Chapter 34
Lower Back and Lower Limb Pain

Karl E. Misulis

Lower kick pain is one of the most common causes of neurological and neurosurgical consultation. The cost to society is huge, with estimates of up $80 billion per year in direct and indirect health care costs and loss of productivity. Many of the patients who present with lower back pain have either developed or exacerbated their pain as a result of their occupations. Lower limb pain is a common accompaniment to lower back pain but can occur independently.

The differential diagnosis of lower back and lower leg pain is huge, including neural, bony, and non-neurological causes. Although we usually think of lower back pain as being either radiculopathy or mechanical low back pain, we cannot forget other possible sources of pain, including urolithiasis, tumors, and other intra-abdominal processes.

ANATOMY

The lumbosacral spinal cord terminates in the conus medullaris at the level of the body of LI vertebra (Figure 34.1). The motor and sensory nerve roots from the lumbosacral cord form the cauda equina. The individual motor and sensory lumbosacral nerve roots unite at the dorsal root ganglion to form the individual spinal nerves. These anastomose in the lumbosacral plexus (Figure .34.2), from which run the major nerves supplying the leg (Table 34.1).

Pain in the lower back can have many origins. The differential diagnosis can be narrowed depending on whether the leg also has pain. A factor complicating this simple differential diagnosis is that local spine pain can cause referred pain, that is, pain felt at a distance, because of the common nerve root innervation of the spinal location of the pain and a distant part of the leg.

Causes of lower back pain without leg involvement include ligamentous strain, facet pain, muscle strain, bony destruction, and inflammation. Causes of lower back plus lower limb pain include radiculopathy and plexopathy. Important causes of leg pain without low back pain include sciatic neuropathy, femoral neuropathy, peroneal neuropathy, meralgia paresthetica, and peripheral neuropathies.

Isolated tibial neuropathy is uncommon. Individual peripheral nerve lesions usually arc caused by local trauma, entrapment by connective tissue, or involvement with mass lesions.

Lower back pain is occasionally caused by non-neurological and nonskeletal lesions, with some of the most important being urolithiasis, ovarian cysts and carcinoma, endometriosis, and bladder infection.

DIAGNOSIS

The first step to diagnosis is establishing the localization. History and examination usually allow differentiation between mechanical, neuropathic, and non-neurological pain.

History and Examination

History

History should focus on the following features of the pain; lower back and leg pain should be evaluated separarely.

- Mode of onset
- Character
- Distribution
- Associated motor and sensory symptoms
- Bladder and bowel control
- Exacerbating and remitting factors
- History of predisposing factors (e.g., cancer, osteoporosis)

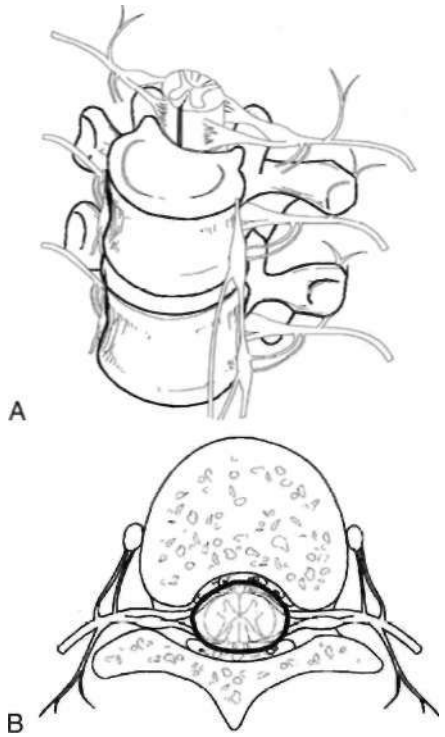

FIGURE 34.1 Oblique (A) and axial (B) views of the spine showing iiiKitomioil rdutionsliips licrwi'i'n ru-nr.il unil lionv elements.

For example, the acute onset of lower back pain radiating down the leg suggests a lumbosacral radiculopathy. Onset with exertion suggests a herniated disc as a cause of the radiculopathy. Onset with a motor vehicle accident could also be caused by a disc herniation, although contusion of a nerve root without ongoing compression is more common after this type of trauma. Progressive symptom development can be from any expanding lesion, such as a tumor, or a gradually expanding disc extrusion.

Symptoms in patients with lower back and leg pain usually are more prominent than the signs of neurological dysfunction. Therefore, if examinations shows sensory and motor signs in a specific radicular or neural distribution, this mandates evaluation for a structural lesion.

Examination

The neurological examination is targeted to determine whether the symptoms are accompanied by abnormal neurological signs. General examination of the lower limb is important. Muscle groups to be tested include the following:

- Hip girdle muscles:
- Hip flexors (psoas, sartorius)
- Hip extensors (gluteus maximus, semitendinosus, semimembranosus, biceps femoris}
- Hip adductors (adductor group: longus, brevis, magnus)
- Hip abductors (gluteus medius, gluteus minimus, piriformis)
- Knee muscles:
- Knee extension (quadriceps)
- Knee flexion {semitendinosus, semimembranosus, biceps femoris}
- Ankle and foot muscles:
- Foot plantar flexion (gastrocnemius)
- Foot dorsiflexion (tibialis anterior}
- Foot everters (peroneii)
- Foot inverters (tibialis posterior)
- Toe extension (extensor digitorum)
- Great toe extension (extensor hallucis longus)
- Toe plantar flexion (flexor digitorum longus)
- Great toe flexion (flexor hallucis longus)

Sensory examination should examine the important nerve roots and peripheral nerve distributions: the femoral, peroneal, tibial, and lateral femoral cutaneous, lumbar roots L2-L5, and sacral root SI. Reflexes to be studied include the Achilles, patellar, and plantar reflexes.

Exacerbation of pain with some maneuvers can also be revealing. Stretch of damaged nerves results in increased pain by deforming the axon membrane, thereby increasing membrane conductance and producing repetitive action potentials. Straight leg raising augments pain in a lumbosacral radiculopathy. Hip extension exacerbates pain of upper lumbar radiculopathy or damage to the upper parts of the lumbar plexus, such as from carcinomatous infiltration or inflammation.

Armed with the abnormalities recognized from this history and examination, the neurologist may come to a conclusion about the localization of the lesion. This narrows the differential diagnosis.

THE DIFFERENTIAL DIAGNOSIS OF LOWER BACK AND LEG PAIN

Differential diagnosis of lower back and leg pain can be addressed as shown in Tables 34.2 through 34.5, Classification into mechanical and neuropathic pain narrows the differential diagnosis. The possibility of non-neui ologic causes should always lie remembered.

Some basic guidelines for differential diagnosis are as follows:

- Pain confined to the lower back generally is caused by a low back disorder.
- Pain confined to the leg usually is caused by a leg disorder, although neuropathic pain from lumbar spine disease can radiate down the leg without back pain in a minority of patients.
- Pain in both the low back and the leg usually is caused by lumbar radiculopathy or, less commonly, lumbosacral plexopathy,

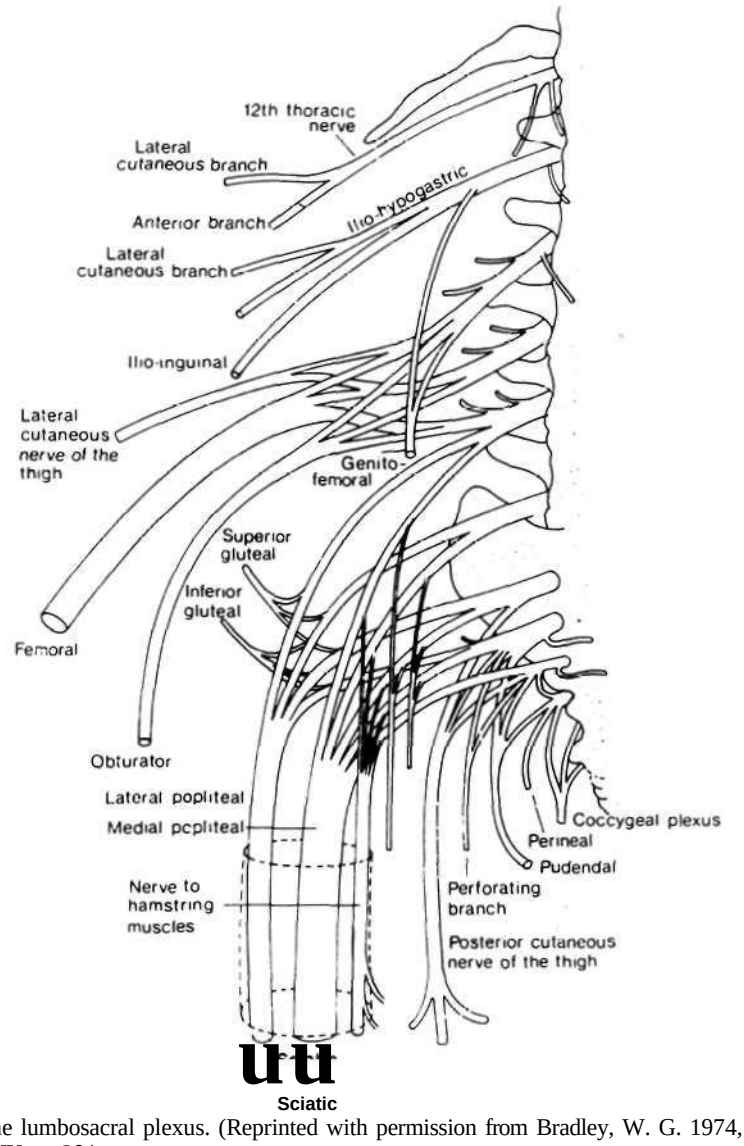

FIGURE 34.2 Anatomy of the lumbosacral plexus. (Reprinted with permission from Bradley, W. G. 1974, *Disorders of the Peripheral Nerves,* BlackweU, Oxford, UK, p. 29.)

- Clinical findings confined to one nerve root distribution usually are caused by intervertebral disc disease or lumbosacral spondylosis producing radiculopathy.
- Clinical findings that involve several nerve distributions usually are caused by plexus lesions, with cauda equina lesions being the alternative diagnosis.
- Bilateral lesions suggest proximal damage in the spinal canal, affecting the roots of the cauda equina.
- Impairment of bladder control indicates either a cauda equina lesion or, less commonly, a bilateral sacral plexopathy.
- More than one lesion may complicate neurological localization.
- Non-neurological causes of lower back pain are possible.

Multiple lesions can make differential diagnosis more difficult. For example, radiculopathies at two or more levels may look like a plexopathy or peripheral neuropathic process.

Non-neurological causes of lower back pain include urolithiasis; ovarian cysts; pelvic carcinoma; bladder infection; and other retroperitoneal lesions including tumor, abscess, and hematoma. These conditions produce pain that does not radiate unless neural structures arc involved. Early involvement of bowel or bladder function and abdominal pain suggests one of these non-neurological conditions.

Evaluation

Diagnostic evaluation of lower back and lower leg pain begins with proper clinical localization and classification of the complaint. Diagnostic tests are summarized in Table 34.6.

Table 34.1: Motor and sensory function of lumbosacral nerves

Nerve	*Origin*	*Motor function*	*Sensory function*
Femoral	Lumbar plexus, L2–L4	Extension of the knee, flexion of the thigh	Anterior thigh
Saphenous	Distal sensory branch of the femoral nerve	None	Inside aspect of the lower leg
Lateral femoral cutaneous	Branch of the lumbar plexus, L2–L3	None	Lateral thigh
Obturator	Lumbar plexus, L2–L4	Adduction of the thigh	Medial aspect of the upper thigh
Sciatic	Combined roots from the lumbosacral plexus, partially separated into tibial and peroneal divisions	Foot plantar and dorsiflexion, foot inversion and eversion	Lateral, anterior, and posterior aspects of the lower leg and foot
Tibial	Lumbosacral plexus, L4–S3	Plantar flexion and inversion of the foot	Posterior lower leg and sole of the foot
Peroneal	Lumbosacral plexus, L5–S2	Dorsiflexion and eversion of the foot	Dorsum of the foot and lateral lower leg
Superficial peroneal	Distal sensory branch of the peroneal nerve	None	Dorsum of the foot
Sural	Cutaneous branches of the peroneal and tibial nerves	None	Lateral foot to sole

Table 34.2: Classification of lower back and lower limb pain

Type	*Examples*
Mechanical pain	Facet pain
	Bony destruction
	SI joint inflammation
	Osteomyelitis
	Lumbar spondylosis
Neuropathic pain	Polyneuropathy
	Radiculopathy from disc disease, zoster, and diabetes
	Mononeuropathy, including sciatic, femoral, lateral femoral cutaneous, and peroneal neuropathies
	Plexopathy from cancer, abscess, hematoma, and autoimmune processes
Non-neurological pain	Urolithiasis
	Retroperitoneal mass
	Ovarian cyst or carcinoma

Table 34.3: Differential diagnosis of lower back and leg pain

Disorder	*Clinical features*	*Diagnosis*
Radiculopathy	Back pain radiating into the leg in a dermatomal distribution. Sensory loss and motor loss are in a root distribution. Increased pain with coughing or straining.	Suspected when neuropathic pain radiates from the back down into the leg in a single nerve distribution. Disc or mass can be seen on MRI or CT. Zoster and diabetes can cause radiculopathy without abnormal studies.
Plexopathy	Back and leg pain with a neuropathic character, dysesthesias, burning, or electric sensation. Back pain can develop when the cause is mass lesion in the region of the plexus.	Suspected when patient has leg pain in more than one peripheral nerve distribution. MRI of the plexus or CT of the abdomen and pelvis can show mass or hematoma.
Spinal stenosis	Pain in the lower back, buttocks, and legs, especially with standing, walking, and lumbar spine extension.	MRI or CT shows obliteration of the subarachnoid space.

CT = computed tomography; MRI = magnetic resonance imaging.

Table 34.4: Differential diagnosis of isolated lower back pain

Disorder	*Clinical features*	*Diagnosis*
SI joint inflammation	Pain lateral to the spine as the sacrum inserts into the top of the iliac bone. Pain is exacerbated by movement and pressure but does not radiate down the leg.	Clinical diagnosis. Radiographs can show degenerative changes in the joint. Bone scan shows increased uptake in the region.
Facet pain	Unilateral or bilateral paraspinal pain without radiation, increased by spine motion, especially extension. No motor, sensory, or reflex deficits.	Clinical diagnosis. Radiographs can show facet degeneration.
Ovarian cyst or cancer	Pain in the hip and lower back, often but not always extending to the lower quadrant. Bowel disturbance may develop with advanced disease.	Abdominal and pelvic CT shows mass lesion in the ovary.
Retroperitoneal mass, abscess, hematoma	Pain in the back, lateral to the spine. May be associated with superimposed neuropathic pain if there is plexus or proximal nerve involvement.	CT or MRI shows hematoma or mass in the abdomen.
Urolithiasis	Pain in the upper- to mid-back laterally, which may radiate to the groin. No radiation down the leg.	Radiographs may show stones. Intravenous pyelography typically shows obstruction of flow. Contrasted abdominal CT usually shows the stone and any obstruction.

CT = computed tomography; MRI = magnetic resonance imaging.

Table 34.5: Differential diagnosis of isolated leg pain

Disorder	*Clinical features*	*Diagnosis*
Peroneal neuropathy	Loss of sensation on the dorsum of the foot. Weakness of foot and toe dorsiflexion.	Slowed nerve conduction velocity across the region of entrapment, usually at the fibular neck. EMG may show denervation in peroneal-innervated muscles, especially tibialis anterior without involvement of the short head of the biceps femoris.
Femoral neuropathy	Pain and sensory loss in the anterior thigh, often with weakness of the quadriceps and suppression of the knee reflex.	NCS can sometimes be performed but may be technically difficult. EMG may show denervation in a distribution limited to the femoral nerve.
Piriformis syndrome	Pain from the back or buttock down the posterior thigh. Exacerbation by sitting or climbing stairs. Stretch of the piriformis (flexion and adduction of the hip) worsens pain.	Clinical diagnosis. Pain radiating down the leg in a sciatic nerve distribution, exacerbation of the pain by flexion and adduction of the hip. EMG and NCS can show proximal sciatic nerve damage.
Meralgia paresthetica (lateral femoral cutaneous nerve dysfunction)	Pain and loss of sensation in the distribution of the lateral femoral cutaneous nerve on the lateral aspect of the thigh.	Clinical diagnosis. Nerve conductions are difficult to perform on this nerve.
Claudication	Pain in the thigh and lower leg with exertion, not so with lumbar spine extension. Ischemic changes in the legs distally.	Suspected with exertional leg pain without back pain. Ultrasound or angiography confirms the arterial insufficiency.
Plexopathy	Back and leg pain that has a neuropathic character, dysesthesias, burning, or electric sensation. Plexitis has no associated back pain.	Suspected when patient has leg pain in more than one peripheral nerve distribution. Magnetic resonance imaging of the plexus or computed tomography of the abdomen and pelvis can show cause.

EMG = electromyography; NCS = nerve conduction study.

Table 34.6: Diagnostic studies for lower back and lower limb pain

Diagnostic test	*Advantages*	*Disadvantages*
Magnetic resonance imaging	Sensitive for identification of lumbar disc herniation, spinal stenosis, paravertebral mass in the region of the plexus, and perineurial tumors.	May overemphasize structural lesions. May miss vascular lesions of the spinal cord. The radiologist may not notice paravertebral disorders because they are not the focus of interest. Cannot be performed on patients with some implanted metallic and electrical equipment.
Noncontrast CT	Shows osteophytes and lateral disc herniations best. Can show bone fractures and extension of fragments into regions that may contain neural elements.	Cannot identify neural elements without intrathecal contrast. Disc herniations without bony involvement may be missed.
Myelography with postmyelographic CT	Definitive test for identifying lumbar disc herniation, osteophytes, and intervertebral foraminal stenosis. Very sensitive when combined with postmyelographic CT scanning, and this sequence should be routine.	May miss far-lateral disc herniations. Is invasive, with a small risk of serious adverse effects.
Nerve conduction studies and electromyography	Sensitive for identification of specific nerve, root, or peripheral neuropathic involvement.	Patients may have clinically significant radiculopathy without electromyographic evidence of denervation (or vice versa if the radiculopathy is old).
Discogram	Can identify disc anatomy in comparison to bony and neural anatomy. May confirm disc level if it produces pain that reproduces patient's complaints.	Invasive test, but risk of serious complications is low. Seldom performed in routine practice.

CT = computed tomography,

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is commonly performed to assess the lumbosacral spine and the lumbosacral plexus. It also can be used to evaluate the peripheral nerves in the pelvis and lower limbs.

MRI of the lumbosacral spine has the highest yield when the patient has back pain associated with radicular distribution of pain. Isolated back pain with no clinical symptoms or signs in the leg is seldom associated with significant findings on MRI. Intraspinal disorders that may not be revealed by MRI without contrast enhancement include neoplastic meningitis and some chronic infectious meningi tides.

MRI of the lumbosacral plexus and peripheral nerves is still a developing field. It can reveal masses, infiltration, and even inflammatory lesions but can miss other disorders.

Nerve Conduction Study and Electromyography

Nerve conduction study (NCS) and electromyography (EMG) are performed for two main purposes. First, these studies are an important aid to the neurological examination of the peripheral nervous system and can help neurological localization. Second, EMG can determine whether there are signs of denervation that indicate nerve damage. In relation to nerve root injury, this information may help to determine whether surgery will be performed. EMG can show signs of active and chronic denervation in all neuropathic conditions, but fibrillation potentials and positive sharp waves do not appear for up to 4 weeks after a nerve injury.

Entrapment neuropathy or nerve root compression, which can be responsible for lower limb pain, is likely to slow nerve conduction velocity across the region of the compression. Conduction velocities proximal and distal to the compression usually are normal, so conduction across the affected nerve segment must be studied. Radiculopathy typically is associated with normal NCS in the peripheral branches of the nerves, but the F wave is slowed. Normal NCS and EMG do not rule out the presence of a radiculopathy.

Mechanical lower back pain is associated with no EMG or NCS alterations. Therefore, these studies usually are not indicated unless there are symptoms or signs of neural involvement.

Myelography and Postmyelographic Computed Tomography

With the advent of **MRI,** myelography has been performed less commonly. If adequate information is not obtained from noninvasive studies, myelography may be indicated.

Lumbar puncture is performed and radio-opaque dye is infused into the cerebrospinal fluid (CSF). Conventional radiographs arc performed as the dye is manipulated through the CSF pathways. Postmyelographic computed tomography (CT) is performed in most instances,

Radiography

Plain radiographs arc performed for patients with acute bony trauma and for almost all patients with isolated lower back pain. Among the potential findings are degenerative joint disease, vertebral body collapse, bony erosion, subluxation, or other fracture. Radiographs of the pelvis and long bones arc also performed and may show fractures and destructive lesions.

Bone Scan

Bone scan is important, especially when there is suspicion of neoplastic bone involvement, to examine multiple bone regions. Multifocal involvement makes neoplastic causes more likely than infectious causes for the destruction.

SYNDROMES

Lower Back and Leg Pain

Lumbar Spine Stenosis

Lumbar spine stenosis is a disorder that affects mainly late-middle-aged and older adults. The cause is multifactorial, with disc disease, bony hypertrophy, and thickening of the ligamentum flavum being the most important. Some of the symptoms are undoubtedly caused by direct pressure of these tissues on the cauda equina and exiting nerve roots, but a major contributor appears to be compression of the vascular supply of the nerve roots. Standing is associated with extension of the lumbar spine, which causes protrusion of the ligamentum flavum. Compression of the vascular supply creates nerve root ischemia, which can produce severe pain and weakness.

Diagnosis is suspected in patients with lower back pain that is exacerbated by standing and walking and relieved promptly by sitting. Lying down, especially in the prone position, may exacerbate the pain, again through lumbar extension, a feature that helps to differentiate lumbar spine stenosis from lumbar radiculopathy.

Diagnosis is confirmed by **MRI** or CT of the lumbar spine, which shows obliteration of the subarachnoid space at the level of the lesion. The hypertrophied ligamentum flavum and osteophyte formation usually is evident on these studies. If there is doubt about the diagnosis, myelography with postmyelographic CT scanning can be performed, but this invasive test is seldom needed.

Treatment usually is surgical decompression, which usually improves the exertional back and leg pain, Conservative management with symptom control often is ineffective. Weakness or sphincter disturbance means that conservative measures should be abandoned.

Lumbosacral Radiculopathy

Lumbosacral radiculopathy usually is caused by either herniated disc material or osteophytes infringing on the neural foramen. Herniated disc is most common in young patients; osteophyte formation is more common in older patients.

Patients present with back pain radiating down the leg in a distribution appropriate to the involved nerve root. The most common lumbosacral radiculoparhy is of the SI nerve root, produced by a lesion at the 1,5-Sl interspace. Table 34.7 presents the typical motor, sensory, and reflex deficits associated with lumbosacral radiculopathy at individual levels.

Radiculopathy is suspected in the presence of lower back pain with radiating pain in a nerve root distribution. Motor, sensory, and reflex deficits are not always present, so the diagnosis is suspected on the basis of symptoms without objective signs.

Diagnosis is confirmed by MRI, which can show disc protrusion or osteophyte encroachment with nerve root compression. Myelography with posrmyclogram CT is still considered the gold standard for diagnosis of radiculopathy, although the noninvasive MRI is used much more often. Myelography is especially common for patients with implanted electronic devices and metallic heart valves, who cannot undergo MRI. NCS usually is normal in patients with lumbosacral radiculopathy. EMG can reveal denervation in a nerve root distribution and usually can differentiate peripheral neuropathic processes from radiculopathy. EMG can also determine whether there is denervation with radiculopathy, which can help the physician determine whether surgery is necessary.

Management of lumbosacral radiculopathy depends on the severity of symproms, including pain and weakness. If the symptoms are mild, anti-inflammatory agents may suffice. Muscle relaxants can produce short-term relief of muscle spasm and pain.

Table 34.7: Lumbosacral radiculopathy

Roof	*Motor deficits*	*Sensory deficits*	*Reflex deficits*
L2	Psoas, quadriceps	Lateral and anterior upper thigh	None
L3	Psoas, quadriceps	Lower medial thigh	Patellar
L4	Tibialis anterior, quadriceps	Medial lower leg	Patellar
L5	Tibialis anterior, peroneus longus, gluteus medius	Lateral lower leg	None
S i	Gastrocnemius, gluteus maximus	Lateral foot, digits 4 and 5, outside of sole	Achilles

Surgical options for lumbosacral radiculopathy are considered when the patient has intractable pain, refractory to conservative care; when weakness is prominent, especially if it is unresponsive to conservative management; and when sphincter disturbance is present. Sphincter disturbance caused by lumbar disc disease or spondylosis often necessitates urgent surgery. Such patients should not be given a trial of conservative therapy,

How much conservative treatment should be given to patients with weakness before surgical options are considered? In general, weakness should prompt at least consideration of surgery. Patients may have mild and transient weakness that responds to conservative therapy, but if weakness is prolonged or severe, the expected recovery is compromised. Increasing evidence for success of conservative treatment will make surgery less common (Rust and Olivero 1999).

Intractable pain without motor loss and with or without sensory loss can be treated sutgically, but treatment effectiveness is limited.

Plexopathy

Neoplastic Lumbosacral Plexopathy

Neoplasms affecting the lumbosacral plexus can be solid or infiltrating. Infiltrating tumors such as lymphoma usually are treated by radiation therapy, which is commonly followed by chemotherapy for the systemic cancer.

Solid tumors affecting the lumbosacral plexus rarely can be completely surgically excised without producing severe damage to the plexus. Radiation therapy is given initially.

Pain often is relieved shortly after the radiation therapy has begun. Duting initial treatment, anticonvulsants often are used to relieve the neuropathic pain. Pure analgesics also are used often, and sustained-release opiate formulations arc effective in treating this condition.

Plexus Injury [ruin Retroperitoneal Abscess

Retroperitoneal abscess usually is caused by peritonitis from gastrointestinal neoplasms or follows surgery, Retroperitoneal abscess can affect the lumbosacral plexus. Patients present with abdominal and flank pain, often with overt signs of systemic infection, with fever, malaise, elevated white blood cell counts, and elevated C-rcactive protein. Diagnosis is confirmed by CT of the abdomen.

Management usually begins with surgical drainage followed by long-term antibiotics. Narcorics usually are needed for the pain of retroperitoneal abscess.

Plexus Injury from Retroperitoneal Hematoma

Retroperitoneal hematoma usually is caused by a bleeding disorder, a pelvic fracture, or abdominal surgery. Occasionally, bleeding around the site of arteriography can result in tracking of blood into the region of the lumbosacral plexus. Diagnosis is suspected in patients with leg motor and sensory symptoms who are at risk for intra-abdominal hemorrhage. Diagnosis is confirmed by CT of the abdomen, which can show blood in the region of the plexus.

Treatment of plexus hematoma is supportive. Evacuation of the hematoma is seldom needed, and surgery is commonly reserved for patients in whom there is continued blood loss, which must be corrected.

Leg Pain without Lower Back Pain

Peripheral Nerve Syndromes

Peripheral nerve palsy is commonly caused by sustained com press i mi. ['en meal palsy is rhe nuisr common lower extremity syndrome, caused by pressure at the fibular neck. Femoral neuropathy commonly results from intra-abdominal causes and can be difficult to differentiate from upper lumbar plexopathy. Some individual peripheral nerve palsies are discussed in this section,

Diagnosis of peripheral nerve palsy is clinical, with symptoms and signs confined to one neural distribution. Patients usually present with neuropathic pain and sensory loss. Dysesthesias and paresthesias in the affected distribution are common. Reflex abnormalities depend on the individual nerve affected.

Definitive treatment of peripheral nerve entrapment is surgical release. Surgery is not always necessary, and conservative management may be successful. Tumor infiltration of peripheral nerve can be treated surgically, but radiation therapy can shrink the tumor and relieve pain. Conservative management includes physical therapy to improve pain and function, anti-inflammatory agents to improve pain, anticonvulsants to improve pain, and counseling on methods to avoid subsequent damage. The counseling includes prevention of nerve compression and nerve stretch. For example, peroneal nerve compression at the fibular neck can be improved by avoiding pressure on the posterior knee with the knee extended and avoiding squatting with the knee acutely bent.

Femoral Neuropathy

The femoral nerve usually is injured in the pelvis, as it passes beneath the inguinal ligament, or in the leg. Intra-abdominal disorders including mass lesions and hematoma are commonly implicated. Femoral artery puncture for angiography may also be a cause, either directly or via the resultant hematoma. Patients present with weakness that is most easily detected in the psoas because the quadriceps is so strong. Sensory loss is over the anterior thigh and medial

aspect of the calf; this loss has a saphenous nerve distribution (the terminal sensory branch of the femoral nerve). This distribution of sensory loss is helpful to differentiate femoral neuropathy from lumbar radiculopathy. The patellar reflex usually is depressed.

Diagnosis can be supported by electromyographic evidence of denervation in the quadriceps but not in the lower leg or posterior thigh muscles; the adductors are especially important to test because they are innervated by the same nerve roots as the femoral nerve but by the obturator nerve. A normal elcctromyogram cannot rule out this diagnosis because many patients do not have active or chronic denervation. NCS of the femoral nerve is difficult, especially in large patients, who are predisposed to development of femoral neuropathy.

Treatment is seldom surgical, except for the removal of a massive psoas or iliacus hematoma. Weight loss and avoidance of marked hip flexion can reduce the chance of persistent damage. Physical therapy will aid recovery of motor power. Femoral neuropathy usually improves.

Meralgia Paresthetica

Dysfunction of the lateral femoral cutaneous nerve is commonly caused by compression as it passes beneath the inguinal ligament. Obesity and pregnancy predispose to this disorder.

Meralgia paresthetica is the sensory syndrome of pain and sensory loss on the lateral thigh. Patients present with numbness and often pain on the lateral thigh. There are no motor deficits. Mcralgia paresthetica is differentiated from femoral neuropathy by the lateral distribution of the sensory findings and the absence of motor and reflex abnormalities.

NCS can be performed of the lateral femoral cutaneous nerve, but this is technically difficult even in the best circumstances. It is even more difficult in obese patients, wini arc at risk for entrapment of the lateral femoral cutaneous nerve.

Treatment is conservative. Weight loss usually is effective in preventing recurrence. Anticonvulsants and tricyclic antidepressants are effective for the neuropathic pain. Surgery is rarely performed, and there is controversy about its indications and effectiveness.

Sciatic Neuropathy

The sciatic nerve is most likely to be injured as it leaves the sciatic notch and descends into the upper leg. Compression can occur in patients suffering prolonged coma, especially in very thin patients. The sciatic nerve is also susceptible to injury from pelvic and sacral fractures, hip surgery or dislocation, needle injection injuries, and any penetrating injury.

Patients present with pain that is usually close to the level of the sciatic nerve lesion, although there may be substantial radiation of the pain. Loss of sensation is prominent below the knee, sparing the medial lower leg (the territory of the saphenous branch of the femoral nerve). Weakness can affect all muscles of the lower leg, but peroneal-innervated muscles are more likely to demonstrate weakness for two reasons. First, tibial-innervated foot extensors are so strong that substantial weakness would have to be present for weakness to be evident on examination. Second, the peroneal division of the sciatic nerve is more susceptible to compression injury than the tibial division, even high in the thigh.

Diagnosis is clinical, although EMG can show denervation in sciatic-innervated muscles; signs of denervation may not be seen until 4 weeks after injury. NCS usually is normal, but F-wave study may show slowing.

Treatment of sciatic compression is supportive, with avoidance of recurrent compression. Tricyclic antidepressants and anticonvulsants are commonly used for the neuropathic pain, and in some patients with acute sciatic injury, opiates are needed to deal with the pain in the short term. Surgical exploration and decompression are performed only when there is a clear structural lesion such as neural or perineural tumor.

Piriformis Syndrome

Piriformis syndrome is an uncommon condition in which the sciatic nerve is compressed by the piriformis muscle in the posterior glureal area. Hypertrophy of the piriformis muscle and other anatomic variants predispose to piriformis syndrome. This condition may affect not only the main sciatic trunk but also the superior gluteal nerve. Patients present with pain in the buttock radiating down the leg that is exacerbated by adduction and flexion of the hip. Pain tends to be aggravated by prolonged sitting, climbing steps, and other maneuvers that irritate the piriformis muscle.

Diagnosis is clinical. A patient with symptoms of sciatic neuropathy has typical clinical features on examination and no signs of radiculopathy or spinal stenosis. Spinal claudication can be confused with piriformis syndrome, so imaging of the spine is commonly performed and would be unremarkable.

Piriformis syndrome usually is managed with anti-inflammatory agents for acute exacerbations and physical therapy, which can be tailored to piriformis syndrome. Local injections of corticosteroids are given occasionally. Surgical treatment is rarely performed, and there is controversy about the indications and expected effectiveness of surgical treatment.

Peroneal Neuropathy

Peroneal neuropathy is commonly caused by compression of the nerve as it passes from the popliteal fossa across the fibular neck into the anterior compartment of the lower leg.

Patients often present with foot drop from weakness of the tibialis anterior. Diagnosis is confirmed by NCS and EMG, with slowing of peroneal nerve conduction across the region of entrapment, usually across the fibular neck. EMG shows active and chronic denervation in many patients because the common presenting complaint of foot drop indicates axonal damage.

Peroneal neuropathy may be produced by prolonged bed rest; hyperflexlon of the knee, usually from an occupational activity; coexisting peripheral neuropathy, predisposing to pressure palsy; fibrous band attached to the peroneus longus, predisposing to nerve compression; pressure in obstetric stirrups; prolonged crossed legs; and stretch and compression by the contracted tibialis anterior muscle in ballet dancers. A fibrous band beneath the superficial head of the peroneus longus is found in a much larger proportion of patients with peroneal entrapment than in normal patients (Dellon, Ebmer, and Swier 2002}.

Polyneuropathy

Peripheral neuropathy is a common cause of lower extremity pain and has a wide differential diagnosis. Among the most common causes are diabetes mellitus, familial neuropathy, metabolic neuropathies, and vasculitis.

Patients present with pain, which has a differing character depending on the type of neuropathy. Small fiber neuropathies present with burning pain that is often worse in the evening. Large fiber neuropathies present with dysesthesias and paresthesias, often with electric-shock-likc pains.

Diagnosis usually is confirmed by NCS and EMG. Axonal neuropathy is more common than demyelinating neuropathy. Occasionally, patients with a predominantly small fiber sensory neuropathy have a normal NCS. Laboratory studies for peripheral neuropathy typically are performed as outlined in Chapter 82.

Treatment is with tricyclic antidepressants or anti-convulsants. Amitriptyline is commonly used for patients with small fiber neuropathic pain. Anticonvulsants are predominantly used for patients with large fiber neuropathic pain. When patients have symptoms of both, treatment with gabapentin or oxearba/epinc can be helpful. Combination therapy with a tricyclic and anticonvulsant is occasionally beneficial. Pure analgesics occasionally are used on a nightly basis to assist with sleep.

Plcxopathy

Lumbosacral Plexitis

Lumbosacral plexitis is similar to brachial plexitis, a presumed autoimmune process, but may be less common. Management of idiopathic lumbosacral plexitis is supportive, with no medical intervention known to alter the course of the disease.

Anticonvulsants are commonly used. Corticosteroids and high-dose intravenous immunoglobulin are also used occasionally, although it is not clear that their benefits outweigh the risks. This is one situation m which pure opiates are commonly used because the duration of the pain usually is weeks rather than months. As the pain abates and the weakness is more prominent, the analgesics usually can be tapered and discontinued. Sustained-release opiates are especially helpful for patients with plexitis.

Diabetic Amyotrophy

Diabetic amyotrophy is lumbosacral plexopathy seen in diabetics. The disorder is thought to be an inflammatory vasculopathy, with damage that is probably immune mediated. Patients present with pain in the hip and thigh associated with weakness of the quadriceps, psoas, and adductors. The plexopathy is more often unilateral than bilateral,

Diagnosis is suggested by the proximal pain and weakness in a patient with known diabetes. This must be differentiated from lumbar radiculopathy and other structural lesions in the region of the plexus. NCS and EMG show coexistent peripheral polyneuropathy and denervation in proximal muscles including quadriceps, psoas, and adductors. MRI and CT do not show a structural lesion,

Treatment is symptomatic. Immune-modulating treatment with immune globulin may reduce the duration of the deficit but is not routinely administered. Most patients improve, although recovery is incomplete for most. The pain abates before the weakness.

Herpes Zoster

Reactivation of the varicella zoster virus produces pain in a single nerve root distribution. Patients present with severe neuropathic pain confined to one root distribution. Most patients develop a vesicular rash in the same cutaneous distribution, but the pain often begins before development of skin changes, and the skin changes are variable. Eventually, the rash crusts over and leaves some pigmentary changes. The pain abates as the inflammation recedes, although the patient may be left with sensory or motor deficit. Weakness can be evident in muscle innervated predominantly by a single nerve root.

Diagnosis is clinical, and when the rash is present at onset, structural imaging usually is not necessary. NCS and EMG often are not needed, but they may show denervation in affected muscles if there is persistent nerve root damage. Differential diagnosis is broader before development of the rash and includes radiculopathy from other causes including disc disease and osteophytes.

Treatment with antiviral agents such as acyclovir or famciclovir should begin within 72 hours of onset of symptoms. This may help to hasten recovery and reduce the incidence of postherpetic neuralgia. Corticosteroids often are used, and the chance of disseminated zoster is not appreciably higher in immune-competent patients. Corticosteroids reduce acute neuropathic pain and may reduce the incidence of postherpetic neuralgia. Corticosteroids are more important for zoster ophthalmicus than for lower limb zoster.

Claudication of Leg Arteries

Arterial claudication is discussed here because it is an important element in the differential diagnosis of spinal stenosis. Vascular disease of the iliac arteries and terminal branches produces marginal perfusion of lower limb muscles. Walking and other moderate activities exacerbate the ischemia, producing pain and weakness with exertion. In this feature, it may resemble spinal stenosis, but it is distinguished from vascular ischemia by a lack of back pain with claudication, lack of exacerbation of leg pain by recumbent lumbar extension, and vascular changes in the leg that should be absent in spinal stenosis.

Claudication is diagnosed by vascular imaging. Ultrasound can be a good screening test, but angiography can provide the definitive diagnosis and, in some people, treatment through angioplasty.

Lower Back Pain without Leg Pain

Mechanical Lower Back Pain

Mechanical lower back pain usually is caused by strain of paraspinal muscles and ligaments, with local inflammation. Muscle tears may also cause acute lower back pain. Therefore, mechanical lower back pain usually is a combination of bony, muscular, and connective tissue pain. Patients present with pain in the lower back without radicular symptoms and show no motor, sensory, or reflex abnormalities oil examination.

Diagnosis is by clinical features and exclusion of other causes. In the absence of objective neurological deficits, spinal MRI usually is not needed initially, but radiography may be performed to look for bony fractures or erosion, NCS and EMG usually are not indicated. In the absence of signs of bony or neural desttuction, conservative management may begin. If the patient does not respond to initial treatment, further study with MRI can be performed.

Mechanical lower back pain usually is treated by an initial period of rest of about 2 days followed by an increase in activity. Physical therapy can be very helpful during this initial treatment period. After the initial treatment, self-help guidelines are followed to reduce the likelihood of recurrent lower back pain. Muscle relaxants can help reduce the tightness of the muscles, which impedes movement and successful physical therapy.

Patients who do not respond to conservative management may benefit from epidural blocks. Surgery for "bulging discs" is occasionally performed on patients who have clinically apparent mechanical back pain, but the likelihood of response is not high.

Facet Pain Syndrome

Pain from the facet joints of the lumbosacral spine usually is not an isolated entity but rather a component of mechanical back pain. Pain results from long-term degenerative changes in the facet joints, usually caused by strain. Repetitive strenuous activity, excessive weight, and abnormal posture may predispose to facet pain. Acute trauma to the back may produce active joint inflammation that can be self-limited.

Facet pain usually is lateral to the spine and exacerbated by extending the spine or bending toward the affected side. Facet pain often is bilateral. Prolonged sitting or walking up steps, as well as retaining one position for a prolonged time, tend to exacerbate the pain.

Patients present with pain without motor, sensory, or reflex deficit unless there is coexistent radiculopathy or spinal stenosis. Diagnostic studies usually are normal. Chronic degenerative changes may be seen in radiographs, but with acute facet damage even radiographs may be unremarkable.

Facet pain usually is treated with anti-inflammatory agents and physical therapy. Change in exacerbating activity usually is helpful. Facet blocks can be performed but often are not necessary. As part of physical therapy, traction can change the character of weight bearing on the joints. Physical therapy can strengthen paraspinal muscles and improve posture.

Lumbar Spine Osteomyelitis

Vertebral osteomyelitis is most common in the lumbar region and may develop as a sequela of trauma, urinary tract infection, respiratory infections, and other causes of sepsis. Patients present with lower back pain, which may develop weeks after the inciting infection has abated. There is limitation of the motion of the spine and tightness of the paraspinal muscles. There is local lumbar spine pain with percussion tenderness.

Diagnosis is suspected in patients with lower back pain without radiation associated with systemic signs of infection {fever, elevated C-rcactivc protein, and elevated white blood cell count). MRI shows changes in the vertebral body and often in adjacent psoas muscle. Radiographs show degeneration of the disc margin of the vertebral body and disc space narrowing. Needle biopsy usually can reveal the

causative organism in most patients. Open biopsy usually is not necessary.

Treatment is with antibiotics and bed rest. Surgical debridement is needed for patients who do not respond to antibiotics.

Lumbar Spine Compression

Compression of the lumbar vertebral bodies occurs in the setting of acute trauma, osteoporosis, infection, or tumor. The latter may predispose the lumbar vertebrae to collapse with minimal trauma or stress. Patients present with severe lower back pain, usually without radicular symptoms. If the collapse results in bone compressing the nerve roots, radicular pain may develop in addition to the lower back pain. If there is compression of the cauda equina, diffuse weakness of the legs with sphincter disturbance can develop.

Diagnosis is suspected when a patient presents with lower back pain, which is exacerbated by movement, jarring, or certain postures such as bending or twisting. Radiographs and CT scan can easily show the bony destruction. Bone scan confirms the damage and can screen for other regions of damage. However, these studies usually cannot differentiate the cause of the compression. MRI is better able to make this differentiation, but it is not exact (Tan, Tsou, and Chee 2002).

Treatment consists of immobilization of the fracture site, which may include bracing. Pure analgesics often are needed, especially at night. Corticosteroids should be avoided if the cause is osteoporotic but can be very helpful for malignant vertebral collapse. Malignant collapse usually is treated by radiation therapy; surgery is performed if the spine is unstable because of the destruction or if there is no known primary tumor in a patient with presumed neoplastic cord involvement. The benefits of acute surgical decompression for neoplastic cauda equina compression are controversial.

/.*innl*w *Discitis*

Discitis is an inflammatory process affecting the intervertebral discs of any level, often occurring in the lumbar spine. Discitis usually is a benign nonbacterial process in children. In adults, bacterial infection is more common, especially mycobacterial. Discitis caused by recent lumbar surgery is likely to be caused by resistant bacteria.

Patients present with lower back pain with marked restriction of flexion of the spine because flexion increases pressure on the disc and disc space. Patients with benign discitis have no systemic symptoms, but patients with postoperative infection have overt signs of infection associated with elevated erythrocyte sedimentation rate and white blood cell count.

Diagnosis is suggested by the presence of severe lower back pain without a radicular component, with tenderness and spasm of the paravertebral muscles, associated with willingness of the patient to flex the hips but not the spine, The erythrocyte sedimentation rate usually is increased, even in benign discitis. Diagnosis can be confirmed by MRI, which shows decreased signal intensity of the disc on Tl-weighted images and increased signal on T2-weighted images. Bone scan shows increased uptake in the region of the infected disc. Radiographs show disc space narrowing. Adults with discitis may progress to fusion of the adjacent vertebral bodies. MRI is the most sensitive test for discitis but cannot differentiate septic from aseptic discitis. Therefore biopsy is needed if there is any reasonable concern that there is active bacterial infection.

Treatment begins with bed rest, and antibiotics are given to most patients. Surgery usually is not necessary; even tuberculous discitis is successfully treated with antibiotics in more than 80% of cases (Bhojraj and Nene 2002). The treatment is age-dependent, with resistant bacteria being more likely to be the cause of the discitis in older patients and benign discitis more likely in younger patients.

Neurological Investigations and Related Clinical Neurosciences

Chapter 35
Laboratory Investigations in Diagnosis and Management of Neurological Disease

Walter G. Bradley, Robert B. Daroff, Gerald M. Fenichel, and Joseph Jankovic

The history and examination are the keys to making the diagnosis in a patient with neurological disease (see Chapter 1), However, laboratory investigations are becoming increasingly important in diagnosis and management. A test may be diagnostic (e.g., the finding of cryptococci in the cerebrospinal fluid of a patient with a subacute meningitis, a low vitamin E level in a patient with ataxia and tremor, or a low serum vitamin $B|_2$ level in a patient with a combined myelopathy and neuropathy). A test may help assess the extent to which the nervous system is functioning normally. For instance, the finding of an abnormally delayed visual evoked response in one eye in a patient with possible multiple sclerosis will show that there has been demyelination in that optic nerve and may help confirm the diagnosis.

Laboratory tests should be directed to prove or disprove the hypothesis that a certain disease is responsible for the condition in the patient. They should not be used as a fishing expedition. Sometimes, a physician who cannot formulate a differentia] diagnosis from the clinical history and examination is tempted to order a wide range of tests to see what is abnormal. This approach is likely to add to the confusion because "abnormalities" may be found that have no relevance to the patient's complaints. For instance, many patients are referred to neurologists to determine whether they have multiple sclerosis because their physicians requested magnetic resonance imaging (MRI) of the brain for some other purpose, such as the investigation of headaches. If the MRI shows small T2-weightcd abnormalities in the centrum semiovale (changes that are seen in a proportion of normal older adults and in those with hypertension and diabetes), the neuroradiologist will report that the differential diagnosis includes multiple sclerosis, despite the fact that the patient has no multiple sclerosis symptoms.

Results of laboratory tests can be used to determine response to treatment. For instance, the high erythrocyte sedimentation rate in a patient with cranial arteritis falls with corticosteroid treatment and control of the condition. A rising erythrocyte sedimentation rate as the corticosteroid dosage is reduced indicates that the condition is no longer adequately controlled and that headaches and the risk of loss of vision will soon return,

It is important to use laboratory tests judiciously and to understand their sensitivity, specificity, risks, and costs. The physician must understand the hematological, biochemical, and bacteriological studies and the specific ncurodiagnostic investigations. These include clinical neurophysiology, neuroimaging, neurogenetic DNA testing, and the neuropathological study of biopsied tissue. The neurologist must also have a working knowledge of a number of related disciplines that bring specific investigations to aid in neurological diagnosis. These include neuroendocrinology, neuroepidemiology, neuroimmunology and ncurovirology, neuropsychology, nenro-ophthalmology, neuro-otology, and neurourology. Chapters 36 to 47 describe these disciplines and the investigations they offer.

Biopsy of skeletal muscle or peripheral nerve may be needed to diagnose neuromuscular diseases. A brain biopsy may be needed to diagnose a tumor, infection, vasculitis, or rarely degenerative disease of the nervous system (see Chapter 52).

USE OF LABORATORY TESTS IN DIAGNOSIS

The investigations used to diagnose neurological disease change rapidly. Genetic studies of DNA mutations in the blood now allow the diagnosis of Huntington's disease, a

growing number of spinocerebellar ataxias, a form of autosomal dominant dystonia (DYT1), Duchenne and other muscular dystrophies, many forms of Charcot-Marie-Tooth disease, Rett's syndrome, fragile X premutation, and a variety of other neurogenetic disorders (see http://www.genetests.org; http://www.geneclinics.org).

Blood tests for human immunodeficiency virus, Lyme disease, other infections, and various paraneoplastic syndromes affecting the nervous system can also be diagnostic. For example, there are three types of anti-Purkinje cell antibodies: anti-Yo (PCA-I), seen with tumors of breast, ovary, and adnexa; atypical anti-cytoplasmic antibody (anti-Tr or PCA-Tr), seen with Hodgkin's disease and tumors of the lung and colon; and PCA-2, identified mostly with lung tumors. In addition, there are three antineuronal antibodies: anti-Hu (ANNA-1), seen in possible conjunction with encephalomyelitis, small cell lung tumor, and tumors of breast, prostate, and neuroblastoma; anti-Ri (ANNA-2), found with tumors of breast and ovary; and atypical Anti-Hu, seen with tumors of lung, colon, adenocarcinoma, and lymphoma. Anti-CV2 (CRMP) antibody, expressed by oligodendrocytes, is associated with a syndrome of ataxia and optic neuritis and has been seen with small cell lung carcinoma.

Antibodies directed to a serum protein, Ma (anti-Mai and anti-Ma2), have been seen in patients with limbic encephalitis associated with testicular and other rumors. Antibodies directed to amphiphysin have been detected in patients with a cerebellar syndrome and small cell lung carcinoma. Antibodies against a glutamare receptor are rarely seen in patients with a pure cerebellar syndrome associated with cancer and a variety of autoimmune diseases. Antibodies against glutamic acid decarboxylase (anti-GAD) have been seen in patients with the stiff man syndrome and in patients with ataxia in a setting of an autoimmune disease such as diabetes, thyroid disease, and vitiligo. Antigliadin antibodies are helpful in evaluating patients with unexplained ataxia. As a result of advances in laboratory technology, genetic, immunological, and other blood tests arc expanding our ability to confirm the diagnosis of an increasing number of neurological disorders, obviating more invasive studies.

MRI is replacing computed tomography for most conditions, and magnetic resonance angiography and venography have largely replaced conventional arteriography. Many older investigations have been abandoned in favor of the newer, less invasive tests, as in the case of pneumoencephalography and direct puncture carotid angiography. The neurologist must know enough about each laboratory test to request it appropriately and to interpret the results intelligently. As a rule, it is unreasonable to order a laboratory test if the result will not influence diagnosis or management. Tests should be used to diagnose and treat patients, not to protect against litigation. When used judiciously, laboratory investigations serve both purposes; when ordered indiscriminately, they serve neither.

DIAGNOSTIC **YIELD** OF LABORATORY TESTS

When choosing tests, one must decide what information will help distinguish between the diseases on the differential diagnostic list. A test is justified if the result will confirm or rule out a certain disease or alter patient management, provided it is not too risky or painful. A lumbar puncture (LP) is justified if the patient has a clinical picture of meningitis, when it may confirm the diagnosis and probably reveal the responsible organism. However, one should not order culture and sensitivities on every sample of cerebrospinal fluid (CSF) sent to the laboratory if meningitis is not in the differential diagnosis. LP is not justified unless an abnormal finding will aid in the diagnosis.

The physician should provide full clinical information and highlight the questions for which answers are being sought from the investigations. The electrophysiologist will look more carefully for evidence of denervation in a certain myotome if the patient has a syndrome suggesting herniation of that disc. The neuroradiologist will take additional views to search for evidence of a posterior communicating artery aneurysm if the neurologist says there is a third nerve palsy in the patient with a subarachnoid hemorrhage.

INTERPRETATION OF **RESULTS** OF **LABORATORY INVESTIGATIONS**

Every biologic measurement in a population varies over a normal range, which usually is defined as plus or minus two or three standard deviations *(SD)* from the mean value. Two .SDs encompass 96% and three *SDs* encompass 99% of the measurements from a normal population. Even with three *SDs,* 1 normal person in 100 has a value outside the normal range. Therefore an abnormal result may not indicate the presence of a disease. It is also important to know the characteristics of the normal population used to standardize a laboratory test. Ranges that were normalized using adults are almost never correct for newborns and children. Ranges that were normalized using a hospital population may not be accurate for ambulatory people.

An abnormal test result may not be caused by the disorder under investigation. For example, an elevated serum creatine kinase concentration can result from recent electromyography or intramuscular injection, liver disease, or myocardial infarction, in addition to a primary muscle disease. A common problem for pediatric neurologists is centrotemporal spikes on the electroencephalogram (EEG) in a child with headache or learning disability who has never had a seizure. The EEG probably should not have been ordered in the first place. To give such a patient anticonvulsant drugs would compound poor judgment in diagnosis with worse judgment in management.

The neurologist should personally review test results that are ordered. In most instances, imaging studies should be reviewed, and where appropriate the neuroradiologist should participate. Similarly, for those experienced in pathology, biopsies may he reviewed with the neuropathologist. The neurologist who knows the patient may be of great help in interpreting the imaging or the pathologic study.

RISK AND COST OF INVESTIGATIONS

If two different tests provide equivalent informarion, the physician should choose the one that causes the least pain and risk. The costs of the two tests also should be considered. However, the diagnostic capability of the two tests may not be identical, and the more expensive test may not be better. The cost of a test must he considered in the context of the total cost of the illness. An expensive test that shortens a hospital stay may be cost-effective. The selection of laboratory tests and the sequence in which they are performed are important components of good medical practice.

Risk-to-Benefit Analysis

The neurologist makes judgments about the risk-to-henefit ratio of tests every day. The following examples can help clarify the principles used in making these decisions.

Lumbar Puncture

The risks and benefits of LP must be weighed in every patient. The LP may yield a specific diagnosis, such as subarachnoid hemorrhage or bacterial meningitis. It may help confirm the diagnosis, such as by showing raised intracranial pressure in benign intracranial hypertension. The LP may yield information that is not specific but aids in confirming the diagnosis. A fourfold increase in the CSF protein concentration (without an increase in the cell count) suggests one of the following diagnoses: an acute or chronic inflammatory demyelinative polyradiculoneuropathy, schwannoma or meningioma in the CSF pathways, or spinal compression that obstructs the flow of CSF (Froin's syndrome). A moderately increased number of lymphocytes, an increased *y*-globulin concentration, and oligoclonal bands in the CSF point to an immunologic process in the central nervous system, such as multiple sclerosis.

LP carries significant risks, the most disastrous being cerebral or cerebellar herniation. The LP may suddenly release elevated CSF pressure produced by an expanding supra tentorial lesion and may force the medial temporal lobe through the tentorium cercbelli to compress the midbrain or an expanding infratentorial lesion to push the cerebellar tonsils through the foramen magnum and compress the cervicomedullary junction (see Chapter 56B). These herniations can be fatal, and an LP should never be performed in a patient in whom there is a possibility of a space-occupying lesion without examination of the fundi for evidence of papilledema or of a recent computed tomography scan or MRI, at least in adult patients. LP is justified in some situations despite increased intracranial pressure. The prime example is acute meningitis, in which CSF examination is essential to establish the diagnosis and identify the organism. Other risks of LP include the production of meningitis as a result of contamination of the needle, a post-LP (low-pressure) headache, a spinal epidural hematoma in a patient with a coagulopathy, or the later development of an implantation dermoid (if the needle is inserted without the trocar).

Cerebral Arteriography

The question of whether to request percutaneous cerebral arteriography (see Chapter 37C) entails analysis of the risks and benefits for each patient. In a stroke patient, the study may show thrombotic or embolic occlusion of arteries and abnormalities of the arterial wall, including arteriosclerotic plaques, fibromuscular hyperplasia, medial dissection, and arteritis. It also may demonstrate an intracranial aneurysm or arteriovenous malformation. Any of these findings can clarify the diagnosis, treatment, and prognosis.

