brachial or radial approach for left-sided heart catheterization is relatively contraindicated if there is evidence of severe brachiocephalic or ulnar arterial disease.

Brachial Approach

To use the brachial cutdown approach, local anesthetic is introduced into an area 3 to 4 cm in diameter, approximately 1 cm above the flexor crease of the arm, after which a transverse cutdown is performed. If both right- and left-sided heart catheterization is planned, the incision should be wide (2 to 3 cm in length) and located over the brachial artery; if only right-sided heart catheterization is contemplated, a small incision can be made directly over a brachial vein. Once the skin incision is made, the subcutaneous tissues are separated by blunt dissection with a curved hemostat. The vein and artery are isolated with bands, separated from adjacent tissues, and cleaned. The catheters are introduced under direct vision and are advanced into the great vessels and heart.

After catheterization by the brachial cutdown approach, the catheters are removed, and the vein used for right-sided heart catheterization is ligated. The artery used for left-sided heart catheterization is rendered free of thrombi, and the arteriotomy is repaired. After blood flow has been successfully restored to the distal arm, the wound is flushed with saline, the incision is sutured, and the site of the cutdown is appropriately dressed. Alternatively, the brachial approach can be performed percutaneously in a manner similar to the femoral approach described in the next section.

Brachial artery hematoma. Hematoma complication after brachial artery catheterization and urokinase administration.

Femoral Approach

To use the percutaneous femoral approach, local anesthetic is introduced into an area 3 to 4 cm in diameter 3 to 4 cm below the inguinal ligament (the inguinal ligament extends from the anterior superior iliac crest to the symphysis pubis). The anticipated puncture site should overlie bone, thus allowing for adequate vessel compression when the sheaths are removed. A small incision (approximately $^1/_2$ cm in length) is made over the vessel(s) to be used for catheter introduction and passage, after which a "tunnel" is constructed (using a straight hemostat) at a 30- to 45-degree angle to the surface of the skin and to the approximate depth of the desired femoral vessel. An 18-gauge needle is introduced through the skin incision and tunnel into the lumen of the femoral artery or vein. Once blood flows freely through the needle, a Teflon-coated guidewire is advanced into the lumen of the punctured vessel. The wire is held firmly in place as the needle is removed, and the wire is wiped to remove blood and thrombi. Then, a sheath with a side arm port is advanced over the wire into the vessel lumen, and the wire is removed. The side arm port allows continuous pressure monitoring and infusion as catheters are advanced through the sheath to the heart. After catheterization, the vascular sheaths are

removed, and hemostasis is achieved by applying pressure over the puncture site (generally 1.0 to 1.5 cm cephalad to the skin incision) for sufficient time to ensure the cessation of bleeding. Hemostasis is generally obtained by applying direct pressure to the puncture site on the femoral vein for 5 to 10 minutes and on the femoral artery for 20 to 30 minutes. Subsequently, the patient is required to remain in bed and to immobilize the involved limb for 8 to 24 hours, depending on sheath size. The percutaneous brachial technique is performed in a similar manner by creating a tunnel 1 cm above the flexor crease of the arm.

Radial Approach

Diagnostic and interventional catheterization procedures can be performed via percutaneous cannulation of the radial artery with No. 5 or 6 Fr sheaths. Because of its small caliber, the radial artery may spasm during sheath placement or catheter manipulation, requiring treatment with intraarterial nitroglycerin or a calcium channel blocker. Bleeding is uncommon with the radial approach, but radial artery thrombosis occurs in 5% to 10% of patients, usually without sequelae provided that a preprocedure Allen's test result confirmed adequate perfusion of the hand through the ulnar artery. The major advantage of the radial approach is that it allows the patient to ambulate soon after catheterization, which is conducive to the performance of outpatient diagnostic and interventional procedures.

Allen's test. To test the competence of the collateral circulation of the radial and ulnar arteries, a patient is asked to pump his or her hands after which both arteries are occluded (1). Then the pressure on one artery is released (2). Rapid return of blood flow signifies a normal response. The same steps are repeated with the other artery (3). Combined, 4.

Transseptal Approach

In situations in which access to the left atrium is necessary, a transseptal catheterization is performed. With this technique, a long sheath is placed percutaneously in the right femoral vein and advanced to the right atrium over a guidewire. A special transseptal needle is advanced through the sheath and used to puncture the interatrial septum. The sheath is then advanced over the needle into the left atrium and the needle withdrawn from the body. Through the sheath, left atrial pressure can be measured, and catheters can be placed for therapeutic procedures, such as mitral valvuloplasty. The transseptal approach should not be attempted in the patient with (a) severely distorted or malaligned cardiac anatomy, (b) left atrial thrombus, (c) left atrial myxoma, or (d) a bleeding diathesis. In experienced hands, significant complications (cardiac perforation, pericardial tamponade, ventricular fibrillation, cerebrovascular event, or death) occur in 1% to 2% of transseptal procedures (11).

Left Ventricular Puncture

In rare circumstances, placement of a catheter in the left ventricle across the aortic (or mitral) valve is not advisable. For example, advancement of a catheter across a tilting disc prosthetic valve may result in catheter entrapment. Accordingly, direct puncture of the left ventricle through the chest wall can be performed to measure left ventricular pressure and to perform left ventriculography. With this approach, after generous local anesthesia, an 18-gauge needle is inserted at the apical impulse and directed toward the long axis of the left ventricle (toward the right shoulder). When heart pulsations or ventricular ectopy are noted, the needle is in contact with the ventricular epicardium, and it is slowly advanced until pulsatile blood flow is noted. Left ventricular pressure can be measured directly through the needle. If ventriculography is to be performed, the needle can be exchanged over a guidewire for a No. 4 or 5 Fr pigtail catheter. Significant complications (cardiac tamponade, hemothorax, pneumothorax, ventricular fibrillation) occur in 3% to 10% of these procedures, and vasovagal reactions occur in approximately 5% (12).

Endomyocardial Biopsy

Percutaneous endomyocardial biopsy may be performed to obtain pieces of myocardial tissue for microscopic examination. Most commonly, tissue is obtained from the right ventricle; however, left ventricular biopsy also can be performed. From the femoral or internal jugular vein, a long biopsy sheath with a side arm port is advanced to the right ventricle over a guidewire. Then, under fluoroscopic guidance, the bioptome is advanced through the long sheath and directed toward the interventricular septum. After it has exited the end of the sheath, its jaws are opened, and it is advanced to the septum. The jaws are then tightly closed, and the bioptome is briskly withdrawn through the sheath to tear away a small piece of tissue. This procedure is repeated until three to five tissue specimens are obtained. Local complications related to vascular access (i.e., venous thrombosis, hemorrhage, pneumothorax, recurrent laryngeal nerve injury) are the most common problems associated with this

procedure and occur in 1% to 2% of patients. Transient arrhythmias or right bundle branch block from catheter manipulation is common, but sustained rhythm abnormalities are not. Cardiac perforation is rare (13), occurring in less than 0.05% of procedures, but may lead to pericardial tamponade and hemodynamic collapse, especially if not recognized promptly and treated appropriately. Other rare complications include tricuspid regurgitation (due to chordal tear) and formation of coronary artery to right ventricular fistulae (14).

Right-Sided Heart Catheterization

During routine right-sided heart catheterization, measurements of pressures and oxygen saturations in the venae cavae, right atrium, right ventricle, pulmonary artery, and pulmonary capillary wedge position can be performed, and CO can be quantified (see Table 79.1 for normal values). The measurement of right-sided pressures helps one to evaluate the severity of tricuspid or pulmonic stenosis, to assess the presence and severity of pulmonary hypertension, and to calculate pulmonary vascular resistance. In the absence of pulmonary vein stenosis (a rare condition), the pulmonary capillary wedge pressure accurately reflects left atrial pressure. The determination of oxygen saturations from the various right-sided heart chambers is used to assess the presence, location, and magnitude of intracardiac left-to-right shunting, such as occurs with atrial or ventricular septal defect or patent ductus arteriosus. Occasionally, angiography is performed to define right-sided anatomic abnormalities or to evaluate the severity of right-sided valvular regurgitation.

Flows	
Cardiac index (L/min/m²)	2.6–4.2
Stroke volume index (mL/m²)	35–55
Pressures (mm Hg)	
Aorta/systemic artery	
Peak systolic/end diastolic	100–140/60–90
Mean	70–105

Oxygen consumption (mL/min/m²)	110–150
AVO₂ difference (mL/dL)	3.5–4.5

AVO₂, arteriovenous.

TABLE 79.1 NORMAL HEMODYNAMIC VALUES

For optimal measurement of right-sided heart pressures, a relatively stiff, large-lumen, nonflotation catheter is used, which can be advanced until it “wedges” in a small pulmonary artery. The catheter’s position in the pulmonary capillary wedge location is confirmed by obtaining blood with an oxygen saturation greater than 95%. Alternatively, a softer, balloon-tipped flotation catheter can be used. With this catheter, the acquisition of a blood sample to confirm the pulmonary capillary wedge position is often difficult, and the fidelity of the pressure recordings obtained with it is less ideal than that obtained with a stiffer, large-lumen catheter; however, its ease of passage and paucity of complications make it more suitable for use by operators with limited experience. Furthermore, because it is flow directed, it often can be advanced through the right side of the heart without fluoroscopic guidance. Finally, addition of a thermistor to the flotation catheter’s distal portion allows one to measure CO by the thermodilution technique.

Left-Sided Heart Catheterization

With left-sided heart catheterization, one can assess (a) mitral and aortic valvular function, (b) left ventricular pressures and function, (c) systemic vascular resistance, and (d) coronary arterial anatomy. To perform angiography or to measure the pressure in the left ventricle, one usually advances a catheter retrograde across the aortic valve. In rare circumstances in which this is impossible (e.g., severe aortic stenosis or a tilting-disc prosthetic valve in the aortic position), transseptal catheterization is performed, and the catheter is advanced to the left ventricle antegrade across the mitral valve.

During most catheterizations, pressures are measured directly from each of the cardiac chambers except the left atrium. The left atrial pressure is generally recorded “indirectly,” that is, as the pulmonary capillary wedge pressure. To accomplish this, an end-hole catheter is placed in the pulmonary artery and advanced into the pulmonary arterial tree until it is effectively wedged. If the catheter is wedged adequately, the resultant pressure is left atrial, and the blood withdrawn from it is fully saturated. The demonstration that fully saturated blood can be withdrawn from the catheter confirms that the pressure is indeed left atrial. When a direct left atrial pressure recording is needed, a transseptal catheterization can be performed.

HEMODYNAMIC MEASUREMENTS

Cardiac Output

The role of the heart is to deliver an adequate quantity of oxygenated blood to the body. This flow of blood is known as the *CO* and is expressed in liters per minute. Since the magnitude of CO is proportional to body surface area, one person may be compared with another by means of the cardiac index (i.e., the CO adjusted for body surface area). The normal cardiac index is 2.6 to 4.2 L per minute per m^2 of body surface area (Table 79.1). The two commonly used methods of measuring CO are the Fick method and the indicator dilution technique. The latter can be performed by thermodilution or the injection of indocyanine green.

Fick Method

The measurement of CO by the Fick method is based on the hypothesis that the uptake or release of a substance by an organ is the product of the blood flow to that organ and the regional AV concentration difference of the substance (15). To measure CO in humans, this principle is applied to the lungs, and the substance measured is oxygen (O_2). By measuring the amount of O_2 extracted from inspired air by the lungs and the AVO_2 difference across the lungs, pulmonary blood flow may be calculated. Because pulmonary blood flow is similar to systemic blood flow in most people, the Fick method allows one to measure systemic blood flow. The Fick formula for the calculation of CO is:

$$\text{CO (L/min)} = \frac{O_2 \text{ consumption (mL/min)}}{AVO_2 \text{ difference across the lungs (mL/L)}}$$

The normal O_2 consumption index (O_2 consumption per m^2 of body surface) is 110 to 150 mL per minute per m^2 (Table 79.1) (16). In general, the O_2 consumption is higher for men than women and decreases gradually with age. It increases with hyperthyroidism, hyperthermia, and exercise, whereas it decreases with hypothyroidism and hypothermia. In many laboratories, the O_2 consumption is estimated from a nomogram, formula, or table. However, studies (17) have demonstrated a poor relationship between estimated and measured O_2 consumption (Fig. 79.1), in part because of the wide range of values among patients (eFig. 79.1.1) (16). Thus, to determine CO accurately via the Fick method, O_2 consumption should be measured directly.

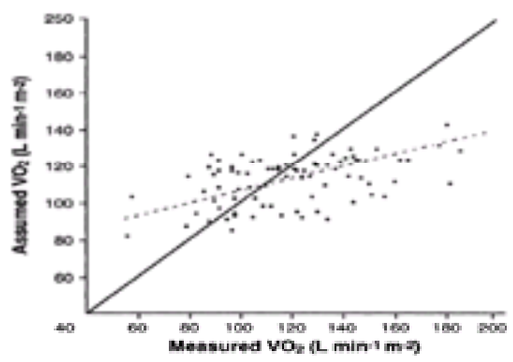

FIGURE 79.1 Comparison of measured (*x*-axis) and assumed (*y*-axis) oxygen consumption (VO_2), with the latter derived from a formula. The relationship between the measured and assumed oxygen consumptions is poor. (From Kendrick AH, West J, Papouchado M, et al. Direct Fick cardiac output: are assumed values of oxygen consumption acceptable? *Eur Heart J* 1988;9:337–342, with permission.)

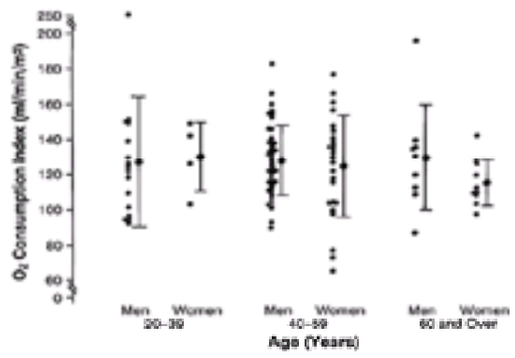
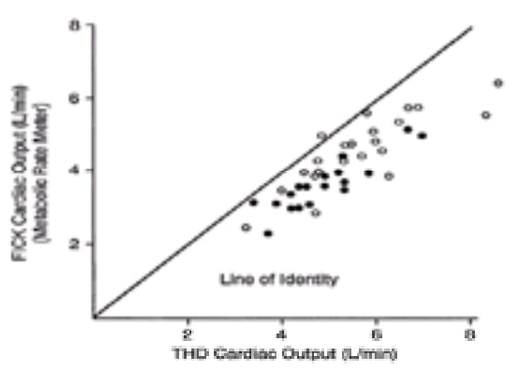


***e*FIGURE 79.1.1** Oxygen consumption (indexed to body surface area) for men and women in three age groups: 20 to 39 years, 40 to 59 years, and 60 years or older. Each symbol represents the data from one patient, and the means and standard deviations for each group are displayed. Although the mean values for oxygen consumption are similar for each of the groups, the range of values is large (65 to 250 mL per minute per m^2), so that an estimate of oxygen consumption in an individual subject may be markedly inaccurate. (From Dehmer GJ, Firth BG, Hillis LD. Oxygen consumption in adult patients during cardiac catheterization. *Clin Cardiol* 1982;5:436–440, with permission.)

The O_2 consumption can be determined directly by two methods. The most reliable method involves collecting a timed sample (usually 3 to 4 minutes) of expired air in a special receptacle called a *Douglas bag*. The volume of this collection is measured, and the difference in O_2 content between inspired and expired air is calculated. From these data, the person's O_2 consumption (in mL per minute) is determined. More commonly, O_2 consumption is determined by commercially available polarographic machines (i.e., MRM-2, Waters Instruments, Rochester, MN; MedGraphics System, Medical Graphics, St. Paul, MN), which have carbon dioxide, or oxygen, or both kinds of sensors and continuously measure air flow and fractional content of carbon dioxide, oxygen, or both from expired air collected through the port of a mouthpiece or tight-fitting face mask. Because of potential inaccuracies of the polarographic systems (*e*Fig. 79.1.2) (18), laboratories that use them should regularly assess their reliability by comparing results obtained with them with other methods, such as a standard Douglas bag collection.



***e*FIGURE 79.1.2** Comparison of thermodilution (THD) cardiac output (*x*-axis) and the Fick cardiac output (*y*-axis), with the latter calculated using oxygen consumption measured with the metabolic rate meter. Open and closed circles represent data collected at two different hospitals, and the line of identity is shown. Compared with the thermodilution technique, the results of Fick using the oxygen consumption measured with the metabolic rate meter were consistently low. (From Lange RA, Dehmer GJ, Wells PJ, et al. Measurement of oxygen consumption and cardiac output: limitations of the metabolic rate meter. *Am J Cardiol* 1989;64:783–786, with permission.)

Determining the AVO_2 difference across the lungs requires that blood from the vessels entering and draining the lungs (i.e., the pulmonary artery and vein) be analyzed for O_2 content. Since the O_2 content of pulmonary venous blood is similar to that of systemic arterial blood (provided that a right-to-left shunt is not present), systemic and pulmonary arterial samples are usually obtained for the Fick determination of CO. The O_2 content of pulmonary and systemic arterial blood may be measured directly or calculated from the O_2 saturation of the blood and its hemoglobin (Hgb) concentration: O_2 content = Hgb (in g per 100 mL) × 1.36 (mL O_2 per g Hgb) × saturation, where 1.36 is the maximum O_2-carrying capacity of 1 g of Hgb. The normal AVO_2 difference is 3.0 to 4.5 vol percent (mL O_2 per dL of blood). The following is an example of the Fick calculation of CO: (a) O_2 consumption = 250 mL per minute; (b) Hgb = 14 g per dL; (c) systemic arterial O_2 saturation = 0.95 (95%); (d) pulmonary arterial O_2 saturation = 0.65 (65%); and (e) 10 = dL per L (conversion factor).

$$CO = \frac{250}{(14)(1.36)(10)(0.95) - (14)(1.36)(10)(0.65)} = 4.38 \text{ L per minute}$$

The Fick method has several potential sources of error (19). First, an incomplete collection of expired air causes an underestimation of O_2 consumption, leading to the calculation of a falsely low value for CO. This is the most common source of error. Second, incorrect timing of the collection of expired air leads to an inaccurate estimate of O_2 consumption. Third, analysis of the Douglas bag contents should be performed soon after its collection, since air may diffuse in or out of the bag if a substantial delay between collection and analysis is allowed to occur. Fourth, with commercially available polarographic systems, determination of the fractional content of oxygen or carbon dioxide may be inaccurate if the gas sensors are not calibrated regularly and correctly. Fifth, spectrophotometric determination of the O_2 saturations may be inaccurate if certain substances, such as indocyanine green, have been introduced into the blood. Finally, the mixed venous blood sample must, indeed, be *mixed venous*. It is generally obtained from the pulmonary artery; it must not be partially contaminated by pulmonary capillary wedge blood or left-to-right shunted blood.

The average error in determining O_2 consumption is approximately 6%, and that for AVO_2 difference is 5%. When the AVO_2 saturation difference is small, errors in measurement are magnified. Therefore, the Fick method is most accurate in the patient with a low CO (i.e., one with a relatively wide AVO_2 saturation difference) and least accurate in one with a high CO (i.e., one with a relatively narrow AVO_2 saturation difference) (Table 79.2).

Method	Most reliable	Least reliable
Fick	Low cardiac output	High cardiac output
Thermodilution	High cardiac output	Pulmonic regurgitation Tricuspid regurgitation Intracardiac shunting
Indocyanine green	High cardiac output	Aortic regurgitation Mitral regurgitation Low cardiac output Intracardiac shunting
Angiographic	Normal shaped ventricle	Extensive segmental wall motion abnormalities Dilated ventricle Aortic regurgitation* Mitral regurgitation*

*In these circumstances, angiographic output is greater than forward cardiac output (see text).

TABLE 79.2 METHODS FOR DETERMINING CARDIAC OUTPUT AND CONDITIONS IN WHICH THEY ARE MOST (OR LEAST) RELIABLE

Indicator Dilution Technique

The indicator dilution technique is based on the principle that the volume of fluid within a container can be determined if one adds a known quantity of indicator to the fluid and then measures the concentration of the indicator after it has completely mixed with the fluid. To determine CO, a known amount of indicator is injected into the circulation and allowed to mix completely in the blood, after which its concentration is measured over time. A time-concentration curve is generated (Fig. 79.2), and a minicomputer calculates the area of the inscribed curve.

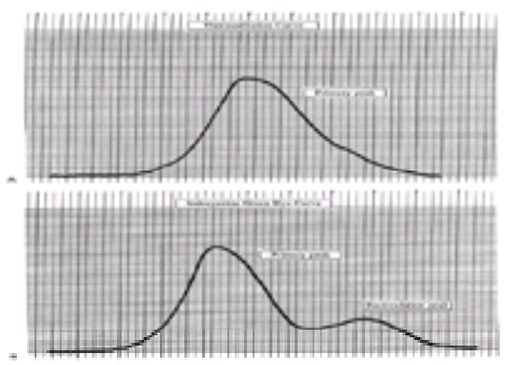


FIGURE 79.2 Time-activity curves for the indicator dilution technique for determining cardiac output: thermodilution **(A)** and indocyanine green **(B)**. With indocyanine green, a primary peak and a recirculation peak are present, whereas with thermodilution, only a primary peak is observed.

The indicator most often used to measure CO is cold saline or 5% dextrose in water. A balloon-tipped flow-directed polyvinyl chloride catheter with a thermistor at its tip and an opening 25 to 30 cm proximal to the tip is inserted into a vein and advanced to the pulmonary artery, so that the proximal opening is located in the venae cavae or right atrium, and the thermistor is in the pulmonary artery. Five to 10 mL of iced fluid is injected into the proximal port, and the change in temperature at the thermistor is recorded (20,21). CO via the thermodilution method is calculated with a computer via the equation:

$$\mathrm{CO} = \frac{(T_B - T_I)(\mathrm{vol})(60)(1.10)(0.825)}{\int \Delta T_B(t)\,dt}$$

in which T_B = body temperature, T_I = temperature of the injectate, vol = volume of the injectate (in milliliters), 60 = number of seconds in 1 minute, and 1.10 = ratio of the products of specific heat and gravity for normal saline and blood; 0.825 is an empiric factor that accounts for the warming of injectate within the catheter. The denominator of the equation is the integral of the change in blood temperature during the injection of cold and is reflected by the area of the inscribed curve (Fig. 79.2). The thermodilution technique is relatively inexpensive, easy to perform, widely available, and does not require arterial sampling or blood withdrawal. In most patients, it accurately determines pulmonary blood flow, which (in the absence of intracardiac shunting) is similar to systemic blood flow. However, certain conditions may render the results of the thermodilution technique unreliable, including (a) tricuspid or pulmonic regurgitation (22) and (b) intracardiac shunting (Table 79.2).

Indocyanine green, an easily detectable, water-soluble, nontoxic substance, can also be used for the indicator dilution measurement of CO (23). To do so, (a) a known concentration (5 to 10 mg) of indicator must be injected; (b) there must be complete mixing of the indocyanine green between the sites of injection and sampling; and (c) there must be no metabolism or disappearance of the indicator between the sites of injection and sampling. In most catheterization laboratories that use this method, CO is measured by injecting indocyanine green into the pulmonary artery as blood is withdrawn at a constant rate from a systemic artery through an optical densitometer (Fig. 79.2). The lungs, left atrium, and left ventricle act as adequate mixing sites, and there is no degradation of indocyanine green between the pulmonary and systemic arteries. The calculation of CO by the indicator dilution technique is usually done by a minicomputer, which establishes that the downslope of the inscribed curve is exponential. It then computes the area inscribed by the curve, excluding the recirculation peak. The results obtained with this method compare favorably with those of other techniques for measuring CO, but it may provide inaccurate results in circumstances in which the recirculation peak cannot be easily separated from the primary peak (e.g., low CO) or when one of the valves between the site of injection and sampling (i.e., mitral or aortic) is regurgitant (Table 79.2).

To ensure an accurate assessment of CO via the indicator dilution technique, great care must be taken to (a) inject an exact amount of indicator, (b) inject the indicator as rapidly as possible (so that, in fact, it is delivered as a bolus), (c) calibrate the densitometer and recorder systems precisely, and (d) ensure that the withdrawal of blood (in the case of indocyanine green) at the sampling site is uniform and not accompanied by air bubbles. If care is taken to eliminate these potential sources of error, the indicator dilution technique is a reliable method of measuring CO. It is most accurate in individuals with a high CO and least accurate in those with a low CO and in those with valvular regurgitation between the sites of indicator injection and sampling (24) (Table 79.2).

Angiographic Technique

From the left ventriculogram, one can determine the volume of blood ejected with each heart beat (stroke volume) and then multiply it by heart rate, yielding the angiographic CO. In patients with mitral or aortic regurgitation, a portion of the blood ejected from the left ventricle regurgitates into the left atrium or ventricle and does not enter the systemic circulation. In these patients, the angiographic CO exceeds the forward output. The measurement of CO by the angiographic method is potentially erroneous in patients with extensive segmental wall motion abnormalities or misshapen ventricles, in whom the determination of stroke volume may be inaccurate (Table 79.2).

Pressure Measurement

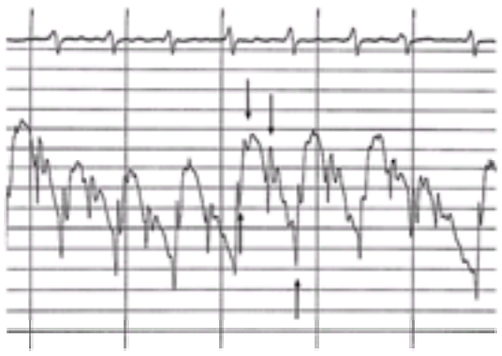
Fluid-Filled Systems

One of the most important functions of cardiac catheterization is the accurate measurement and recording of intracardiac pressures. Once a catheter has been positioned in the desired cardiac chamber, it is connected directly or through stiff, fluid-filled tubing to a pressure transducer, which transforms a pressure signal into an electrical signal (via a Wheatstone bridge). The accurate measurement of pressures requires close attention to the details of the catheter-transducer system, including proper transducer balancing as well as removing air bubbles and blood from the catheters and connections. Errors in pressure measurement may occur in several ways. First, an accurate zero reference is essential. All manometers must be referenced to the same zero level, and their position must be adjusted if the patient's position is altered. Second, pressure transducers must be calibrated frequently, preferably before each pressure recording. To allow for a meaningful interpretation of hemodynamic data, they should be collected (a) with the patient in a steady state, (b) in close temporal proximity to one another (all pressure measurements and

assessments of CO should be completed within 10 to 15 minutes), and (c) before the introduction of radiographic contrast material or other agents known to alter hemodynamic variables.

Micromanometer-Tipped Catheters

With a fluid-filled recording system, distortion of the pressure waveform (eFig. 79.2.1) occurs as a result of (a) motion of the catheter within the heart (so-called catheter whip artifact), (b) amplification of the systolic pressure in the periphery, (c) catheter movement caused by closing or opening of valves, and (d) excessive damping or augmentation of the frequency response of the system. Despite these shortcomings, the pressure recordings obtained with a fluid-filled system provide adequate information in most clinical situations. However, when it is important to obtain precise pressure recordings with undistorted contours (e.g., in the patient with suspected constrictive or restrictive physiology), such a system may be inadequate. To improve the frequency response and to decrease distortion of the pressure recordings, micromanometer pressure chips have been mounted on the end of catheters to measure intracardiac pressures directly (Millar Instruments, Houston, TX). These catheters provide undistorted high-fidelity pressure recordings, such as are necessary to assess pressure waveform contours (especially in the tachycardic patient) and to measure accurately the rate of ventricular pressure rise (dP/dT) or other sophisticated hemodynamic variables.



***e*FIGURE 79.2.1** A pulmonary arterial pressure recording obtained through a balloon-tipped flow-directed catheter. There is distortion of the pressure waveform (*arrows*) from “catheter whip” caused by motion of the catheter within the heart and catheter movement caused by closing or opening valves. Such pressure recording artifacts can be minimized by using a stiff large-lumen catheter or a micromanometer-tipped catheter to record pressures. The distance between each horizontal line represents 4 mm Hg, and the distance between each vertical time line represents 1 second.

Balloon-Tipped Flow-Directed (Swan-Ganz) Catheters

In 1970, the balloon-tipped flow-directed catheter was introduced for right-sided heart catheterization at the bedside, without the need for fluoroscopy (25). At present, it is widely used to monitor right-sided heart and pulmonary capillary wedge pressures in the critically ill patient in the intensive care unit. The catheter, which has an inflatable balloon at its tip, is made of polyvinylchloride and, therefore, is extremely soft. The standard balloon-tipped catheter has a thermistor at its tip and three lumens. One lumen allows inflation of the balloon with air; the other two lumens allow one to measure pressures and to obtain blood specimens at the catheter tip or an opening 25 to 30 cm proximal to the tip. When the catheter is inserted into a vein and advanced to the pulmonary artery, the proximal opening is located in the vena cava or right atrium, and the distal orifice and thermistor are in the pulmonary artery.

Before using the balloon-tipped catheter, the balloon should be inflated in saline to exclude air leakage, and the catheter lumen should be flushed with saline. A temporary transvenous pacing catheter should be positioned in the right ventricle in patients with a preexisting left bundle branch block before passage of any catheter from the right atrium to the pulmonary artery, because such passage may induce a transient right bundle branch block. The balloon-tipped catheter may be inserted at the bedside percutaneously (via the femoral, internal jugular, subclavian, or basilic vein) or by direct exposure of the brachial vein. When it is introduced without the use of fluoroscopy, it should be advanced 20 to 30 cm into the vasculature (depending on the site of introduction) before the balloon is inflated. The catheter is marked at 10-cm intervals to facilitate this procedure. Before advancing the catheter, blood should be aspirated through it to ensure that it is intravascular. The balloon is inflated gently with up to 1.5 mL of air to facilitate its flow-directed passage from the right atrium to the pulmonary artery. If there is resistance to balloon inflation, the catheter should be advanced or withdrawn carefully until the balloon can be inflated freely. The catheter is then connected to a pressure transducer to record right atrial pressure. It is also valuable to obtain a blood sample for oximetric analysis in each right-sided heart chamber or vessel where pressures are recorded to exclude left-to-right intracardiac shunting.

Once a blood sample and pressure have been obtained from the right atrium, the balloon is inflated and the catheter gently advanced while observing pressure and the electrocardiogram. If the catheter does not pass easily through the right ventricle to the pulmonary artery, or significant ventricular ectopy occurs, it should be withdrawn to the right atrium and the procedure repeated. Once it has passed to the pulmonary artery and the pressure has been recorded, it is advanced gently (with the balloon still inflated) until the waveform changes to that of a pulmonary capillary wedge pressure. A fully oxygenated blood specimen from this site confirms that the catheter is truly in a wedged position. When the balloon is deflated, the waveform should revert to that of pulmonary arterial pressure.

It is occasionally impossible to pass the balloon-tipped catheter without the use of fluoroscopic guidance, particularly in the patient with a large right atrium or ventricle or the subject with pulmonary hypertension. In this case, it may be necessary to introduce a 0.025-in. J-tipped guidewire into the catheter to stiffen it, after which it is advanced under fluoroscopic visualization. Passage of the catheter without the use of fluoroscopy is easier when the site of vascular entry is central (i.e., internal jugular or subclavian vein) rather than peripheral.

The balloon-tipped flow-directed catheter offers several advantages over the more traditional stiff catheter used for right-sided heart catheterization; however, it also has drawbacks. Because it is unusually soft, perforation of the major vessels or heart is virtually impossible, whereas such perforation occasionally occurs with the use of a stiff catheter. As indicated, the flow-directed catheter can be inserted and advanced without fluoroscopic control, although catheter manipulation is easier with fluoroscopic assistance. Apart from its safety, the balloon-tipped flow-directed catheter is equipped with a distal thermistor to measure CO by the thermodilution technique.

The major disadvantages of the balloon-tipped flow-directed catheter stem from the same features that are responsible for its advantages. First, because the catheter is unusually soft, the pressure recordings obtained through it may contain a good deal of “catheter whip,” that is, artifact introduced by the movement of the catheter itself within the heart. Second, since the catheter is no larger than No. 7 Fr in size and yet contains several lumens, the distal lumen is small, making the aspiration of blood difficult. Third, since this catheter is advanced in the direction of blood flow, its placement in the pulmonary artery may be impossible if flow within the right-sided heart chambers is bidirectional. For example, advancing a balloon-tipped flow-directed catheter to the pulmonary artery in a patient with severe tricuspid regurgitation may be difficult, since the jet of regurgitation directs the catheter from the right ventricle back into the right atrium. Despite these limitations, this catheter almost always allows one to measure right-and left-sided filling pressures and to make appropriate therapeutic decisions regarding fluid and drug administration.

The risks and complications of the balloon-tipped flow-directed catheter are similar to those of any catheter used for right-sided heart catheterization: ventricular irritability or transient right bundle branch block during passage through the right ventricle and local inflammation or infection at the site of entrance. In addition, because of its softness, the balloon-tipped catheter is easily knotted. Improper or prolonged inflation of the balloon can lead to rupture of a small pulmonary artery or to subsegmental pulmonary infarction, respectively. By and large, however, the balloon-tipped flow-directed catheter is extremely safe. Once it is positioned in the pulmonary artery, it may be left in place for 48 to 96 hours.

Pressure Waveforms

Right atrial systole follows the P wave of the electrocardiogram and produces the ‘a’ wave of the right atrial pressure tracing (Fig. 79.3). With atrial relaxation, there is a decline in the pressure, which is known as the *‘x’ descent*. This descent may be interrupted by a slight upward deflection, the ‘c’ wave, due to tricuspid valve closure. Filling of the right atrium from the venous circulation and retrograde movement of the tricuspid valve annulus during right ventricular systole produce the ‘v’ wave, which follows the QRS complex on the electrocardiogram. When the tricuspid valve opens, blood from the right atrium empties into the right ventricle, and the right atrial pressure declines, producing the ‘y’ descent. During diastole, the right ventricular and right atrial pressures are equal if tricuspid stenosis is absent. Typically, the peak ‘a’ wave, ‘v’ wave, and mean right atrial pressures are reported. In the normal right atrium, the peak ‘a’ wave is higher than the peak ‘v’ wave pressure.

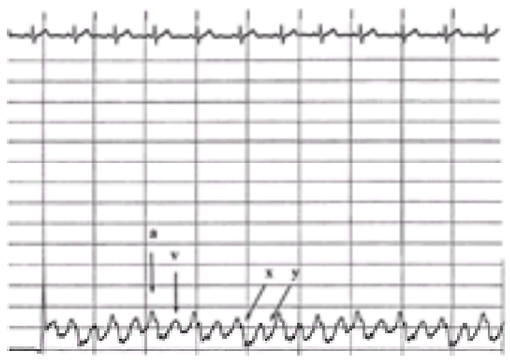


FIGURE 79.3 Typical pressure tracings from the right atrium. There is an ‘a’ wave, ‘x’ descent, ‘v’ wave, and ‘y’ descent, which correlate with right atrial systole, relaxation, filling, and emptying, respectively. The distance between each horizontal line represents 4 mm Hg, and the distance between each vertical time line represents 1 second.

In the right ventricular pressure tracing, atrial systole produces an ‘a’ wave, which occurs after the P wave of the electrocardiogram (Fig. 79.4). Right ventricular systole follows the QRS complex of the electrocardiogram and gives rise to the rapidly increasing systolic pressure waveform. With ventricular relaxation, the pressure waveform declines and reaches a nadir, after which continuous filling of the chamber from the right atrium causes a slow, steady rise in the pressure waveform. The peak systolic and end diastolic (measured at the peak of the QRS complex of the electrocardiogram) right ventricular pressures are usually reported. Similar pressures are reported for the left ventricle.

FIGURE 79.4 Simultaneous surface electrocardiogram and right ventricular pressure recordings. The right ventricular peak systolic pressure averages 45 mm Hg, and the end diastolic pressure (measured at the R-wave peak of the QRS complex) averages 16 mm Hg. The distance between each horizontal line represents 4 mm Hg, and the distance between each vertical time line represents 1 second.

The normal pulmonary arterial pressure consists of a systolic wave that coincides with right ventricular systole and follows the QRS complex of the electrocardiogram (Fig. 79.5). The decline of this pressure wave may be interrupted by a notch, the incisura, which is due to pulmonic valve closure, and the nadir of the decline represents the end diastolic pressure. The pulmonary arterial systolic, end diastolic, and mean pressures are usually reported. Similar pressures are reported for the aorta and peripheral arteries.

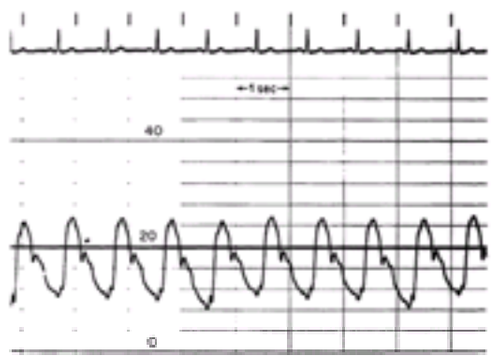

FIGURE 79.5 Simultaneous surface electrocardiogram and pulmonary arterial pressure tracings. The pulmonary arterial pressure averages 25/10 mm Hg, and the incisura, caused by closure of the pulmonic valve, is evident on the downslope of the pressure contour. The distance between each horizontal line represents 4 mm Hg, and the distance between each vertical time line represents 1 second. (From Willard JE, Lange RA, Hillis LD. Cardiac catheterization. In: Kloner RA, ed. *The guide to cardiology*, 3rd ed. New York: Wiley, 1995:145–164, with permission.)

When a catheter is advanced to the pulmonary capillary wedge position and its position confirmed oximetrically (by aspirating blood with an O_2 saturation greater than 95%), the pressure waveform obtained is a transmitted left atrial pressure (Fig. 79.6). The configuration of the waveform is similar to a right atrial pressure, in that there is an ‘a’ wave, ‘x’ descent, ‘v’ wave, and ‘y’ descent, which correlate with left atrial systole, relaxation, filling, and emptying, respectively. In the left atrium, however, the peak ‘v’ wave pressure is typically higher than the peak ‘a’ wave pressure. Transmission of the left atrial pressure through the pulmonary vasculature usually causes modest distortion of the pressure waveform (eFig. 79.6.1). To obtain the most accurate representation of left atrial pressure, the pulmonary capillary wedge pressure should be measured through a stiff catheter with a large lumen (26). Time is required for transmission of the left atrial pressure through the pulmonary vasculature. Thus, if left atrial and pulmonary capillary wedge pressures are recorded simultaneously, a 50- to 100-ms time difference is noted, with the pulmonary wedge pressure occurring later.

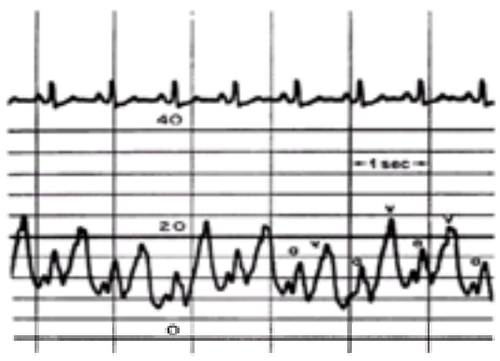

FIGURE 79.6 Pulmonary capillary wedge pressure tracing obtained through a stiff, large-lumen catheter, the position of which was confirmed oximetrically. Like the right atrial pressure tracing, there is an ‘a’ wave and ‘v’ wave, which correlate with atrial systole and filling, respectively. The distance between each horizontal line represents 4 mm Hg, and the distance between each vertical time line represents 1 second. (From Willard JE, Lange RA, Hillis LD. Cardiac catheterization. In: Kloner RA, ed. *The guide to cardiology*, 3rd ed. New York: Wiley, 1995:145–164, with permission.)

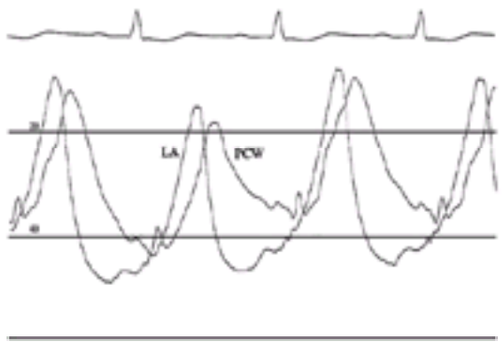
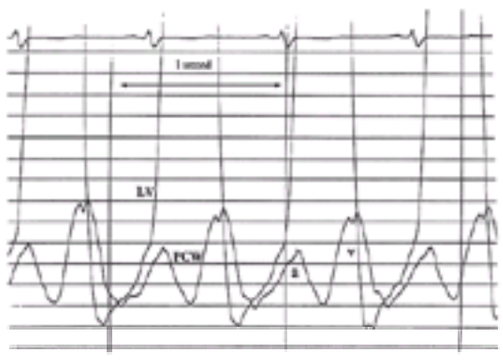


***e*FIGURE 79.6.1** Simultaneous recording of left atrial (LA) and pulmonary capillary wedge (PCW) pressures. In the absence of pulmonary vein stenosis, the PCW pressure is an accurate reflection of the LA pressure. However, there is a time delay and mild distortion of the pressure contour. The pressure peak and nadir are damped, and the 'y' descent is splayed as the LA pressure is transmitted through the pulmonary vasculature to the PCW position.

In addition to the recording of pressures from each of the cardiac chambers, it is important that the pressures from certain chambers be examined simultaneously to confirm or exclude the presence of valvular abnormalities (26,27). Thus, left ventricular and left atrial (or pulmonary capillary wedge) pressures should be recorded simultaneously to ascertain if mitral stenosis is present (*e*Fig. 79.6.2 and Fig. 79.7). Likewise, the left ventricular and systemic arterial pressures should be displayed concurrently to evaluate the presence or absence of left ventricular outflow tract obstruction (*e*Fig. 79.7.1 and Fig. 79.8). The recording of intracardiac and peripheral vascular pressures may demonstrate hemodynamic findings consistent with valvular regurgitation. For instance, large regurgitant waves in the pulmonary capillary wedge tracing may be indicative of mitral regurgitation or other causes of left atrial pressure or volume overload (Fig. 79.9) (28). Conversely, a wide peripheral arterial pulse pressure in conjunction with a greatly elevated left ventricular end diastolic pressure is suggestive of aortic regurgitation. In short, both the absolute level and the qualitative configuration of the intracardiac and peripheral vascular pressures are important in the diagnosis and quantitation of valvular heart disease. The normal intracardiac and peripheral vascular flows, pressures, and resistances are listed in Table 79.1.



***e*FIGURE 79.6.2** Simultaneous recording of left ventricular (LV) and pulmonary capillary wedge (PCW) pressures in a patient without mitral valve disease. The distance between each horizontal line represents 4 mm Hg. The PCW 'a' wave corresponds with the 'a' wave of the LV pressure trace, and the PCW 'v' wave occurs with the downslope of the LV trace. During diastole, the LV and PCW pressures are superimposed (there is no gradient between PCW and LV).

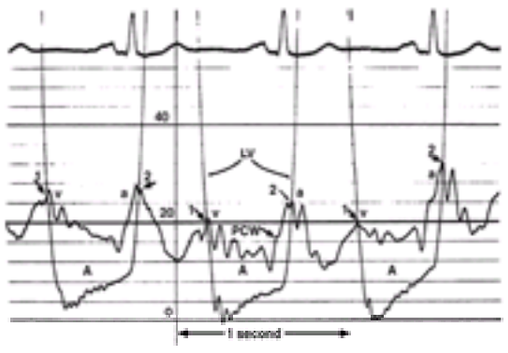


FIGURE 79.7 Simultaneous recording of left ventricular (LV) and pulmonary capillary wedge (PCW) pressures in a patient with severe mitral stenosis. Throughout diastole (from points 1 to 2), there is a pressure gradient (A) between the LV and PCW pressures. This patient had a cardiac output of 3,740 mL per minute and a heart rate of 68 beats/min. The mean diastolic filling period was 0.49 seconds per beat, and the mean pressure gradient was 13 mm Hg. Using Gorlin's equation, the mitral valve area is:

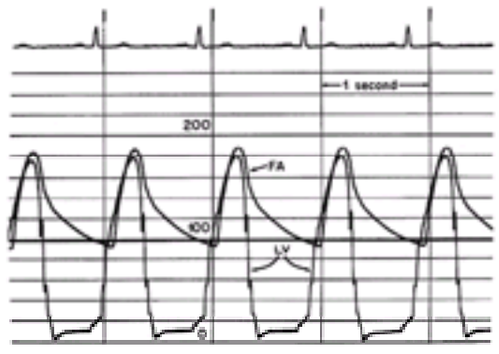
$$\frac{3{,}740/(68)(0.49)}{(38)(\sqrt{13})} = 0.8\ \text{cm}^2$$

(From Willard JE, Lange RA, Hillis LD. Cardiac catheterization. In: Kloner RA, ed. *The guide to cardiology*, 3rd ed. New York: Wiley, 1995:145–164, with permission.)



***e*FIGURE 79.7.1** Simultaneous recording of left ventricular (LV) and femoral arterial (FA) pressures in a patient without aortic stenosis. The pressure scale (in millimeters of mercury) is shown. There is no gradient during systole between LV and FA. (From Willard JE, Lange RA, Hillis LD. Cardiac catheterization. In: Kloner RA, ed. *The guide to cardiology*, 3rd ed. New York: Wiley, 1995:145–164, with permission.)

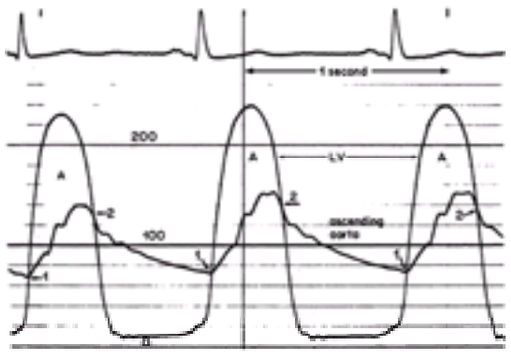


FIGURE 79.8 Simultaneous recording of left ventricular (LV) and ascending aortic pressures in a patient with severe aortic stenosis. Throughout systole, there is a pressure gradient (A) between the LV and ascending aorta. The patient had a cardiac output of 3,350 mL per minute and a heart rate of 62 beats/min. The systolic ejection period (between points 1 and 2) was 0.36 seconds per beat, and the mean systolic pressure gradient was 83 mm Hg. Thus, the aortic valve area was:

$$\frac{3{,}350/(62)(0.36)}{44.5(\sqrt{83})} = 0.4\ \text{cm}^2$$

(From Willard JE, Lange RA, Hillis LD. Cardiac catheterization. In: Kloner RA, ed. *The guide to cardiology*, 3rd ed. New York: Wiley, 1995:145–164, with permission.)

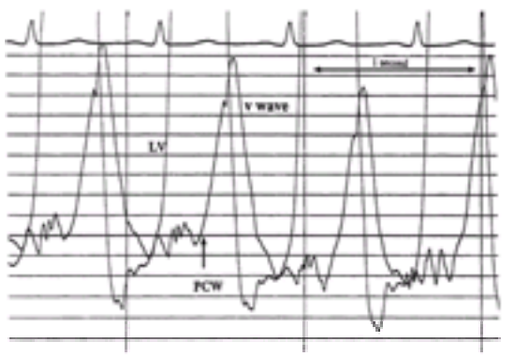

FIGURE 79.9 Simultaneous recording of left ventricular (LV) and pulmonary capillary wedge (PCW) pressures from a patient with severe mitral regurgitation. The PCW pressure tracing demonstrates large regurgitant ‘v’ waves.

Vascular Resistance

The resistance of a vascular bed is calculated by dividing the pressure gradient across the bed by the flow through it. Thus,

$$\text{Systemic vascular resistance} = \frac{\text{mean systemic arterial pressure} - \text{mean right atrial pressure}}{\text{systemic blood flow}}$$

and

$$\text{Pulmonary vascular resistance} = \frac{\text{mean pulmonary artery pressure} - \text{mean pulmonary vein pressure}}{\text{pulmonary blood flow}}$$

Since pulmonary venous pressure is not usually measured, left atrial or pulmonary capillary wedge pressure is substituted for it. Resistances are expressed in (a) resistance units (mm Hg per L per minute), (b) dynes-second-cm^{-5} (resistance units × 80), or (c) Wood units (resistance units × body surface area in m^2). The normal values for vascular resistances are displayed in Table 79.1.

An increased systemic vascular resistance is usually present in patients with systemic arterial hypertension. It may also be seen in the patient with a reduced forward CO and compensatory arteriolar vasoconstriction. In turn, a reduced systemic vascular resistance may be present in the patient with an inappropriately increased CO, the causes of which include AV fistula, severe anemia, high fever, sepsis, and thyrotoxicosis. An elevated pulmonary vascular resistance may be caused by primary lung disease, Eisenmenger’s syndrome (alterations in the pulmonary vasculature in response to increased pulmonary flow and pressure), and a greatly elevated pulmonary venous pressure due to left-sided myocardial or valvular dysfunction or both.

ASSESSMENT OF VALVULAR HEART DISEASE

Valvular Stenosis

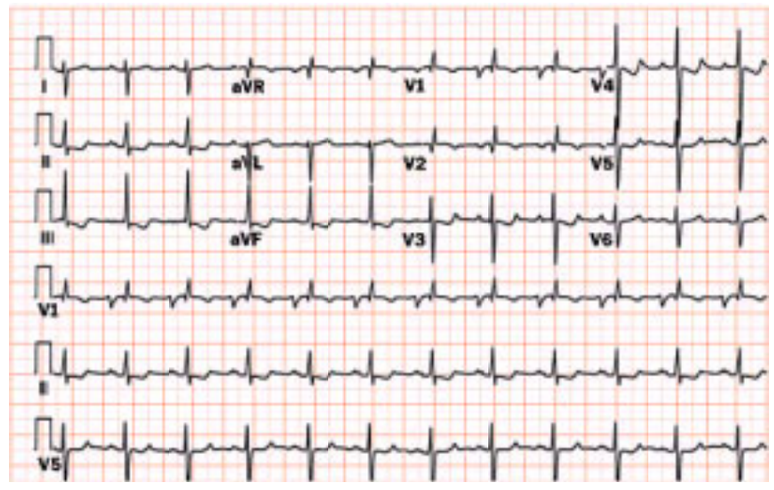
Through the application of standard fluid dynamic principles, the resistance to blood flow through a stenotic valve can be expressed as an effective valve orifice area (29). The data required for the calculation of a valve area may be obtained during cardiac catheterization. Specifically, the pressures on either side of a stenotic valve and the flow across it must be known. The Gorlin’s equation is then used to calculate the valve area:

$$\text{Valve area} = \frac{\text{CO}/(\text{DFP or SEP})(\text{heart rate})}{(\text{constant})\sqrt{\text{mean pressure gradient}}}$$

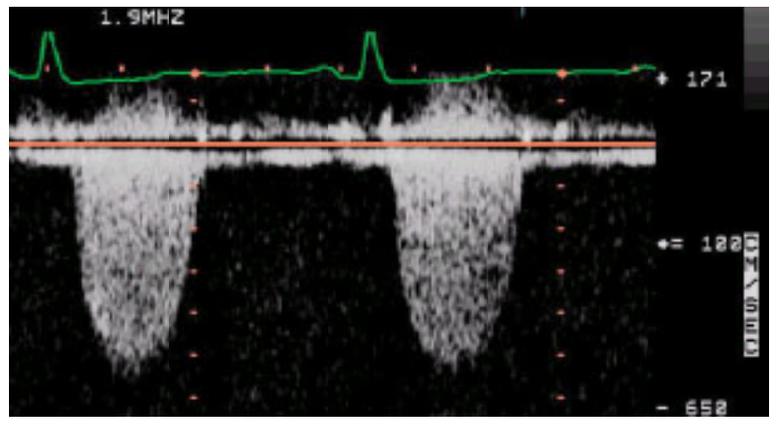
where DFP is diastolic filling period and SEP is systolic ejection period. If an atrioventricular valve (mitral or tricuspid) is being evaluated, the diastolic filling period is used; if the aortic or pulmonic valve is involved, the systolic ejection period is used. The filling periods and transvalvular gradient are measured from pressure tracings obtained simultaneously from either side of the stenotic valve. The constant used is 38.0 for the mitral valve and 44.5 for the other valves. The mean pressure gradient is the average gradient throughout systole (for aortic and pulmonic valves) or diastole (for mitral or tricuspid valves).

The normal mitral valve orifice area is 4 to 6 cm^2, and substantial stenosis may occur before a pressure gradient appears. A mitral valve with an effective orifice area less than 1.0 cm^2 is considered severely stenotic (Fig. 79.7); 1.1 to less than 1.5 cm^2, moderately stenotic; and 1.6 to less than 2.0 cm^2, mildly stenotic. A valve area greater than 2.0 cm^2 is not necessarily normal, but does not usually constitute a hemodynamically significant obstruction to flow. The normal aortic valve has a cross-sectional area of 3 to 4 cm^2, but hemodynamically important aortic stenosis does not develop until the valve orifice area falls below 1.1 to 1.3 cm^2. Specifically, an aortic valve with an effective orifice area less than 0.7 cm^2 is severely stenotic (Fig. 79.8); 0.8 to 1.0 cm^2, moderately stenotic; and 1.1 to 1.3 cm^2, mildly stenotic. The normal pulmonic valve has a cross-sectional area similar to the aortic valve. Although Gorlin’s equation can be applied to the pulmonic valve, by convention the severity of stenosis is based on the peak right ventricular systolic pressure. Pulmonic stenosis with a right ventricular peak systolic pressure of 25 to less than 50 mm Hg is termed mild; 50 to less than 100 mm Hg, moderate; and greater than 100 mm Hg, severe. Finally, the tricuspid valve is large, with a normal orifice area of 6 to 10 cm^2. The assessment of the severity of tricuspid stenosis is most accurate when right atrial and right ventricular pressures are recorded simultaneously. Patients with a tricuspid valve area less than 3.0 cm^2 in the presence of medically refractory right-sided heart failure should be considered for appropriate mechanical intervention (i.e.,

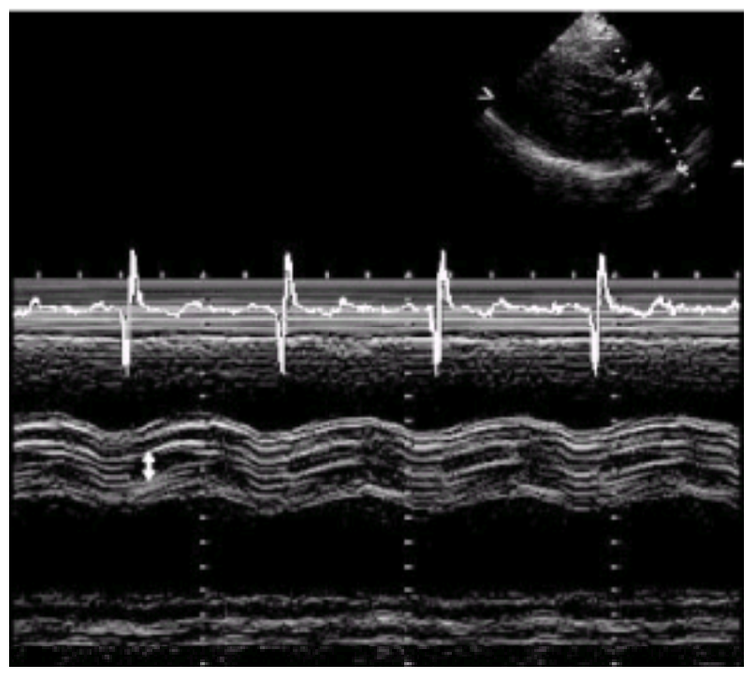
balloon valvuloplasty, open commissurotomy, or valve replacement).



Mitral stenosis. Left atrial enlargement and right ventricular hypertrophy have developed secondary to mitral stenosis, causing fixed pulmonary hypertension.



Continuous wave Doppler through a stenotic aortic valve. The maximal velocity is 5.5 m/sec, consistent with a peak pressure gradient of 121 mm Hg.



M-mode through a stenotic aortic valve. Note the thickened aortic leaflets with decreased excursion. (The small arrow designates the limited excursion of the aortic leaflets.)

It is essential that all the variables used to calculate a valve area (CO, systolic ejection period or diastolic filling period, heart rate, and pressure gradient) be measured in close temporal proximity to one another and with the patient in a hemodynamically stable state. Great care must be exercised in the acquisition of these data, since the decision for operative intervention is based on the calculated valve area.

Valvular Regurgitation

The presence and severity of mitral regurgitation may be evaluated qualitatively by observing the amount of radiographic contrast material that regurgitates into the left atrium during left ventricular systole on a standard left ventriculogram (*e*Fig. 79.9.1). The magnitude of regurgitation is estimated as trivial (1+), mild (2+), moderate (3+), or severe (4+) (see Left Ventriculography, later in this chapter). To obtain a quantitative assessment of the severity of mitral regurgitation, one can calculate the volume of blood that regurgitates from the left ventricle into the left atrium per minute (so-called regurgitant volume) by measuring the difference between the angiographic CO (determined by left ventriculography) and the forward CO (determined by the Fick method or thermodilution). The regurgitant fraction is the percentage of the total angiographic output that regurgitates into the left atrium: It is the quotient of the regurgitant volume and the angiographic output. Typically, valvular regurgitation with a regurgitant fraction 0.6 or greater is severe; 0.40 to 0.59, moderate; 0.20 to 0.39, mild; and less than 0.20, trivial.

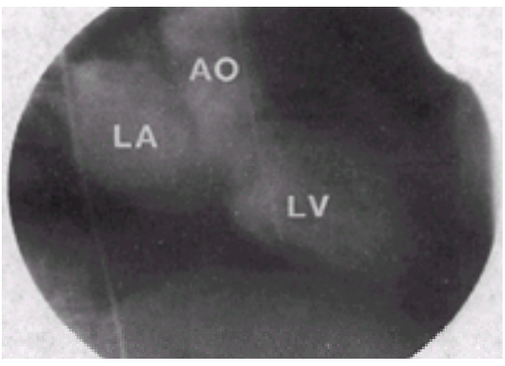
Video 79.3 Left ventriculography with severe mitral regurgitation. After contrast injection in the left ventricle, the left atrium achieves the equal opacity to the left ventricular cavity indicative of severe (4+) mitral regurgitation. Before contrast injection, calcification in the mitral annulus and descending aorta is evident. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



***e*FIGURE 79.9.1** A single plane (30-degree right anterior oblique) left ventriculogram in a patient with severe (4+) mitral regurgitation. The left atrium (LA) is opacified with radiographic contrast material that has regurgitated through an incompetent mitral valve. Ao, aorta; LV, left ventricle.

The presence and severity of aortic regurgitation may be evaluated qualitatively by observing the amount of radiographic contrast material that regurgitates into the left ventricle during ventricular diastole by aortography; it is also graded as trivial (1+), mild (2+), moderate (3+), or severe (4+) (see Aortography, later in this chapter). As with mitral regurgitation, a quantitative assessment of the severity of aortic regurgitation can be obtained by calculating the regurgitant volume and fraction.

ASSESSMENT OF INTRACARDIAC SHUNTING

Left-to-Right Shunting

In the patient with known or suspected congenital heart disease, as well as the subject with unexplained heart failure, cardiac catheterization may be performed to assess the presence, location, and magnitude of intracardiac shunting. To accomplish this, several techniques may be used (Table 79.3) (30).

Method	Able to localize?	Able to quantify?	Minimal Qp/Qs reliably detected
Oximetry	Yes	Yes	1.5-1.9 at level of atrium 1.3-1.5 at level of ventricle 1.3 at level of great vessels
Indocyanine green	No	Yes	1.35
Angiography	Yes	No	Unknown

TABLE 79.3 COMPARISON OF METHODS TO DETECT, LOCALIZE, AND QUANTIFY INTRACARDIAC LEFT-TO-RIGHT SHUNTING

Video 79.6 Transesophageal echo with color Doppler flow demonstrating a secundum atrial septal defect with left-to-right flow. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Oximetric Assessment

The oximetric detection and localization of intracardiac left-to-right shunting is based on the principle that oxygenated blood shunted from the left side to the right side of the heart causes an abnormal increase (“step up”) in the oxygen content or saturation of blood in the chamber into which shunting occurs. To detect the presence and site of the left-to-right shunt, multiple blood samples are obtained from the pulmonary artery, right ventricle, right atrium, and venae cavae, and the oxygen content or saturation of each sample is evaluated for evidence of such a step up. An abnormal step up is present when the right atrial oxygen content is greater than 1.9 mL per dL higher than that of the venae cavae; the right ventricular oxygen content is greater than 0.9 mL per dL higher than that of the right atrium; or the pulmonary arterial oxygen content is greater than 0.5 mL per dL higher than that of the right ventricle (31,32). The oxygen content of blood can be measured directly or calculated from the saturation [saturation × hemoglobin (gram per deciliter) × 1.36 mL O_2 per g of hemoglobin].

The oximetric quantitation of shunting is accomplished by calculating pulmonic (Qp) and systemic (Qs) blood flows according to the Fick principle, where:

$$\text{Qp (L per minute)} = \frac{\text{Oxygen consumption (mL per minute)}}{\text{AV oxygen content difference across the lungs (mL per L)}}$$

and

$$\text{Qs (L per minute)} = \frac{\text{Oxygen consumption (mL per minute)}}{\text{AV oxygen content difference across the body (mL per L)}}$$

The AV oxygen content difference across the lungs is the difference in oxygen contents between pulmonary arterial and venous blood. The AV oxygen content across the body is the difference in oxygen contents between systemic arterial and mixed venous blood, with the latter obtained from the chamber immediately before

(proximal to) the site of shunting. For example, if a ventricular septal defect is present, the mixed venous chamber is the right atrium; if a patent ductus arteriosus is present, the mixed venous chamber is the right ventricle. An example of the calculations for a patient with an intracardiac left-to-right shunt is presented in Table 79.4.

Chamber	O_2 saturation (%)	O_2 content (mL/dL)	O_2 content difference (mL/dL)
Venae cavae	65	13.1	0.4
Right atrium	67	13.5	2.2
Right ventricle	78	15.7	0.2
Pulmonary artery	79	15.9	
Systemic artery	97		
Site of O_2 step up = right ventricle		Mixed venous chamber = right atrium	

$$Qp = \frac{250\ \text{mL/min}}{(0.97 - 0.79)\,(15\ \text{gHb/L})\,(1.36\ \text{mL}\ O_2/\text{g hemoglobin})\,(10\ \text{dL/L})} = 5.81\ \text{L/min}$$

$$Qs = \frac{250\ \text{mL/min}}{(0.97 - 0.67)\,(15\ \text{gHb/L})\,(1.36\ \text{mL}\ O_2/\text{g hemoglobin})\,(10\ \text{dL/L})} = 4.08\ \text{L/min}$$

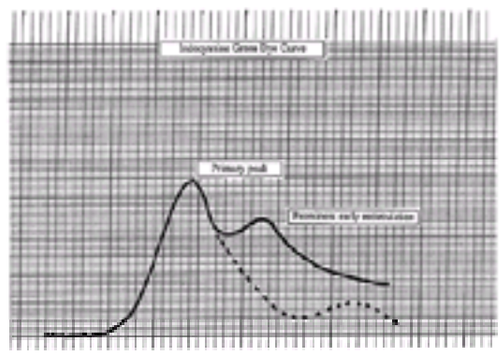
[a]Measured oxygen consumption = 250 mL per minute; Hemoglobin = 15 g per dL; Qp/Qs ratio = 5.81/4.08 = 1.3.

TABLE 79.4 OXIMETRIC ASSESSMENT OF THE PRESENCE, SITE, AND SIZE OF LEFT-TO-RIGHT INTRACARDIAC SHUNTING IN A PATIENT WITH A VENTRICULAR SEPTAL DEFECT[a]

The oximetric determination of intracardiac left-to-right shunting is highly specific but relatively insensitive, in that an oximetric assessment reliably demonstrates the presence of a moderate or large shunt but may fail to detect a small one (Table 79.3) (30).

Indocyanine Green Assessment

As described previously, when a bolus of indocyanine green is introduced into a right-sided heart chamber and its concentration measured in systemic arterial blood, a concentration-time curve is inscribed, which is characterized by a primary peak and a recirculation peak. In the patient with left-to-right intracardiac shunting, the inscribed curve demonstrates prominent early recirculation (*e*Fig. 79.9.2) due to indocyanine green's rapid recirculation to the systemic arterial system through the intracardiac shunt. Since the area of the inscribed recirculation curve is proportional to shunt flow, the magnitude of shunting can be calculated with this technique (33,34). Although this method cannot identify the site of left-to-right shunting, it can detect shunts with a Qp/Qs as small as 1.35; thus, it is somewhat more sensitive than oximetry (35).



***e*FIGURE 79.9.2** A time-concentration curve following injection of indocyanine green into the pulmonary artery, with withdrawal of blood from the aorta in a patient with a large left-to-right intracardiac shunt through an atrial septal defect. In comparison with the normal curve (*dotted line*), there is a prominent early recirculation peak.

Angiographic Assessment

When radiographic contrast material is introduced into a left-sided chamber during angiography in a subject with left-to-right intracardiac shunting, its movement into a right-sided chamber may be visualized. The reliability of any angiographic technique for detecting or localizing intracardiac left-to-right shunting depends on the location of the defect and the obliquity in which the angiogram is performed. Left-sided angiography may be used to detect and localize certain kinds of intracardiac left-to-right shunts. For example, the interventricular septum may be visualized by performing left ventriculography in a 40- to 50-degree left anterior oblique projection, allowing the diagnosis of a ventricular septal defect. A communication between the thoracic aorta and the pulmonary artery (i.e., patent ductus arteriosus or aortopulmonary window) may be identified by performing aortography in the left anterior oblique or left lateral projections. In contradistinction, atrial septal defects and anomalous pulmonary venous drainage are difficult to visualize angiographically. Although angiography can detect and localize certain intracardiac left-to-right shunts, it cannot measure the magnitude of shunting.

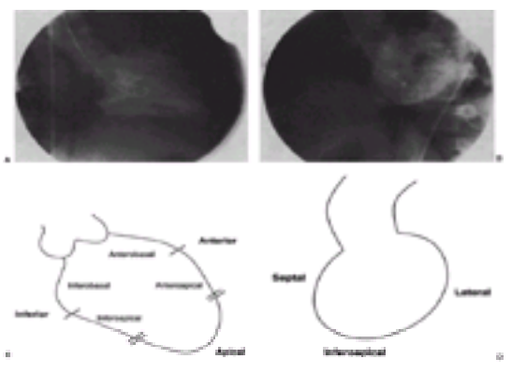
Right-to-Left Shunting

In the patient with right-to-left intracardiac shunting, passage of unoxygenated blood from the venous circulation to the systemic circulation results in arterial desaturation (less than 95%). When desaturation is due to other conditions (i.e., a ventilation-perfusion mismatch or hypoventilation), it is corrected when 100% oxygen is administered, whereas this does not happen when the arterial desaturation is due to right-to-left shunting. Thus, demonstration of a systemic arterial oxygen saturation less than 95% that does not correct with the administration of 100% oxygen (via face mask) is consistent with right-to-left intracardiac shunting.

ANGIOGRAPHY

Left Ventriculography

Cineangiocardiography of the left ventricle allows one to assess (a) global and segmental left ventricular function, (b) left ventricular volumes and ejection fraction, and (c) the presence and severity of mitral regurgitation. To achieve adequate opacification, a large bolus of radiographic contrast material must be delivered to the left ventricle over a short period of time. In the normal adult, 40 to 60 mL of contrast material is injected over 3 to 4 seconds; thus, 10 to 20 mL are injected per second. As the contrast material is injected into the left ventricle, cineangiography is performed. Ventriculography may be performed in two projections (biplane) or more commonly in one projection (single plane), which is usually performed in the 30-degree right anterior oblique projection. If biplane cineangiographic equipment is available, two projections, 90 degrees apart in obliquity (60-degree left anterior oblique and 30-degree right anterior oblique), are performed (*e*Fig. 79.9.3).



***e*FIGURE 79.9.3** With biplane ventriculography, two projections 90 degrees apart in obliquity are performed: 30-degree right anterior oblique **(A)** and 60-degree left

anterior oblique **(B)**. The segments of the left ventricle that are visualized with each obliquity are labeled **(C,D)**. With typical single-plane ventriculography, only the right anterior oblique projection is obtained.

A variety of catheters may be used for left ventriculography, but all have certain features in common. First, the catheter should be of sufficient size so that a high-pressure injection of contrast material does not cause it to recoil, with resultant ventricular ectopy. Second, the catheter should be designed so that the jet of injected contrast material exits a series of side holes rather than just an end hole; as a result, the chance of a high-pressure jet of contrast material being injected into the endocardium (endocardial staining) is minimized. Finally, although the angiographic catheter should have multiple side holes for the injection of contrast material, these holes should be confined to the distal 2 to 3 cm of the catheter to avoid contrast injection into both the left ventricle and the ascending aorta.

Left ventriculography allows for calculation of left ventricular volumes and ejection fraction using a standard area-length formula (36,37 and 38). End diastolic and end systolic volumes are measured; from these, left ventricular stroke volume is derived (end diastolic volume minus end systolic volume), and ejection fraction is calculated (stroke volume divided by end diastolic volume). The normal values for left ventricular volumes and ejection fraction are displayed in *e*Table 79.4.1. In addition to the calculation of left ventricular volumes, segmental wall motion may be assessed. A segment of the left ventricular wall with reduced systolic motion is said to be *hypokinetic*; a segment that does not move during ventricular contraction is *akinetic*; and one that moves paradoxically during ventricular systole is termed *dyskinetic*. Finally, the presence and severity of mitral regurgitation may be evaluated qualitatively during sinus beats as trivial (1+), mild (2+), moderate (3+), or severe (4+): (a) with 1+, contrast material enters the left atrium during systole and clears with each beat; (b) with 2+, contrast opacification of the left atrium does not clear with each beat and is less dense than the left ventricle; (c) with 3+, opacification of the left atrium is equal to that of the left ventricle; and (d) with 4+, the presence of one of three findings is observed—opacification of the left atrium greater than that of the left ventricle, opacification of the left atrium in one systolic ejection period, or the presence of contrast material in a pulmonary vein.

***e*TABLE 79.4.1** NORMAL ANGIOGRAPHIC VALUES

LV end diastolic volume index	50–90 mL/m^2
LV end systolic volume index	13–35 mL/m^2
LV stroke volume index	35–55 mL/m^2
LV ejection fraction	0.55–0.70%

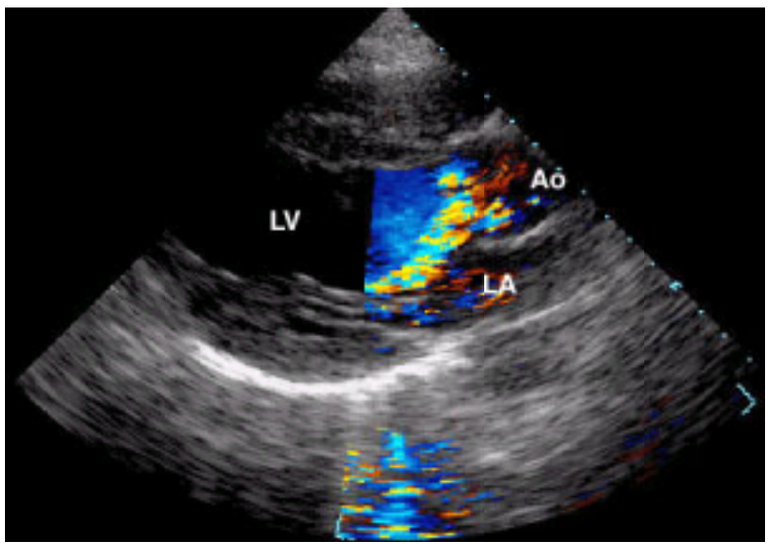
LV, left ventricular.

Right Ventriculography

Cineangiography of the right ventricle allows one to assess global right ventricular function as well as the presence and severity of tricuspid regurgitation. Right ventriculography may be performed in single or biplane projections. Single plane right ventriculography is usually performed in a 30-degree right anterior oblique projection. If biplane angiography is available, a 60-degree left anterior oblique projection is also performed. To achieve adequate opacification, a bolus of 24 to 36 mL of radiographic contrast is injected over 2 seconds as cineangiography is performed. The presence and severity of tricuspid regurgitation may be qualitatively evaluated in a manner similar to mitral regurgitation: trivial (1+), mild (2+), moderate (3+), or severe (4+). There are no reliable methods for the quantitative assessment of right ventricular volumes or ejection fraction by ventriculography.

Aortography

Aortography is performed with the rapid injection of a large amount of radiographic contrast material into the aorta. A proximal aortogram is performed to assess the competency of the aortic valve, to evaluate the anatomy of the proximal aorta and large vessels that supply the head and neck, and occasionally to assess the presence of bypass graft anastomoses that have been difficult or impossible to cannulate selectively. In turn, a distal aortogram is performed to assess the presence of vascular abnormalities (e.g., aneurysm, dissection, intraluminal thrombus, coarctation). The catheters used for aortography are similar to those used for left ventriculography. For proximal aortography, 50 to 60 mL of contrast material is injected over 2.0 to 2.5 seconds and filmed either by cineangiography or rapid cut film angiography. The standard proximal aortogram is filmed in a 45- to 60-degree left anterior oblique projection. The severity of aortic regurgitation may be qualitatively evaluated during sinus beats as trivial (1+), mild (2+), moderate (3+), or severe (4+): (a) with 1+, contrast material enters the left ventricle during diastole and clears with each beat; (b) with 2+, contrast opacification of the left ventricle does not clear with each beat and is less dense than the ascending aorta; (c) with 3+, opacification of the left ventricle is equal to that of the aorta; and (d) with 4+, opacification of the left ventricle is greater than that of the aorta, or the left ventricle is opacified in one diastolic filling period (39).



Parasternal long-axis view (transthoracic echo) with color Doppler demonstrating the posteriorly directed aortic insufficiency caused by prolapse of the anterior leaflet of a bicuspid aortic valve. Note that the jet hits the anterior mitral leaflet.

VIDEO

Video 79.7 Transgastric view (transesophageal echo) of the mitral valve in a patient with severe aortic insufficiency. Note the fluttering of the anterior mitral leaflet (*left*) due to the jet of aortic insufficiency hitting it (color flow seen on the left). VIDEO

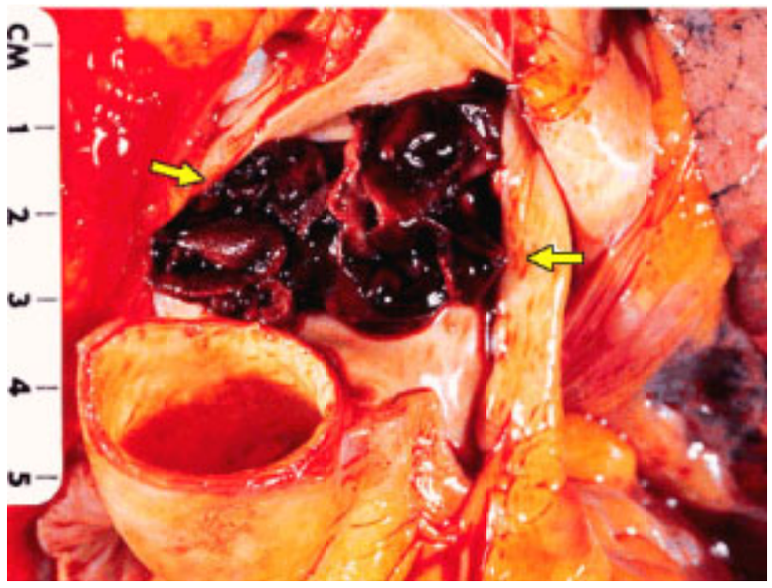
Video 79.9 Aortography in a patient with giant cell aortitis, a severely dilated aorta, and aortic regurgitation. After contrast injection, approximately 1+ aortic regurgitations are evident. The ascending and descending aorta are significantly enlarged (left anterior oblique view). *This video must be viewed with QuickTime. If you*

do not have QuickTime you may download it here.

Video 79.10 A 49-year-old male patient with bicuspid aortic valve and severe aortic regurgitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Pulmonary Angiography

Pulmonary angiography is performed primarily to confirm or to exclude the presence of pulmonary emboli (40,41). A large-bore angiographic catheter is advanced from a systemic vein to the main pulmonary artery and is positioned so that it does not recoil into the right ventricle during the injection of contrast material, with resultant ventricular irritability. A large amount of contrast material (40 to 60 mL) is injected over 2 to 3 seconds. During the injection, cineangiography or rapid cut film angiography is performed.



Saddle embolism of the pulmonary artery. The pulmonary artery has been opened via an anterior incision. Multiple fragments of thrombi protrude from the open pulmonary artery and are wedged into both the left and right pulmonary artery branches (*yellow arrows*).

Video 79.11 Pulmonary angiogram in moderately severe mitral regurgitation. In this pulmonary angiogram, several phases of contrast passage are evident. In the first phase, the pulmonary artery and its branches are seen, followed by a pacification of the pulmonary veins, the left atrium, and the left ventricle. Because much regurgitation is present, there is slow clearing of contrast from the left atrium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

If injection into the main pulmonary artery does not provide a definitive diagnosis, subselective injections are made into those segments of lung where the suspicion of pulmonary emboli is highest. These injections can be made with either a small power injection through the same angiographic catheter or a hand injection through a balloon-tipped catheter.

Analysis of the films must be meticulous, as the radiographic findings associated with pulmonary embolism may be subtle. Radiographic signs diagnostic of pulmonary embolism include a large intraluminal filling defect or an abrupt pulmonary arterial cutoff. Other radiographic signs, such as localized oligemia and asymmetry of pulmonary blood flow, are suggestive but not strictly diagnostic of embolism.