However, arteriography has risks. These include thrombosis of the artery at the site of puncture, dissection of a vessel wall, and cerebral infarction from thrombosis, embolism, or dissection. The likelihood that a patient being considered for cerebral arteriography will experience a particular complication is influenced by patient-specific factors, including age and the presence of arteriosclerosis and other diseases. These patient-specific probabilities of risk must be balanced against the potential benefits the angiographic information may provide, specifically the likelihood of demonstrating a treatable condition. Arteriography is definitely indicated in a previously healthy 55-year-old woman with an acute transient right hemiplegia and aphasia and a left carotid artery bruit, especially when carotid ultrasound studies suggest a 75% internal carotid artery stenosis. Invasive angiography clearly is not indicated in a 75-year-old woman with unstable congestive cardiac failure and advanced carcinoma of the breast who suffers a similar transient ischemic attack. Noninvasive techniques may he adequate for revealing the cause of the patient's symptoms, thereby avoiding the risks of catheter cerebral angiography. Carotid Doppler ultrasound and transcranial Doppler studies can be as reliable as angiography for demonstrating extracranial occlusive disease (Chapter 37D). Magnetic resonance angiography, a technique that images the main extracranial and intracranial vessels noninvasively, may obviate invasive angiography in patients with extracranial occlusive disease,

arteriovenous malformations, or a family history of intracranial aneurysms,

Craniotomy and Brain Biopsy

Brain biopsy carries significant risks that always necessitate discussion of the risk-to-benefit ratio with the patient and family. There are four main situations in which a brain biopsy may be considered: intraparenchymal brain tumor, intraparenchymal infectious lesion, intracranial vasculitis, and cerebral degenerative disease. The risk-to-be nef it analysis is influenced by the availability of computer-assisted stereotactic technology to obtain a biopsy through a burr hole. This allows tissue to be obtained for pathological and bacteriological study with little risk.

Open craniotomy for brain biopsy is significantly more risky. The patient's age, the presence of other diseases, lesion location, and the patient's wishes must all be taken into account when considering open brain biopsy. Hemorrhage, infection, postbiopsy epileptic seizures, and the production of a neurological deficit are the main risks of the procedure. The risk of a permanent neurological deficit is slight if the biopsy is from a "silent" area of the brain, such as the nondominam frontal lobe. It has a high risk of worsening the neurological deficit {unless that deficit is already total) if the lesion is located in the sensorimotor cortex, Bioca's speech area, or the internal capsule.

The treatability of the possible cause of the disease is the crucial benefit for inclusion in the risk-to-benefit analysis. If the neuroimaging study suggests a malignant glioma, for which treatment is ineffective, biopsy may not be considered justified. If it suggests a primary lymphoma of the brain, which is likely to respond to radiotherapy, then confirmatory biopsy may be recommended. If the differential diagnosis in a patient with acquired immunodeficiency syndrome includes toxoplasmosis or lymphoma, it may be reasonable to give antitoxoplasma therapy rather than perform a brain biopsy. Biopsy is needed only if the lesions do not respond to 2-3 weeks of treatment. Figure 35.1 presents a risk-to-be nef it analysis and prioritization of investigations for an 80-year-old man with a possible cerebral degeneration.

Cost-to-Benefit Analysis

Cost-to-benefit analysis often presents the physician with an ethical dilemma. The patient and family want everything possible done, no matter what the cost. Society complains that health care costs arc skyrocketing. Any effort at cost containment may place society's interests in conflict with those of the patient. MRI and magnetic resonance angiography are safer procedures than arteriography for diagnosing an arteriovenous malformation but may be more costly. Where only limited funding is available for health care, the money must be used to purchase the most cost-effective care for the greatest number of people. Clearly, physicians should acquaint themselves with the costs of the tests they order.

PRIORITIZATION OF TESTS

The order in which to undertake tests depends on their diagnostic specificity, invasiveness, and benignity. Therefore most blood studies are performed before neuroimaging and LP. Sometimes a therapeutic trial is used as an investigation. For instance, in a patient with possible herpes simplex encephalitis, risk-to-benefit analysis indicates that an FFG, an MRI scan of the brain, and an LP with polymerase chain reaction study of the CSF for *Herpes simplex* are better than a brain biopsy. With typical changes of herpes simplex encephalitis and a response to a therapeutic trial of acyclovir, brain biopsy may be avoided. Time may be used as an investigation. For instance, occasionally it may be difficult to differentiate a stroke from a tumor on the basis of clinical history, examination, and neuroimaging studies. A reasonable plan is to follow the patient and repeat the scan in 2-4 weeks rather than immediately performing a brain biopsy.

QUANTITATIVE DIAGNOSTIC METHODS

When a new laboratory test is developed, its sensitivity (the frequency with which the test is abnormal in patients with a particular disease) and specificity (the frequency with which the test is abnormal in people without the particular disease) must be determined. If a test is very sensitive but has poor specificity, then it may not be useful for diagnosis. For instance, the erythrocyte sedimentation rate is very sensitive in cranial arteritis, but is elevated in so many other conditions that it cannot be used to diagnose the condition. Of more use is a test that is highly specific even if it has a lower sensitivity. For instance, the acetylcholine receptor antibody titer is raised in only about 60% of patients with myasthenia gravis but in almost no other condition. The specificity and sensitivity can be used to quantitate the extent to which a test result makes a diagnosis of a certain disease more or less likely.

DECISION ANALYSIS

Diagnostic acumen and treatment success are the hallmarks of the experienced neurologist. This acumen can be taught and can be learned from years of practice. Decision analysis is a method developed to provide insight into the processes of diagnosis and management of a

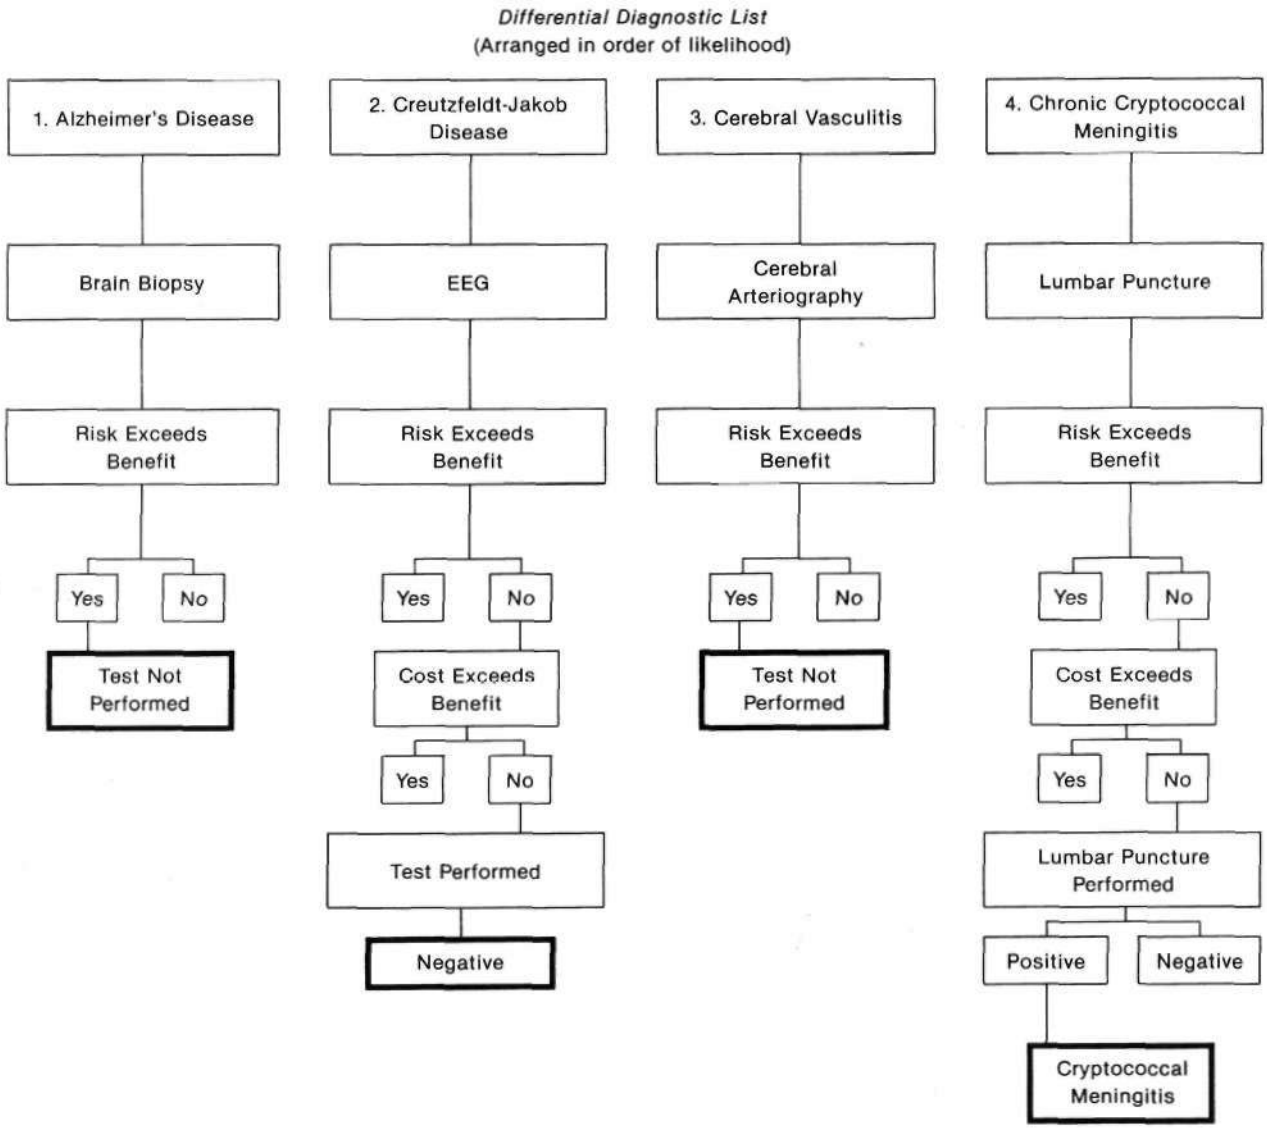

FIGURE 35.1 Flowchart of the decision process involved in choosing investigations to elucidate the diagnosis in an 80-year-old man with a 3-month history of a progressive dementia. The differential diagnosis includes Alzheimer's disease, Creutzfcldr-Jakob disease, cerebral vasculitis, and cryptococcal meningitis. A brain biopsy was not performed, and an electroencephalogram (EEG) did not show typical changes of Creutzfeldt-Jakob disease. The analysis suggests that arteriography is justified to look for a vasculitis, but the lumbar puncture revealed cryptococcal meningitis before the angiography was performed.

complex disease, where often insufficient data are available. Plame reviewed Bayesian methods and decision analysis in the first edition of this textbook (Plante 1991). Decision analysis can help identify areas of uncertainty in currently accepted diagnostic and management methods. Decision analysis forces the clinician to make quantitative estimates of each of the many factors entering into a clinical decision and to calculate the risk-to-bene fit ratio of each management decision. Decision analysis is an excellent teaching tool. Because crucial quantitative data often ate not available, this necessitates a search for such data, either from the literature or through new research.

RESEARCH INVESTIGATIONS AND TEACHING HOSPITALS

Because many readers are neurologists in training, we shall briefly mention the use of investigations in teaching and research centers. Clinical research is closely regulated in most parts of the world, and research investigations cannot be performed until the protocol is approved by an institutional review board or an ethics-in-research committee. The peer review process is designed to ensure that the risks of the research study are justified, taking into account thk- patient's particular disease and the likely benefits of the research. The institutional review board ensures that the

patient receives full information contained in an informed consent form and understands the risks of the study and what is likely to he learned from the research. No patient should be coerced, knowingly or unknowingly, into participating in a research procedure. Once the institutional review hoard gives permission for a research project, it continues to monitor the study to ensure that the research conforms to the protocol.

In a teaching hospital, the attending or consultant physician is legally and ethically responsible for the care provided to a patient by physicians in training. The attending neurologist must ensure that every investigation is justified for diagnostic and management purposes. We are all legally and ethically bound to ensure that the patient understands the reason for each investigation and gives informed consent. The neurologist in training must learn to use tests judiciously and not to perform them simply for curiosity ot education. The two-way discussion with more senior neurologists about the rationale, risk-to-bene fit, and cost-to-benefit analyses of each investigation is an important part of the learning process.

PATIENT CONFIDENTIALITY

Some diagnostic tests, such as the DNA genetic test for Huntington's disease, and the test for human immuno-deficiency virus 1, necessitate prior counseling about the implications of these tests for the individuals and their families. Results of such tests should be kept separate from the rest of the chart to maintain strict confidentiality for the patient.

PLACE OF LABORATORY INVESTIGATIONS IN NEUROLOGICAL DISEASE MANAGEMENT

The standard neurological examination is designed more to detect abnormal function for diagnostic purposes than to quantify the neurological abnormalities. One would like to use laboratory investigations to measure the response of the disease to treatment. Laboratory investigations usually are quantitative and may be helpful in managing disease. Generally, abnormal laboratory values return toward normal as a disease improves or become increasingly abnormal as it worsens. The vital capacity in a patient with (luillam-Barre syndrome is an example in which the impairment in vital capacity decreases as the disease improves. This is not always true, however. In Duchenne's muscular dystrophy, the scrum creatine kinase concentration decreases as the disease worsens because fewer muscle fibers remain to release enzyme inro the scrum. In myasthenia gravis the patient's condition can go from minimal weakness to total paralysis unrelated to the titers of acetylcholine receptor antibodies in the blood. Therefore monitoring laboratory values cannot always be used as an index of disease severity or response to treatment. Other limitations on the use of laboratory tests to monitor disease progression include sampling errors and test sensitivity and specificity.

Quantitative tools provide important information for measuring a patienr's status objectively during the course of a disease. They can be as simple as visual acuity measurement, how many serial numbers from 1 to 100 a patient can count on a single breath, or the frequency and severity of headaches each month. Alternatively, they can be sophisticated measurements, such as the force of maximum voluntary muscle contraction or the temperature perception threshold for an area of skin. They can be Eliminated scores of semiquantitative assessments such as the Kurtzke scale devised to follow patients with multiple sclerosis, the Norris score for amyotrophic lateral sclerosis, or the Z scores of muscle strength. Quantitative measures of neurological function allow much better assessment of the response of a disease to treatment than does the routine neurological examination.

Chapter 36
Clinical Neurophysiology

A. ELECTROENCEPHALOGRAPHY AND EVOKED POTENTIALS

Ronald G. Emerson and Timothy A. Pedley

The techniques of applied electrophysiology are of practical importance in the diagnosis and management of certain categories of neurological disease. Modern instrumentation pi: mi its the selective investigation oi various functional aspects of the centra! and peripheral nervous systems. Electroencephalography (EEG) and evoked potentials are measures of electrical activity generated by the central nervous system. Despite the introduction of positron emission tomography, functional magnetic resonance imaging, and magnetoencephalography (MEG), EEG and evoked potentials are the only readily available laboratory tests of brain physiology. As such, they are generally complementary to anatomical imaging techniques such as computed tomography (CT) or magnetic resonance imaging, especially when it is desirable to document abnormalities that are not associated with detectable structural alterations in brain tissue, furthermore, EEG provides the only continuous measure of cerebral function over time.

This chapter is not intended as a comprehensive account of all aspects of EEG and evoked potentials. Rather, it describes the scope and limitations of electrophysiological testing as currently used.

ELECTROENCEPHALOGRAPHY

Physiological Principles of EEG

Electroencephalographic signals are generated by the cerebral cortex. Spontaneous electroencephalographic activity is a reflection of currents flowing in the extracellular space. These currents are generated by the summation of excitatory and inhibitory synaptic potentials occurring on thousands or even millions of cortical neurons. Individual action potentials do not contribute directly to electroencephalographic activity. Conventional EEG is a continuous graph of the spatial distribution of changing voltage fields at the scalp surface recorded over time that result from ongoing synaptic activity in the underlying cortex.

In addition to reflecting the spontaneous intrinsic activities of cortical neurons, EEG depends on important afferent inputs from subcortical structures, including the thalamus and brainstem reticular formation. For example, thalamic afferents probably are responsible for entraining cortical neurons to produce the rhythmic oscillations that characterize such normal patterns as the alpha rhythm and sleep spindles. Similarly, an electroencephalographic abnormality may result directly from disruption of cortical neural networks or indirectly from modification of subcortical inputs onto cortical neurons.

EEG is not the same as electrocorticography because not all potentials recorded at the cortical surface are detectable at the scalp. In the case of epileptiform activity, it has been estimated that 20-70% of cortical spikes do not appear on the electroencephalogram, depending on the region ot cortex involved. This is largely because of the pronounced voltage attenuation that occurs in overlying cerebrospinal fluid and dura. Large areas of cortex must be involved in similar activity for a discharge to appear on the electroencephalogram. Furthermore, potentials involving surfaces of gyri are recorded more readily than are potentials arising in the walls and depths of sulci. Activity generated over the lateral convexities of the hemispheres is recorded more

accurately than is activity coming from interhemispheric, mesial, or basal areas.

The following considerations limit the usefulness of EEC First, surface recordings cannot be used to determine unambiguously the nature of synaptic events contributing to a particular electroencephalographic wave. Second, EEG is rarely specific as to cause because different diseases and conditions produce similar electroencephalographic changes. In this regard, EEG is analogous to findings on the neurological examination; hemiplegia caused by a stroke cannot be distinguished from one caused by a brain tumor. Third, many potentials occurring at the brain surface involve such a small area or are of such low voltage that they cannot be detected at the scalp. EEG results may be normal despite clear indications from other data of focal brain dysfunction. Finally, abnormalities in brain areas inaccessible to EEG electrodes (some cortical areas and almost all subcortical and brainstem regions) do not affect EEG directly but may exert remote effects on patterns of cortical activity.

Normal Electroencephalographic Activities

Spontaneous fluctuations of voltage potential at the cortical surface are in the 100- to 1000-mV range but at the scalp arc only 10-100 uV. Different parts of the cortex generate distinct potential fluctuations, which also differ in the waking and sleep states.

In most normal adults, the waking pattern of electroencephalographic activity consists mainly of sinusoidal oscillations occurring at 8-12 Hz, which are most prominent over the occipital area (alpha rhythm) (Figure 36A.1A). The alpha rhythm is attenuated (or blocked) by eye opening, mental activity, and drowsiness. Activity faster than 12 Hz (beta activity) normally is present over the frontal areas and may be especially prominent in patients receiving barbiturate or benzodiazepine drugs. Activity slower than 8 Hz is subdivided into delta activity (1-3 Hz) and theta activity (4-7 Hz). Adults normally may show a small amount of theta activity over the temporal regions; the percentage of intermixed theta frequencies increases after age 60. Delta activity is not present normally in adults when they are awake but appears when they fall asleep (Figure 36A.1B). The amount and amplitude of slow activity (theta and delta) correlate closely with the depth of sleep. Slow frequencies are abundant on the electroencephalograms of newborns and young children, but they disappear progressively with maturation.

Common Types of Electroencephalographic Abnormalities

Focal Arrhythmic (Polymorphic) Slow Activity

Polymorphic slow activity is irregular or amorphous activity in the delta (1-4 Hz) or theta (4-7 Hz) range, which, when continuous, has a high correlation with a localized cerebral lesion such as infarction, hemorrhage, tumor, or abscess. Intermittent focal slow activity also **may** indicate localized parenchymal dysfunction but is less predictive than polymorphic slow activity.

Intermittent Rhythmic Stow Waves

Paroxysmal bursts of generalized, bisynchronous rhythmic theta or delta waves usually indicate thalamocortical dysfunction and arc seen with metabolic or toxic disorders, obstructive hydrocephalus, and deep midline or posterior fossa lesions and also as a nonspecific functional disturbance in patients with generalized epilepsy. Focal bursts of rhythmic waves laterali/ed to one hemisphere usually indicate deep (typically thalamic or periventricular) abnormalities, often structural.

Generalized Arrhythmic (Polymorphic) Slow Activity

Diffuse disturbances in background rhythms marked by excessive slow activity and disorganization of waking EEG patterns are seen in encephalopathies of metabolic, toxic, or infectious origin and in people with brain damage caused by a static encephalopathy.

Voltage Attenuation

Voltage attenuation is caused by cortical disease. Generalized voltage attenuation usually is associated with diffuse depression of function such as after anoxia or with certain degenerative diseases (e.g., Huntington's disease). The most severe form of generalized voltage attenuation is electrocerebral inactivity, which is corroborative evidence of brain death in the appropriate clinical setting. Focal voltage attenuation reliably indicates localized cortical disease such as porencephaly, atrophy, or contusion or an extra-axial lesion, such as a meningioma or subdural hematoma.

Epileptiform Discharges

Epileptiform discharges are spikes or sharp waves that occur interictally in patients with epilepsy and sometimes in people who do not have seizures but have a genetic predisposition to epilepsy. Epileptiform discharges may be focal or generalized depending on the seizure type.

Recording **Techniques**

The following section summarizes the recording methods in common use. Details are provided in the American EEG Society's guidelines (1994).

A series of small gold, silver, or silver-silver chloride discs are symmetrically positioned over the scalp on both

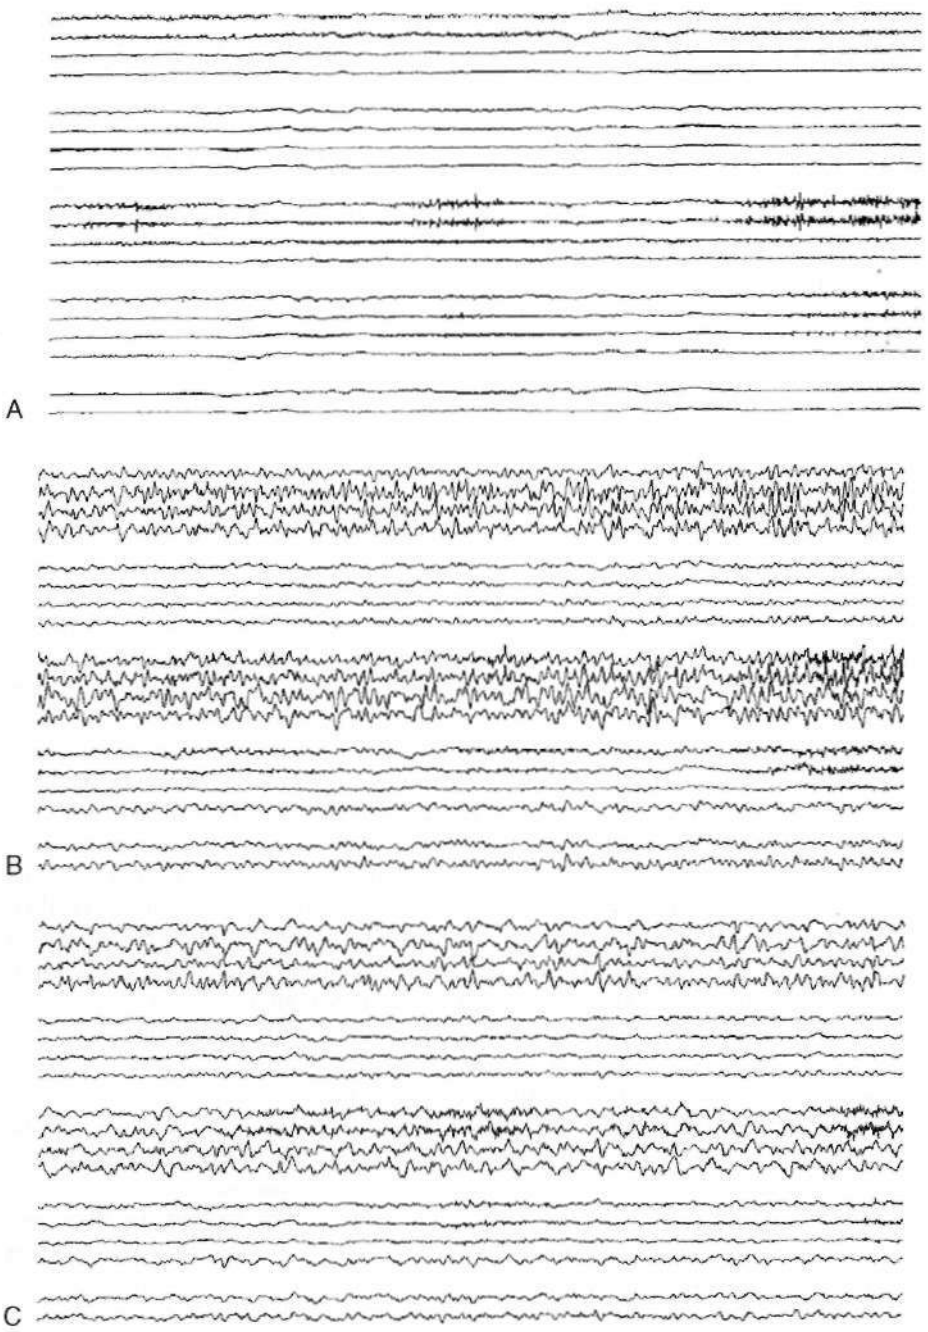

FIGURE 36A.1 Samples of normal electroencephalography from two patients. (**A**) Waking activity is characterized by a 9-Hz alpha rhythm that attenuates when the eyes are opened (EO) and returns when eyes are closed (EC). (**B**) Stage 2 sleep is characterized by 2- to 5-Hz background activity, on which are superimposed vertex waves and sleep spindles.

sides of the head in standard locations (the International Ten-Twenty system).

These recording electrodes are interconnected in chains, and the potential difference between pairs of electrodes is recorded. In practice, 16 or more channels (one pair of electrodes equals one amplifier channel) of electroencephalographic activity arc recorded simultaneously. Electrode pairs are interconnected in different arrangements called montages to permit a comprehensive survey of the brain's electrical activiry. Typically, montages are designed to compare symmetrical areas of the two hemispheres or anterior and posterior regions or parasagittal and temporal areas in the same hemisphere.

Spontaneous brain wave activity is recorded for 30-45 minutes. In addition, most patients are routinely subjected to two types of activating procedures: hyperventilation and photic stimulation. In some patients, these techniques provoke abnormal focal or generalized alterations in activity that are of diagnostic importance and would otherwise go undetected (Figure 36A.2),

Sleep, sleep deprivation, and placement of additional electrodes at other recording sites are useful in detecting specific kinds of epileptiform potentials.

Other maneuvers are carried out depending on the clinical question posed. For example, epileptiform activity may occasionally be activated only by movement or specific

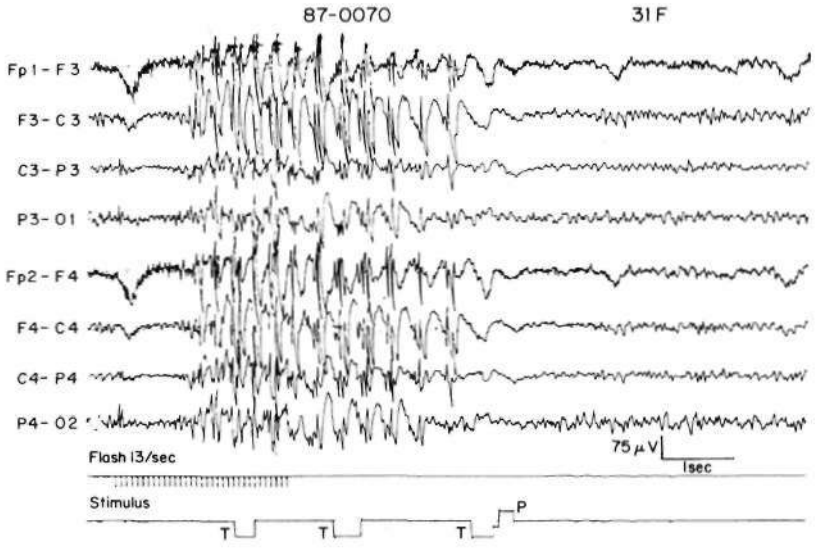

FIGURE 36A.2 Intermittent stroboscopic light stimulation at 13 per second elicited generalized bursts of 4- to 5-Hz spike-wave activity, called a photoparoxysmal (photoconvulsive) response. The spike-wave paroxysm was associated with a brief absence, as documented by the patient's (P) inability to respond to a tone given by the technologist (T). Normal responsiveness returned immediately on cessation of the spike-wave activity. The remainder of the electroencephalogram was normal.

sensory stimuli. Vasovagal stimulation may be important in some types of syncope.

Clinical Uses of Electroencephalography

EEG assesses physiological alterations in brain activity. Many changes are nonspecific, but some are highly suggestive of specific entities (epilepsy, herpes encephalitis, or metabolic encephalopathy). EEG is useful also in following the course of patients with altered states of consciousness and in certain circumstances may provide prognostic information. It can be important in determining brain death,

EEG is not a screening test but is ordered to answer a particular problem posed by the patient's condition. Sufficient clinical information must be provided so that an appropriate test can be designed that allows a meaningful electrographical clinical correlation. The question to be addressed by EEG should be specifically stated on the request.

EEG interpretation should be rational and based on a systematic analysis that uses consistent parameters that permit comparisons to be made with findings expected from the patient's age and circumstances of recording. High-quality recording is needed for accurate interpretation. Trained technologists understand the importance of meticulous electrode application, proper use of instrument controls, recognition and elimination of artifacts where possible, and appropriate selection of recording montages to allow optimal display of cetebral electrical activity.

Epilepsy

EEG usually is the most helpful laboratory test when a diagnosis of epilepsy is considered. Because the onset of seizures is unpredictable and their occurrence is infrequent in most patients, EEG usually is obtained when the patient is not having a seizure. Fortunately, electrical abnormalities in EEG occur in most patients with epilepsy even between attacks. However, interictal findings must be interpreted with caution. Although certain patterns of abnormality may support a diagnosis of epilepsy, most epileptiform discharges correlate poorly with the frequency and likelihood of recurrence of epileptic seizures. In certain cases, they may not even help in distinguishing epilepsy from other paroxysmal but nonepilcptic conditions. Furthermore, a substantial number of patients with unquestionable epilepsy have consistently normal electroencephalograms. The most convincing proof that a patient's episodic symptoms are epileptic is obtained by recording an electrographical seizure discharge during a typical behavioral attack. Although ictal tracings greatly increase EEG sensitivity in assessing the pathophysiology of specific behavioral episodes, the clinician must still be aware of limitations inherent in such recordings.

The only elcctroenccphalographic finding that has a high correlation with epilepsy is epileptiform activity, consisting of spikes and sharp waves that arc clearly distinct from ongoing background activity. Both clinical and experimental evidence supports a specific association between epileptiform discharges and seizure susceptibility. Only 2% of nonepilcptic patients have epileptiform electroencephalograms, whereas as many as 90% of patients with epilepsy show epileptiform activity, depending on the circumstances of the recording and the number of studies obtained.

In addition to epileptiform patterns, electroencephalograms in patients with epilepsy often show excessive focal or generalized slow-wave activity. Less often, asymmetries of frequency or voltage exist. These findings are not unique to epilepsy and may be seen in other conditions such as static encephalopathies, brain tumors, migraine, and trauma. In patients with unusual spells, nonspecific changes

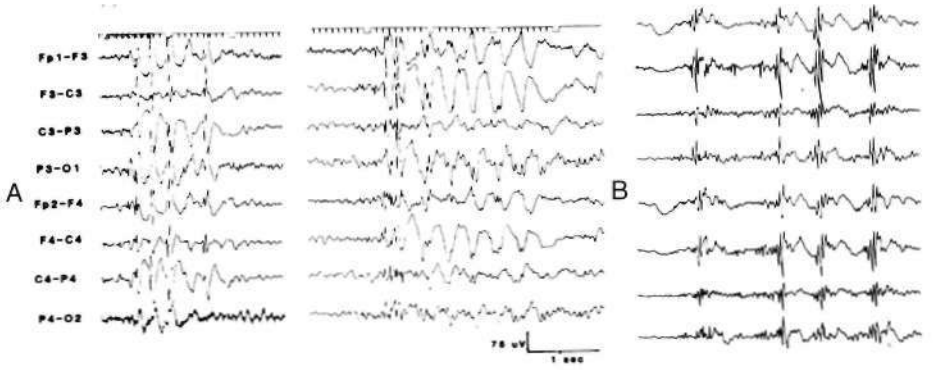

FIGURE 36A.3 Examples of generalized spike-wave patterns from different patients with primary generalized (idiopathic) epilepsy. The patient in (**A**) had mainly tonic-clonic seizures, with occasional absence attacks. The patient in (**B**) had juvenile myoclonic epilepsy.

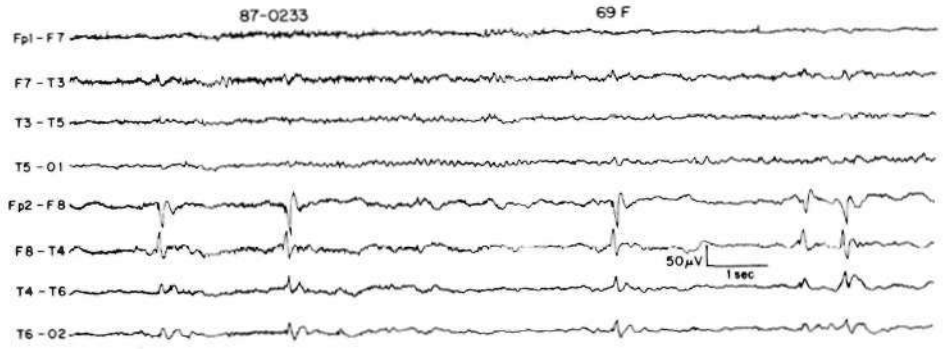

FIGURE 36A.4 Focal right anterior temporal spikes occurring in a 69-year-old woman with complex partial seizures after a stroke involving branches of the right middle cerebral artery.

on EEG should be weighed cautiously and not considered direct evidence for a diagnosis of epilepsy. On the other hand, when clinical data are unequivocal or when epileptiform discharges occur as well, the degree and extent of background electroencephalographic changes may provide information important for judging the likelihood of an underlying focal cerebral lesion, a more diffuse encephalopathy, or a progressive neurological syndrome. Additionally, electrocncephalographic findings may help determine prognosis and aid in the decision to start or discontinue antiepileptic medication.

The type of epileptiform activity on EEG is helpful in classifying a patient's seizure type correctly and sometimes in identifying a specific epileptic syndrome (see Chapter 73). Clinically, generalized tonic-clonic seizures may be generalized from the outset or secondary to spread from a focus. Lapses of awareness with automatisms may be a manifestation of a generalized nonconvulsive form of epilepsy (absence seizures) or of focal epileptogenic dysfunction (temporal lobe epilepsy). The initial clinical features of a seizure may be uncertain because of postictal amnesia or nocturnal occurrence. In these and similar situations, EEG can provide information crucial to the correct diagnosis and appropriate therapy.

In generalized seizures of nonfocal origin, KEG typically shows bilaterally synchronous diffuse bursts of spikes and spike-wave discharges (Figure 36A.3). All generalized epileptiform patterns share certain common features, although the exact expression of the spike-wave activity varies depending on whether the patient has pure absence, tonic-clonic, myoclonic, or atonic-astatic seizures. EEG also may distinguish between primary and secondary generalized epilepsy. In primary generalized epilepsy, no demonstrable cerebral disease exists, whereas in secondary generalized epilepsy, evidence of brain damage can be found. Typically, primary (idiopathic) generalized epilepsy is associated with normal or near normal electroenccphalographic background rhythms, whereas secondary (symptomatic) epilepsy is associated with some degree of generalized slow-wave activity.

Consistently focal epileptiform activity is the signature of pun nil (focal) epilepsy (Figure 36A.4). With the exception of the benign focal epilepsies of childhood, focal epileptiform activity results from neuronal dysfunction caused by demonstrable brain disease. The waveform of focal epileptiform discharges is largely independent of localization, but a reasonable correlation exists between spike location and the type of ictal behavior. Anterior temporal spikes are almost always associated with complex partial seizures, rolandic spikes with simple motor or sensory seizures, and occipital spikes with primitive visual hallucinations or diminished visual function as an initial feature.

In addition to distinguishing epileptiform from non-epilcptiform abnormalities, electroencephalography analysis sometimes identifies specific electroclinical syndromes such as hypsarrhythmia associated with infantile spasms (West's syndrome) (Figure 36A.5); 3-Hz spike-and-wave

FIGURE 36A.5 Electroencephalographic pattern, called hypsarrhythmia, from an 8-month-old boy with infantile spasms. Background activity is high voltage and unorganized with abundant multifocal spikes.

activity associated with typical absence attacks (petit mal epilepsy) (Figure 36A.6); generalized multiple spikes and waves (polyspike wave) associated with myoclonic epilepsy, including so-called juvenile myoclonic epilepsy of Janz (see Figure 36A.3B); generalized sharp and slow waves (slow spike and wave) associated with Lennox-Gastaut syndrome (Figure 36A.7); central-midtcmporal spikes associated with benign rolandic epilepsy (Figure 36A.8); and periodic lateralized epileptiform discharges associated with acute destructive cerebral lesions including hemorrhagic cerebral infarction, a rapidly growing malignancy, or herpes simplex encephalitis (Figure 36A.9).

The increased availability of special monitoring facilities for simultaneous video and EEG recording and ambulatory EEG recorders has improved diagnostic accuracy and the reliability of seizure classification. Prolonged, continuous recordings through one or more complete sleep-wake cycles are the best way to document ictal episodes and should be considered in patients whose interictal electroencephalograms are normal or nondiagnostic and in clinical dilemmas that can be resolved only by recording actual behavioral events. Although electroencephalograph ic documentation of an ictal discharge establishes the epileptic nature of a corresponding behavioral change, the converse is not necessarily true. Sometimes the recording is so obscured by muscle or movement artifacts that it is impossible to know whether any electroencephalographic change has occurred. In these circumstances, postictal slowing usually indicates an epileptic event if similar slow waves are not present elsewhere in the recording and if the electroencephalogram subsequently returns to its baseline condition. In addition, focal seizures that are not accompanied by altetation in consciousness occasionally have no detectable scalp correlate. On the other hand, persistence of alpha activity and absence of slowing during and after an apparent convulsive episode are inconsistent with an epileptic generalized tonic-clonic seizure.

Focal Cerebral Lesions

The use of FKG to detect focal cerebral disturbances has declined because of the development and widespread availability of computerized anatomical imaging techniques. Nonetheless, EEG has a role in documenting focal physiological dysfunction in the absence of

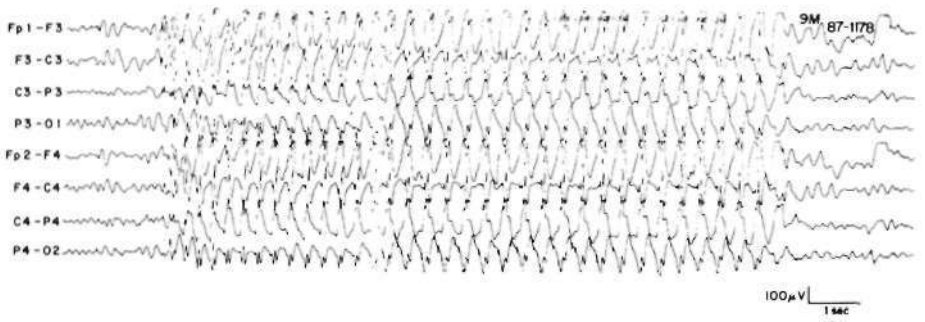

FIGURE 36A.6 A 3-Hz spike-and-wave paroxysm from a 9-year-old boy with absence seizures (petit mal epilepsy). During this 12-second discharge, the child was unresponsive and had rhythmic eye blinking.

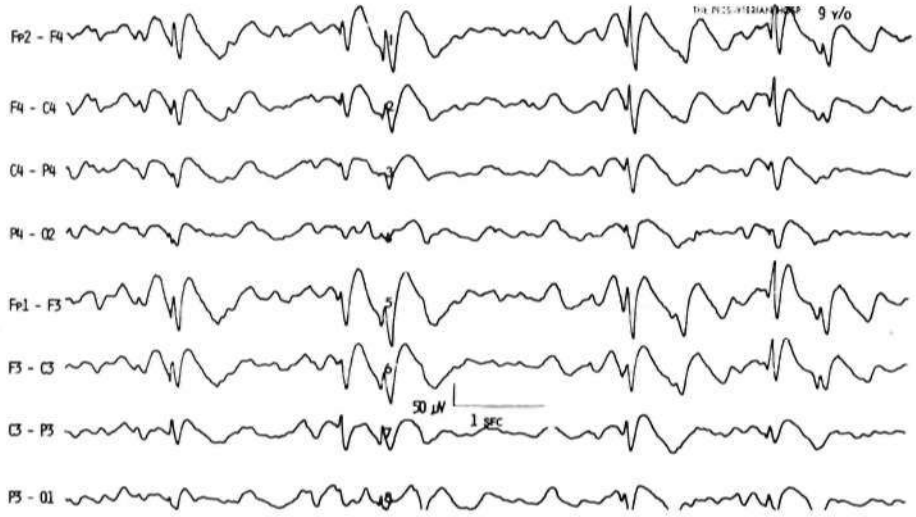

FIGURE 36A.7 Generalized sharp- and slow-wave discharges in a 9-year-old child with mental retardation and uncontrolled typical absence, tonic, and atonic generalized seizures. This constellation of clinical and electroencephalographica I features constitutes the Lennox-Gastaut syndrome.

discernible structural disorders and in evaluating the functional disturbance produced by known lesions.

Focal delta activity is the usual electroencephalographic sign of a focal brain disturbance. A structural lesion is likely if the delta activity is continuously present; shows variability in waveform, amplitude, duration, and morphology (known as arrhythmic or polymorphic activity); and persists during changes in wake-sleep states (Figure 36A, 10). The localizing value of focal delta is increased when it is topographically discrete or associated with depression or loss of superimposed faster background frequencies. Superficial lesions tend to produce limited electroencephalographic changes, whereas deep cerebral lesions produce hemispheric or even bilateral delta activity.

Bilateral paroxysmal bursts of rhythmic delta waves with frontal predominance (Figure 36A.11) were once attributed to subfrontai, deep midline, or posterior fossa lesions. They are now known to be nonspecific and seen mote often with diffuse encephalopathies. Focal or lateralized intermittent bursts of rhythmic delta waves as the prominent electroencephalographic abnormality suggest a deep supra tentorial (periventricular or diencephalic) lesion.

The character and distribution of the electroencephalographic changes caused by a focal lesion depend on its size, its distance from the cortical surface, the specific structures involved, and its acuity. A small stroke critically located in the thalamus may produce widespread hemispheric slowing and alteration in sleep spindles and alpha rhythm regulation. The same sized lesion located at the cortical surface produces few or no electroencephalographic findings.

Single lacunae usually produce little or no change in the electroencephalogram. Similarly, transient ischemic attacks not associated with chronic cerebral hypoperfusion or imminent occlusion of a major vessel do not significantly

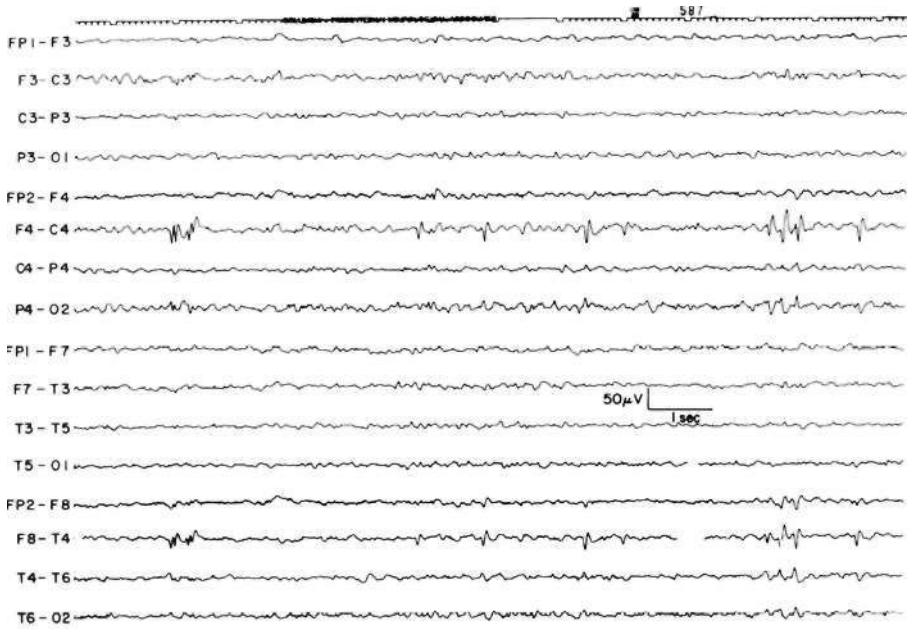

FIGURE 36A.*8* Electroencephalogram obtained during drowsiness in a 10-year-old hoy with benign rolandic epilepsy. Stereotyped diphasic or triphasic sharp waves occur in the right centtal-parietal and midtemporal regions.

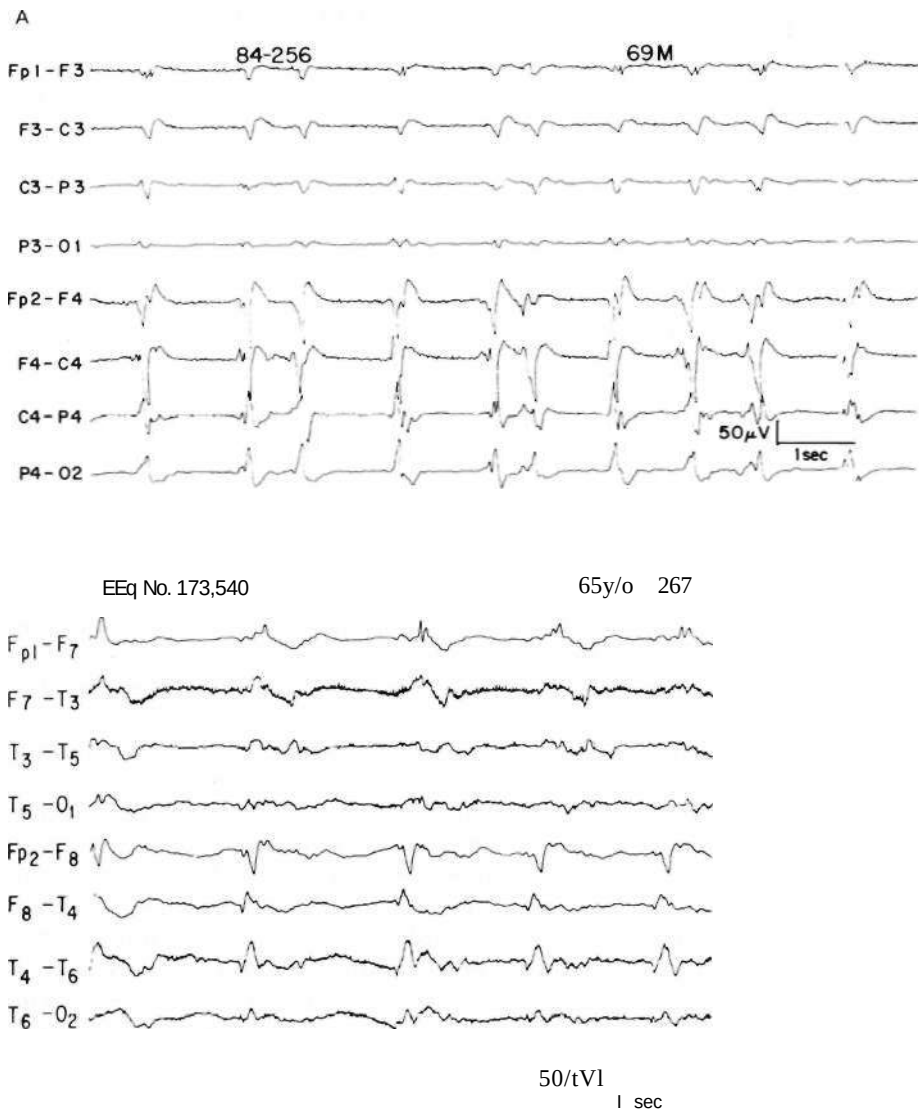

FIGURE 36A.9 Two examples of periodic lateralized epileptiform discharges (PLEDs). (A) Right parasagittal I'LEDs in a 69-year-old man with severe brain damage caused by meningitis with multiple cerebral infarctions. (B) A 65-year-old woman with herpes simplex encephalitis. PLEDs ate bilateral but have *a* right-sided predominance.

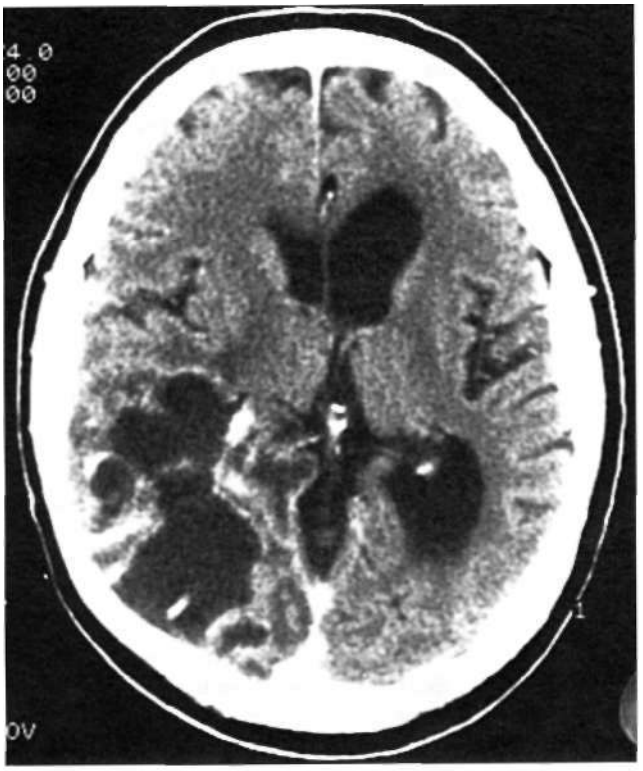
affect the electroencephalogram outside the symptomatic period. Superficial cortical or large, deep hemispheric infarctions usually are associated with localized electro-encephalograph ic abnormalities.

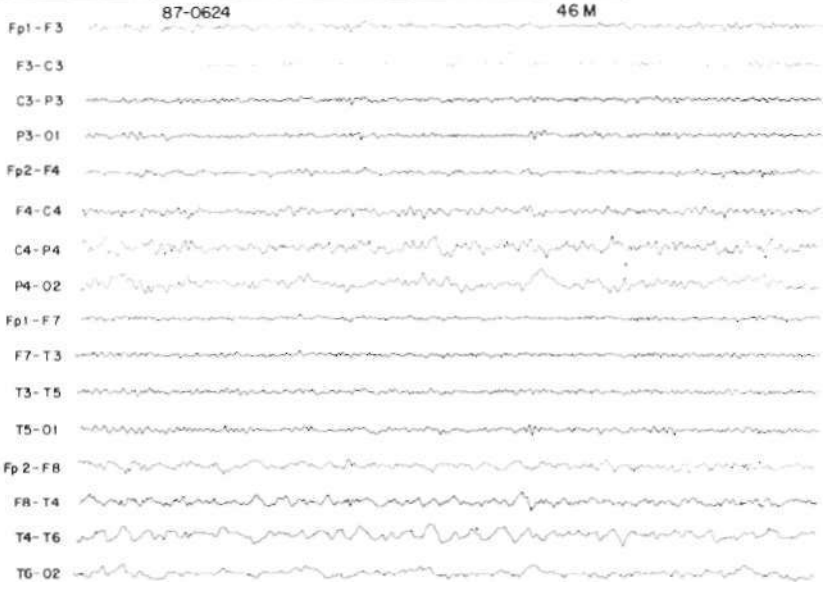
Focal electroencephalographic changes (and other non-epileptiform abnormalities) are common in migraine. The likelihood of an abnormal electroencephalogram and the severity of the abnormality are related to the timing and character of the migraine attack. Focal clectrocnccphalo-graphic abnormalities are more likely with complicated rather than with common migraine and during rather than between headaches, Electroencephalographic changes seen with brain tumors arc caused by disturbances in bordering brain parenchyma; tumor tissue is electrically silenr. Focal electroencephalographic changes are caused by interference with patterns of normal neuronal synaptic activity, by destruction or alteration of the cortical neurons, and by metabolic effects caused by changes in blood flow, cellular metabolism, or the neuronal microenvironment. More diffuse elrerriH'iiu/pha log rapine changes are the consequence of increased intracranial pressure, shift of midline structures, or hydrocephalus. EEG is especially helpful in following the extent of cerebral dysfunction over time, distinguishing between direct effects of the neoplasm and superimposed metabolic or toxic encephalopathies, and differentiating among epileptic, ischemic, and noncercbral causes of episodic symptoms.

The role of EEG in treating patients with head injuries is limited. Transitory generalized slowing is common after concussion. A persistent area of continuous, localized slow-wave activity suggests cerebral contusion even in the absence of a focal clinical or CT abnormality, and unilateral voltage depression suggests subdural hematoma. EEG in the first 3 months after injury does not predict post-traumatic epilepsy.

Altered States of Consciousness

EEG has a major role in evaluating patients with altered levels of consciousness. EEG complements the clinical





B

FIGURE 36A.10 (At A 46 year-old man with a glioblastoma involving the right Temporal and parietal lobes. (B) The electroencephalogram demonstrates continuous arrhythmic slowing over die right temporal and paricto-occipital areas. [11 addition, loss of the alpha rhythm and overriding faster frequencies are seen in corresponding areas of the left cerebral heinisplu'iv.

examination when consciousness is depressed significantly because EEG permits a reasonably critical assessment of supratentorial brain function. Abnormalities typically are nonspecific in origin. However, a generally good correlation exists with the clinical state. Some findings are more suggestive of particular causes than of others and occasionally are prognostically useful. Specific questions that EEG may help answer, depending on the clinical presentation, include the following:

Are psychogenic factors playing a major role?
Is the process diffuse, focal, or multifocal?
Is unrecognized epileptic activity depressing consciousness (nonconvulsive status cpilcpticus)?

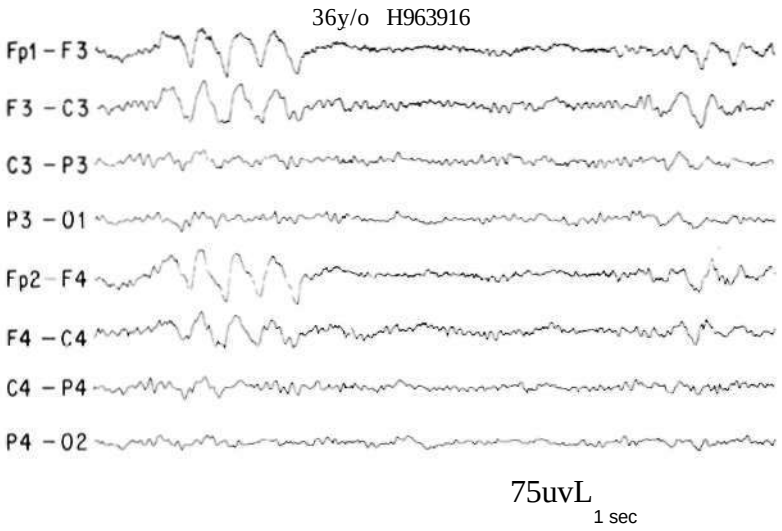


FIGURE 36A.11 Bursts of intermittent rhythmic-delta waves in a 36-year-old man with primary generalized epilepsy and tonic-clonic seizures. Generalized spike-wave activity occurred elsewhere in the electroencephalogram. The intermittent rhythmic delta waves are a nonspecific manifestation of his generalized epileptic disorder. (Courtesy Dr. Bruce J. Fisch,)

- Is there evidence of improvement despite little change in the clinical picture?
- Arc there findings that assist in assessing prognosis?

Metabolic Encephalopathies

Metabolic derangements affecting the brain diffusely are one of the more common causes of altered mental function in a general hospital. Generalized slow-wave activity is the main electroencephalographic indication of decreased consciousness. The degree of electroencephalographic slowing parallels closely the patient's mental status and ranges from only minor slowing of alpha rhythm frequency (slight inattentiveness and decreased alertness) to continuous delta activity (coma). Slow-wave activity sometimes becomes bisynchronous and assumes a high-voltage and sharply contoured triphasic morphology, especially over the frontal head regions (Figure 36A.12). These triphasic waves were originally considered diagnostic of hepatic failure but are now known to occur with equal frequency in several metabolic disorders. The value of triphasic waves is that they suggest a metabolic cause in an unresponsive patient.

Some electroencephalographic features increase the likelihood of a specific metabolic disorder. Prominent, generalized rhythmic beta activity raises the suspicion of drug intoxication in a comatose patient. Severe generalized voltage depression indicates impaired energy metabolism and suggests hypothyroidism if anoxia and hypothermia can be excluded. A photoconvulsive response is seen more often with uremia than with other causes of metabolic encephalopathy. Focal seizure activity is common in patients with hyperosmolar coma.

Hypoxia

Hypoxia, with or without circulatory arrest, produces a wide range of electroencephalographic abnormalities depending on the severity and reversibility of the brain

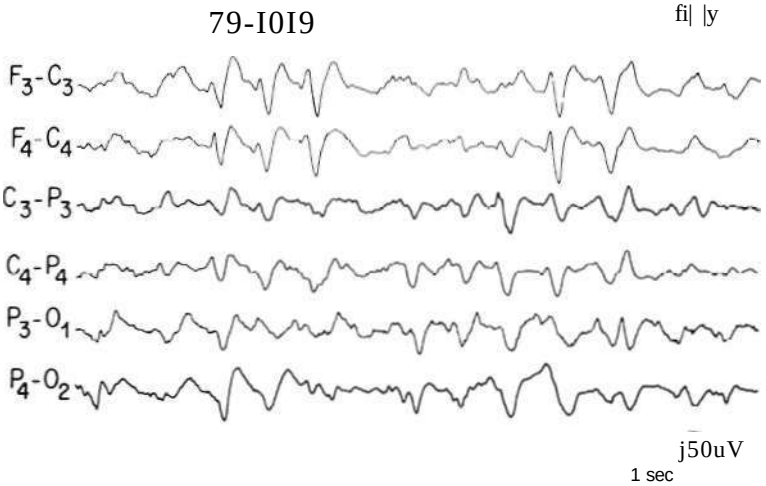

FIGURE 36A.12 Triphasic waves in a 61-year-old man with hepatic failure. (Courtesy Dr. Bruce J. Fisch.)

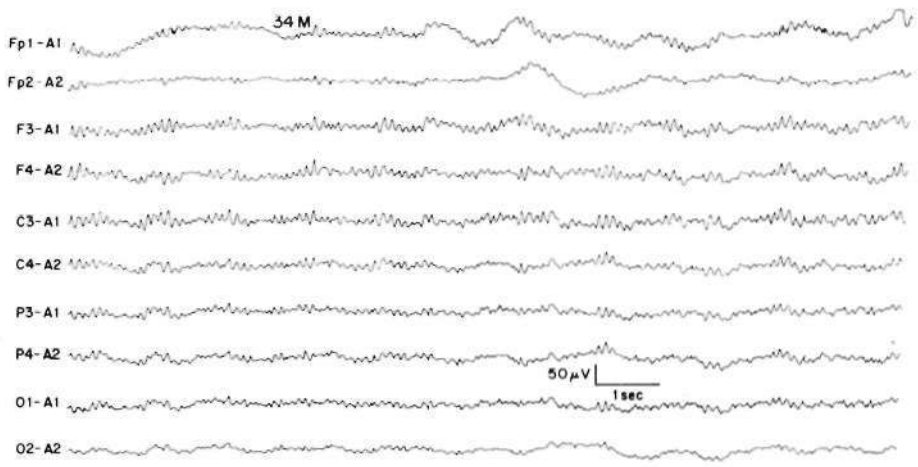

FIGURE 36A.13 Alpha coma in a 34-year-old man with severe hypoxic-ischemic brain damage after subarachnoid hemorrhage with diffuse prolonged cerebral vasospasm. Unlike the normal alpha rhythm, the alpha-range activity in this comatose patient is widespread but maximal frontally, unrcactive, and superimposed on low-voltage arrhythmic delta frequencies.

damage. An electroencephalogram obtained *6* hours or more after the hypoxic insult may show patterns that have prognostic value. The validity of such findings is strengthened if sequential electroencephalograms are obtained, Electroencephalographs: abnormalities associated with poor neurological outcome are alpha coma, burst suppression, and periodic patterns.

The term *alpha coma* refers to the apparent paradoxical appearance of monorhythmic alpha frequency activity in the electroencephalogram of a comatose patient; the electroencephalogram may appear normal to the inexperienced observer (Figure 36A.13). In contrast to normal alpha activity, the alpha pattern of alpha coma is generalized, often maximal frontally, and unreactive to external stimuli.

The burst suppression pattern consists of occasional generalized bursts of medium- to high-voltage mixed-frequency slow-wave activity, sometimes with intermixed spikes, with intervening periods of severe voltage depression or cerebral inactivity {Figure 36A.14). The bursts may be accompanied by strong myoclonic body jerks.

The periodic pattern consists of generalized spikes or sharp waves that recur at a fixed interval, typically 1-2 per second {Figure 36A. 15). Sometimes the periodic shatp waves occur independently over each hemisphere. A postanoxic periodic pattern usually is accompanied by myoclonic jerks of the limbs or whole body.

The prognostic value of these patterns is related exclusively to cause. Similar findings are seen with potentially reversible causes of coma including deep anesthesia, drug overdose, and severe liver or kidney failure.

Infections Diseases

Herpes simplex encephalitis is the one infectious disease for which EEG is useful in initial assessment. Early and accurate diagnosis is important because the response to acyclovir is best when treatment is started early. Although a definitive diagnosis is made only by brain biopsy, characteristic clcctrocncephalographic changes in the clinical setting of encephalitis help select patients for early treatment and biopsy. The electroencepbalographic result usually is abnormal and suggests the diagnosis of herpes infection before CT lesions are recognized.

Other forms of viral encephalitis are expected to cause diffuse polymorphic slow-wave activity, and a normal electroencephalogram result raises doubt about the diagnosis. With herpes simplex encephalitis, the majority of

FIGURE 36A.14 Suppression burst pattern in a 53-year-old woman with anoxic encephalopathy after cardiorespiratory arrest. The patient died several days later. (Courtesy Dr. Barbara S. Koppel.)

FIGURE 36A.15 Periodic partem in a patient witli anoxic encephalopathy after cardiorespiratory arrest. The patient was paralyzed with pancuronium because of bilateral myoclonus.

patients show focal temporal or frontal temporal slowing that may be unilateral or, if bilateral, asymmetrical. Periodic sharp-wave complexes over one or both fronto-temporal regions (occasionally in other locations and sometimes generalized) add additional specificity to the electroencephalographic findings (see Figure 36A.9B). These diagnostic features usually appear between the second and fifteenth day of illness and are sometimes detected only with serial tracings.

Bactetial meningitis causes severe and widespread electroencephalographic abnormalities, typically profound slowing and voltage depression, but viral meningitis produces few significant changes. Although CT has replaced EEG in evaluating patients with suspected brain abscess, focal electroencephalographic changes may be seen in the early stage of cercbritis, before an encapsulated lesion is demonstrable on CT,

Electroencephalographic abnormalities usually diminish as the patient recovers, but the rate of resolution of clinical deficits and the elcctrographic findings may be different. It is not possible to predict residual neurological morbidity or postencephalitic seizures by electroencephalographic criteria. An early return of normal electroencephalographic activity does not preclude persistent neurological impairment.

Brain Death

The diagnosis of bram death rests on strict clinical criteria that, when satisfied unambiguously, permit a conclusive determination of irreversible loss of brain function. In the United States, brain death usually is defined as irreversible cessation of all functions of the entire brain, including the brainstem. Because EEG is a measure of cerebral (especially cortical) function, it has been widely used, in association with clinical evaluation, to provide objective evidence that brain function is lost. Several studies have demonstrated that enduring loss of cerebral electrical activity (called electrocerebral inactivity or electrocerebral silence) accompanies clinical brain death and is never associated with recovery of neurological function. Determination of electrocerebral inactivity is technically demanding and requires a special recording protocol. Reference should be made to criteria established by the American EEG Society (1994).

Temporary and reversible loss of cerebral electrical activity can be seen immediately after cardiorespiratory resuscitation, drug overdose from central nervous system depressants, and severe hypothermia. Therefore, accurate interpretation of an electroencephalogram demonstrating electrocerebral inactivity must take into account these exceptional circumstances. The clinical criteria for establishing the diagnosis of brain death are summarized in Chapter 5 1.

Aging and Dementia

Because EEG is a measure of cortical function, theoretically it should be useful in the diagnosis and classification of dementia. However, the utility of single

electroencephalographic examinations in evaluating patients with known or suspected dementing illnesses often is disappointing. Two important reasons for this are problems in distinguishing the effects on cerebral electrical activity of normal aging from those caused by disease processes and the absence of generally accepted quantifiable methods of analysis and statistically valid comparison measures.

With increasing age over 65, a slight reduction in the total amount of alpha activity and in the alpha rhythm frequency is normal. Normal older adults also show slightly higher amounts of theta and delta activity, especially over the temporal and frontoremporal regions, and changes in sleep patterns. Early in the course of some dementing illnesses, there may be no apparent electroencephalographic abnormality (this is the rule with Alzheimer's disease), or the normal, age-related changes may become exaggerated, differing more in degree than in kind.

In practice, EEG can assist in evaluating suspected dementia by confirming abnormal cerebral function when the possibility of a psychogenic disorder exists and by delineating whether the process is focal or diffuse. Sequential electroencephalograms usually are more helpful than a single tracing, and a test early in the course of the illness may provide more specific information than one performed later. Overall, the degree of electroencephalographic abnormality shows a good correlation with the degree of dementia.

Electroencephalographic findings in Alzheimer's disease are highly dependent on timing. The electroencephalogram initially is normal or shows an alpha rhythm at or just below the lower limits of normal. Generalized slowing appears as the disease progresses. In patients with focal cognitive deficits, low-frequency activity is accentuated over the corresponding brain area. Continuous focal slowing is sufficiently unusual to suggest the possibility of another diagnosis. Prominent focal or bilateral independent slow-wave activity, especially in company with a normal alpha rhythm, favors multifocal disease, such as multiple cerebral infarcts. A specific cause sometimes is suggested. For example, an electroencephalogram showing generalized typical periodic sharp wave complexes in a patient with dementia is virtually diagnostic of Creutzfeldt-Jakob disease (Figure 36A.16).

Event related evoked potentials have been applied to the study of dementia. These are long-latency events (i.e., potentials occurring more than 150 milliseconds after the stimulus) that are heavily dependent on psychic and cognitive factors. Ideally, they measure the brain's intrinsic mechanisms for processing certain types of information and arc potentially valuable in the electrophysiologic assessment of dementia. The best known of the event-related potentials is the P300, or P3, wave. The place of these long-latency evoked potentials in evaluating dementia is still under investigation, but it may be possible to help distinguish between types of dementia by the pattern of electrophysiological abnormality (Goodin 1999).

Computerized Electroencephalography

For decades, electroencephalographic recording instruments were simple analog devices consisting of banks of amplifiers connected to a multichannel strip chart recorder. In recent years, electroencephalographic recording technology has shifted to digital paperless systems in which amplified electroencephalographic signals are converted to a digital format and stored on a computer disc rather than printed on paper. The electroencephalographer interprets the electroencephalogram by viewing it on a computer display rather than on paper. Fundamentally, routine interpretation of EEG, as well as its clinical significance

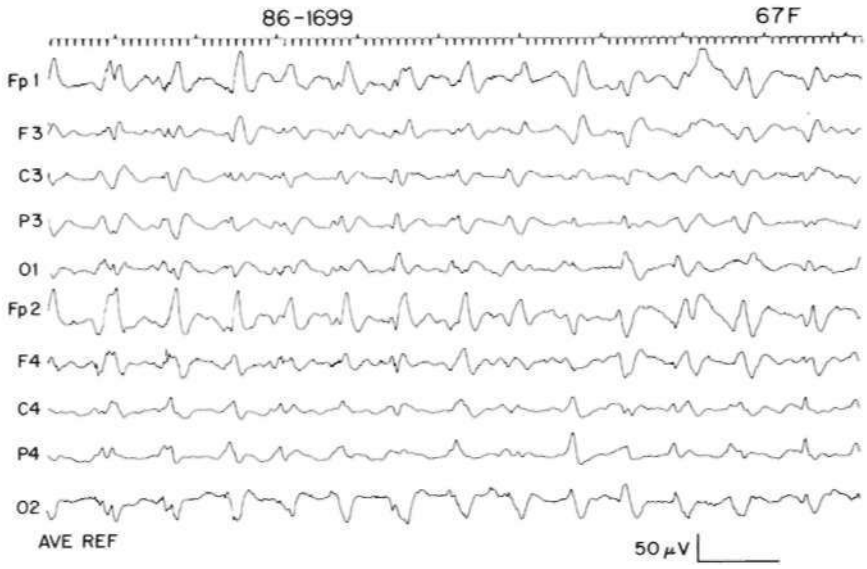

FIGURE 36A.16 Periodic sharp-wave pattern in a 67-year-old woman with Creutzfeldt-Jakob disease. Generalized bisynchronous diphasic sharp waves occur approximately L5-2.0 per second.

and applications, has not been altered by this change in recording technology. However, digital recording systems have facilitated electroencephalographic interpretation and made it possible for the clectroencephalographer to use a variety of signal-processing and display techniques that greatly supplement standard methods of analysis.

In a conventional paper-based EEG system, all recording variables, including sensitivity, filter settings, and the manner in which scalp-recorded signals are combined and displayed (montages), are fixed by the technologist when the KEG is recorded. In digital EEG systems, the electro-cncephalographer can adjust all these parameters when the electroencephalogram is interpreted. Thus a given wave-form or pattern can be examined using a number of different instrument settings. In addition, digital EEG systems permit the use of certain sophisticated montages (e.g., Laplacian montage) that are not available using analog recording systems. Although this flexibility does not change the interpretive strategies used to read an electro-encephalogram, it does allow them to be used much more effectively than was possible using paper-based recording systems.

Although conventional paper recording techniques generally are adequate for standard 20- or 30-minute EEG, they are poorly suited to long-term or continuous EEG. For example, a 24-hour electroencephalographic recording could produce a stack of paper more than 1 foot high. In contrast, digital EEG recording systems are well suited to storage and rapid review of lengthy recordings. For patients undergoing long-term electroencephalographic recordings as part of the diagnosis or management of epilepsy, a time-locked digital video image of the patient generally is recorded along with the electroencephalogram, and the data can be processed automatically to detect most interictal and ictal epileptiform activity. Automatic spike and seizure detection software is now a standard component of commercial epilepsy monitoring systems.

Computerized recording techniques have also made continuous electroencephalographic monitoring practical in inrensive care units. A growing body of literature supports the utility of continuous electroencephalographic monitoring for patients with nonconvulsive seizures, threatened or progressing cerebral ischemia, severe head trauma, and metabolic coma. Furthermore, new insights are emerging concerning the clinical significance of certain periodic electroencephalographic patterns as long-term monitoring becomes routine in the intensive care unit (Brenner 2002). Fully automated, robust systems analogous to those used for cardiac monitoring are not yet available. However, compressed spectrograms, which graphically summarize the frequencies present in several hours of EEG on a single screen, can be used to facilitate the interpretation of continuous electroencephalographic recordings by allowing the elcctrocnccphalographer ro rapidly pinpoint important changes in the electroencephalogram and sometimes to spot patterns or trends that might otherwise go unnoticed (Plate 36A.I) (Scheuer 2002), It must be emphasized that although frequency spectral analysis and similar mathematical methods can be very useful adjunctive techniques, they are properly used in clinical practice only in conjunction with standard EEG. The very data reduction th.it makes them useful also makes them LIHSLJiC;I1>1L- lor stand-alone use.

Topographical mapping displays can be useful in depicting spatial relationships and electroencephalographic features in a graphical manner similar to brain scans. For example, topographical maps can show electroencephalographic voltage distributions over the scalp at a particular point in time (Plate 36A.II). They also may be used to illustrate the distributions of particular frequencies in the electroencephalographic background.

In addition to facilitating EEG interpretation, mathematical techniques can be applied to extract attributes that are not apparent from visual inspection of raw electroencephalographic waveforms. Averaging techniques, useful in improving the signal-to-noise ratio of electroencephalographic transients such as spikes and sharp waves, reveal field distributions and timing relationships that cannot otherwise be appreciated. Recently, dipole source localization techniques have been used to characterize interictal spikes and ictal discharges in patients with epilepsy. Although these methods may contribute to localization of the seizure focus (Ebersole 2000), they are based on several critical assumptions that, when applied without recognition of their limitations, can result in anatomically and physiologically erroneous conclusions (Emerson et al. 1995). Finally, some success has been reported in the application of a variety of linear and nonlinear mathematical techniques to seizure prediction, or at least the detection of preictal changes minutes, or even longer, before any change is observable either clinically or in the routine electroencephalographic display {Jcrgcr et al. 2001; Lift and Lehnertz 2002). Although it is too early to assess their ultimate utility, these techniques are likely to provide important insights into the physiology of the interictal and preictal states, and they could also lead to important therapeutic advances.

M ag n etoen ceph a lo g rap h y

Magiu-rocncephalograpliy (MEG) is a measure of brain function equivalent to EF,G. The same neuronal sources that generate electrical activity also give rise to magnetic-fields. However, MEG differs from EEG in several ways that are theoretically useful. Electroencephalographic potentials are attenuated substantially by the overlying cerebrospinal fluid, dura, and skull. Magnetic fields are less affected by these structures. In addition, EEG measures cortical current sources oriented in all directions but emphasizes radially oriented dipoles. MEG more accurately measures tangential dipoles that are parallel to the cortical

surface. However, the limitations that apply to dipole source localization of elcctrocncephalographic signals apply similarly to magnet oencephalographic signals.

To date, MEG has been used mainly to localize sources of evoked potentials and focal epileptiform activity {Baumgartner et al. 2000). It also has been applied, in a more limited way, to investigations of patients with psychiatric disorders, stroke, and migraine. Because of the shielding requirements and the complex and costly instrumentation necessary to measure neuromagnetic fields, MEG has been and is likely to remain limited to research applications.

EVOKED POTENTIALS

Evoked potentials are electrical signals generated by the nervous system in response to sensory stimuli. The timing and location of these signals arc determined by the sensory system involved and the sequence in which different neural structures are activated. The stimulus paradigms used in clinical practice are chosen so that the responses they evoke arc sufficiently stereotyped to allow the limits of normal to be clearly defined. Violation of these limits indicates dysfunction of the sensory pathways being studied. An overview of recording methods, criteria for abnormality, and [imitations of use is provided by the American EEG Society's guidelines (1994).

Because of their low voltage, evoked potentials generally are not discernible without computer averaging to distinguish them from ongoing elcctrocncephalographic activity and other sources of electrical noise. Exceptions are the visual responses evoked by transient flash stimuli, which are seen in routine EEG as photic driving. Typically, however, it is necessary to present the stimulus repeatedly, averaging the time-locked brain or spinal cord responses to a series of identical stimuli while allowing unrelated noise to average out.

In the clinical setting, evoked potential studies are viewed properly as an extension of the neurological examination. Like any neurological sign, they help reveal the existence and often suggest the location of neurological lesions. Evoked potentials therefore are most useful when they detect clinically silent abnormalities that might otherwise go unrecognized or when they assist in resolving vague or equivocal symptoms and findings. Like EEG, evoked potentials are tests of function; they are not usually etiologically specific.

Visual Evoked Potentials

Cerebral visual evoked potentials (VEPs) are responses of the visual cortex to appropriate stimuli. The composite retinal response to visual stimuli, electroretinography, may he recorded separately, and the procedure may lie indicated

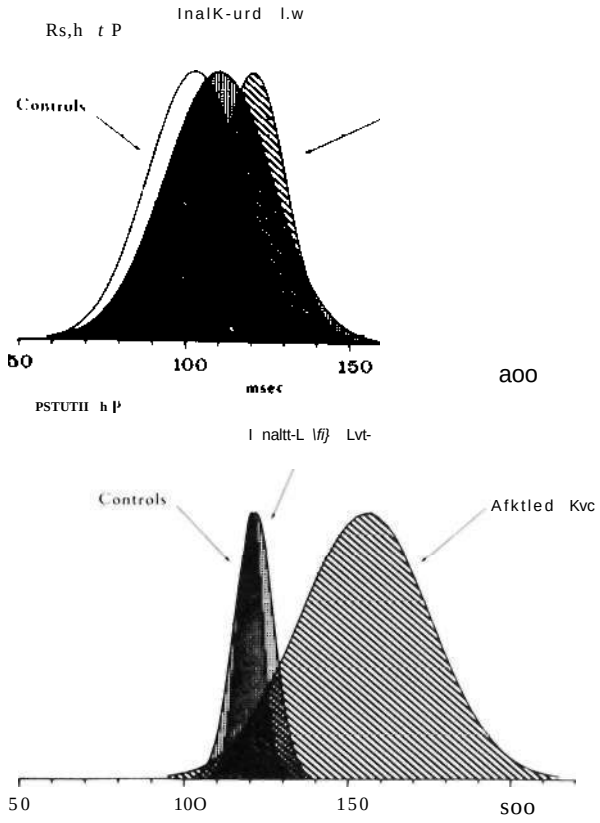

FIGURE 36A. 17 Distributions of latencies of the major occipital positivity to flash (A) and pattern shift (B) stimulation in healthy controls and in the affected and unaffected eyes of patients with optic neuritis. The superior sensitivity of pattern shift visual evoked potentials (EP) to dcmyclinating lesions is clearly demonstrated. (Reprinted with permission from Halliday, A. M. 1982, "The visual evoked potential in the investigation of diseases of the optic nerve," in *FA'oked Potentials in Clinical Testing,* ed A. M. Halliday, Churchill Livingstone, New York.)

in certain clinical situations. The cerebral VEP is obtained by averaging the responses from occipital scalp electrodes generated by 100 or more sequential stimuli. Stimulus characteristics arc critically important in determining what portion of the visual system will be tested by the VEP and what the sensitivity of the test will be to the presence of lesions. Initial clinical applications of VEPs used a stroboscope flash stimulus, but the utility of the flash-evoked VEP is severely limited by the great variability of responses among normal individuals and its insensitivity to clinical lesions (Figure 36A.17). Occasionally, flash VEPs may provide limited information about the integrity of visual pathways when the preferred patrcrn reversal stimulus cannot be used, as in infants or other patients unable to cooperate for more sensitive testing methods.

Normal Visual Evoked Potential

More sensitive and reliable responses are obtained using ;i pattern reversal stimulus. The subject focuses on

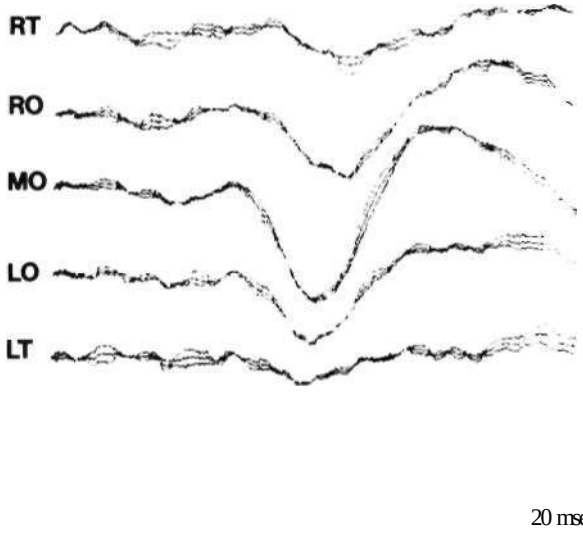

FIGURE 36A.18 Normal pattern reversal visual evoked potentials to full-field monocular stimulation. The MO electrode is in the posterior midline over the occiput. RO and RT are 5 and 10 cm, respectively, to the right of MO, and LO and I.T are 5 and 10 cm, respectively, to the left of MO. All electrodes are referred to Fpz (a midline frontopolar electrode). The response is largest at MO and symmetrically distrihutcd left and right of midline.

a high-contrast checkerboard of black and white squares displayed on a video or optical projection screen. The stimulus is the change of black squares to white and white squares to black (pattern reversal). When appropriate check sizes are used (15—40 minutes of arc at the subject's eye), the VF.P is generated primarily by foveal and parafoveal elements. Monocular full-field stimulation is almost always used so that the test is most sensitive to lesions of the optic nerve anterior to the chiasm. However, it is possible to modify the stimulus presentation so that only selected portions of the visual field are stimulated, permitting detection of postchiasmatic abnormalities as well. VEPs elicited by pattern reversal stimuli show less intersubject variability than do flash VEPs and are much more sensitive to lesions affecting the visual pathways.

A few investigators have further refined the pattern shift stimulus by using a black and white sinusoidal grating rather than a checketboard pattern. This appears to enhance test sensitivity by permitting selective stimulation of retinal elements responsive to specific spatial frequencies and of cortical elements sensitive to both spatial frequency and orientation.

A normal pattern reversal VEP to full-field monocular stimulation is illustrated in Figure 36A,18. The VEP waveform is deceptively simple. It is the sum of many waveforms generated simultaneously by various areas of the retinotopically organized occipital cortex. By selectively stimulating portions of the visual field, it is possible to dissect the full-field VEP into its component waveforms. For example, Figure 36A.19, recorded from the same person as Figure 36A.18, illustrates VEPs to nght and left hemifield stimulation. It is apparent that the full-field VEP is the sum of the two hemifield responses. In principle, it is possible to divide the visual fields into progressively smaller components and to record the VEP to each independently.

Clinical interpretation of the pattern reversal VEP is based primarily on measurement of the latency of the PI 00 component (the major positive wave having a nominal latency of approximately 100 milliseconds in normal

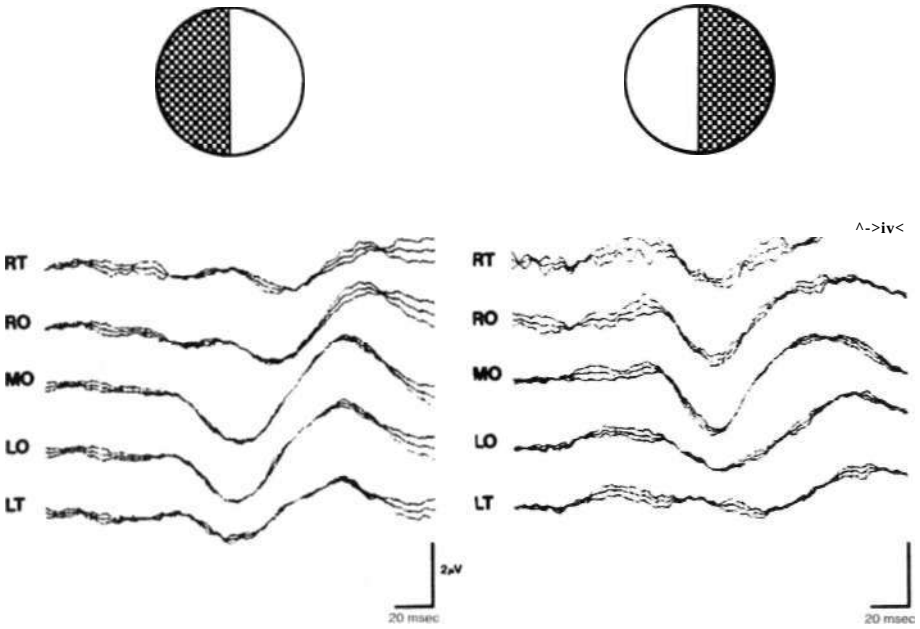

FIGURE 36A.19 Normal pattern shift visual evoked potentials to right and left hemifield stimulation of one eye in the same subject as shown in Figure 36A.I8. Partial field responses arc asymmetrical about the midline, with the largest positivities ipsilateral to the stimulated field.

subjects) after stimulation of each eye separately. Less emphasis is placed on measurement of P100 amplitude, although intereye differences of more than 50% may be significant. The absolute PI00 latency is measured for each eye, and then the intereye PI00 latency difference is determined. These values are compared with the laboratory's normative data and a conclusion reached regarding whether the responses arc normal or abnormal. Finally, the clinical significance of the findings should be interpreted, whenever possible, in the context of other relevant clinical data.

Because optic nerve fibers from the temporal retina decussate at the chiasm, unilateral prolongation of P100 latency after full-field monocular stimulation implies an abnormality anterior to the optic chiasm on that side. Bilateral delay of the P100, demonstrated by separate stimulation of each eye, can be caused by bilateral lesions either anterior or posterior to the optic chiasm or by a chiasmal lesion. Unilateral hemispherical lesions do not alter the latency of the full-field PI00 (because of the contribution from rhe intact hemifield) but do alter the scalp topography of the response.

Visual Evoked Potentials in Neurological Disease

Acute optic neuritis is accompanied by marked attenuation or loss of Pi00 amplitude after pattern reversal stimulation of the affected eye. After the acute attack, the VEP shows some recovery, but P100 latency almost always remains prolonged, even if functionally normal vision is restored. In patients with a history of optic neuritis, P100 latency typically is prolonged, but waveform amplitude and morphology often are well preserved (Figure 36A.20). Factors contributing to changes in PHK) probably include the combined effects of patchy conduction block, areas of variably slowed conduction, temporal dispersion of the afferent volley in the optic nerve, loss of some components

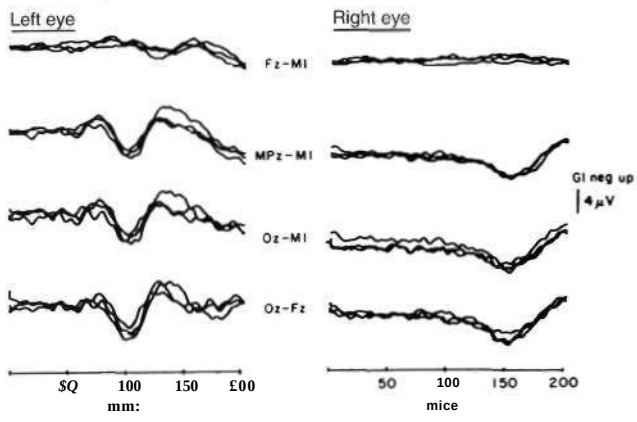

FIGURE 36A.20 Pattern shift visual evoked potentials in a patient with right optic neuritis iUustrating marked delay of the PI00 component from the right eye. As is typical of demyelinating optic neuropathies, the waveform is largely preserved.

Table 36A.1: Some causes of abnormal visual evoked potentials

Ocular disease
- Major refractive error
- Lens and media opacities
- Glaucoma
- Retinopathies

Compressive lesions
- Extrinsic tumors
- Optic nerve tumors

Noncompressive lesions
- Demyelinating disease
- Ischemic optic neuritis
- Nutritional and toxic amblyopias (including pernicious anemia)
- Leber's hereditary optic atrophy

Diffuse central nervous system disease
- Adrenoleukodystrophy
- Spinocerebellar degenerations
- Parkinson's disease

of the normal VEP, and the appearance of previously masked components.

Pattern shift VEPs are abnormal in nearly 100% of patients with a definite history of optic neuritis. More important, the pattern shift VEP is a sufficiently sensitive indicator of optic nerve demyelination that it can reveal asymptomatic and clinically undetectable lesions. Therefore 70-80% of patients with definite multiple sclerosis but no history of optic neuritis or visual symptoms have abnormal VEPs. Many patients with abnormal VF.Ps have normal neuro-ophthalmological examination results.

Pattern reversal VEPs arc highly sensitive to demyelinating lesions but are not specific for multiple sclerosis. A partial list of other causes of abnormal VEPs is given in Table 36A.1.

VEPs may be helpful in distinguishing hysteria or malingering from blindness. A normal pattern reversal VEP is strong evidence of psychogenic illness. However, rare cases have been reported in which essentially normal VEPs were present in cortical blindness because of bilateral destruction of area 17, wirh preservation of areas 18 and 19, or bilareral occipital infarcts with preservation of area 17 (Epstein 2000).

Brainstem Auditory Evoked Potentials

Brainstem auditory evoked potentials (BAEPs) are signals generated in rhe auditory nerve and brainstem by an acoustical stimulus. A brief stimulus, usually a sharp click, is given to one car through an earphone, while the opposite ear is masked with white noise to prevent its stimulation by transcranial!)' conducted sound. The normal BAEP consists of a series of waves that occur within the first 10 milliseconds after the stimulus. The BAEP is extremely low voltage (only approximately 0.5 uV), and typically 1000-2000 recordings are averaged to resolve the BAEP waveform.

Normal Brainstem Auditory Evoked Potentials

Unlike VEPs, which are cortical responses, BAEPs are generated in or caudal to the mesencephalon. BAEPs characteristically resist the effects of metabolic disturbances and pharmacologic agents. Indeed, in the absence of anatomical lesions, BAEPs persist essentially unchanged into deep coma or in the presence of general anesthesia.

A normal BAEP is illustrated in Figure 36A.21. The components designated by roman numerals are produced by summated neuronal activity in anatomical structures that are activated sequentially by the afferent sensory volley. Uncertainty exists regarding the relative contributions to the scalp-recorded BAEP of synaptic potentials occurring in nuclear structures and compound action potentials in fiber tracts. Although the following electro-anatomical relationships may be somewhat oversimplified, they are useful for purposes of clinical localization. Wave I, corresponding to Nl of the electrocochleogram, represents the auditory nerve compound action potential and arises in the distalmost pottion of the nerve. Wave II is generated mainly in the proximal eighth nerve but probably also includes a contribution from the intra-axial portion of the nerve and perhaps the cochlear nucleus as well. Wave III is generated in the lower pons, in the region of the superior olive and trapezoid body. The generators of waves IV and V lie in rhe upper pons and the midbrain, as high as the inferior colliculus. Waves II and IV are inconsistently identified in some normal individuals, so clinical interpretation of BAEPs is based primarily on latency measurements of waves I, III, and V. Despite decussation of brainstem auditory pathways at multiple levels, clinical experience indicates that unilateral BAEP abnormalities usually reflect lesions ipsilateral to the stimulated car.

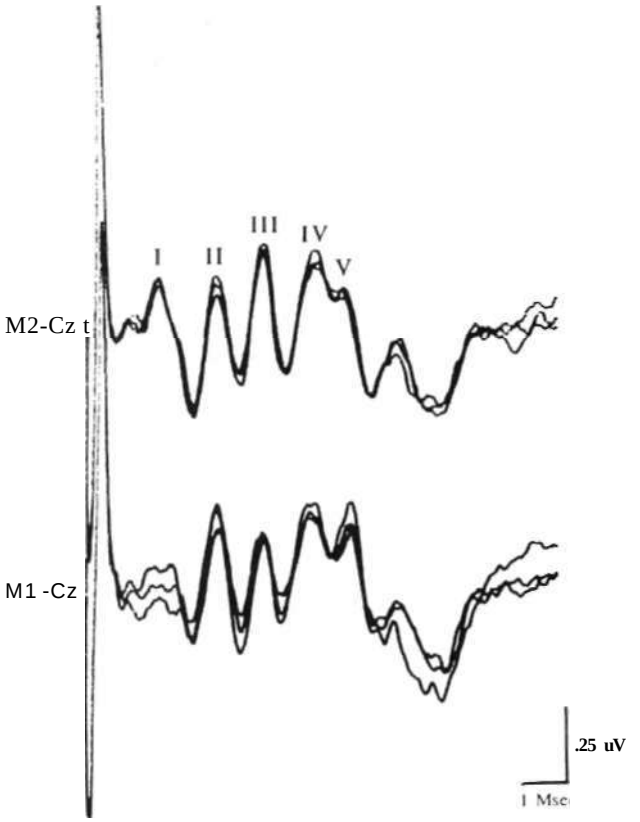

FIGURE 36A.21 Normal brainstem auditory evoked potentials. .Major components are labeled with roman numerals and discussed more fully in the text. M2 is an electrode over the mastoid process ipsilatcral to the stimulated car, in this case the right. Left and right mastoid electrodes are connected to an electrode at the vertex (Cz).

Brainstem Auditory Evoked Potentials in Neurological Disease

Auditory nerve disorders have several effects on the BAEP, in part related to the nature and size of the lesion. Findings range from prolongation of the I-III imerpcak interval, to preservation of wave I with distortion or loss of later components, to loss of all BAEP components. Any of these abnormalities can be seen with acoustic neurinomas and other cerebellopontine angle tumors (Figure 36A.22). In fact, the BAEP may be the most sensitive screening test for acoustic neurinoma, detecting abnormalities in more than 90% of patients. The sensitivity of the test can be further extended by using a range of stimulus intensities and evaluating the effect on components of the BAEP (the latency intensity) (Figure 36A.23).

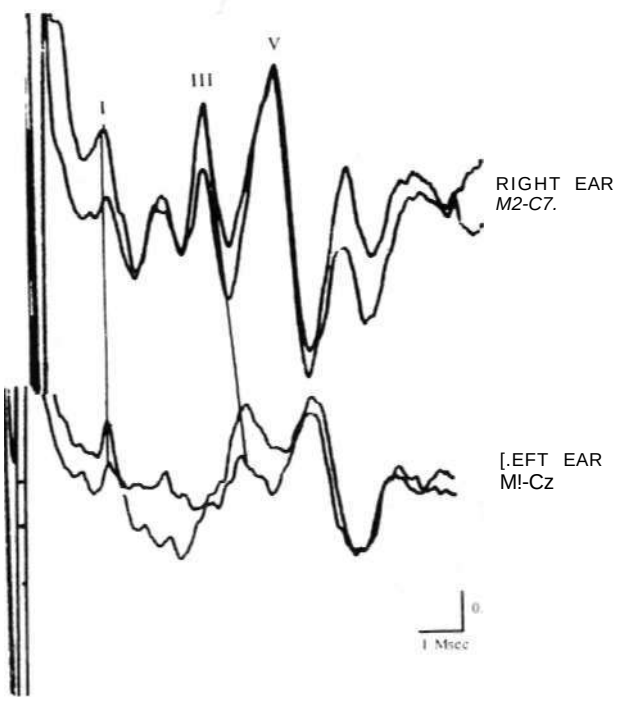

FIGURE 36A.22 Brainstem auditory evoked potentials in a patient with a left acoustic neurinoma. There is prolongation of the I-1II interval on that side, and the overall response is not as well formed as that from the normal ear.

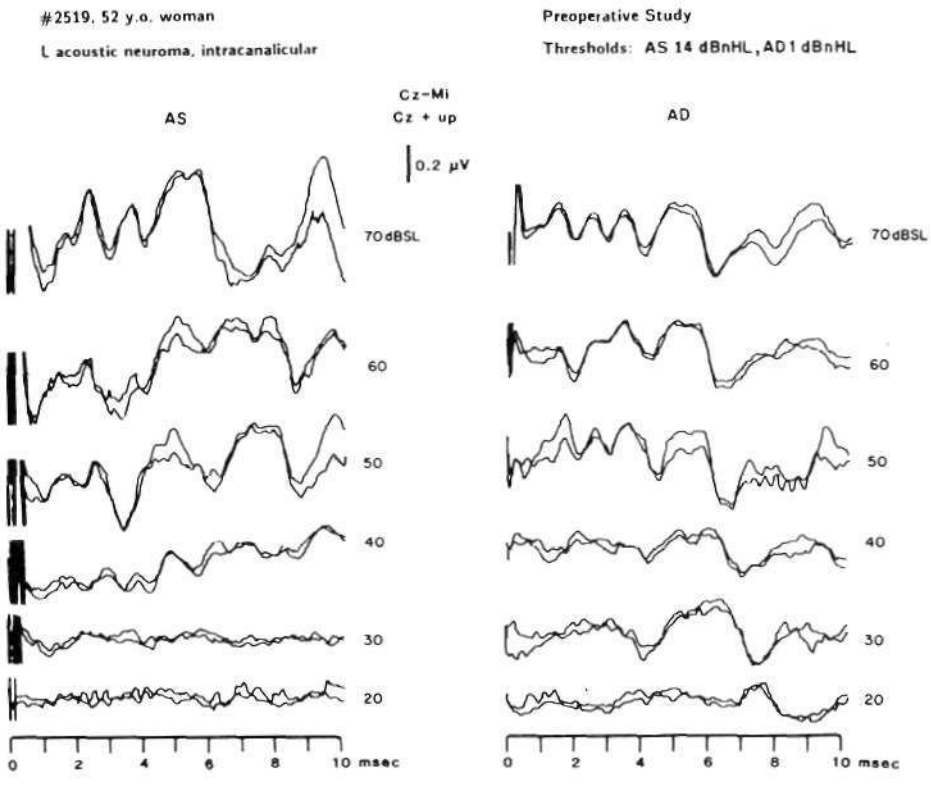

FIGURE 36A.23 Brainstem auditory evoked potential wave V latency plots as a function of increasing stimulus intensity from 20 to 70 dBSL (decibels sound level) in a woman with a left intracanalicular acoustic neurinoma. Brainstem auditory evoked potentials at 70 dBSL are normal bilaterally, but responses at lower intensities are asymmetrical, and the response threshold is elevated on the left.

In patients with focal brainstem lesions that impinge on the auditory pathways, the BAEP is abnormal, and the type of abnormality reflects the lesion's location and extent. For example, Figure 36A.24 illustrates a BAEP obtained from a patient with a brainstem hemorrhage that involved the rostral two thirds of the pons but spared the caudal one third. Waves IV and V are absent, but waves I, II, and III are normal. BAEPs are normal when brainstem lesions do not involve auditory pathways, as is often the case in the locked-in syndrome produced by ventral pontine infarction, or with Wallenberg's lateral medullary syndrome. In contrast, pontine gliomas nearly always produce abnormal BAEPs.

Nearly 50% of patients with definite multiple sclerosis have abnormal BAEP results. Of greater clinical importance, approximately 20% of patients with possible or

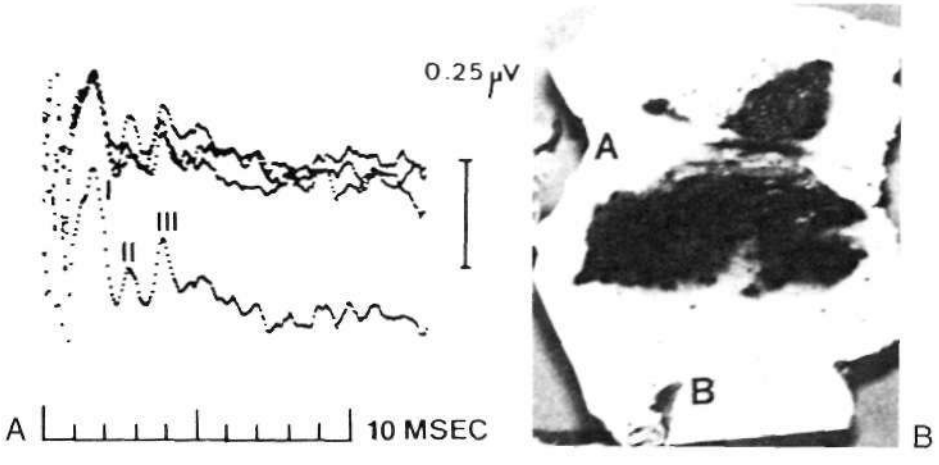

FIGURE 36A.24 Brainstem auditory evoked potentials recorded from a patient with a brainstem hemorrhage sparing the lower one third of the pons. Waves I, II, and III are preserved, but later components are lost. The figure shows a coronal section through the pons. (A) Pontomesencephalic border. (B) Pontomedullary border. (Reprinted with permission from Chiappa, K. H. 1985, "Evoked potentials in clinical medicine," in *Clinical Neurology*, eds A. B. Baker & L. H. Baker, Harper & Row, New York.)

probable multiple sclerosis have an abnormal 15 A HP result, even in the absence of clinical signs or symptoms referable to the brainstem. In such cases, abnormalities usually consist of absence or decreased amplitude of BAEP component waves, most often of waves IV and V, or increased 111—V interpeak latency. Occasionally, prolongation ot the I-III interpeak interval occurs, probably reflecting involvement of the central myelin, which covers the proximal and immediately intra-axial portion of the auditory nerve.

BAEPs may document brainstem involvement in patients with nonfocal neurological diseases, especially those affecting myelin such as metachromaric leukodystrophy and adrenoleukodystrophy. In such diseases, the BAEP also may show electrophysiologic abnormalities in clinically asymptomatic heterozygotes.

BAEPs ate used to assess hearing in young children and in patients otherwise unable to cooperate with standard audiologicnl testing. A latency intensity study, discussed previously, permits characterization of the response threshold for wave V and the relationship between wave V latency and stimulus intensity. Such testing allows estimation of hearing threshold and may distinguish between conductive and sensorineural types of hearing impairment. However, brainstem audiometry is not really a hearing test per se but a measure of the brainstem's sensitivity to auditoty input. The BAEP is normal in the rare patient with deafness resulting from bilateral cortical lesions. On the other hand, patients with multiple sclerosis or a pontine glioma often have abnormal BAEP results but normal hearing (although their ability to localize sound accurately in space may be diminished). One limitation to using BAEPs to test hearing is that the brainstem must be intact, so that BAEP alterations teflect dysfunction in the peripheral hearing apparatus (Lueders and Terada 2000).

Somatosensory Evoked Potentials

After electrical stimulation of a peripheral nerve, recordings from electrodes placed over [lie spine and scalp reveal a series of waves that reflect sequential activation of neural structures along the afferent somatosensory pathways. The dorsal column-lemniseal system is the major substrate of the somatosensory evoked potential (SEP), although other nonlcmniscal systems, such as the dorsal spinocerebellar tract, have been shown to contribute to SEP generation. In clinical practice, SEPs usually arc elicited by stimulation of the median nerve at the wrist, the common peroneal nerve at the knee, or the posterior tibial nerve at the ankle.

Normal Median Nerve Somatosensory Evoked Potentials

Figure 36A.25 shows a normal SEP elicited by median nerve stimulation. The accompanying diagram indicates presumed generator sources for the various components of

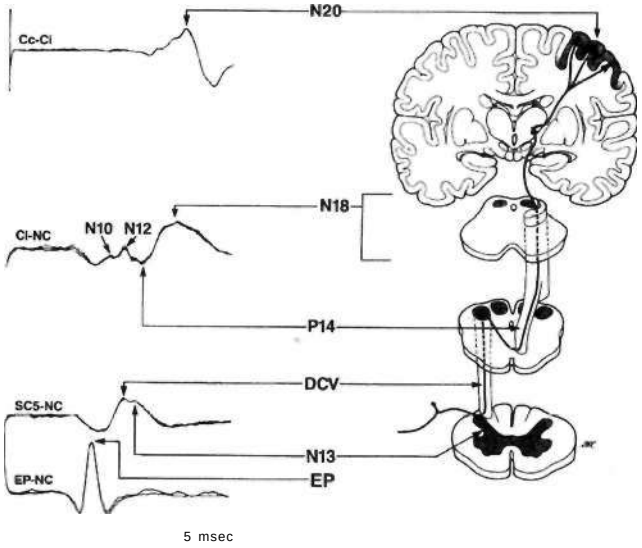

FIGURE 36A.25 Presumed generator sources of median nerve somatosensory evoked potential. Cc and Ci are central-parietal scalp locations contralateral (Cc) and ipsilateral (Ci) to the stimulated nerve. They are 2 cm posterior to the C3 and C4 placements of the International Ten-Twenty System. EP and SOS are electrodes located over Erb's point and the spinous process of the fifth cervical vertebra, respectively. NC is a noncephalic (such as elbow) reference.

rhe SEP. An electrode at Erb's point ipsilateral to the stimulated arm registers the afferent volley as it passes through the brachial plexus. The Erb's point potential serves as a reference point against which the latencies of subsequent components are measured. Electrodes ovet the midcervical dorsal spine record two independent but partially overlapping waveforms that reflect local activity in the spinal cord. The first of these, designated DCV (dorsal column volley), is the afferent volley in the cuneate tract. The second, N13, represents postsynaptic activity in the central gray matter of the cervical cord generated by input from axon collaterals off the primary large-fiber affcrents. Nl.i is accompanied by a simultaneous potential of opposite polarity (PI3) over the anterior neck. Lesions such as syringomyelia, which disrupt the central gray matter, may selectively affect the N13/P13.

SEP components generated in the brainstem are best recorded by an electrode placed on the scalp away from the primary sensory area. This electrode "sees" subcortical activity that is volume conducted to the scalp surface. The P14 wave is generated in the cervicomcdnllaiy region, probably by the caudal medial lemniscus. This is followed by a long-duration negative wave, N18, whose origin is uncertain but probably includes postsynaptic activity from multiple generators in the brainstem. Figure 36A.26 illustrates preservation of the P14 but loss of the N18 and all later waves in a patient with an arteriovenous malformation of the right pons. This is probably the electrophysiological equivalent of functional transection of the medial lemniscus at a pontine level.

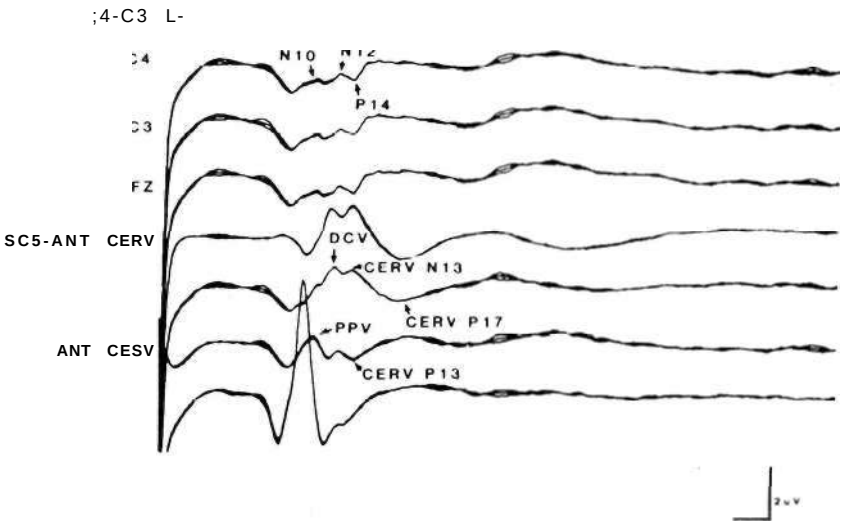

FIGURE 36A.26 Left median nerve somatosensory evoked potentials in a patient with a right pontine arteriovenous malformation. All components after P14 (cervicomedullary potential) arc absent. Unless otherwise labeled, a right elbow reference was used.

The initial cortical response to the afferent sensory volley is designated N20 and is best recorded by a scalp electrode placed directly over the primary sensory cortex contralateral to the stimulated side. The N20 is also a composite waveform made up of signals from mulriple generators within or close to the primary cortical receiving area. This can be demonstrated by selective stimulation of cutaneous and muscle spindle afferent fibets in the median nerve, which are known to project to adjacent but distinct cottical regions, or by observation of state-dependent changes in the N20 (Figure 36A.27). Sleep, for example, attenuates small inflections that are often present on the waking N20, a phenomenon probably caused by downward modulation of some genetators contributing to N20 and to alterations in thalamic input to cortex during sleep.

Normal Posterior Tibia! Nerve Somatosensory Evoked Potentials

In many ways, SEl's to posterior tibial nerve stimulation are analogous to median nerve SEPs, When the posterior tibial nerve is stimulated, tecordings from electrodes over the lumbar spine show two distinct potentials (Figure 36A.28). One (PV) is produced by the afferent volley in the lumbar nerve roots and gracile tract, and the other (N22) is a SLimmated synaptic potential generated in the gray matter of the lumbar cord. Because of its stability, fixed latency, and high voltage, the N22 lumbar potential is used clinically as a reference point against which latencies of subsequent components are measured. Additionally, determination of the spinal level where N22 voltage is maximal

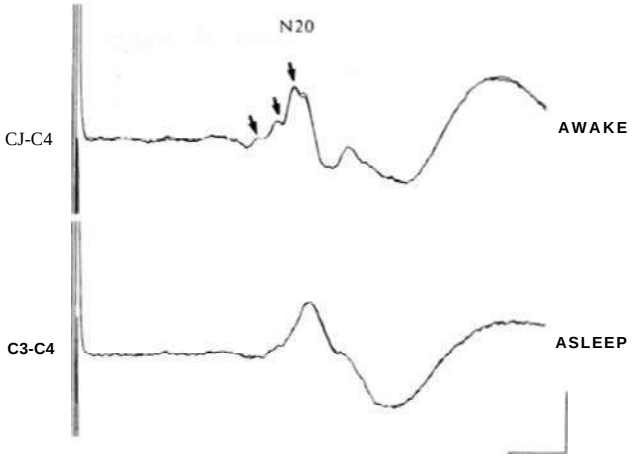

FIGURE 36A.27 Right median nerve somatosensory evoked potentials recorded in a normal subject awake and asleep after sedation with diazepam. Note the state-dependent change in morphology of the N20. Multiple small inflections present on the rising limb of N20 during wakefulness disappear during sleep.

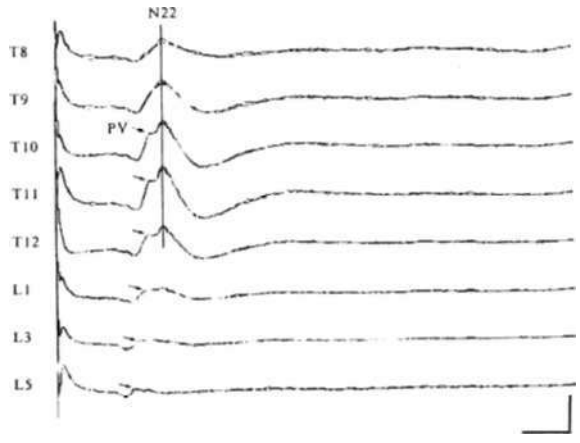

FIGURE 36A.28 Recordings over the lumbar and lower thoracic spine after posterior tibial nerve stimulation. Recording electrodes are referenced to the iliac crest. Note the increasing latency of the propagated volley (PV) and the appearance at T12 of a second, stationary potential (N22). See text for details.

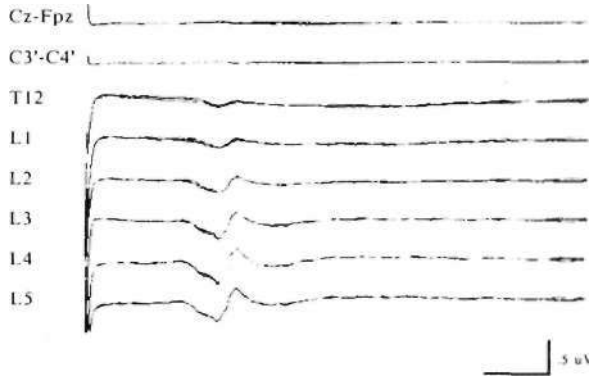

FIGURE 36A.29 Posterior tibial nerve somatosensory evoked potentials in a patient with a tethered spinal cord. The maximal amplitude of the lumbar potential, normally between T10 and T12, is caudally displaced. The cortical response is absent also. Unless labeled otherwise, an iliac crest reference was used.

provides an approximate indication of the position of the lumbar cord enlargement. Tins is sometimes clinically useful if there is a question of spinal cord tethering (Figure 36A.29).

Subcortical activity from posterior tibial nerve stimulation consists of a positive wave, P31, followed by a long-duration negative wave, N34 (Figure 36A.30). These components are analogous to the P14 and N1S following median nerve stimulation and probably are generated by the afferent volley in the caudal medial lemniscus and by postsynaptic activity in the rostral brainstem, respectively.