CONTROVERSIES AND PERSONAL PERSPECTIVES

There is considerable controversy regarding the value and safety of right-sided heart catheterization. In many centers, right-sided heart catheterization is performed routinely in conjunction with coronary angiography. In those with proper indications (eTable 79.4.2), it may provide valuable diagnostic and prognostic information, which influences therapy in 35% to 55% of cases (42). In contrast, right-sided heart catheterization seldom provides information that influences patient management in the absence of these indications (43). In these individuals, therefore, it should not be performed routinely.

***e*TABLE 79.4.2** INDICATIONS FOR RIGHT-SIDED HEART CATHETERIZATION
Known or suspected
Valvular heart disease
Congenital heart disease
Restrictive or constrictive heart disease
Pulmonary hypertension
Cardiac tamponade
Heart failure
Decompensated
Etiology undefined
Myocardial infarction
With hypotension
With pulmonary congestion
With mechanical complication
Unexplained right-sided heart failure

When performed by physicians experienced with the technique, right-sided heart catheterization is extremely safe. Over the past two decades, we have performed over 4,700 right-sided heart catheterizations with a stiff large-lumen (e.g., No. 8 Fr Goodale Lubin) catheter with no major complications (i.e., infection, hemorrhage, perforation, or death) and only one (0.02%) minor complication (femoral vein thrombosis).

An observational study (44) suggested that routine right-sided heart catheterization in critically ill patients is associated with an increased mortality. In such patients, physicians with limited catheterization experience often place an indwelling flow-directed pulmonary artery catheter. Complications associated with such indwelling catheters (i.e., pulmonary arterial perforation, sepsis, bacterial endocarditis, and large vein thrombosis) and placement by less experienced operators may account for the observed increased mortality. Some (45) have recommended a moratorium on routine right-sided heart catheterization in critically ill patients until properly conducted, randomized trials have assessed its utility and safety.

In our opinion, right-sided heart catheterization should not be performed in critically ill patients unless done so (a) by a physician experienced with the technique, (b) in

a patient with a clear indication, or (c) for training purposes.

Likewise, left-sided heart catheterization should be performed only for a proper indication (eTable 79.4.3) and in a facility capable of handling complications. Free-standing or mobile catheterization facilities without immediately available hospital and surgical support are ill equipped to handle serious catheterization-related complications. Patients with unstable symptoms or clinical features suggestive of an increased risk for cardiac or vascular complications (Table 79.1) should undergo catheterization in an inpatient setting (46).

***e*TABLE 79.4.3** INDICATIONS FOR THERAPEUTIC LEFT-SIDED HEART CATHETERIZATION

Angina pectoris
Unstable or rest
With exertion
Despite medical therapy
With evidence of extensive coronary artery disease by noninvasive testing
Acute myocardial infarction (for primary angioplasty)
After myocardial infarction
Evidence of extensive coronary artery disease by noninvasive testing
Postinfarction angina
Depressed left ventricular function
Failure to reperfuse following thrombolytic therapy
Cardiogenic shock
Valvular stenosis (with symptoms)
Valvular regurgitation
With symptoms
With impaired left ventricular systolic function
Congestive heart failure
Suspected congenital heart disease
Sudden cardiac death
Major noncardiac surgery and evidence of extensive coronary artery disease by noninvasive testing

THE FUTURE

Cardiac catheterization plays a central role in the diagnostic evaluation of the patient with suspected or known cardiac disease, and it offers percutaneous therapeutic possibilities in many individuals. Over the next decade, the indications for therapeutic catheterization (e.g., percutaneous coronary revascularization, endoluminal stenting, and intracardiac defect closure) will continue to increase as the techniques, equipment, and operator skill improve.

OVERVIEW

Percutaneous coronary intervention (PCI), traditionally known as *percutaneous transluminal coronary angioplasty* (PTCA), has emerged, predominantly as balloon angioplasty, in its first 20 years as the most common major medical intervention.

It is performed under local anesthesia, occasionally even as an outpatient procedure. For optimal performance, it requires state-of-the-art radiographic and dilatation equipment as well as a properly trained operator with an experienced crew.

It works best for single-vessel disease, but it may also be of great value for double-vessel disease and for selected triple-vessel disease, particularly in patients who are old, fragile, or have had prior coronary artery bypass grafting (CABG). It plays a dominant role in the treatment of acute myocardial infarction.

The major drawbacks are low success rates in old and long chronic total coronary occlusions, fatal outcomes in approximately 1%, acute ischemic complications in approximately 5%, and clinically significant restenosis within the first months in approximately 20% of cases. Its strong points are a greater than 90% success rate, the possibility for the patients to immediately return to a normal life, the repeatability of the procedure, and the paucity of complications after the first 24 hours or of recurrences after the first 6 months. Stents have proved to be an important complement to PCI. Although unequivocally required in less than one-half the lesions, routine stenting and even direct stenting are about to become the standard approach.

The current focus in related research is on technical advances in the crossing of chronic total coronary occlusions and on improved antiplatelet and antithrombin therapy to reduce acute occlusions. The restenosis problem, already ameliorated by stenting, is about to be further curbed by brachytherapy and drug-eluting stent coatings.

GLOSSARY

Ad hoc: Performed during diagnostic catheterization.

Culprit lesion: Lesion responsible for current event or predominant symptoms.

Fr: French, diameter unit for equipment, 1 Fr = 0.33 mm.

Guidewire: Wire over which to advance balloon catheter.

Guiding catheter: Catheter through which to introduce balloon catheter into coronary artery.

Monorail: Catheter type with side exit for guidewire in distal portion.

HISTORICAL PERSPECTIVE

Coronary balloon angioplasty is an offspring of transluminal angioplasty of peripheral arteries initiated by Dotter and Judkins in 1964 (1). Their method of dilating stenoses by successively introducing a coaxial double catheter with a diameter of 8 Fr (2.7 mm) and 12 Fr (3.7 mm), respectively, was crude. It required an access hole with a diameter equal to the target lumen. The surgically oriented care system for peripheral artery disease in the United States further impeded the development of the method. In Germany, angiology, an important subspecialty of internal medicine, provided fertile soil for such a technique.

Gruentzig had introduced the Dotter method at the University Hospital in Zurich in 1971, inspired by Zeitler from Germany. For several years, he experimented with different balloon types (2). In 1974, he performed the first balloon angioplasty in a peripheral artery using a form-constant polyvinyl chloride balloon in Zurich (3). In 1975, Gruentzig presented the double-lumen balloon catheter, which was introduced over a guidewire (4). In 1976, he presented a poster at the American Heart Association meeting in Miami demonstrating the feasibility of coronary balloon angioplasty in dogs. In 1977, the coronary dilatation balloon was used by Gruentzig in Zurich in a patient for the first time (5).

On March 22, 1976, in Zurich, a first PTCA attempt had been aborted by Gruentzig. It occurred as a last resort procedure in a patient with inoperable end-stage coronary artery disease and failed because the coronary ostium could not be engaged with the guiding catheter introduced through the arm because of iliac artery disease. On May 9, 1977, the first intraoperative balloon angioplasty procedure was performed in San Francisco jointly by Gruentzig, Myler, and Hanna, a cardiac surgeon. On September 16, 1977, in Zurich, a 38-year-old man with a single discrete stenosis of the left anterior descending coronary artery (LAD) became the first patient to undergo PTCA, or PCI as it is currently referred to (5). As the fellow in charge, I have followed the patient since. He has remained free of complications and recurrence for longer than 20 years, a living triumph of the method (6).

Primary success in the first 50 patients in Zurich was 64% without mortality. Emergency bypass operation was required in 14%, and infarction occurred in 6% (7,8).

In 1986, the Monorail principle (9) facilitated the use of guidewires (10). The shortened segment riding on the guidewire simplified exchanges over a standard length wire.

After the first clinical use of a coronary stent on March 28, 1986, by Puel in Toulouse (11), the pattern of PCI changed. The stent, first a rare and then a common ally of the balloon, matured to its Siamese twin, much in contrast to the balloon's many other short-lived companions and alternatives.

Twenty-four years after the birth of PCI, the method is thriving in spite of a tight medico-economic situation. With more than 1 million procedures performed yearly worldwide, it tops the list of major medical interventions.

In its first two decades, PCI has withstood the scrutiny of local and global peer review. It has been analyzed in numerous single-institution and multicenter registries. It has been subjected to a flurry of well-focused and meticulously monitored randomized studies. It has seen its indications expanded and then cropped again. It has turned out far from perfect but likable and extremely useful, just as Gruentzig had presaged.

MECHANISM

Dissection of intima and media, usually in thin areas of the plaque or adjacent to it, and dilatation of the vessel circumference (Fig. 80.1) constitute the key mechanisms for the luminal gain achieved by PCI (12,13 and 14). A stent prevents elastic recoil and keeps loose intimal flaps or plaque components out of the way. Reendothelialization commonly smoothes the rough surface within a few weeks. Yet, in unstented lesions together with constrictive remodeling (15), it may also cause restenosis.

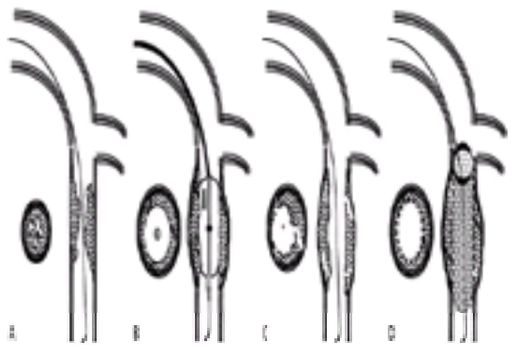

FIGURE 80.1 Schematic diagram of the primary mechanisms of balloon angioplasty and stenting. The initial gain in lumen derives from vessel dilatation and rearrangement of the noncompressible parts of the plaque made possible by an intimal dissection **(A–C)**. A stent avoids recoil and tacks flaps to the wall **(D)**.

PROCEDURE

Personnel

Primary Operator

Table 80.1 represents a reasonable compromise for a minimum curriculum to independence, considering the training facilities available and the general standard of practicing interventional cardiologists. For maintenance of skill, 50 to 75 cases per year are required. Such a low figure is only acceptable in case of a more active training period in the past and an experienced interventional environment (peers and team) as support.

General (internal) medicine (yr)	2
Clinical cardiology (yr)	3
Invasive cardiology (yr)	0.5
Diagnostic catheterization (cases)	
As assistant	50
As operator	100
Interventional cardiology (yr)	1
Therapeutic catheterization (percutaneous coronary intervention) (cases)	
As assistant	50
As operator	50
Practical courses	1

TABLE 80.1 MINIMUM CURRICULUM OF INTERVENTIONAL CARDIOLOGISTS BEFORE INDEPENDENCE

Assistants

At least one sterile person is advisable to assist the primary operator with catheter exchanges and manipulations. An additional person has to be on hand to fetch material, tend to the patient, and summon help in case of need. The more experienced the crew, the more expertly and expeditiously the case will be handled. A single physician suffices in general, but an additional physician with advanced resuscitation skills must be available within minutes and a spare angioplasty operator within the hour. An on-call 24-hour service is imposed by the unpredictable nature of coronary artery disease in general and freshly dilated coronary arteries in particular.

Surgical Standby

A surgical standby under the same roof remains the ideal setting. However, coronary angioplasty without in-house surgery is a valid option to foster ad hoc procedures and to avoid waiting periods. The risk for myocardium and life during typical PCI procedures is low (Fig. 80.2), lower than the risk of cardiac events during an extended waiting period (16).

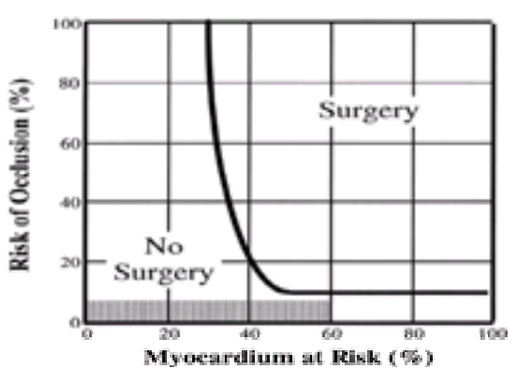

FIGURE 80.2 Chart to estimate the need for emergency bypass surgery at any stage of percutaneous coronary intervention. The hatched area encompasses the

typical percutaneous coronary intervention indications and risks in the era of stents and glycoprotein IIb/IIIa antagonists. It lies outside of the area where (emergency) surgery appears beneficial.

There are important precautions for PCI without in-house surgery. There should be no local legal objections, and the respective operators should be particularly well trained, the case selection adapted, the patient informed, and the institution fully equipped for advanced resuscitation and intensive care.

Material

*e*Table 80.1.1 lists standard and optional equipment and gear for PCI in 2001.

***e*TABLE 80.1.1** EQUIPMENT FOR PERCUTANEOUS CORONARY INTERVENTION IN 2001

Standard	**Optional**
Balloons	Atherectomy devices
Guidewires	Drills, grinders, lysers, softeners
Guiding catheters	Catchers, suckers, mashers
Digital x-ray	Laser (debulker/wire)
Stents	Local drug delivery
Covered	Angioscopy
Coated (eluting?)	Intravascular ultrasound
Adenosine diphosphate antagonists	Drugs against restenosis
Glycoprotein IIb/IIIa antagonists	Brachytherapy
Femoral plugs + sutures	Percutaneous cardiopulmonary support
Aortic counterpulsation	Percutaneous left ventricular assist device

Radiographic Equipment

Catheterization laboratories have to meet high standards to be fit for interventional cardiology. Biplane fluoroscopy is helpful but less important than digital image enhancement and automated cine loops. In the event of a breakdown of the radiographic equipment during a critical phase of a case, a spare unit providing angulated fluoroscopy should be available (17).

The storage medium is digital. Exchange is possible via data lines (local area networks or Internet), compact disk, or digital versatile disk. Still-frame hard copies are useful for the hospital chart, the patient, and the referring physician.

Monitoring Equipment

Pressure curves and electrocardiographic (ECG) tracings have to be displayed throughout the case. Pertinent ECG changes and symptoms, such as ST-segment alterations, malignant arrhythmia, and chest pain during balloon inflation, should be recorded.

Balloon Catheter

A modern balloon catheter is sleek, has a slippery coating inside (reduced guidewire friction) and outside, a low crossing profile, good “trackability” and “pushability,” inflates and deflates rapidly, tolerates pressures up to 30 bar with contained expansion (compliance), and comes in a variety of diameters and lengths.

Guiding Catheter

The coronary guiding catheters are derived from diagnostic catheters. Their walls are thinner but still torque-true and kink-resistant. Diameters of guiding catheters currently range from 5 Fr (1.7 mm) to 8 Fr (2.7 mm).

Guidewire

The guidewire has to transmit torque reliably from the stiff outside end to the floppy tip. It should provide minimal resistance during advancement but optimal support for the catheters introduced over it. Hydrophilic coating reduces friction and guarantees easy advancement but harbors the risk of occult perforations of thin-walled healthy peripheral coronary arteries with subsequent tamponade. The wire tip may be equipped with a Doppler ultrasound crystal, a pressure port, a ball tip, or an optical lens for angioscopic tissue analysis or laser transmission. A diameter of 0.014 in. (0.36 mm) is standard.

Accessories

An adjustable Y connector prevents leaking and permits contrast medium injections and pressure monitoring through a single arterial access after the introduction of the guidewire and the balloon catheter into the guiding catheter. The wire torquer ensures controlled rotation of the wire tip. The Indeflator affords effortless inflations and maintains constant negative pressure in the balloon lumen of the catheter while the balloon is not inflated.

Technique

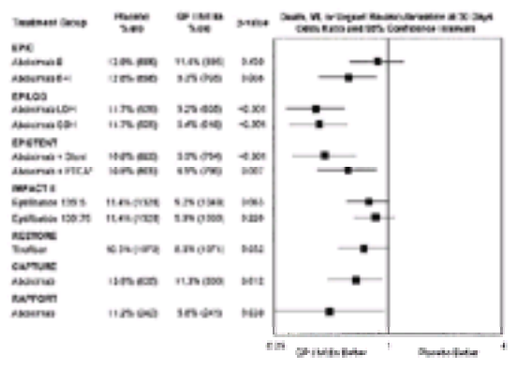
The classic point of access is the right femoral artery. Alternatives are the left femoral artery as well as either subclavian, brachial, or radial arteries. Femoral puncture site closure devices (resorbable plugs or subcutaneous sutures) shorten bed rest. The radial approach features easy hemostasis and immediate mobilization. However, it renders manipulations more painstaking, limits the selection of catheters and instruments, and carries a risk of radial artery occlusion that at the moment may be clinically silent but regretted later (e.g., on the occasion of subsequent CABG).

It is useful to observe ECG and symptomatic reaction of the patient during balloon occlusions. Marked ST-segment elevation, severe pain, malignant ectopy, or an immediate decrease in blood pressure imposes close monitoring after the intervention. Collaterals seen during the diagnostic study or documented by washout collaterometry (prompt washout of contrast medium blocked out distal to the balloon during inflation) project a low subsequent risk for the patient and allow for abridged and simplified aftercare.

Adjunctive Drug Therapy

Platelet inhibitors have to be administered at the latest at the inception of the procedure. Acetylsalicylic acid is standard except for unequivocal allergy. Clopidogrel, a thienopyridine interfering with glycoprotein IIb/IIIa receptors by reducing adenosine diphosphate activation, is advocated in addition in case of stenting. Its role in plain balloon angioplasty remains to be examined.

Intravenous direct glycoprotein IIb/IIIa receptor blockers (abciximab, tirofiban, or eptifibatide) have proved efficacious in large trials (18,19,20 and 21). Abciximab reduces death and myocardial infarction as well as the need for subsequent myocardial revascularization (*e*Fig. 80.2.1).



***e*FIGURE 80.2.1** Death, myocardial infarction (MI), or urgent repeat revascularization at 1 month for the glycoprotein (GP) IIb/IIIa interventional trials. B, bolus; B+I, bolus plus infusion; LDH, low-dose, weight-adjusted heparin; PTCA, percutaneous transluminal coronary angioplasty; SDH, standard-dose heparin; 135/.5 and 135/.75 eptifibatide doses, 135 mg per kg bolus, followed by infusions of 0.5 or 0.75 mg per kg per minute. (From Lincoff AM, Califf RM, Topol EJ. Platelet glycoprotein IIb/IIIa receptor blockade in coronary artery disease. *J Am Coll Cardiol* 2000;35:1103–1115, with permission.)

Heparin is part of the standard regimen. Doses employed vary without a clear-cut clinical difference between a bolus of 5,000 or 20,000 U (22). Low-molecular-weight heparin has not yet been tested in the setting of catheter interventions. Direct thrombin antagonists (hirudin, hirulog, and so forth) have yet to show clinical superiority to heparin worth their expense.

Heparin complication. Extensive purpura from heparin treatment.

The original contrast medium diatrizoate (ionic, high osmolar) has been largely abandoned in favor of nonionic agents for comfort reasons. Ioxaglate (ionic, low osmolar) is an alternative sharing an anticoagulant property with diatrizoate.

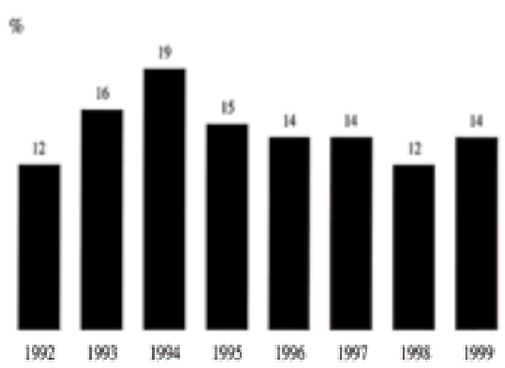
Aftercare

The level of surveillance after the procedure depends on the clinical situation and the result of PCI. ECG monitoring for a few hours is advised but not indispensable for the routine case (23). Any bleeding from the puncture site should be carefully assessed. Chest pain should prompt an immediate ECG for comparison with the baseline tracing. Patients with nonabating chest pain should be monitored for arrhythmia and reinvestigated by catheterization.

Hospital discharge of uncomplicated cases is usually the morning after the intervention. A control ECG before discharge should be standard, and cardiac enzymes should be checked in case of problems. The value of a stress test before discharge is controversial. It is safe but rarely performed.

INDICATIONS

The steady increase of yearly PCI cases was mainly due to an earlier invasive diagnosis of coronary artery disease in addition to a more aggressive attitude with elderly patients. The share of multivessel PCI did not increase over the 1990s in Europe (24) (*e*Fig. 80.2.2) or Canada (25) despite stents. Many patients undergoing PCI today would have been treated medically a decade ago. Three-vessel disease of the major branches, however, has largely remained the domain of CABG.



***e*FIGURE 80.2.2** Percentage of multivessel percutaneous coronary interventions in Europe in the 1990s. Despite the steep increase of stent use during that period, multivessel percutaneous coronary interventions in a single session did not increase. The figures are based on the official registry of the European Society of Cardiology, representing roughly 500,000 procedures per year.

Clinical Indications

Clinical indications and contraindications are listed in Table 80.2. They have to be customized to patients and situations, which requires experience. They are met by the vast majority of patients undergoing coronary angiography. Age is not as important for PCI as it is for CABG.

Indications
Acute myocardial infarction
Angina (stable or unstable)
Angina equivalent (arrhythmia, dyspnea, dizziness, and so forth)
Objective signs of reversible ischemia
Resting electrocardiogram
Stress test
Stress echocardiography
Holter monitoring
Scintigraphy
Positron emission tomography
Contraindications
Rapidly terminal cardiac or other disease (exception: uncontrollable angina)
Prolonged cardiogenic shock after myocardial infarction

TABLE 80.2 CLINICAL INDICATIONS AND CONTRAINDICATIONS

Angiographic Indications

Angiographic indications and contraindications are listed in *e*Table 80.2.1.

***e*TABLE 80.2.1** ANGIOGRAPHIC INDICATIONS AND CONTRAINDICATIONS
Indications
One to four lesions suitable for percutaneous coronary intervention
Not immediately life threatening
Vessel diameter (planned balloon size) greater than or equal to 2.5 mm
Lesion(s) subtending functional, viable, or collateral-relevant myocardium
Contraindications
Left main stem stenosis (exceptions: protected by graft or collaterals, ideal lesion, inoperable patient)
Left main stem equivalent stenoses (exceptions: staged procedures, ideal lesions, inoperable patient)
Last remaining vessel (exceptions: ideal lesion, inoperable patient)
Three-vessel disease (exceptions: ideal lesions, secondary vessels, staged procedures, inoperable patient)
Lesion characteristics
Chronic total occlusion
No collaterals to distal artery
Long and old
No stump
Extensive bridging collaterals
Thrombotic stenosis with nonsignificant underlying lesion
Diffusely diseased, small-caliber coronary artery
Diffusely diseased old venous graft

Lesion Location and Morphology

It is important but difficult to determine what makes a lesion significant enough to warrant PCI. There are different means to assess the functional significance of a stenosis. Clinical tests (exercise ECG, stress echocardiography, scintigraphy, and so forth) are not very sensitive and lack specificity for the individual lesion. Quantitative coronary angiography of the lesion is operator dependent and lacks precision almost to the degree of visual estimates (26). Intravascular ultrasound and pressure measurements (27,28) or angioscopy (29) are more objective, but they engender additional costs and risks.

To assess hemodynamic significance may mean barking up the wrong tree. The ultimate threat is not the occurrence of angina but the thrombotic occlusion of the vessel causing infarction and death. Although an individual mild stenosis has a low infarct potential, the hazard is clearly there. Collaterals are rare with mild lesions, which renders their occlusion particularly dangerous.

Restricting PCI to flow-limiting lesions ignores its potential for plaque sealing (i.e., significantly reducing the risk of subsequent thrombotic occlusion thanks to the neoendothelium overgrowing the inflicted wound) (30,31). The hypothesis about such an effect is derived from the event-free long-term course regularly observed after uncomplicated balloon angioplasty. Even restenosis is highly unlikely to produce infarction because of the different nature of the narrowing (smooth neoendothelium rather than rupture-prone atherosclerotic plaque), yet the hypothesis has not been prospectively validated and may be annihilated if a stent is implanted (small but significant risk of late infarction). Methods to elucidate the instability of a plaque seem called for (32), but they provide merely a snapshot assessment. An active plaque is meaningful, but an inactive plaque is not because it may turn active any time. Plaque passivation with statins (33) is a proved and ubiquitously applicable alternative or complement to plaque sealing by balloon angioplasty, the latter being only attractive as an ad hoc procedure for a mild lesion at a strategically important site (proximal in a large vessel).

Lesions involving branch points are technically not a particular challenge with modern equipment. However, they are fraught with a higher rate of complications and restenoses.

Thrombus-containing lesions have lost most of their ominous doom in the era of stents, glycoprotein IIb/IIIa antagonists, and protection devices.

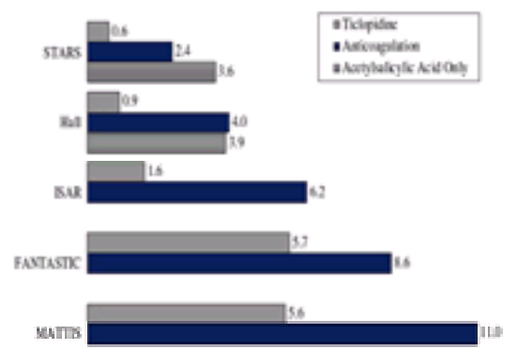
RESULTS

Results of high-volume providers show an edge over those of occasional operators (34,35). Hence, the recommended volume of 200 yearly cases per center is being challenged by some as too small (35).

Impact of Stenting

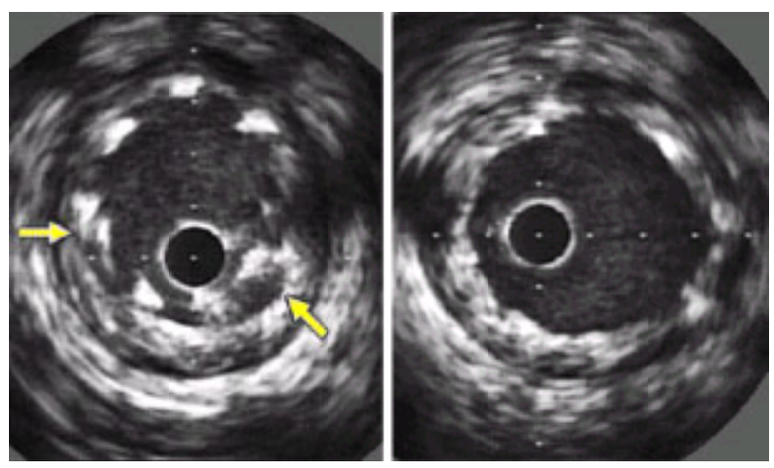
Among the various mechanical additions or alternatives to balloon angioplasty, only the stent has stood the test of time (11,36). Stenting does not complicate the procedure, some difficulties in negotiating the stent notwithstanding (compared with a naked balloon, slightly stiffer). Stenting yields an immediate result that is appealing to the eyes of the operator and the patient.

The initial problems with stent thrombosis have largely been overcome with a two-pronged antiplatelet regimen (acetylsalicylic acid and a thienopyridine). However, subacute stent thrombosis remains a concern (37) (*e*Fig. 80.2.3). The stent showed its real potential more where it was least expected, in the prevention of restenosis (38,39). Albeit highly effective in remedying impending occlusion due to obstructive dissection, routine stenting loses the advantage on balloon angioplasty over the first few weeks due to the occurrence of subacute thromboses virtually unknown to balloon angioplasty. Elective stenting has either the same or a higher (sub)acute event rate when compared with balloon angioplasty and provisional stenting. This holds true for all comers (38), diabetic patients (19), restenoses (40), small vessels (41), long lesions (42), chronic occlusions (43), LAD stenoses (44), saphenous vein grafts (45), unstable angina, or acute infarctions (46).

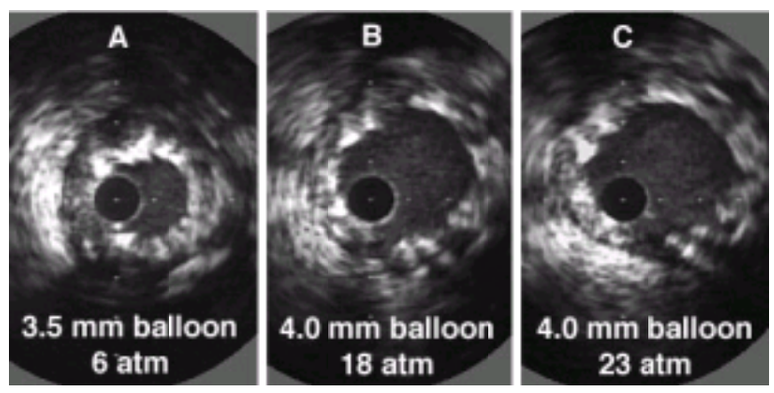


***e*FIGURE 80.2.3** Cardiac events at 30 days with different regimens of platelet inhibition or anticoagulation after stenting (37). In selected patients [Stent Antithrombotic Regimen Study (STARS), Hall, Intracoronary Stenting and Antithrombotic Regimen (ISAR) trials], ticlopidine yields much lower event rates than in less selected patients [Full Anticoagulation versus Aspirin and Ticlopidine Trial (FANTASTIC), Multicenter Aspirin and Ticlopidine Trial after Intracoronary Stenting (MATTIS)].

The Optimal PTCA versus Primary Stenting-1 trial (47) appears to make clear that elective stenting, performed as direct stenting according to the Doppler Endpoint Balloon Angioplasty Trial Europe-II (39), is the way to go. Provisional (conditional) stenting seems to require intravascular ultrasound as a cumbersome and costly additional decisional tool to remain competitive (48). Yet the sole effect of elective stenting is that a reintervention is spared for every tenth stent implanted. Some of these reinterventions may be operator driven because a patient may be taken back for an additional intervention more readily if no stent had been implanted the first time, not to forget that an in-stent restenosis tends to be more intricate to treat than an unstented restenosis. The risk of acute occlusion in the first hours after balloon angioplasty is not really eliminated but rather deferred to the first days and weeks by stenting. Some of these stent problems fail to be brought to the attention of the operator. This makes them more dangerous, but, paradoxically, enhances the benefit of stenting as perceived by the operator.



Intravascular ultrasound assessment of stent deployment. In the left panel, incomplete stent expansion is evident, which is improved after further balloon dilatation.



Intravascular ultrasound in stent deployment. These images show the effect of both increased balloon size and pressure on the size of the in-stent lumen.

The outcome of balloon angioplasty is reliably stable for decades if not for life after a few hours of risk for acute closure and a few months of risk for restenosis. Before stents were available, approximately 70% of dilated lesions never had an acute problem or a restenosis (perfect outcome impossible to improve on). Stenting all patients means ignoring the 70% of patients whose result can be jeopardized but not improved by a stent for the benefit of the 30% with potential for improvement. Admittedly, it is impossible to accurately predict to which group the dilated lesion of the patient will belong. Yet, experienced operators do have clues and apply them to the benefit of the patient. A stenting rate of 50% to 70% could well be the trademark of an accomplished and astute interventional cardiologist.

Complications

The threat of a major acute complication haunts the operator more than the possibility of recurrence but is talked about less.

Atheroemboli. Digital necrosis resulting from severe atheroemboli.

Cholesterol emboli. Purpura secondary to cholesterol emboli are shown (*yellow arrows*).

Livedo reticularis. Mottled reddish discoloration of the lower extremities with accompanying multiple ulcerations associated with atheroemboli.

Embolus. Dislodged thrombus that embolized to the toes and caused gangrene (*arrows*).

Brachial artery hematoma. Hematoma complication after brachial artery catheterization and urokinase administration.

Mortality

In-hospital mortality after PCI ranges from virtually naught in young patients with single-vessel disease (49) to approximately 70% in patients with cardiogenic shock after myocardial infarction (50). Overall, it lies below 2% (51) and has remained stable during the period of general adoption of stenting (Fig. 80.3) (24,25). Mortality reduction was achieved in randomized studies with PCI compared with fibrinolysis in acute infarction (52), with stenting in conjunction with abciximab (19), with abciximab in mixed PCI cases at 3 years (pooled studies), and with PCI rather than conservative treatment in unstable angina (53).

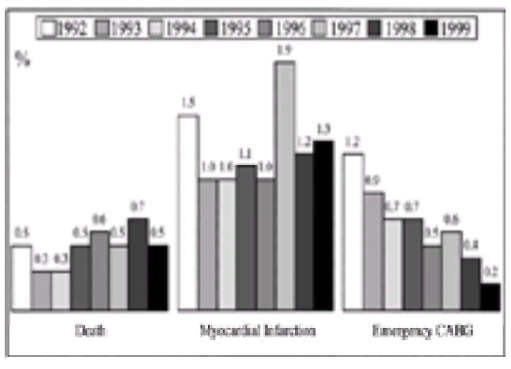

FIGURE 80.3 Evolution of adverse events in the European registry (some underreporting likely). Based on almost 500,000 percutaneous coronary intervention cases reported per year, there was no clear trend in terms of mortality or infarction rate since 1992 despite a marked increase of stenting. The reduction in need for emergency coronary artery bypass grafting (CABG) was a continuation of a trend that started 20 years ago. Yet there is an impact of stenting for the final reduction below 1%.

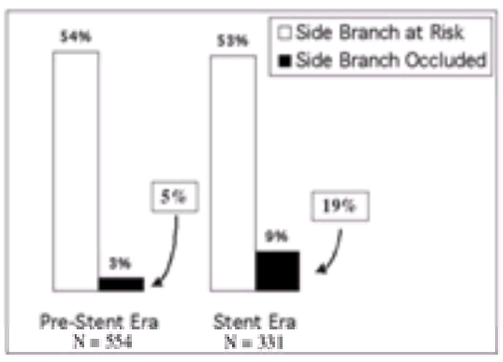
Myocardial Infarction

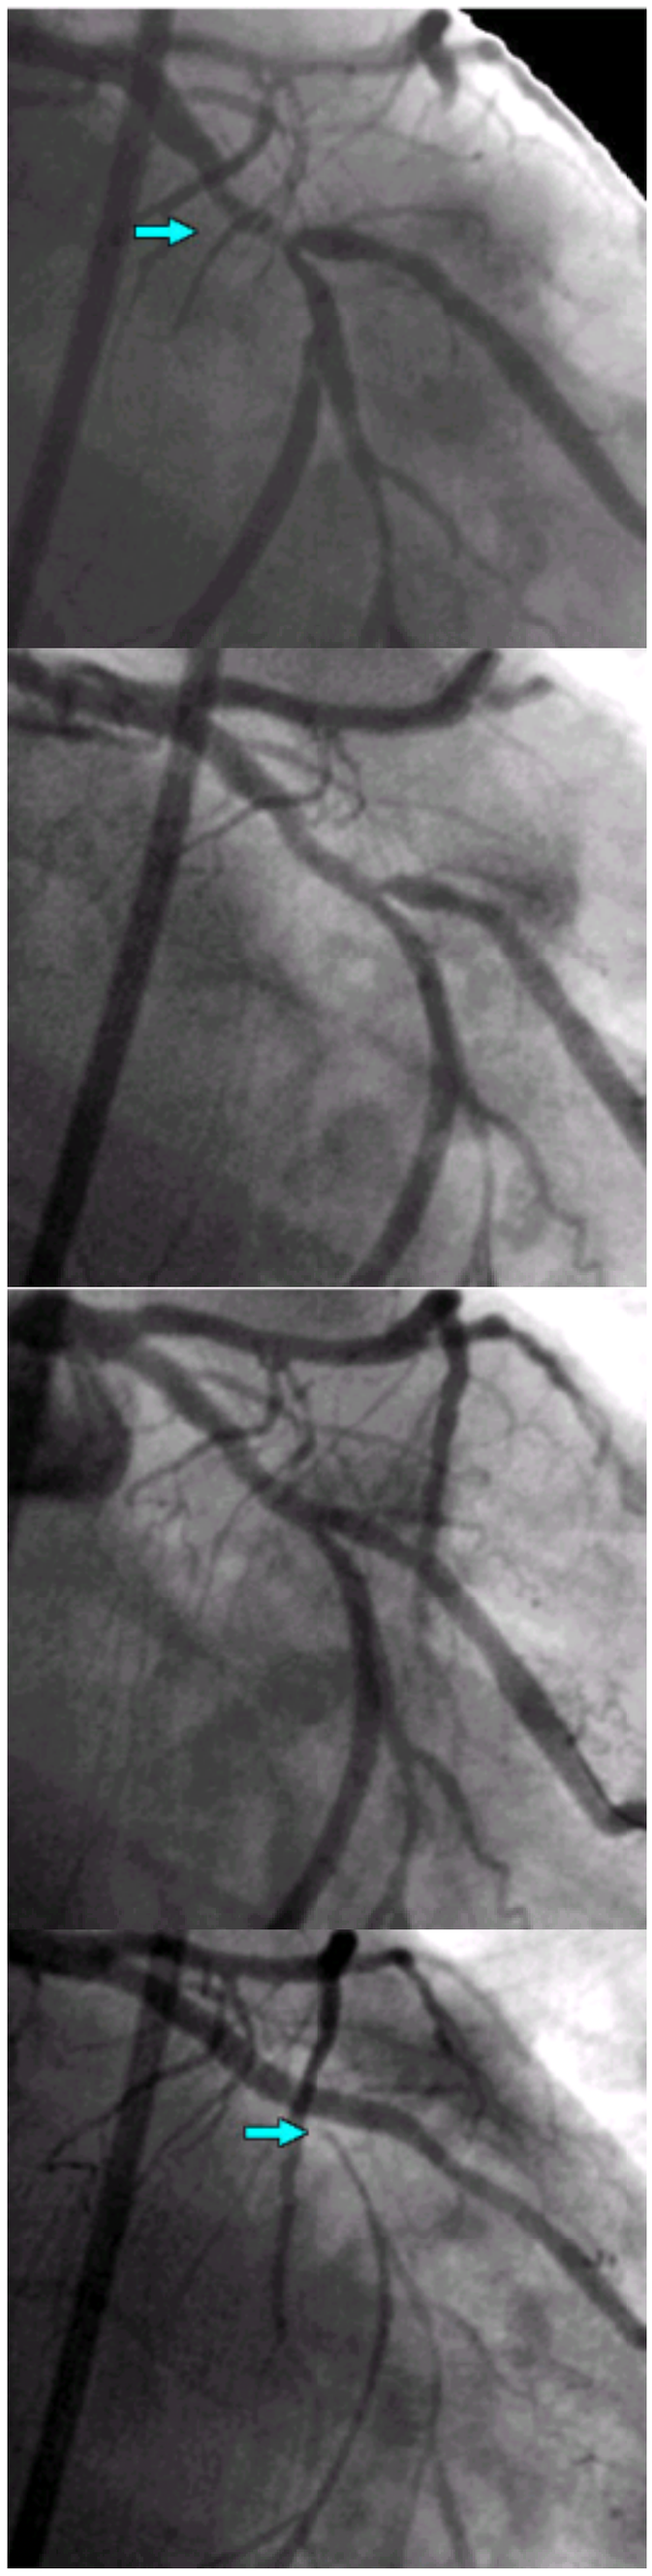
The incidence of PCI-induced myocardial infarction varies widely according to definitions used. Yet it has remained fairly stable over time (Fig. 80.3) (24,25). It is estimated that approximately 8% of patients show a creatine kinase release of greater than three times the upper limit of normal after PCI (54). This alone may be relevant to long-term outcome (54,55) [e.g., by doubling cardiac mortality from 5% to 10% over 1 year (56) and from 10% to 20% over 5 to 10 years (54,57)].