The initial cortical response to posterior tibial nerve stimulation is .1 prominent positivity (P3S) that is recorded from scalp electrodes placed at the vertex and central parasagittal regions, close to the cortical areas representing the leg (Figure 36A.30). This positive potential usually is maximal just lateral to the

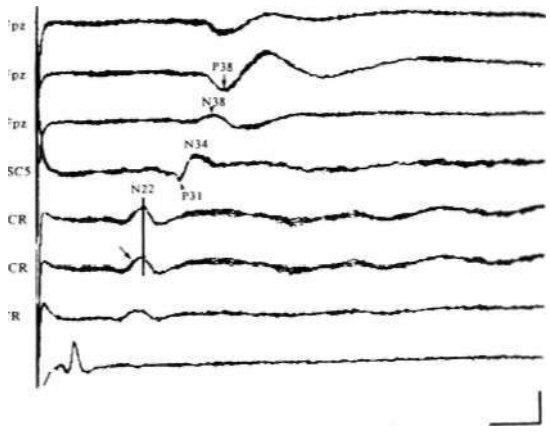

FIGURE 36A.30 Normal posterior tibial somatosensory evoked potentials. The lower channel is a bipolar recording between two electrodes over the popliteal fossa.

stimulated nerve. This apparently paradoxical localization of the P38 reflects the mesial location of the primary sensory area for the leg and foot within the interhemispheric fissure.

Somatosensory Evoked Potentials in Neurological Disease

SEP abnormalities arc produced by a wide variety of conditions that disturb conduction m the somatosensory system. These include focal lesions (tumors, strokes, cervical spondylosis) and diseases that affect the nervous system more diffusely (hereditary ataxias, subacute combined degeneration, vitamin E deficiency). Ninety percent of patients with definite multiple sclerosis have either upper- or lower-limb SEP abnormalities. Furthermore, an abnormal SEP is found in 50-60% of patients with multiple sclerosis even in the absence of symptoms or signs referable to the large-fiber sensory system. Other diseases that affect myelin, such as Pelizaeus-Merzbacher disease, metachromatic leukodystrophy, ad re no leukodystrophy, and adrenomyeloncLiropathy, also produce SEP abnormalities. In cases of adrenoleukodystrophy and adrcnomycloncuropathy, SEP abnormalities can be demonstrated in heterozygotes.

Many lesions alter the SEP by producing a conduction delay or block. This results in prolonged interpeak latencies or attenuation or even loss of one or more SEP components. Abnormally large SEPs, involving exaggeration of cortical components occurring after N20 (median nerve), are characteristic of patients with progressive myoclonus epilepsy, some patients with photosensitive epilepsy, and children with late infantile ceroid lipofuscinosis (Figure 36A.31) (Emerson, 2003).

Motor Evoked Potentials and Magnetic Coil Stimulation

It is possible to assess the functional integrity of the descending motor pathways using motor evoked potentials (MEPs). MEP studies generally entail stimulating the motor cortex and recording the evoked compound motor action potential over appropriate target muscles. The motor cortex may be stimulated either by directly passing a brief, high-voltage electrical pulse through the scalp or by using a time-varying magnetic field to induce an electrical current in the brain.

Whereas transcranial electrical stimulation is painful, magnetic coil stimulation is essentially painless. Therefore, whereas transcranial electrical stimulation is used for intraoperative motor system monitoring in anesthetized patients, magnetic stimulation generally is used in studies of waking subjects and patients.

Direct electrical stimulation of the motor cortex produces a series of signals that are recordable from the pyramidal tract. The earliest wave, the D (direct) wave, results from direct activation of the pyramidal axons. Subsequent

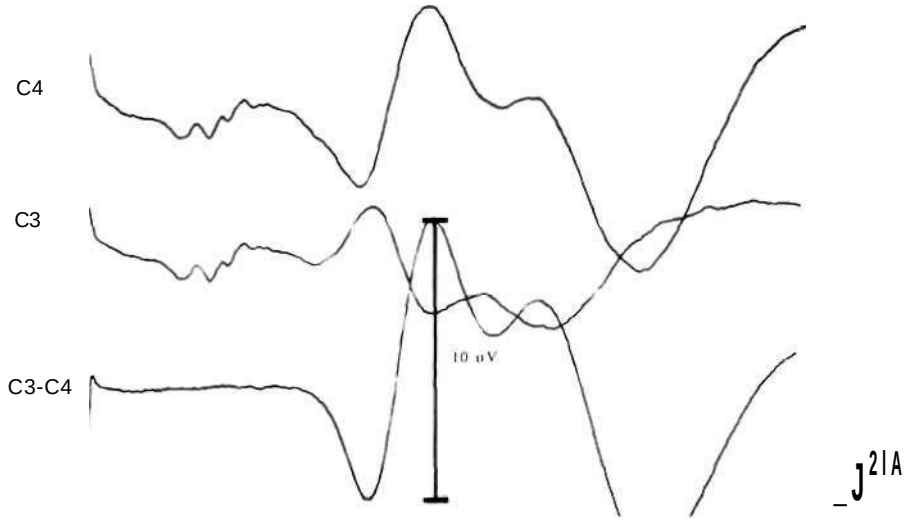

FIGURE 36A.31 Recording from central-parietal scalp electrodes after median nerve stimulation in a patient with cortical myoclonus. Marked exaggeration of later cortical components exists. A noncephalk reference was used in the upper two tracings.

signals, the I (indirect) waves, are thought to reflect indirect trans-synaptic activation of pyramidal cells. Transcranial electrical stimulation is capable of eliciting both D and I waves, but transcranial magnetic stimulation generally elicits only I waves. For this reason, MEPs evoked by transctanial magnetic stimulation occur at slightly greater latency and are less stable than those evoked by trans-cranial electrical stimulation.

It is possible to measure the central motor conduction time by subtracting the latency of the MEP elicited by cervical or lumbar stimulation from that obtained by transcranial stimulation. For MEPs elicited by transcranial magnetic stimulation, this interval encompasses the time needed for activation of cortical interneurons, trans-synaptic activation of pyramidal neurons, conduction of the efferent volley through the pyramidal tract, and depolarization of the spinal motor neuron.

Although the clinical utility of MEPs is not fully defined, they provide information about motor pathways that complements data about sensory pathways obtained from SEPs. MEPs often are abnormal in patients with mye-lopathies caused by cervical spondylosis (Figure 36A.32), where they appear to be sensitive to eatly, preclinical spinal cord compression. They are often delayed in parients with multiple sclerosis and may he more sensitive to demyelinat-ing lesions than VEPs or SEPs. In motor neuron disease, pyramidal tract conduction delays can be demonstrated in patients without upper motor neuron signs.

MEPs also offer insights into the pathophysiology and evolution of disorders affecting the motor system. Patients with cerebral palsy may demonstrate enhanced MEPs in some muscle groups because of aberrant corticospinal projections. In Parkinson's disease, MEP latencies are normal, but their amplitudes may be elevated, possibly because of spinal disinhibition or corticomotoneuronal hyperexcitability. MEPs have been used to study brain plasticiry and to document cortical reorganization after spinal cord injury and amputation.

Transcranial magnetic coil stimulation provides a means to study normal cortical physiology by transiently inter-rupting the regional function. Disruption of cortical processing produced by single or repetitive magnetic stimuli has been used to study not only the function of motor system but also cortical somatosensory, visual, and language processing function. Finally, potential therapeutic uses for transcranial magnetic stimulation in parkinsonism,

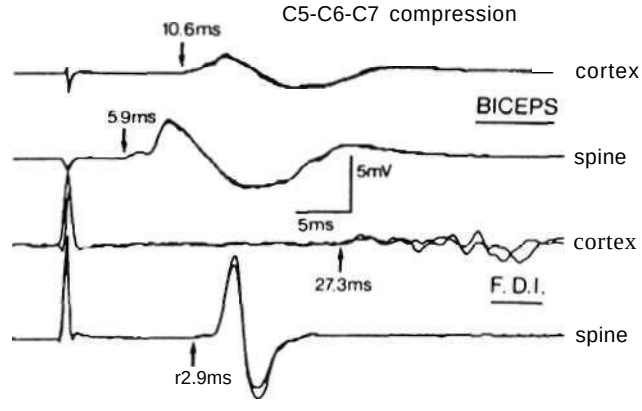

FIGURE 36A.32 Motor evoked potentials (MEPs) recorded from biceps and first dorsal interosseous (FDI) muscles in a patient with cervical spondylosis producing C5-C7 spinal cord compression. MEPs recorded from biceps are normal after magnetic stimulation over both motor cortex and cervical spine. MEPs recorded from FDI are normal after stimulation over the cervical spine but are of abnormally low voltage and polyphasic after cortical stimulation. (Reprinted with permission from Macrtens de Noordhout, A., Remade, J. M., Pepin, J. L., et al. 1991, "Magnetic stimulation of the motor cortex in cervical spondylosis," *Neurology,* vol. 41, p. 75-80.)

dystonia, and depression have been proposed (Cracco and Cracco 1999; Hallett 2000; Mills 1999).

Intraoperative Monitoring

Electrophysiological monitoring to assess the functional integrity of the brain and spinal cord during neurosurgical and orthopedic procedures has become routine in many centers. Such monitoring reduces neurological morbidity by detecting adverse effects at a time when prompt correction of the cause can prevent permanent neurological injury. In addition, monitoring may provide information about the mechanisms of postoperative neurological abnormalities and occasionally lead to changes in surgical approach or technique.

Monitoring can be done using EEG, sensory evoked potentials (usually BAEPs or SEPs), and MEPs. Which monitoring modality or combination of modalities is used depends on the type of surgery, the neural structures judged to be most at risk, and previous experience with complications of the particular surgical procedure. Because neurological injury can occur suddenly and may be irreversible, the ideal monitoring method is one that detects impending, not permancnr, damage. A certain percentage of false-positive results therefore is highly desirable. Experienced monitoring teams learn that small changes in recorded signals are common during surgery because of clinical and technical factors that have negligible effects on outcome. Other variables that affect electrical signals are the type of anesthesia, temperature, blood pressure, and neuromuscular blockade. Detetmining what constitutes a significant and reproducible change that warrants alerting the surgeon or anesthesiologist is a critical aspect of monitoring.

Patients occasionally experience a new postoperative neurological abnormality despite uneventful monitoring. It is rare for a major neurological complication ro occur in a part of the nervous system that was monitored directly and accurately judged to be normal throughout the operation. More often, complications arise when structures not monitored directly arc involved (e.g., infarction of the ventral spinal cord when only dorsal column function was monitored using SEPs) or when a significant pre-existing abnormality masks even moderate changes from baseline. Minor and usually transient neurological symptoms and signs (e.g., sensory dysesthesias, mild weakness, temporary neurogenic bladder) occur occasionally with stable intraoperative electrophysiological measures.

Klectrucneephalographic monitoring lias been used extensively in patients undergoing carotid endarterectomy, during embolization of arteriovenous malformations, and for clipping or removal of some aneurysms. Computer-assisted methods are used commonly to process primary Electroencephalographic data to compress what is otherwise an unmanageable amount of information and to present the data in a more easily interpretable manner. Monitoring is especially helpful in selecting patients for shunting during occlusion of the carotid artery. With monitoring, overall intraoperative major morbidity for endarterectomy can be as low as 1%.

Monitoring auditory nerve function using BAEPs, with or without electrocochleography, is useful in any neurosurgical or neuro-otological procedure that risks injury to the eighth cranial nerve. Risk of hearing loss is minimized in patients with small, especially intracanalicular, acoustic neurinomas and other cerebellopontine angle tumors, and in patients undergoing microvascular decompression for hemifacial spasm or trigeminal neuralgia. Monitoring facial nerve function by recording compound nerve or muscle action potentials after direct stimulation of the intracranial portion of the seventh nerve has greatly reduced the incidence of permanent facial palsy after cerebellopontine angle sutgety.

SEPs are used routinely to monitor baseline and spinal cord function during neurosurgical and orthopedic procedures. They provide useful and sensitive feedback information about the integrity of the dotsal column somatosensory system. MEPs are particularly sensitive to the effects of spinal cord ischemia, compression, distraction, and blunt trauma and are used also to monitor spinal cord function during surgical procedures. They complement SEPs because SEPs may not detect surgical injuries that are limited to the lateral and anterior spinal cord (Emerson and Adams 1999).

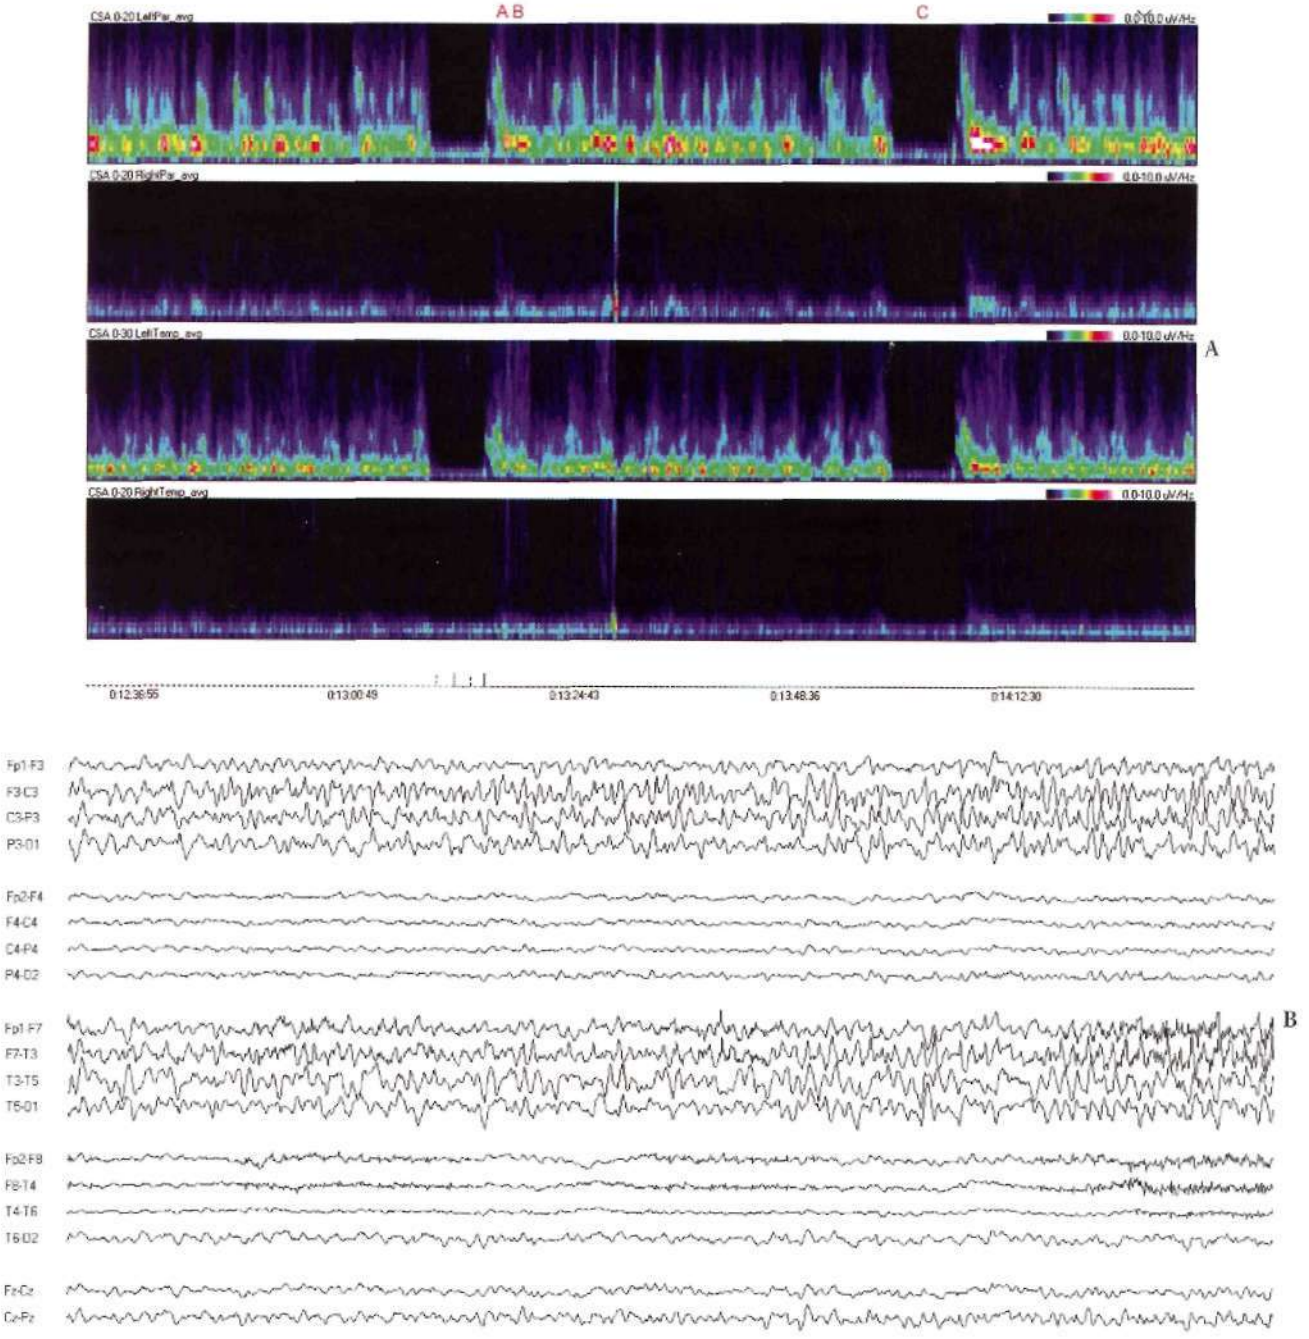

PLATE 36A.I Frequency spectrograph depicting 2 hours of electroencephalographic (EEG) recordings from a patient in focal status epilepticus. (A) The upper two panels show activity in right and left parasagittal electrode derivations, respectively; the lower two panels depict activity in temporal derivations. Time is represented on the horizontal axis. The vertical axis on each panel corresponds to frequency, from 1 Hz on the bottom to 20 Hz at the top. The colors indicate EEG voltage at a given frequency; from black for 0 μV/Hz to purple for 10 μV/Hz. This spectrograph shows bursts of high-voltage, high-frequency (*green*) activity recurring approximately every 5 to 7 minutes, most prominent in the left parasagittal panel. This EEG demonstrates a pattern of recurring electrographic seizures, as illustrated by representative EEG traces B and C, corresponding to points A and B on the spectrograph. Additionally, there are two quiescent periods with no activity (*black*) at most frequencies, corresponding to periods of postictal voltage depression, also illustrated in trace D.

Clinical Neurophysiology

B. CLINICAL ELECTROMYOGRAPHY

Bashar Katirji

Clinical electromyography (EMG), also called *electradtagnostic examination,* is a distinct medical discipline that plays a pivotal role in the diagnosis of neuromuscular disorders. The F.MG study should be preceded by a detailed neurological examination, although it should serve as an independent procedure to provide the referring physician with an objective assessment of the neuromuscular system.

The EMG examination is composed of two main tests: nerve conduction studies (NCSs) and needle EMG. These tests complement each other and often are necessary to make a final diagnosis. The electromyographer must first obtain a focused history and examination to design the best electrodiagnostic study (Katirji 2002). The electromyographer must know the normal nerve conduction values, normal values of motor unit action potentials (MUAPs) in different muscles, how needle EMG findings differ in different diseases, and how to differentiate between specific and nonspecific findings. Additional electrodiagnostic procedures include F waves, H reflexes, blink reflexes, repetitive nerve stimulation, and single-fiber EMG.

NERVE CONDUCTION STUDIES

Principles

Electrical stimulation of nerve fibers initiates impulses that travel along motor, sensory, or mixed nerves and evoke a compound action potential. There arc three types of NCS: motor, sensory, and mixed. Conduction characteristics of motor fibers are assessed indirectly by studying the compound muscle action potential (CMAP) recorded from the muscle; sensory fibers are assessed by analyzing the sensory nerve action potential (SNAP) recorded from the nerve. Mixed NCSs assess directly the sensory and motor fibers simultaneously by recording from mixed nerve action potential (MNAP). The use of standard NCSs allows precise lesion localization and accurate characterization of peripheral nerve function.

Stimulators

Two different kinds of surface (percutaneous) electric stimulators are used in NCSs. Constant voltage stimulators regulate voltage output so that current varies inversely with the impedance of the system including the skin and subcutaneous tissues. Constant current stimulators change voltage according to impedance so that the amount of current that reaches the nerve is specified within the limits of skin resistance. As the current flows between the cathode (negative pole) and anode (positive pole), negative charges accumulate under the cathode, depolarizing the nerve, and positive charges under the anode hyperpolarize the nerve. In bipolar stimulation, both electrodes are placed over the nerve trunk, with the cathode closer to the recording site. If the cathode and anode of the stimulator are inadvertently reversed, anodal conduction block of the propagated impulse may occur. This is caused by hyperpolarization at the anode, which may prevent the nerve

impulse evoked by the depolarization occurring under the cathode from proceeding past the anode,

Supramaximal stimulation of a nerve that results in depolarization of all available axons is a paramount prerequisite to all NCS measurements. To achieve supramaximal stimulation, current (or voltage) intensity is slowly increased until it reaches a level at which the recorded potential docs not increase. Then, the current should be increased an additional 20-30% to ensure that the potential does not change further.

Recording Electrodes

Surface electrodes are used for recording the CMAP, SNAP, or MNAP. The advantages of surface recording are that these evoked responses are reproducible and change only slightly with the position of the electrodes in relation to the recording muscle or nerve. In contrast, needle electrode recording registers only a small portion of the muscle or nerve action potentials, but with less interference from neighboring discharges. Needle recordings improve the recording from small atrophic muscles or a proximal muscle not excitable in isolation. Ring electrodes are convenient to record the antidromic sensory potentials from digital nerves over the proximal and distal interphalangeal joints.

Recording Procedure

A pre-pulse preceding the stimulus triggers the sweep on a storage oscilloscope. The amplifier sensitivity determines the size (amplitude) of the potential. Overamplification truncates the response, and underamplification prevents accurate measurements of the takeoff from baseline. Digital averaging is a major improvement in recording low-amplitude responses. Signals time-locked to the stimulus summate at a constant latency and appear as an evoked potential, distinct from the background noise. The signal-to-noise ratio increases in proportion to the square root of the trial number. For example, four trials give twice as big a response as a single stimulus, and nine trials give three times the amplitude. Modern instruments digitally indicate the latency and amplitude when the desired spot on the waveform is marked.

Motor NCSs

Motor NCSs are performed by stimulating a motor or mixed peripheral nerve while recording the CMAP from a muscle innervated by that nerve. A pair of recording electrodes consists of an active lead (Gl) placed on the belly of the muscle and an indifferent lead (G2) on the tendon (belly-tendon recording). The propagating muscle action potential, originating under Gl located near the motor point, gives rise to a simple biphasic waveform with initial negativity. Initial positiviry suggests incorrect positioning of the active electrode or a volume-conducted potential from distant muscles activated by anomalous innervation or by accidental spread of stimulation to other nerves.

The nerve is stimulated at two or more points along its course. Typically, it is stimulated distally near the recording electrode and more proximally to evaluate its proximal segment. Several measurements are evaluated with motor NCSs (Figure 36B.1):

CMAP amplitude. This is usually measured from baseline to negative pink and expressed in millivolts, When recorded with surface electrodes, CMAP amplitude is a semiquantitative measure of the number of axons conducting between the stimulating and the recording points. CMAP amplitude also depends on the relative conduction speed of the axons, the integrity of the neuromuscular junctions, and the number of muscle fibers that are able to generate action potentials.

CMAP duration. This is usually measured as the duration of the negative phase of the evoked potential and is expressed in milliseconds. It is a function of the conduction rates of the various axons forming the examined nerve and the distance between the stimulation and recording electrodes. **The** CMAP generated from proximal stimulation has a longer duration and a lower amplitude than **that** obtained from distal stimulation.

CMAP area. This is usually limited to the negative phase area under the waveform and shows linear correlation with the product of the amplitude and duration. It is measured in millivolts per millisecond and requires electronic integration using computerized equipment. The ability to measure CMAP area has replaced the need to measure its duration.

Latencies. This is the time interval between nerve stimulation (shock artifact) and the onset of the CMAP. It is expressed in milliseconds and reflects the conduction rate of the fastest-conducting axon. Whenever it is technically possible, the nerve is typically stimulated at two points: a distal point near the recording site (distal latency) and a more proximal point (proximal latency). Both latencies depend mostly on the length of the nerve segment and, to a much lesser extent, on neuromuscular transmission time and propagation time along the muscle membrane.

Conduction velocity. This is a computed measurement of the speed of conduction and is expressed in meters per second. Measurement of conduction velocity allows the comparison of the speed of conduction of the fastest fibers between different nerves and subjects, irrespective of the length of

the nerve. It is calculated after the length of the nerve segment is incorporated between distal and proximal stimulation sites. The nerve length is estimated by measuring the surface distance along the course of the nerve and should be more than 10 cm to improve the accuracy of surface measurement.

$$\text{Motor conduction velocity} = \frac{\text{Distance}}{\text{Proximal latency} - \text{Distal latency}}$$

As with latencies, motor conduction velocity measures the speed of conduction of the fastest axon. However, in contrast to motor latencies, motor nerve conduction velocity is a pure nerve conduction time because neuromuscular transmission time and muscle fiber propagation time are common to both stimulation sites, and the latency difference between two points is the time for the nerve impulse to travel from one stimulus point to the other.

Sensory NCSs

Sensory axons are evaluated by stimulating a nerve while recording the transmitted potential from the same nerve at a different site. Therefore, SNAPs arc true nerve action potentials. Antidromic sensory NCSs are performed by recording potentials directed toward the sensory receptors, whereas orthodromic studies arc obtained by recording potentials directed away from these receptors. Sensory latencies and conduction velocities are identical with either method, but SNAP amplitudes generally are higher in antidromic studies. Because the thresholds of some motor axons are similar to those of large myelinated sensory axons, superimposition of action potentials from distal muscles may obscure antidromically recorded SNAPs. Fortunately, latencies can still be measured accurately because the large-diameter sensory fibers conduct 5-10% faster than motor fibers. This relationship may change in disease states that selectively affect different fibers.

SNAPs may be obtained by stimulating and recording a pure sensory nerve (such as the sural and radial sensory nerves), stimulating a mixed nerve while recording distally over a cutaneous branch (such as the antidromic median and ulnar sensory responses), or stimulating a distal cutaneous branch while recording over a proximal mixed nerve (such as the orthodromic median and ulnar sensory-studies). Similar ro their motor counterparts, several measurements are recorded with sensory NCS (Figure 36B.2):

SNAP amplitude. This is a semiquantitative measure of the number of sensory axons that conduct between the stimulation and recording sites. It is calculated from the baseline to negative peak or from negative peak to positive peak and expressed in microvolts.

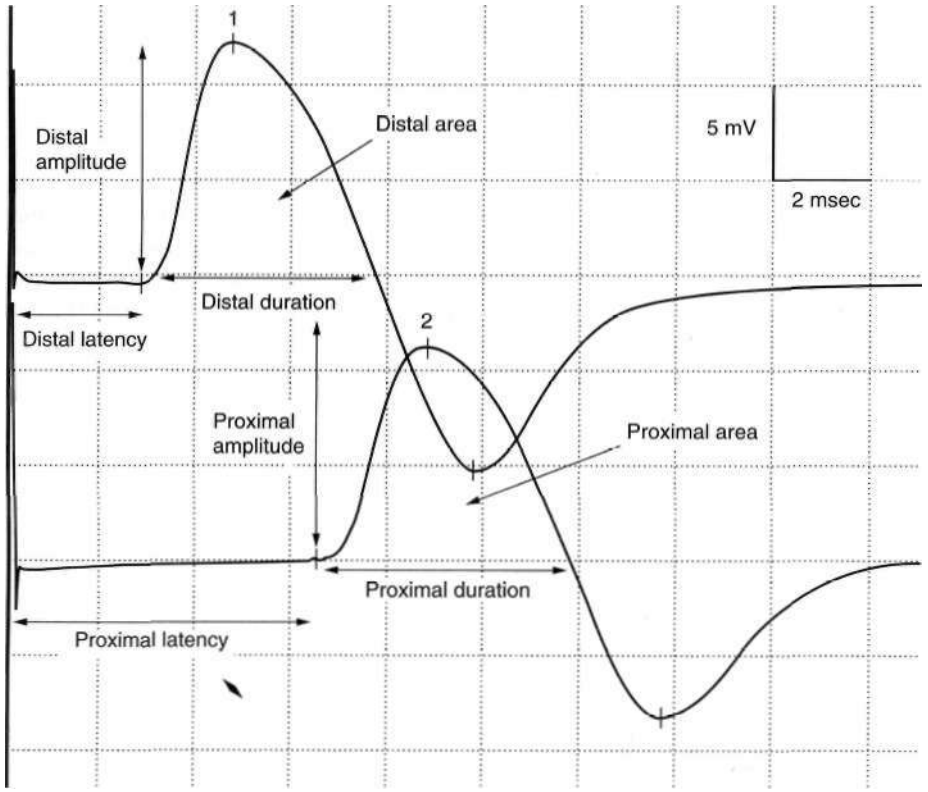

FIGURE 36B.1 Motor nerve conduction study of the median nerve showing a typical compound muscle action potential (CMAP) with distal and proximal stimulations, showing the distal and proximal latencies and CMAP amplitudes, durations, and areas. The proximal CMAP has a lower amplitude (12.6 mV vs. 11.3 mV) and atea (37.3 mV/ms vs. 34.50 mV/ms) than the distal CMAP because of tempotal dispersion and phase cancellation.

SNAP duration and area may be measured but are not useful because of significant temporal dispersion and phase cancellation.

Latencies. With sensory NCSs, often only a single distal site is stimulated. Sensory distal latencies may be measured (in milliseconds) from the stimulus artifact to the peak of the negative phase (peak latency) or from the stimulus artifact to the onset of the SNAP (onset latency). Onset latency may be obscured by a large shock artifact, a noisy background, or a wavy baseline. Although peak latency does not reflect the fastest-conducting sensory fibers, it is easily defined and more precise than onset latency.

Conduction velocity. This requires stimulation at a single site only because the latency consists of only the nerve conduction time from the stimulus point to the recording electrode. It may be also done with distal and proximal stimulation sites. Sensory conduction velocities are calculated similarly to their motor counterparts; only onset latencies (not peak latencies) are used to calculate the speed of the fastest conducting fibers.

$$\text{Sensory conduction velocity} = \frac{\text{Distance}}{\text{Proximal onset latency} - \text{Distal onset latency}}$$

$$\text{Sensory conduction velocity} = \frac{\text{Distance}}{\text{Onset latency}}$$

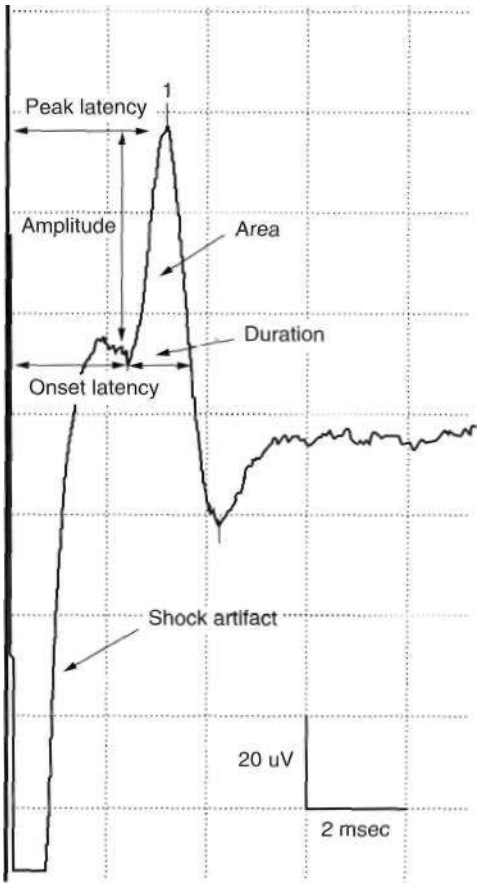

FIGURE 36B.2 Antidromic median sensory nerve conduction study after stimulation at the wrist, revealing peak and onset latencies and sensory nerve action potential amplitude, duration, and area. The shock artifact interferes with the accurate determination of onset latency, whereas peak latency is easily-determined.

Mixed NCSs

Mixed NCSs are performed by stimulating and recording from nerve trunks with sensory and motor axons. Often, these tests are done by stimulating a nerve trunk distally and recording more proximally because the reverse is often contaminated by large CMAPs that obscure the lower-amplitude MNAPs. When the nerve is deep (as at the elbow or knee), the MNAP may be very low in amplitude ot unelicitable because tissue interposes between the nerve and recording electrode. Therefore, these studies are limited to evaluating mixed nerves in distal nerve segments, such as in the hand or foot during the evaluation of carpal tunnel syndrome and tarsal tunnel syndrome, respectively.

Segmental Stimulation in Short Increments

Routine NCSs are sufficient to localize the site of involvement in entrapment neuropathies. However, during the evaluation of a focal demyelinating lesion, inclusion of the unaffected segments in conduction velocity calculation dilutes the effect of slowing at the injured site and decreases the sensitivity of the test. Therefore, incremental stimulation across shorter segment helps localize an abnormality that might otherwise escape detection. More precise localization entails inching the stimulus in short increments along the course of the nerve. The study of short segments provides better resolution of restricted lesions. Assume a nerve impulse conducting at a rate of 1,0 cm per 0.2 millisecond (50 m per second); for a 1-cm segment there is dcmyelination that doubles the conduction time to 0.4 millisecond per cm. In a 10-cm segment, normally covered in 2.0 milliseconds, a 0.2-millisecond increase would constitute a 10% change, or approximately one standard deviation, well within the normal range of variability. However, the same 0.2-millisecond increase would represent a 100% change in latency if measured over a 1-cm segment. The large per-stcp increase in latency more than compensates for the inherent measurement error associated with stimulating multiple times in short increments.

The inching technique is particularly useful in assessing sensory conduction in patients with carpal tunnel syndrome (Kimura 1979). With stimulation of a normal median nerve in 1-cm increments across the wrist, the latency changes

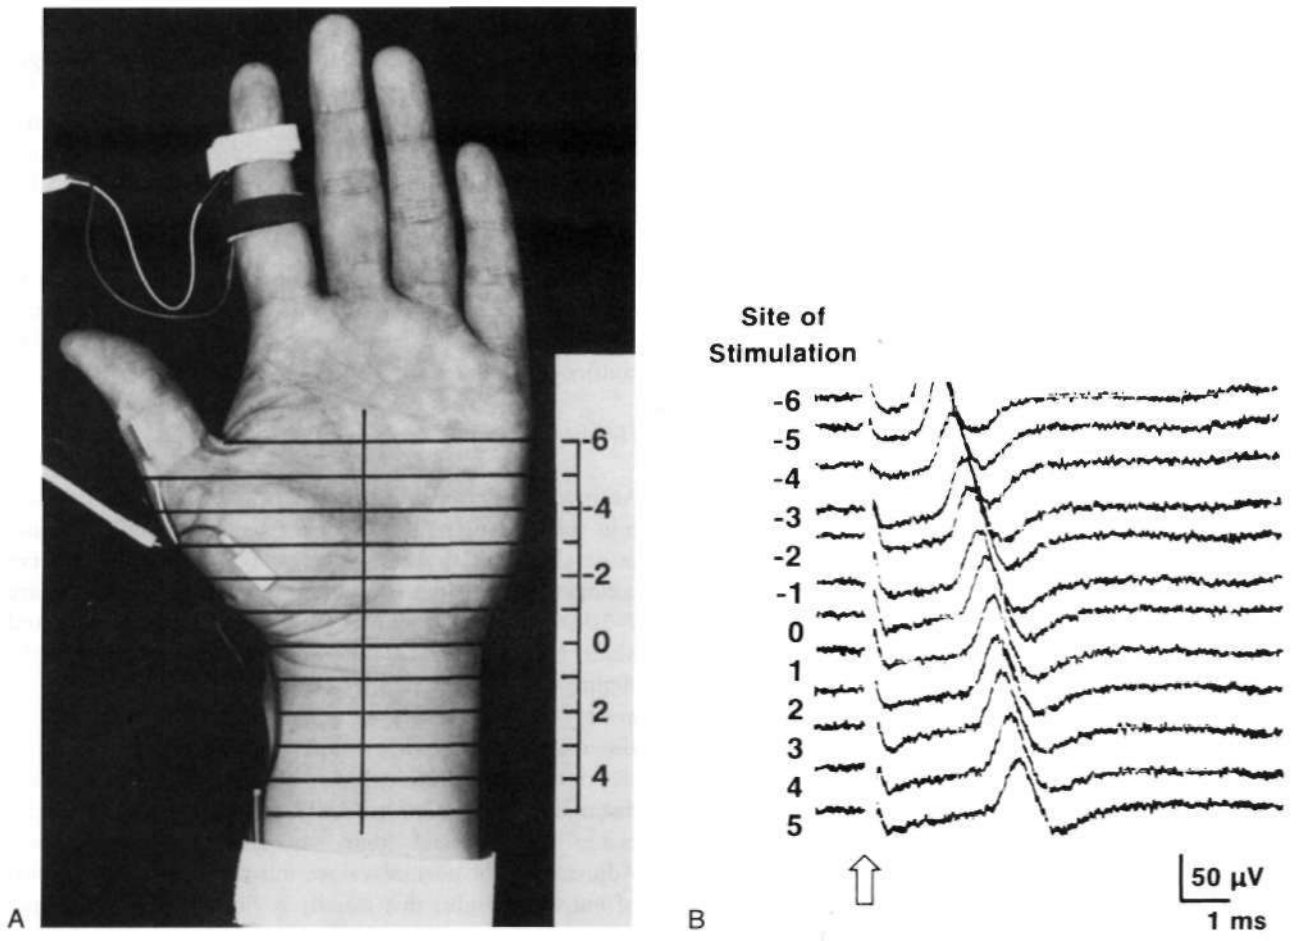

FIGURE 36B.3 (A) Twelve sites of stimulation in 1-cm increments along the length of the median nerve. The 0 level is at the distal crease of the wrist, corresponding to the origin of the transverse carpal ligament. Sensory nerve action potentials (SNAPs) and compound muscle action potentials are recorded from the second digit and abductor po I lie is brevis, respectively. (B) SNAPs in a normal subject recorded after stimulation of the median nerve at multiple points across the wrist. The site of each stimulus is indicated on the left. The latency increased linearly as the stimulus site was moved proximally in 1-cm increments. (Reprinted with permission of the author and publisher from Kimura, J. 1979, "The carpal tunnel syndrome: Localization of conduction abnormalities within the distal segment of the median nerve," Brain, vol. 102, pp. 619-635. By permission of Oxford University Press, Inc.)

approximately 0.16-0.21 millisecond per centimeter from midpalm to distal forearm (Figure 36B.3). A sharply localized latency increase across a 1-cm segment indicates a focal abnormality of the median nerve (Figure 36B.4). An abrupt change in waveform usually accompanies the latency increase across the site of compression. Segmental stimulations are useful in other focal mononeuropathies such as ulnar neuropathies at the elbow or wrisr (Campbell, Pridgeon, and Sahni 1992; Mcintosh, Preston, and Logigian 1998).

Physiological Variability and Common Sources of Error

The major pitfalls in NCSs usually result from Technical errors in the stimulating or recording systems (Kimura 1997}. They result from spread of the stimulating current to a nerve not under study; eliciting an unwanted potential from distant muscles; anomalous innervation; the effect of temporal dispersion; or errors in the measurement of nerve length and conduction time.

Temperature

Nerve impulse propagation slows by 2.4 m per second, or approximately 5% per degree centigrade from 38^{c} to 29"C of body temperature. Also, cooling results in a higher CMAP and SNAP amplitude and longer duration, probably because of accelerated and slowed Na^{+} channel inactivation (Rutkove, Kothari, and Shefner 1997). Therefore a CMAP or SNAP with high amplitude and slow distal latency or conduction velocity should raise the suspicion of a cool limb.

To reduce this type of variability, skin temperature is measured with a plate thermistor; this measurement correlates linearly with the subcutaneous and intramuscular

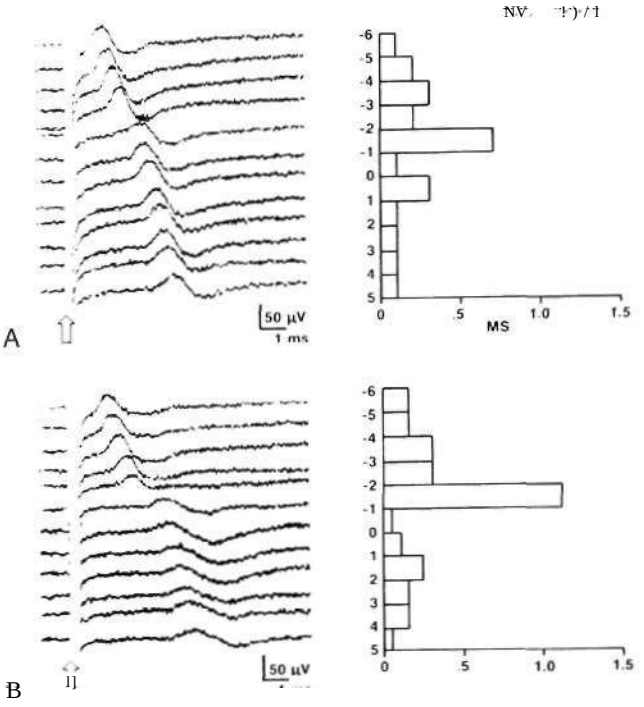

FIGURE 36B.4 Sensory nerve action potentials in a patient with the carpal tunnel syndrome. A sharply localized showing was found from -2 to -1 in both hands, representing a segmental conduction velocity of (A) 14 m per second on the left and (B) 9 m per second on the right. Note a distinct change in waveform of the sensory potential at the point of localized conduction delay. Double-humped appearance at -2 on the left suggests sparing of some sensory axons at this level. (Reprinted with permission of the author and publisher from **Kimura,** J. 1979, "The carpal tunnel syndrome: Localization of conduction abnormalities within the distal segment of the median nerve," *Brain,* vol. 102, pp. 619-635. By permission of Oxford University Press, Inc.)

temperatures. If the skin temperature falls below 33°C, it is necessary to warm the limbs by immersion in warm water. Warming packs or a hydrocollator can also be used, particularly in bedridden or intensive care units patients. Adding 5% of the calculated conduction velocity for each degree below 33°C theoretically normalizes the result. However, such conversion factors are based on experience with healthy subjects and may not apply to patients with abnormal nerves.

Age

because myelination is incomplete at birth, nerve conduction velocities are roughly one half the adult value in full-term newborns and one third that of term newborns in 23- to 24-week premature newborns. They reach adult values at 3-5 years (Thomas and Lambert I960). Motor and sensory nerve conduction velocities tend to increase slightly in the arms and decrease in the legs during childhood up to 19 years. With aging, conduction velocities slowly decline after 50 years of age, so that the mean conduction velocity is reduced about 10% at 60 years of age.

Aging also causes a diminution in SNAP and CMAP amplitudes, which decline slowly after the age of 60 years. This affects SNAP amplitudes more prominently, so much that normal upper limb SNAP amplitude drops up to 50% by age 70, and lower limb SNAPs in many healthy subjects above the age of 60 years are low in amplitude or unevokable. Therefore absent lower extremity SNAPs in older adults must always be interpreted with caution and are not necessarily considered abnormal without other confirmatory data.

Height and Nerve Segment Lengths

An inverse relationship between height and nerve conduction velocity suggests that longer nerves generally conduct more slowly rhan shorter nerves. For example, the nerve conduction velocities of the peroneal and tibial nerves are 7-10 m per second slower than those of the median and ulnar nerves. This cannot be explained entirely by the slightly lower temperature of the legs as compared with the arms. Possible factors to account for the length-related slowing include abrupt distal axonal tapering, progressive reduction in axonal diameter, or shorter internodal distances. For similar reasons, nerve impulses propagate faster in proximal than in distal nerve segments. Adjustments of normal values must be made for patients of extreme height; this usually is no more than 2 m per second below the lower limit of normal.

Anomalies

Two anomalous peripheral innervations are important to recognize because they have a significant effect on NCSs. These are the Martin-Gruber anastomosis and the accessory deep peroneal nerve.

In the Martin-Gruber anastomosis, anomalous fibers cross from the median to the ulnar nerve in the forearm. The communicating branches usually consist of motor axons that supply the ulnar-innervated intrinsic hand muscles, particularly the first dorsal interosseous muscle, the hypothenar muscles (abductor digiti minimi), the thenar muscles (adductor pollicis, deep head of flexor pollicis brevis), or a combination of these muscles (Gutmann 1993). Martin-Gruber anastomosis occurs in approximately 15-20% of the population and is sometimes bilateral. On **ulnar** NCS recording from the abductor digiti minimi or first dorsal interosseous, this anomaly manifests as a drop in the ulnar CMAP amplitude between distal and proximal stimulation sites (simulating the appearance of conduction block). With distal stimulation (at the wrist), the CMAP reflects all ulnar motor fibers, whereas proximal stimulation activates only the uncrossed fibers, which are fewer in number. This anomaly can be confirmed by median nerve stimulation at the elbow that evokes a small CMAP from the

abductor digiti minimi or first dorsal interosseous, which is not present on median nerve stimulation at the wrist. When anomalous fibers innervate the thenar muscles, stimulation of the median nerve at the elbow activates the nerve and the crossing ulnar fibers, resulting in a large CMAP, often with an initial positivity caused by volume conduction of action potential from the ulnar thenar muscles to the median thenar muscles. In contrast, distal median nerve stimulation evokes a smaller thenar CMAP without the positive dip because the crossed fibers are not present at the wrist. Also, the median nerve conduction velocity in the forearm is spuriously fast, particularly in the presence of carpal tunnel syndrome, because the CMAP onset represents a different population of fibers at the wrist than at the elbow. An accurate conduction velocity may be obtained by using collision studies that abolish action potentials of the crossed fibers (Kimura 1976; Sander, Quinto, and Chockroverty 1997).

The accessory deep peroneal nerve is present in 20-30% of the population. It is a branch of the superficial peroneal nerve that usually arises as a continuation of the muscular branch that innervates the peroneus longus and hrevis muscles. It passes behind the lateral malleolus and terminates in the extensor digirorum brevis on the dorsum of the foot. During peroneal motor NCS recording from the extensor digitorum hrevis, the peroneal CMAP amplitude is larger stimulating proximally than distally because the anomalous fibers arc not present at the ankle (Gutmann 1993). This anomaly can be confirmed by stimulation behind the lateral malleolus, which yields a small CMAP that approximately equals the difference between the CMAP amplitudes evoked with distal and proximal peroneal nerve stimulations.

Temporal Dispersion and Phase Cancellation

The CMAP, evoked by supramaximal stimulation, represents the summation of all individual MUAPs directed to the muscle through the stimulated nerve. Typically, as the stimulus site moves proximally, the CMAP slightly drops in amplitude and area and increases in duration. This is caused by temporal dispersion, in which the velocity of impulses in slow-conducting fibers lags increasingly behind those of fast-conducting fibers as conduction distance increases. With dispersion, there is also a slight positive and negative phase overlap and cancellation of MUAP waveforms (Figure 36B.5). The final result of temporal dispersion and phase cancellation is a reduction of CMAP amplitude and area and prolongation of its duration.

Physiological temporal dispersion affects the SNAP more than the CMAP (Figure 36B.6). This difference is related to two factors. First is the disparity between sensory fiber and motor fiber conduction velocities. The range of conduction velocities between the fastest and slowest individual human myelinated sensory axons is almost twice that of the motor

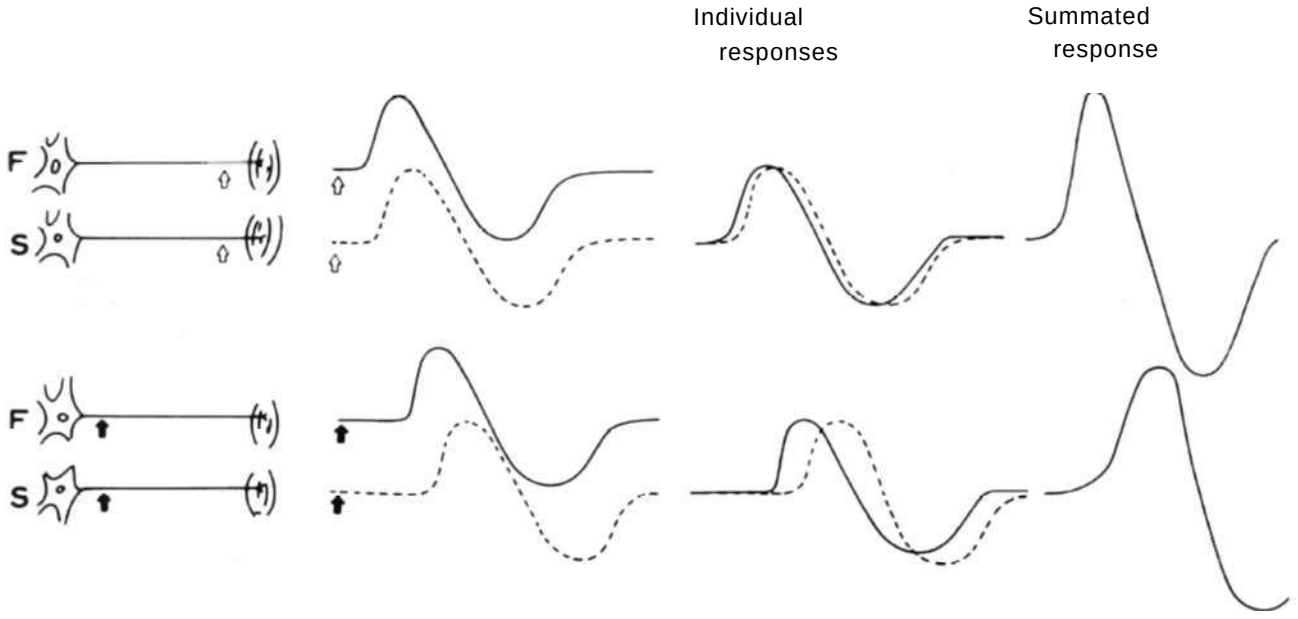

FIGURE 36B.S Compound muscle action potentials showing the relationship between fast-conducting (F) and slow-conducting (S) motor fibers. With distal stimulation, two unit discharges representing motor unit potentials sum to produce a muscle action potential twice as large. With proximal stimulation, motor unit potentials of long duration still superimpose nearly in phase despite the same latency shift of the slow motor fiber. Thus, a physiological temporal dispersion alters the size of the muscle action potential only minimally, if at all. Phase cancellation increases substantially when the latency difference between fast- and slow-conducting fibers is increased by a demyelinating neuropathy. This gives the false impression of motor conduction block, (Reprinted with permission from Kimura, J-, Machida, M., Ishida, T., et al. 1986, "Relation between size of compound sensory or muscle action potentials and length of nerve segment," *Neurology,* vol. 36, pp. *647-652.)*

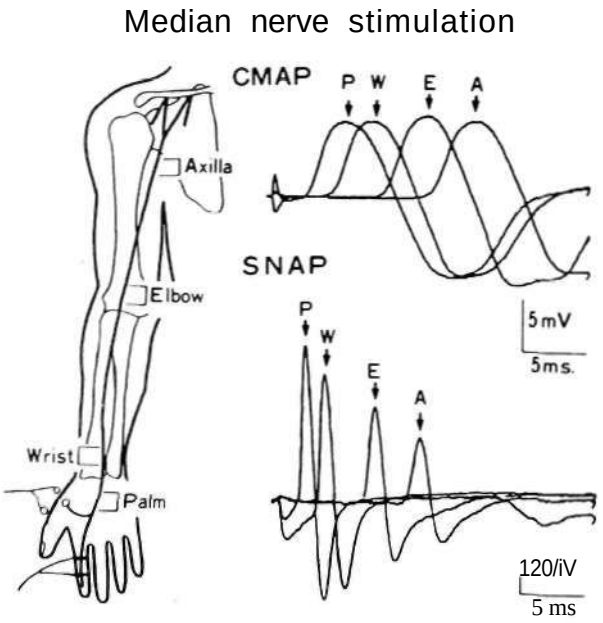

FIGURE 36B.6 Simultaneous recordings of compound muscle action potentials (CMAPs) from the thenar eminence and sensory nerve action potentials (SNAPs) from index and middle fingers after stimulation of the median nerve at palm (P), wrist (W), elbow (E), and axilla (A). With progressively more proximal stimulation, CMAPs remained nearly the same; for SNAPs, however, both amplitude and the area under the waveform became much smaller.

axons (25 m per second and 12 m per second, respectively). The second factor is the difference in duration of individual unit discharges between nerve and muscle. With short-duration biphasic sensory spikes, a slight latency difference could line up the positive peaks of the fast fibers with the negative peaks of the slow fibers and cancel both (Figure 36B.7). In longer-duration MUAPs, the same latency shift would only partially superimpose peaks of opposite polarity, and cancellation would be less of a factor.

Intertrial Variability

Principal factors contributing to an intertrial variability include errors in determining surface distance and measuring latencies and amplitudes of the recorded response. Amplitudes vary most, probably reflecting a shift in the recording site. NCSs are more reproducible when done by the same examiner, and there is a significant degree of interexaminer difference (Chaudhry et al. 1991).

Electrodiagnosis by NCS

Although it is often necessary to obtain both the NCS and needle EMG on most patients in order to make a final eleetrodiagnostic impression, certain neuromuscular diagnoses may be evident on NCSs.

Focal Nerve Lesions

Nerve fibers may be injured by a variety of mechanisms, including compression, ischemia, traction, and laceration. Anatomically, nerve lesions are classified as *neurapraxia* (first-degree injury), in which distortion of myelin occurs near the nodes of Ranvicr, producing segmental conduction block without wallerian degeneration; *axonotmesis* (second-degree injury), in which the axon is interrupted

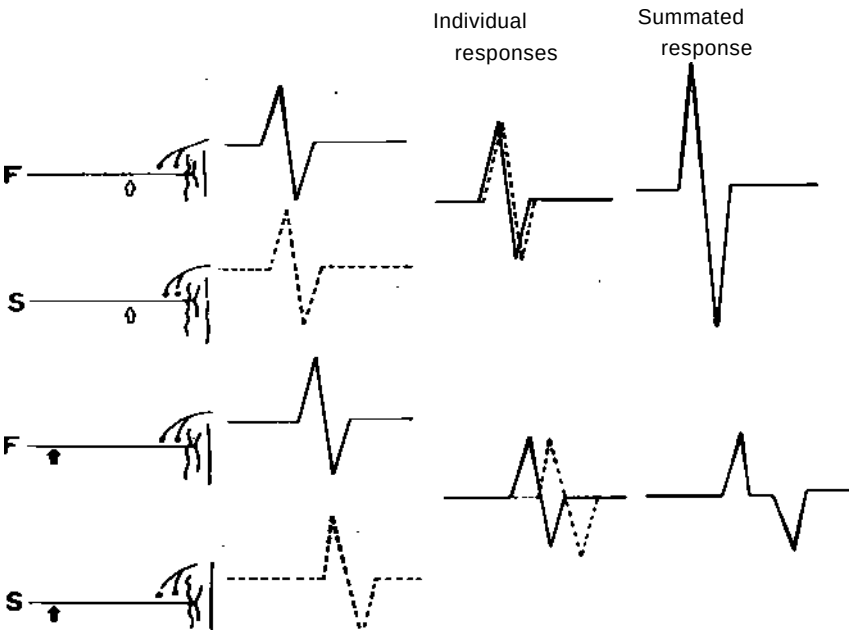

FIGURE 36B.7 Sensory nerve action potentials. A model for phase cancellation between fast-eonducting (F) and slow-conducting (S) sensory fibers. With distal stimulation, two unit discharges sum in phase to produce a sensory action potential twice as large. With proximal stimulation, a delay of the slow fiber causes phase cancellation between the negative peak of the fast fiber and positive peak of the slow fiber, resulting in a 50% reduction in *si/.e* of the summated response. (Reprinted with permission from Kimura, J., Machida, M., Ishida, T., et al. 1986, "Relation between size of compound sensory or muscle action potentials and length of nerve segment," *Neurology,* vol. 36, pp. 647-652.)

but all the supporting nerve structures remain intact; and *tieurotmesis,* in which the nerve injury is severe, resulting in complete disruption of the nerve with all the supporting structures (Seddon 1943; see Chapter *56D),* The latter category is often subdivided into three categories: a third-degree injury, in which the endoncurium is disrupted with intact pefineurium and epineurium; a fourth-degree injury, in which all neural elements are disrupted except the epineurium; and a fifth-degrec nerve injury, in which the nerve is transected, resulting in complete discontinuity of the nerve. However, the clectrodiagnostic studies alone cannot accurately distinguish between the five degrees of nerve injuries that involve axonal degeneration but can separate the first level, demyelination (ncurapraxia), from the other five levels (Wilbourn 2002).