The use of perfusion balloon angioplasty to treat an acute inferior myocardial infarction. Normal antegrade flow is restored (C) beyond the area of total occlusion in the mid right coronary artery (A) after a prolonged inflation with a perfusion balloon catheter (B).

Side branch occlusions constitute the most prominent reason for creatine kinase elevations in otherwise successful procedures. Stents increase their incidence (*e*Fig. 80.3.1) (58,59) while reducing the rate of acute occlusion of the main axis. Sudden death, the dominant lethal mechanism after the first year, is probably accounted for by arrhythmogenic foci around patches of myocardial fibrosis. They may also be caused by microemboli, partially preventable by the use of abciximab or a similar drug (19).



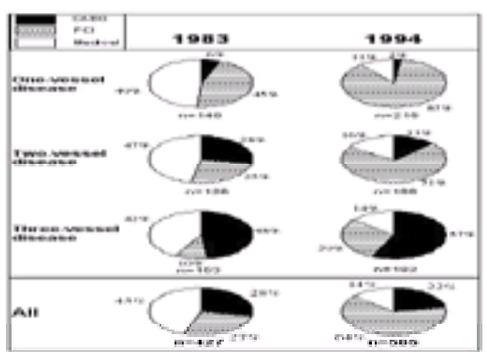
***e*FIGURE 80.3.1** Incidence of side branches at risk and actually occluded (percentages in square frames) in the pre-stent (58) and stent (59) eras.



Successfully treated side branch closure. Arrow in A demonstrates a bifurcation lesion involving the mid-left circumflex and the origin of a large-caliber obtuse marginal branch. Balloon angioplasty is performed sequentially in the mid- and then obtuse marginal (B,C). After Palmaz-Schatz stent deployment in the obtuse marginal, there is subtotal occlusion of the atrioventricular circumflex branch (D, *arrow*), which is "jailed" by the stent. A guidewire and balloon are advanced through the stent struts, and flow is restored to the distal atrioventricular circumflex and obtuse marginal branch after balloon inflation (E).

Need for Emergency Coronary Bypass Surgery

Most centers have reduced emergency CABG for failed PCI to far below 1% (Fig. 80.3). The techniques to deal with acute occlusions have evolved (stent, glycoprotein IIb/IIIa antagonists). The indications have expanded predominantly toward minor coronary heart disease (60) (*e*Fig. 80.3.2), not justifying CABG, particularly after the threshold for emergency CABG was raised because acute CABG for a small infarction was found not to be worthwhile (Fig. 80.2).

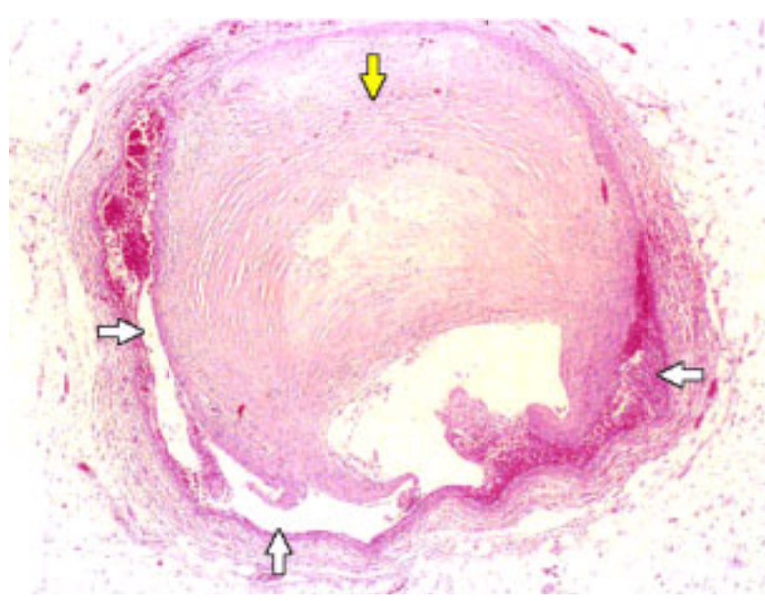


***e*FIGURE 80.3.2** Recommendations for treatment of two cohorts of consecutive patients approximately a decade apart with significant coronary artery disease. The recommendation for percutaneous coronary intervention (PCI) has increased for all stages. Coronary artery bypass grafting (CABG) has maintained its share in three-vessel disease. (From Delacrétaz E, Meier B. Use of coronary angioplasty, bypass surgery, and conservative therapy for treatment of coronary artery disease over the past decade. *Eur Heart J* 1998;19:1042–1046.)

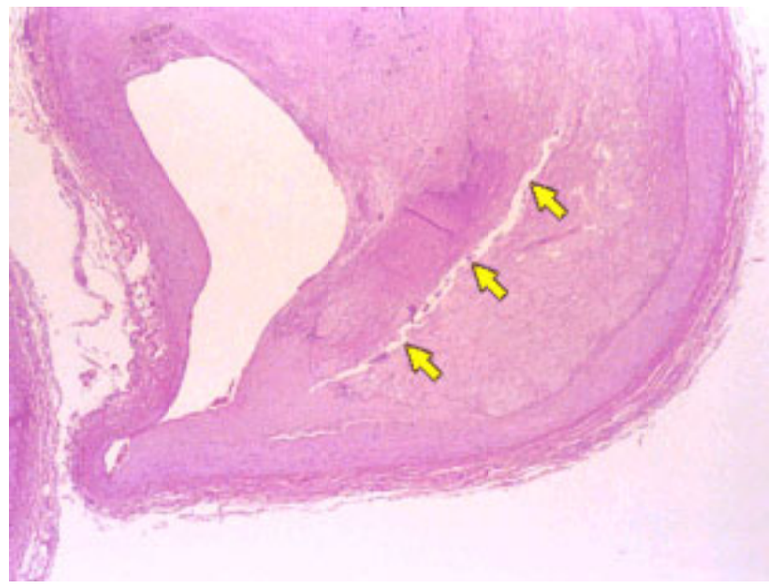
This modification in case selection for emergency CABG has led to a more dismal outcome for the few patients still referred to emergency CABG, which is not explained by their pre-PCI but by their precarious post-PCI situation.

Coronary Dissection

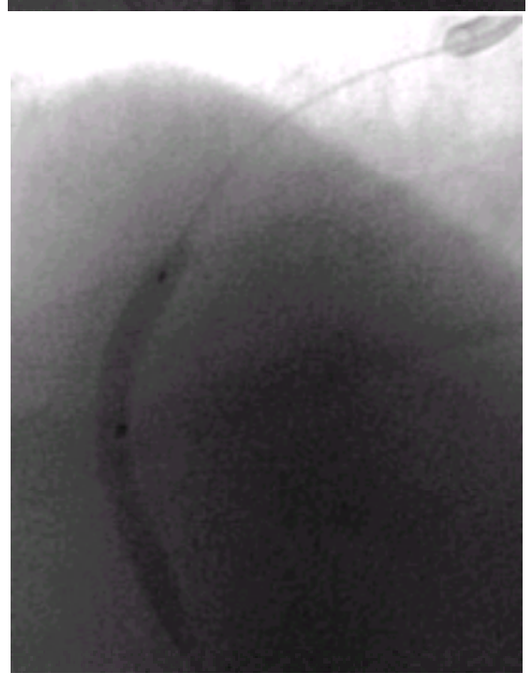
Dissections create luminal space but they may also occlude the vessel acutely if they are long, spiral, or form a cul-de-sac retaining blood bound to coagulate. The risk factors for an occlusive dissection (diffuse, tight, eccentric, tortuous, or overdilated lesions) have lost most of their importance in the wake of the liberal use of stents.



Linear, circumferential dissection 2 days after balloon angioplasty of a restenotic lesion. Note the extensive neointimal proliferation (*yellow arrow*) and dissection (*white arrows*).



Restenotic lesion. Residual tear in atherosclerotic plaque (*yellow arrows*) and large amount of neointimal proliferation 76 days after balloon angioplasty.



“Bailout” stent placement for a long dissection complicating balloon angioplasty. After balloon angioplasty of a long lesion of the mid-right coronary artery (A), a long linear dissection flap is apparent (B, *arrows*). A 39-mm-long AVE stent is deployed across the area of dissection (C). No residual stenosis is present after stent placement (D).

VIDEO

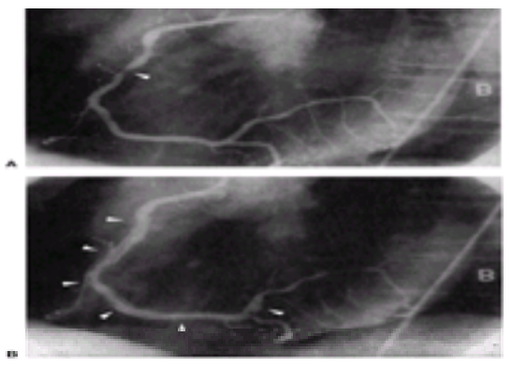
Video 80.6 Coronary dissection by intravascular ultrasound. A tissue flap is seen protruding in the lumen of the vessel after high-pressure postdilatation of a Palmaz-Schatz stent in the adjacent segment. Angiographically, this flap was visualized as an area of ‘peri-stent’ haziness. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The risk of acute occlusion for nonstented lesions varies according to the degree of dissection. In the era before glycoprotein IIb/IIIa antagonists, it amounted to approximately 5% to 10% and was largely limited to the first 12 hours after the discontinuation of heparin (61). Stented dissections may have a significantly lower risk the first day, but part of this advantage is lost to subacute occlusions occurring up to several weeks after implantation. Particularly long stenoses may fare better without stenting (*e*Fig. 80.3.3), also because of the difficulty of treating long in-stent restenoses. Glycoprotein IIb/IIIa antagonists provide a valid alternative.



***e*FIGURE 80.3.3** Long spiral dissection (**B**, *arrows*) in the right coronary artery of a 60-year-old woman, resulting from angioplasty of a short stenosis (**A**, *arrow*) in a diffusely affected artery. The dissection kept obstructing flow and was therefore extended down the artery by additional distal balloon inflations until flow was again unimpeded. The dissection was not stented because of its length. The further course was uneventful.

Coronary Thrombosis

Stenting combined with novel antiplatelet agents is the preferred method of dealing with thrombosis (62,63 and 64). The place of specific antithrombin agents is still uncertain (63,64). Thrombus-extracting devices or removable embolization filters are in clinical evaluation (see Chapter 81).

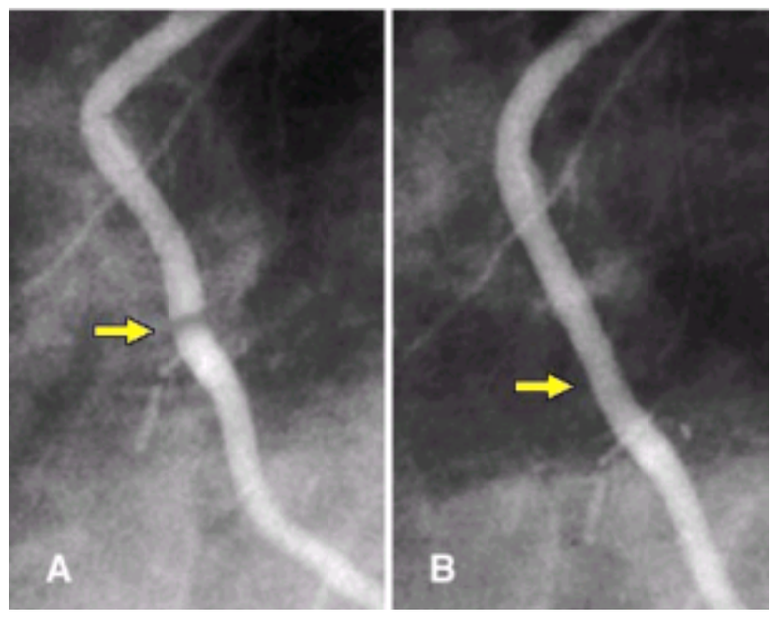
VIDEO

Video 80.7 A 59-year-old male patient with acute inferior myocardial infarction. Large angiographically visible thrombus in the mid-portion of the right coronary artery distal to a severe stenosis. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

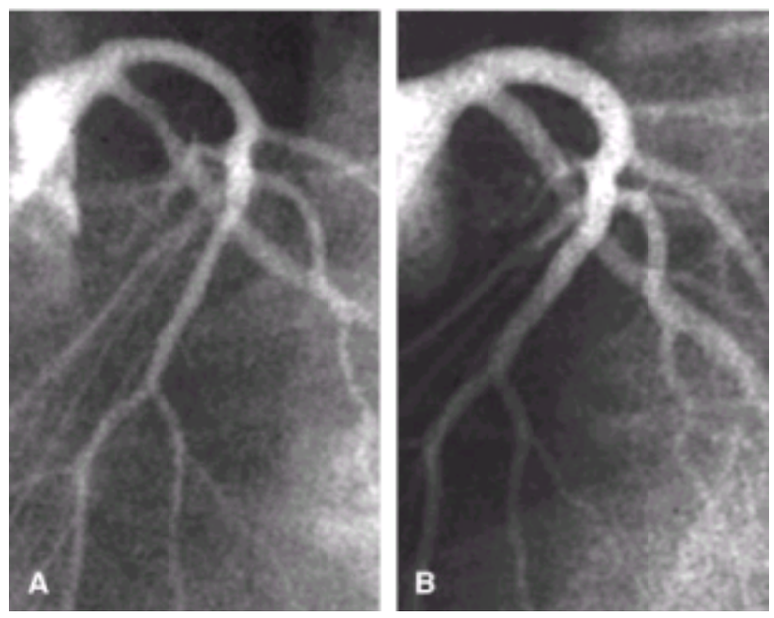
Coronary Spasm

Mechanical stimuli beget coronary spasm. Standard vasodilatory pretreatment for PCI is commonly effective. If spasm occurs just the same, reinforced nitrates or

additional calcium antagonists by the oral, intravenous, or intracoronary route are recommended.



Spasm of the left internal mammary artery after bypass surgery. In the left panel, a significant stenosis is evident that is completely resolved after administration of nitroglycerin. Spasm of the left internal mammary bypass graft can lead to ischemia in the perioperative period after coronary surgery.



Spasm of the left main coronary artery and proximal left anterior descending and left circumflex coronary arteries. The caliber of the left main, proximal left anterior descending, and circumflex arteries are smaller than the distal vessels. This can be better appreciated after administration of intracoronary nitroglycerin.

No-(Re)Flow Phenomenon

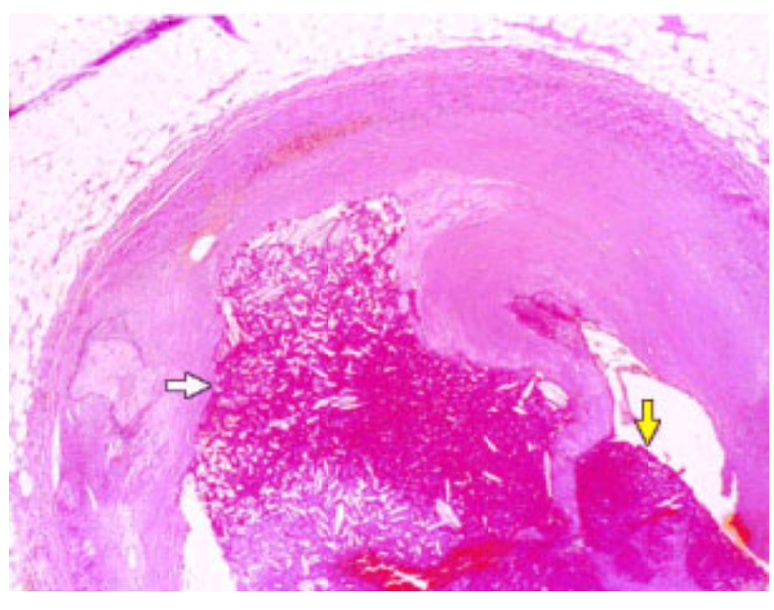
The no-(re)flow phenomenon (65) presumably originates from proximally released vasoactive substances or microembolizations producing spasm and occlusion of small intramyocardial vessels. It may be quite refractory to vasodilators and even glycoprotein IIb/IIIa antagonists and is more germane to stenting than to balloon angioplasty.

VIDEO

Video 80.8 Slow flow noted in the right coronary artery after coronary intervention. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Coronary Perforation or Rupture

Coronary perforation at the site of the lesion with a guidewire may not be rare, especially during recanalization attempts of chronic total occlusions. It is innocuous unless the perforation is enlarged by the balloon catheter. Distal perforations with hydrophilic guidewires represent a new hazard. They occur silently and perhaps multiply while balloons or stents are being introduced with the operator ignoring the wire tip (often outside the visible frame). They have a reduced tendency to seal spontaneously because the walls of normal peripheral vessels are thin.



Organized intraplaque thrombus (*white arrow*) with overlying, near-occlusive fresh thrombus (*yellow arrow*). Ruptured atherosclerotic lesion of the right coronary artery 5 days after a balloon angioplasty procedure.

Low blood pressure in the wake of a PCI involving a hydrophilic guidewire evokes suspicion of tamponade.

Coronary rupture by subintimal or oversized balloon inflation or debulking devices is a rare but serious complication with a mortality of approximately 10% (66). Coronary ruptures can be acutely plugged with a balloon inflation. This may permanently cover the defect with a tissue flap and solve the problem. Implantation of a

(covered) stent at the ruptured site or sacrifice of the vessel by embolization or exclusion (covered stent in main vessel at bifurcation) are further options short of surgery (67). Cardiac tamponade is always first treated by pericardiocentesis. The aspirated blood may be reinjected into a vein to avoid anemia.

Results with Special Indications

Elderly Patients

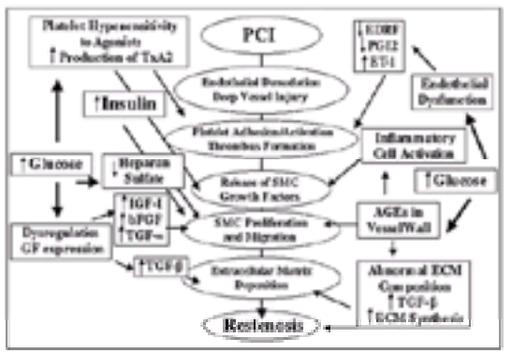
Aged patients are constituting a growing group of candidates for any medical intervention in light of the general aging of industrialized peoples. Coronary artery disease affects 20% of geriatric patients and is the reason for approximately 25% of their morbidity and more than 50% of their mortality (68).

Elderly patients should be spared CABG because of increased operative morbidity and mortality. On the other hand, they typically have diffuse disease and are difficult to catheterize. Their PCI results are less favorable than those of general PCI patients. The early results seem to be better than those with CABG. Yet, geriatric patients undergoing CABG fare better during follow-up in spite of having been sicker initially (69).

Diabetic Patients

Diabetic patients experience increased risks with virtually any major intervention. Their propensity for complications and recurrences after PCI has been highlighted (70). In-hospital mortality is 3% rather than 1% as with nondiabetics. The reintervention rate over 10 years is roughly 60% in diabetics and 50% in nondiabetics. The outcome with CABG has proved better than that with PCI in diabetics (71,72), at least in the ones on insulin (73). Glycoprotein IIb/IIIa antagonists hold potential to improve results with PCI (19).

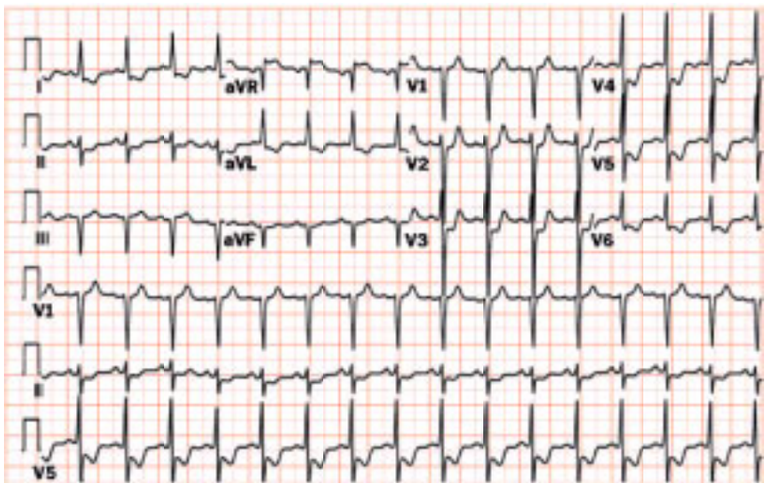
The 7-year mortality of treated diabetics in the Bypass Angioplasty Revascularization Investigation trial was 44% with PCI and 24% with CABG. Mortality in nondiabetics was approximately 14% with both therapies (72). More brittle plaques, higher blood viscosity, enhanced platelet aggregation, increased thromboxane A_2 levels, endothelial dysfunction, and impaired endogenous fibrinolysis must account for the problems of diabetics with PCI (74). Some factors explaining the high recurrence are depicted in eFigure 80.3.4 (75). Many are favorably influenced by stents and novel anticoagulant and antiaggregant compounds. Abciximab yields results in stented diabetics comparable with those of nondiabetics in terms of mortality, lumen at follow-up, or reinterventions (19).



***e*FIGURE 80.3.4** Mechanisms for (re-)stenosis formation in diabetes. (Modified from Aronson D, Bloomgarden Z, Rayfield EJ. Potential mechanisms promoting restenosis in diabetic patients. *J Am Coll Cardiol* 1996;27:528–535.)

Unstable Angina

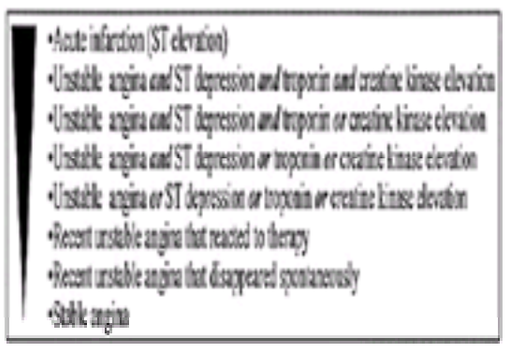
Unstable angina hints at the severity of the culprit lesion, but it does not necessarily inform about the extent of coronary artery disease.



Subendocardial ischemia. Anterolateral ST-segment depression is consistent with diffuse subendocardial ischemia versus non–Q-wave myocardial infarction.

PCI of the unstable plaque (fissured atheroma with partial thrombosis) engenders more acute occlusions than routine PCI. The stent and new antiaggregant or antithrombotic agents have improved on this (19,20,63). Pretreatment with abciximab (19) or eptifibatide (76) is recommended before stenting and the ideal time for PCI appears early (77). Postponing PCI carries the risk of an intercurrent infarction while increasing cost (53).

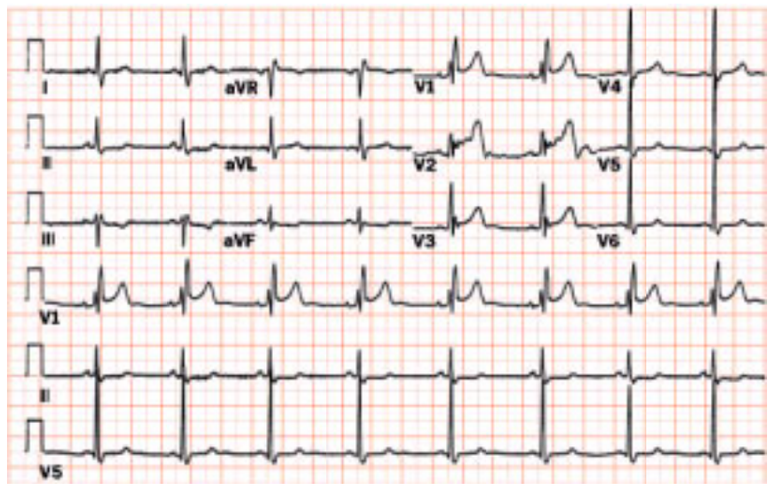
A preliminary risk assessment is recommended according to *e*Figure 80.3.5.



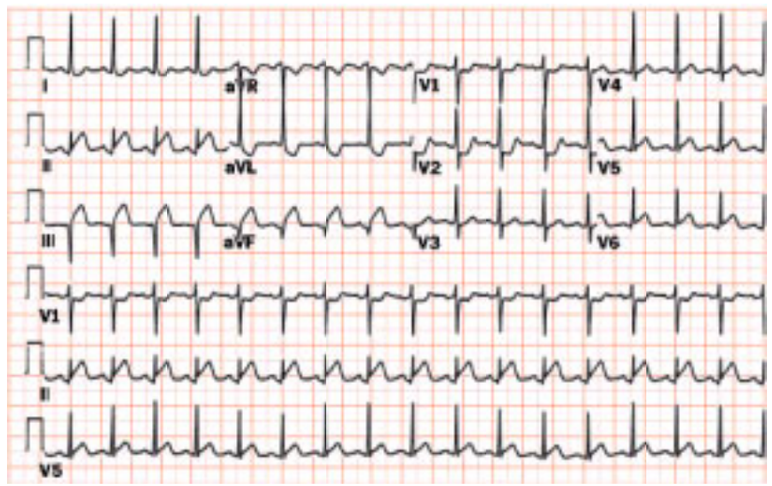
***e*FIGURE 80.3.5** Urgency of coronary angiography and percutaneous coronary intervention in various stages of coronary syndromes.

Acute Myocardial Infarction

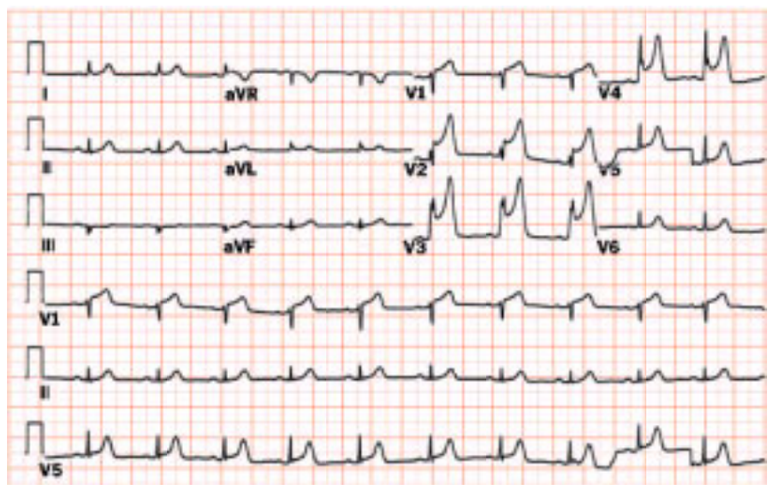
In the early 1980s, there were enthusiastic reports about PCI for failure or incomplete success of intracoronary fibrinolysis with streptokinase (78) and for prevention of reocclusion after successful fibrinolysis, in case a significant stenosis persisted (79). A first randomized trial proved the superiority of acute PCI over intracoronary streptokinase in 1986 (80). Then in the late 1980s, clot-specific fibrinolytic agents appeared, and large-scale randomized trials (81,82) seemed to push aside acute PCI for good.



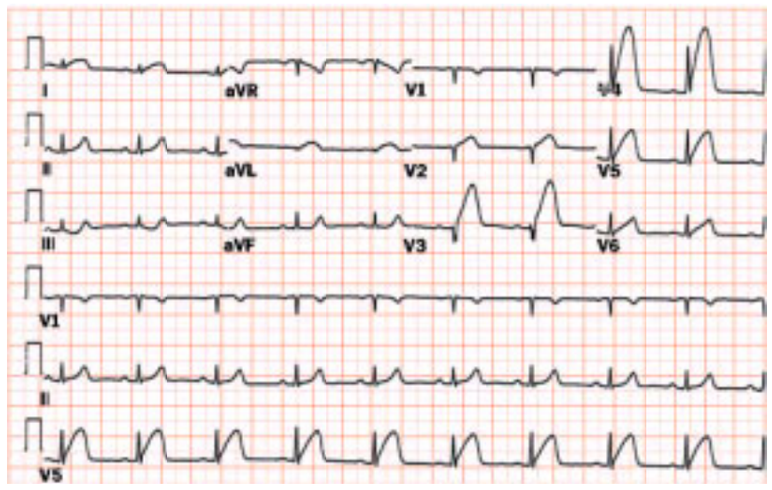
Anterior myocardial infarction in setting of right bundle branch block. ST-segment elevation in the anterior precordial leads as well as primary T-wave changes support acute anteroseptal myocardial infarction.



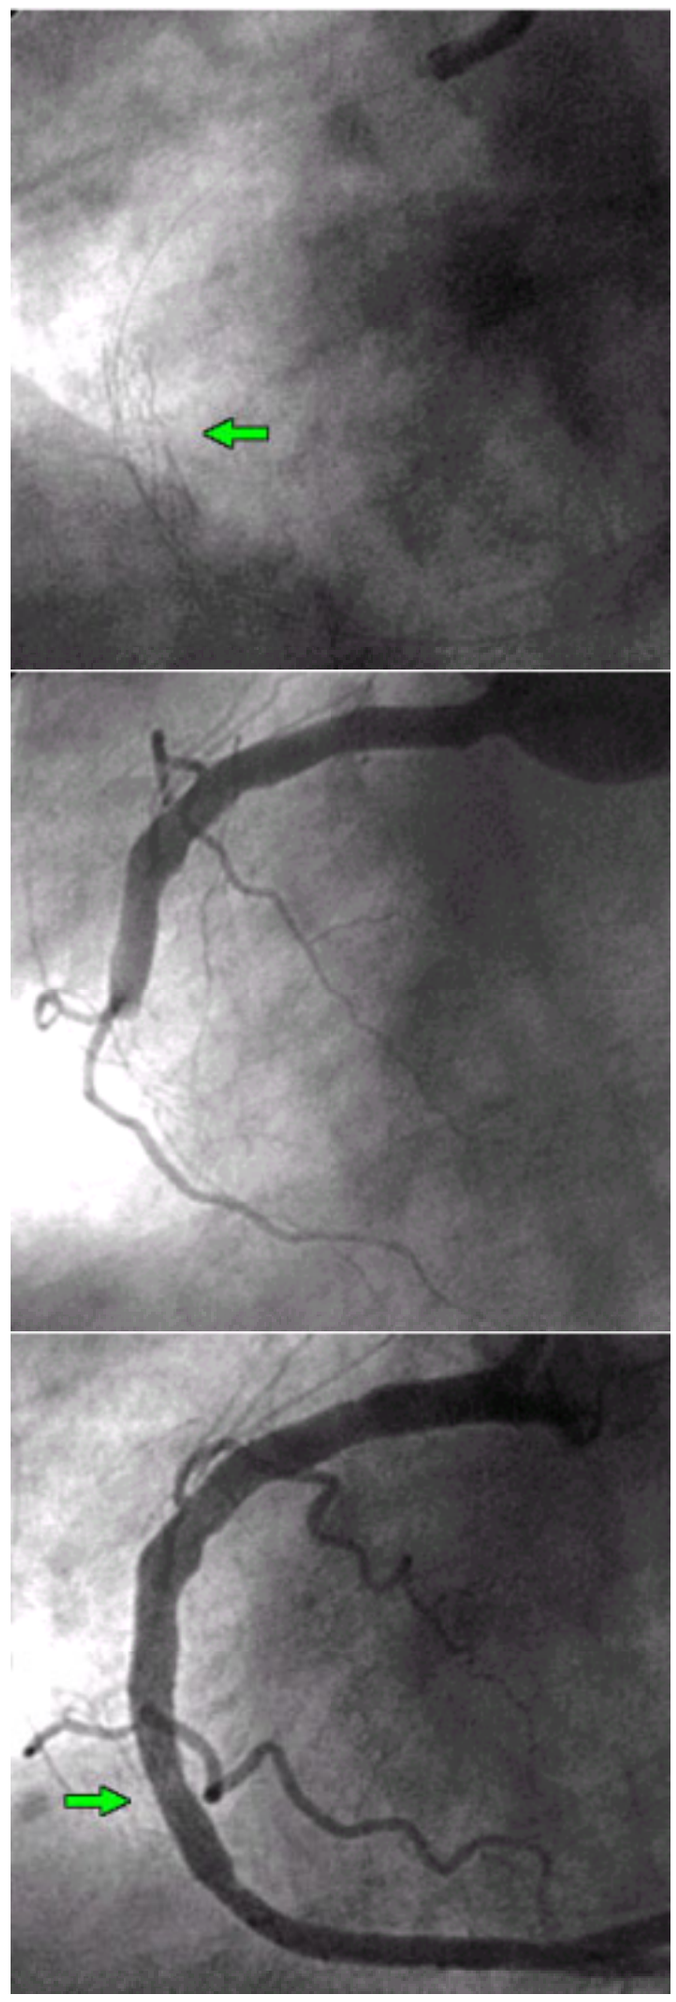
Acute inferoposterior myocardial infarction. Note ST segment elevation in leads II, III and aV_F with ST depression in leads V_1 and V_2.



Acute anteroseptal myocardial infarction. Dramatic ST segment elevations in leads V_1 through V_5 with associated hyperacute T-wave changes are noted.



Acute anterolateral myocardial infarction. Note classic “tombstoning” of ST-T waves in the anterolateral precordial leads.



Primary stent placement for an acute inferior myocardial infarction. After the administration of abciximab, a Palmaz-Schatz biliary stent (B) is deployed across the area of acute occlusion in the mid right coronary artery (A), resulting in normal antegrade flow and no residual stenosis (C).

New randomized trials (83,84 and 85) swung the pendulum back again showing that PCI was superior to fibrinolysis for the initial hours of acute infarction. However, direct angioplasty is logistically more demanding than intravenous fibrinolysis. In addition, the investment of time and money is the same whether acute angioplasty is carried out for a substantial LAD infarction, in which it may be well invested, or for a small left circumflex coronary artery infarction, in which it is unlikely to benefit the outcome (86). This explains why direct angioplasty, although regaining popularity, is still less frequently used than fibrinolysis. Primary PCI is currently the routine treatment for acute infarction only in active PCI centers.

Ongoing infarction is one of the most pressing and rewarding indications for PCI. Mortality is beneficially influenced when compared with fibrinolysis (52). Although coronary flow may be restored somewhat later with direct PCI than with fibrinolysis, particularly if the latter is aided by the dethrombotic effect of a glycoprotein IIb/IIIa antagonist (Fig. 80.4) (87,88 and 89), reperfusion is more complete and the underlying stenosis has simultaneously been taken care of (Fig. 80.5). PCI facilitated by a glycoprotein IIb/IIIa antagonist, a fibrinolytic agent, or both appears therefore as the ideal approach.

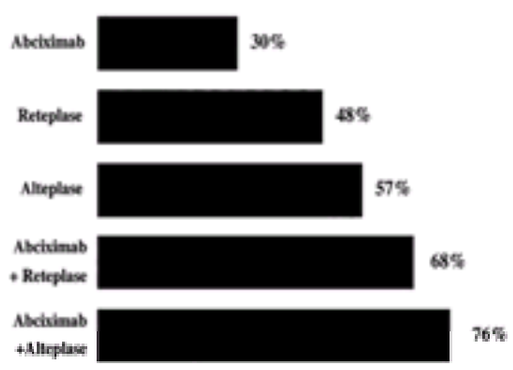


FIGURE 80.4 Flow restoration at 90 minutes by thrombolytic drugs for acute infarction. The combination of abciximab with reteplase (87,88) or alteplase (89) yields the highest patency rates.

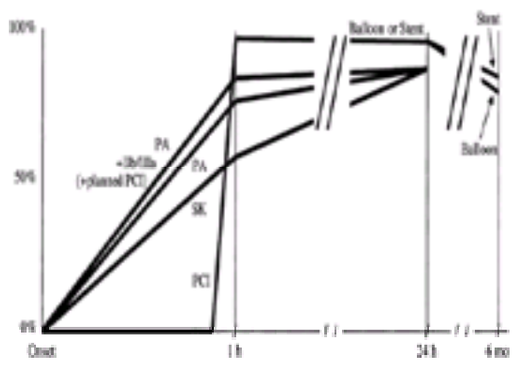

FIGURE 80.5 Percentage of normal coronary flow over time with primary percutaneous coronary intervention (PCI) or (facilitated) systemic fibrinolysis for treatment of acute myocardial infarction. The goal is to stay as high and as far to the left as possible. Up to 1 hour, the combination of a plasminogen activator (PA) with a glycoprotein IIb/IIIa antagonist (IIb/IIIa) is preferable to PA alone or to streptokinase (SK). Meanwhile, immediate percutaneous coronary intervention should be readied. The stent is clearly superior to the balloon only during follow-up that is depicted up to 6 months.

PCI for acute myocardial infarction is an exception in many respects. It dictates an ad hoc procedure and, for most, imposes restriction to the culprit vessel in multivessel disease. Although it carries a higher overall complication rate than elective PCI, it has a smaller potential to harm. The major complication of PCI, abrupt closure of the lesion, is relatively innocuous when starting with an occluded vessel.

There are data warranting stenting for all cases with PCI for infarction. Although acute results are not improved, reinterventions are reduced (Fig. 80.6) (46,90). However, the stent increases no-reflow problems and side branch occlusions. Both damage myocardium; a later restenosis does not. An experienced interventional cardiologist knows to select cases not to stent (good result with crisp flow after balloon dilatation). Direct stenting is not attractive, as the extent of the lesion cannot be anticipated in totally occluded arteries.

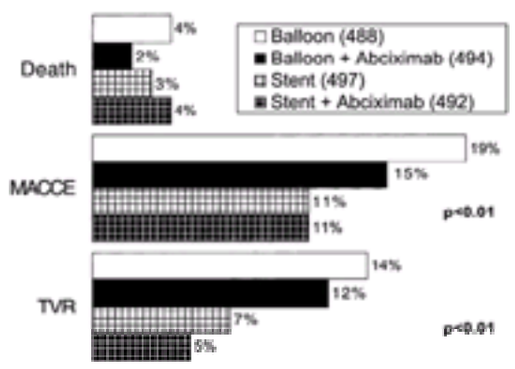

FIGURE 80.6 Randomized trial comparing balloon angioplasty for acute infarction to stenting with or without abciximab. At 6 months, there was an advantage of stenting over balloon angioplasty irrespective of the use of abciximab. It was significant only for target vessel revascularization (TVR) and remained so when major adverse cardiac and cerebral events (MACCE) were pooled. (From Stone GW. Stenting and IIb/IIIa receptor blockade in acute myocardial infarction: an introduction to the CADILLAC trial. *J Invasive Cardiol* 1998;10:36B–47B.)

PCI for cardiogenic shock is warranted unless the shock is too advanced or too long-standing or the patient is old (50,91). In 2000, a percutaneous left ventricular assist device was introduced that may aid these patients as a bridge to recovery or transplantation.

PCI should be done acutely for myocardial infarction if it can be performed within the hour. Otherwise (or perhaps in any case) modern fibrinolysis, preferably supported by a glycoprotein IIb/IIIa antagonist, should be initiated and PCI treatment appended if feasible. Only sizable infarctions (greater than or equal to three ECG leads with ST elevation) qualify for fibrinolysis or PCI.

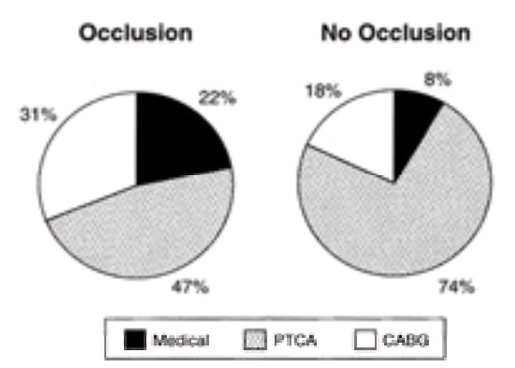
Poor Left Ventricular Function

PCI can be performed with any left ventricular function. A swift introduction of the equipment and a short dilatation is tolerated by all patients even without the use of perfusion balloons, aortic counterpulsation, or left ventricular assist devices. In case of problems, however, the possibilities of PCI to sustain life in patients with severely compromised left ventricular function are more limited than with CABG. Therefore, a markedly reduced left ventricular function tends to favor CABG as a revascularization method. PCI is a valid option in inoperable cases, however, or when only one discrete lesion is at stake, or lesions are attempted in the hope of revitalizing nonfunctional myocardium. Some operators favor the prophylactic insertion of the intraaortic balloon pump (92), but supportive randomized data are lacking. Percutaneously insertable left ventricular assist devices requiring an oxygenator (93) have been partially supplanted by a simplified approach harvesting oxygenated blood from the left atrium.

Chronic Total Coronary Occlusion

Chronic total occlusions are present in 20% to 40% of patients with angiographic documentation of coronary artery disease (94). They constitute the most frequent reason to abstain from PCI.

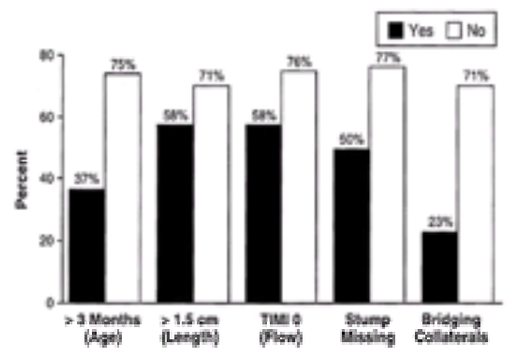
Approximately every third patient undergoing coronary angiography presents at least one total occlusion. eFigure 80.6.1 depicts that the presence of occlusions significantly sways the choice of therapy toward CABG.



***e*FIGURE 80.6.1** Recommendations for therapy in 220 consecutive patients with and 357 patients without at least one chronic total coronary occlusion at coronary angiography. The presence of occlusion favors the recommendation for coronary artery bypass grafting (CABG) rather than percutaneous transluminal coronary angioplasty (PTCA). (Adapted from Delacrétaz E, Meier B. Therapeutic strategy with total coronary artery occlusions. *Am J Cardiol* 1997;79:185–187.)

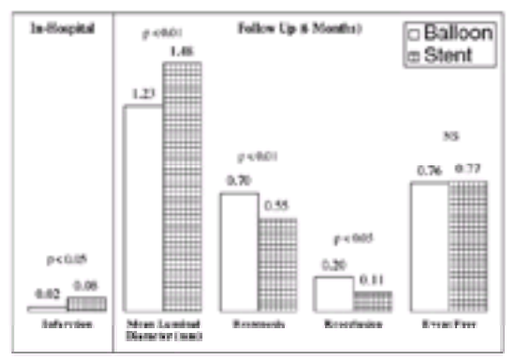
The success rates vary from below 50% to almost 90% according to the cases selected. The key determinants of success are completeness, age, and length of

occlusion; presence of local (bridging) collaterals; and absence of a stump (eFig. 80.6.2) (95). They remain instrumental even after hydrophilic and other dedicated guidewires have improved the crossing potential with this indication.



***e*FIGURE 80.6.2** Success with recanalization of chronic total coronary occlusions according to some important variables in roughly 5,000 patients from pooled reports. (Adapted from Puma JA, Sketch MH Jr, Tcheng JE, et al. Percutaneous revascularization of chronic coronary occlusions: an overview. *J Am Coll Cardiol* 1995;26:1–11.)

With recanalized chronic occlusions, as with fresh occlusions in acute infarction, there is evidence that overall results with stents are superior to those with balloons only. There may be more side branch occlusions, but restenoses and reocclusions are reduced (eFig. 80.6.3) (43). Again, judicious rather than indiscriminate use of stents is warranted.



***e*FIGURE 80.6.3** In-hospital infarction rate and 6-month follow-up in a multicenter randomized trial comparing stenting with balloon angioplasty after successful recanalization of a chronic total coronary occlusion in 410 patients. At the price of an increased in-hospital infarction rate, a better angiographic result at follow-up was achieved, without, however, reducing the overall event rate. NS, not significant. [From Buller CE, Dzavik V, Carere RG, et al. Primary stenting versus balloon angioplasty in occluded coronary arteries: the Total Occlusion Study of Canada (TOSCA). *Circulation* 1999;100:236–242, with permission.]

The high recurrence rate even after stenting is disturbing. However, only the minority of recurrences are reocclusions, and reocclusions, early or late, are unlikely to cause a myocardial infarction, thanks to the reliable recruitability of the previous collaterals (96).

The immediate and long-term clinical yield of PCI of chronic total occlusions is not as spectacular as that of PCI of stenoses, but patients with sustained patency avoid remodeling of the left ventricle (97), improve their exercise capacity (98), enjoy a drastically reduced need for CABG (99,100), and, perhaps, even live longer (99). One of the first randomized studies showing improved survival with PCI pertained to recanalization of totally occluded LADs (101).

Single- and Multivessel Disease

Single-vessel disease still represents the best indication for PCI and accounts for roughly one-half its patients (51).

The correlation between symptoms and therapy is plain. The myocardial function is usually good. The intervention is short, the risk is small and quite accurately predictable, and the rate of restenosis is acceptable. Serial stenoses in a single vessel compromise the outcome to a certain extent, but they still represent a good indication for PCI. More than 85% of PCI procedures worldwide are single-vessel interventions (24,25,51).

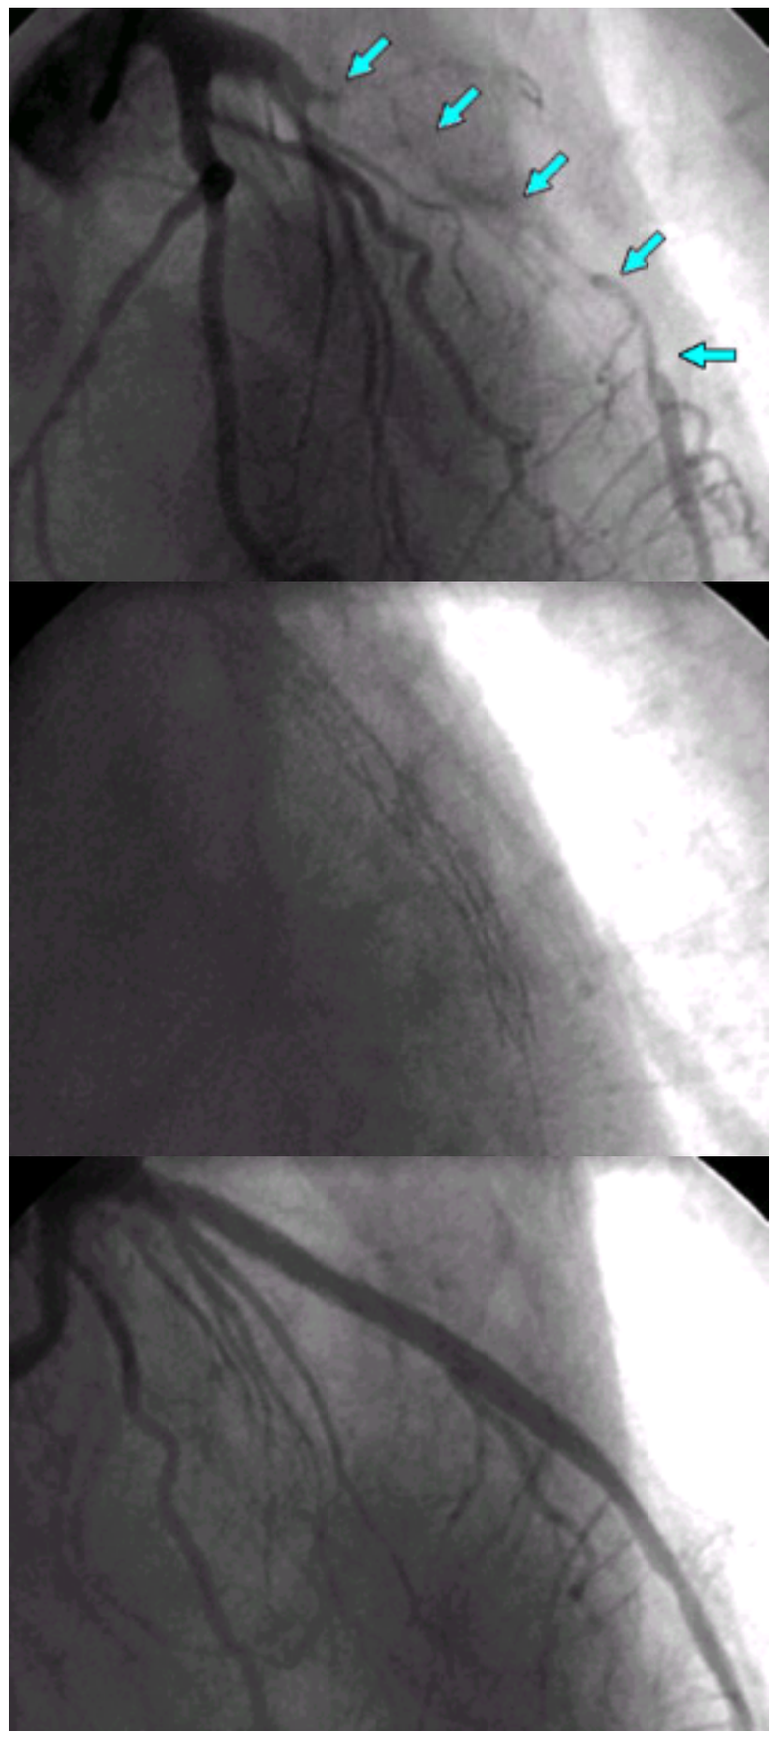
Multivessel disease can and should be considered for PCI in patients with inoperable disease or provided full revascularization at an acceptable risk is projected (for instance, if protective collaterals are present or if the patient is willing to undergo staged procedures) or a culprit lesion can be identified (particularly in the elderly or otherwise poor surgical candidate).

Multivessel disease is a risk factor for acute complications after PCI even if only one vessel is attempted (102).

If several vessels are approached, the acute risk augments further, and there is an increased likelihood of restenosis and other late cardiac events. Complete revascularization is less a prerequisite with PCI than with CABG because of the repeatability of PCI.

Proximal Left Anterior Descending Coronary Artery

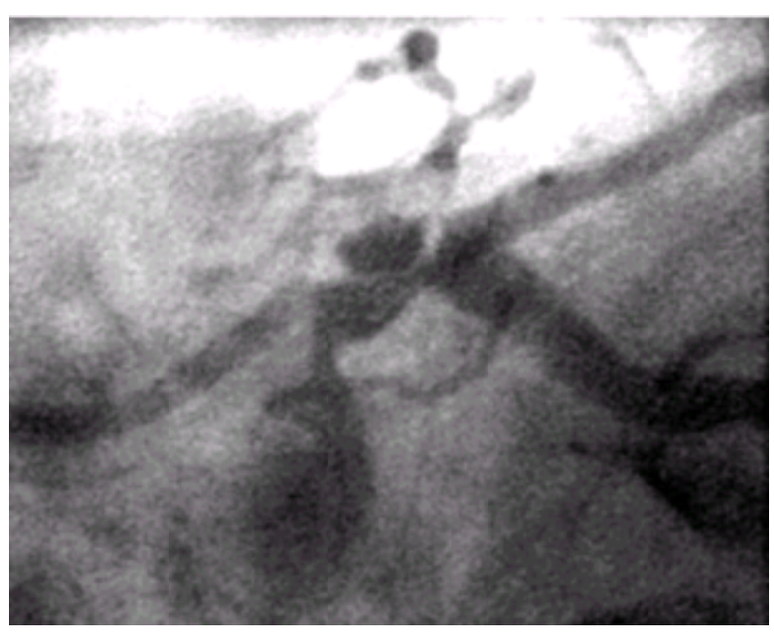
PCI of the proximal LAD has proved effective but it harbors significant jeopardy to cardiac function and survival in case of acute vessel occlusion. It has also been shown to have an increased incidence of restenosis, especially if the ostium of the LAD is involved (103). In contrast to single-vessel disease of other locations, PCI of the proximal LAD has a difficult stand against CABG with the internal mammary artery (104), even with elective stenting (105) and before minimally invasive surgical techniques have been fully exploited (106).



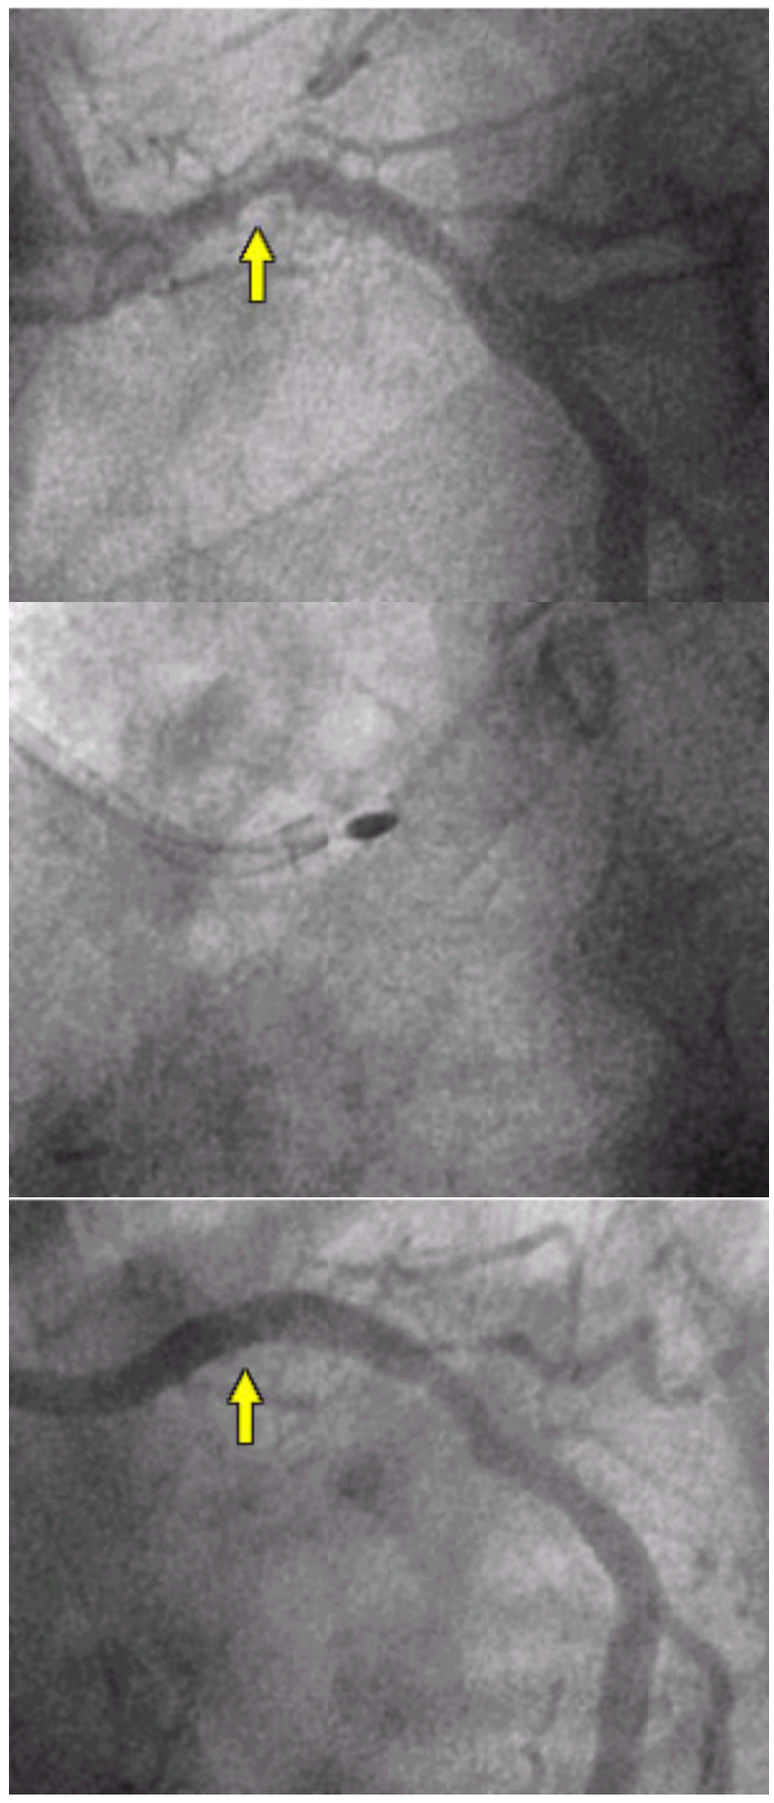
Placement of a long AVE stent in the mid-left anterior descending coronary artery. The arrows in A demonstrate a long area of severe diffuse disease involving the mid-left anterior descending artery. A 39-mm-long radiopaque AVE stent is deployed within the diseased segment (B), yielding an excellent final angiographic result (C).

Left Main Stem

PCI for left main coronary artery stenosis has been considered, tried, shunned, and retried (107). The high mortality discourages the elective use of PCI for unprotected left main stenosis (108). Stents and glycoprotein IIb/IIIa antagonists have yet to overcome this apprehension although modern PCI of a discrete left main lesion not involving the bifurcation is probably as safe and effective as CABG. Protected left main lesions (patent bypass graft or copious collaterals to at least one vessel of the left circulation) and acutely or chronically occluded left main lesions have always been a valid indication for PCI.



Severe ulcerated plaque of the left main trunk discovered on diagnostic angiography.



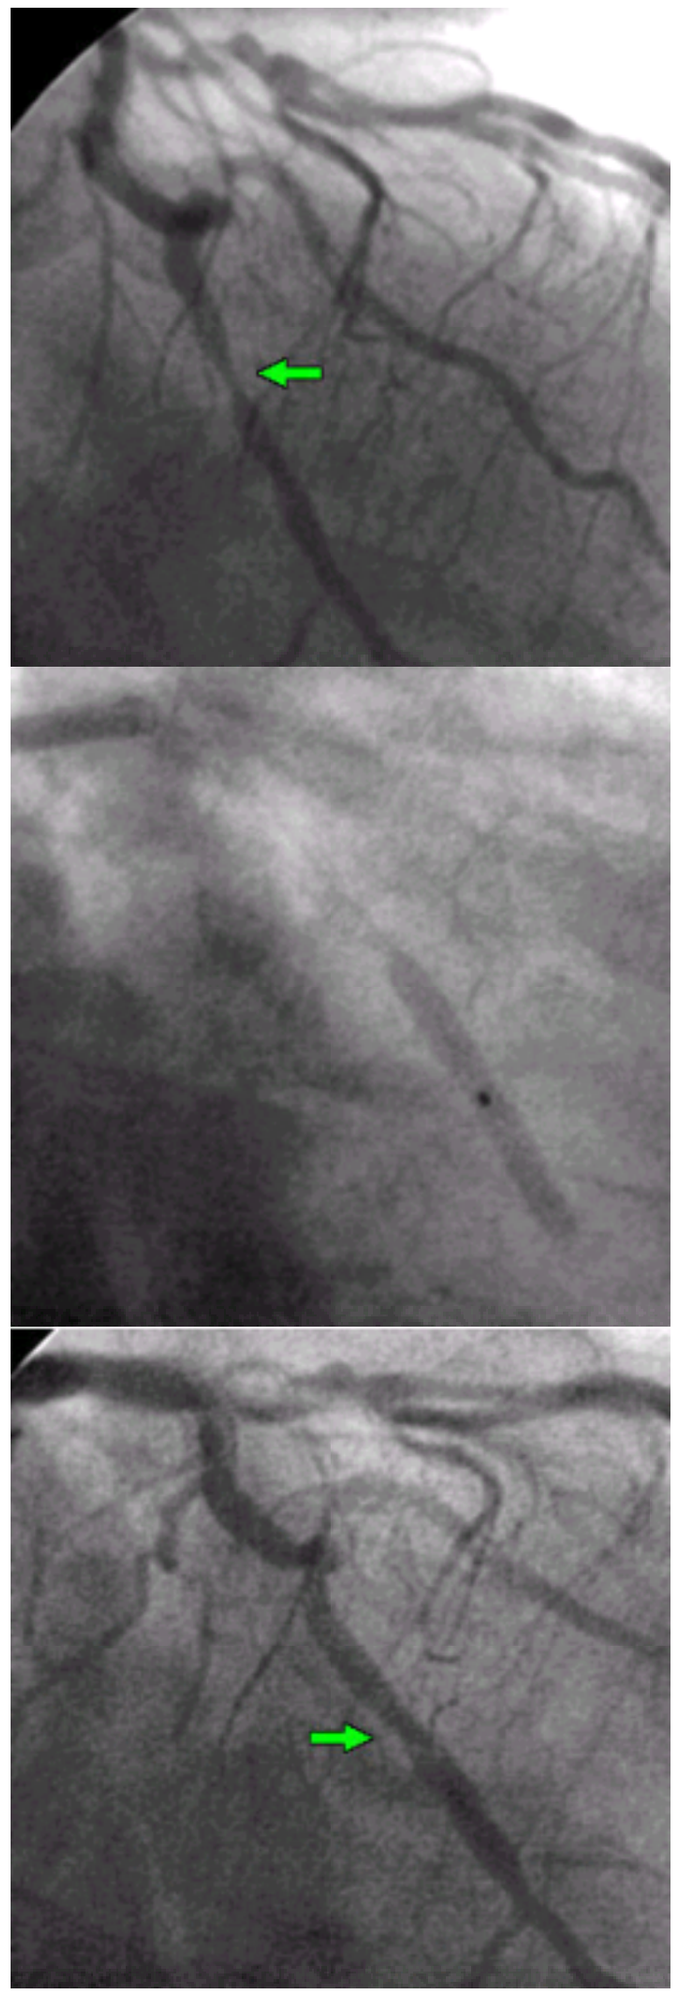
Rotational atherectomy of a "protected" left main trunk. A severe stenosis (A, *arrow*) is present in the left main trunk and compromises flow to the left circumflex. The left anterior descending artery is "protected" by a patent left internal mammary artery graft. Rotational atherectomy followed by stent implantation is successfully performed (B,C).

Video 80.9 Ostial left main coronary artery disease. Contrast injection reveals severe narrowing of the ostium of the left main coronary artery. In this patient, after coronary artery bypass graft surgery there was rapid acceleration of the underlying coronary disease leading to this left main stenosis. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

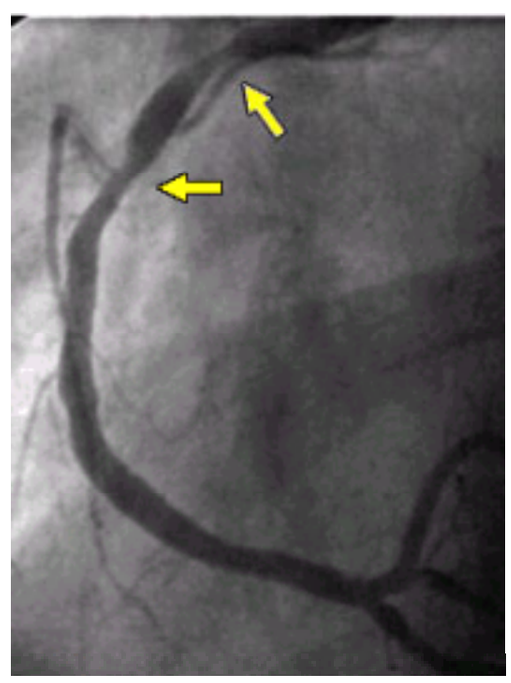
Video 80.10 Left anterior oblique caudal view of the left main trunk showing severe ostial stenosis. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

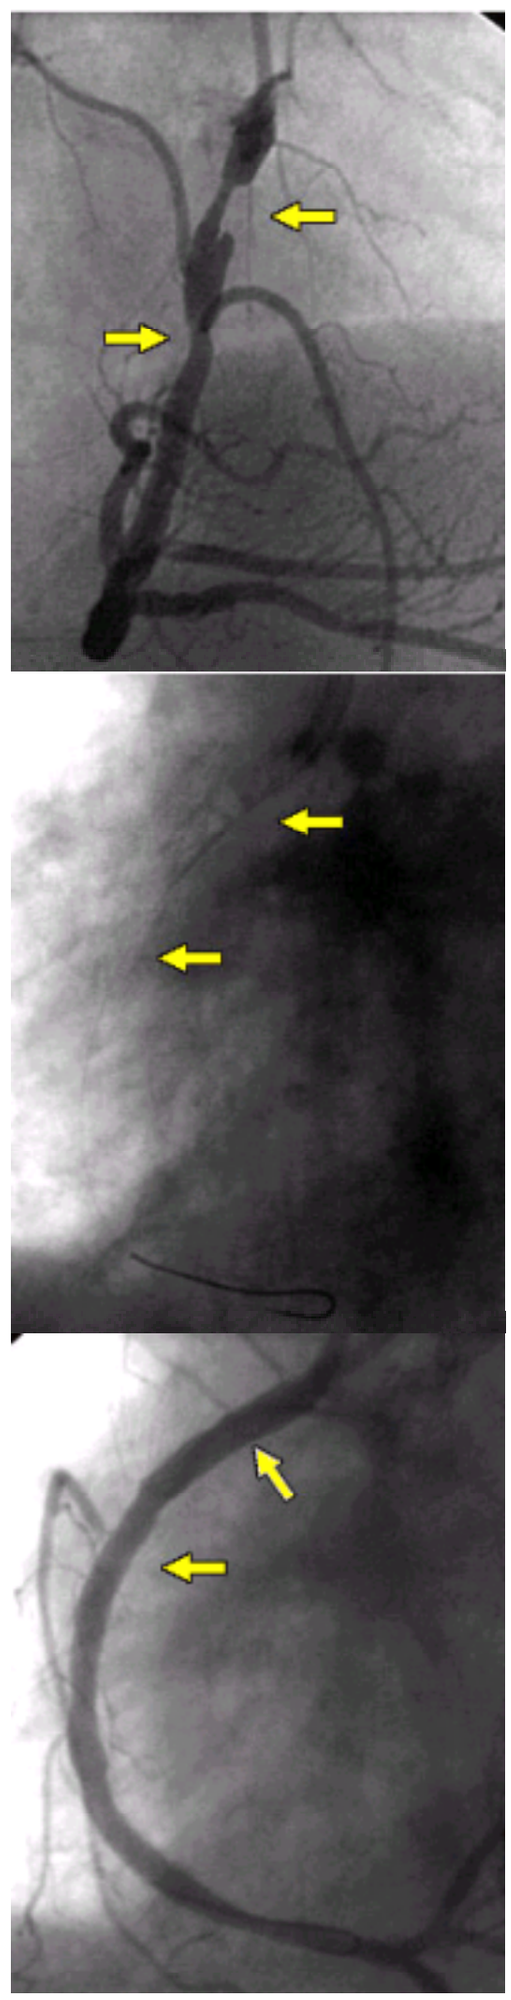
Ostial, Small, Long Diffuse, or Calcified Lesions

For many years, the search was on for a solution to the problems encountered with balloon angioplasty when dealing with ostial, small, long diffuse, or calcified lesions. Initially, it appeared that directional atherectomy might be helpful for ostial lesions and rotablation or laser for small vessels with long and diffuse lesions.



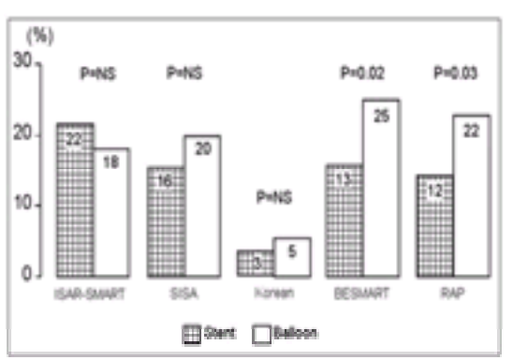
Balloon angioplasty of the lateral branch of the left circumflex (A). Stand-alone balloon angioplasty (B) resulted in substantial reduction in stenosis severity with no angiographic evidence of dissection (C).





Sequential stenosis in the proximal right coronary artery (A,B) treated with different stent types. A Palmaz-Schatz coronary stent is implanted across the more distal stenosis (C, *lower arrow*), then a Palmaz-Schatz balloon stent (more radiopaque) is used to treat the more proximal lesion (C, *upper arrow*) in a segment with a large normal reference vessel area. The postintervention result is shown in D.

The stent has replaced directional atherectomy for ostial lesions because it yields better long-term results, is more readily applicable, and produces fewer acute complications. Nice angiographic results can also be obtained in long diffuse lesions by implanting multiple or long stents, again with fewer technical or clinical problems than by using rotablation or lasing. The high recurrence rate remains a problem, however, particularly in small vessels (eFig. 80.6.4) (41,109,110).



***e*FIGURE 80.6.4** Need for reintervention in randomized trials (approximately 400 patients each) comparing stenting with balloon angioplasty in small arteries. The results are controversial. The Bestent in Small Arteries Trial (BESMART) and Restenosis en Arterias Pequeñas (RAP) trial using the same stent model showed an advantage for stenting in reduction of restenosis and reintervention. The other trials, Intracoronary Stenting and Antithrombotic Regimen-(Munich) Small Artery Stenting (ISAR-SMART) (41), Stent to Prevent Restenosis in Small Arteries (SISA), and Korean (110), using other stents, did not. NS, not significant.

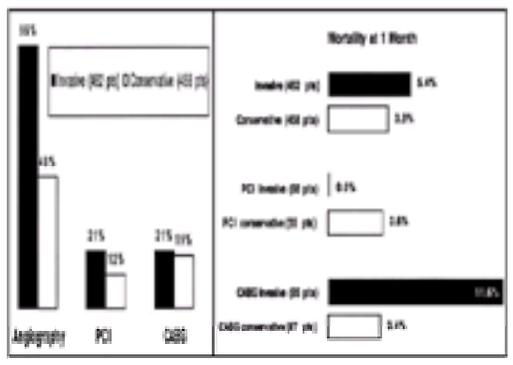
Calcifications only play a role if they are circumferential, and the stenosis fails to yield to maximal balloon pressure. These situations have all but disappeared, with balloons tolerating pressures up to 30 bar. For the few remaining cases, rotablation may be tried.

Comparison with Alternative Therapies

Medical therapy is the foremost alternative to PCI for single-vessel disease except for proximal LAD stenoses in which surgery must be considered and yields better results than PCI (104,105,111) or medical therapy (111) regarding the need for further interventions. The Angioplasty Compared to Medicine (112) and Coronary

Angioplasty versus Medical Therapy for Angina-2 (113) trials have randomized patients between PCI and medical treatment. The advantage of PCI was quite conspicuous but limited to exercise performance and quality of life.

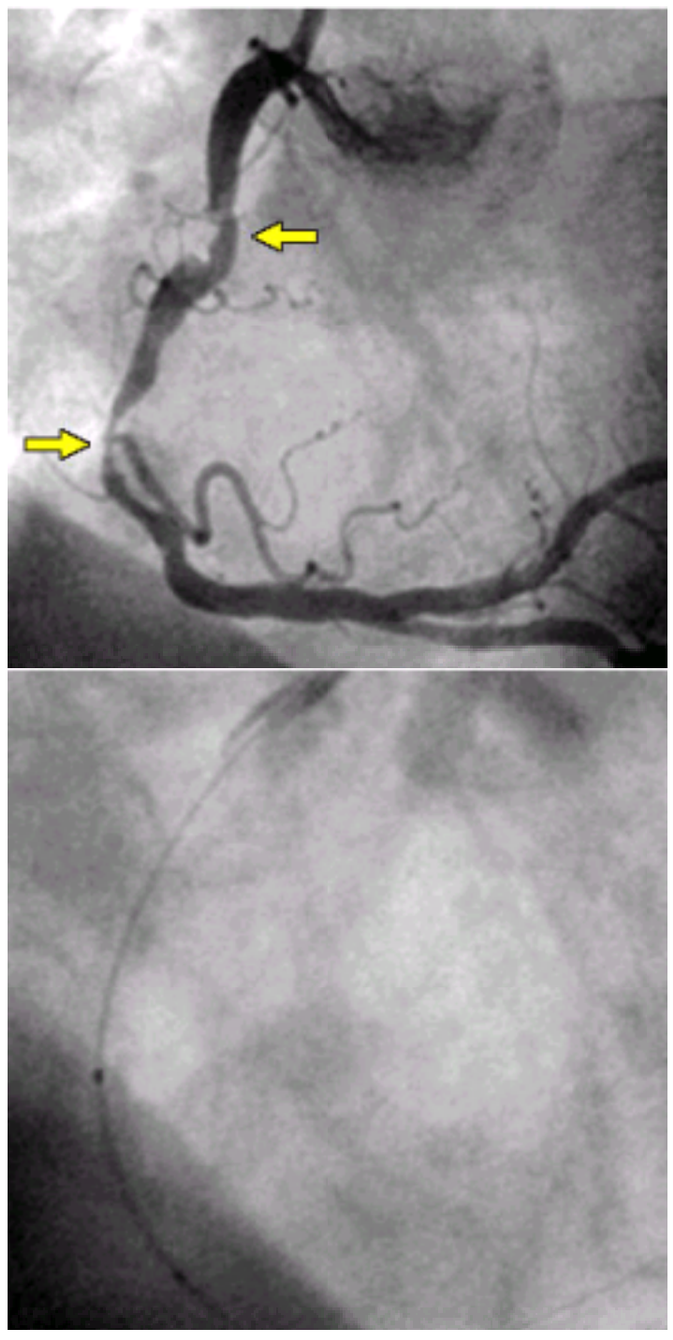
In unstable situations or after non-Q infarction, randomized trials gave mixed results. The Veterans Affairs Non-Q Wave Infarction Strategies In-Hospital Study found a negative influence of invasive workup and treatment after non-Q infarction (114). However, eFigure 80.6.5 reveals that the actual difference in invasive attitude was small, and the rather negative outcome in the invasive group was entirely due to an appalling 11.6% mortality in the patients randomized to the invasive arm and treated with CABG. Mortality in the PCI patients was nil, and the differences in outcome had disappeared at 3 years. The Fast Revascularisation during Instability in Coronary Artery Disease II trial clearly advocates an invasive attitude early in unstable angina based on a significant reduction in major cardiac events, in particular mortality at 1 year (53). The Treat Angina with Aggrastat (Tirofiban) and Determine Cost of Therapy with an Invasive or Conservative Strategy trial confirms the value of such an attitude even after pretreatment with tirofiban (77).

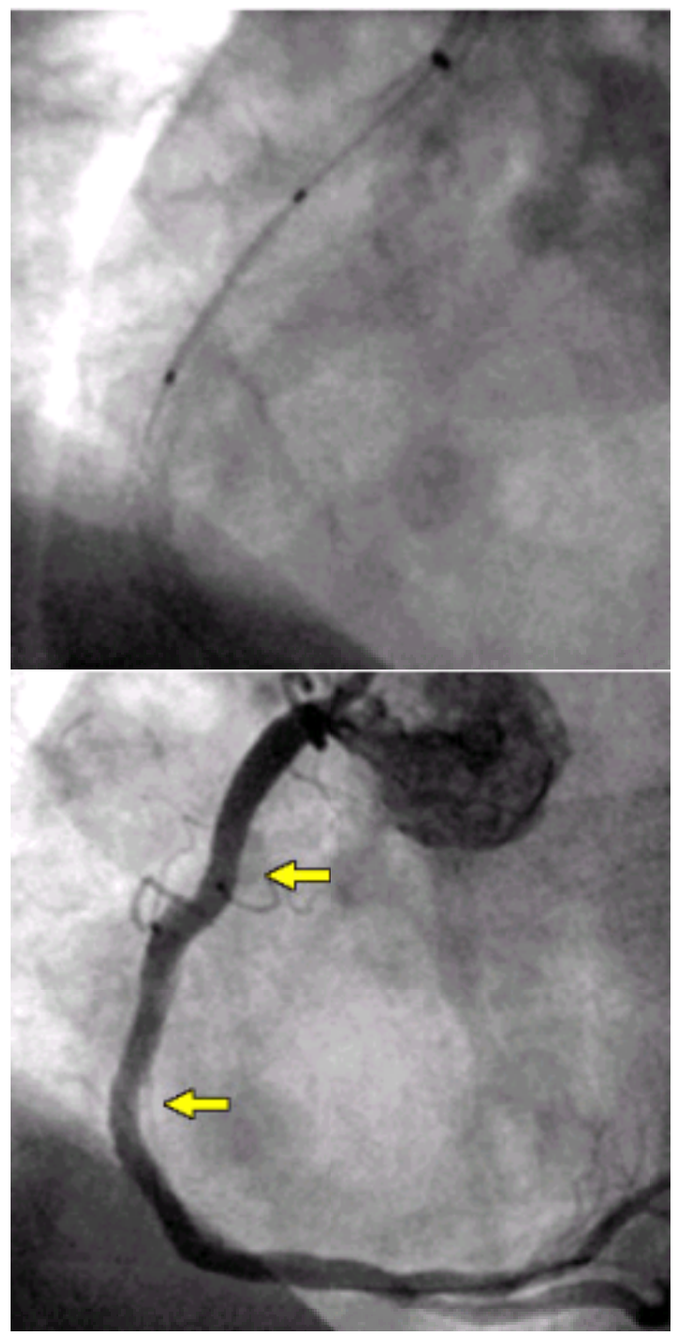


***e*FIGURE 80.6.5** Randomized trial comparing invasive with conservative therapy in 920 patients (pts) after non-Q infarction (114). The borderline significant increase in mortality with invasive strategy does not speak against percutaneous coronary intervention (PCI) because of the poor adherence to the randomized strategy (*left panel*) and the absence of lethal outcomes in patients randomized to the invasive arm and treated with PCI (*right panel*). CABG, coronary artery bypass grafting.