Demyelinativc Mononeuropathy. When focal injury to myelin occurs, conduction along the affected nerve fibers may be altered. This may result in conduction slowing or block along the nerve fibers. *Conduction block* is caused by interruption of action potential transmission across the nerve lesion and is the electrophysiological correlate of ncurapraxia. It is usually the result of loss of several myelin segments (segmental or internodal demyelination). A nerve lesion manifesting with conduction block is best localized when it can be bracketed by two stimulation points, one distal to the site of injury and one proximal. In conduction block, it is characteristic to find that stimulation distal to the lesion elicits a normal CMAP, whereas proximal stimulation elicits a response with reduced amplitude (partial conduction block) or absent response (complete conduction block; Figure 36B.8A).

There are several limitations to the diagnosis of demyelinative conduction block. First, reduced CMAP size may result from phase cancellation between peaks of opposite polarity because of abnormally increased temporal dispersion. Such excessive desynchronization often develops in acquired demyelinativc neuropathies. If the distal and proximal responses have dissimilar waveforms, the discrepancy in amplitude or area between the two may represent in part a phase cancellation rather than true conduction block. Therefore, for a diagnosis of partial conduction block, there should be a significantly lower CMAP amplitude and smaller area with stimulation proximal to the injury site, when compared with the CMAP distal to it, without evidence of significant prolongation of CMAP duration. More than 50% decrement of the CMAP amplitude and area across the lesion usually is the criterion for definite conduction block. Second, distal demyelinating lesions, causing conduction block of the nerve segment between the most distal stimulating point and the recording site, manifest as unelicitable or low CMAP amplitudes at both distal and proximal stimulation sites. This finding mimics the NCSs seen with axonal degeneration. Third, the prominent temporal dispersion normally seen in evaluating SNAPs precludes the use of these potentials to diagnose conduction block. Fourth, conduction block may also follow axonal loss before the completion of wallerian degeneration.

Focal slowing of conduction usually is the result of widening of the nodes of Ranvier (paranodal demyelination). Slowing often is synchronized and affects all large myelinated fibets equally. This results in prolongation of distal latency (if the focal lesion is distal) or slowing in conduction velocity (if the focal lesion is proximal; Figure 36B.8B). However, CMAP amplitude, duration, and area are normal and do not change when the nerve is stimulated proximal to the lesion. *Desynchronized slowing {differential slowing)* occurs when conduction velocity is reduced at the lesion site along a variable number of the medium or small nerve fibers (average or slower conducting axons). Here, the CMAP is dispersed with prolonged duration on stimulations proximal to the lesion. The speed of conduction along the injury site (latency or conduction velocity) is normal because at least some of the fastest-conducting axons are spared (Figure 36B.8C). When both synchronized and desynchronized slowing coexist, the dispersed CMAP with prolonged duration is also accompanied by slowing of distal latency or conduction velocity.

Axon Loss Mononeuropathy. After acute focal axonal damage, the distal nerve segment undergoes wallerian degeneration. Characteristically, unelicitable or low CMAP amplitudes with distal and proximal stimulations are signs of complete or partial motor axonal loss lesions. The CMAP amplitudes are a reliable estimate of the amount of axonal loss except in the chronic phase, in which reinnervation via collateral sprouting often increases the CMAP and gives a misleadingly low indication of the extent of original axonal loss.

In partial axon loss lesions, distal latencies and conduction velocities are normal or borderline. Selective loss of fast-conducting fibers associated with more than a 50% reduction in mean CMAP amplitude can slow conduction velocity up to 80% of normal value because the velocity represents the remaining slow-conducting fibers. Motor conduction velocity may be slowed to 70% of normal value, with reduction of CMAP amplitude to less than 10% of normal.

Soon after axonal transaction (i.e., for the first 48 hours), the distal axon remains excitable. Therefore stimulation distal to the lesion elicits a normal CMAP, whereas proximal stimulation elicits a response with reduced amplitude (conduction block pattern; Figure 36B.8D). This has been called *axonal noncontinuity, early axon loss,* or *axon-discontinuity conduction block.* However, soon the distal axons undergo wallerian degeneration, and the distal CMAP decreases and reaches its nadir in *5-6* days; the distal SNAP lags slightly behind and reaches its nadir in 10-11 days (Figure 36B.9). The difference between the decline of the SNAP and CMAP amplitudes after axon loss nerve lesions probably is related to neuromuscular

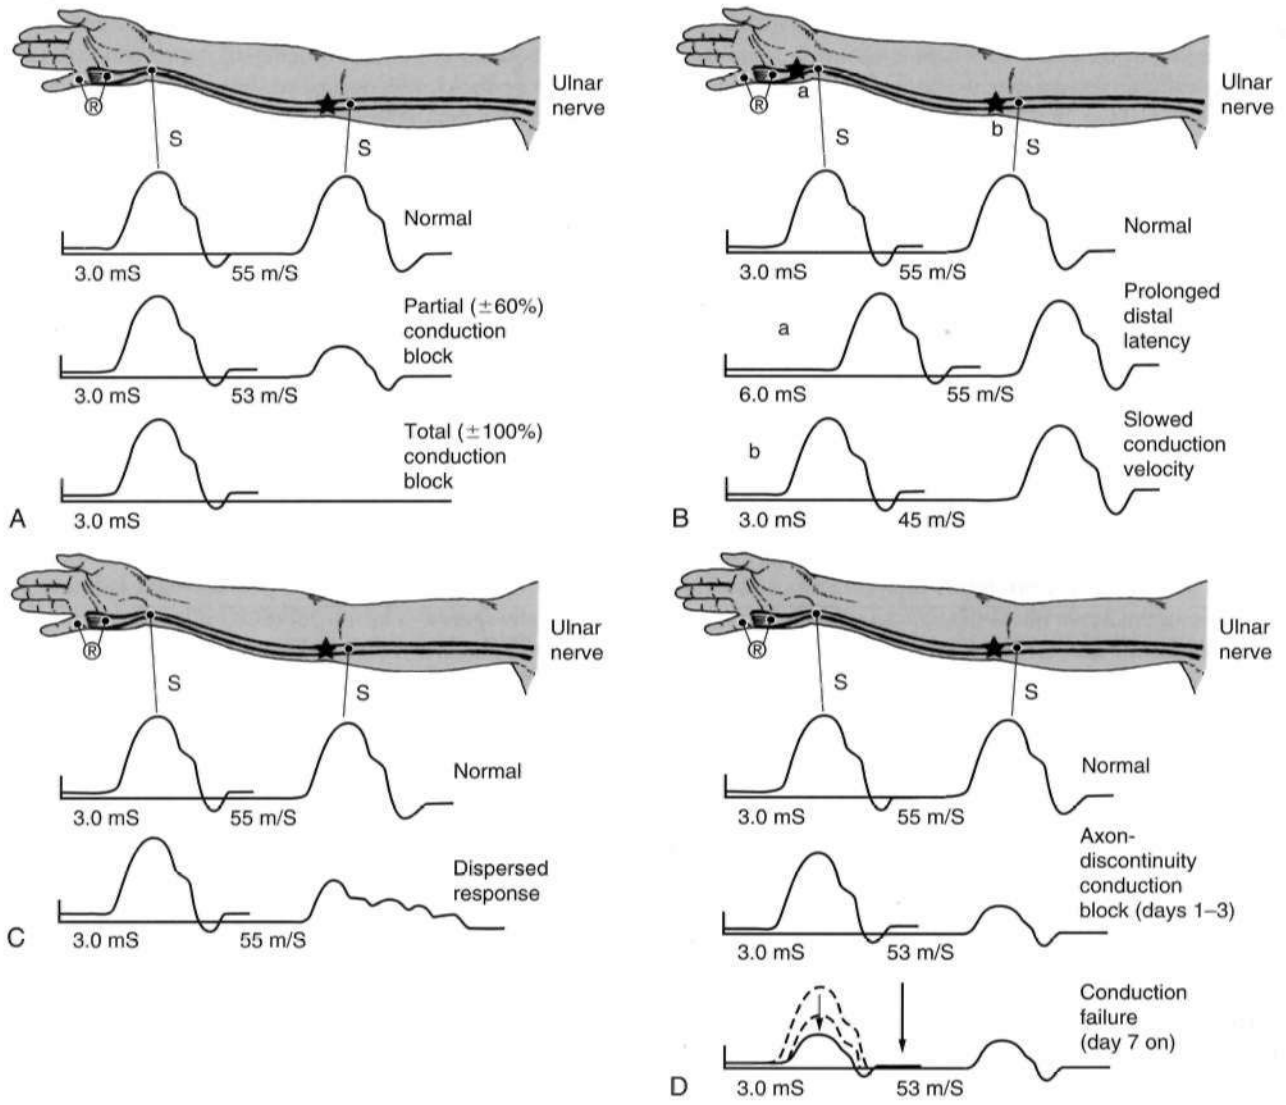

FIGURE 36B.8 Nerve conduction studies. (A) Demyelinative conduction block. (B) Focal synchronized slowing. (C) Focal desynchronized slowing (dispersion). (D) Axon loss. R = recording; S = stimulation. (Reprinted with permission from Wilbourn, A. J. 2002, "Nerve conduction studies. Types, components, abnormalities and value in localization," *Neurol Clin*, vol. 20, pp. 305-338.)

transmission failure, which affects only the CMAP amplitude. This is supported by the fact that mixed nerve action potentials, recorded directly from nerve trunks, follow the time course of SNAPs.

To distinguish between conduction blocks caused by demyelination and those caused by axon loss, the nerve is stimulated beiow the lesion after 11 days, when tJL^aiLTJiiiiL; axons would have lost their excitability. A reduced amplitude of the evoked potential from stimulation above and below the lesion indicates axonal loss (Figure 36B.8D). In contrast, if the distally evoked CMAP still has higher amplitude than the proximally elicited response, this indicates partial segmental demyelination.

The identification of conduction block in the early days of axonal loss is extremely helpful in localizing a peripheral nerve injury, particularly the closed type, in which the exact site of lesion is not apparent. Awaiting the completion of wallerian degeneration results in diffusely low or unevok able CMAPs (regardless of stimulation site), which does not allow accurate localization of the injury site. Needle EMG is useful, but localization by this method is suboptimal because peripheral nerves may not have motor branches from long segments (such as the median and ulnar nerves in the arms),

Preganglionic (Intraspinal Canal) Lesions. Damage to the sensory axons in the nerve roots located proximal to the dorsal root ganglion does not affect the SNAP amplitude because the peripheral sensory axons originating from the unipolar dorsal root ganglion neurons remain intact. Because the dorsal root ganglia usually are located outside

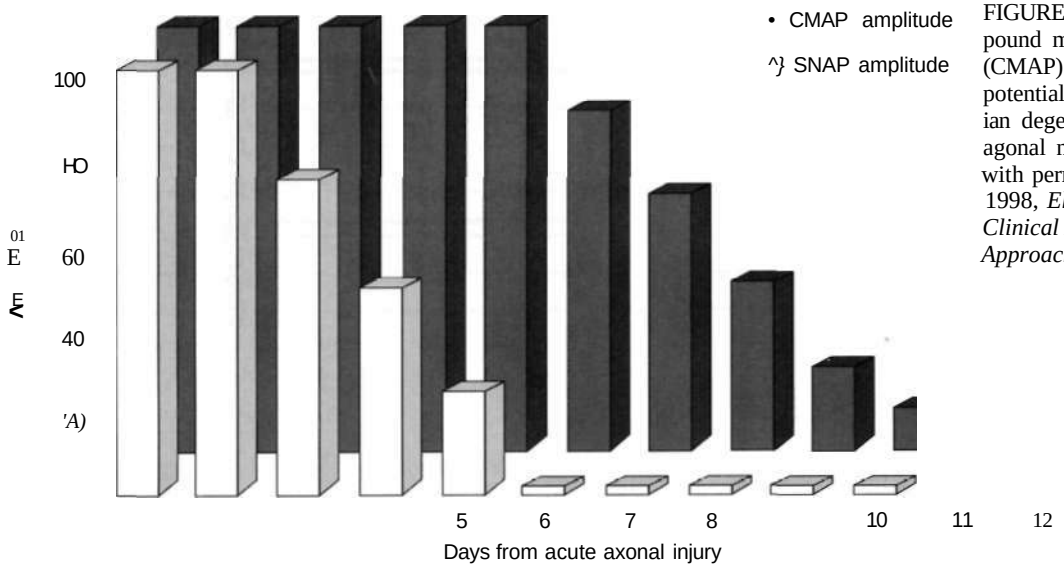

FIGURE 36B.9 Distal compound muscle action potential (CMAP) atid sensory nerve action potential (SNAP) during wallerian degeneration after an acute agonal nerve injury. (Reprinted with permission from Katirji, B. 1998, *Electromyography in Clinical Practice: A Case Study Approach*, Mosby, St Louis.)

the spinal canal and within the intervertebral foramina, axon loss intraspinal canal lesions (such as radiculopathies or root avulsions) have no effect on SNAP amplitudes. However, these nerve root lesions often result in motor axon degeneration as reflected by abnormal needle EMG and, when severe, by low-amplitude CMAP. In contrast to intraspinal canal lesions, axon loss extraspinal lesions (such as plexopathies) affect the CMAP as well as the SNAP amplitudes when mi\ed nerves undergo walk-nan degeneration.

Generalized Neuropathies

NCSs are essential in diagnosing peripheral polyneuropathies. They are very useful in confirming the diagnosis and establishing the types of fibers affected (large fiber sensory, motor, or both). Most importantly, NCSs often can identify the primary pathological process of the various polyneuropathies: axonal loss or segmental demyelination.

Demyelinating Polyneuropathies. The hallmark of demyelinating polyneuropathies is a widespread increase in conduction time caused by impaired saltatory conduction. Therefore, the NCSs are characterized by significant slowing of conduction velocities (<75% of lower limit of normal) and distal latencies (>130% of upper limit of normal).

With distal stimulation, the CMAP amplitude is mildly or moderately reduced because of abnormal temporal dispersion and phase cancellation, and the distal latency is delayed by demyelination. With more proximal stimulation, the CMAP amplitude is lower because of temporal dispersion and conduction block along some fibers. The proximal conduction velocity is markedly slowed because of increased probability for the nerve action potentials to pass through demyelinated segments (Figure 36B.10C).

Chronic demyelinating polyneuropathies may be further distinguished by NCSs into inherited and acquired polyneuropathies. Inherited demyelinaring polyneuropathies such as Charcot-Marie-Tooth disease type I are characterized by uniform slowing without conduction blocks, and the abnormalities usually are symmetrical. In contrast, acquired demyelinating polyneuropathies, such as chronic inflammatory demyelinating polyneuropathy, often have asymmetrical nerve conductions, even when there is no apparent clinical asymmetry. In addition, multifocal conduction blocks and excessive temporal dispersions at nonentrapment sites are characteristic of acquired demyelinating polyneuropathies.

Axonal Polyneuropathies. Axonal polyneuropathies produce length-dependent dicback degeneration of axons. The major change on NCS is a decrease of the CMAP and SNAP amplitudes, more marked in the lower extremities. In contrast, conduction velocities and distal latencies are normal (Figure 36B.10B). As with mononeuropathics, selective loss of many fast-conducting fibers associated with more than a 50% reduction in mean CMAP amplitude can slow conduction velocity to 70-80% of normal value.

NEEDLE ELECTROMYOGRAPHIC EXAMINATION

Principles and Techniques

The motor unit consists of a single motor neuron and all the muscle fibers it innervates. A single motor unit consists of either type I or type II muscle fibers, but never both. All muscle fibers in one motor unit discharge simultaneously when stimulated by synaptic input to the lower motor neuron or by electrical stimulation of the axon. The ratio of muscle fibers per motor neuron (motor unit or innervation ratio) is variable and ranges from 3 to I for extrinsic eye

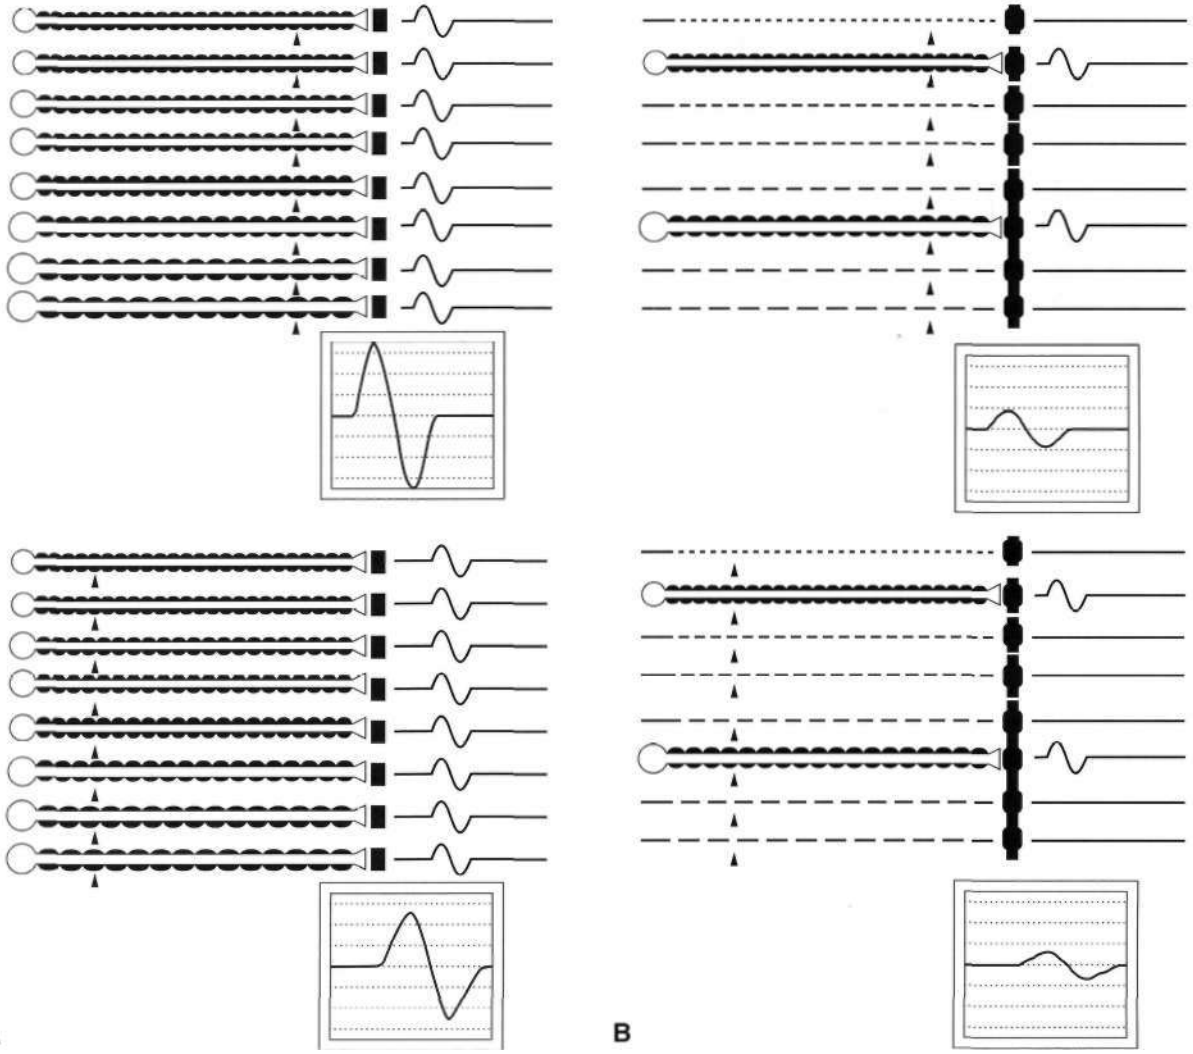

FIGURE 36B.10 Computerized model of peripheral motor nerve: (A) normal, (B) axonal degeneration, and (C) segmental demyelination. (Reprinted with permission from Brown, W, F. & Bolton, C. F. (eds) 1989, *Clinical Electromyography*, Butterworth-Heiiiem;inn, Boston.)

muscles to several thousand to 1 for large limb muscles. The smaller ratio generally occurs in muscles that perform fine gradations of movement. The distribution of muscle fibers in a muscle is wide, with overlap between different motor units.

The muscle fiber has a resting potential of 90 mV, with negativity inside the cell. The generation of an action potential reverses the transmembrane potential, which then becomes positive inside the cell. An extracellular electrode, as used in needle **EMG,** records the activity resulting from this switch of polarity as a predominantly negative potential (usually triphasic, positive-negative-positive waveforms). However, when recording near a damaged region, action potentials consist of a large positivity followed by a small negativity,

Concentric and Teflon-coated monopolar needle electrodes are equally satisfactory in recording muscle potentials, with little appreciable difference. Although monopolar needles are less painful, an additional reference electrode must be placed nearby, which often results in greater electrical noise caused by electrode impedance mismatch between the intramuscular active electrode and the surface reference disk.

The electromyographer first identifies the needle insertion point by recognizing the proper anatomical landmark and the activation maneuver for the sampled muscle. EMG evaluation is performed in four steps (Daube 1991):

1. Inserting or slightly moving the needle causes insertion a 1 activity that results from needle injury of muscle fibers.
2. Spontaneous activity is assessed in relaxed muscle by moving the needle a small distance and pausing a few seconds. The needle is relocated in four quadrants of the muscle from a single insertion to make these evaluations.

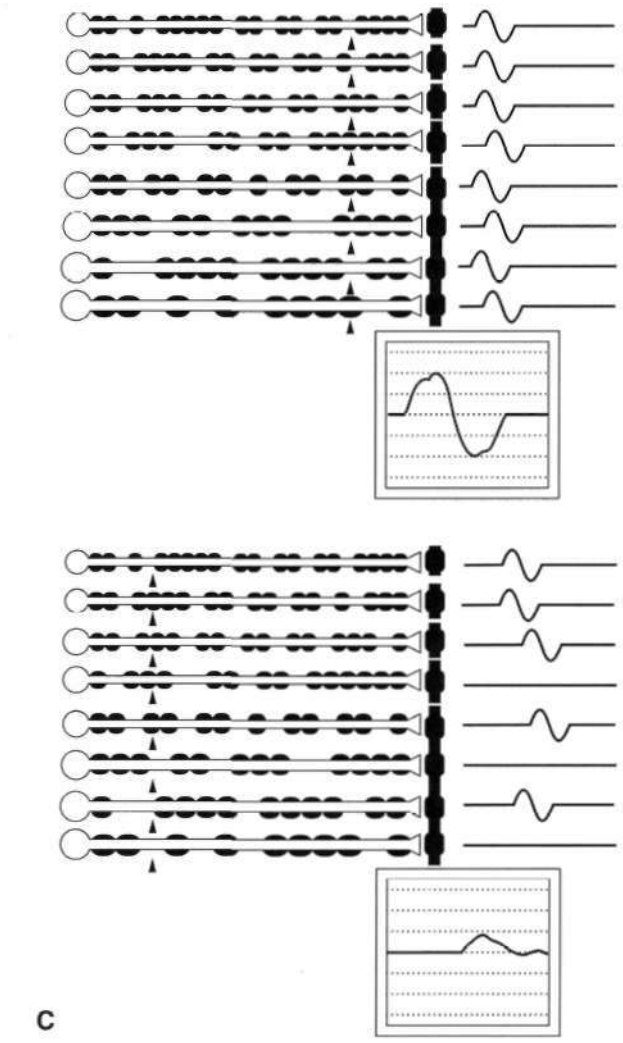

FIGURE 36B.10, cont'd.

3. A minimal contraction is obtained to assess the morphology of several MUAPs that are measured on the oscilloscope or hard copy.
4. The intensity of muscle contraction is increased to assess the recruitment pattern of MUAPs, Maximal contraction normally fills the screen, producing the interference pattern,

Oscilloscope sweep speeds of 10 milliseconds per division best define spontaneous and voluntary activities. Most laboratories use an amplification of 50 pV per division for insertional and spontaneous activity and 200 pV per division for voluntary activity.

Insertional and Spontaneous Activity

Normal Insertional and Spontaneous Activity

Brief bursts of electrical discharges accompany insertion and repositioning of a needle electrode into the muscle, slightly outlasting the movement of the needle. On average, insertional activity lasts for a few hundred milliseconds. It appears as a cluster of positive or negative repetitive high-frequency spikes, which make a crisp static sound over the loudspeaker.

At rest, muscle is silent, with no spontaneous activity except in the motor endplate region, the site of neuromuscular junction, which is usually located near the center of rhe muscle belly. Normal and abnormal insertional and spontaneous activities are listed in Table 36B.1 (Preston and Shapiro 2002). Two types of normal endplate spontaneous activity occur together or independently: endplate noise and endplate spikes.

Endplate Noise. The tip of the needle approaching the endplate region often registers recurring irregular negative potentials, 10-50 uV in amplitude and 1-2 milliseconds in duration. These potentials are the extracellularly recorded miniature endplate potentials, nonpropagating depolarizations caused by spontaneous release of acetylcholine quanta. They produce a characteristic sound on loudspeaker much like a scashell held to the ear.

Endplate Spikes, These are intermittent spikes, 100-200 pV in amplitude and 3-4 milliseconds in duration, firing irregularly at 5-50 impulses per second. Their characteristic irregular firing pattern distinguishes them from the regular firing fibrillation potentials. They have a clacking or buzzing sound on the loudspeaker. The waveform of the endplate spike is also distinguished by its initial negative deflection. The endplate spikes arc discharges of single muscle fibers generated by activation of intramuscular nerve terminals irritated by the needle. The similarity of the firing pattern of endplate spikes to discharges of muscle spindle afferents suggests that they may otiginatc in the intrafusal muscle fibers.

Abnormal Insertional and Spontaneous Activity

Prolonged versus Decreased Insertional Activity. An abnormally prolonged (increased) insertional activity indicates instability of the muscle membrane, often seen in conjunction with denervation, myotonic disorders, or necrotizing myopathies such as inflammatory myopathies. Insertional positive waves, initiated by needle movements only and identical to the spontaneous discharges, may follow the increased insertional activity, lasting few seconds. This isolated activity usually signals early denervation of muscle fibers, such as 1-2 weeks after nerve injury. A marked reduction or absence of insertional activity suggests either fibrotic or severely atrophied muscles or functionally incxcitable muscles, such as during the attacks of familial periodic paralysis.

Fibrillation Potentials. Fibrillation potentials are spontaneous action potentials of denervated single muscle fibers

Table 36B.1: Insertional and spontaneous activity

Potential	*Source generator and morphology*	*Sound on loudspeaker*	*Stability*	*Firing rate*	*Firing pattern*
Endplate noise	Miniature endplate potentials (monophasic negative)	Seashell	—	20–40 Hz	Irregular (hissing)
Endplate spike	Muscle fiber initiated by terminal axonal twig (brief spike, diphasic, initial negative)	Sputtering fat in a frying pan	—	5–50 Hz	Irregular (sputtering)
Fibrillation (brief spike)	Muscle fiber (brief spike, diphasic or triphasic, initial positive)	Rain on a tin roof or tick-tock of a clock	Stable	0.5–10 Hz (occasionally up to 30 Hz)	Regular
Positive sharp wave	Muscle fiber (diphasic, initial positive, slow negative)	Dull pops, rain on a tin roof, or tick-tock of a clock	Stable	0.5–10 Hz (occasionally up to 30 Hz)	Regular
Myotonia	Muscle fiber (brief spike, initial positive, or positive wave)	Revving engine	Waxing and waning amplitude	20–150 Hz	Waxing and waning
Complex repetitive discharge	Multiple muscle fibers time-linked together	Machine	Usually stable, may change in discrete jumps	5–100 Hz	Perfectly regular (unless overdriven)
Fasciculation	Motor unit (motor neuron or axon)	Corn popping		Low (0.1–10 Hz)	Irregular
Myokymia	Motor unit (motor neuron or axon)	Marching soldiers		1–5 Hz (interburst), 5–60 Hz (intraburst)	Bursting
Cramp	Motor unit (motor neuron or axon)		—	High (20–150 Hz)	Interference pattern or several individual units
Neuromyotonia	Motor unit (motor neuron or axon)	Pinging	Decrementing amplitude	Very high (150–250 Hz)	Waning

that result from the resting membrane potential of the denervated fiber being reduced to the level at which it can fire spontaneously. Fibrillation potentials have two types of waveforms: brief spikes and positive waves. Brief spikes usually arc triphasic, with initial positivity {Figure 36B.11 A). They range from 1 to 5 milliseconds in duration and 20 to 200 pV in amplitude when recorded with a concentric needle electrode. If the needle electrode is placed near the endplatc zone, brief spike fibrillation potentials resemble physiological endplate spikes with an initial negativity. Positive waves have an initial positivity and subsequent slow negativity and have a characteristic sawtooth appearance (Figure 36B.11B). Recording near the damaged part of the muscle fiber incapable of generating an action potential accounts for the absence of negative spike. Although usually seen together, positive sharp waves tend to precede brief spikes after nerve section, possibly because they can be triggered by the insertion of a needle in already irritable muscle membrane.

Fibrillation potentials are triggered by spontaneous oscillations in the muscle fiber membrane potential. They typically fire in a regular pattern at a rate of 1-30 Hz. The sound produced by fibrillation potentials is crisp and clicking, reminiscent of the sound caused by ram on the roof or the tick-tock of a clock.

Fibrillation potentials are the electrophysiological markers of muscle denervation. Based on their distribution, they are useful in localizing lesions to the anterior horn cells of the spinal cord, root, plexus, or peripheral nerve. Insertional positive waves may appear within 2 weeks of acute denervation, but fibrillation potentials do not become full until about 3 weeks after axonal loss. Because of this latent period, their absence does not exclude recent denervation. Also, late in the course of denervation, muscle fibers that are remnervated, fibrotic, or severely atrophied show no fibrillation potentials. A numerical grading (from 0 to 4) is used to semiquantitate fibrillation potentials because their density is a rough estimate of the extent of denervated muscle fibers: 0, no fibrillations; +1, persistent single trains of potentials (>2 seconds) in at least two areas; +2, moderate number of potentials in three or more areas; +3, many potentials in all areas; +4, abundant spontaneous potentials nearly filling the oscilloscope.

Fibrillation potentials are also seen in necrotizing myopathies, such as the inflammatory myopathies and muscular dystrophics. Tins is probably caused by segmental necrosis of muscle fibers, leading to effective denervation of the distant segments as they become physically separated from the neuromuscular junction, or by the resting membrane potential of partially damaged fibers being reduced to the level that allows spontaneous discharges to occur. Also, damage to the terminal intramuscular motor axons, presumably by the inflammatory process, may also result in muscle fiber denervation. In disorders of the neuromuscular junction such as myasthenia gravis and botulism, fibrillation potentials are rare, but when they occur they are explained by a neuromuscular transmission blockade, resulting in effective denervation of muscle fibers.

Fasciculation Potentials. Fasciculation potentials are spontaneous discharges of a motor unit. They originate from the motor axon anywhere along its length and may stem also from the spinal cord. Fasciculation potentials fire randomly and irregularly and undergo slight changes in amplitude and waveform from time ro time, giving them a corn popping sound on the loudspeaker. They have a much lower firing rate than voluntary MUAPs and are unaffected by slight voluntary contraction of agonist or antagonist muscles.

Fasciculation potentials are most common in diseases of anterior horn cells but also occur in radiculopathies, entrapment neuropathies, peripheral polyneuropathies, and the cramp fasciculation syndrome. They are seen also in tetany, thyrotoxicosis, and overdose of anticholinesterase medication. In addition, they may occur in healthy people. There is no reliable method of distinguishing "benign" from "malignant" fasciculation potentials except that the benign discharges tend to fire more quickly, whereas grouped fasciculation potentials from multiple unirs are more common in motor neuron disease. Most importantly, the association of fasciculation potentials with fibrillation potentials or other neurogenic MUAP changes is strong evidence of a lower motor neuron disorder.

Myotonic Discharges. Myotonic discharges, a special type of abnormal insertional activity, appear either as a sustained run of sharp positive waves, each followed by a slow negative component of longer duration, or as a sustained run ot negative spikes with a small initial positivity iFigure 36B.11C). Myotonic discharges are recurring single-fiber potentials, showing, as with fibrillation potentials, two types of waveforms depending on the spatial relationship between the recording surface of the needle electrode and the discharging muscle fibers. Of the two types, the positive sharp waves are initiated usually by needle insertion injuring muscle membrane, whereas the negative spikes, resembling the brief spike form of fibrillation potentials, tend to occur at the beginning of slight volitional contraction. Both positive sharp waves and negative spikes typically wax and wane in amplitude over the range of 10 LIV to 1 mV, varying inversely to the rate of firing. Their frequency ranges from 20 to 150 Hz and gives rise to a characteristic noise over the loudspeaker, simulating an accelerating or decelerating motorcycle or chainsaw.

Myotonic discharges may occur with or without clinical myotonia in the myotonic dysttophies (types I and II), myotonia congenita, and paramyotonia congenita. They may also accompany other myopathies, such as acid maltasc deficiency, polymyositis, colchicine myopathy, and myotubular myopathy, as well as hyperkalemic periodic paralysis.

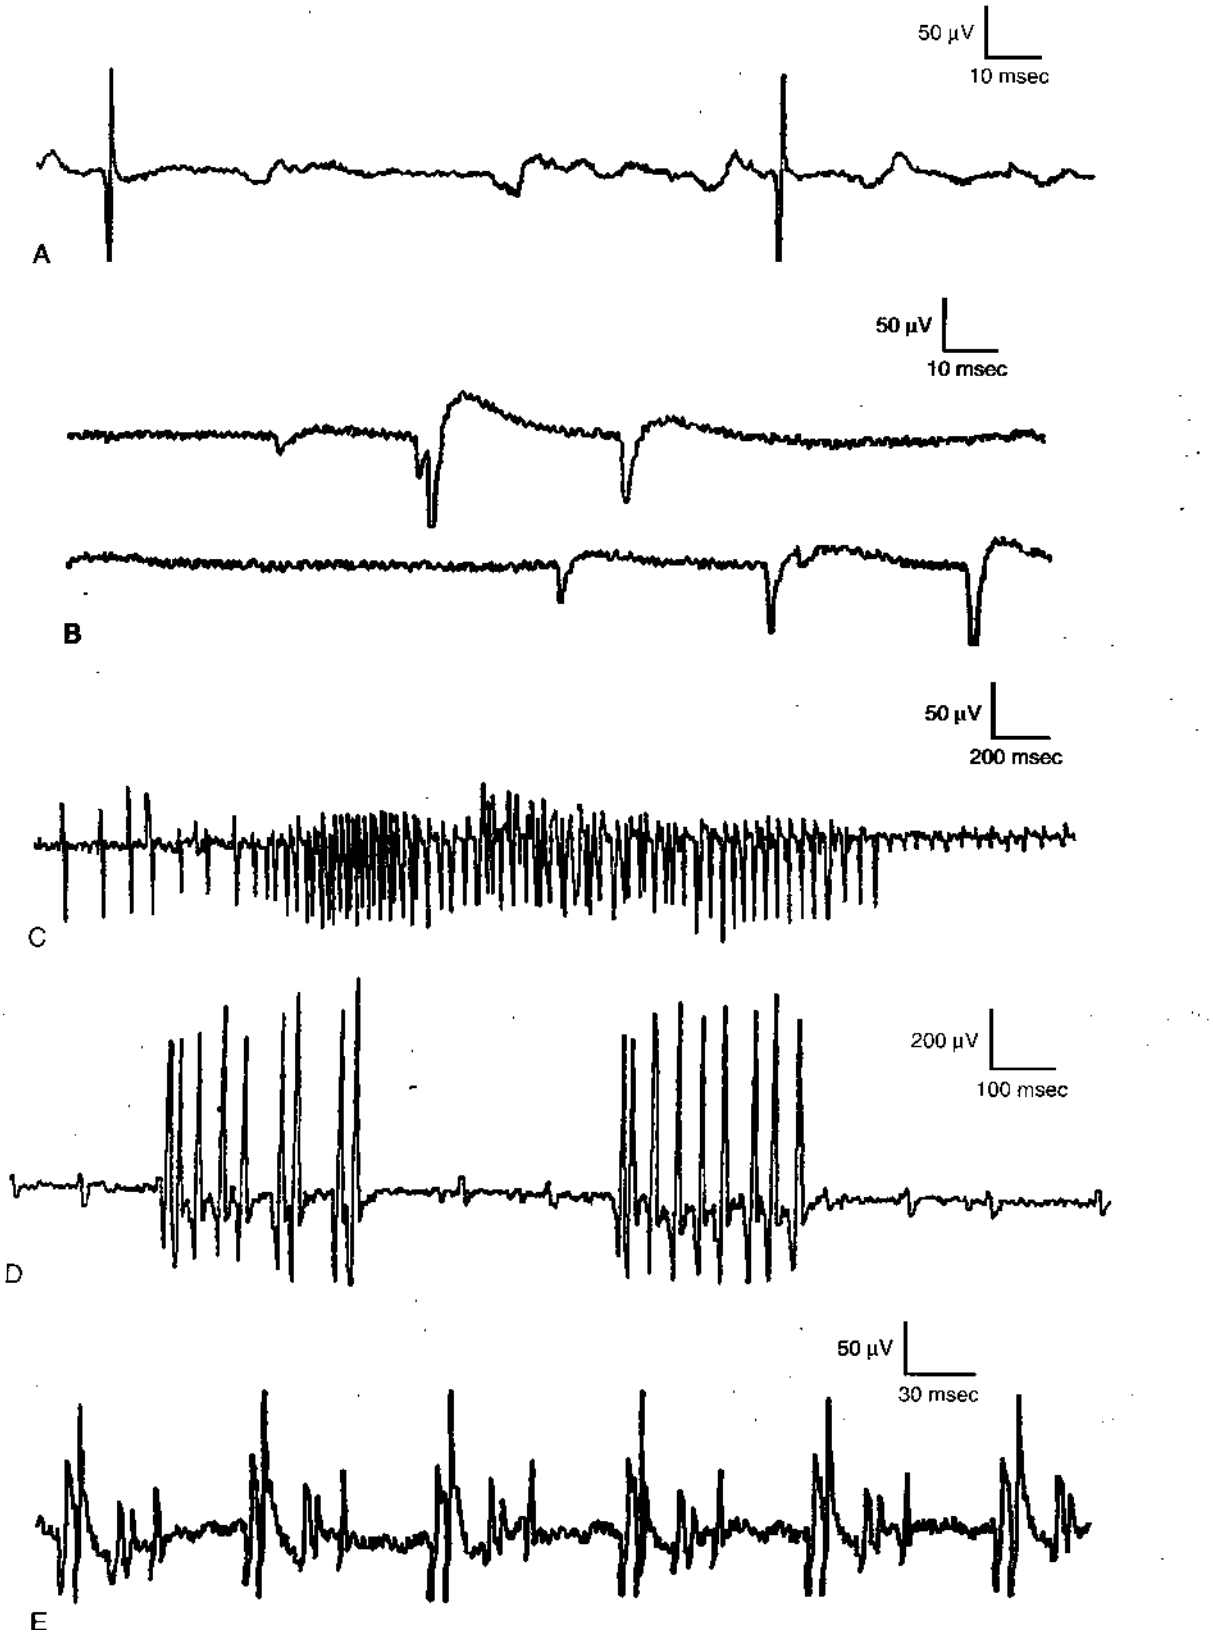

FIGURE 36B.11 Abnormal insertional activities. (A) Brief spike fibrillation potentials. (B) Positive waves. (C) Myotonic discharge. (D) Myokymic discharge. (E) Complex repetitive discharge. {Reprinted with permission from Preston, D. C. 8c Shapiro, B. E. 2000, *EMG Waveforms,* Butter wort h-Heinemann, Boston.)

Myokymic Discharges. Myokymia results from complex bursts of grouped repetitive discharges in which motor units fire repetitively, usually with 2-10 spikes discharging at a mean of 30-40 Hz (Figure 36B.11D). Each burst recurs at regular intervals of 1-5 seconds, giving the sound of marching soldiers on the loudspeaker. Clinically, myokymic discharges often give tise to sustained muscle contractions, which have an undulating appearance beneath the skin ("bag of worms"). Myokymic discharges probably originate ectopically in motor nerve fibers and accordingly arc amplified by increased axonal excitability, such as after hypcrvcntilation-induced hypocapnia.

Myokymic discharges in facial muscles suggest a brainstem glioma or multiple sclerosis, wheteas those occurring in limb muscles are seen with radiation plcxopathies, Guillain-Bane syndrome, and carpal tunnel syndrome.

Complex Repetitive Discharges. A complex repetitive discharge results from the nearly synchronous firing of a group of muscle fibers. One fiber in the complex serves as a pacemaker, driving one or several other fibers ephaptically so that the individual spikes in the complex fire in the same order as the discharge recurs. One of the late-activated fibers reexcites the principal pacemaker to repeat the cycle. The entire sequence recurs at slow or fast rates, usually in the range of 5-100 Hz. The discharge ranges from 50 pV to 1 mV in amplitude and up to 50-1000 milliseconds in duration. The complex waveform contains 10 or more distinct spikes and remains uniform from one discharge to another (Figure 36B.11E). These discharges typically begin abruptly, maintain a constant rate of firing for a short period, and cease as abruptly as they started when the chain reaction eventually blocks. They produce a noise that mimics the sound of a machine gun on a loudspeaker.

Complex repetitive discharges are abnormal discharges but are nonspecific because they are seen in many chronic disorders, including chronic neuropathies and myopathies. They may also be found in the iliopsoas or cervical pataspinal muscles of apparently healthy people, probably implying a clinically silent neuropathic process.

Neuromyotonic Discharges. Neuromyotonic discharges are rare discharges in which muscle fibers fire repetitively at high frequency (150-250 Hz), either continuously or in recurring decrementing bursts, producing a pinging sound on the loudspeaker. The discharge continues during sleep and diminishes in intensity with progressively distal nerve blocks, implicating the entite axon as the site of generation (Harik et al. 1976). Many cases of neuromyoronia are associated with the syndtome of continuous motor unit activity (Isaac's syndrome), which may have an autoimmune origin, with the target antigen probably peripheral nerve potassium channels (Hart et al. 1997). Other conditions associated with neuromyoronia include anticholinesterase poisoning, tetany, and chronic spinal muscular atrophies.

Cramp Discharges. A muscle cramp is a sustained involuntary muscle contraction. On needle FMG, ctamp discharge consists of MUAPs usually firing at a rate of 40-60 Hz, with abrupt onset and cessation. Cramps most often occur in healthy people but ate exaggerated by hyponatremia, hypocalcemia, myxedema, pregnancy, postdialysis state, and the early stages of motor neuron disease. Clinically, cramps may resemble muscle contractures that accompany sevetal of the metabolic muscle diseases and are characterized by complete electrical silence on needle F.MG.

Voluntary MUAPs

MUAP Morphology

The MUAP is the exttacellular electrode recording of a small portion of a motor unit. The waveform is dictated by the inherent properties of the MUAP and the spatial relationships between the needle and individual muscle fibers. Slight repositioning of the electrode causes major changes in the electrical profile of the same motor unit. Therefore, one motor unit can give rise to MUAPs of different morphology at different recording sites. The amplitude, dutation, and number of phases charactetize the MUAP.

Amplitude. MUAP amplitude is the maximum peak-to-peak amplitude and tanges from several hundred microvolts to a few millivolts with a concentric needle and is substantially greater with a monopolar needle. The amplitude of an MUAP decreases to less than 50% at a distance of 200-300 pm from the source and to less than 1% a few millimeters away. Therefore, only a small number of individual muscle fibers located near the tip of the tecording electrode determine the amplitude of an MUAP (probably less than 20 muscle fibers lying within a 1-mm radius of the electrode tip). In general, amplitude indicates muscle fiber density and not the motot unit territory.

Duration, MUAP duration reflects the activity from most muscle fibers belonging to a motor unit because potentials generated more than 1 mm away from the electrode contribute to the initial and terminal low-amplitude portions of the potential. The duration indicates the degree of synchrony among many individual muscle fibers with variable length, conduction velocity, and membrane excitability. A slight shift in needle position or rotation influences duration much less than the amplitude. MUAP duration is a good index of the motor unit tetritory and is the parametet that best reflects the number of

muscle fibers in a motor unit. It is measured from the initial deflection away from baseline to the final return to baseline and normally varies from 5 to 15 milliseconds, depending on the sampled muscle and the age of the subject.

Long-duration MUAPs often show high amplitude and arc the best indicators of reinnervation. They occur with increased number or density of muscle fibers or a loss of synchrony of fiber firing within a motor unit, as seen with lower motor neuron disorders. Short-duration MUAPs often have low amplitude. They occur in disorders associated with loss of muscle fibers, as seen with myopathies {Figure 36B.12).

Phases. A phase constitutes the portion of a waveform that departs from and returns to the baseline. The number of phases equals the number of negative and positive peaks extending to and from the baseline, or the number of baseline crossings plus one. Normal MUAPs have four phases or less, but about 5-15% of MUAPs have five phases or more, and tins may he up to 25% in proximal muscles, particularly the deltoid and iliacus. Increased polyphagia is a nonspecific MUAP abnormality seen in myopathics and neuropathies. An increased number of polyphasic MUAPs suggests desynchronized discharge, loss of individual fibers within a motor unit, or temporal dispersion of muscle fiber potentials within a motor unit. Excessive temporal dispersion, in turn, results from differences in conduction time along the terminal branch of the nerve or over the muscle fiber membrane. In early reinnervation after severe denervation in which the newly sprouting axons only begin to leinnervate few muscle fibers, the MUAP may also be polyphasic, with short duration and low amplitude ("nascent" MUAP).

Some MUAPs have a serrated pattern, making several turns or directional changes without crossing the baseline; this also indicates desynchronization among discharging muscle fibers. Satellite potential {linked potential or parasite potential) is a late spike of MUAP, which is distinct but time-locked with the main potential. It implicates early reinnervation of muscle fibers by collateral sprouts from adjacent motor units.

MUAP Stability

Motor units normally discharge semirhythmically, with successive potentials showing nearly identical configuration

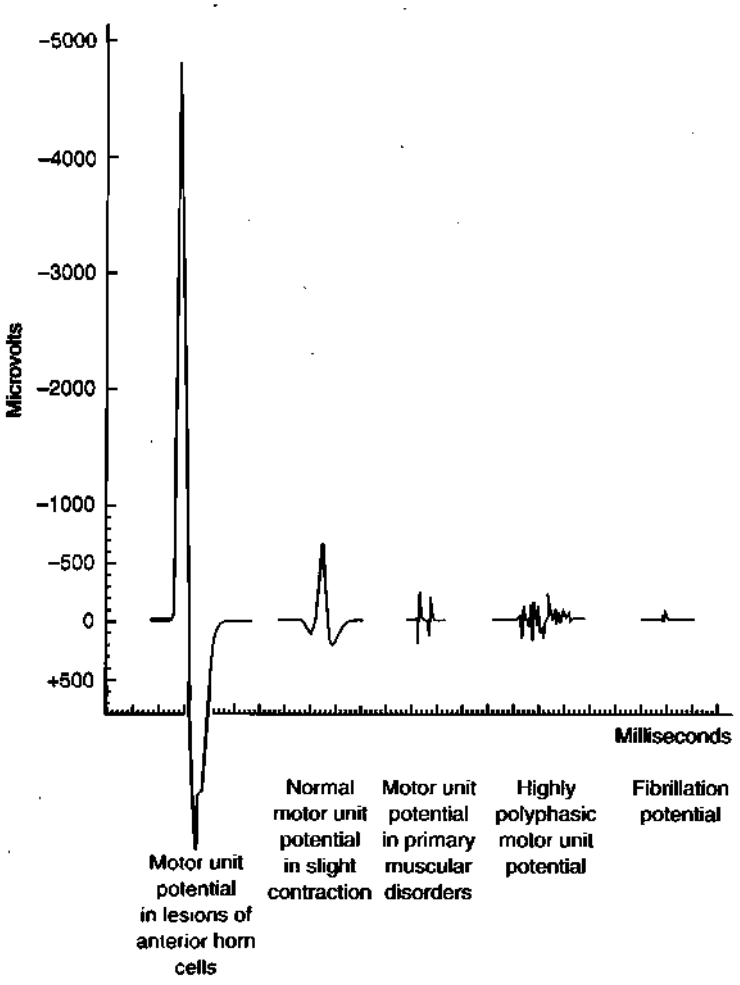

FIGURE 36B.12 Motor unit action potentials in health and disease, (Reprinted with permission from Daube, J. 1991, "Needle electromyography in clinical electromyography," *Muscle Nerve,* vol. 14, pp. 685-700.)

because all muscle fibers of the motor unit fire during every discharge. The morphology of a repetitively firing unit may fluctuate if individual muscle fibers intermittently block within the unit. Moment-to-moment MUAP variability indicates deficient neuromuscular transmission as recurring discharges deplete the store of immediately available acetylcholine (Figure 36B.13). This instability is consistent with not only a neuromuscular junction disorder, such as myasthenia gravis, the myasthenic syndrome, or botulism, but also with motor neuron disease, subacute radiculopathy, or polyneuropathy, and with the early stages of reinnervation.

MUAP Firing Patterns

During constant contraction, a healthy person initially excites only 1 or 2 motor units semirhythmically. The motor units activated early are primarily those with small, type I muscle fibers. Large, type II units participate later during strong voluntary contraction. Greater muscle force brings about not only recruitment of previously inactive units but also more rapid firing of already active units, with both mechanisms operating simultaneously (Erim et al. 1996).

Recruitment frequency is a measure of motor unit discharge, defined as the firing frequency at the time an additional unit is recruited. In normal muscles, mild contraction induces isolated discharges at a rate of 5-10 Hz. This depends on the sampled muscle and the types of motor units studied. The reported ranges for healthy people and those with neutomuscular disorders overlap. *Recruitment ratio* is the average firing rate divided by the number of active units. This ratio normally should not exceed five, for example, with thtee units each firing less than 15 Hz. A ratio of 10, with two units firing at 20 Hz each, indicates a loss of motor units.

Activation is the central control of motor units that allows an increase in the firing rate and fotce. Failure of descending impulses also limits tecruitment, although here the excited motor units discharge more slowly than expected for normal maximal contraction. Thus, a slow rate of discharge (poor activation) in an upper motor neuron disorder (such as stroke or myelopathy) or in volitional lack of effort (such as that caused by pain, hysterical paralysis, or malingering) stands in sharp contrast to a fast rate of dischatge of a lower motor neuron weakness (decreased recruitment).

With greater contraction, many motor units begin to fire rapidly, making recognition of individual MUAPs difficult, hence the name *interference pattern. A* number of factors influence the spike density and the average amplitude of the summated response. These include descending input from the cortex, number of motor neurons capable of discharging, firing frequency of each motor unit, wavefoim of individual potentials, and phase cancellation. An incomplete interference pattern may be caused by poor activation or reduced recruitment. Recruitment may be assessed during maximum contraction by examination of the interference pattern, or during moderate levels of contraction by estimation of the number of MUAPs firing for the level of activation. Evaluating maxima! compaction is most valuable in excluding mild degrees of decreased recruitment.

In myopathy, low-amplitude, short-duration MUAPs produce a smaller force per motor unit than normal MUAPs. Many units must be recruited instantaneously to support a slight voluntaty effort in patients with moderate to severe weakness (early recruitment). With early recruitment, a full interference pattern is attained at less than maximal contraction, but its amplitude is low because fiber density is low in individual motor units. In advanced myopathies with scvetc muscle weakness, loss of muscle fibers is so extensive that whole motor units effectively disappear, resulting in a decreased recruitment and an incomplete interference pattern, mimicking a neuropathic change.

Electrodiagnosis by Needle EMG

Upper Motor Neuron Lesions

Patients with uppet motot neuron lesions have normal inscrtional activity, no spontaneous activity at rest, and

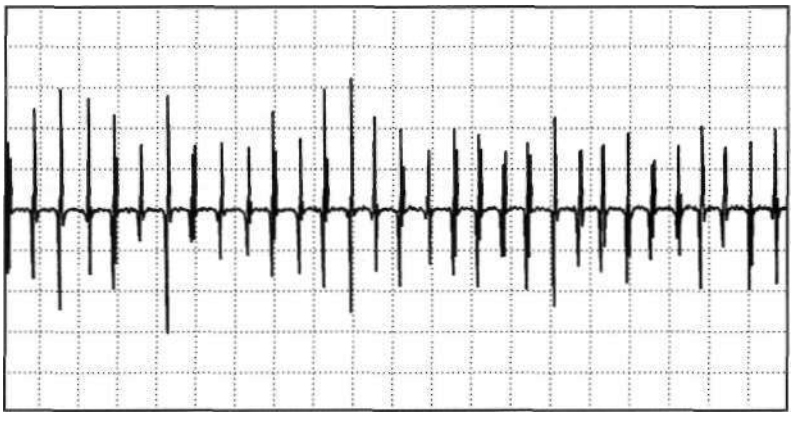

FIGURE 36B.13 Motor unit action potential instability (moment-to-moment variation) in a patient with myasthenia gravis. (Reprinted with permission from Katirji, B. 1998, *Electromyography in Clinical Practice: A Case Study Approach,* Mosby, St Louis.)

normal MUAP morphology. The only abnormality is a reduced interference pattern and a poor activation (slow rate of motor unit discharge; Figure 36B.14). Recruitment, measured by either recruitment frequency or ratio, is normal. Hysterical weakness or poor effort produces a similar pattern, except that motor unit firing may be irregular.

Lower Motor Neuron Lesions

I he fust needle FMG change occurring after an acute lower motor neuron insult is an abnormal recruitment pattern. Recruitment frequency and ratio increase in lower motor neuron lesions because fewer motor units fire for a given strength of contraction. Also, interference pattern with maximal contraction decreases, and in the extreme case, only a single motor unit fires rapidly, producing a picket fence-like pattern.

Insertional activity is increased after the first week, and insertional positive waves may appear within 2 weeks after acute denervation. However, spontaneous fibrillation potentials become present in all abnormal muscles after only .3 weeks. Kasciculation potentials accompany electrical denervation changes in diseases of the anterior horn cells, roots, and peripheral nerves but do not have pathological significance when they appear alone. Limb myokymic discharges may be seen, usually with entrapments, radiation plexopathy, or Guillain-Barre syndrome. Complex repetitive discharges denote a chronic disorder and accompany lower motor neuron disorders as well as myopathies.

MUAPs are normal in morphology in the acute phase of denervation, but signs of reinnervation become apparent as early as 1 month later. Reinnervation causes first an increased number of MUAP turns and phases and then an increased amplitude and duration. Amplitude generally reflects fiber density, and duration reflects motor unit territory. The expected MUAP from lower motor neuron lesions is a long-duration, high-amplitude polyphasic unit (see Figures 36B.12 and 36B.14). The exceptions are MUAPs seen in early reinnervation in which motor units acquire few muscle fibers, resulting in brief, small polyphasic MUAPs ("nascent" MUAPs), mimicking myopathic processes.