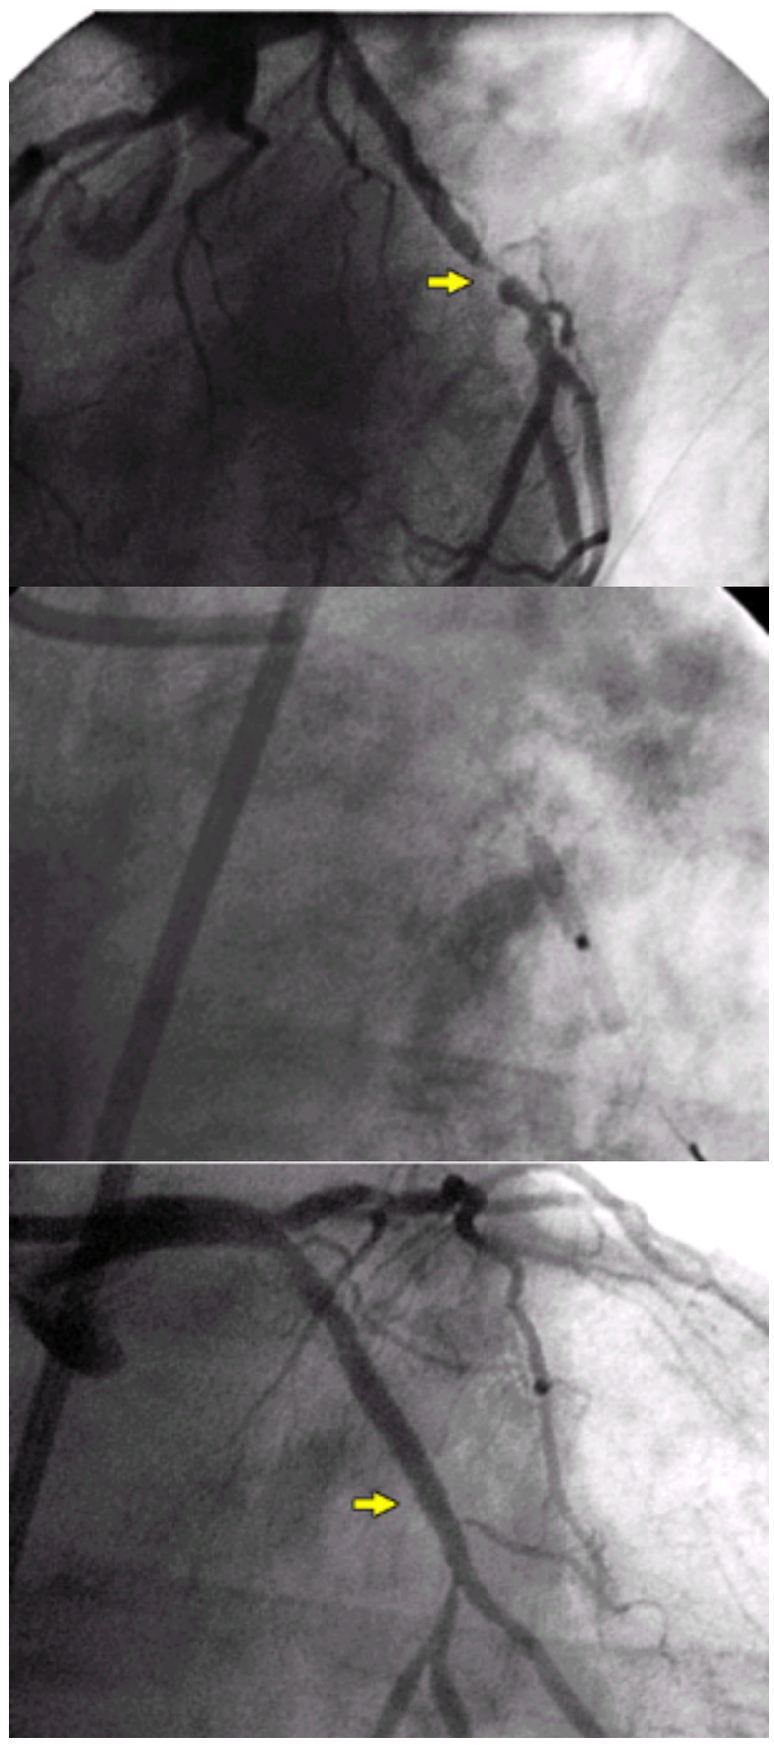
Under more stable auspices, the Atorvastatin versus Revascularization Treatment trial suggested that an aggressive treatment with a statin (80 mg of atorvastatin) for 18 months was at least equal to an invasive strategy in patients with significant coronary artery disease (115). This does not take into account that the rate of PCI in the conservative group accrues over time, manifesting that the underlying problem, the stenosis, will need to be addressed sooner or later. The same can be said for the Deferral versus Performance of PTCA Based on Coronary Pressure Derived Fractional Flow Reserve trial. It shows that a stenosis not reaching hemodynamic significance when assessed invasively by its fractional coronary flow reserve can be left undilated for at least 2 years without increasing the risk for cardiac events (116).

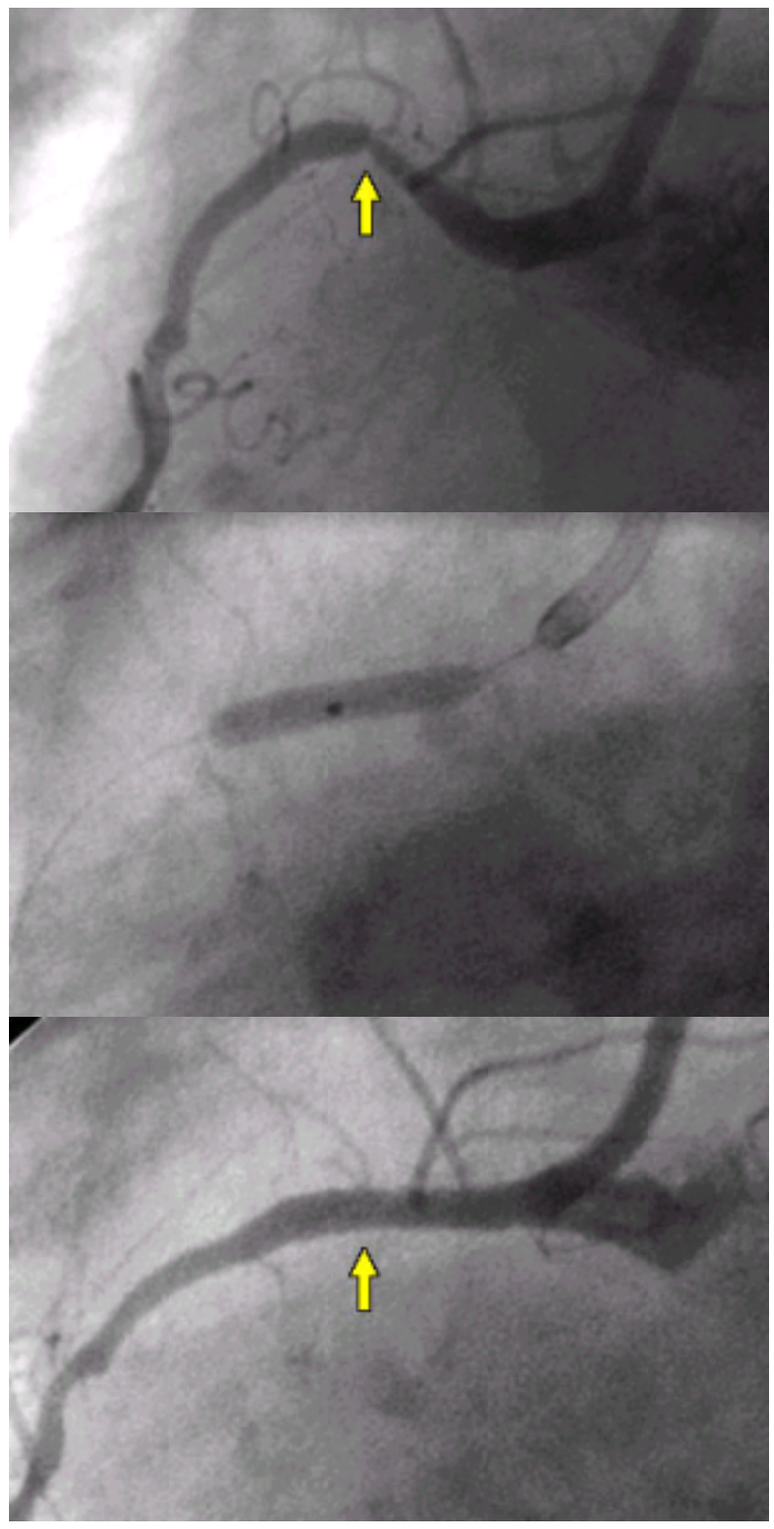
In multivessel disease, PCI has been compared with CABG in numerous randomized trials first without (72,117,118,119,120 and 121) and then with elective stenting (122,123).





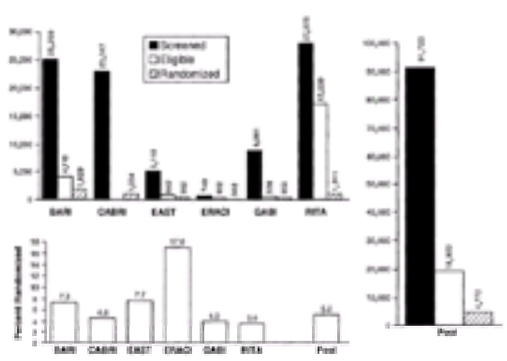
Use of multiple Palmaz-Schatz stents to treat sequential stenoses (A, *arrows*) in the right coronary artery. The first stent is deployed across the more distal lesion (B), then the second stent is deployed across the proximal stenosis (C). The result of the intervention is shown in D.





The strategy of multiple stent implantation in a patient with multivessel disease. Initially, a discrete lesion in the mid left circumflex artery (A) is successfully treated with a Palmaz-Schatz coronary stent (B,C). A second Palmaz-Schatz stent is then implanted in the proximal right coronary artery (D–F).

It has to be stressed that the inclusion rate of screened patients was minimal (*e*Fig. 80.6.6). Patients analyzed do not represent the average multivessel patient undergoing diagnostic coronary angiography.



***e*FIGURE 80.6.6** Screened, eligible, and randomized patients in various trials randomizing patients with multivessel disease between percutaneous coronary intervention and coronary artery bypass grafting. In all studies, only a small percentage of screened patients were finally randomized (*right panel*). BARI, Bypass Angioplasty Revascularization Investigation; CABRI, Coronary Angioplasty versus Bypass Revascularization Investigation; EAST, Emory Angioplasty versus Surgery Trial; ERACI, Argentine Trial of Percutaneous Transluminal Coronary Angioplasty versus CABG; GABI, German Angioplasty Bypass Surgery Investigation; RITA, Randomised Intervention Treatment of Angina (also including single-vessel disease).

The results across the board show similar mortality and infarction rates between the two methods, with a tendency to more early significant infarctions in CABG patients and more later mortality in PCI patients (124). With PCI, there is a markedly higher need for further coronary interventions than with CABG, reflecting the restenosis problem after PCI. This is somewhat mitigated by stents, according to the Arterial Revascularization Therapy Study and Stent or Surgery trials, but still remains significant with reinterventions in approximately 25% of patients after stenting versus 15% after CABG (122,123).

Patients on antidiabetic treatment were analyzed separately in some of the studies. They had a generally poor 7-year survival, but it was significantly better with CABG (76%) than with PCI (56%) (72). This difference could be blunted in the future by generous use of abciximab (125).

Rehabilitation

Return-to-work rates are not only dependent on the physical and mental ability of the patient to resume a normal life but also on the attitude of the medical professionals, on regional customs, and on the welfare system. Following a successful PCI without complications, normal physical activity can be resumed as early as 12 hours after the intervention. CABG is clearly no match for this. Only a few patients, however, take full advantage of this feature of PCI, and the average time to resume gainful activity amounts to several days to weeks in most countries.

Quality of life in the early phase after PCI is better than after CABG for obvious reasons, but at 1 year the opposite is true (126). On the other hand, quality of life after PCI is superior to that with medical treatment because of reduced symptoms and improved exercise capacity (113).

ECONOMIC ASPECTS

A procedure that prolongs life in the elderly tends to engender further medical expenses. Even with the proof for life extension by PCI pending, it is likely that the

repeated use of the method will keep coronary patients around longer than medical treatment alone. These patients are in general economically nonproductive and likely to need further costly medical care on top of general financial sustenance. Moreover, the cost of a PCI procedure is affected by a number of variables. Mostly, it is operator dependent (127). New devices tend to be more expensive (128).

It is estimated that $10,000 invested in an invasive strategy for coronary artery disease affords 1 life-year. For an additional $6,000 invested into abciximab, another year can be gained (129). This can be compared with the $6,000 to be invested into CABG for left main disease to save 1 life-year. The focus should, however, remain on the quality of life gained per investment.

The CABG package is costly during the first month (surgery, intensive care, prolonged hospital stay, rehabilitation program, and absence from work), but little additional expenditure is expected in the first year thereafter. The PCI package accrues cost over almost the entire first year (repeat interventions). A comparative cost analysis, including the first month only, will heavily favor PCI (130). Accumulated cost at 1 year seems more reasonable but may disfavor PCI. Repeat interventions in the subsequent years are virtually limited to those for disease progression after PCI while interventions for graft attrition (venous in particular) add up to those for disease progression after CABG.

In the socialized medical system of the United Kingdom, the aggregated costs of PCI at 2 years were 20% lower than those of CABG (130). Similar balances ensued from a study in Argentina (131). Some U.S. authors confirm this (132). Yet some observed a more or less rapid equalization of cost (133,134). The more systematic use of stents and glycoprotein IIb/IIIa antagonists adds cost to PCI up front. The reduced need for early or late reintervention should make up for this (129). On the surgical side, off-pump surgery has failed to show a cost benefit so far (135).

PCI is no exception to other sophisticated medical techniques. It can be used to the advantage of mankind but it is costly. Whether this luxury is offered to the entire population and how close to home and with how short a waiting period is ultimately a decision up to the local political authorities. Plenty of doctors are easily beguiled by PCI and offer it to the patients provided there are adequate logistics and reimbursement. Lastly, PCI is at the base of an entire industry spanning from manufacturing of dedicated equipment to specialized hospitals and worldwide teaching activities. These important aspects need to be factored into the economic calculations as well.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Several issues of PCI cannot be solved based on evidence and remain highly subjective and thus controversial. They have to be seen in the light of variable geographic, economic, temperamental, and philosophical backgrounds and are also subject to change as time goes by. It is difficult to deal with such topics in a way applicable to all situations, everywhere, and at any time.

The question of where PCI should be performed and by whom has been iteratively debated with high emotions. A high-volume operator working at a high-volume institution, backed up by a high-volume cardiac surgical program, is the ideal setting. However, this means that the population with coronary artery disease will have to converge at the few megacenters to receive PCI under scientifically optimal circumstances. Approximately one center for 2 million people will suffice. It will perform between 2,000 and 4,000 PCIs per year with five to ten primary operators. The operators will not be assisted by doctors because those would decrease quality while learning the trade, spread out, and dilute the high-volume scenario. Interventional cardiologists would be trained exclusively to replace retiring operators and to meet the growing demand for procedures.

But will the patients like that? Many of them prefer get the treatment at their local hospital by their familiar cardiologist. There, they find their way around. There, they know people and people come to visit. Most patients do not care so much about the theoretic variance in the quality of PCI. First, they are unable to grasp the subtle differences, and, second, most PCI results are good, anyhow, even with low-volume teams. Referring doctors like to deal with angioplasty operators they know personally, rather than sending their patients to an anonymous “superinstitution.” Smaller communities can use the business involved, too. Concentration of the facilities to PCI “hubs” hurts their economy and keeps away investors and settlers.

When respected authorities, let alone governments, set regulations, they should honor these facts to a reasonable degree. It seems unwise to set limits that “outlaw” a substantial number of current operators. It is unlikely that they will abandon their practice, as that jeopardizes their professional existence. Nevertheless, guidelines should be clear regarding what is preferable, and reasonable minimal standards must be set.

Indications for PCI are another topic in which science and the “real world” diverge. Data show that the risk of coronary lesions is related to the extent of ischemia they produce. Scientifically, one could deduct that it is unethical to dilate lesions for which objective proof of ischemia or at least hemodynamic significance is lacking. Yet, this disregards patients with lesions that at the time of an “objectively unwarranted” PCI were not significant in terms of ischemia but that would have caused an infarction under conservative treatment while waiting for them to attain a hemodynamically significant degree.

Admittedly, it is currently impossible to predict these exceptions, but it is equally impossible to predict with accuracy which lesion will adhere to the rules. Moreover, it is customary in many centers around the globe to include the eventuality of an unanticipated spontaneous occlusion of the lesion when pondering a PCI indication. Imposing a different approach with costly assessment of the functional significance of the stenosis or the instability of the plaque is difficult to enforce and may not be to the benefit of the patients overall.

THE FUTURE

PCI is currently one of the dominant assets of modern health care. It engenders abundant medical literature, occupies a significant segment of medical education programs, and is a remarkable economic factor. It produces gigantic costs but also tax revenue. It creates income, jobs, and career opportunities for countless people. It unequivocally benefits well-being and perhaps even longevity of the elder generations of industrialized countries.

Figure 80.7 reflects the past and the future of technical aspects. Stenting will be the rule before long. The approach will be direct stenting to save time and spare the predilatation balloon. The stents will be drug eluting, which will not complicate the procedure or the logistics. New gimmicks will come and go as before, but the balloon-mounted stent will reign.

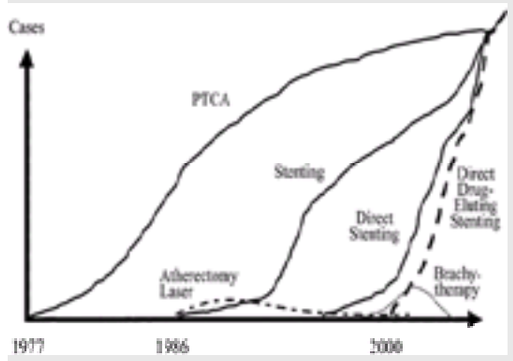


FIGURE 80.7 Past and future of percutaneous coronary intervention. The increase in cases may regain momentum once direct drug-eluting stenting has completely taken over. PTCA, percutaneous transluminal coronary angioplasty. (Modified from ideas of M. E. Bertrand and P. W. Serruys.)

The immediate future of balloon angioplasty is bright because coronary artery disease will remain the number one health problem of industrialized countries for quite some time and become increasingly prevalent in the rest of the world. It is bright because further improving technologies will expand the role of PCI for this disease, especially for its early, and perhaps for its very late, stage. The disease is increasingly discovered and documented at the early stage, and the general aging of the population creates a growing need for PCI at that end of the spectrum.

On the other hand, economic constraints increasingly frustrate those capable and willing to perform the procedure. Quality assurance activities take up more and more of the time of the interventional cardiologist. Finally, primary prevention will succeed in drastically reducing the need for PCI in middle age, stripping it of its coveted role as the most important intervention in modern medicine for people in their “best years.” Then again, there is nothing wrong with this.

RADIATION

Studies of restenosis have identified at least four mechanisms that contribute to luminal narrowing. These include elastic recoil of the artery, local thrombus formation, neointimal formation, and vascular remodeling (1,2,3,4 and 5). The relative contribution of these processes in humans is variable, with poststent restenosis dominated by neointimal hyperplasia and postballoon angioplasty restenosis primarily attributable to elastic recoil and negative remodeling of the target arterial segment (4).

Video 81.1 Severe in-stent restenosis involving the distal right coronary artery **(A)** and successful angioplasty **(B)**. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

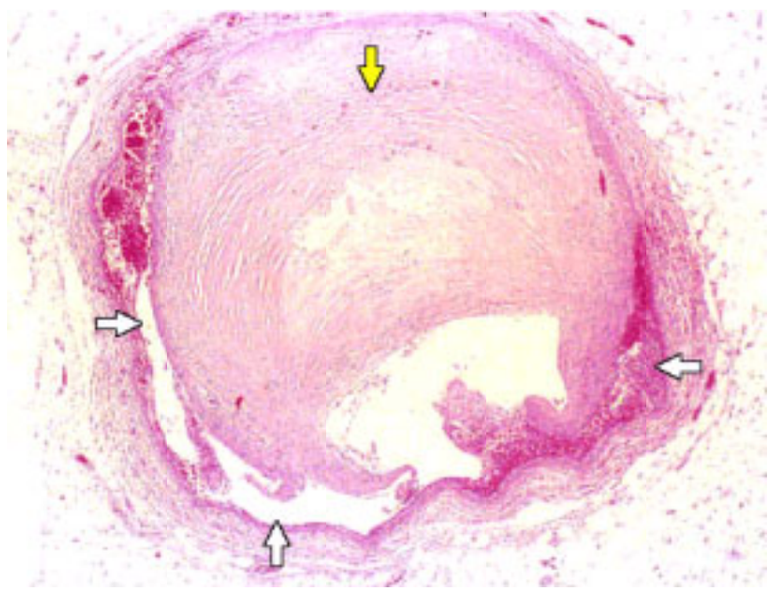
VIDEO

Video 81.2 Severe in-stent restenosis involving the distal right coronary artery **(A)** and successful angioplasty **(B)**. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

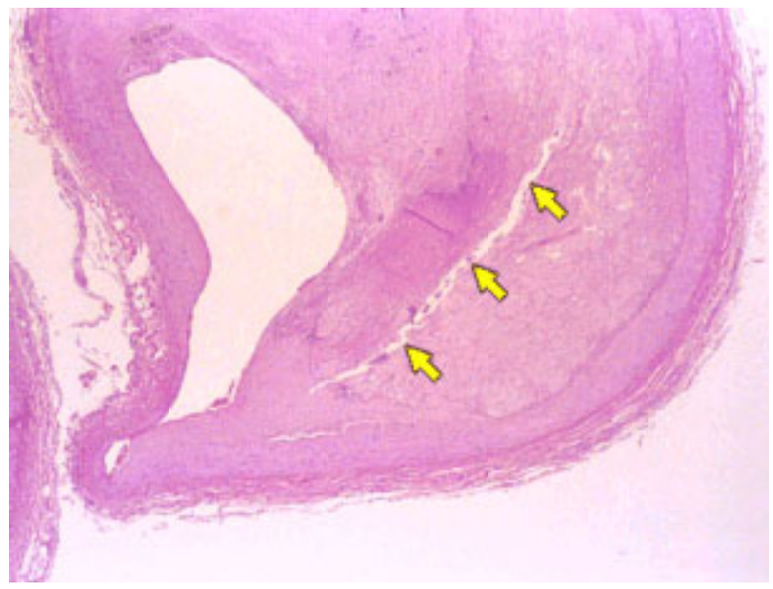
VIDEO

Video 81.3 Anomalous origin of the left circumflex coronary artery from the right sinus with in-stent restenosis 7 months post procedure. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

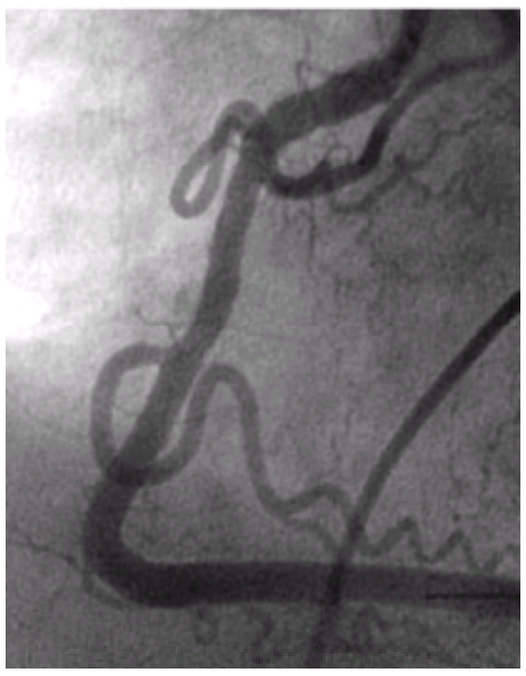
The reduction of neointimal proliferation has been the primary target of experimental and clinical restenosis efforts. The predominant cell type in the neointima has a smooth muscle phenotype; however, a significant amount of extracellular matrix is elaborated to form the bulk of the neointimal mass. More recent studies have suggested probucol (6) and tranilast (7) may both reduce restenosis rates in certain settings, although each compound has significant limitations.



Linear, circumferential dissection 2 days after balloon angioplasty of a restenotic lesion. Note the extensive neointimal proliferation (*yellow arrow*) and dissection (*white arrows*).



Restenotic lesion. Residual tear in atherosclerotic plaque (*yellow arrows*) and large amount of neointimal proliferation 76 days after balloon angioplasty.

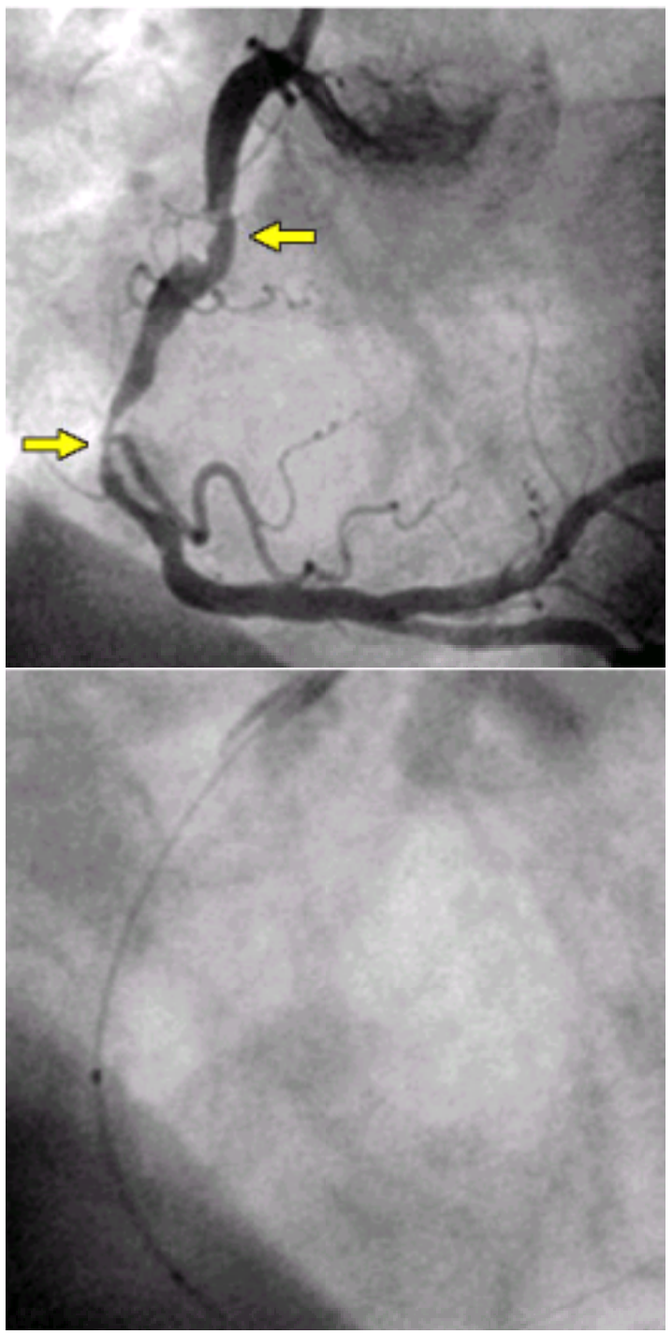


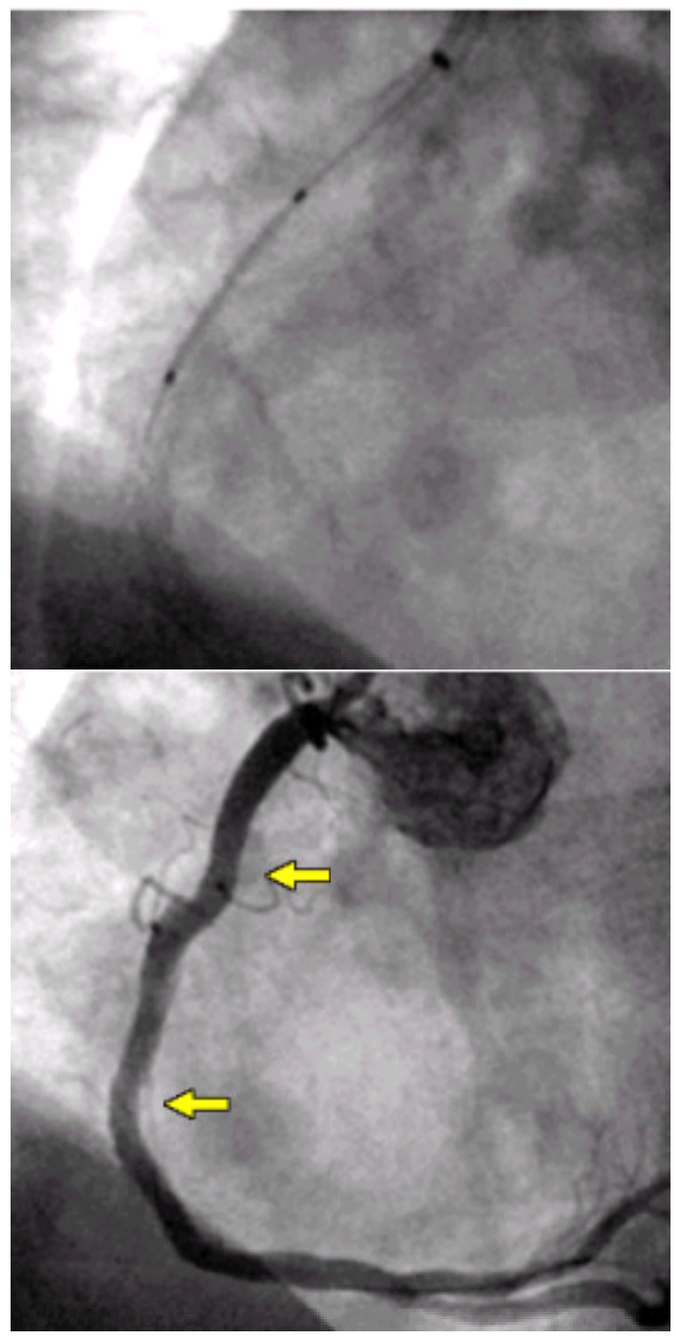
Rotational atherectomy to treat in-stent restenosis. Diffuse restenosis within a previously placed Palmaz-Schatz stent (A, *arrows*) is treated with rotational atherectomy (B), followed by adjunctive stent placement (C). The postintervention result is shown in D.

Attempts to minimize elastic recoil and remodeling using permanently deployed metallic stents have led to a decrease in restenosis rates in carefully controlled clinical trials (8,9). Even in these trials, however, the mass of neointimal tissue seen as a consequence of stent implantation is greater than the neointimal tissue seen in response to balloon angioplasty (10). Furthermore, stents are commonly used to treat lesions that deviate significantly from “ideal” lesions, as defined by these large studies. Multiple stents, newer stent designs, and intentional oversizing of stents are all associated with higher restenosis rates.

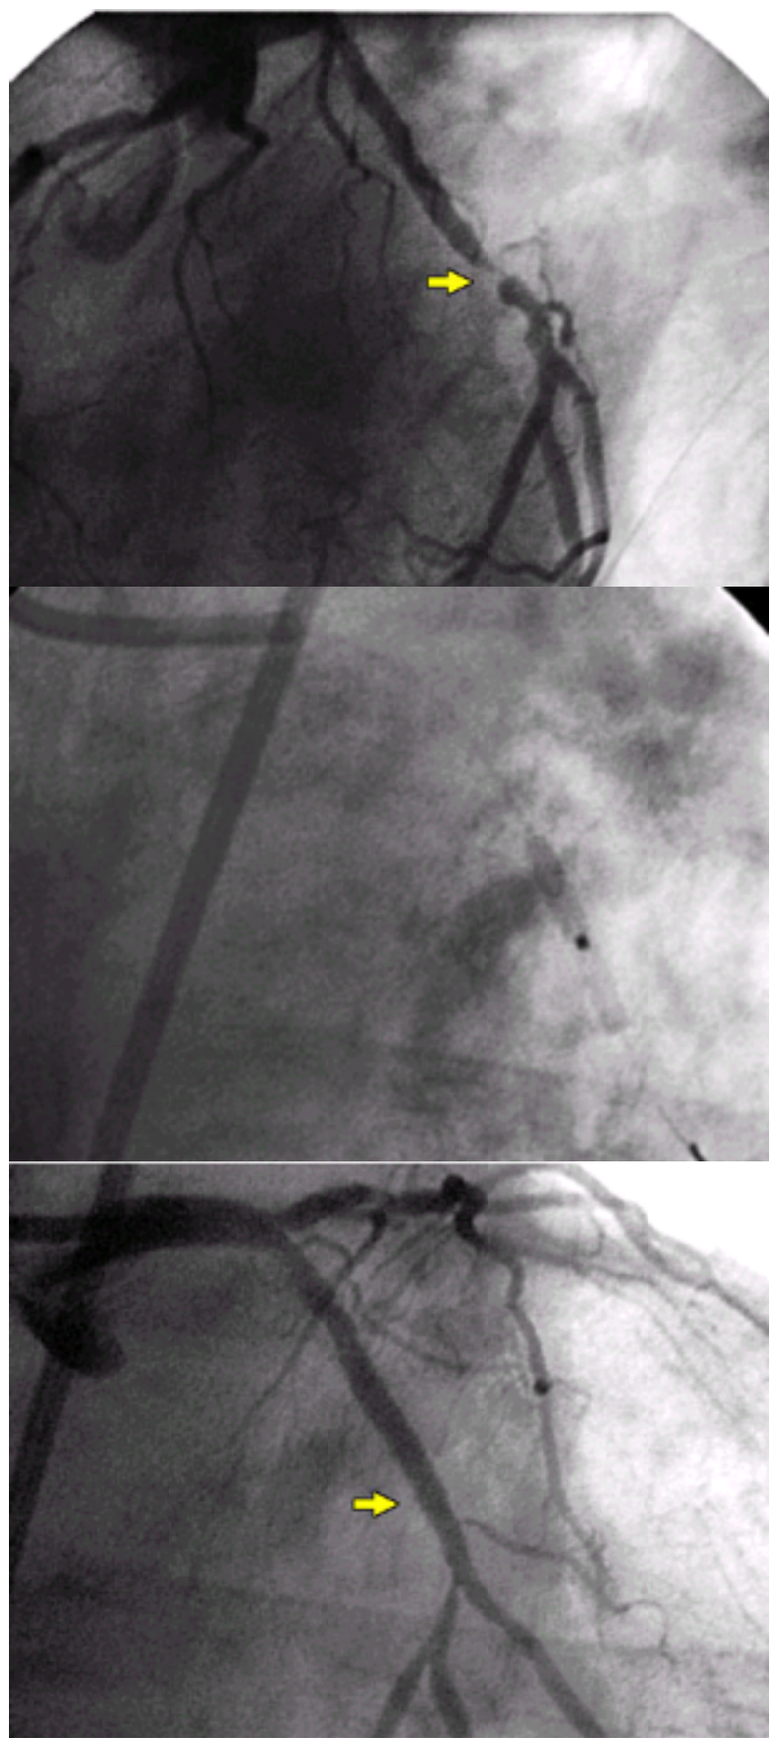
Video 81.4 Chronic total occlusion of the mid-portion of the right coronary artery **(A)** and subsequent successful recanalization **(B)**. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

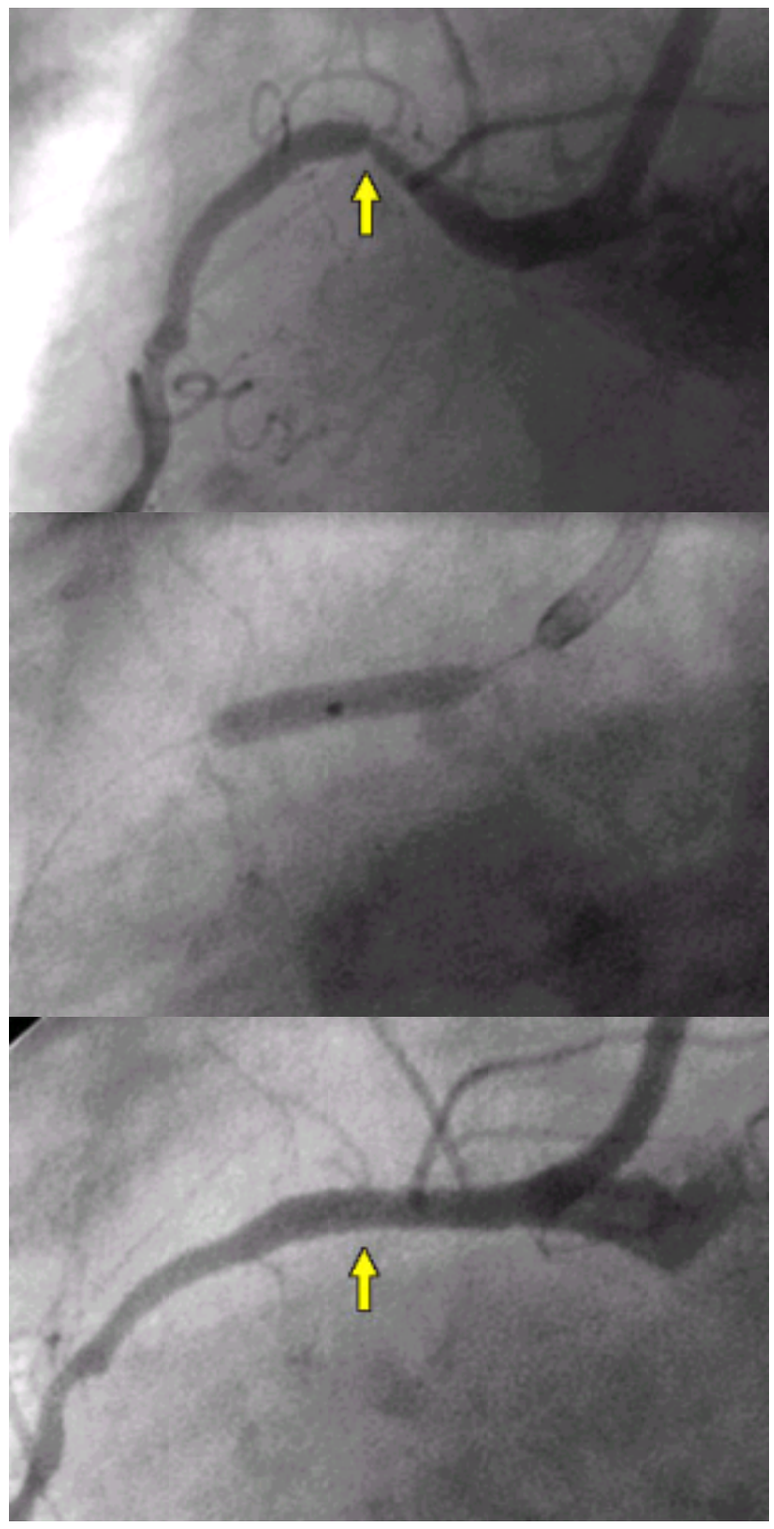
Video 81.5 Chronic total occlusion of the mid-portion of the right coronary artery **(A)** and subsequent successful recanalization **(B)**. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*





Use of multiple Palmaz-Schatz stents to treat sequential stenoses (A, *arrows*) in the right coronary artery. The first stent is deployed across the more distal lesion (B), then the second stent is deployed across the proximal stenosis (C). The result of the intervention is shown in D.





The strategy of multiple stent implantation in a patient with multivessel disease. Initially, a discrete lesion in the mid left circumflex artery (A) is successfully treated with a Palmaz-Schatz coronary stent (B,C). A second Palmaz-Schatz stent is then implanted in the proximal right coronary artery (D–F).

There is a long history of clinical use of ionizing radiation, both diagnostic and therapeutic. Fluoroscopic studies use x-rays in the 60- to 100-keV range; keloids, pterygia, cerebral arteriovenous malformations, heterotopic bone formation, and thyroid hyperplasia are all “benign” proliferative processes that are safely and successfully treated with ionizing radiation from external photon sources (gamma or x-rays) or systemic administration of a beta-emitting radioisotope (11). Radiation doses required to destroy function in mature nondividing cells are greater than doses required to stop the proliferative activity of dividing cells (12). Because the mass of neointima is thought to be generated by proliferating cells, therapeutic radiation treatments for prevention of restenosis have been initially studied in animal models.

Ionizing radiation, from x-rays, gamma rays, or beta particles, causes cell death at appropriate doses. Gamma radiation from an endovascular iridium-192 (^{192}I) source was first shown to inhibit intimal hyperplasia as a result of mechanical injury to the aorta of rabbits over 30 years ago (13). With the advent of clinical percutaneous revascularization several decades later, the use of ionizing radiation was extended to prevention of neointimal responses consequent to balloon-induced coronary injury using intravascular radiation sources (14,15,16 and 17). These observations were subsequently confirmed and extended by a number of groups, most notably in regard to the efficacy of beta sources of radiation in preventing experimental neointimal hyperplasia (18,19).

Clinical trials subsequently examined the effects of beta and gamma brachytherapy in treating patients with in-stent restenosis, as well as to prevent restenosis in percutaneous treatment of *de novo* coronary lesions. The initial studies suggested the expected magnitude of inhibition of subsequent restenosis events available using radiation. In addition, several surprising findings from the early rounds of clinical studies modified the technique and management of patients undergoing brachytherapy. Two important issues raised in these studies include an apparent prolonged susceptibility to stent thrombosis in patients undergoing new stent implantation at the time of brachytherapy, and the arterial response at the edges of the radiated field. This section reviews the basic science and the preclinical and clinical studies leading to release of this addition to the interventional armamentarium.

Characteristics of Radiation

The effects of a given activity (eTable 81.0.1) of a gamma or beta source on tissue vary dramatically. This difference stems from the differences in the dose of ionizing radiation absorbed from the energetic photons of gamma sources compared with the far more effective beta-mediated local energy absorption. Similar considerations account for differences in shielding requirements necessary for safe delivery of radiation.

***e*TABLE 81.0.1** GLOSSARY OF RADIATION TERMS

Becquerel (Bq)	Unit of radioactivity equal to 1 disintegration per sec (dps)
Brachytherapy	Therapeutic radiation delivered from an intravascular source
Curie (Ci)	Unit of radioactivity equal to 3.7 × 107 Bq
Gray (Gy)	Newer unit of absorbed dose of radiation, equal to 100 rad
Half-life	Time for decay of one-half of the starting amount of a radioisotope
keV	Thousand electron volts, a measure of the energy of the emitted particle
MeV	Million electron volts
Rad	Unit of absorbed radiation dose corresponding to 100 ergs/g. One centigray (cGy) equals 1 rad
Rem	Absorbed dose (in rad) corrected for the relative biologic effectiveness of the source of radiation (this weighting factor is unity for photons and electrons)
Roentgen (R)	Measure of ionizations (or exposure) produced in air by photons (e.g., x-rays or gamma rays) equal to 2.58×10^{-4} coulomb/kg
Sievert (Sv)	Absorbed dose (in Gy) corrected for the relative biologic effectiveness of the source of radiation (1 Sv = 100 rem)

Radiation dose is a measure of the amount of energy from a source of ionizing radiation deposited in a mass of a particular material. The dose of radiation absorbed by a tissue determines the biologic effect of that radiation. Dose depends on the type of radiation (e.g., beta, gamma, or neutrons), the amount of radiation, and properties of the absorbing material itself. Absorbed dose is measured in units of rad or gray, and effective and equivalent doses in rem or sievert (*e*Table 81.0.1). The relevant properties of isotopes currently in use or being studied are listed in *e*Table 81.0.2.

***e*TABLE 81.0.2** PROPERTIES OF RADIOISOTOPES

Isotope	Relevant therapeutic decay mode	Half-life	Maximum energy (MeV)	Average energy (MeV)
^{32}P (phosphorus-32)	Beta	14.262 d	1.71	0.60
^{48}V (vanadium-48)	Positron	15.9375 d	0.69	0.14

^{90}Sr (strontium-90)	Beta	28.78 yr	0.55	0.20
^{90}Y (yttrium-90)	Beta	64.10 h	2.28	0.90
^{188}W (tungsten-188)	Beta	69.4 d	0.35	0.10
^{188}Re (rhenium-188)	Beta	17.02 h	2.12	0.75
^{133}Xe (xenon-133)	Beta	5.2 d	0.35	0.10
^{192}Ir (iridium-192)	Photon (gamma)	73.83 d	0.6	0.37
^{125}I (iodine-125)	Photon (gamma, x-ray)	60.14 d	0.035	0.028
^{103}Pd (palladium-103)	Photon (x-ray)	16.97 d	0.023	0.021

Biologic Considerations

Ionizing radiation may interact with individual cells via direct ionization of DNA or other critical molecules, or indirectly by ionizing water molecules to form free radicals, which themselves are freely diffusible and can damage chromosomal DNA or critical membrane sites.

In general, the radiation dose necessary to destroy the function of a differentiated cell, such as a smooth muscle cell or endothelial cell, is far greater than the dose of radiation necessary to prevent cell division. Most lethally irradiated cells die during the mitotic process (12). It is unclear what, if any, the relative contribution of apoptosis is to postirradiation cell death seen in the arterial wall.

In radiotherapy of parenchymal organs, injury to capillaries and arterioles of normal parenchyma accounts for the majority of delayed effects of radiation. Experimental studies of large arteries (greater than 100 µm in diameter) have revealed that these vessels are less sensitive to radiation than smaller caliber vessels. Rarely, arterial perforation may occur. Large veins appear to be even more resistant to radiation than corresponding size arteries (20).

The risk of late coronary artery disease (CAD) as a consequence of radiation therapy has been best assessed in studies of patients irradiated for thoracic neoplasms. A retrospective analysis of Hodgkin's disease patients who received mediastinal radiation as part of their treatment reported a relative risk of myocardial infarction of 2.56 (21). Another retrospective study reported a relative hazard of death of 3.2 in patients who received high-dose radiation involving the heart for treatment of carcinoma of the left breast (22). Factors that were thought to be important in this increased mortality were the irradiated volume, radiation energy, fractionation (number and size of individual treatments), and total dose. Finally, a review of 2,232 Hodgkin's disease patients receiving mantel radiation reported the overall relative risk for cardiac death was 3.1 (confidence interval, 2.4 to 3.7). Mediastinal radiation of 30 Gy or less (n = 385 patients) did not increase risk; above 30 Gy (n = 1,830), relative risk was 3.5 (confidence interval, 2.7 to 4.3) (23). Interestingly, the relative risk decreased as the age at the time of treatment increased. The latency for these events in the population was as long as 5 years. The risk of secondary neoplasms because of radiation of a small volume of tissue appears to be exceedingly low.

The consequences of fibrosis at a localized coronary treatment site may be minimized in a stented vessel. Additional unexpected consequences of local radiation treatment to the coronary artery may include poor healing of localized dissection flaps, which normally seal well with time. Establishment of the late consequences of localized intravascular radiation may require collection of data on the initial patients undergoing these procedures for a period of greater than 5 years.

Preclinical Studies

A number of approaches to delivery of radiation to an arterial segment in the hope of preventing luminal compromise by neointimal tissue have been studied in various animal models. Broadly, these approaches can be categorized as external radiation source therapies, endovascular radiation delivery from a removable source (termed *brachytherapy*), or stent-based permanent radioisotope-coated stents. Intravascular radiation sources minimize the volume of tissue irradiated compared with external sources and should minimize the late complications due to unintended collateral irradiation of surrounding tissues.

Gamma radiation from an endovascular ^{192}I source was first shown to inhibit intimal hyperplasia because of mechanical injury to the aorta of rabbits in 1964 (13). With the advent of clinical percutaneous revascularization several decades later, the use of ionizing radiation in animal models of arterial injury was rediscovered (14,16,20,24,25). Subsequently, a number of investigators studied the efficacy of beta radiation, using a variety of isotopes (19,26). In addition to catheter-based radiation delivery, permanently implanted beta-emitting radioactive stents have been used as a platform to deliver vascular radiation (27,28,29 and 30). These systems apply beta (or potentially gamma) radiation locally from an endovascular source. Local radioisotope sources minimize the volume of tissue radiated. One of the guiding principles of radiation therapeutics is to minimize volume of irradiated tissue and dose to surrounding healthy tissue. It is noteworthy that the kinetics of radiation dose administration are far different in implanted stents, as compared with removable sources. In the latter, the entire dose is administered to the vessel wall in a maximum of 30 minutes, compared with the several-month time period for a phosphorus-32 (^{32}P)–coated stent. The relevant biologic parameter to consider is the time for DNA repair, and time to cell division relative to deposited dose. When a fixed dose of ionizing radiation is deposited with leisurely kinetics, the integrated dose is less effective in preventing cell division, compared with a dose delivered in a short time. Indeed, subsequent animal (31,32) and clinical (33,34) studies have borne out the more problematic nature of this sort of irradiation technique.

When a porcine coronary artery is subjected to a stretch injury by an oversized balloon, significant media and adventitia laceration may occur, leading to a proliferative neointimal response at the injury site that mimics the proliferative aspects of the response of a human coronary artery to balloon angioplasty. Between 15 and 20 Gy of gamma radiation delivered from an intracoronary ^{192}I source produced focal fibrosis of the media and markedly decreased neointima formation after overstretch balloon injury by approximately 75% in swine at both 30 days and 6 months (16,20,25,35). Similar results have been reported using endovascular beta-emitting sources, such as encapsulated yttrium-90 (^{90}Y) or strontium-90 (^{90}Sr)/^{90}Y (19,36) or rhenium-188 (^{188}Re) liquid-filled balloon sources (37,38). There was no evidence in any of these studies of perivascular, myocardial, or pericardial pathology. Further studies examining the dose-response relationship between endovascular gamma radiation and suppression of neointimal growth has shown that the minimal suppressive dose to the vessel wall lies between 1,000 and 1,500 cGy for gamma sources and approximately 18 Gy for beta sources (19,20,39).

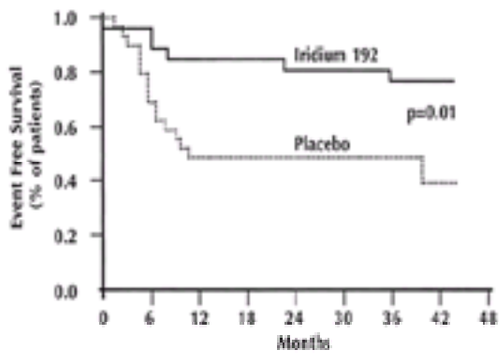
Late Effects

The administration of significant doses of therapeutic radiation has been associated with a vasculopathy, which affects vessels in the radiated region (40). In parenchymal organ radiation, the principal effect of radiation injury to blood vessels is at the level of the capillaries and arterioles. The effects on large arteries, such as the epicardial coronary arteries, analyzed in retrospective studies of patients who have received radiation for thoracic neoplasms, appear to be dose-related and inversely related to the age of the patient at the time of irradiation (23). The earliest evidence of coronary disease appears 5 years after radiation. These data are derived from studies of patients who have received fractionated doses of radiation and have had the entire heart in the radiated field. The long-term effects of single-dose (as opposed to fractionated dose) radiation of the magnitude suggested by the animal trials are not known. It is clear, however, that the risk of late complication, such as myocardial infarction or pericarditis, is related to the volume of radiated tissue (12). The late risk of radiation to the arterial wall is thus minimized when the volume of treated tissue is small, as with treatment by endovascular sources.

Clinical Studies

In-Stent Restenosis

The clinical utility of brachytherapy has been best studied for patients with in-stent restenosis, although some data exist for treatment of *de novo* lesions following native coronary angioplasty or stent placement. Animal studies initially suggested a prominent antiproliferative effect in irradiated arterial segments. Because in-stent restenosis is primarily a problem related to neointimal proliferation, with minimal vascular recoil or remodeling, the greatest benefit from radiation was hypothesized to occur in this patient population. A number of significant double-blind clinical trials using gamma sources [Scripps Coronary Radiation to Inhibit Proliferation Post Stenting (SCRIPPS) (41,42), Washington Radiation for In-Stent Restenosis Trial (WRIST) (43), GAMMA-1 (44)] and a beta source [Sr-90 Treatment of Angiographic Restenosis Trial (START) (45) and Intimal Hyperplasia Inhibition with Beta In-Stent Trial (INHIBIT)] have been reported to show striking efficacy in preventing restenosis for patients with established in-stent restenosis (Table 81.1). SCRIPPS 3-year follow-up, reported from the most recent SCRIPPS study (42), provides evidence for continued clinical benefit for at least 3 years (*e*Fig. 81.0.1).



***e*FIGURE 81.0.1** SCRIPPS study. Kaplan-Meier curves for event-free survival in iridium-192 (^{192}Ir) and placebo groups. Event-free survival was defined as survival without myocardial infarction or repeated revascularization of target lesion. Curves diverge at 3 months, and the difference increases over the next 7 months, after which clinical events are infrequent. (From Teirstein PS, Massullo V, Jani S, et al. Three-year clinical and angiographic follow-up after intracoronary radiation: results of a randomized clinical trial. *Circulation* 2000;101:360–365, with permission.)

Trial (reference)	Patient population	Source	No. of Patients	Binary restenosis rate (%)
Gamma sources

TABLE 81.1 SELECTED BRACHYTHERAPY TRIALS

The GAMMA-1 study represents the first large, placebo-controlled, multicenter study of gamma irradiation to treat in-stent restenosis with a maximum lesion length of 45 mm. The primary end point of this study, a composite of death, myocardial infarction, or the need for repeated revascularization of the target lesion during the 9-month follow-up, occurred in 43.8% of the placebo-treated patients compared with 28.2% of the radiated patients (p <.02). The entire benefit conferred by radiation was a diminished need to revascularize. This study underlined the problems of late stent thrombosis occurring when a stent was newly implanted in the freshly radiated arterial segment (*vide infra*). These late thrombotic events only occurred after discontinuation of either ticlopidine or clopidogrel antiplatelet therapy.

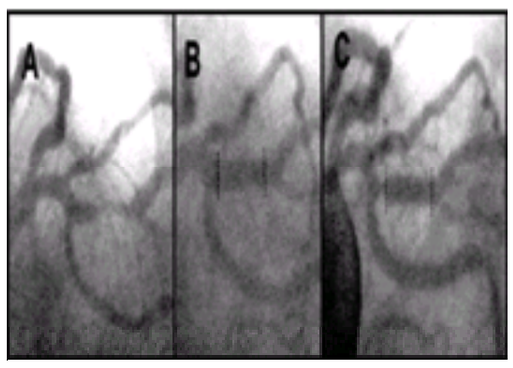
INHIBIT was a prospective, placebo-controlled, double-blind, multicenter study of 332 patients with in-stent restenosis and maximum lesion length of 47 mm, randomized to receive 20 Gy at 1 mm into the vessel wall, from a centered ^{32}P beta-emitting wire source at the time of percutaneous revascularization. The primary end point from which this study was powered was 9-month angiographic binary restenosis. There was a 33% reduction in the frequency of 9-month major adverse cardiac events (MACE), defined as death, Q-wave myocardial infarction, or target vessel revascularization, in the brachytherapy group (p <.037), due exclusively to a decrease in the rate of target vessel revascularization from 31% to 20%. There were three different antiplatelet regimens used during this trial, to minimize the concurrently appreciated risk of late thrombosis (*vide infra*).

Prolonged "Subacute" Thrombosis

Several concerns were raised by these and other early clinical trials. One predictable effect of intravascular radiation was impairment of the wound-healing response consequent to arterial injury. Indeed, intravascular ultrasound studies of coronary arteries that underwent balloon angioplasty had evidence of unhealed dissections at 6 months post–*de novo* balloon angioplasty (46). An important clinical correlate of the inhibition of the healing response is a prolongation of the course of the normal stent-healing process. Indeed, late (post–30 day) acute thromboses occurred in patients treated with brachytherapy plus either angioplasty or new stent implantation, when given standard 30-day ticlopidine/clopidogrel plus aspirin antithrombotic therapy (47). A pooled analysis of the gamma radiation trials—GAMMA-1, SCRIPPS, and WRIST—suggests a late thrombosis rate as high as 6%, particularly in patients in whom new stents were implanted in the radiated arterial segment. Preliminary evidence from trials using prolonged antiplatelet regimes (clopidogrel for greater than 3 months) suggests a marked reduction in this complication. However, it is notable that there are reports of late sudden stent thrombosis greater than 1 year after stent implantation (48), and alternative mechanisms, such as late positive vascular remodeling with stent dehiscence, may be responsible for these events.

Edge Effects

An additional problem noted first in studies of radioactive stent implants (34) (eFig. 81.0.2) is increased frequency of the occurrence of restenosis at one or both edges of the radiated field. Initially thought to be limited to radioactive stents, these events have now been seen with nonradioactive stents and with edge effects seen with removable-source brachytherapy treatments. There is significant speculation as to the cause of these observations or if these findings are even radiation related. We initially demonstrated a proliferative effect of low-dose radiation together with balloon coronary injury in a porcine model (39). Careful analysis has suggested that these edge effects may represent a "geographic miss" of radiation with regard to the zone of instrumented coronary artery (49). Alternatively, plaque shifting may account for the appearance of "new" lesions at the edge of the instrumented segment (50). A multicenter dose-finding study using ^{90}Y, a beta emitter, in which compulsive attention was directed to minimizing geometric miss, reported both a low incidence of core angiography laboratory detection of this technical problem and a notable lack of edge effects (51), together with late loss index of only 0.04 in balloon-treated *de novo* lesions. Typical late-loss indices for balloon-treated arteries are 0.50 to 0.60, depending on the prevalence of diabetics in the study. This suggests that geographic miss and the consequent propensity for edge effects may be significantly abated with careful attention to registering adequate doses of radiation throughout the instrumented segment of the coronary artery. It is important to note that the instrumented segment of the vessel is almost always significantly larger than the initially defined target lesion.



***e*FIGURE 81.0.2** Proximal edge restenosis 6 months after implantation of a radioactive stent. Baseline angiography **(A)** demonstrates a tight stenosis in the proximal obtuse marginal branch. **(B)** Final result after implantation of a 20-µCi radioactive stent. At 6-month follow-up **(C)**, there is no late loss inside the stent, but a tight stenosis exists at the proximal edge of the stent. [From Albiero R, Nishida T, Adamian M, et al. Edge restenosis after implantation of high activity (32)P radioactive beta-emitting stents. *Circulation* 2000;101:2454–2457, with permission.]

De Novo Lesions

Evidence for efficacy of brachytherapy in *de novo* lesions is less compelling and rests on small open-label groups of patients. A large, international, multicenter, double-blind, placebo-controlled trial using Sr/^{90}Y beta sources together with angioplasty to treat *de novo* coronary stenoses (Beta-Cardiac Cath) is scheduled to be reported later in 2001. The future investigation of brachytherapy clearly lies in defining high-risk subsets, such as long lesions, small-caliber reference vessels, diabetics, or chronic occlusions, which might benefit from *de novo* brachytherapy at the time of initial revascularization.

Durability of Restenosis Benefit

Radiation biologists have noted that the expected durability of the restenosis inhibition effects engendered by radiation depends on the proliferative capacity of the residual cells capable of producing the restenotic mass. In fact, theoretical studies have suggested that at the doses used currently, a recurrence of restenosis might be expected to occur at approximately 3 years. There is still a relative paucity of data regarding the durability of the brachytherapy. It is noteworthy that even after 18 months after gamma radiation, Teirstein and colleagues (42) report continued MACE events in the radiated group. In the radioactive stent population, these stents appear to simply delay rather than permanently inhibit restenosis. The ultimate value of this therapy will depend on long-term outcome studies.

Beta versus Gamma Radiation Sources

Substantial differences in handling and dwell times are required for these two classes of sources. Based on physical considerations, beta sources are more easily shielded, deposit a greater fraction of their emitted energy locally, and provide less collateral dose to nontarget tissues than do gamma sources. Because the efficiency of beta energy deposition is greater than comparable gamma sources, the intraarterial dwell time for a brachytherapy treatment for beta sources is generally substantially shorter than for available gamma sources. Because of the steep slope of their energy fall-off curve, beta-emitting isotopes obligate larger luminal and endothelial cell doses than do beta sources. The majority of the large clinical studies to date has reported on the efficacy of ^{192}I, a gamma emitter. More recently, two multicenter studies using beta sources to treat in-stent restenosis [Sr-90 Treatment of Angiographic Restenosis Trial (Sr/^{90}Y) and INHIBIT (P32)], have been announced (Table 81.1). Both studies featured significant reduction of restenosis rates and clinical event rates. The disparity between the clinical evidence for the two sorts of systems appears to be narrowing; however, no direct head-to-head clinical trial has been performed.

Delivery Systems

Currently, three systems have European CE (Conformité Européene) marks, and two of these systems have received marketing approval in the United States by the Food and Drug Administration. The Cordis Checkmate System is based on a ribbon source containing encapsulated ^{192}I gamma sources delivered via a manually operated afterloader device, which deposits the sources in a dedicated, noncentered catheter. Additional shielding is placed around the patient during the dwell time, and typically all personnel leave the room to minimize exposure to the source. Typical dwell times are 15 to 30 minutes per site treated. A variety of source train lengths are available, minimizing the necessity for stepped application. The Novoste Beta-Cath Catheterization Laboratory System is based on small canisters containing Sr/^{90}Y, which are delivered hydraulically down a dedicated, noncentered catheter. A single source length is currently available, allowing treatment of a 20 mm long arterial segment. The Guidant Galileo System, available for routine clinical use only in Europe, is based on an 0.018-in. ^{32}P beta-emitting source wire that is delivered to a dedicated spiral perfusion balloon using an automated remote afterloader. The latter two systems have typical dwell times of less than 5 minutes per treatment site. In the United States, the only currently approved indication for coronary brachytherapy is for the treatment of in-stent restenosis. Treatment of an adjacent site in the artery to ensure adequate margins of therapy by moving the source to another site and a second brachytherapy treatment are not approved.

Stent-Based Beta Implants

Despite initially exciting animal studies using beta isotope–impregnated stents (29,52), clinical trials have been decidedly disappointing. Initial studies were troubled by inadequate doses to prevent restenosis (53). As the activity on the stents increased, the absorbed radiation dose effectively prevented in-stent restenosis, but did not ameliorate the problem of edge restenosis (34). Finally, advocates of radioactive stents suggest a number of variations intended to minimize the edge effects seen. Final reports of the value of “hot end” stents, “cold end” stents, and radioactive stents deployed with attention to minimizing edge barotraumas are still awaited. A report of 1-year follow-up of moderate activity ^{32}P stents (6 to 12 µCi) by a combination of quantitative coronary angiography and integrated electrocardiographic-gated IVUS revealed delayed, rather than inhibited, neointimal proliferation. Indeed, 35% of the patients had had clinical events by 1-year follow-up (54). The latter suggests that these variations in stent dosimetry and implantation techniques are unlikely to provide long-term inhibition of restenosis using these devices.

Controversies and Personal Perspectives

Coronary brachytherapy is at the early stages of clinical adoption as a significant treatment modality for in-stent restenosis. Significant improvements in intermediate-term clinical event rates and secondary restenosis rates have been demonstrated using a variety of radiation sources and radiation delivery systems. The role of brachytherapy for preventing restenosis when *de novo* lesions undergo percutaneous revascularization remains to be defined. It is likely that certain anatomic and clinical subgroups (e.g., long lesions, small-diameter vessels, diabetics, and possibly vein graft lesions) might benefit from primary brachytherapy treatment at the time of initial intervention. The duration of antiplatelet therapy remains a controversial question. The most feared complication of coronary brachytherapy is “delayed subacute thrombosis,” which has occurred as late as 18 months after treatment. Clarification of an optimal duration and regimen of antiplatelet therapy becomes even more critical as stents are implanted into newly radiated segments of coronary arteries. Finally, the utility of brachytherapy relative to newly evolving technologies, such as drug-eluting stents (55) and alternative energy therapies (e.g., sonotherapy), will be closely scrutinized in the ensuing several years.

EMBOLI PROTECTION

Microembolization has traditionally been regarded as a relatively infrequent contributor to the major complications of percutaneous arterial revascularization or coronary acute ischemic syndromes. Although limited autopsy series demonstrate embolization of plaque and thrombotic material into the microcirculation of some patients with unstable angina or myocardial infarction who die suddenly (56), it is occlusion of the epicardial vessel that has been thought to be the important culprit leading to myocardial ischemia and infarction. Similarly, angiographically apparent distal embolization during coronary balloon or device intervention is uncommonly observed (typically in less than 2% of cases) and is usually confined to procedures performed in degenerated bypass grafts or in the presence of intraluminal thrombus, suggesting that abrupt closure of the target epicardial coronary vessel is the most frequent cause of periprocedural myocardial necrosis. In the cerebrovascular and peripheral circulations, however, emboli play a more conspicuous role in the pathogenesis of spontaneous stroke and systemic arterial ischemic events. The availability of new imaging techniques that allow demonstration of microembolization in living patients, such as myocardial contrast echocardiography, transcranial Doppler, and magnetic resonance imaging, has enhanced our appreciation of the frequency and importance of microvascular obstruction in arterial disease states and revascularization procedures. With this understanding has come the recognition that some of the clinical benefit derived from pharmacologic agents intended to treat the epicardial atherosclerotic plaque may in fact be related to suppression of distal embolization. Most recently, devices have been specifically designed to protect the microvasculature from embolization during revascularization procedures.

Pathophysiology

Erosion or rupture of the atherosclerotic plaque, occurring spontaneously in the acute ischemic syndromes or induced by percutaneous revascularization devices, exposes thrombogenic lipid and subendothelial matrix, resulting in platelet aggregation and initiation of the coagulation cascade. A growing thrombotic mass may lead to partial or complete thrombotic arterial occlusion and end-organ ischemia or infarction. Beyond the effects of *in situ* epicardial vessel thrombosis, distal embolization of plaque and thrombotic material may also occur, producing microvascular obstruction and patchy infarction. The mechanical obstruction caused by the embolized plaque and thrombus appears to be amplified by associated inflammation, which further contributes to endothelial dysfunction, microvascular spasm, impaired tissue perfusion, and end-organ necrosis. In the coronary vasculature, distal embolization may be a frequent cause of observed elevations in circulating levels of myocardial creatine kinase or troponin, which have been correlated with adverse clinical outcome during acute ischemic syndromes or after angioplasty. Interestingly, left ventricular dysfunction occurring as a result of distal embolization seems to be out of proportion to the quantity of infarcted myocardium, suggesting a particular “mechanical disadvantage from multiple microinfarcts with multiple border zones” (57). Moreover, microinfarctions may predispose to late ventricular arrhythmias and sudden cardiac death.

Clinical Evidence

Microembolization may be a relatively frequent event among patients with acute coronary ischemic syndromes or after percutaneous coronary intervention. In a series of 32 patients dying within 3 weeks of undergoing balloon angioplasty or receiving thrombolytic therapy for acute myocardial infarction, thrombotic or atheromatous emboli were observed on autopsy in 26 (81%) (58). Without the pathologic confirmation afforded by postmortem examination, however, the occurrence of

microembolization in clinical practice can only be inferred from surrogate measurements, and the frequency and consequences of this event are likely underappreciated.

“Reperfusion” therapy for acute ST-elevation myocardial infarction is directed at restoration of infarct vessel patency, based on the paradigm that recanalization of the epicardial artery translates into improved tissue-level perfusion. A dissociation may exist, however, between epicardial artery patency and the quality of myocardial reperfusion. In a pioneering study, Ito and associates (59) described 39 patients with anterior myocardial infarction in whom myocardial contrast echocardiography demonstrated absence of tissue-level reflow in 23%, despite restoration of infarct artery patency; patients without microcirculatory reflow had significantly less recovery of left ventricular function than those in whom myocardial perfusion had been achieved. Subsequent series using contrast echocardiography (60) or magnetic resonance imaging (61) confirmed the absence of microcirculatory reflow in 25% to 37% of patients following coronary recanalization, a finding that was correlated with larger infarct size, adverse remodeling, and more frequent cardiovascular complications. More recently, Gibson and colleagues have established an angiographic index of quality of myocardial reperfusion, demonstrating that mortality is lowest among patients with normalization of both epicardial artery and tissue-level blood flow following fibrinolytic therapy for acute myocardial infarction (62). Similarly, among patients undergoing primary angioplasty or stenting for acute infarction, inadequate myocardial reperfusion despite restoration of infarct vessel patency has been associated with substantially diminished mortality benefit (63). The dissociation between epicardial and microcirculatory reperfusion may in part explain why long-term mortality with primary stenting has tended to be higher than with balloon angioplasty, despite the consistent reduction in restenosis achieved with stents (64).

Embolization, visualized angiographically as a new filling defect or “cutoff” in a distal vessel, has been reported to complicate 1% to 2% of percutaneous coronary revascularization procedures. Additionally, however, “slow-reflow” or “no-reflow” phenomena may also occur in 6% or more of patients undergoing coronary intervention, characterized by profound reduction in epicardial anterograde coronary flow without evidence of vessel dissection, thrombosis, or embolization (65,66). This angiographic observation likely represents diffuse embolization and obstruction of the distal microvasculature and appears to be most frequent with revascularization of saphenous vein grafts, during acute coronary syndromes, in the presence of coronary thrombus, or with ablative device technologies (66,67 and 68). Using sensitive techniques such as technetium-99m sestamibi scintigraphy, regional myocardial hypoperfusion has been observed in as many as 87% of patients undergoing rotational atherectomy (69). The no-reflow phenomenon has been consistently associated with an increased risk for periprocedural death or myocardial infarction (66,68).

Assessment of postprocedural myocardial enzyme release (creatine kinase MB fraction or troponin) provides further insight into the prevalence of microembolization during coronary revascularization. In published reports in which enzyme determinations were made according to a systematic schedule in all patients, postprocedural rates of myocardial infarction have typically been in the range of 8% to 12% (70,71,72 and 73). Yet only a minority of these enzyme elevations can be attributed to recognized complications during the angioplasty procedure, such as target vessel or side branch closure; consequently, reported infarction rates are only 2% to 5% in studies in which enzymes were measured only in patients suspected of having an event (74,75,76 and 77). Distal microembolization represents the likely cause of many of the “silent” or unsuspected myocardial infarctions following coronary intervention. These events are clinically important in that a number of studies have demonstrated that patients who experience myocardial infarctions during and after coronary intervention are at significantly greater risk for late cardiac death than those who do not (78,79,80,81,82 and 83).

Balloon angioplasty and stenting of extracranial carotid stenoses appear to provide long-term results similar to those of surgical endarterectomy with regard to patency and stroke prevention (84). An important potential limitation of this technique, however, is dislodgement and embolization of atherosclerotic and thrombotic fragments from the carotid plaque, which may be associated with transient or permanent neurologic sequelae. Embolic load during percutaneous carotid revascularization appears to be greater than with endarterectomy (85). Plaque fragments in experimental models range in size as large as 1 mm in greatest dimension, with evidence of neuronal ischemia following embolization to the brain of particles as small as 200 µm (86). During percutaneous carotid revascularization procedures in humans, embolization of particulate material can be documented by transcranial Doppler in virtually all patients, with the maximum number of emboli signals occurring during stent deployment and balloon inflation (87).

The most compelling evidence for the ubiquitous nature of arterial microembolization during percutaneous revascularization derives from the clinical experience using distal emboli protection devices (see Mechanical Approaches to Embolization, later in this chapter). Aspirated blood or filter contents from these devices demonstrate the presence of grossly visible or microscopic embolic material in the majority of cases following stenting of carotid arteries, saphenous vein grafts, and even native coronary vessels (88). Examination of retrieved debris reveals atherosclerotic, thrombotic, and calcific particles, ranging in size as large as 2 mm or more.

Pharmacologic Approaches to Embolization

Pharmacologic approaches to prevent or treat embolization have focused primarily on vasodilators or antithrombotic agents. Vasodilators are intended to enhance clearance of microparticulate debris from the vasculature or counteract the adverse effect of vasoconstrictive mediators released from upstream plaque. Antithrombotic agents are used to enhance endogenous dissolution of thrombotic emboli, as well as to prevent amplification of the cascade of platelet activation and thrombus formation in the microvasculature. Clinical results with potent antiplatelet agents appear to be particularly promising.

Observational series have suggested that intracoronary administration of nitroglycerin or verapamil may improve distal coronary flow in many patients who experience the no-reflow state during coronary intervention (65). However, a report of 136 patients with no reflow did not show an influence of verapamil or sodium nitroprusside on death or myocardial infarction (68). In a randomized trial of 40 patients undergoing primary percutaneous intervention for acute myocardial infarction, intracoronary administration of verapamil was associated with immediate improvement in microvascular perfusion as assessed by myocardial contrast echocardiography and better recovery of left ventricular regional wall motion (89).

Adenosine exerts a protective effect during myocardial ischemia and infarction through multiple potential mechanisms. Improvements in microcirculatory flow may occur by direct vasodilation due to activation of A_2-receptors on endothelial and vascular smooth muscle cells, by prevention of neutrophil adherence and superoxide release, or by inhibition of platelet aggregation (90). In a small randomized trial of 54 patients undergoing primary angioplasty for acute myocardial infarction, administration of intracoronary adenosine was associated with improvements in coronary flow, better recovery of infarct zone regional wall motion, and lower rates of death compared with placebo (91). Similarly, patients receiving intravenous adenosine during fibrinolytic therapy for anterior myocardial infarction in a pilot study showed evidence of reduction in infarct size (92). Efficacy of adenosine in this setting has not yet been confirmed in large-scale randomized trials.

There are substantial data to suggest that part of the clinical benefit derived from intravenous platelet glycoprotein IIb/IIIa inhibitors may be through improvements in microvascular perfusion. Several randomized placebo-controlled trials have demonstrated unequivocally that administration of these agents during and after coronary intervention reduces the risk of death, myocardial infarction, or emergency repeat revascularization over 30 days by as much as 50% (93). The predominant adverse event prevented by this therapy is periprocedural myocardial infarction; as discussed previously, these infarctions are usually not associated with recognized complications in the epicardial artery but may often be due instead to microembolization.

The antiembolic effect of glycoprotein IIb/IIIa inhibitors seems particularly evident in high-risk settings and with device technologies for coronary intervention. For example, abciximab neutralized the threefold excess risk for non–Q-wave myocardial infarction seen with directional coronary atherectomy relative to balloon angioplasty in one trial (94). During saphenous vein graft interventions using transluminal extraction atherectomy (95) or other techniques (96), rates of angiographically apparent embolization were reduced from 21% to 30% with conventional therapy to 0% to 3% with abciximab.

The most compelling evidence for an effect of glycoprotein IIb/IIIa blockade on microembolization is derived from studies using imaging techniques or end points that directly assess the quality of myocardial perfusion. During rotational atherectomy, regional myocardial hypoperfusion representing diffuse microembolization was detected by Tc-99m sestamibi scintigraphy in only 33% versus 87% of patients who did or did not receive adjunctive abciximab, respectively (69). In an important mechanistic study, Neumann and colleagues randomized 200 patients with acute myocardial infarction to abciximab or conventional therapy during stenting. Despite restoration of normal epicardial artery flow by stenting in virtually all patients in both treatment groups, patients who had received abciximab had improved tissue-level perfusion as measured by Doppler peak flow velocity in the infarct-related artery or improvements in regional and global left ventricular function (97). Similarly, improvements in myocardial perfusion and coronary flow reserve have been observed during elective stenting with the glycoprotein IIb/IIIa antagonist eptifibatide (97a). Outside of the setting of percutaneous revascularization, abciximab appears to improve myocardial reperfusion during fibrinolytic therapy for acute myocardial infarction. Among a subgroup of patients who had achieved normal epicardial artery flow 90 minutes after administration of various combinations of tissue-type plasminogen activator and abciximab in a dose-ranging study, treatment with abciximab plus half-dose tissue-type plasminogen activator was associated with a substantially higher rate of complete ST-segment resolution than was tissue-type plasminogen activator alone (69% vs. 44%, respectively, $p = .0004$) (98).

Mechanical Approaches to Embolization

Although antiplatelet therapy may reduce embolization of thrombotic debris and ongoing platelet aggregation in the distal vasculature, these agents would not be expected to diminish the release of atherosclerotic and matrix material into the microcirculation. Mechanical approaches for preventing embolization were first applied to percutaneous revascularization of the carotid arteries. In 1987, Theron and colleagues described six patients in whom temporary occlusion of the internal carotid artery with a balloon catheter was used to prevent cerebral embolization during angioplasty (99). Technological advances have allowed development of low-profile

catheters or wires that can safely access the distal vasculature and retrieve embolic debris. These devices are under clinical evaluation in the carotid and peripheral circulation for revascularization of diseased saphenous vein grafts and most recently in native coronary arteries. At the time of this writing, only the PercuSurge system is approved for clinical use in the United States.

There are two major categories of emboli protection devices. Occlusion catheters employ a compliant balloon that is inflated distal or (less commonly) proximal to the site of revascularization to arrest blood flow in the treated artery. Embolic material is aspirated or flushed to a branch vessel (typically the external carotid) before the balloon is deflated and blood flow restored. Filter devices are delivered distal to the atherosclerotic lesion on a guidewire to capture emboli produced by manipulation of the plaque. Advantages of the balloon occlusion approach include the potential to capture nearly all embolic particles, regardless of size; disadvantages stem from the obligate arrest of blood flow, with resultant end-organ ischemia, unpredictable patient tolerance, and the need to perform a hasty procedure with suboptimal angiographic visualization of the revascularization site. The principal strength of filter technique is preserved blood flow, permitting longer procedures to be performed with less distal ischemia and ongoing angiographic visualization of the target lesion; disadvantages include the inability of a filter to capture particles smaller than the pore size, as well as generally larger crossing profiles.

The antiemboli device for which there is currently the most clinical experience is the occlusive PercuSurge Guardwire Balloon Protection System (Medtronic MVE, Minneapolis, MN). It consists of a hollow guidewire with its lumen connected to a compliant distal occlusion balloon and a separate aspiration catheter. The distal balloon is inflated 2 to 10 cm beyond the lesion, occluding the vessel lumen, after which standard angioplasty balloons or stents are delivered to the stenosis over the wire. The interventional procedure is performed and catheters are exchanged for the aspiration catheter, through which suction is applied to remove loose embolic material trapped behind the occlusion balloon. The occlusion balloon is then deflated and the wire removed.