Radiculopathies. Needle EMG is the most sensitive and specific clcctrodiagnostic test for identifying cervical and lumbosacral radiculopathies, particularly those associated with axon loss. Needle EMG is useful in the accurate localization of the level of the root lesion. Finding signs of denervation (fibrillation potentials, decreased recruitment, and long-duration, high-amplitude polyphasic MUAPs) in a segmental myoromal distribution (i.e., in muscles innervated by the same roots via more than one peripheral nerve), with or without denervation of the paraspinal muscles, localizes the lower motor neuron lesion to the root level (Wilbourn and Aminoff 1998). A normal SNAP of the corresponding dermatome ensures that the lesion is within the spinal canal (i.e., proximal to the dorsal root ganglia}. For example, in an *IS* radiculopathy, the tibialis anterior (peroneal nerve) and tibialis posterior (tibial nerve) may be abnormal on needle EMG, as may the lumbar

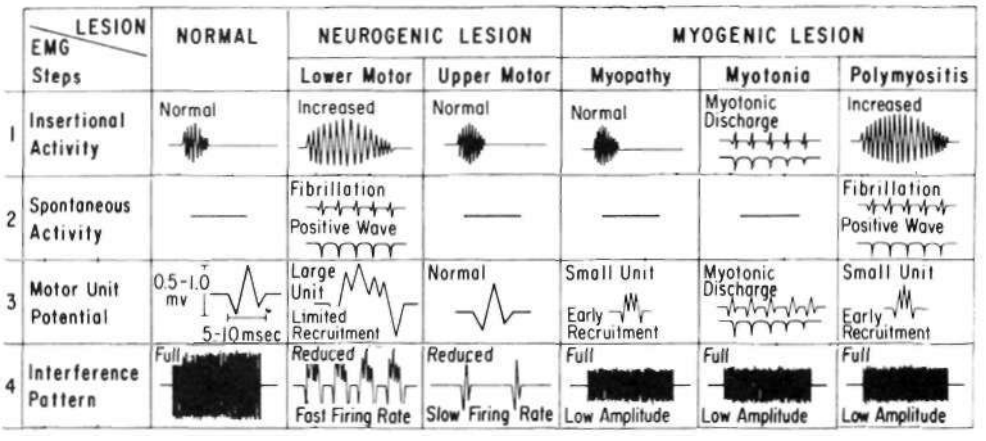

FIGURE 36B. 14 A summary of characteristic electromyographic (EMG) findings in normal subjects, patients with neurogenic lesions, and those with myogenic lesions. Insertional activity is greater in lower motor neuron lesions and polymyositis and consists of myotonic discharges in myotonia. Spontaneous activity generally occurs in lower motor neuron disorders and in inflammatory myopathy. Motor unit action potentials usually are large and polyphasic, with reduced recruitment in lower motor neuron conditions; in myopathics and polymyositis motor units are small with early recruitment. Interference pattern is reduced in both upper and lower motor neuron lesions, as well as in hysterical weakness; however, firing rate is rapid in lower motor neuron lesions and normal in upper motor neuron lesions and hysteria (m which the rate may be irregular also). Interference pattern is full but of low amplitude in myopathic lesions. (Reprinted from Kimura, J. 1989, *Electrodiagnosis in Diseases of Nerve and Muscle: Principles and Practices*, 2nd ed, FA Davis, Philadelphia.)

paraspinal muscles, but the superficial peroneal SNAP is normal.

Plexopathies. The diagnosis of brachial and lumbosacral plexopathies requires a solid knowledge of peripheral nerve anatomy. Brachial plexus anatomy is particularly complex, so multiple NCSs or muscle EMGs are needed to evaluate it. An important task of the elcctrodi a gnostic evaluation is to differentiate between lesions affecting the brachial plexus (postganglionic) and those involving the roots (preganglionic). This is parricularly important in brachial plexus traction injuries, which may mimic root avulsions (Ferrante and Wilbourn 2002), In avulsions, the dorsal root ganglia remain intact, and their peripheral axons do not undergo walletian degeneration. Therefore the SNAPs in root avulsions are spared, whereas they are low in amplitude or absent in brachial plexopathies when studied after the completion of wallerian degeneration (more than 10 days from injury),

Mononeuropathies. The needle EMG is most useful when axon loss mononeuropathies are examined after the completion of wallerian degeneration. These lesions cannot be localized by NCSs because they are not associated with focal conduction slowing or conduction block, as seen with demyelinating mononeuropathies. The NCSs in axon loss lesions often show low-amplitude or absent CMAPs, and SNAPs with normal or slightly slowed distal latencies and conduction velocities.

The principle of localizing an axon loss mononeuropathy by needle EMG is similar to manual muscle strength testing on clinical examination. Typically, the needle EMG reveals neurogenic changes (fibrillation potentials, reduced MUAP recruitment, or chronic neurogenic MUAP morphology changes) that are limited to muscles innervated by the involved nerve and located distal to the site of the lesion. However, localization of axon loss peripheral nerve lesions by needle EMG is suboptimal because some nerves have very long segments from which no motor branches atise (such as the median and ulnar nerves in the aim). Also, needle EMG may falsely localize a partial nerve lesion more distally along the affected nerve because of fascicular involvement of nerve fibers or effective reinnervation of ptoximally situated muscles (Wilbourn 2002).

Needle EMG is particularly useful in assessing the progress of reinnervation occurring spontaneously or after nerve repair. MUAP recruitment and morphology help in assessing the process of muscle fiber reinnervation that occuts after proximodistal regeneration of nerve fibers from rhe site of the injury or collateral sprouting. Early proximodistal regeneration of nerve fibers in severe axon loss lesions often manifests as brief, small, polyphasic (nascent) MUAPs. Collateral sprouting causes an increased number of MUAP turns and phases followed by an increased duration and amplitude of MUAPs.

Peripheral Polyneuropathies. Peripheral polyneuropathies are indicated by characteristic widespread abnormalities on NCSs, and the needle EMG is most useful in depicting the temporal profile of the illness. In demyelinating polyneuropathies, the needle EMG may show signs of mild axonal loss, not suspected on clinical examination, with fibrillation potentials and tcinncrvated MUAPs. In axon loss polyneuropathy, fibrillation potentials typically develop within 2-3 weeks, and reinnervated MUAPs become apparent within 1-2 months. In acute polyneuropathies, such as the Guillain-Barre syndrome, needle EMG during the acute phase of illness may show only reduced recruitment of MUAPs in weak muscles with normal MUAP morphology and no spontaneous activity. In active and progressive axon loss polyneuropathies, a combination of fibrillation potentials with reduced recruitment of reinnervated MUAPs is most prominent distally. In chronic and very slowly progressive polyneuropathies, reinnervation may completely keep pace with active denetvation, yielding few or no fibrillation potentials but reduced recruitment of reinnervated MUAPs.

Anterior Horn Cell Disorders. Needle EMG is the most important electrodiagnostic study for providing evidence of generalized lower motor neuron degeneration, even early in the course of the illness in apparently unaffected limbs. Needle EMG often shows signs of active denervation (fibrillation potentials), chronic denervation (reinnervared and unstable MUAPs), and reduced MUAP recruitment.

The electrodiagnostic studies can evaluate only lower motor neuron degeneration, whereas upper motor neuron degeneration must be assessed clinically. Therefore the diagnosis of amyotrophic lateral sclerosis (ALS) is based on clinical evaluation, with the electrodiagnostic studies playing a supporting role. There are three reasons ro perform electrodiagnostic studies in patients with suspected ALS: (1) to confirm lower motor neuron dysfunction in clinically affected regions, (2) to detect electrophysiological evidence of lower motor neuron dysfunction in clinically uninvolved regions, and (3) to exclude other pathophysiological processes (Chad 2002).

Although lower motor neuron degeneration may ultimately affect almost the entire neuraxis (brainstem and cervical, thoracic, or lumbosacral segments of spinal cord) in ALS, there is an increasing need to establish the diagnosis of ALS eatly in the illness so that patients can participate in clinical trials. Lambert's initial criteria of detecting fibrillation and fasciculation potentials in muscles of the lower as well as the upper extremities or in the extremities as well as rhe head are stringent. These criteria have evolved into denervation in at least three extremities or two extremities and cranial muscles (with the head and neck considered an extremity). Recently, the revised El Escorial criteria recommended

that needle EMG signs of lower motor neuron degeneration should be present in at least two of the four central nervous system regions (i.e., the brainstem, cervical, thoracic, or lumbosacral regions; Brooks ct al. 2000).

In patients with suspected motor neuron disease, NCSs are useful mostly in excluding other neuromuscular diagnoses such polyneuropathies. Sensory NCSs usually are normal in anterior horn cell disorders, whereas motor NCSs are either normal or yield low CMAP amplitudes consistent with motor neuronal loss. Motor conduction velocities are normal or slightly slowed but never below 70% of the lower limits of normal. Also, the NCSs do not show other demyelinating features, such as conduction blocks that are characteristics of multifocal motor neuropathy, a treatable disorder that may mimic lower motor neuron disease.

Myopathic Disorders

Insertional activity usually is normal except in the late stage of the disease, when it is reduced by atrophy and fibrosis. Spontaneous activity is absent except in necrotizing myopathies (such as inflammatory myopathics and muscular dystrophies). MI JAP amplitude and duration are reduced by random loss of fibers from the motor unit (see Figure 36B.I2). Regeneration ol muscle fibers sometimes gives rise to long-duration spikes and satellite potentials. Early recruitment is the rule because more motor units are needed to maintain a given force in compensation for the small size of individual units (see Figure 36B.14).

A disadvantage of the electrodiagnosis of myopathies is that the EMG findings in myopathy are not always specific enough to make a final diagnosis. Exceptions include myotonia, which occurs in myotonic dystrophies, myotonia congenita, paramyotonia congenita, hyperkalemic periodic paralysis, acid maltasc deficiency, and some toxic myopathies (such as due to colchicine); and fibrillation potentials, which occur in inflammatory myopathies and progressive muscular dystrophies (such as Becker and Duchenne muscular dystrophy; Table 36B.2), Another disadvantage of the needle EMG is that it is either normal or has subtle abnormalities in some myopathies, such as the metabolic and endocrine myopathics (Lacomis 2002). Therefore, a normal needle EMG does not exclude a myopathy.

In polymyositis and dermatomyositis, it is essential to recognize the changing pattern on needle EMG at diagnosis, after treatment, and during relapse. Fibrillation potentials appear first at diagnosis or relapse and disappear early during remission. Abnormal MUAP morphology becomes evident later and takes longer to resolve (Wilbourn 1993). The presence of fibrillation potentials is also helpful in differentiating exacerbation of myositis from a corticosteroid-induced myopathy.

SPECIALIZED ELECTRODIAGNOSTIC STUDIES

F Wave

A supramaximal stimulus applied at any point along the course of a motor nerve elicits a small late motor response (F wave) after the CMAP (M response). This long-latency F wave is a very small CMAP that results from backfiring of antidromically activated anterior horn cells, averaging 5-10% of the motor neuron pool. The F wave's afferent and efferent loops arc the motor neuron, with no intervening synapse (Fisher 2002). The F wave latencies measured from the stimulus artifact to the beginning of the evoked potential vary by a few milliseconds from one stimulus to the next. Therefore, an adequate study requires **that** about 10 F waves be clearly identified. If the stimulator is moved proximally, the F wave latency decreases because the action potential travels a shorter distance (Figure 36B.15).

The minimal F wave latency is the most reliable and useful measurement and represents conduction of the largest and fastest motor fibers. The most sensitive criterion of abnormality in a unilateral disorder affecting a single nerve is a minimum latency difference between the two sides or between two nerves in the same limb. Absolute latencies are useful only for sequential reassessment of the same nerve. The F wave conduction velocity provides a better comparison between proximal and distal (forearm or leg) segments. F wave chronodispersion reflects the degree of scatter among consecutive F waves, is determined by the difference between the minimal and maximal F wave latencies, and indicates the range of motor conduction velocities in the nerve. F wave persistence is a measure of the number of F waves obtained for the number of stimulations and usually is greater than 50% except when one stimulates the peroneal nerve while recording the extensor digitorum brevis.

F wave latencies arc prolonged in most polyneuropathies, particularly the demyelinating type. In the early phases of Cuillain-Barre syndrome, the routine motor nerve studies may be entirely normal, with prolonged or absent F responses, which implies proximal demyelination (Gordon and Wilbourn 2001). F wave latencies in radiculopathies have a limited use; they may be normal despite partial motor axonal loss, and most muscles have multiple root innervation (Wilbourn and Aminoff 1998).

H Reflex

The H reflex, named after Hoffmann for his original description, is an electrical counterpart of the stretch reflex elicited by a mechanical tap to the Achilles tendon (Katirji and Weissman 1994). The group 1A sensory fibers and alpha motor neurons form the respective afferent and efferent arcs of this predominantly monosynaptic reflex.

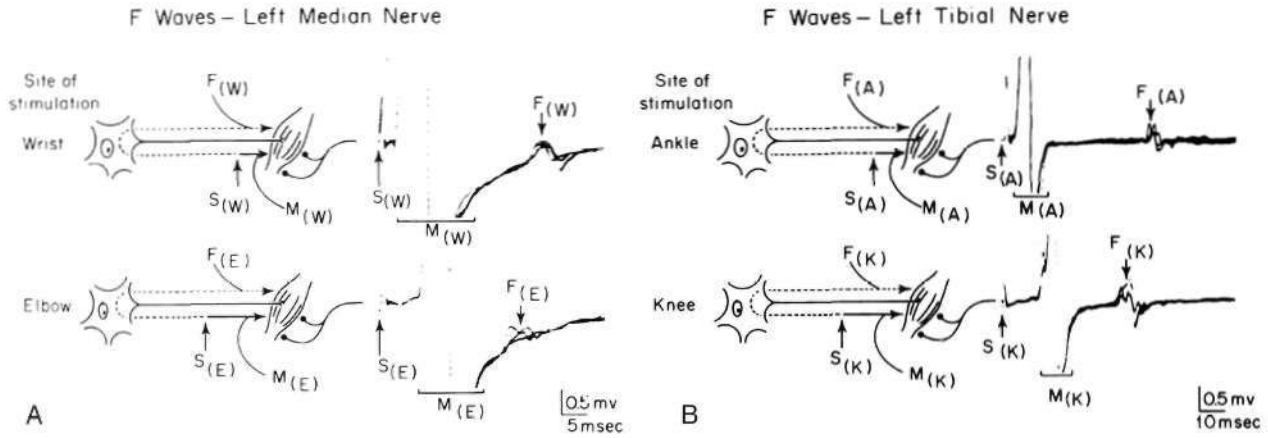

FIGURE 36B.1S (A) Normal *M* response *{horizontal brackets)* and F wave *{small arrows)* recorded from the thenar muscles using surface electrodes. Sites of supramaximal stimulus (S) to the median nerve are shown, with these consecutive traces superimposed for each. As the stimulus was moved from the wrist (W) to the elbow (E), the latency of the M response increased, whereas that of the F wave decreased. The figures on the left are schematic illustrations showing the centrifugal *(solid arrows)* and centripetal *{dotted arrows)* impulses carrying the M response and F wave, respectively. (Modified from Kimura, J. 1974, "F-wave velocity in the central segment of the median and ulnar nerves: A study in normal subjects and patients with Charcot-Marie-Tooth disease," *Neurology* [Minneapolis], vol. 24, pp. 539-546.) (B) Normal M response *{horizontal brackets)* and F wave *[smalt arrows)* recorded from the abductor hallucis using surface electrodes. Supramaximal stimulus (S) was delivered to the tibial nerve at the ankle (A) and knee (K). Three consecutive traces are superimposed for each. As the stimulus was moved ftom ankle to knee, the latency of the M response increased, whereas that of the F wave decreased. (Reprinted with permission from Kimura, J., Bosch, P., & Lindsay, G. M. 1975, "F-wave conduction velocity in the central segment of the peroneal and tibial nerves," *Arch Pbys Med Rebabil,* vol. 56, pp. 492-497.)

The H reflex and F wave can be distinguished by increasing stimulus intensity. The H reflex is best elicited by a long-duration stimulus, submaximal to produce an M response (Figure 36B.16), whereas the F wave requires supramaximal stimulus intensity. In contrast to the F wave, which can be elicited from any limb muscle, the H reflex stimulating the tibial nerve while recording the soleus muscle is the most reproducible and commonly used in clinical practice. The H reflex latency and amplitude, determined by the sensory and motor conduction of the nerve, are better than routine NCSs in the early phases of Guillain-Barre syndrome (Gordon and Wilbourn 2001) and in the diagnosis of mild polyneuropathy or mild SI radiculopathy (Nishida et ah 1996).

Blink Reflex

The blink reflex generally evaluates the trigeminal and facial nerves and their connections in the pons and medulla. It has an afferent limb, mediated by sensory fibers of the supraorbital branch of the ophthalmic division of the trigeminal nerve, and an efferent limb, mediated by motor fibers of the facial netve.

With two-channel recording, the blink reflex has two components: an early Rl and a late R2 response. The Rl response is present only ipsilateral to the stimulation and usually is a simple triphasic waveform with a disynaptic pathway between the main trigeminal sensory nucleus in the midpons and the ipsilateral facial nucleus in the lower pontine tegmentum. The R2 response is a complex waveform and is the electrical counterpart of the corneal reflex. It is typically present bilaterally, with an oligosynaptic pathway between the nucleus of the trigeminal spinal tract in the ipsilatetal pons and medulla and interneurons forming connections to the ipsilatetal and contralateral facial nuclei.

The blink reflex is most useful in unilateral lesions such as facial palsy, trigeminal neuropathy, or pontine or medullary lesion (Kimura 1983). With facial nerve lesions, the Rl and R2 potentials are absent ot delayed with supraorbital stimulation ipsilateral to the lesion, whetcas the R2 response on the contralateral side is normal. With trigeminal nerve lesions, the ipsilateral Rl and R2 and contralateral R2 ate absent or delayed, whereas all responses arc normal with contralateral stimulation. With a midpontine lesion involving the main sensory trigeminal nucleus or the pontine interneurons to the ipsilateral facial netve nucleus, supraorbital stimulation on the side of the lesion results in an absent or delayed Rl but an intact ipsilatetal and contralateral R2. Finally, with a medullary lesion involving the spinal tract and trigeminal nucleus or the medullary interneurons to the ipsilateral facial nerve nucleus, supraorbital stimulation on the affected side results in a normal Rl and contralateral R2 but an absent ot delayed ipsilateral R2. In demyelinating polyneuropathies such as Guillain-Barre syndrome or Charcot-Marie-Tooth disease type 1, all the blink responses may be markedly delayed, reflecting slowing of motor fibcts ot sensory fibers,

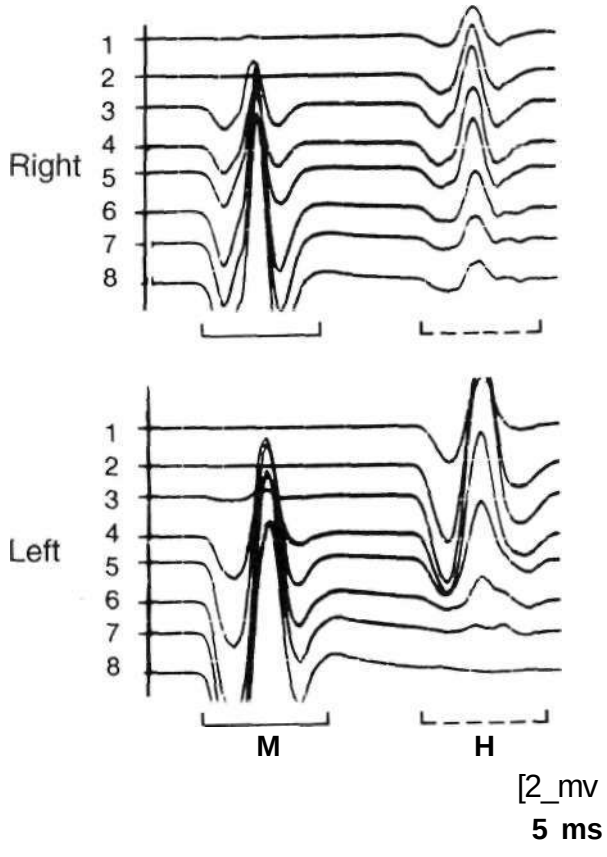

FIGURE 36B.16 H reflex recorded from the solcus after stimulation of the tibial nerve at the knee. Shock intensity was gradually increased from subthreshold level (1) to supramaximal stimulation (8}. Note initial increase and subsequent decrease in amplitude of the reflex potential with successive stimuli of progressively higher intensity. The 11 reflex normally disappears with shocks of supramaximal intensity that elicit a maximal M response.

Repetitive Nerve Stimulation

Principles

Repetitive stimulation of motor or mixed nerves is performed to evaluate patients with suspected neuromuscular junction disorders, including myasthenia gravis, Lambert-Eaton myasthenic syndrome, botulism, and congenital myasthenic syndromes. The design and plans for repetitive nerve stimulation depend on physiological facts inherent to the neuromuscular junction that dictate the type and frequency of stimulations used in the diagnosis of neuromuscular junction disorders. The CMAP obtained during routine NCSs represents the summation of all muscle fiber action potentials generated in a muscle after supramaximal stimulation of all motor axons while recording via surface electrode placed over the belly of a muscle.

- A quantum is the amount of acetylcholine in a single vesicle, which contains approximately 5000-10,000 acetylcholine molecules. Each quantum (vesicle) released results in a 1-mV change of postsynaptic membrane potential. This occurs spontaneously during rest and forms the basis of the miniature endplate potential.
- The number of quanta released after a nerve action potential depends on the number of quanta in the immediately available (primary) store and the probability of release: $m = p$ x «, where m = the number of quanta released during each stimulation, p = the probability of release (effectively proportional to the concentration of calcium and typically about 0.2, or 20%), and n = the number of quanta in the immediately available store. In normal conditions, a single nerve action potential triggers the release of 50-300 vesicles (quanta) with an average equivalent to about 60 quanta (60 vesicles). In addition to the immediately available store of acetylcholine located beneath the presynaptic nerve terminal membrane, a secondary (or mobilization) store starts to replenish the immediately available store after 1-2 seconds of repetitive nerve action potentials. A large tertiary (or reserve) store is also available in the axon and cell body.
- The endplate potential is the potential generated at the postsynaptic membrane after a nerve action potential. Because each vesicle released causes a 1-mV change in the postsynaptic membrane potential, this results in about a 60-mV change in the amplitude of the membrane potential.
- In normal conditions, the number of quanta (vesicles) released at the neuromuscular junction by the presynaptic terminal far exceeds che postsynaptic membrane potential change necessary to reach the threshold needed to generate a postsynaptic muscle action potential. This safety factor results in an endplate potential that is always above threshold and results in muscle fiber action potential. In addition to quanta! release, several other factors contribute to the safety factor and endplate potential, including acetylcholine receptor conduction properties, acetylcholine receptor density, and acetylcholinesterase activity (Boonyapisit, Kaminski, and Ruff 1999).
- After depolarization of the presynaptic terminal, voltage gated calcium channels open, leading io calcium influx. Through a calcium-dependent intracellular cascade, vesicles are docked into active re lease zones, and acetylcholine molecules are released. Calcium then diffuses slowly out of the presynaptic terminal in 100-200 milliseconds. The rate at which motor nerves arc repetitively stimulated dictates whether calcium accumulation plays a role in enhancing the release of acetylcholine. At slow rate of repetitive nerve stimulation (i.e., a stimulus every 200 milliseconds or more, or a stimulation rate <5 Hz), the calcium role in acetylcholine release is not increased, and subsequent nerve action potentials reach the nerve terminal long after calcium has dispersed. In contrast, with rapid

repetitive nerve stimulation (i.e., a stimulus every 100 milliseconds or less, or a stimulation rate >10 Hz), calcium influx is greatly increased, and the probability of release of acetylcholine quanta increases.

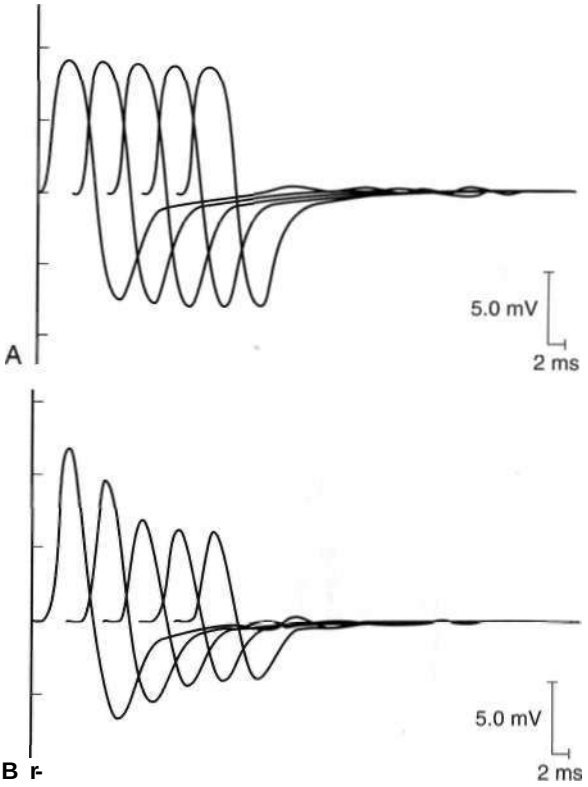
Slow Repetitive Nerve Stimulation

Slow repetitive nerve stimulation usually is performed by application of three to five supramaximal stimuli to a mixed or motor nerve at a rate of 2-3 Hz. This rate is **low** enough to prevent calcium accumulation but high enough to deplete the quanta in the immediately available store before the mobilization store starts to replenish it. Three to five stimuli is adequate because the maximal decrease in acetylcholine release occurs during the first three to five stimuli.

Calculation of the decrement with slow repetitive nerve stimulation entails comparing the baseline CMAP amplitude with the lowest CMAP amplitude (usually the third or fourth). The CMAP decrement is expressed as a percentage and calculated as follows:

$$\% \text{ Decrement} = \frac{\text{Amplitude (1st response)} - \text{Amplitude (3rd or 4th response)}}{\text{Amplitude (1st response)}} \times 100$$

In normal conditions, slow repetitive nerve stimulation does not cause a CMAP decrement. Although the second through fifth endplate potentials fall in amplitude, they remain above threshold (because of the normal safety **factor)** and ensure generation of muscle fiber action potential with each stimulation. In addition, the secondary store begins to replace the depleted quanta after the first few seconds, with a subsequent rise in the endplate potential. Therefore, all muscle fibers generate muscle fiber action potentials, and the CMAP docs not change. In postsynaptic neuromuscular junction disorders (such as myasthenia gravis), the safety factor is reduced because there are fewer available acetylcholine receptors. Therefore, the baseline endplate potential is reduced but usually still above threshold. Slow repetitive nerve stimulation results in a decrease in endplate potential amplitudes at many neuromuscular junctions. As endplate potentials decline below the threshold, there is a decline in the number of muscle fiber action potentials produced, leading to a CMAP decrement (Figure 36B.17). In presynaptic disorders (such as Lambert-Eaton myasthenic syndrome) the baseline endplate potential is low, with many endplates not reaching threshold. Therefore, many muscle fibers do not fire, resulting in a low baseline CMAP amplitude (Table 36B.3). With slow repetitive nerve stimulation, there is further CMAP decrement, caused by the further decline of acetylcholine release with the subsequent stimuli, resulting in further loss of many endplate potentials and muscle fiber action potentials (Katirji and Kaminski 2002).



FTGURE 36B.17 Slow (2-Hz) repetitive nerve stimulation (A) in a healthy control subject and (B) in a patient with generalized myasthenia gravis showing compound muscle action potential decrement. (Reprinted with permission from Katirji, B. 1998, *Electromyography in Clinical Practice: A Case Study Approach,* Mosby, St Louis.)

In myasthenia gravis, the diagnostic yield of slow repetitive nerve stimulation increases if the following recommendations are applied:

1. Obtain slow repetitive nerve stimulation at rest and after exercise. If there is a reproducible CMAP decrement (>10%) at rest, slow repetitive nerve stimulation should be repeated after the patient exercises for 10 seconds to demonstrate repair of the decrement (post-tetanic facilitation). If there is no or equivocal decrement (<10%) at rest, the patient should perform maximal volunrary exercise for 1 minute. Then, slow repetitive nerve stimulation should be repeated every 30 seconds afterward and for *3-5* minutes after exercise. Because the amount of acetylcholine released with each stimulus is at its minimum 2-5 minutes after exercise, slow repetitive nerve stimulation after exercise increases the chance of detecting a defect of neuromuscular transmission at the neuromuscular junction by demonstrating a worsening CMAP decrement (postcxercise exhaustion).
2. Record from clinically weakened muscles. Most technically feasible nerves for slow repetitive nerve stimulation are the median, ulnar, and spinal accessory

Table 36B.3: CMAPs and RNS in neuromuscular junction disorders

Neuromuscular junction defect	*Disorder*	*CMAP*	*Slow RNS*	*Rapid RNS'*
Postsynaptic	Myasthenia gravis	Norma]	Decrement	Normal or decrement
Presynaptic;	Lambert-Eaton myasthenic syndrome	Low	Decrement	[ncri'iiinn

*Or post-brief exercise CMAP.
CMAP = compound muscle action potential; RNS = repetitive nerve stimulation.

nerves. Facial repetitive nerve stimulation is indicated in patients with oculobulbar weakness, but this study is difficult and often associated with a large stimulation artifact. The diagnostic sensitivity is clearly higher for slow repetitive nerve stimulation recording in proximal muscles than in distal muscles.

3. Warm the extremity studied (skin temperature should be above 32^{C}C). This decreases false negative results because cooling improves neuromuscular transmission and may mask the decrement.
4. Discontinue all cholincsterase inhibitors for 12-24 hours (if clinically possible). This also decreases the false negative rate of slow repetitive nerve stimulation.

Rapid Repetitive Nerve Stimulation

Rapid repetitive nerve stimulation is most useful in patients with suspected presynaptic neuromuscular junction disorders such as Lambert-Eaton myasthenic syndrome or botulism. The optimal frequency is 20-50 Hz for 2-10 seconds. A typical rapid repetitive nerve stimulation applies 200 stimuli at a rate of 50 Hz (i.e., 50 Hz for 4 seconds). Calculation of CMAP increment after rapid repetitive nerve stimulation is as follows:

$$\%\ \text{increment} = \frac{\text{Amplitude (highest response)} - \text{Amplitude (First response)}}{\text{Amplitude \{first response)}} \times 100$$

A brief (10-sccond) period of maximal voluntary isometric exercise is much less painful and has the same effect as rapid repetitive nerve stimulation at 20-50 Hz (Tim and Saunders 1994). A single supramaximal stimulus is applied to generate a baseline CMAP. Then, the patient performs a 10-second maximal isometric voluntary contraction, which is followed by another stimulus that produces the postexercise CMAP.

With rapid repetitive nerve stimulation or postexercise CMAP evaluation, two competing forces act on the nerve terminal. First, stimulation tends to deplete the pool of readily available synaptic vesicles. This depletion reduces transmitter release by reducing the number of vesicles that are released in response to a nerve terminal action potential. Second, calcium accumulates in the nerve terminal, thereby increasing the probability of synaptic vesicle release. In a normal nerve terminal, the effect of depletion of readily available synaptic vesicles predominates, so that with rapid repetitive nerve stimulation, the number of vesicles released decreases. However, the cndplate potential docs not fall below threshold because of the safety factor. Therefore the supramaximal stimulus generates muscle fiber action potentials at all endplates, and no CMAP decrement occurs. In fact, rapid repetitive nerve stimulation or brief (10 seconds) exercise in normal subjects often leads to a slight physiological increment of the CMAP that does not exceed 40% of the baseline CMAP. This is probably-caused by increased synchrony of muscle fiber action potentials after tetanic stimulation (post-tetanic pseudo-facilitation).

In a presynaptic disorder (such as Lambert-Eaton myasthenic syndrome), very few vesicles are released and many muscle fibers do not reach threshold, resulting in low baseline CMAP amplitude. With rapid repetitive nerve stimulation, the calcium concentrations in the nerve terminal can rise high enough to stimulate synaptic vesicle fusion for a sufficient number of synaptic vesicles to result in an endplate potential capable of action potential generation. This leads to many muscle fibers reaching threshold and firing and results in a CMAP increment (see Table 36B.3). The increment often is higher than 200% in Lambert-Eaton myasthenic syndrome and is 30-100% in patients with botulism (Figure 36B.18).

In a postsynaptic disorder (such as myasthenia gravis), rapid repetitive nerve stimulation causes no change of CMAP because the depleted stores are compensated by the

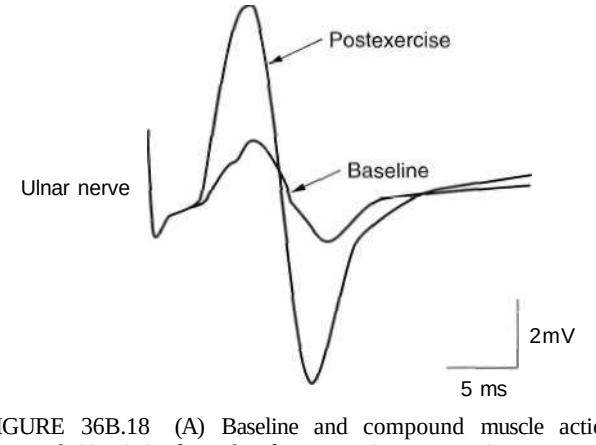


FIGURE 36B.18 (A) Baseline and compound muscle action potential (CMAP) after a brief exercise (postexercise) in a patient with Lambert-Eaton myasthenic syndrome. Note the significant CMAP increment (294%) after exercise.

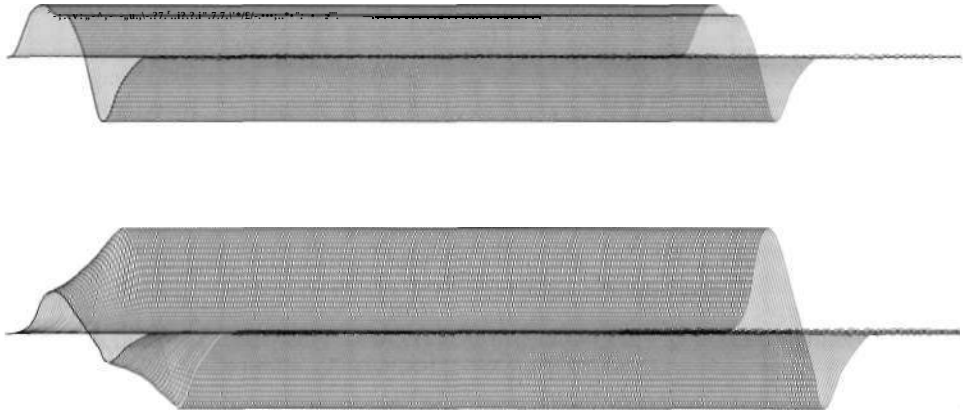

FIGURE 36B.18, cont'd. (B) Rapid (50-Hz) repetitive nerve stimulation in a control subject *{upper panel)* and in a patient with Lambert-Eaton myasthenic syndrome *{lower panel).* There is no CMAP increment in the control, whereas a significant (250%) increment is apparent in the patient. calcium influx. In severe postsynaptic blockade (such as during myasthenic crisis), the increased quantal release cannot compensate for the marked neuromuscular block, resulring in a drop in endplate potential amplitude, Therefore fewer muscle fiber action potentials are generated with an associated CMAP decrement.

Single-Fiber Electromyography

There are several technical requirements for performing single-fiber EMG, First, a concentric single-fiber needle electrode allows the recording of single-muscle fiber action potentials. The small side port on the cannula of the needle serves as the pickup area. A single-fiber needle electrode records from a circle of 3O0-|4irj radius, as compared with the 1-mm radius of a conventional EMG needle. Second, the amplifier must have an impedance of 100 megohms or greater to counter the high electrical impedance of the small lead-off surface, the gain is set higher for single-fiber EMG recordings than for conventional EMG, the sweep speed is faster, and the filter should have a 500-Hz low frequency to attenuate signals from distant fibers. Third, an amplitude threshold trigger allows recording from single muscle fiber, and a delay line permits the entire waveform to be viewed even though the single-fiber potential triggers the sweep. Fourth, computerized equipment assists in data acquisition, analysis, and calculation.

Voluntary {recruitment) single-fiber EMG is a common method for activating muscle fibers. A mild voluntary contraction produces a biphasic potential with a duration of approximately 1 millisecond and an amplitude that varies with the recording site. Single-fiber potentials suitable for study must have a peak-to-peak amplitude greater than 200 uV, rise time less than 300 ps, and a constant waveform. The needle is rotated, advanced, and retracted until a potential meets these criteria. *Stimulation single-fiber EMG* is a newer technique performed by inserting another monopolar needle electrode near the intramuscular nerve twigs and stimulating at a low current and constant rate. This method does nor require patient participation and therefore may be performed on children or on uncooperative or comarose patients. Single-fiber EMG is useful in assessing fiber density or in jitter analysis.

fiber Density

Fiber density is calculated as the number of single-fiber potentials firing almosr synchronously with the initially identified single-fiber potential. Increased muscle fiber clustering indicates collateral sprouting. Simultaneously firing single-fiber potentials within 5 milliseconds after the triggering single-fiber unit are counted at 20-30 sites. For example, in the normal extensor digitorum communis muscle, single fibers fire without nearby discharges in 65-70% of random insertions, with only two fibers discharging in 30-35% and with three fibers discharging in 5% or fewer. An average number of single-muscle fiber potentials per recording site can be calculated. In conditions producing loss of the normal mosaic distribution of muscle fibers from a motor unit, such as reinncrvation, fiber density increases.

Jitter

Jitter is the variability of the time interval between two muscle fiber action potentials (muscle pair) innervated by the same motor unir, that is, it is the variability of the interpotential intervals between repetitively firing paired single-fiber potentials (Stalberg and Trontelj 1997; Figure 36B.19). Jitter can be determined by using a commercially available computer program. It is calculated as the mean

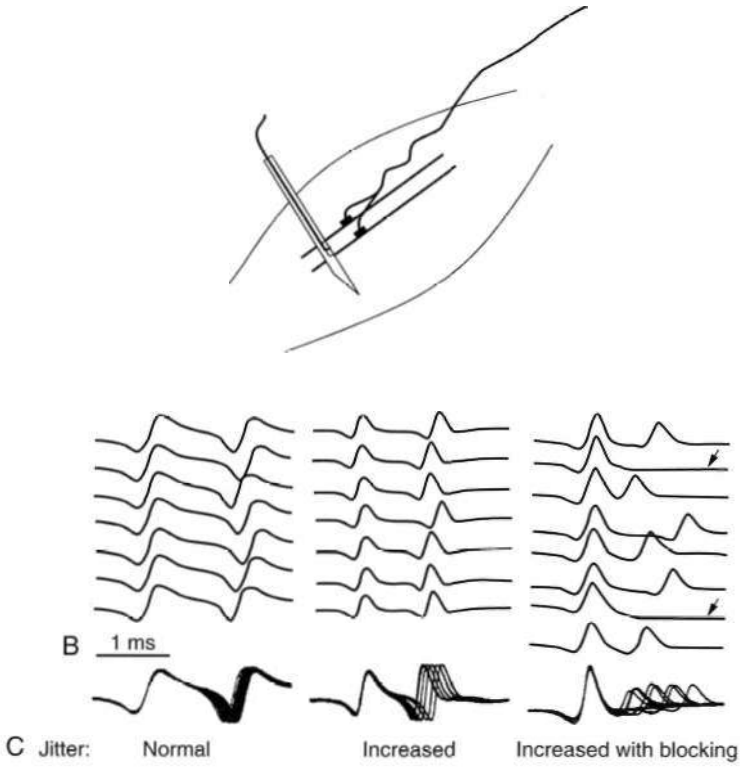

FIGURE 36B.19 Voluntary single-fiber electromyographic jitter study (A). The jitter is measured between two single-muscle fiber action potentials innervated by the same motor unit. Normal, moderately increased jitter in a patient with myasthenia gravis, and greatly increased jitter with intermittent blocking *(arrows)* in a patient with myasthenia gravis. The upper tracings (B) are shown in a raster mode, and the lower tracings (C) are superimposed. (Reprinted from Stalberg, E. & Trontelj, J. V. 1997, "The study of normal and abnormal neuromuscular transmission with single fibre electromyography," / *Neuroses Methods,* vol. 74, pp. 145-154, with permission from Elsevier Science,)

value of consecutive interval differences over a number of 50-100 discharges, as follows:

$$MCD = [IPI\ 1 - IPI\ 2] + [IPI\ 2 - IPI\ 3] + \text{-•-} + [IPI(N-1) - IPIN]/N - 1.$$

where MCD is the mean consecutive difference, **IPI** 1 is the intetpotential interval of the first discharge, IPI 2 of the second discharge, etc., and N is the number of discharges recorded.

Neuromuscular blocking is the intermittent failure of transmission of one of the two muscle fibct potentials. This reflects the failure of one of the muscle fibers to transmit an action potential caused by the failure of the cndplate potential to reach threshold. Blocking is the most extreme abnormality of the jitter and is measured as the percentage of dischatges of a motor unit in which a single-fibet potential does not fite. For example, in 100 discharges of the pair, if a single potential is missing 30 times, the blocking is 30%. In general, blocking occurs when the jitter values are significantly abnormal.

The results of single-fibet EMG jitter study are expressed by the mean jittet of all potential pairs, the percentage of pairs with blocking, and the percentage of pairs with normal jittet. Because jitter may be abnormal in 1 of 20 recorded potentials in healthy subjects, the study is considered to indicate defective neuromuscular transmission if the mean jitter value exceeds the upper limit of the normal jitter value for that muscle, more than 10% (more than two pairs) exhibits jitter values above the upper limit of the norma! jittet, or there is any neuromuscular blocking.

Jitter analysis is highly sensitive but not specific. Although it is often abnormal in myasthenia gravis and other neuromuscular junction disorders, it may also be abnormal in a variety of neuromuscular disorders including motor neuron disease, neuropathies, and myopathics. Thetefore the diagnostic value of jitter must be considered in light of the patient's clinical manifestations, and NCSs and needle EMG findings.

Chapter 37
Neuroimaging

A. STRUCTURAL NEUROIMAGING

Evelyn M. L. Sklar, Armando Ruiz, Robert M. Quencer, and Steven F. Falcone

Major technological developments in neuroimaging have resulted in the detection and characterization of neurological diseases that were not demonstrated by earlier imaging methods. Magnetic resonance imaging (MRI) in particular has had the greatest effect on the practice of neurology since the advent of computed tomography (CT) in the 1970s.

This chapter reviews the basic principles of CT and MRI, discusses other imaging techniques, and illustrates and describes the findings in neurological diseases.

BASIC PRINCIPLES OF NEUROIMAGING PROCEDURES

Computed Tomography

CT provides a cross-sectional image of the body. The images produced are based on the principle of tissue absorption of x-rays. A beam of x-rays is transmitted through the body, and the x-ray attenuation of a volume of tissue (voxel) is recorded. Shades of gray then are applied to the voxels, depending on the amount of x-ray absorption. A scan is produced as shades of black and white. Differences in the shades of gray directly reflect the differences in x-ray attenuation of different tissues. Tissues have different attenuation properties depending on the atomic number of their constituent atoms and physical density. The attenuation of a material can be described as an attenuation coefficient, which is then translated to a CT number on an arbitrary scale (Hounsfield units). The images are acquired in an axial or coronal plane and then may be reformatted in any desirable plane.

Contrast agents have increased the sensitivity and specificity of CT, The mechanism of enhancement is based on disruption of the blood-brain barrier by disease processes. This barrier normally restricts the movement of many substances from the bloodstream to the brain. On CT and MRI, only areas where the blood-brain barrier is damaged, such as tumors and inflammatory processes, enhance.

In 1989, spiral CT (helical or volume acquisition) was introduced clinically. With spiral CT, instead of by movement of the patient through the CT gantry at discrete intervals, each representing a slice, data are acquired continuously by constant rotation of the x-ray tube-detector system and the constant movement of the patient through the gantry. With spiral CT a long segment of the body (e.g., chest and abdomen) can be scanned during a single 20- to 30-second breath hold, eliminating problems of misregistration. A major advantage of spiral CT over conventional CT is the optimization of contrast administration. With short scanning times, less contrast material may be needed. Spiral CT also allows one to time the contrast administtation, optimizing the enhancement.

If the volumetric imaging capabilities of spiral CT are combined with optimal contrast enhancement, spiral CT angiography can be performed. Spiral CT also allows the acquisition of multiplanar two-dimensional (2D) and thtee-dimcnsional (3D) images, particularly for evaluating the carotid vessels both intracranially and at the neck level. Helical CT also creates 3D refotmations of the skeletal structutes of the calvatium, facial bones, and spine (Figure 37A.1),

Magnetic Resonance Imaging

In MRI, the images result from the varying intensities of radio wave signals emanating from the tissue where hydrogen nuclei have been excited by a radio frequency (RF) pulse. Contrast in the MRI is the result of these differences in signal intensities. The initial level of intensity and its rate of decay depend on different physical properties of tissues, so different tissues show different intensity signals depending on the time between RF excitation and the sampling time chosen. Hydrogen is the most commonly used nucleus for MRI because of its abundance in biological tissues and the physical properties of the field sttcngths of the magnets available for clinical use.

When placed in a magnetic field, the majority of the hydrogen atoms align in the direction of the field. A 90-degree pulse produced by an RF transmitter then causes the net magnetization vector to rotate away from its primary alignment to produce net magnetization in a different plane. The resulting transverse component of the field is responsible for producing the MRI signal.

The loss of magnetization from the transverse plane occurs by two distinct relaxation processes: spin-lattice and spin-spin. Spin-lattice telaxation is the return of magnetization to equilibrium with the applied magnetic field *(z*-direction). This process is represented by the time constant T1. One Tl period is the amount of time in which 63% of the longitudinal magnetization has been regained. Spin-spin relaxation is the loss of nuclear spin phase coherence. The protons dcphase, resulting in a decrease in the transverse magnetization, causing a decrease in signal. Dephasing caused by molecular interaction alone is called *T2.* Dephasing produced by molecular interactions and spatial variation of the external magnetic field is called *T2 *.* Signal is measured at a time interval, echo time (TF), after the RF excitations. The time between excitations is called *repetition time* (TR).

The previous steps are the basis for the acquisition of spin-echo sequences. In Tl-weighted images, tissues with short relaxation times appear bright, whereas tissues with long Tl relaxation times (e.g., cerebrospinal fluid [CSF], cyst, edema) appear dark. In T2-weighted images, tissues with long T2 relaxation times (e.g., fluids) appear bright. In general, Tl-weighted images provide excellenr anatomical details whereas T2-wcighted images provide information about pathological conditions.

The four major types of magnets are permanent, hybrid, resistive, and superconducting. The field sttength achievable with a resistive magnet is limited, whereas it is possible to achieve magnetic fields of much greater strength with superconductive magnets. A set of coils called *sbitn coils* is used to adjust the static field to establish a high degree of homogeneity in the magnetic field.

Contrast agents have been used widely in MRI. As in CT, the enhancement of central nervous system (CNS) pathology is based on disruption of the blood-brain barrier. Unlike conventional contrast agents used in CT that are directly visualized, those used in MRI (called *paramagnetic contrast agents)* produce local alterations in the magnetic environment that influence the MRI signal intensity. It is the effect on proton relaxation that appears on the MRI, not the contrast material itself.

Fat Suppression Techniques

The fat suppression technique suppresses the normal bright signal of fat on Tl-weighted images to improve the visualization of enhancing lesions located in fatty areas such as the neck, orbits, and skull base and those in the spinal canal (e.g., to differentiate between normal epidural fat and enhancing scar in patients with previous spinal surgery). This technique takes advantage of the fact that water and fat protons resonate at different frequencies. The application of an additional 90-degree pulse sequence allows a chemical saturation of fat protons, nulling its signal.

Fast Spin-Echo Sequences

Fast spin-echo sequences are intended to acquire images (proton density, T2-weighted) in a fraction of the time needed by the conventional spin-echo sequences. The sequence is acquired by phase encoding of several echoes during a particular TR (echo train) instead of the traditional single echo during a conventional spin-echo sequence. The reduction in scan time improves image quality by increasing the signal-to-noise ratio or the spatial resolution of the scan. There are two main disadvantages to fast spin-echo techniques. First, a "true" proton density-weighted image cannot be obtained. The signal of CSF is brighter than in a conventional spin-echo proton density sequence; therefore, lesions adjacent to brain surface and the ventricular edges arc inconspicuous and difficult to detect. Furthermore, with fast spin-echo T2-weighted images there is less loss of signal intensity from fat, a fact that limits the evaluation of bright lesions against a fatty background.

Additional advantages of fast spin-echo sequences include less loss of signal intensity and susceptibility effect seen when dealing with ferromagnetic substances or materials (e.g., evaluation of spine lesions in patients with orthopedic metallic instrumentation),

Gradient-Recalled Echo Sequences

Gradient-recalled echo sequences are faster than spin-echo sequences. The MRI signal is produced by using a dephasing and a readout gradient without a 180-degree

RF pulse. The images acquired are noisier than spin-echo images and include more artifacts because of changes in magnetic susceptibility between tissues. The gradient-recalled echo "T2-like" images are useful in detecting blood-containing lesions or collections in early and chronic-stages (deoxyhemoglobin and hemosiderin, respectively). Tl-weighted gradient-recalled echo sequences with thin slices arc used to generate Tl-weighted 3D volume data acquisition. These data can be reformatted to generate images in any plane.

Magnetization Transfer Contrast Imaging

In magnetization transfer contrast imaging, the magnetization transfer pulse selectively saturates prorons bound to tissue macromolccules, which typically have restricted motion. Later, the magnetization is transferred from the bound protons to the unbound water protons surrounding these macromolecules. Magnetization transfer pulses can be obtained with Tl-weighted images, thus decreasing the white matter signal, which in turn allows enhancing lesions to become more conspicuous on postcontrast Tl-weighted images (e.g., brain merastasis, multiple sclerosis [MS] plaques). Magnetization transfer conrrast pulses are used also to suppress the background signal when performing time-of-flight magnetic resonance angiography (MRA) studies.

Diffusion-Weighted Magnetic Resonance Imaging

Diffusion-weighted MRI (DWI) of the brain is a new method based on echo-planar imaging. To date, this sequence has been used primarily to detect cerebral ischemia. This technique is not widespread because specialized hardware and software are needed. Given the potential of DWI to improve acute stroke management and the increase in the number of MRI systems that perform this sequence, diffusion-weighted imaging of the brain will certainly become a staple in the workup of acute cerebral ischemia.

Physics

Diffusion is the process of random molecular motion (Brownian motion). Free diffusion in biological systems usually occurs in CSF. Isotropic restricted motion occurs in a homogeneous medium and is directionally invariant, as in gtay matter. White matter is inhomogeneous; it contains cell membranes, myelin, and nerve fibers. Therefore diffusion of water in the whire matter is an orientation-dependent (anisotropic) phenomenon. The measured value of the mobility of water is known as the apparent diffusion coefficient (ADC). Alterations in the restriction of water movement that are central in the pathophysiological changes that occur in ischemia result in changes in the ADC of water.

DWI is designed to detect the random movement of water protons. Noninvasive spatially varying magnetic gradients that label water protons ate applied. The technique generates a series of images with various degrees of diffusion encoding, from very little to intense diffusion encoding. The degree of diffusion encoding is indicated by the b value. A b value of zero indicates no diffusion encoding and essentially corresponds to a conventional T2-weightcd image in which the CSF is high signal, with white matter appearing dark and gray matter appearing brighter than white matter. In images with higher b values (greater degrees of diffusion encoding), both the CSF and the brain parenchyma become darker, the former at a more rapid rate because of the free diffusion of water protons in CSF. When large b values are applied in a particular direction, diffusion can be made the dominant image contrast mechanism, enabling variations in diffusion to be visualized, including their directional dependence.

The differences in the rate of change of signal intensiry at different b values allow calculation of ADC, which is a quantitative measure of water diffusion. Normal white matter regions in the brain, which have unrestricted water movement (high diffusion rates) along the orientation of their fibers, have high ADC values and appear bright on the calculated ADC image. In contrast, gray matter regions, with restricted water movement (low diffusion rates), have low ADC values and appear dark on the calculated ADC image. A typical protocol generates diffusion-weighted images with multiple b values.

Diffusion images ate best obtained by applying the diffusion gradient in three orthogonal axes *{x, y, z)* because water movement in the brain parenchyma is anisotropic. The individual images generated from the application of the diffusion gradients in the three otthogonal axes are summed and displayed as a trace image for both the calculated ADC images and the diffusion-weighted images. This allows the cancellation of high-signal regions on the diffusion-weighted images and low-signal regions on the ADC images that would result from normal white matter tracts when diffusion is applied perpendicular to the white matter tracts.