In an initial feasibility report, no embolic events or ischemic complications occurred during stenting of degenerated saphenous vein grafts in 15 patients using the Guardwire Balloon Protection System (100). During the subsequent multicenter phase II registry experience of 106 patients treated for vein graft stenosis, the in-hospital MACE rate of 4.9% was approximately 70% lower than for historic controls. The efficacy of this device for saphenous vein graft interventions was convincingly demonstrated in a randomized controlled trial of 555 patients. The PercuSurge system was successfully deployed in 93% of cases; rates of in-hospital MACE were reduced from 17.3% to 8.8% (p = .001), myocardial infarction from 16.5% to 8.4%, and no-reflow from 8.0% to 3.4% (99a). Preliminary experience with this device during stenting of native coronary vessels for acute myocardial infarction produced similarly favorable results: Normal myocardial perfusion was achieved in 55% of patients, compared with only 19% to 28% of patients who had undergone stenting for acute infarction without emboli protection in previous trials (101). The Guardwire system has also been used successfully in several pilot studies of carotid stenting, with recovery of particulate material ranging in size from 50.0 µm to 1.6 mm. Approximately 5% of patients were intolerant of the occlusion balloon, however, developing transient neurologic symptoms immediately or at some point during the procedure. The number of embolic signals on transcranial Doppler was reduced by 65% to 80% as compared with unprotected carotid stenting, and rates of neurologic complications (stroke or transient ischemic attack) compared favorably with historic controls.

The Parodi Anti-Emboli System (ACT/DBI, Santa Clara, CA) uses an alternative approach to occlusive emboli protection, that of proximal balloon occlusion and passive flow reversal. It consists of a double-lumen guide catheter with a balloon at its tip; once the balloon is inflated in the common carotid artery proximal to a stenosis, flow reversal is achieved by creating a temporary artery-to-vein shunt through the lumen of the catheter connected to a sheath in the femoral vein. The stent procedure is then performed via the main lumen of the guide catheter, with embolic particles captured by a filter in the artery-to-vein connection. A favorable preliminary clinical experience has been reported (102).

A variety of filter designs are under clinical evaluation for carotid, native coronary, and vein graft interventions. Examples of “supported” filters are the Angioguard (Cordis J&J, Warren, NJ) and the TRAP (Microvena, White Bear Lake, MN), while “unsupported” designs include the EPI Filter Wire (Embolic Protection Inc., Campbell, CA). The Angioguard consists of a standard-diameter (0.014-in.) guidewire with a flexible nitinol basket covered distally with a polyurethane filter (pore size 100 µm). It is expanded distal to the stenosis by removal of a delivery sheath (1.2- to 1.5-mm diameter), then closed and removed following the interventional procedure. Early clinical experience has shown that the Angioguard can be safely tracked beyond coronary, vein graft, and carotid lesion sites, with recovery of particles as large as 2 mm (88); distal blood flow is usually maintained, although abundant embolic material may occlude the filter. The TRAP is a braided mesh, double-layered, nitinol basket mounted on a 0.014-in. guidewire. It is delivered within a 1.2-mm diameter sheath, which is withdrawn to deploy the basket beyond the stenosis. Retrieval is accomplished with a specialized sheath that employs a nitinol mesh funnel to capture the basket and prevent release of embolic debris. During the first clinical experience with this device during vein graft stenting, particles ranging in size from 10 µm to 3 mm were retrieved (103). The EPI Filter Wire is a 0.014-in. guidewire incorporating an oval nitinol wire loop supporting a polyethylene membrane (pore size 80 µm). It is deployed by withdrawal of a 1.2-mm diameter overlying sheath, but can be withdrawn into the central lumen of a standard balloon angioplasty catheter for removal. This device has undergone favorable preliminary evaluation during native coronary, vein graft, and carotid interventions (104).

Controversies and Personal Perspectives

It remains unclear in which settings emboli protection will provide the most clinical benefit. It seems likely that there will be an unequivocal indication for these techniques in the setting of carotid artery stenting, in which the consequences of distal embolization to the brain can be most catastrophic. For myocardial revascularization, certain high-risk settings are also likely to mandate an antiembolic approach. Degenerated saphenous vein grafts or thrombotic native coronary lesions have proven to be particularly difficult problems from the standpoint of embolization during percutaneous revascularization, with only marginal progress achieved with a variety of ablative devices or pharmacologic therapies. For routine percutaneous revascularization of native coronary stenoses, however, the indications for antiembolic devices will be less straightforward. Certainly, embolic debris seems to be a ubiquitous consequence of coronary intervention, even in “simple” native lesions, but the magnitude of risk for clinical consequences from such embolization remains incompletely defined, particularly relative to the potential risk of complications associated with the antiemboli devices.

What is the best approach to antiembolic therapy? There are compelling clinical data that glycoprotein IIb/IIIa inhibitors are indicated in all patients undergoing coronary intervention, but will the availability of distal protection devices render pharmacologic therapy unnecessary in many cases? I suspect this will not be so, as potent antithrombotic agents also affect other mechanisms leading to periprocedural complications as well as provide sustained suppression of embolization after a protection device has been removed. Thus, a combination of both pharmacologic and mechanical approaches will likely prove most beneficial. Which type of device, occlusion versus filter, will be the most efficacious? Although occlusion balloons may capture smaller particles, I anticipate that filters will gain more widespread acceptance due to better patient tolerance and stenosis visualization.

THERAPEUTIC ANGIOGENESIS

Despite the advances in percutaneous and surgical revascularization methods, a limited number of patients have severe ischemia but are poor candidates for conventional revascularization (105). Few options are available for these patients using conventional approaches, and the disability resulting from severe limiting angina is substantial. One potential strategy for “no options” patients is creation of new blood vessel channels in the region of ischemia or therapeutic angiogenesis.

New blood vessel growth may occur as a result of vasculogenesis, arteriogenesis, or angiogenesis (106). Although vasculogenesis is the process responsible for the growth of new blood vessels during embryonic development, its role in the formation of new blood vessels in adults is not known (106). Arteriogenesis involves the formation of new blood vessels that have a fully developed tunica media and may be manifest by the development of new collateral branches in patients with peripheral vascular disease (106). Angiogenesis relates to the development of a new blood vessel that lack a tunica media, such as capillary formation in wound healing (106). It is highly likely that neorevascularization that will benefit patients with no options results from arteriogenesis, and to a lesser extent, angiogenesis. Although the precise stimuli for therapeutic angiogenesis is not known, it likely relates to the combination of chronic ischemia and inflammation and propagation of a cascade of events that induce proliferative, chemotactic, and inflammatory factors (106).

Mechanical Approaches

Both surgical and percutaneous approaches have been used to improve regional blood flow to the ischemic myocardium by injuring the myocardium using laser energy, radiofrequency ablation, or direct myocardial injections. Each of these approaches has substantial differences with respect to the depth of myocardial injury, the laser–tissue interactions, the presence or absence of guidance, and the number of channels created. These differences may have a profound effect on the results of clinical studies in patients with refractory CAD.

Mechanism of Benefit

Three mechanisms of clinical benefit of transmyocardial revascularization (TMR) have been proposed. The first relates to the creation of channels within the myocardium to enhance blood flow into the ischemic area, although pathologic studies have demonstrated that these channels close soon after their creation (107,108,109 and 110). A second potential explanation relates to denervation of cardiac nerve fibers that cause angina (111,112). This mechanism may explain why some patients experience immediate relief after myocardial revascularization. The most likely mechanism of benefit of myocardial revascularization relates to the

stimulation of neorevascularization that improves blood supply to the ischemic myocardium (113,114).

Surgical Transmyocardial Revascularization

TMR by the creation of transmural left ventricular conduits using CO_2 laser was first reported in 12 patients with refractory angina in 1988 (115). Since then, over 3,000 patients have been treated with TMR using the CO_2 laser (116,117) or holmium:yttrium-aluminum-garnet (YAG) laser (118,119). Registry series demonstrated a marked improvement in Canadian Cardiovascular Society (CCS) angina class in these patients (116,117 and 118) and late clinical benefits after TMR has been sustained up to 5 years. One series of 78 patients treated with the CO_2 laser reported a greater than two CCS class improvement in angina status in 68% of patients 5 years after the procedure, and 17% of patients had no angina (120). Some series have also demonstrated improvements in myocardial perfusion as assessed by thallium scintigraphy (121,122) and positron emission tomographic scanning (116). The effect on left ventricular function has been variable (123,124).

Early series of TMR were associated with 5% to 9% perioperative mortality (125); overall morbidity was also high, with a 19% incidence of myocardial infarction, 52% incidence of cardiac ischemia, and a 35% incidence of noncardiac morbidity (126). Patients with adequate myocardial supply to at least one region of the heart through a native coronary artery or patent bypass graft have markedly reduced perioperative mortality (127). Patients with severe, refractory unstable angina also have a high mortality (128). More recent mortality with appropriate patient selection of patients undergoing TMR ranges from 1% to 2% (128).

Four randomized trials have been performed in patients with refractory angina randomly assigned to TMR or continued medical therapy (117,118) (eTable 81.1.1). The first of these studies randomly assigned 200 patients with CCS class III or IV angina that was refractory to medical therapy to treatment with TMR with a CO_2 laser (Heart Laser, PLC Medical Systems, Franklin, MA) or to continued medical therapy (117). In patients assigned to TMR, transmural channels approximately 1 mm in diameter were created with a single pulse of the CO_2 laser (peak power, 850 W) through the left ventricle (117). One channel was created per square centimeter of myocardial surface, resulting in approximately 36 channels per patient (117). Angina had improved by at least two CCS classes in 72% of patients assigned to TMR compared with 13% in those assigned to medical therapy at 12-month follow-up (p <.001) (117). Myocardial perfusion improved by 20% in the TMR group but worsened by 27% in patients treated with conventional therapy (p = .002) (117). The perioperative mortality was 3% with TMR, but survival was not different in the two groups at follow-up (117).

***e*TABLE 81.1.1** RANDOMIZED TRIALS USING TRANSMYOCARDIAL REVASCULARIZATION FOR MEDICALLY REFRACTORY ANGINA

Author	Laser system	No. of patients	Design	No. of channels	End point	Results
Schofield et al. (129)	PLC Medical System CO_2 laser	188	Single-center RCT	30	Mean treadmill exercise time at 3, 6, and 12 mo	Mean exercise time was 40 sec longer in the TMR group than medical management group (p = .152). Mean 12-min walk distance was 33 m longer in the TMR group than medical management group (p = .108). CCS score decreased by two classes in 25% of TMR patients compared with 4% in medical management patients (p <.001).
Burkhoff et al. (124)	CardioGenesis holmium:YAG laser	182	Multicenter RCT	18	Angina status	At 12 mo, total exercise tolerance increased by 65 sec in the TMR group and decreased by 46 sec in the medication-only group (p <.001). CCS score decreased by two classes in 48% of TMR patients and 14% in the medical only group (p <.001). All quality-of-life scores were improved in patients with TMR.
Frazier et al. (117)	PLC Medical System CO_2 laser	192	Multicenter RCT	36	Angina status	At 12 mo, CCS score decreased by two classes in 72% of patients assigned to TMR and 13% in those assigned to medical therapy (p <.001). Patients treated with TMR had a significant improvement in quality of life. Myocardial perfusion increased by 20% in patients treated with TMR and worsened by 27% in patients treated with medical therapy (p <.001). At 12 mo, 2% of patients assigned to TMR were hospitalized because of unstable angina compared with 69% of patients treated with medical therapy (p <.001).
Allen et al. (118)	Eclipse Surgical pulsed holmium laser	275	Multicenter RCT	39	Angina status	At 12 mo, CCS score decreased by two classes in 76% of patients assigned to TMR and 32% of those assigned to medical therapy (p <.001). At 12 mo, 54% of patients assigned to TMR were free of cardiac events compared with 31% of those assigned to medical therapy (p <.001). Exercise tolerance and quality-of-life scores were also higher in patients assigned to TMR.

CCS, Canadian Cardiovascular Society; RCT, randomized controlled trial; TMR, transmyocardial revascularization; YAG, yttrium-aluminum-garnet.

The second randomized trial of TMR assigned 275 patients with CCS class IV angina that was not amenable to surgical or percutaneous revascularization to TMR or to continued medical therapy (118). TMR was performed using a 20-W pulsed holmium laser (Eclipse Surgical Technologies, Sunnyvale, CA). The laser was calibrated to deliver 6 to 8 W per pulse, and the energy was delivered at a rate of 5 pulses per second. Channels were placed every square centimeter, and an average of 39 channels was created per patient. An improvement in two CCS angina classes was found in 76% of patients receiving TMR compared with 32% of patients assigned to continued medical therapy at 1-year follow-up (p <.001) (118). Patients treated with TMR also had a higher rates of freedom from late cardiac events (54% compared with 31% in medically treated patients; p <.001) and cardiac-related hospitalization (61% vs. 33% in medically treated patients; p <.001) (118). Exercise tolerance and quality-of-life scores were also better in patients treated with TMR. The perioperative mortality was 5%. There were no differences in myocardial perfusion or overall survival in the two groups (118). Two additional randomized trials demonstrated similar findings (124,129).

In aggregate, these studies demonstrate a dramatic improvement in symptoms resulting from TMR in patients with medically refractory angina. In some cases, the improvement in symptoms was associated with documented improvements in myocardial perfusion in the regions treated with TMR. The high (1% to 9%) periprocedural mortality seen in some of these studies appears to be lower in those patients who have adequate myocardial perfusion through a native coronary or arterial or venous conduit to one myocardial zone or in those patients with stable angina.

A limited number of studies has evaluated the incremental benefit of TMR performed in conjunction with conventional coronary artery bypass grafting (CABG) in patients with suboptimal surgical anatomy. Preliminary reports suggested that perioperative and late mortality and the need for postoperative left ventricular support were reduced using the combined approach (130,131). A synergistic angiogenic effect of TMR and administration of vascular endothelial growth factor (VEGF) was reported in one preclinical study (132). Whether this effect can also be demonstrated in patients with refractory CAD is the subject of ongoing study.

Percutaneous Methods of Myocardial Revascularization

Percutaneous approaches to myocardial revascularization have been developed, varying by the laser source, delivery catheter types, and use of guidance to direct placement of the laser channels (eTable 81.1.2). These methods are less invasive, can be performed from the femoral access, and have a lower periprocedural mortality than surgical approaches to myocardial revascularization. In contrast to the full-thickness myocardial channel produced with TMR, percutaneous myocardial revascularization results in partial-thickness myocardial channels, generally ranging from 3 to 5 mm in depth. Three percutaneous myocardial revascularization systems have been evaluated.

***e*TABLE 81.1.2** STUDIES USING PERCUTANEOUS MYOCARDIAL REVASCULARIZATION FOR MEDICALLY REFRACTORY ANGINA

Author	Laser source	Manufacturer	No. of patients	Study design	No. of channels	Results
Shawl et al. (133)	Holmium:YAG	Eclipse (PTMR)	27	Phase I registry	17	Mean CCS functional class decreased from 3.6 at baseline to 0.65 at 30 d (p <.01) and 0.94 at 6-mo clinical follow-up.
Whitlow et al. (134)	Holmium:YAG	Eclipse (PTMR)	335	Randomized, unblinded	19	A significant improvement in angina status and exercise time was found in those patients treated with PTMR compared with medical therapy (p = .001). An improvement in angina by two or more classes was achieved in 35% of patients treated with PTMR compared with 15% in those treated with conventional medical therapy. There was one death and five (3%) cases of cardiac tamponade.

Lauer et al. (136)	Holmium:YAG	CardioGenesis (percutaneous myocardial revascularization)	34	Phase I registry	10	Median CCS functional class was reduced from 3.0 at baseline to 1.3 at 6-mo follow-up. Exercise capacity increased from 384 min at baseline to 514 sec at 6 mo.
Oesterle et al. (135)	Holmium:YAG	CardioGenesis (percutaneous myocardial revascularization)	221	Randomized, unblinded	15	Exercise tolerance at 12 mo had increased by a median of 89 sec in patients treated with PTMR compared with 12.5 sec in patients treated with medical therapy only. Angina class was two or more lower in 34.1% of patients treated with PTMR vs. 12.0% in those patients treated with medical therapy.
Kornowski et al. (137)	Holmium:YAG	LaserStar Biosense (DMR)	77	Phase I registry	26	Exercise duration after DMR increased from 293 to 400 sec at 1 mo and 436 sec at 6-mo follow-up (p <.001). CCS angina class increased from 3.3 at baseline to 2.0 at 6-mo follow-up (p <.001). There were no changes in thallium scintigraphy.
Leon et al. (138)	Holmium:YAG	LaserStar Biosense (DMR)	298	Randomized, blinded	10–15 or 20–25	Major adverse cardiac events at 30 d were more common in patients treated with low-dose or high-dose DMR than placebo patients (p <.014). The frequency of class III or IV angina was reduced from 100% to approximately 40% in all three groups.

CCS, Canadian Cardiovascular Society; DMR, direct myocardial revascularization; PTMR, percutaneous transmyocardial myocardial revascularization; YAG, yttrium-aluminum-garnet.

Percutaneous Transmyocardial Myocardial Revascularization

A fluoroscopically guided percutaneous system for myocardial revascularization was developed for use in patients with medically refractory angina. The percutaneous transmyocardial myocardial revascularization (PTMR) technique uses a 5- or 7-cm steerable PTMR catheter (Eclipse Surgical Technologies, Sunnyvale, CA) that is positioned in the left ventricular cavity (133). A SlimFlex laser fiber is introduced and advanced under fluoroscopy to the left ventricular apex, deflected to the myocardial region to undergo laser ablation (133). The laser delivers 3.5 W through the 1-mm-diameter optical fiber in a series of three sequential pulses. The laser channels were spaced 1 cm apart and an average of 15 to 20 channels were created per patients (133).

A pilot study reported clinical benefit in 27 patients treated with the fluoroscopically guided Eclipse holmium:YAG laser system; an average of 17 channels were formed for each patient (133). Mean CCS functional class fell from 3.6 to 0.6 by 30 days after the procedure (133). There were no procedure-related deaths, pericardial effusions, or perforations. A subsequent randomized trial compared the clinical outcomes of 335 patients with CCS class III or IV angina assigned to treatment with PTMR or continued medical therapy (134). An average of 19 channels were placed per patient in those assigned to PTMR. There was one death and five (3%) cases of cardiac tamponade. There was a significant (p = .001) improvement in angina status and exercise time in those patients treated with PTMR compared with medical therapy. An improvement in angina by two or more CCS classes was achieved in 35% of patients treated with PTMR compared with 15% in those treated with conventional medical therapy (133).

Percutaneous Myocardial Revascularization

Another holmium:YAG laser system has been developed as an alternative method of myocardial revascularization in patients with medically refractory disease. The percutaneous myocardial revascularization (PMR) system (CardioGenesis Corporation, Sunnyvale, CA) consists of a 9-Fr coaxial catheter system used to deliver an optical fiber coupled to a holmium:YAG laser (135). The optical fiber, capped with a 1.75-mm lens and four nitinol pedals 3 mm from the tip to prevent full-thickness advancement during laser stimulation, was advanced through the catheter until it made contact with the endocardial surface. Each laser channel was created with four laser pulses of 2 J, and the laser channels are separated by at least 1 cm.

A phase I pilot study reported improved clinical outcomes in 34 patients with severe CAD not amenable to revascularization treated with the fluoroscopically guided CardioGenesis holmium:YAG system (136). PMR was successfully performed in all cases (136). An average of 11 channels were created per patient, and there was one death early after PMR due to a myocardial infarction in an untreated region (136). There was a significant improvement in CCS angina class from 3.0 at baseline to 1-, 3-, and 6-month follow-up. Although there was also a significant increase in exercise time, there was no improvement in myocardial perfusion found to the regions treated with PMR (136).

The Potential Angina Class Improvement from Intramyocardial Channels Trial evaluated the effect of PMR compared with medical therapy in 221 patient with medically refractory angina. Exercise tolerance at 12 months had increased by a median of 89 seconds in patients treated with PTMR compared with 12.5 seconds in patients treated with medical therapy only (135). CCS angina class improved by two or more classes in 34.1% of patients treated with PTMR compared with 12.0% of those patients treated with medical therapy. Angina scores were similarly improved in patients who received PTMR.

Direct Myocardial Revascularization

A third system uses electromechanical mapping to localize the region of myocardium treated with the Biosense Webster Holmium:YAG laser system (137). The Biosense system uses a navigational control at the tip that uses magnetic field emitters and local sensors to determine the precise location of the position of the tip of the catheter. At the conclusion of the left ventricular mapping, an 8-Fr laser catheter is advanced into the left ventricle. The laser source is a pulsed holmium:YAG laser integrated with a 300-µm fiber (LaserStar, Biosense Webster, Diamond-Barr, CA). A single laser pulse (2 J per pulse) is fired perpendicular to the endocardial surface to create 0.5-to 1.0-mm-diameter channels to a depth of 3 to 5 mm. Between 10 and 25 laser pulses are created and successive laser channels are kept greater than 5 mm between successive laser ablation zones.

In a pilot series of 77 patients with chronically refractory angina, percutaneous direct myocardial revascularization (DMR) was performed using left ventricular electromechanical guidance, delivering approximately 26 channels per patient (137). Major cardiac events occurred in 2.6% of patients; one patient required a postprocedural pericardiocentesis. Exercise duration after DMR increased from 387 seconds at baseline to 454 seconds at 30 days to 479 seconds at 6 months' follow-up. CCS angina class decreased from 3.3 at baseline to 2.0 at 6 months' follow-up (137). There were no improvements in the treated zones with dual-isotope scintigraphy at 1 or 6 months after therapy (137).

The DMR in Regeneration of Endomyocardial Channels Trial (DIRECT) evaluated the effect of DMR in 298 "no options" patients with medically refractory angina randomized to receive high-dose DMW (20 to 25 channels per zone), low-dose DMR (10 to 15 channels per zone), or a sham procedure in which the laser was positioned but not fired (138). Patients remained blinded to treatment. MACE at 30 days were more common in patients treated with low-dose or high-dose DMR than placebo patients (p = .014). All patients improved their exercise duration, but there were no incremental benefits in patients treated with low-dose or high-dose DMR (138). The frequency of class III or IV angina was reduced from 100% to approximately 40% in all three groups. All other quality-of-life measurements showed similar improvements in all groups.

Other Methods

A number of non–laser-based methods of performing myocardial revascularization have been developed. Radiofrequency energy has been used to create 1-cm-wide by 2-mm-deep divots on the endocardial surface. Other potential treatments include high-pressure saline jet drilling systems (CorMedica, Natick, MA) and use of cryotherapy to create holes in the endocardium. A rotary cutting and tissue vacuuming device that rotates at 1,000 to 2,000 rotations per minute (AngioTrax, Sunnyvale, CA) creates channels that are 1 mm wide and 5 mm deep, usually in approximately two rows of 10 to 15 channels each.

To date, percutaneous methods of myocardial revascularization have shown benefit in unblinded, randomized clinical trials. The findings in DIRECT, which was the first truly blinded clinical evaluation of patients undergoing percutaneous treatments for refractory myocardial ischemia, failed to demonstrate a clinical benefit, owing to a marked placebo effect that was demonstrated in the patients receiving the sham procedure. The smaller depth of injury and size and number of myocardial channels compared with surgical TMR may explain the reduced benefit in these patients.

Growth Factor Administration

Although a number of potential angiogenic agents have been identified to enhance the natural process of collateral development, only two growth factors, fibroblastic growth factor (FGF) and VEGF, have been developed for clinical use in patients with refractory ischemia. These agents have been developed using both protein-based and gene-based strategies, administered by intravenous, intracoronary, intramyocardial, and intrapericardial delivery. Given the potential that therapeutic angiogenesis

may stimulate vascular growth, it should not be used in patients with unstable angina or accelerated atherosclerosis, proliferative retinopathy, or suspected or confirmed malignancy.

Fibroblast Growth Factor

FGF is a member of a family of nine heparin-binding growth factors that stimulate cells of mesenchymal origin (139). FGF promotes angiogenesis by exerting its action on the endothelial cells (140), and a number of experimental studies have demonstrated the angiogenic effect of FGF (141,142 and 143) (*e*Table 81.1.3).

***e*TABLE 81.1.3** PROTEIN AND GENE-BASED ANGIOGENESIS STRATEGIES USING FIBROBLASTIC GROWTH FACTOR IN PATIENTS WITH REFRACTORY CORONARY ARTERY DISEASE

Author	Agent	No. of patients	Design	Route of administration	Dosage	Results
Schumacher (144)	FGF-1	20	Phase I	Direct i.m. injection at time of left internal mammary artery–left anterior descending	0.01 mg/kg	New capillary formation was found in all patients at the time of 12-wk follow-up angiography; new capillary networks were demonstrated in some patients.
Laham et al. (142)	bFGF	24	Phase I	Sustained release microspheres directly into myocardium at time of coronary artery bypass grafting	Placebo or 10 or 100 µg	Magnetic resonance imaging showed a trend toward a reduction in target vessel ischemia (p <.06). Stress nuclear perfusion imaging at baseline and 3 mo after coronary artery bypass grafting showed a trend toward worsening of infarct size in the placebo group, no change in myocardial perfusion in the placebo group, and a significant improvement in the 100-µg bFGF group (p = .01).
Laham et al. (145)	FGF-2	52	Phase I	Single i.c. bolus	0.33 to 48.00 µg/kg	A significant decrease in angina class, increase in exercise tolerance, and improved regional left ventricular function and perfusion by quantitative magnetic resonance imaging was found in patients receiving FGF-2. No significant improvement in the single-photon emission computed tomographic sestamibi perfusion scans.
Chronos et al. (146)	FGF-2	337	Phase I randomized controlled trial	Single i.c. infusion	Placebo or 0.3, 3.0, or 30.0 µg/kg FGF-2	After 3 mo, the treatment group had an increase in exercise duration of 65 sec compared with 45 sec in placebo-treated patients (p = NS). Older (age >63 yr) patients showed a significant improvement in exercise duration associated with FGF-2 therapy. Although there were also no differences in quality-of-life measurement or Canadian Cardiovascular Society angina class, patients with the severest symptoms had the greatest improvement in angina as a result of therapy. At 180 d, exercise tolerance remained similar in placebo and treatment arms, although there was a persistent trend in a reduction in angina frequency in patients who received treatment.
Grines et al. (150)	Adenovirus 5, FGF-4	79	Phase II randomized controlled trial	Intracoronary injection	Placebo or 5 doses of Ad5FGF-2	There was a greater increase in exercise time in patients receiving Ad5 FGF-2 than those receiving placebo There were no adverse effects in patients during the Ad5 FGF-4 infusion.

FGF, fibroblastic growth factor.

Fibroblast Growth Factor-1

The first clinical use of FGF-1 was reported in 20 patients who underwent direct intramyocardial injection of FGF-1, 0.01 mg per kg, at the time of CABG in the region of the left internal mammary artery to the left anterior descending artery anastomosis (144). Repeat angiography performed 12 weeks later demonstrated a pronounced accumulation of contrast medium in the region of the anastomosis, suggesting new blood vessel growth in FGF-1–treated patients (144).

A subsequent phase I randomized, double-blinded, placebo-controlled study of 24 patients undergoing CABG evaluated the effect of direct intramyocardial administration of basic FGF (bFGF) (142). Patients were assigned to treatment with placebo or 10 or 100 µg bFGF delivered into ischemic myocardium via sustained-release heparin-alginate microcapsules (142). Stress nuclear perfusion imaging at baseline and 3 months after CABG showed a trend toward worsening of perfusion in the placebo group and a significant improvement in the 100-µg bFGF group (p = .01) (142).

Fibroblast Growth Factor-2

Intracoronary recombinant human fibroblast growth factor-2 (rhFGF-2; Chiron Corporation, South San Francisco, CA) was administered as a single 20-minute infusion in a phase I, open-label, dose-escalating study of 52 subjects with advanced CAD (145). A single dose of rhFGF-2 (0.33 to 48.0 µg per kg) was associated with a significant decrease in angina class, increase in exercise tolerance, and improvement in regional left ventricular function and perfusion by quantitative magnetic resonance imaging and radionuclide scintigraphy (145). Adverse effects included transient renal dysfunction and hypotension with higher dose infusions (145).

A subsequent phase II FGF-2 Initiating Revascularization Support Trial compared the efficacy of placebo and three doses (0.3, 3.0, or 30.0 µg per kg) of intracoronary administration of FGF-2 in 337 patients with severe CAD (146). After 3 months, the treatment group had an increase in exercise duration of 65 seconds compared with 45 seconds in placebo-treated patients (p = not significant). Patients older than 63 years showed a significant improvement in exercise duration associated with rhFGF-2 therapy. Although there were also no differences in quality-of-life measurement or CCS angina class, patients with the severest symptoms had the greatest improvement in angina as a result of therapy. At 180 days, exercise tolerance remained similar in placebo and treatment arms (147).

The Therapeutic Angiogenesis with FGF-2 for Intermittent Claudication Trial evaluated the safety and efficacy of intraarterial injection of FGF-2 in a randomized, placebo-controlled, dose-finding phase II study of patients with severe intermittent claudication (148,149). Patients were given placebo, a “single dose” of 30 µg per kg of FGF-2 by intraarterial infusion in both legs at day 1, or a “double bolus” of 30 µg per kg of FGF-2 by intraarterial infusion rFGF-2 in both legs at day 1 and day 30 (149). Single-dose FGF-2 resulted in a significant (p = .026) improvement in the primary end point, peak walking time at 90 days, although the change in peak walking time at 90 days was not different in patients receiving a double bolus compared with those receiving placebo. By 180 days, however, there were no differences among the groups, due to a large increase in peak walking time in the placebo group (148).

Recombinant Adenovirus 5 Fibroblast Growth Factor-4

Genetic delivery of angiogenic proteins may result in higher retention rates within the myocardium when given by intracoronary injection than protein infusions. The phase I/II, dose escalation Adenovirus Gene Therapy (AGENT) trial compared the safety and efficacy of an intracoronary infusion of recombinant adenovirus 5 FGF-4 (Ad5 FGF-4; Collateral Therapeutics, San Diego, CA) in 79 patients with class II or III angina (150). Patients were randomly assigned to placebo or to one of five escalating doses of Ad5 FGF-4 (ranging from 3.2 × 108 to 3.2 × 1,010 viral particles) injected into the left or right coronary artery (150). Preliminary results reported that patients who received active therapy had a greater increase in exercise time than those receiving placebo (150), although there was a substantial improvement in placebo-treated patients. There were no adverse effects in patients during the Ad5 FGF-4 infusion. Although these results are encouraging, the sample size is small and larger studies are needed. A phase III pivotal efficacy trial is planned.

Vascular Endothelial Growth Factor

VEGF is an endothelial cell-specific mitogen that has been implicated as another potent angiogenic agent (151). Endothelial responses to VEGF include proliferation, production of proteases such as plasminogen activators and collagenases that promote capillary bed formation, and triggering migration of monocytes (151).

VEGF has been studied by numerous investigators in various *in vitro* and *in vivo* animal models (152,153). In addition to these favorable responses that promoted angiogenesis, VEGF has also been shown to be a mediator of proliferative retinopathy, age-related macular degeneration, rheumatoid arthritis, and in the formation of

atherosclerotic plaque (151). VEGF has also been shown to promote the release of nitric oxide, resulting in clinical hypotension if given in high doses.

A recombinant human VEGF (rhVEGF) phase I clinical study of 14 patients who received an intracoronary infusion of low-dose rhVEGF (Genzyme, South San Francisco, CA) (0.005 and 0.017 µg per kg) or high-dose rhVEGF (0.05 and 0.167 µg per kg) over 20 minutes demonstrated improved myocardial perfusion in a dose-dependent fashion (154) (*e*Table 81.1.4). The VEGF in Ischemia for Vascular Angiogenesis (VIVA) Trial, a phase II, double-blinded, placebo-controlled trial, randomly assigned 178 patients who were poor candidates for conventional revascularization to treatment with placebo, low-dose (17 µg per kg per min), or high-dose (50 µg per kg per min) intracoronary rhVEGF infusion over 20 minutes followed by a 4-hour intravenous rhVEGF infusion at 3, 6, and 9 days (155). All groups had a similar increase in exercise time, Canadian class angina, and quality of life at 60 days (155,156). At 120 days, the improvement in the placebo group became diminished and the high-dose infusion continued to improved, resulting in a significant improvement in CCS angina class (p = .04) and a trend toward improvement in exercise time (p = .17) in patients treated with high-dose rhVEGF compared with placebo. In a subset analysis of 107 patients who were followed for an additional 8 months, placebo-treated patients continued to worsen, whereas patients receiving high-dose rhVEGF continued to have significant improvement. The occurrence of 1-year death, myocardial infarction, revascularization, or cancer was lower in patients treated with high-dose rhVEGF (11.8%) compared with patients treated with placebo (31.6%) (p <.04) (156).

***e*TABLE 81.1.4** PROTEIN AND GENE-BASED ANGIOGENESIS STRATEGIES USING VASCULAR ENDOTHELIAL GROWTH FACTOR IN PATIENTS WITH REFRACTORY CORONARY ARTERY DISEASE

Author	Agent	No. of patients	Design	Route of administration	Dosage	Results
Hendel et al. (154)	rhVEGF	14	Phase I	i.c. Bolus	Low dose (0.005 and 0.017 µg/kg) or high dose (0.05 and 0.167 µg/kg)	An improvement in myocardial perfusion in a dose-dependent fashion was suggested.
Henry et al. (155)	rhVEGF	178	Phase II randomized controlled trial	i.c. Bolus over 20 minutes, then i.v. infusion at 3, 6, and 9 d	Placebo, or “low dose” (17 µg/kg/min) or “high dose” (50 µg/kg/min)	At the end of 60 d, all groups had a similar increase in exercise time, Canadian Class angina, and quality of life. At 120 d, the improvement in the placebo group became diminished and the high-dose infusion continued to improve, resulting in a significant improvement in Canadian Class (p = .04) and a trend toward improvement in exercise time (p = .17) in patients treated with high-dose rhVEGF compared with placebo.
Symes et al. (158)	phVEGF-165	20	Phase I	Direct i.m. injection by minithoracotomy	125 or 250 µg	Patients had significant reductions in angina, as assessed by nitroglycerin consumption (53.9 per wk at baseline and 9.8 per wk after treatment; p <.03). Improved dobutamine single-photon emission computed tomography in most patients. Improved angiographic Rentrop score in all patients.
Vale et al. (159)	phVEGF-165	13	Phase I	Direct i.m. injection via an endocardial delivery catheter	—	Improvement in single-photon emission computed tomography perfusion of the treated area. Reduction in indices of perfusion by electromechanical mapping.
Rosengart et al. (161)	Ad_{GV}VEGF121.10	21	Phase I	Direct i.m. injection at coronary artery bypass grafting	—	There was no evidence of toxicity related to the administration of the agent or vector. All patients reported an improvement in their angina class. Patients who receive Ad_{GV}VEGF121.10 as sole therapy reported an increase in exercise duration in most cases.

VEGF, vascular endothelial growth factor.

Naked Plasmid DNA Encoding the Vascular Endothelial Growth Factor–165 Gene

A phase I clinical trial demonstrated the safety of naked plasmid DNA encoding the VEGF-165 gene (Vascular Genetics, Research Triangle Park, NC) injected directly into the myocardium of patients via a minithoracotomy (157,158). Angina episodes requiring nitroglycerin therapy were reduced in most patients, and exercise tolerance improved significantly after gene transfer (158,159).

Using another approach, direct intramyocardial administration of the naked plasmid VEGF-165 was achieved using a specially designed delivery catheter that uses electromechanical mapping to localize the region of myocardial injection (160). In this series, 13 consecutive patients treated with a direct intramyocardial injection of VEGF-165 and single-photon sestamibi examinations were used to assess improvements in perfusion over a 60-day follow-up period (160). Partial or complete resolution of perfusion defects seen on the sestamibi scan were improved during the follow-up period. Improvements in the electromechanical mapping profiles were also noted.

Adenovirus Gene Transfer Vascular Endothelial Growth Factor 121.10

A phase I study used a gene-therapy strategy used an E1-E3-adenovirus (Ad) gene transfer vector expressing VEGF121 cDNA (Ad_{GV}VEGF121.10) (GenVec, Inc., Gaithersburg, MD) to induce therapeutic angiogenesis in 21 patients with symptomatic CAD (161). Ad_{GV}VEGF121.10 was administered to 15 patients as an adjunct to CABG and to six patients as sole therapy via a minithoracotomy. There was no evidence of toxicity related to the administration of the agent or vector. All patients reported an improvement in their angina class, and patients who received Ad_{GV}VEGF121.10 as sole therapy reported an increase in exercise duration in most cases (161). These effects were sustained 6 months after the procedure (162).

Candidates for Therapeutic Angiogenesis

Patients who have no options for conventional revascularization may either have a single long-standing occlusion of a proximal vessel that subtends a large amount of myocardium or have undergone one or more prior CABG surgeries, with occlusion or stenoses saphenous vein grafts in association with native CAD that is poorly suited for conventional revascularization. It is estimated that patients with no options account for approximately 4% to 12% of those undergoing coronary arteriography (105). A larger percentage of patients (20% to 30%) have incomplete revascularization due to unsuitable coronary anatomy after conventional revascularization. These patients may also be amenable to alternative approaches targeted at increasing perfusion to ischemic tissues.

It is understandable that an aggressive approach to new blood vessel formation is needed in these patients, as these individuals are “resistant” to physiologic angiogenesis that results in extensive collateral formation in some patients with long-standing occlusion (106). Resistance to therapeutic angiogenesis may occur as a result of medications, with hypercholesterolemia, smoking, and diabetes, among other factors (106).

Because of the potential that therapeutic angiogenesis may be associated with some untoward effects, patients with cancer, diabetic retinopathy, unstable angina, or protein nephropathy have not been included in studies assessing the efficacy of angiogenesis (106).

Controversies and Personal Perspectives

Patients who have refractory angina but are poor candidates for revascularization still have few options for symptom relief. Although the use of systemic and local delivery of growth factors and surgical laser revascularization to promote angiogenesis remains an active area of investigation, the clinical results obtained with these therapies have been somewhat disappointing to date. Adjunct surgical TMR appears to be the best approach to the patient who undergoes CABG but has important residual ischemic zones, and isolated TMR may also benefit patients who require symptom relief from refractory ischemia in zones not amenable to revascularization. It appears that percutaneous approaches may not provide a sufficient extent of injury to promote angiogenesis. The DIRECT trial also emphasized the importance of blinding of the treatment method to patients and their physicians, as the placebo effect may be a powerful stimulus for symptom relief in these patients. Early clinical trial results from intracoronary and intravenous protein and gene-based approaches to angiogenesis have also failed to identify a truly viable approach for the majority

of patients with refractory ischemia, although more investigation is needed.

THE FUTURE

The immediate future will see a refinement in the technology for distal protection devices, with improved flexibility, lower profiles, and reduced risk for vessel injury. The optimal device will be one that can be placed beyond distal lesions in tortuous vessels without interfering substantially with the interventional procedure itself. Clinical investigation will be directed at establishing the optimal clinical and anatomic indications for antiemboli devices, as well as critically assessing the potential complementarity between the pharmacologic and mechanical approaches.

Continued evolution of the molecular approaches to angiogenesis will likely be the next frontier for patientswith refractory CAD and no options. The encouraging preliminary results of the AGENT trial require confirmation in a larger phase III trial that will measure clinical end points in a larger number of patients. Direct intramyocardial injection of growth factors using fluoroscopically or electromechanically guided injection systems may allow more precise delivery of protein-based and gene-based factors into the ischemic myocardium. It is likely that new imaging modalities, such as functional magnetic resonance imaging, may also provide a more sensitive index to assessing the therapeutic effect of angiogenesis.