Clinical Application

How does ischemic tissue affect the contrast of a diffusion-weighted image? It is thought that acute ischemia induces a shift of water from the unconstrained extracellular space to the more constrained intracellular space (cytotoxic edema), This results in a 33-60% decrease in ADC as early as 4 minutes after ischemia in overall models that results in a hypointense region on the calculated ADC map and a hyperinrensc region on the diffusion-weigh ted image (Figures 37A.2 and 37A.3). It is unclear whether changes in diffusion are an early indication of infarction or

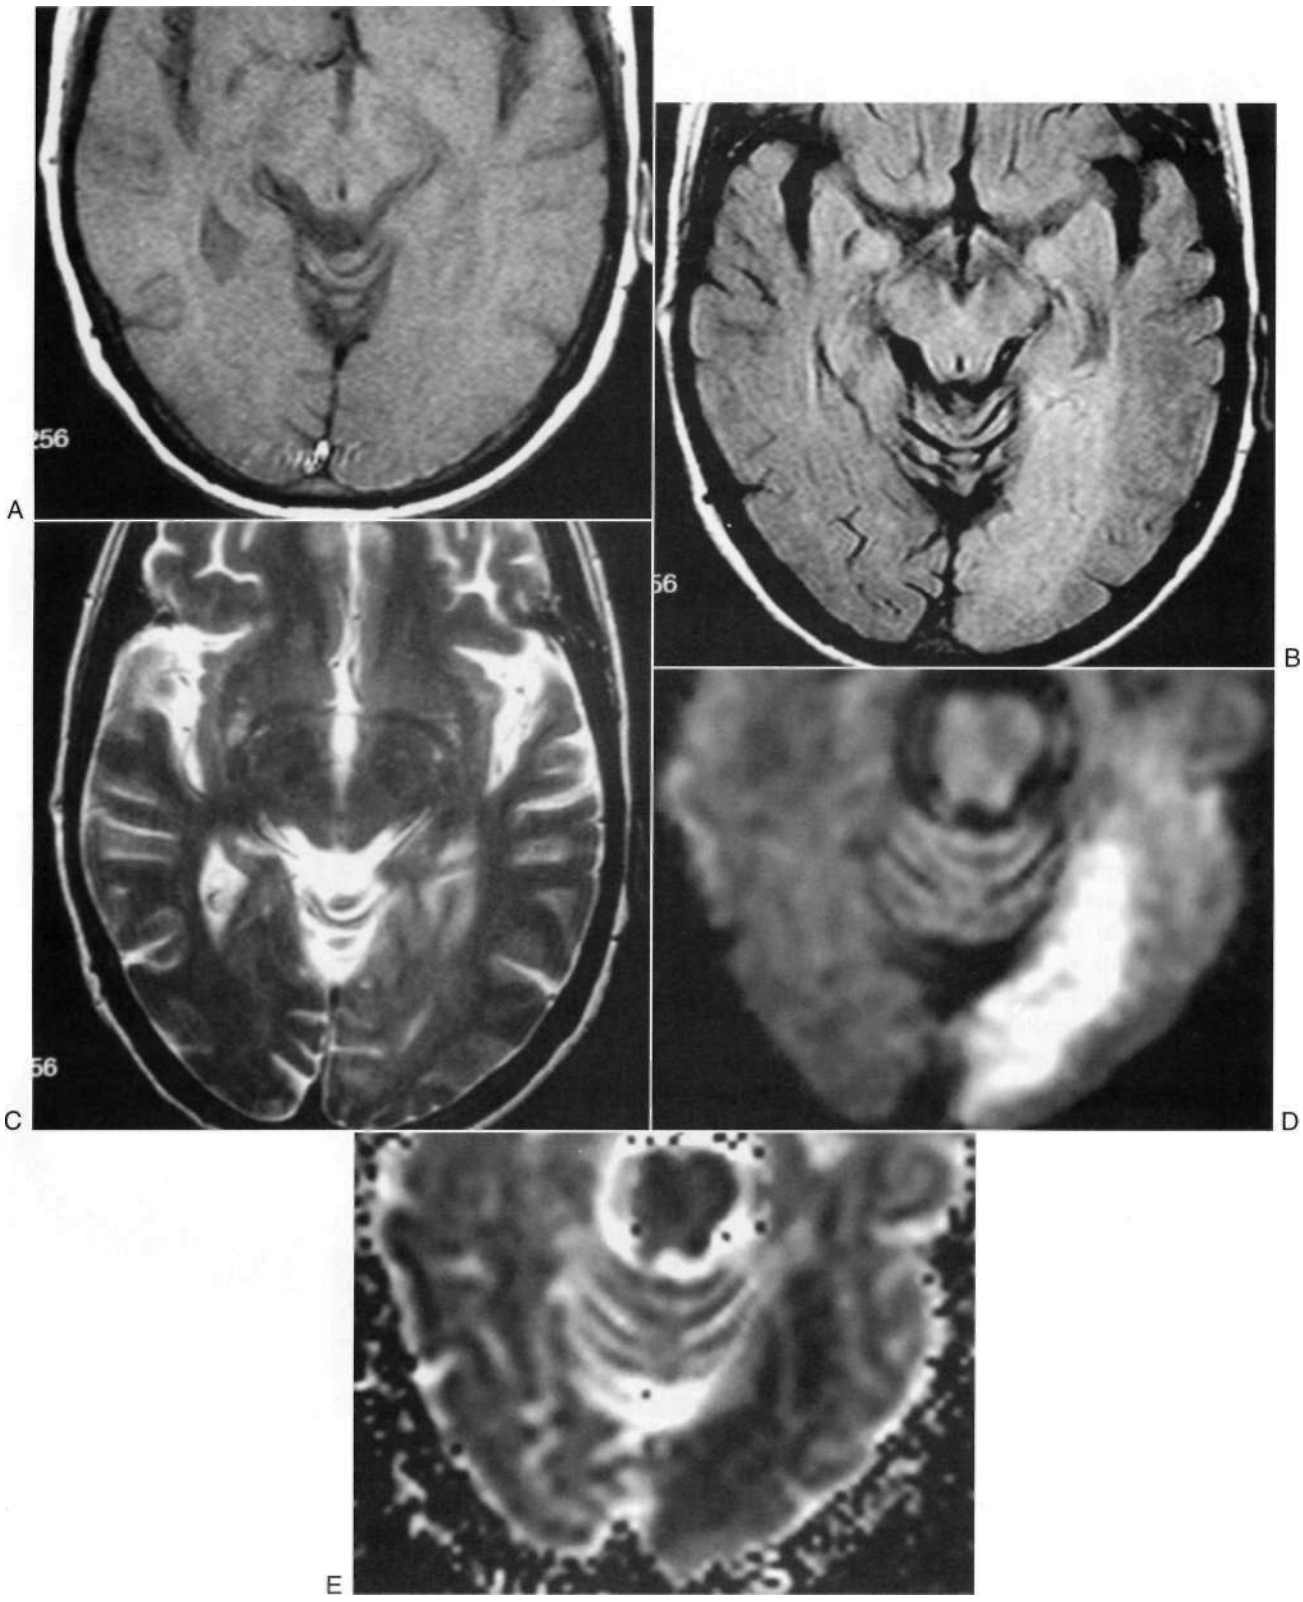

FIGURE 37A.2 Stroke. (A) Axial Tl-weighted image shows subtle effacement of sulci in the left occipital lobe. (B) Axial fluid-attenuated inversion recovery and (C) T2-weighted images show subtle hyper in tensity in the left occipital lobe. (D) Diffusion-weighted image (DWI) and (E) apparent diffusion coefficient (ADC) map demonstrate a matched defect (high signal on DWI and low signal on ADC) consistent with restricted diffusion.

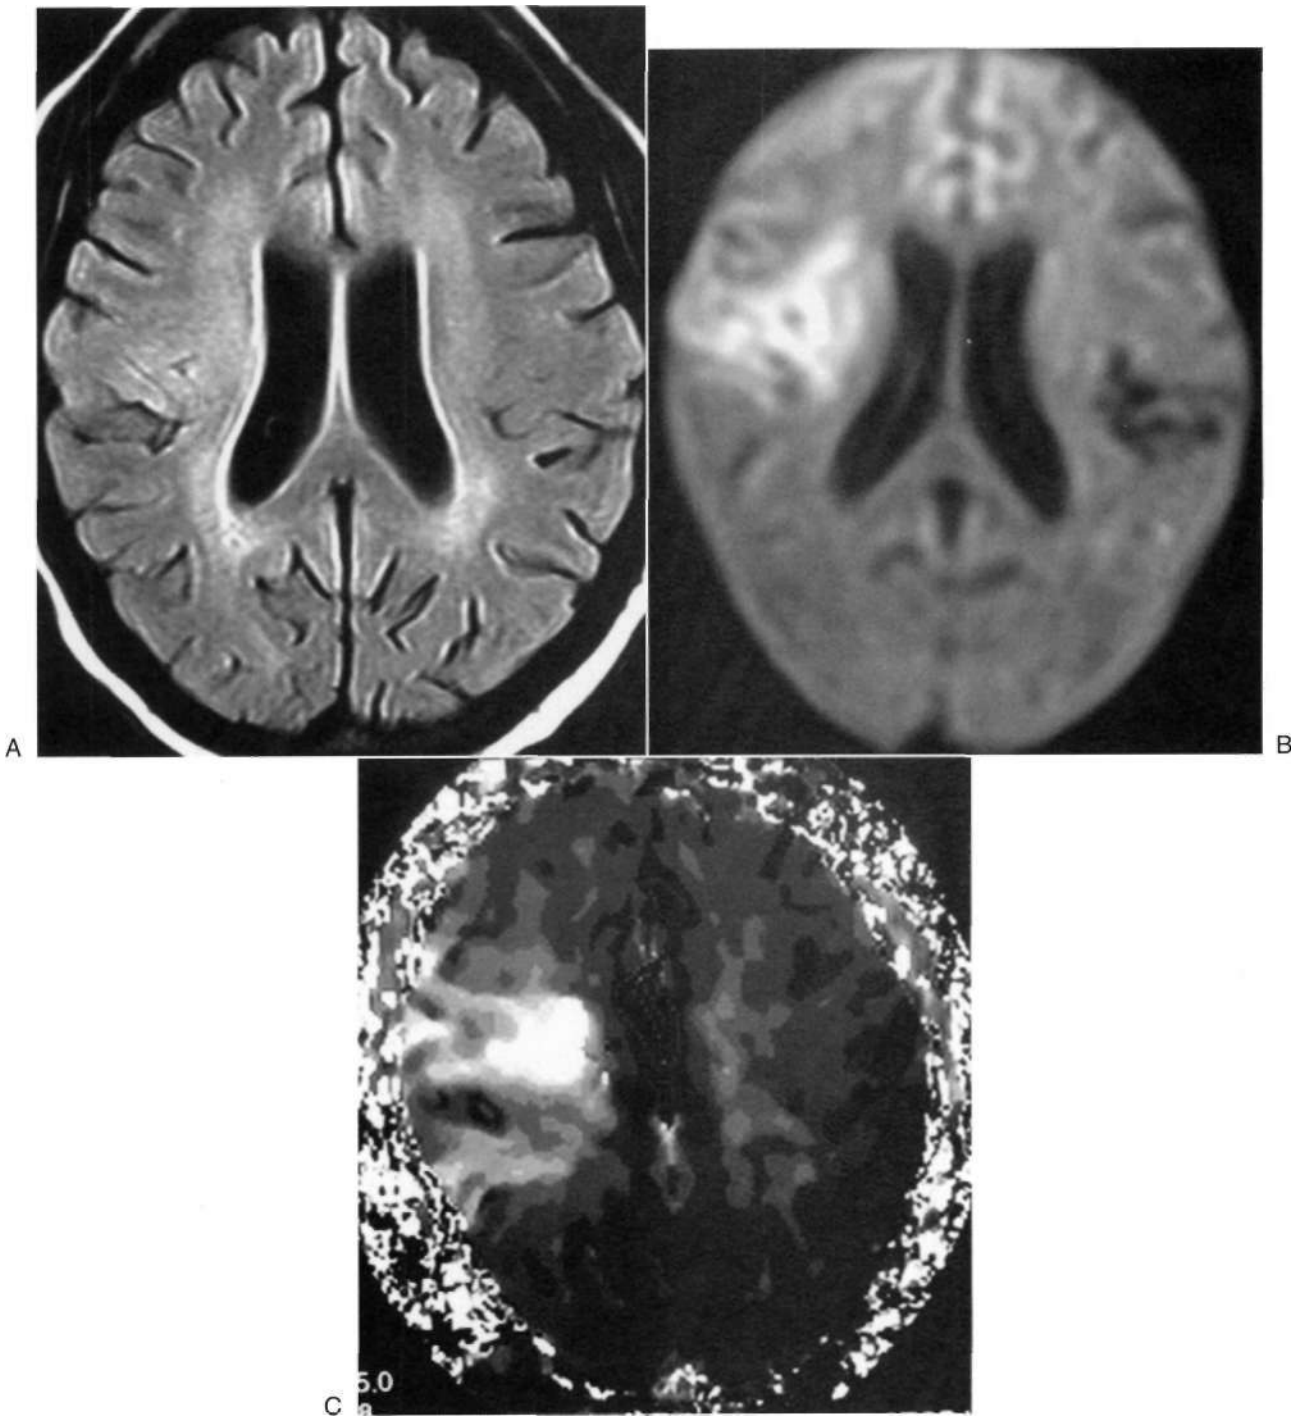

FIGURE 37A.3 Stroke. (A) Fluid-attenuated inversion recovery axial image shows very subtle hyperintensity in the right frontotemporal region. (B) Diffusion-weigh ted image (DWI) shows an area of increased signal, which had a correspondingly low apparent diffusion coefficient (not shown). (C) Time-to-peak (TTP) perfusion map shows an increase in the TTP consistent with a perfusion deficit, which was slightly larger than the DWI deficit. The mismatch is consistent with tissue at risk or the ischemic penumbra.

irreversible ischemia because reversibility has been demonstrated in animals but not in humans. When interpreting these images, one must remember that a T2 component is always present in the diffusion-weighted image contrast even with a large b value. This can result in a phenomenon known as T2 *skine-througk.* Evaluation of the diffusion image along with the calculated ADC maps is necessary to avoid misinterpreting an area of T2 shine-through as a region of restricted diffusion. A true region of restricted diffusion will appear hypcrintense on the DWI but

hypointense on the ADC map (see Figures 37A.2 and 37A.3).

Once infarction occurs, there is an eventual increase in the ADC, which returns to normal and then increases when compared with unaffected tissue. This increase in the ADC is presumably related to an increase in extracellular water in an area of chronic infarction. The time course of elevation of depressed ADC as it relates to a stroke signature is unclear. It is likely that depressed ADCs persist to the end of the second week after the acute ischemic event.

It is still unclear what role diffusion imaging will play in acute stroke management. To date, diffusion imaging has been of value in improving the detection of acutely ischemic brain regions, identifying ischemic regions in patients with multiple white matter abnormalities, identifying acutely ischemic regions adjacent to chronic infarcts, and increasing clinical confidence in diagnosis. It is likely that diffusion-weighted images and magnetic resonance perfusion imaging will play a vital role in diagnosing and managing acute stroke.

It is also important to remember that restricted diffusion may be seen in conditions other than stroke. It may also be seen in abscesses (Figure 37A.4), some infections such as Creutzfeldt-Jakob disease (Figure 37A.5), and other entities such as an epidermoid cyst (Figure 37A.6). In the latter case, it is helpful in distinguishing this entity from an arachnoid cyst because arachnoid cysts do not have restticted diffusion and instead have CSF characteristics.

Perfusion-Weigh ted Magnetic Resonance Imaging

Perfusion-weighted MRI (PWI) of the brain is a functional imaging method that provides physiological information. Although the anatomical information provided by conventional MRI sequences is sensitive in detecting pathological changes, it is not specific. In addition, some neurological diseases including dementia and psychiatric illnesses may have a normal appearance on conventional imaging. PWI may provide clinically useful information differentiating between tumor and radiation necrosis, grading gliomas, detecting perfusion changes in anatomically normal regions in patients with dementia and psychiatric illnesses, and detecting the ischemic penumbra around an area of acute cerebral infarction.

Physics

PWI is sensitive to microvascular tissue-level blood flow. Most clinical experience is with gadolinium-based relative cerebral blood volume (rCBV) perfusion imaging, but techniques are available to obtain information about perfusion without the use of contrast (spin-labeled perfusion). The following is a summary of the physics behind gadolinium-based perfusion imaging.

Gadolinium is a suitable agent for use in perfusion imaging because of the susceptibility effects of gadolinium on $T2^{"1}$, not the 11 shortening effects that are routinely associated with contrast enhancement. In rCBV perfusion imaging, the T2* MRI signal dropoff in a perfused region of brain caused by rapid passage of gadolinium through the capillary bed is used to compute the relative perfusion to that region. This signal drop depends on both the vascular concentration of contrast agent and the density of small (3- to 10-/im) vessels per voxel of tissue. This gadolinium-based rCBV mapping technique also requires quick, susceptibility-sensitive ($T2^{S}$) scanning capabilities. The technique is optimized through fast scanning techniques such as gradient-echo echoplanar MRI. To produce a high intravascular concentration and limit recirculation, contrast should be administered as a tight bolus. We typically inject 5 mL per second with a power injection. A double dose of contrast can improve signal changes, producing a 2()-30% peak signal drop in gray matter at a TE of 100 milliseconds. rCBV maps are constructed using tracer kinetic principles by integrating the signal-time curve for each voxel. Maps are relative in that the arterial input function is not typically measured, so true quantitative volumes are not routinely calculated.

One can envision that a problem will arise in highly permeable regions of severe blood-brain barrier breakdown. In this situation, the Tl shortening effects of gadolinium predominate in lowering the T2* signal of gadolinium, resulting in falsely low rCBV values. This can occur with enhancing tumors and subacute infarcts. To limit the Tl shortening effects of gadolinium, rCBV maps must be mathematically corrected for Tl enhancement. Spin-labeled techniques are not susceptible to this problem but are fraught with other limitations such as long imaging times.

Clinical Applications

As seen with non-magnetic resonance perfusion techniques, PWI can identify an ischemic penumbra in acute stroke. The advantage of magnetic resonance techniques is the improved spatial resolution and the ability to coregister PWIs with DWIs. This is important in distinguishing between irreversible infarcted tissue and ischemic but potentially salvageable tissue. However, this distinction assumes that the DWI abnormalities define the minimal infarct volume.

In humans, three general patterns of DWI and rCBV abnormalities in acute stroke have been described: matched abnormalities, larger rCBV abnormality with the final infarct size greater or equal to the rCBV abnormality, and larger rCBV abnormality with final infarct size between the DWI and rCBV abnormality. Comparing DWI, rCBV, relative cerebral blood flow, mean transit time, and time to peak, rCBV probably is the best predictor of final infarct volume. Relative cerebral blood flow and mean transit time maps overestimate final stroke volume. The identification

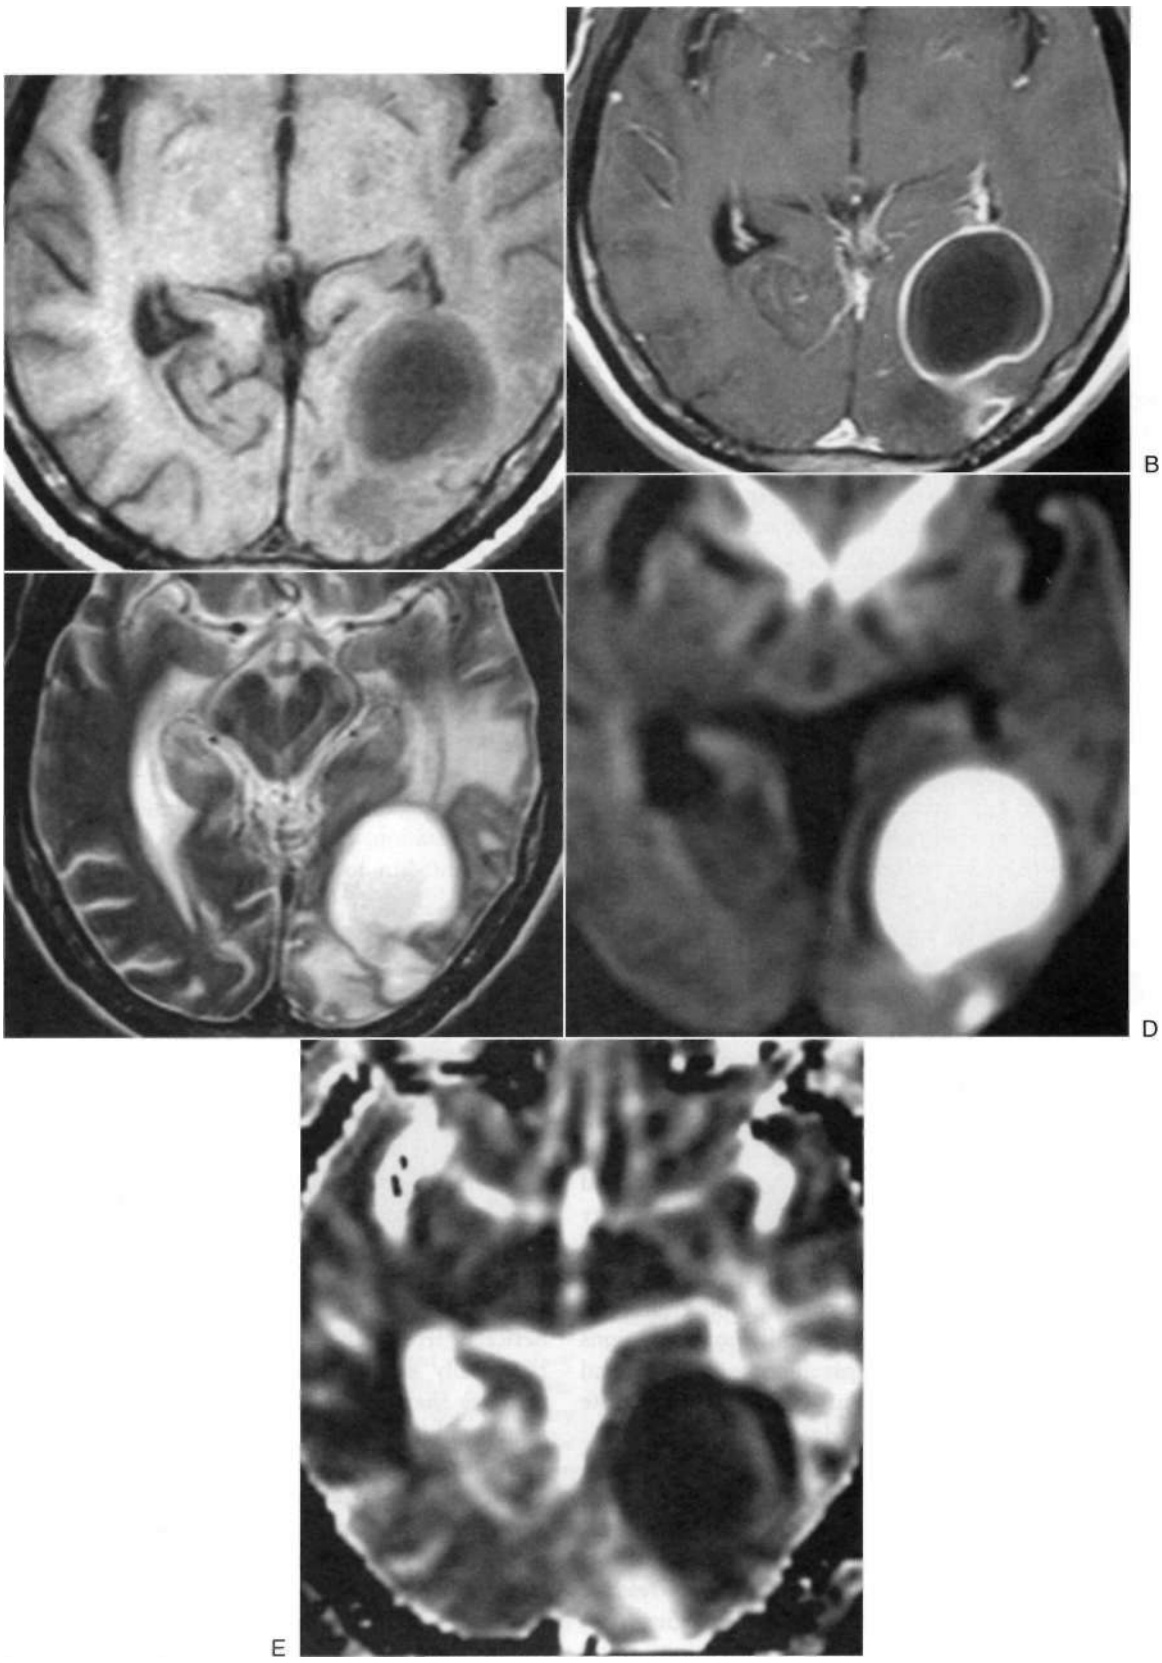

FIGURE 37A.4 Abscess. Tl-weighted axial images (A) before and (B) after contrast administration demonstrate a ring-enhancing lesion in the left occipital lobe. (C) This lesion is hypenntense on T2-weighted image and shows some surrounding edema and mass effect. (D) Diffusion-weighted image and (E) apparent diffusion coefficient map show restricted diffusion in this lesion.

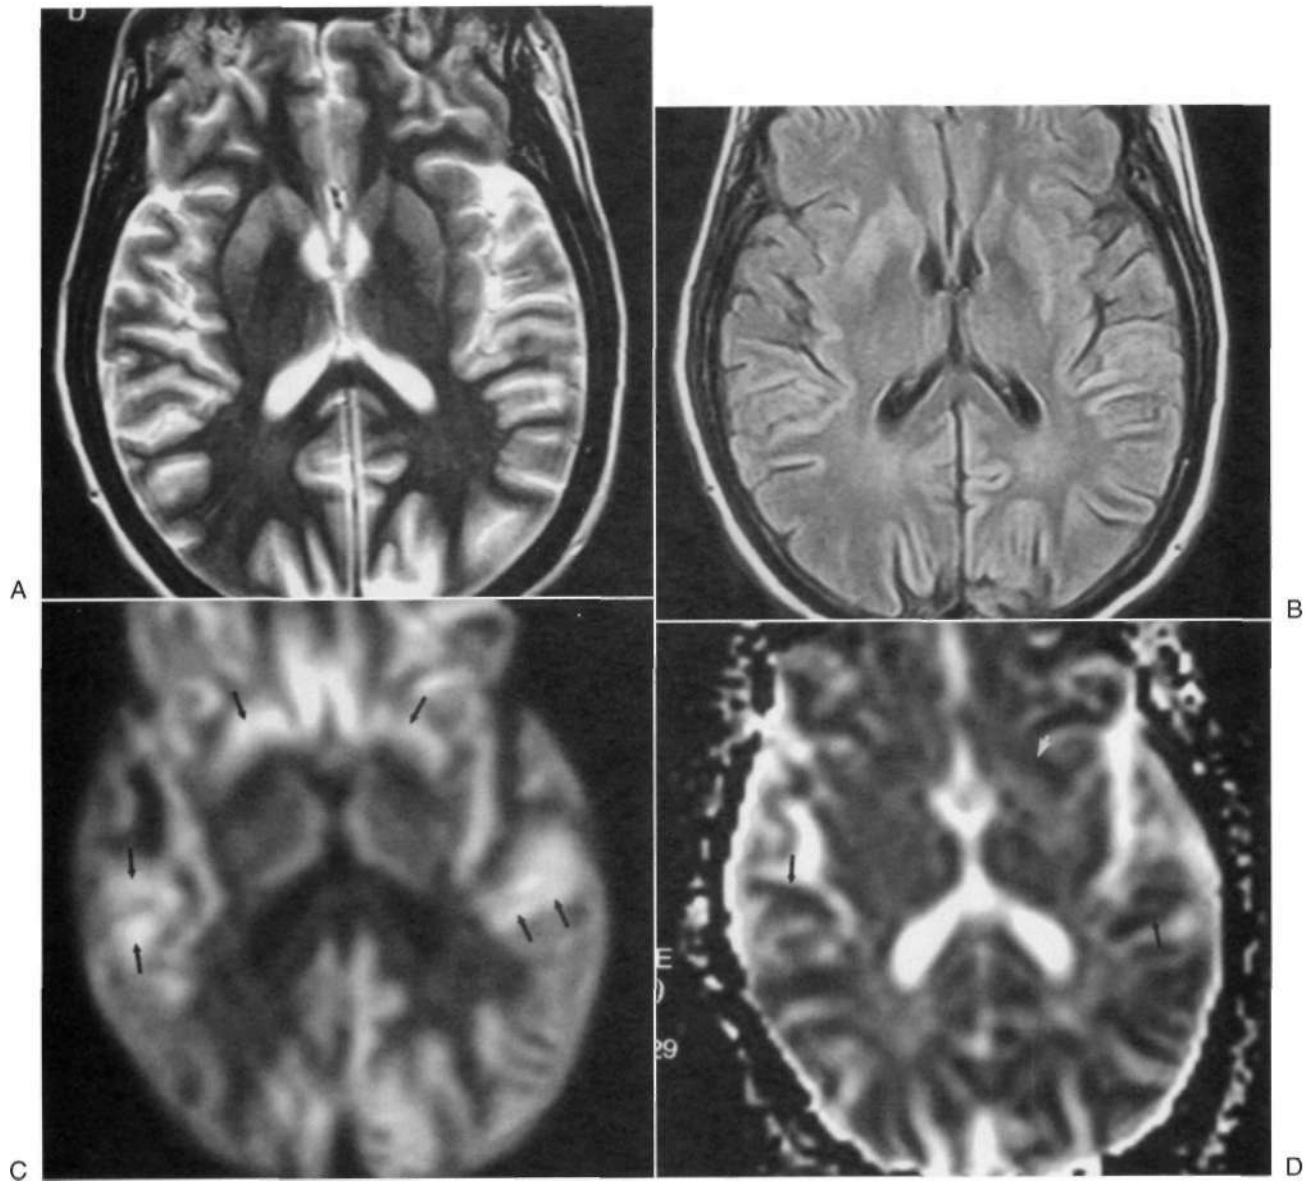

FIGURE 37A.5 Creutzfeldt-Jakob disease. (A) T2 axial and (E) fluid-attenuated inversion recovery axial images show very subtle hyperintensity involving the basal ganglia bilaterally. (C) Diffusion-weighted image and (D) apparent diffusion coefficient map show restricted diffusion in both temporal lobes *(arrows)* and basal ganglia bilaterally *(arrows).*

of rCBV abnormalities greater than DWI probably will be one of the key factots in determining which patients ate most likely to benefit from thrombolysis.

So far, the most extensive clinical application of magnetic resonance perfusion imaging has been in tumor imaging, Potential uses include tumor grading, determining potential biopsy sites, distinguishing recurrent tumor from radiation necrosis, and following response to treatment. In untreated gliomas, rCBV imaging has a high negative predictive value because the absence of incteascd rCBV excludes high-grade tumor irrespective of the enhancement characteristics of the lesion. However, gadolinium-based perfusion imaging is problematic because of blood-brain barrier breakdown ptesent in many tumors. Non-gadolinium-based methods may turn out to be a valuable alternative and ultimately more accurate.

PWI has shown some promise in evaluating dementia and psychiatric illnesses, migtaine, and trauma, but it is too early to know whether any of these applications will result in daily clinical use.

Flu id-Attenuated Inversion Recovery Imaging

In fluid-attenuated invctsion recovery (FLAIR) imaging, a radiofrequency pulse is applied during a chosen inversion time before the conventional spin-echo sequence. With FLAIR, the CSF signal is sttongly attenuated without

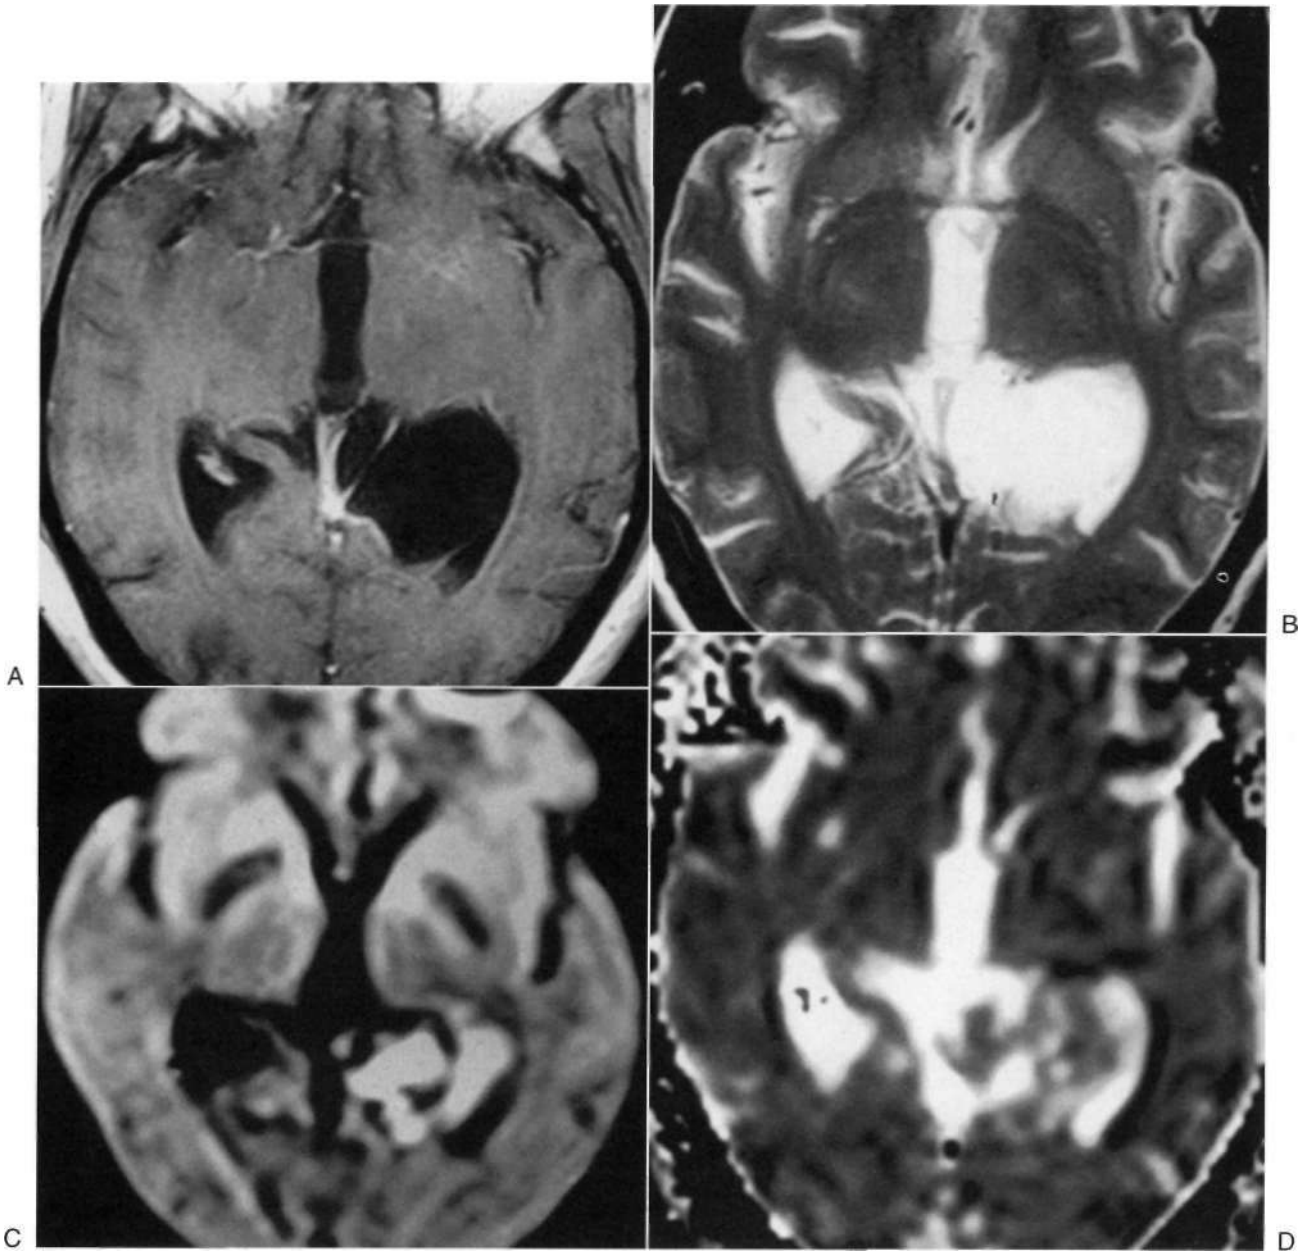

FIGURE 37A.6 Epidermoid tumor. (A) Tl- and (B) T2-weighted axial images show an intraventricular cystic lesion, which has signal intensity similar to that of cerebrospinal fluid (CSF). (C) Diffusion-weighted image and (D) an apparent diffusion coefficient map show that this lesion does not follow CSF characteristics and instead is restricted.

affecting the brain signal. In other words, a T2-like image is obtained in which the CSF appears black. With this technique, pathological lesions, particularly in the periventricular regions, extra-axial collections, and lesions near the brain surfaces, appear more conspicuous (Figure 37A.7).

Echoplanar Imaging

Echoplanar imaging is a fast imaging technique that allows collection of all the data needed to reconstruct an image in a brief interval (30-100 milliseconds). Rapid acquisirion of multiple rows of K space is the fundamental principle for this technique. Echoplanar imaging is ideal for evaluating uncooperative patients, mapping rCBV, and performing functional task activation studies.

Angiography

Many indications exist for cerebral angiography, including the investigation of patients with subarachnoid hemorrhage and intracerebral hemorrhage in whom the cause has not

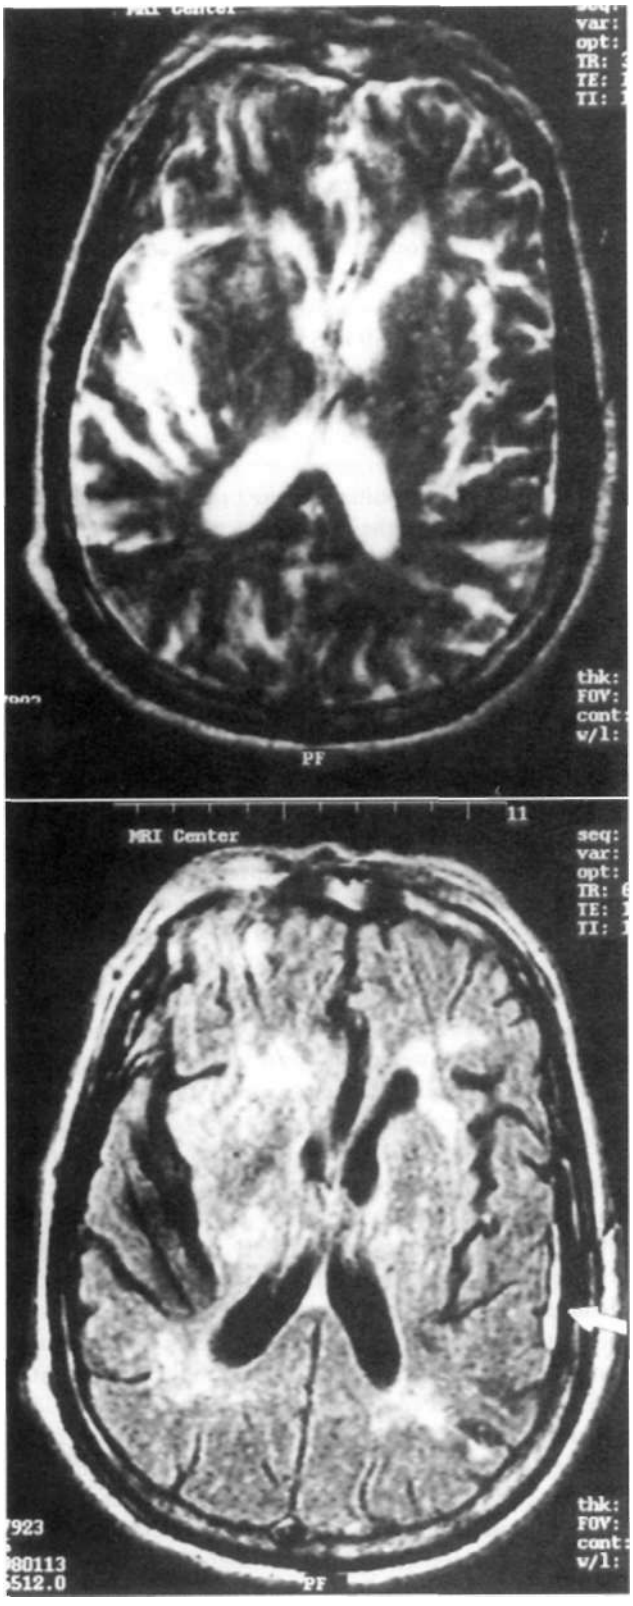

FIGURE 37A.7 Axial T2-weightcd *{top)* and axial fluid-attenuated inversion recovery {FLAIR) image *{bottom)* in an older adult with periventricular white matter ischemic changes. The white matter changes are more conspicuous in FLAIR, as is the incidental small left temporal subdural collection *{arrow).*

been determined clinically or with CT or MRI. Angiography is used also in patients with thromboembolic stroke, especially to evaluate the carotid vessels in the neck and the intracranial vasculatute. In patients with arterial dissections, vasculitis, or tumors at the base of the skull, angiography is indicated also.

Currently, angiography is performed by puncturing the femoral artery and threading a catheter up the iliac artery and into the aortic arch, with subsequent selective catheterization of the carotid or vertebral arteries (see Chaptet 37C). After the desired vessel is entered, an iodine-containing contrast agent is injected and serial films of the vasculatute are obtained for approximately 10 seconds to demonstrate arterial, capillary, and venous phases of the cerebral circulation. More recently, digital subtraction angiography has been substituted for cut-film angiography, in which a computer subtracts the background image and transmits it to a television monitor.

In addition, newer advances in angiographic techniques have allowed expansion in the field of interventional neuroradiology. These procedures include embolization of vascular malformation and tumors, occlusion of cavernous carotid fistulas by detachable balloons, and angioplasty. The advent of the tracker catheter system and its variants has greatly promoted this field. MRA and magnetic-resonance venography offer the advantage of being noninvasive, although they have somewhat lower resolution than catheter angiography (sec Chapter 37B).

Myelography

Myelography is still used in certain cases in which MRI cannot be performed, such as in postoperative patients in whom multiple clips or metallic hardware may produce too many artifacts. CT myelogtaphy also may define nerve root avulsions or dura! tears better than MRI. An iodinated water-soluble agent is injected into the subarachnoid space and roentgenographical images of the spine are obtained. Tilting the myelogram table moves the contrast throughout the spine. The contrast agents can be introduced by a lumbar, C1-C2, or cisternal puncture.

Intraoperative Neurosonography

The field of neurosonology for imaging the cerebral vasculature is reviewed in Chaptet 37D. A high-resolution, portable, real-time sonographic scanner that can be used in the operating room allows the visualization of intraspinal or intracranial abnormalities and permits the surgeon **and** radiologist to assess the progress and final result of surgety before the operation is completed.

The images are obtained using a 7.5-MHz or 5.0-MHz in-line ttansducer, with the optimal focus varying depending on the transducer's RF. The transducer is placed most

commonly in a water bath at the laminectomy site in the case of intraoperative spinal sonography or at the craniotomy or burr hole site in the case of intraoperative cranial sonography.

Intraoperative neurosonography is performed in multiple planes. Images are obtained in each plane by gradually moving the transducer across the operative field. Filmed images are obtained throughout the study.

Magnetic Resonance Angiography

MRA is a very sensitive method for detecting and characterizing blood flow. It produces a blood flow map in which the vessel visualization is based on the physical differences between moving and stationary protons (see Chapter 37B). Image intensity reflects velocity and flow patterns.

There are two major MRA techniques: time-off light angiography and phase contrast angiography. The differentiation between moving and stationary protons depends on the degree of longitudinal or transverse magnetization. Time-of-flight angiography deals with longitudinal magnetization and is sensitive to amplitude, whereas phase contrast angiography deals with transverse magnetization and is sensitive to phase.

Time-of-flight angiography relies on inflow of unsaturated protons into an imaging plane. A volume is repeatedly pulsed, and because stationary nuclei are unable to remagncrizc fully when the repetition period is smaller than the relaxation timeTl, their signal is smaller than that of the fully magnetized nuclei flowing into the excited volume. Therefore inflowing blood has a higher signal than stationary tissue, and the difference between the signals of stationary and flowing protons produces a time-of-flight MRA.

Phase contrast MRA relies on velocity-induced phase shifts of moving protons. A bipolar gradient is applied, and if the proton is stationary, there is no phase shift. However, if the proton is moving, a phase shift occurs. The faster the proton moves, the greater the phase shift. Velocity-induced changes in the transverse magnetization distinguish moving from stationary protons.

MRA can be performed with either a 2D or 3D Fourier transformation (2DFT or 3DFT) gradient-echo technique. In 2DFT techniques, each slice is individually acquired, and even slow flow is identified. In 3DFT or volume acquisition, data are acquired from an entire volume simultaneously. Very thin sections can be obtained with 3DFT, so high resolution can be attained.

The maximal intensity projection is a ray-tracing technique performed at a specific angle. It processes a series of acquired slices by projecting a straight line through these slices. It selects only the pixels along the ray with the highest signal intensity, so only vascular structures are represented in the final image. The procedure is repeated using parallel rays until a full 2D projection is generated. The use of MRA with arteriovenous malformations (AVMs) is illustrated in the following section on vascular malformations.

The source images are the individually reconstructed 2DFT or 3DFT partitions, whereas the collapsed view refers to the maximal intensity projection that "pancakes" all the images into one,

INTRACRANIAL LESIONS

Intra-Axial Brain Tumors

Supratentoriai Tumors

Primary cerebral gliomas make up 40-45% of all intracranial tumors; their incidence peaks in the second decade of life. In adults, most of these are supratentorial, whereas in children, they are mostly located in the posterior fossa. The degree of malignancy is variable, ranging from low-grade pilocytic astrocytomas to glioblastomas.

MRI is more sensitive than CT for tumor detection and delineation, even after contrast administration.

Oligodendrogliomas. Oligodendrogliomas usually have a heterogeneous signal on MRI, with small cystic regions and areas of hemorrhage. Edema usually is not significant, Calcification on CT has been reported in 50-90% of these tumors. One half of the cases demonstrate contrast enhancement (Figure 37A.8).

Low-Gradc Astrocytoma. Low-grade astrocytoma (grades I and II) is an irregular nonhomogeneous lesion, and calcifications are present in approximately 15% of cases. Usually, there is little edema around the lesion, and in general it is noncncapsulated and poorly demarcated from the surrounding parenchyma. With contrast, grade I astrocytomas may show minimal or no enhancement, and grade II astrocytomas enhance in approximately 90% of cases.

Pleomorphic Xanthoastrocytoma. Pleomorphic xanthoastrocyroma is a distinct astrocytoma subtype, more common in children and young adults. Presentation typically occurs in the second or third decade of life. The patient may present with symptoms of seizures. Histologically, the tumor consists of a cyst with lipid vacuoles, fibrillary astrocytes, and multinucleated giant cells. A typical location for this tumor is the temporal region, and an enhancing mural nodule usually is seen. Calcifications occasionally are present.

Dyscmbryoplastic Neuroepithelial Tumor. This benign neoplasm may be the underlying tumor in up to 23% of patients with temporal lobe epilepsy. The neoplasm contains ganglioneuronal elements and may be associated

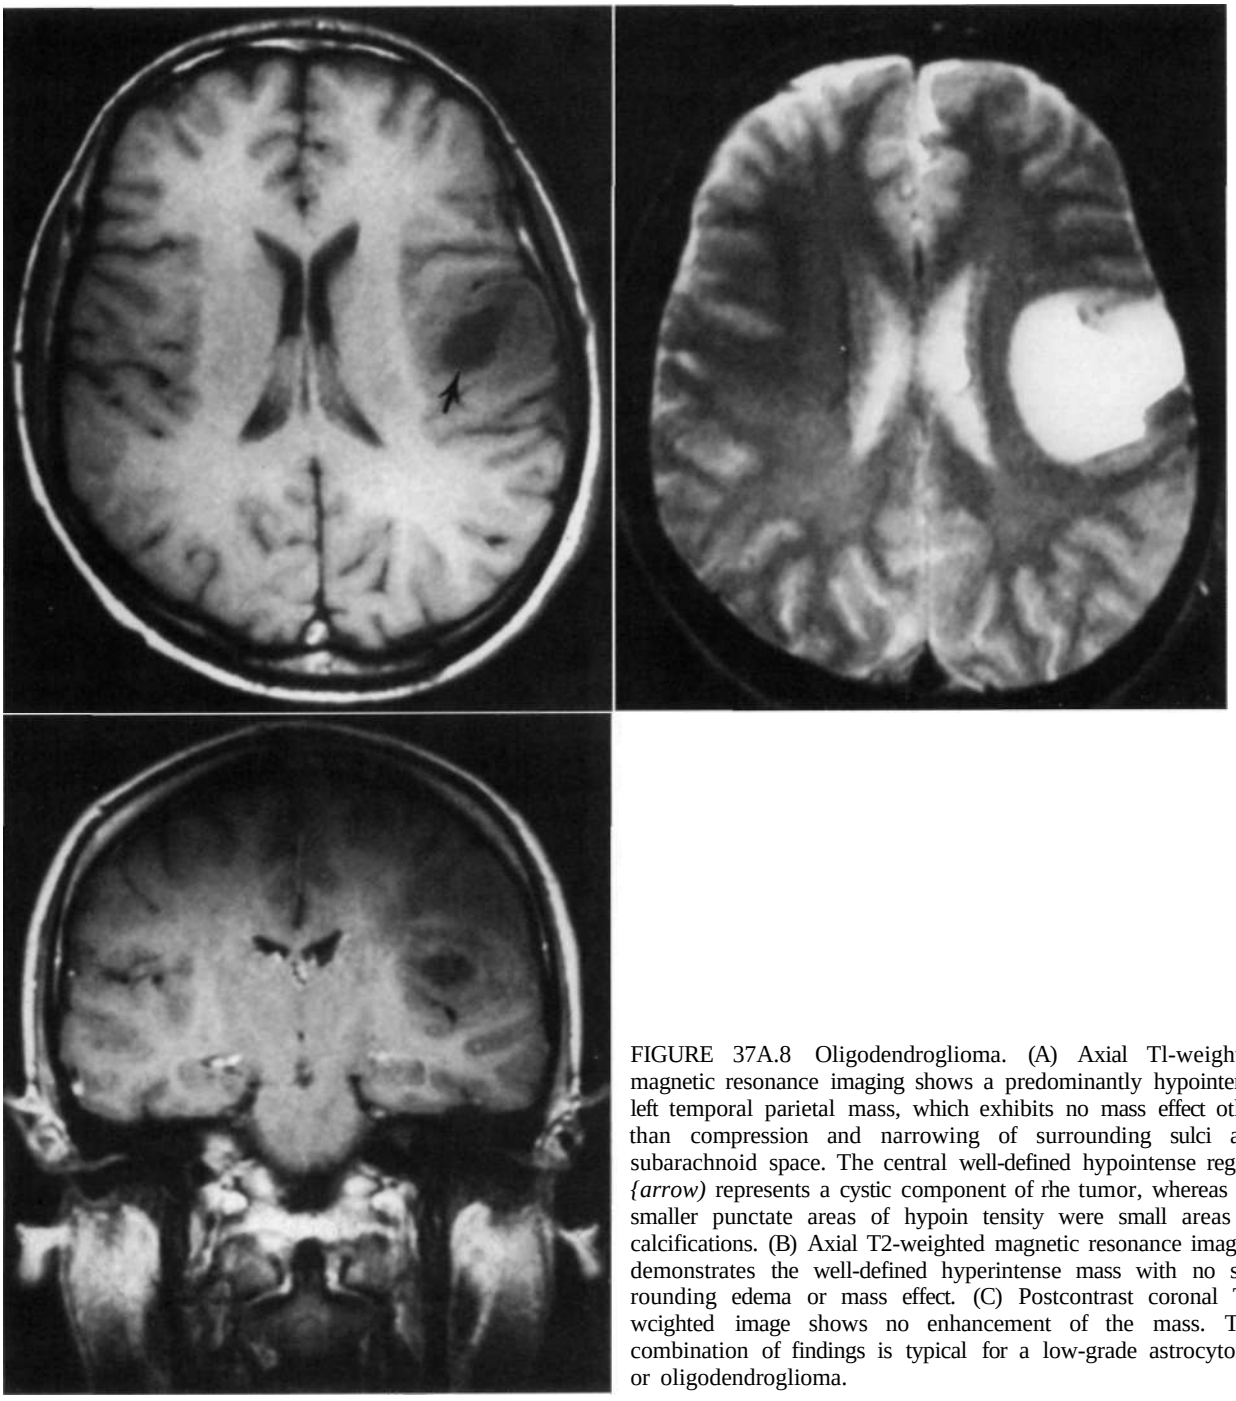

FIGURE 37A.8 Oligodendroglioma. (A) Axial Tl-weighted magnetic resonance imaging shows a predominantly hypointense left temporal parietal mass, which exhibits no mass effect other than compression and narrowing of surrounding sulci and subarachnoid space. The central well-defined hypointense region *{arrow)* represents a cystic component of rhe tumor, whereas the smaller punctate areas of hypoin tensity were small areas of calcifications. (B) Axial T2-weighted magnetic resonance imaging demonstrates the well-defined hyperintense mass with no surrounding edema or mass effect. (C) Postcontrast coronal Tl-wcighted image shows no enhancement of the mass. This combination of findings is typical for a low-grade astrocytoma or oligodendroglioma.

with cortical dysplasia. A cystic lesion may be seen on CT or **MRI,** with or without enhancement.

Ganglioglioma. Ganglioglioma affects mostly children and young adults and contains both neural and glial elements. Most gangliogliomas are supratentorial, with the temporal lobe the predominant site. In imaging studies, they are well circumscribed and typically cystic and often have calcification (Figure 37A.9).

Glioblastoma **Multiforme.** Glioblastomas represent the most malignant end of the spectrum of glial tumors. They represent 15-20% of all intracranial tumors, arc the most common supratentorial neoplasm in adults, and show a male predominance. Peak incidence is between 45 and *55* years of age. They arc located most commonly in the frontal lobe, followed by the temporal lobe. A **"butterfly"** pattern is the characteristic distribution in those glioblastomas, with bihemispheric involvement and infiltrarion of

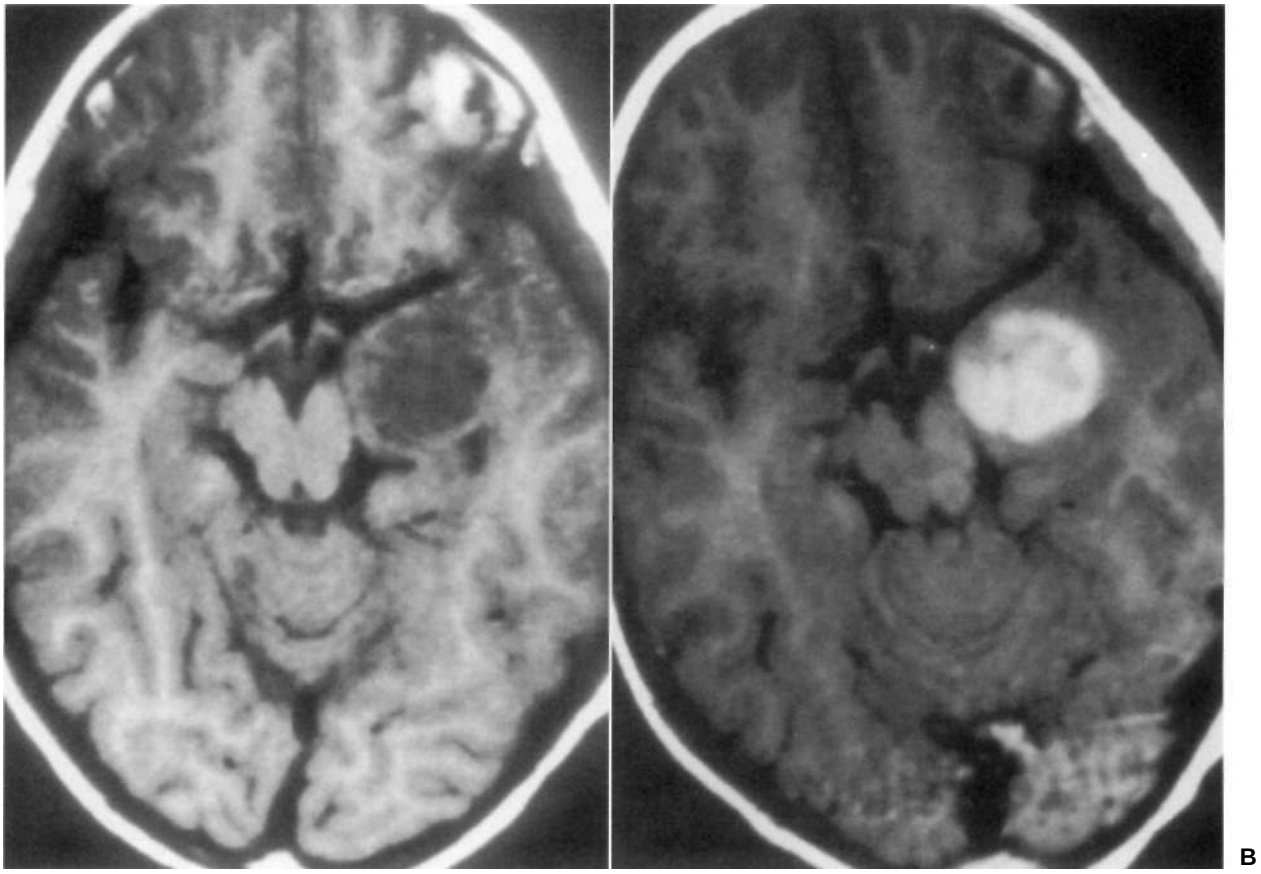

FIGURE 37A.9 Left temporal lobe ganglioglioma. Patient with history of temporal lobe seizure. (A) Axial Tl-weighted image demonstrates a low-signal mass lesion in the medial portion of the left temporal lobe. (B) The lesion enhances nearly homogeneously with gadolinium.

the intervening corpus callosum. Glioblastomas tend to invade the leptomeninges and dura.

MRI usually shows marked tumoral heterogeneity (Figure 37A.10), with necrosis and cystic changes. These tumors tend to bleed, but calcification is rare. The majority of these lesions enhance with contrast, and the enhancement pattern is heterogeneous. One can see ringlike enhancement with thick, irregular nodular areas surrounding necrotic regions {see Figure 37A.10). Regions that enhance correlate with areas of viable tumor tissue at pathological examination, so enhancement is helpful in guiding surgical biopsy. It should be emphasized that one cannot distinguish the exact margins of the tumor from edema. As with all infiltrative gliomas, there is no clear margin microscopically that separates tumor cells from reactive gliosis, edema, or normal brain.

Lymphoma and Metastatic Disease. Primary CNS lymphoma represents approximately 1% of all primary brain tumors, although this incidence has been steadily increasing in the past decade because of its frequent occurrence in patients with acquired immunodeficiency syndrome (AIDS). Focal intracerebral masses arc the most common initial presentation of primary CNS lymphoma, and multiplicity is common. Intracranial metastases from systemic (nonprimary CNS) lymphoma tend to involve the leptomeninges (with or without parenchymal involvement). The appearances of parenchymal lymphoma on neuroimaging studies include masses that involve the deep gray matter structures, periventricular regions, and corpus callosum. The amount of edema seen on MRI varies. Signal intensity also varies, but when these lesions are deep they are often isointense to gray matter on T2-weighted images. In the majority of lymphomas, enhancement is dense and homogeneous (Figures 37A.11 and 37A.12). Secondary brain involvement is indistinguishable from primary CNS lymphoma, but parenchymal as opposed to meningeal involvement is more common with primary lymphoma. Postcontrast MRI is more sensitive than CT for detecting leptomeningeal seeding. Lymphoma in patients with AIDS tends to have more necrosis than in those without AIDS and therefore appears as lesions with ring enhancement and more prominent edema.

Cerebral metastases account for 26% of all clinically detected brain tumors, and 80-85% of them arc supratentorial in location. The optimal screening examination

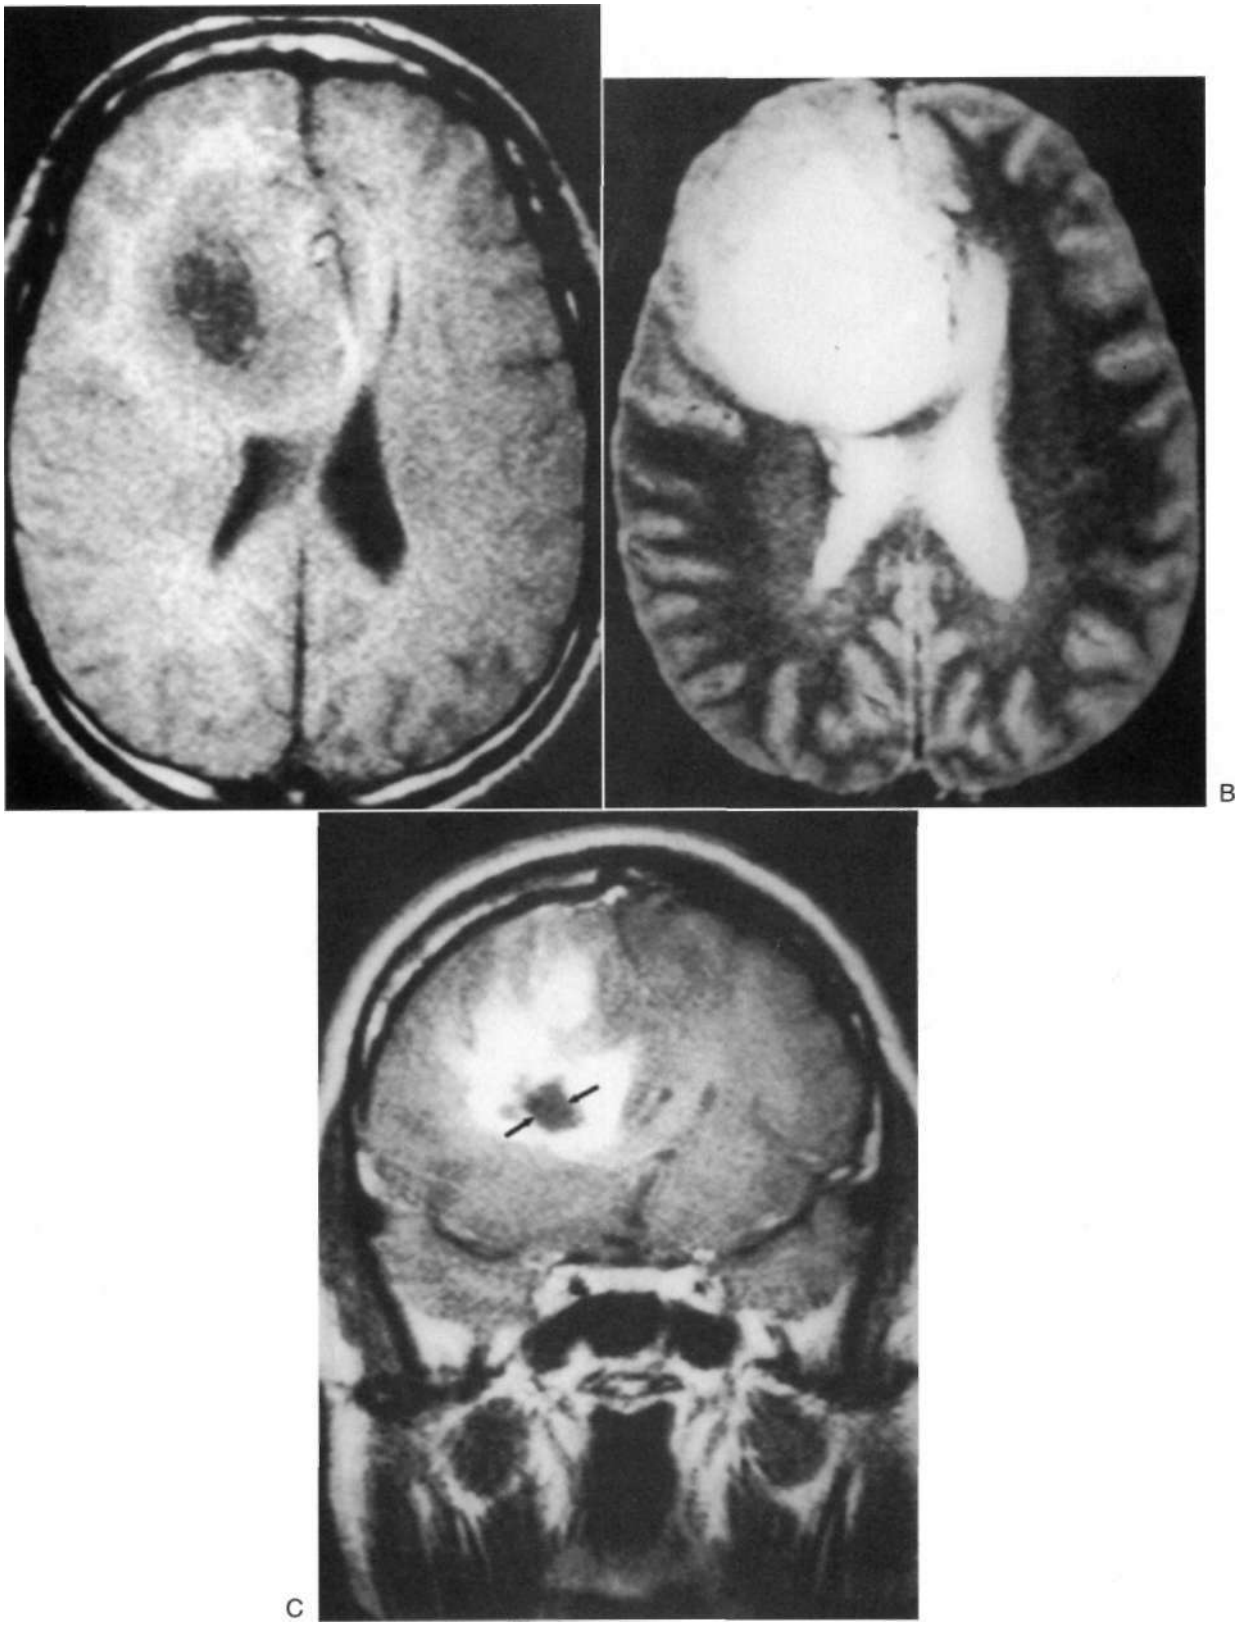

FIGURE 37A.10 Glioblastoma multiforme. (A) Axial T1-weighted image and (B) T2-weighted image reveal a mass lesion compressing the frontal horn and producing shift of the midline. This lesion is isointense to hypointense on Tl weighting and becomes hyperintense on T2 weighting. (C) l'ostcontrast Tl coronal image shows irregular enhancement of this lesion with a central area of hypo in tensity representing a tumor cyst or necrotic tissue *[arrows).*

FIGURE 37A.11 Lymphoma. Mass involving the body of the corpus callosum *{arrows)* is isointense to gray matter on this T2-weighted axial image.

for detecting intracerebral metastases is the postcontrast MRI. Intra parenchymal metastases are most common, with tumors of the king and breast the most common primary sites. Most intracerebral metastases are multiple, but solitary metastases are common (30-50% of cases of metastases). They are found at the gray-white junction, are usually well circumscribed and round, and often are surrounded by edema (Figure 37A.13). The extent of edema bears no relationship to the size of the metastasis or the clinical status of the patient.

On MRI, metastases can be distinguished from edema on T2-weighted images because the metastasis is of variable intensity within an area of high-intensity edema. Peritumoral edema usually is prominent and is identified as fingerlike projections following white matter boundaries. lntratumoral hemorrhage occurs in 20% of metastases.

Contrast increases the ability to detect metastases. CT is highly sensitive to intra parenchymal metastatic disease, but contrast-enhanced MRI detects many lesions that are not detected on CT. In one study, high-dose (triple-dose) gadolinium-enhanced MRI examinations had advantages over the standard gadolinium-enhanced (0.1 mmol per kilogram) examinations in detecting small metastases. In addition, magnetization transfer (a technique that uses special saturation pulses to produce greater than normal enhancement of cortical and subependymal veins and other gadolinium-containing structures) with single-Jose gadolinium-enhanced MRI improves sensitivity to

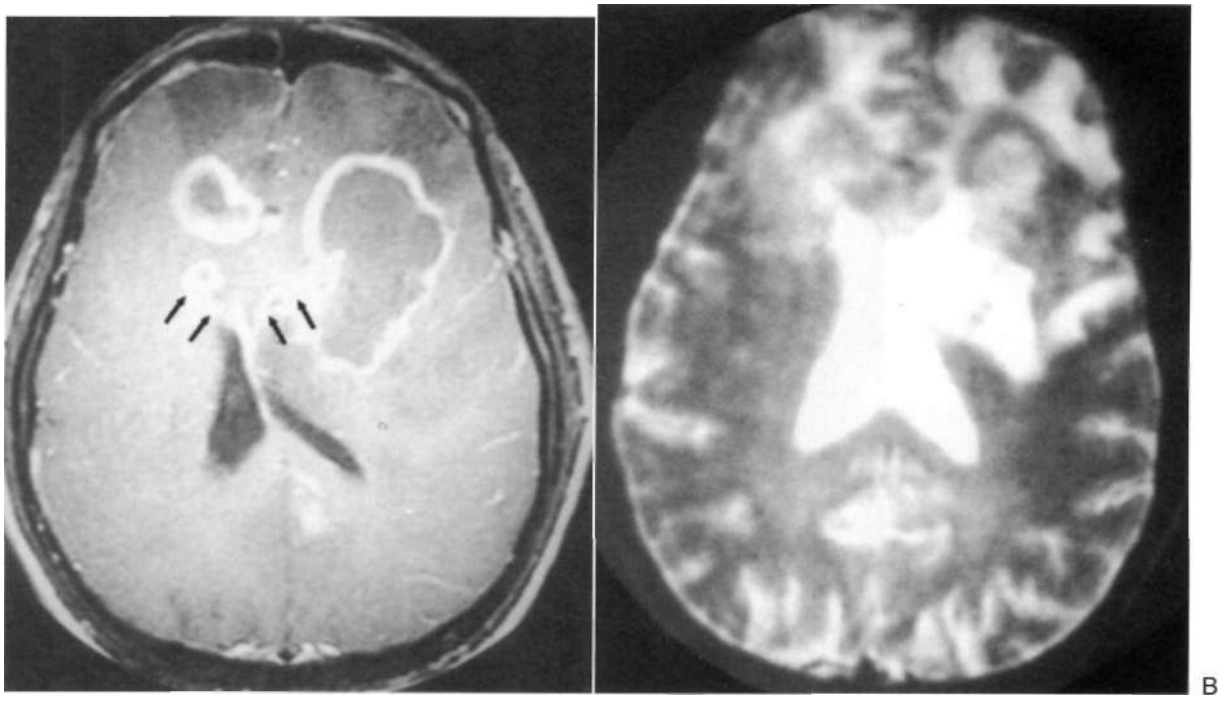

FIGURE 37A.12 Lymphoma. (A) Postgadolinium Tl-weighted image in a patient with lymphoma shows multiple ring-enhancing lesions in the frontal lobes and one lesion in the left occipital parasagittal location. Arrows indicate subependymal enhancement. (B) Axial T2-weighted image demonstrates isointense to hyperintense lesions in the frontal lobes bilaterally corresponding to the ring-enhancing lesions.

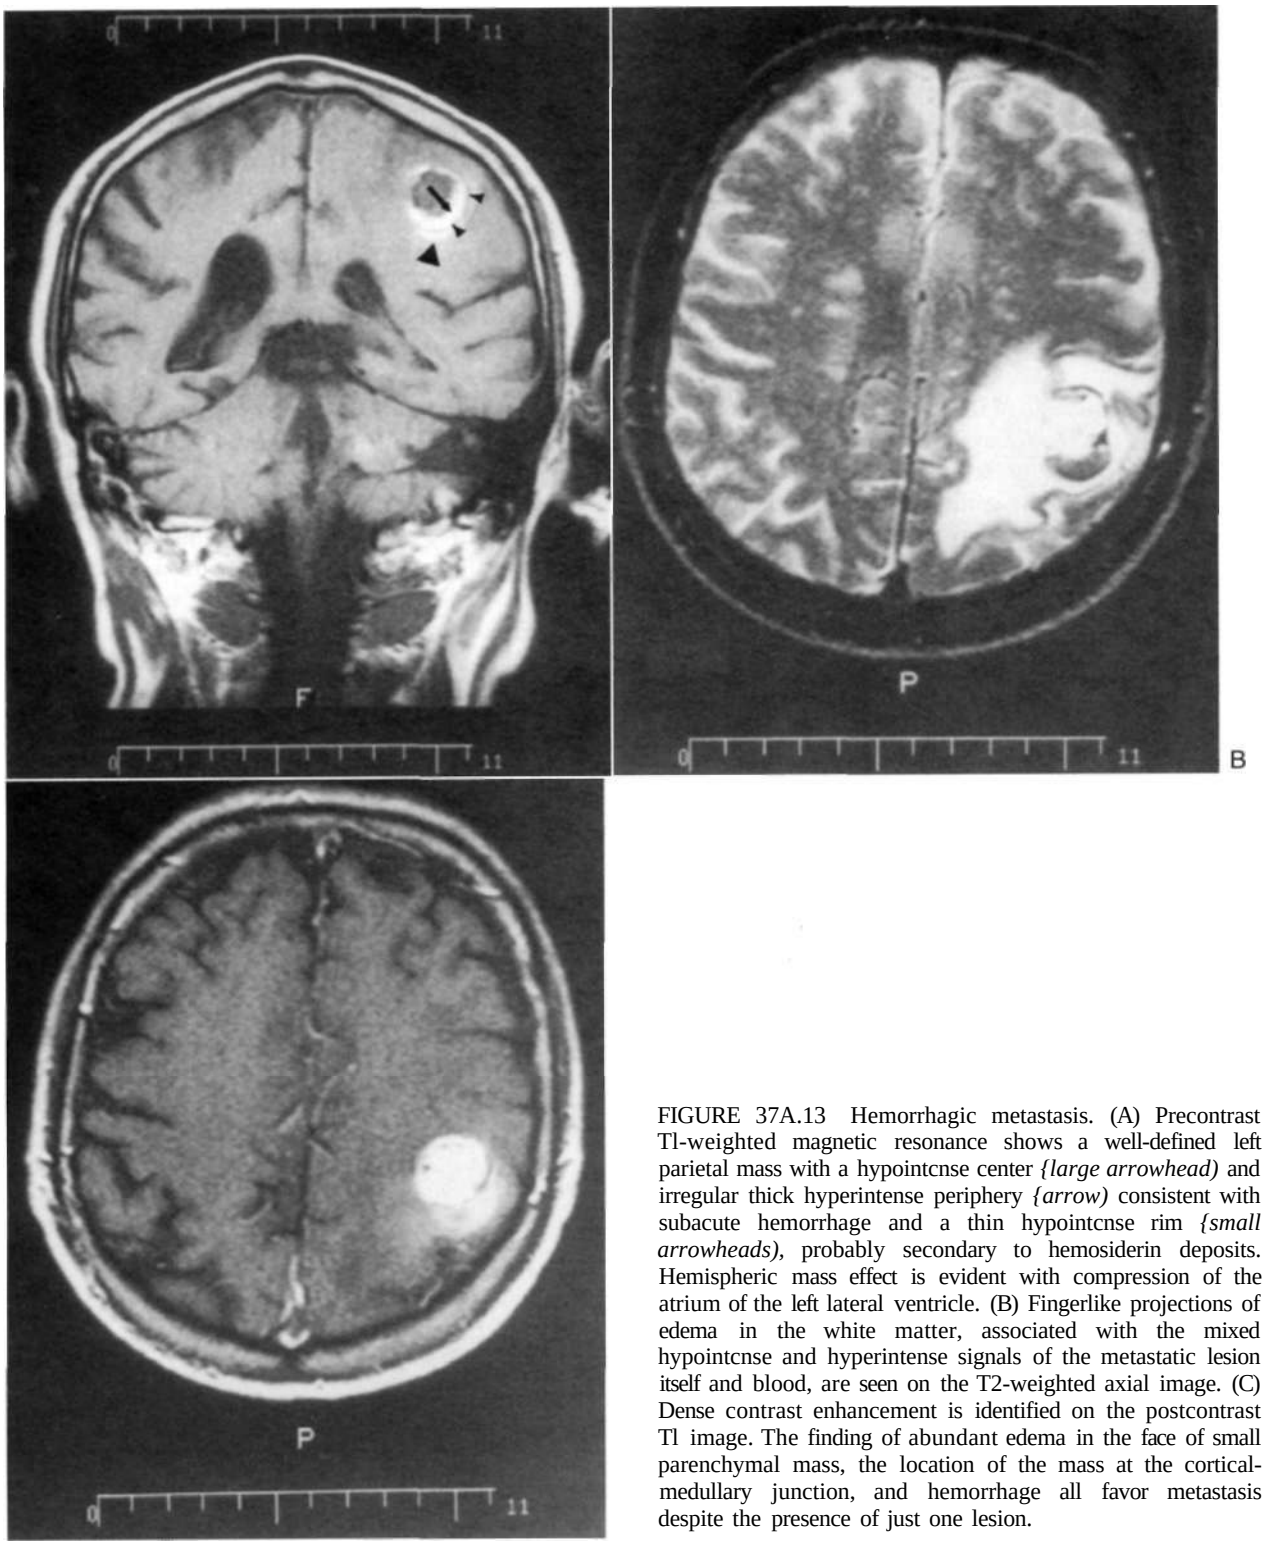

FIGURE 37A.13 Hemorrhagic metastasis. (A) Precontrast Tl-weighted magnetic resonance shows a well-defined left parietal mass with a hypointcnse center *{large arrowhead)* and irregular thick hyperintense periphery *{arrow)* consistent with subacute hemorrhage and a thin hypointcnse rim *{small arrowheads),* probably secondary to hemosiderin deposits. Hemispheric mass effect is evident with compression of the atrium of the left lateral ventricle. (B) Fingerlike projections of edema in the white matter, associated with the mixed hypointcnse and hyperintense signals of the metastatic lesion itself and blood, are seen on the T2-weighted axial image. (C) Dense contrast enhancement is identified on the postcontrast Tl image. The finding of abundant edema in the face of small parenchymal mass, the location of the mass at the cortical-medullary junction, and hemorrhage all favor metastasis despite the presence of just one lesion.

metastases and doubles the relative contrast of enhancing brain lesions. In general, metastases have mote edema and mass effect than inflammatory processes and primary gliomas, a sign that can be helpful in differential diagnostic considerations.

Infrcttentorial Tumors

The postetior fossa is the most common site of primary intracranial tumors in children. The most common tumors of the posterior fossa seen in children are, in order

of decreasing frequency, cerebellar astrocytomas, primitive neuroectodermal tumors (PNETs), ependymomas, and brainstem gliomas. In the adult, infra tentorial tumors make up only 15-20% of all intra-axial brain tumors, the most common being hemangioblastoma and metastasis.

Cerebellar Astrocytoma. The cerebellar astrocytoma is the most common posterior fossa neoplasm in children and also occurs in adults. The typical findings of a cerebellar astrocytoma on MRI include a mass made up of a single large cyst with a solid nodular portion in the wall of the cyst. The solid portion of the tumor enhances with contrast, whereas the cyst wall may or may not enhance. The solid portion is hyperintense to normal brain on T2-weighted sequences, whereas the cystic portion is isointense to CSF. Cerebellar astrocytomas may not be cystic, and if solid they are usually homogeneous in signal intensity. Twenty percent calcify.

Primitive Neuroectodermal Tumors. PNETs are a group of CNS tumors thought to originate from primitive or undifferentiated neuroepithelial cells. The prototype of these tumors is the medulloblastoma. Other tumors included in this category are ependymoblastoma, cerebral neuroblastoma, pinealoblastoma, medulloepithelioina, and pigmented medulloblastoma.

The cerebellar PNET, the medulloblastoma, makes up 25% of all intracerebral tumors in children, second only to cerebellar astrocytoma. The tumors originate most often in the midline, filling the fourth ventricle. These malignant tumors tend to invade the leptomeninges and seed the CSF. On CT, these tumors are high-density lesions that enhance and produce hydrocephalus. On MRI, they have homogeneous to mixed signal intensity {Figure 37A.14). On T2-weighted images, the lesions are nearly isointense to brain parenchyma. These tumors enhance intensely after contrast administration.

Ependymoma. Ependymomas are common tumors in children (10% of pediatric CNS neoplasms), and two thirds are located in the posterior fossa. They are usually intimately associated with the fourth ventricle or its outlet foramina and tend to arise from the floor and track along its lateral recesses into the cerebellopontine angle. The next most common location is the body of the lateral ventricle, although they may be found also in the brain parenchyma, outside the ventricular system.

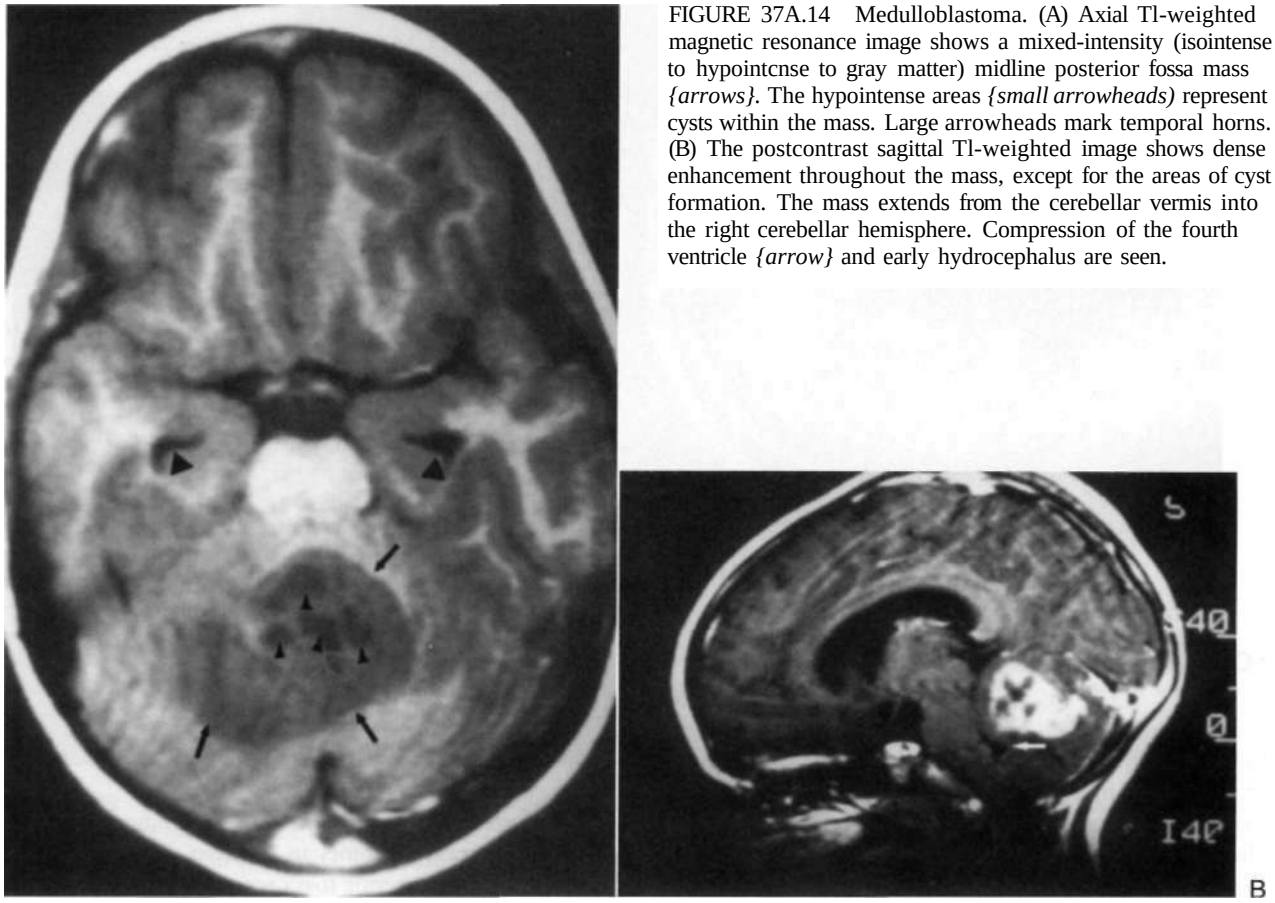

FIGURE 37A.14 Medulloblastoma. (A) Axial Tl-weighted magnetic resonance image shows a mixed-intensity (isointense to hypointcnse to gray matter) midline posterior fossa mass *{arrows}*. The hypointense areas *{small arrowheads)* represent cysts within the mass. Large arrowheads mark temporal horns. (B) The postcontrast sagittal Tl-weighted image shows dense enhancement throughout the mass, except for the areas of cyst formation. The mass extends from the cerebellar vermis into the right cerebellar hemisphere. Compression of the fourth ventricle *{arrow}* and early hydrocephalus are seen.

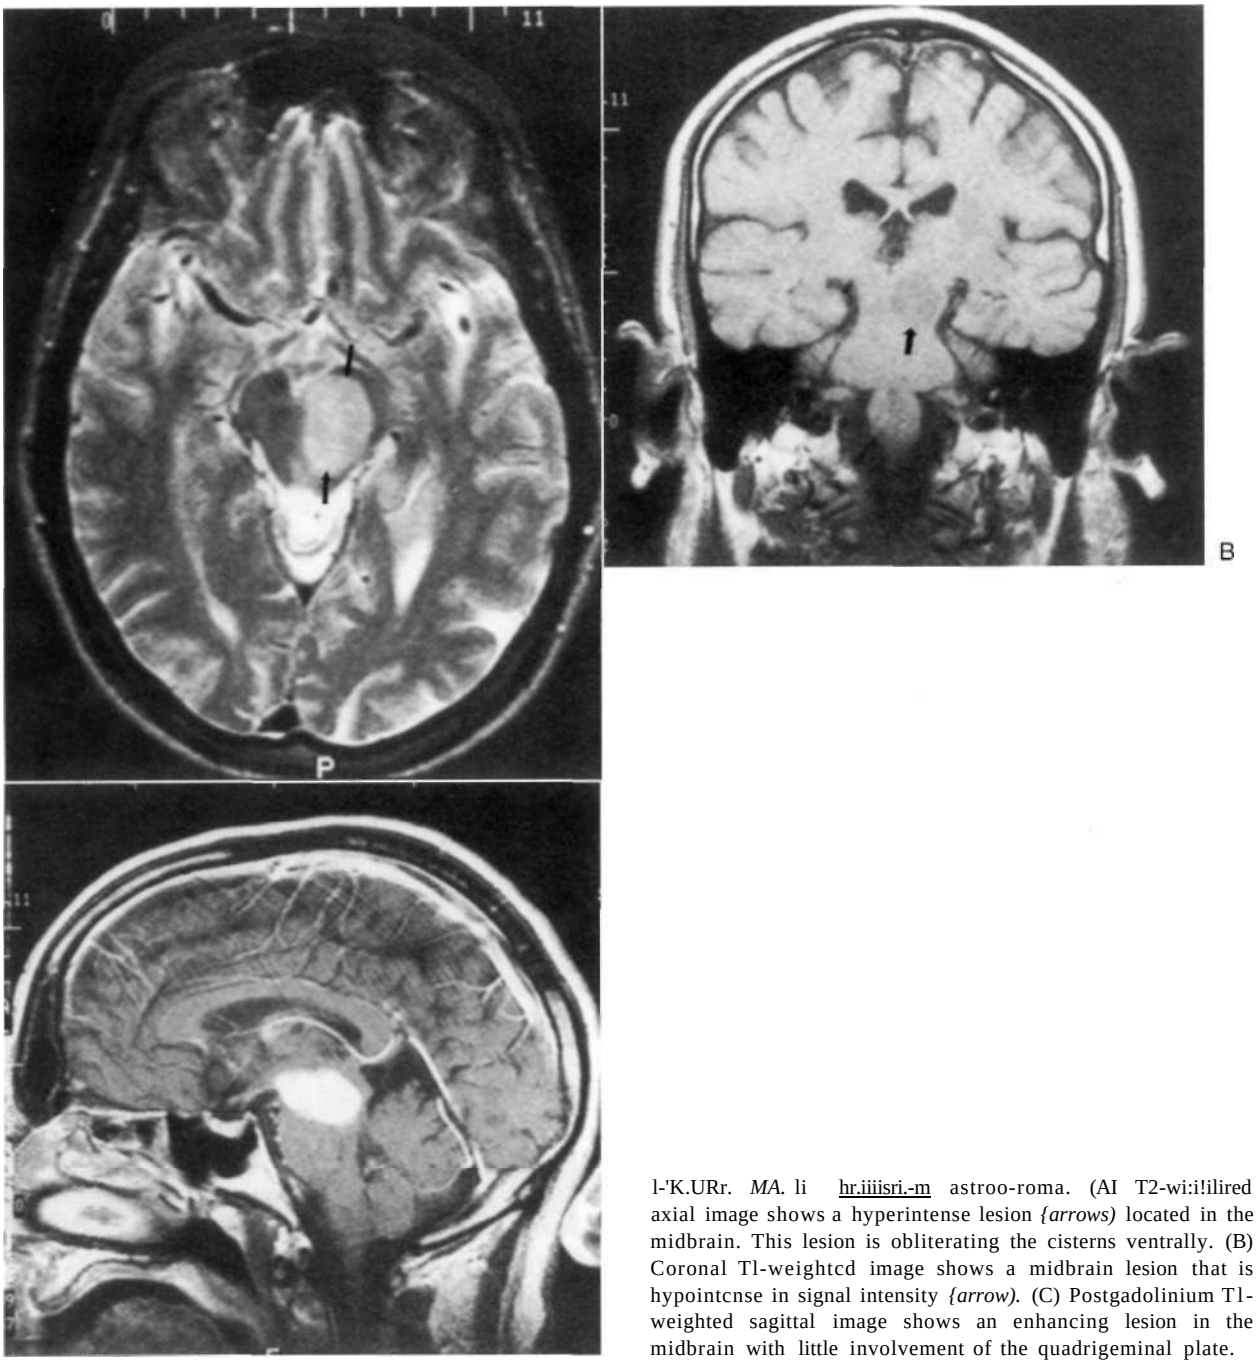
Ependymomas most often present as partially cystic, calcified, and sometimes hemorrhagic masses. They can extend through the foramen magnum and compress the dorsal aspect of the spinal cord (aplastic ependymoma). Almost all enhance with contrast. Seeding of the CSF occurs less often than with the PNF.T lesions.

Brainstem Astrocytoma. Brainstem astrocytomas make up 10% of all childhood brain tumors. The tumor is characteristically located in the pons. The majority are of the diffuse (infiltrative) fibrillary type, and a small minority constitute the more benign juvenile pilocytic astrocytoma. The MRI appearance of brainstem astrocytoma is variable with regard to signal intensity and enhancement. MRI demonstrates these lesions as poorly defined areas of high intensity on long TR-long TE images (Figures 37A.15 and 37A.16). MRI is much better for demonstrating this lesion than CT. When gross enlargement of the brainstem occurs, the size of the cisternal spaces decreases, and when the growth becomes exophytic there may be encasement of



l-'K.URr. *MA.* li hr.iiiisri.-m astroo-roma. (AI T2-wi:i!ilired axial image shows a hyperintense lesion *{arrows)* located in the midbrain. This lesion is obliterating the cisterns ventrally. (B) Coronal Tl-weightcd image shows a midbrain lesion that is hypointcnse in signal intensity *{arrow).* (C) Postgadolinium T1-weighted sagittal image shows an enhancing lesion in the midbrain with little involvement of the quadrigeminal plate.

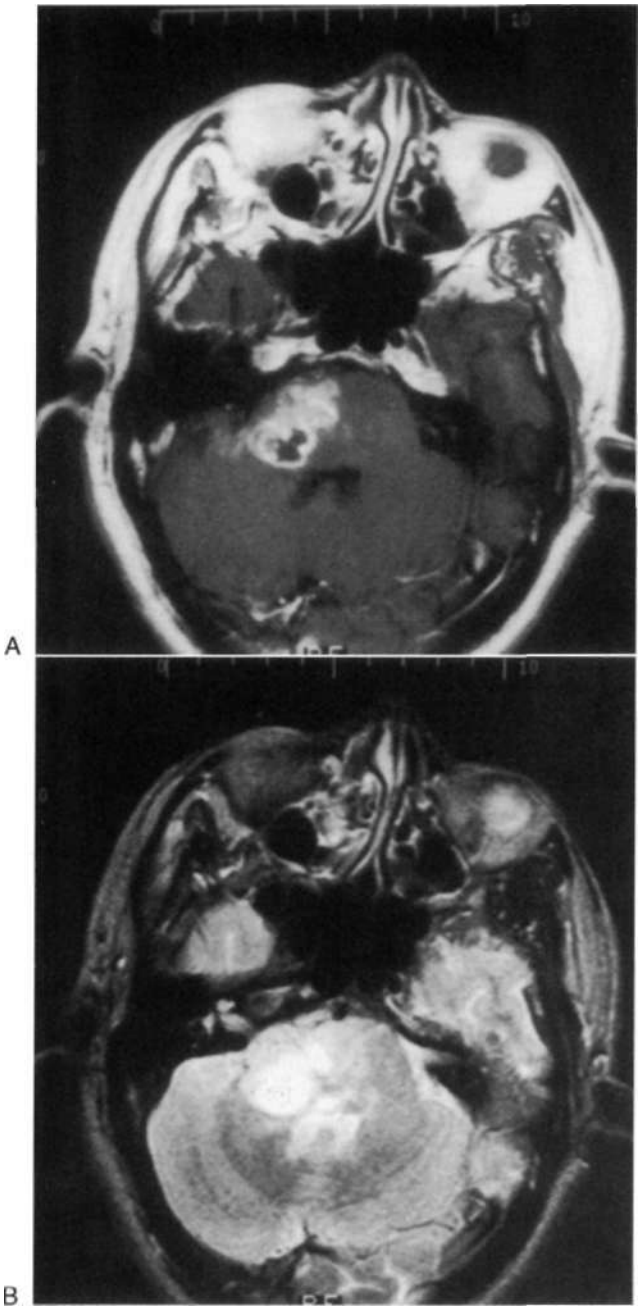


FIGURE 37A.16 Pontine astrocytoma. (A) Axial magnetic resonance imaging scan after gadolinium administration demonstrates a lesion on the right side of the pons, with irregular borders and inhomogeneous enhancement, which is producing enlargement of the pons. (B) The T2-weighted image shows a high-intensity lesion with heterogeneous signal.

the basilar artery. Contrast enhancement occurs in approximately one half of patients and is often **irregular** (see Figure 37A.16).

Hemangiobiastoma. Hemangiobiastoma is the most common primary posterior fossa intra-axial neoplasm in adults. This lesion has a high association with von Hippel-Lindau disease, in which retinal angiomas, cysts and angiomas of the liver and kidney, renal cell carcinoma, and pheochromocytoma occur. Although the cerebellum is the most common site of involvement, supratentorial hemangiobiastoma may be seen occasionally.

Pathologically and in imaging studies, hemangioblastomas are commonly well-demarcated cystic masses with highly vascularized nodules in the wall of the cyst. Importantly, the cyst wall is not tumorous. The vascular nidus always abuts pia mater, giving rise to the alternate theory of origin that rhis is primarily a meningeal-based tumor (Figure 37A.17). Entirely solid hemangioblastomas occur in 30-40% of cases, especially in the supratentorial compartment.

On MRI, the majority of these lesions are cystic and have a peripheral pial-based mural nodule of solid tissue that enhances markedly, and there may be large vessels in or at the periphery of the mass. The cysts can be isointense to CSF on all sequences or slightly hyperintensc to CSF on T1-weighted images, a fact rclared to their high protein content. The mural nodule is slightly hyperintense to gray matter on long TR images.

FIGURE 37A.17 Hemangiobiastoma. Contrast-enhanced computed tomographic scan demonstrates a cystic lesion with an enhancing mural nodule *(arrow),* which is peripheral and pial-based.

Extra-Axial Brain Tumors

Several criteria help establish rhc location of a lesion as extra-axial. A broad dural-based margin strongly suggests an extra-axial lesion. Other characteristics of extra-axial tumors include bony hyperostosis, invasion of the bone, displaced gray matter, buckled white matter, inwardly displaced pial vascular structures, and CSF clefts.

Subependymal Giant Cell Astrocytoma

The classic setting of a subependymal giant cell astrocytoma is a mass in the region of the foramen of Monro in a young adult with tuberous sclerosis. The mass is an astrocytic neoplasm projecting into the ventricle from a subependymal location. It is found in up to 10% of patients with tuberous sclerosis, and it is rare outside the clinical setting of this disease. MRI and CT findings in subependymal giant cell astrocytoma include the typical location, a heterogeneous hyperintense mass with evidence of contrast enhancement, and hydrocephalus (Figure 37A.18). Central regions of hypointensity on MRI may be caused by calcifications.

Central Neurocytoma

This is an intraventricular neoplasm of neuronal origin formerly called intraventricular oligodendroglioma. The lesion usually is located in the lateral ventricular wall, near the foramen of Monro anterior fornices or septum pellucidum. On CT or MRI the lesion appears as a we 11-cireuinscribed nonhomogeneously enhancing mass containing cystic spaces. On CT calcifications may be seen. On plain MRI the lesion is of intermediate signal on Tl andT2 (Figure 37A.19}.

Pineal Tumors

Pineal tumors are uncommon, representing 1% of all intracranial tumors. MRI is excellent at distinguishing true pineal masses from parapineal masses, a differentiation that has clear surgical relevance. Two major groups of pineal tumors are recognized: germ cell tumors and tumors derived from pineal parenchymal cells.

Germ Cell Tumors. The majority of pineal tumors are of germ cell origin. These include the germinoma, teratoma, embryonal carcinoma, choriocarcinoma, and mixed types. Of these, germinomas are the most common. They often seed the subarachnoid space and invade adjacent brain parenchyma. The second most common pineal germ cell tumor is the teratoma, occurring in an earlier age group than germinomas. These can contain hair, reerh, bone, and fat.

Pineal germinomas are well-circumscribed, homogeneous lesions. Nonhemorrhagic germinomas can be of low signal intensity on T2-wcighted image, and they enhance markedly with intravenous contrast. Teratomas, on the

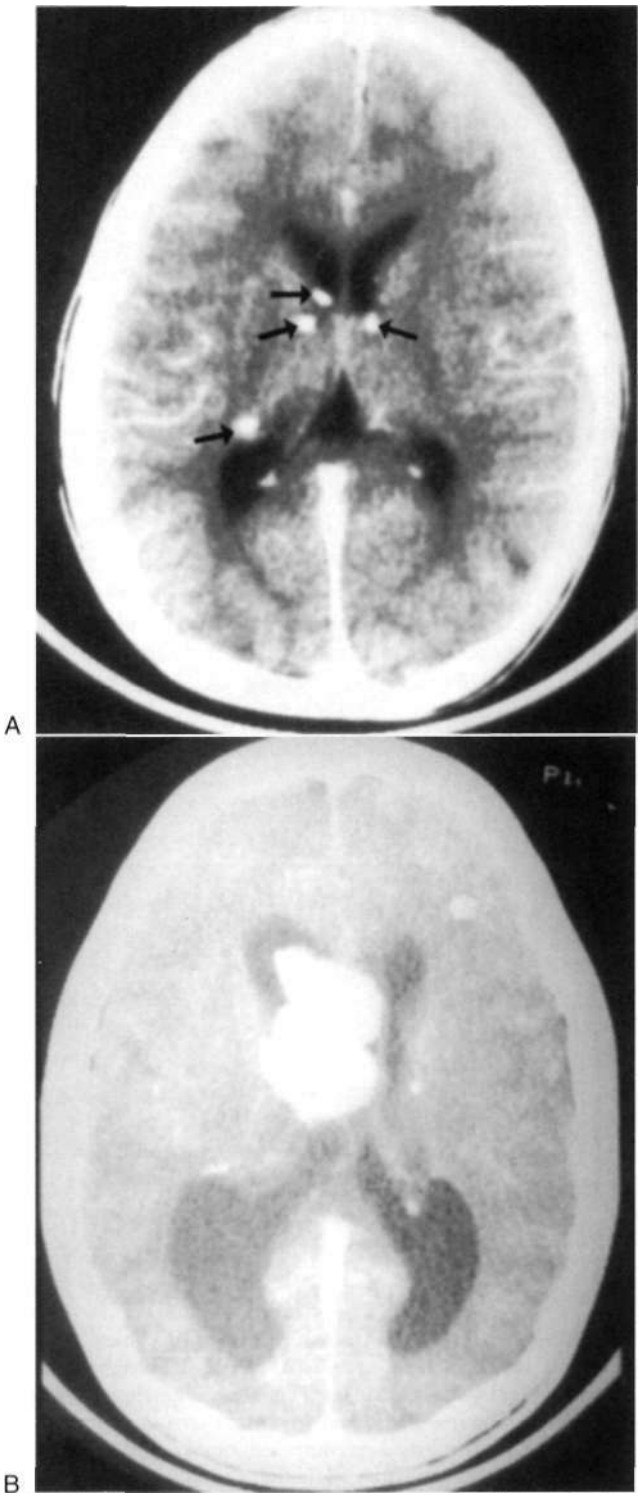

FIGURE 37A.18 Tuberous sclerosis. (A) Multiple calcified periventricular lesions *(arrows)* are seen on this computed tomographic axial scan. (B) In another patient, an enhancing mass lesion is noted in the region of the foramen of Monro with associated hydrocephalus. The diagnosis was subependymal giant cell astrocytoma.

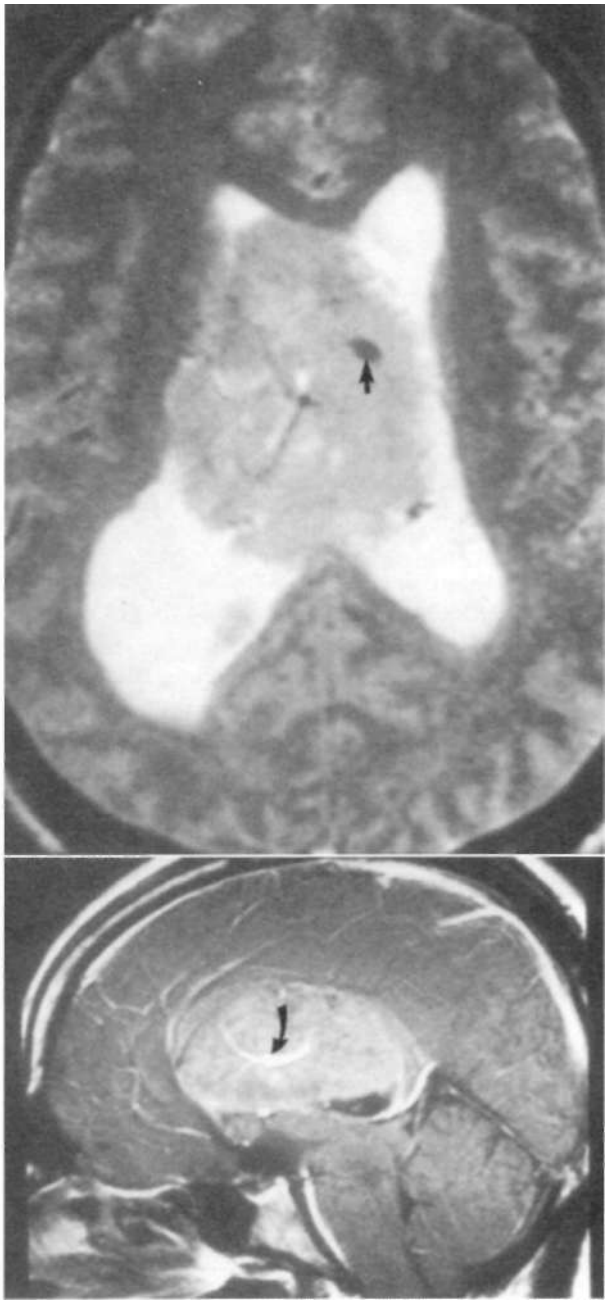

FIGURE 37A.19 Neurocytoma. Patient with clinical signs of increased intracranial pressure. (A) Axial T2-weighted image shows a lateral ventricular mass. The lesion is nearly isointense to gray matter. The rounded signal void areas *{arrow)* represent foci of calcifications continued on computed tomography (not shown). (B) The mass enhances with gadolinium and fills a great portion of the lateral ventricles. Note the enhancing tubular feeding vessel *{curved arrow).*

other hand, are heterogeneous, and their enhancement is variable.

Pineal Ceil Tumors. Pinealoblastoma (a PNKT) is a highly cellular tumor that tends to disseminate early through the subarachnoid pathways with leptomeningeal and subependymal seeding (Figure 37A.20). Pinealoblastoma tends to be isointense to gray matter on Tl-wcighted images (similar to othet PNET tumots) and to enhance densely with contrast.

Pinealocytoma is a tumot of adults that is more benign than pinealoblastoma. It is a well-differentiated, densely enhancing mass that has a high signal on T2-wcightcd sequences. Calcifications are more commonly with pinealocytoma s.

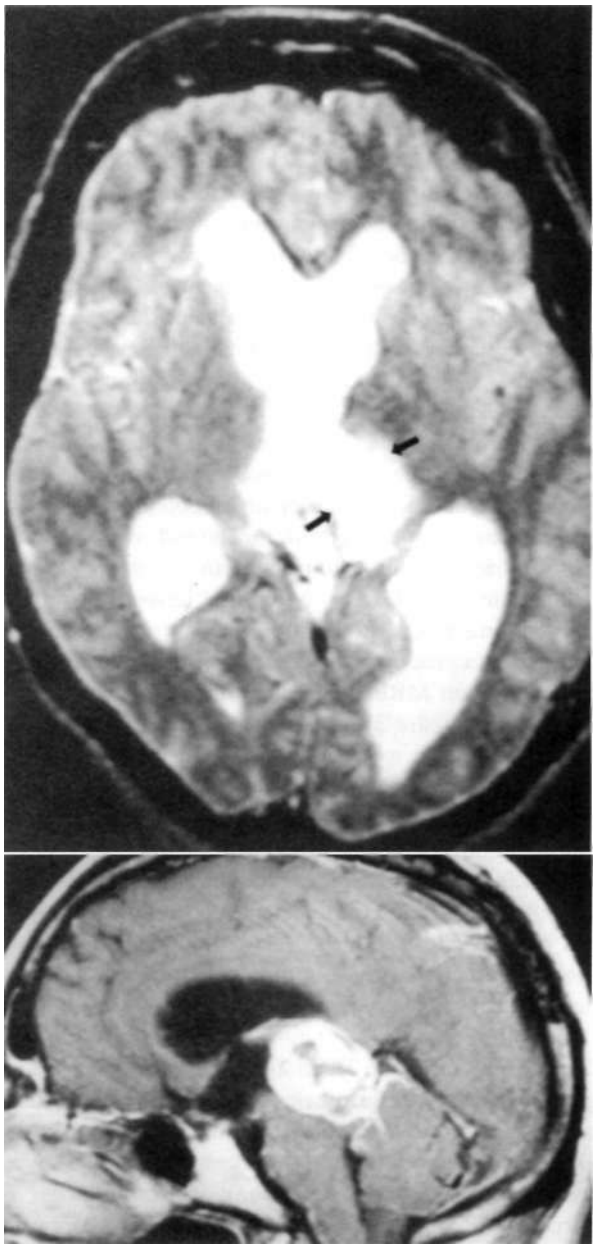

FIGURE 37A.20 Pinealoblastoma. (A) Axial T2-weighted image shows a mass *{arrows),* which is hyper in tense and produces mass effect on the posterior portion of the third ventricle. (B) Postcontrast-enhanccd magnetic resonance sagittal image demonstrates the mass and its effect on the colliculi and on the aqueduct of Sylvius, with resultant hydrocephalus.

Colloid Cysts

Colloid cysts arc benign lesions derived from infolding of the neuroepithelium, which is probably developing choroid plexus. The majority of these lesions are located in the anterosuperior aspect of the third ventricle. They are the most common form of neuroepithelial cysts and contain dense mucoid material and various ions, some of which are paramagnetic.

On MRI, colloid cysts are varied in their signal, ranging from hypoinrense to markedly hyperintense on both Tl- and T2-weighted images. Peripheral contrast enhancement may occur (Figure 37A.21).

Meningiomas

Meningiomas, rhe most common primary nonglial intracranial tumors, have a peak incidence in the middle and later decades of life. Meningiomas have a predilection for cerrain locations: parasagittal plane, cortical convexity, sphenoid wings, tuberculum sellae, parasellar region, olfacrory groove, cerebellopontine angle, clivus, and tentorium. They are usually broad-based and are attached to the adjacent dura.

If high-field strength magnets are used, the detection rate on noncontrast MRI for the meningiomas is comparable to that of contrast CT. **MRI** is superior to CT in determining dural sinus invasion with occluded venous flow and in defining tumor vascularity and arterial encasement. On Tl-weighted images, meningiomas are isointense to hypointense to gray matter, and on T2-weighted images approximately one half are isoinrense and one half are hyperintense to gray matter (Figure 37A.22). There is a good correlation between tumor histology and tumor intensity on T2-weighted images, although exact histological typing by MRI is not possible. Almost all meningiomas that are hyperintense to gray matter on T2-weighted images are of the syncytial or angioblastie type, whereas fibroblastic and transitional cell types are hyperintense to gray matter on T2-weighted images. The majority of meningiomas demonstrate a heterogeneous intensity pattern. Tumor vascularity has been identified in approximately one third of cases, seen as punctate and curvilinear hypointensities. Calcification, seen in 20% of meningiomas, appears as coarse, irregular regions of hypointensity on both T1 - and T2-weighted sequences. Routine MRI may not distinguish complete from near total venous sinus obstruction, and MRA or routine angiography may be needed in these cases for proper surgical planning.

Brain edema is seen in approximately 50% of meningiomas, with the most significant edema associated with meningiomas of the syncytial or angioblastie cell types. Angioblastie meningiomas are considered hisrologically identical to hcmangioblastomas and show tumor neovascularity. A less common variety of meningioma that is clinically more aggressive is histologically similar to the extracranial hemangiopericytoma.

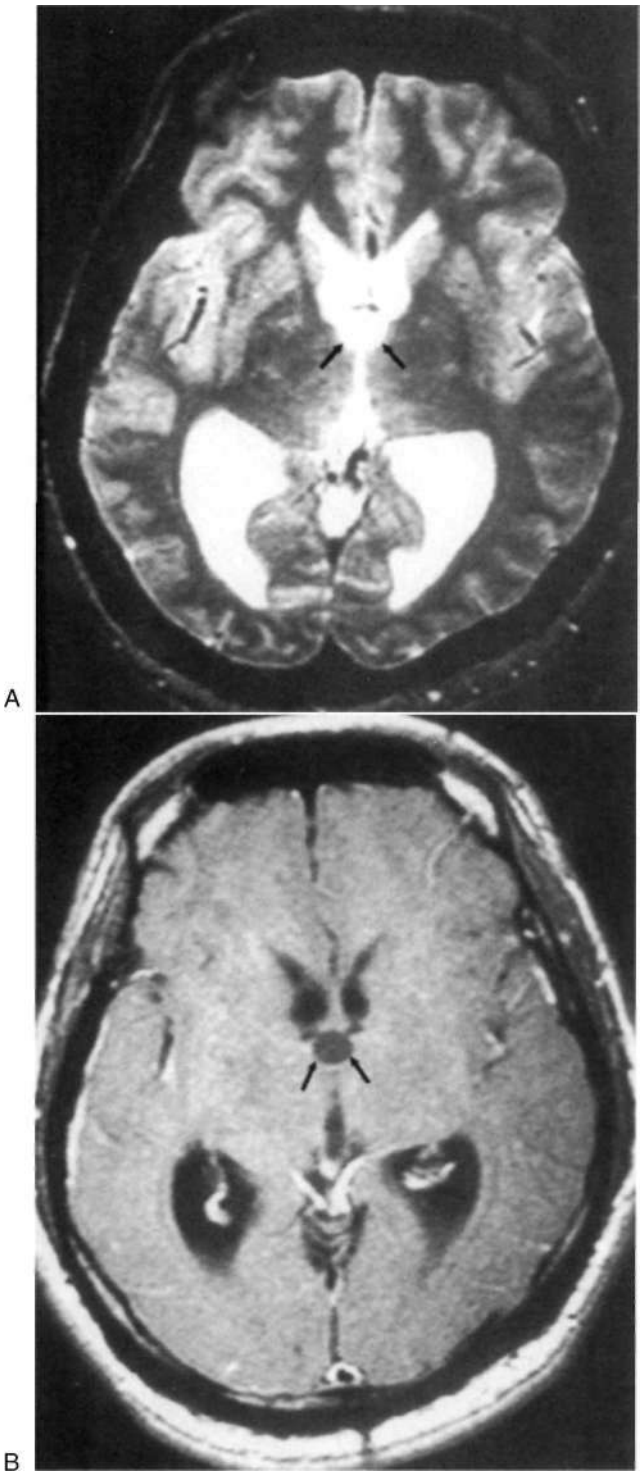

FIGURE 37A.21 Colloid cyst. (A) There is a rounded lesion in the region of the foramen of Monro, which is hyperinrense **on T2-**wcighted image *(arrows).* There is associated hydrocephalus. **(B) Postcontrast Tl-weighted** image shows a hypointense lesion with slight peripheral enhancement *{arrows).*

Hemangiopericytoma

Hemangiopericytoma is a tumor of uncertain origin. It is believed to arise from hemangiopericytes (cells located in vessel walls and responsible for the contraetibility of the vessel). The age of presentation is the fifth decade, The tumot affects mote male than female subjects. The clinical presentation is related to the extra-axial location of the mass.

On imaging, the lesion, when small, is well circumscribed. When large, it tends to be lobulatcd, with cystic spaces that are hyperintense on T2-weighted images. The lesion enhances intensely with gadolinium or iodinated intravenous contrast. In angiography a pial vascularization with intense blush may be seen, although sometimes pial, dural, or both kinds of blood supply may be seen. If the tumor is tescctcd incompletely, it tends to recur. Extracranial metastases from hemangiopericytoma ate not uncommon (Figure 37A.23).

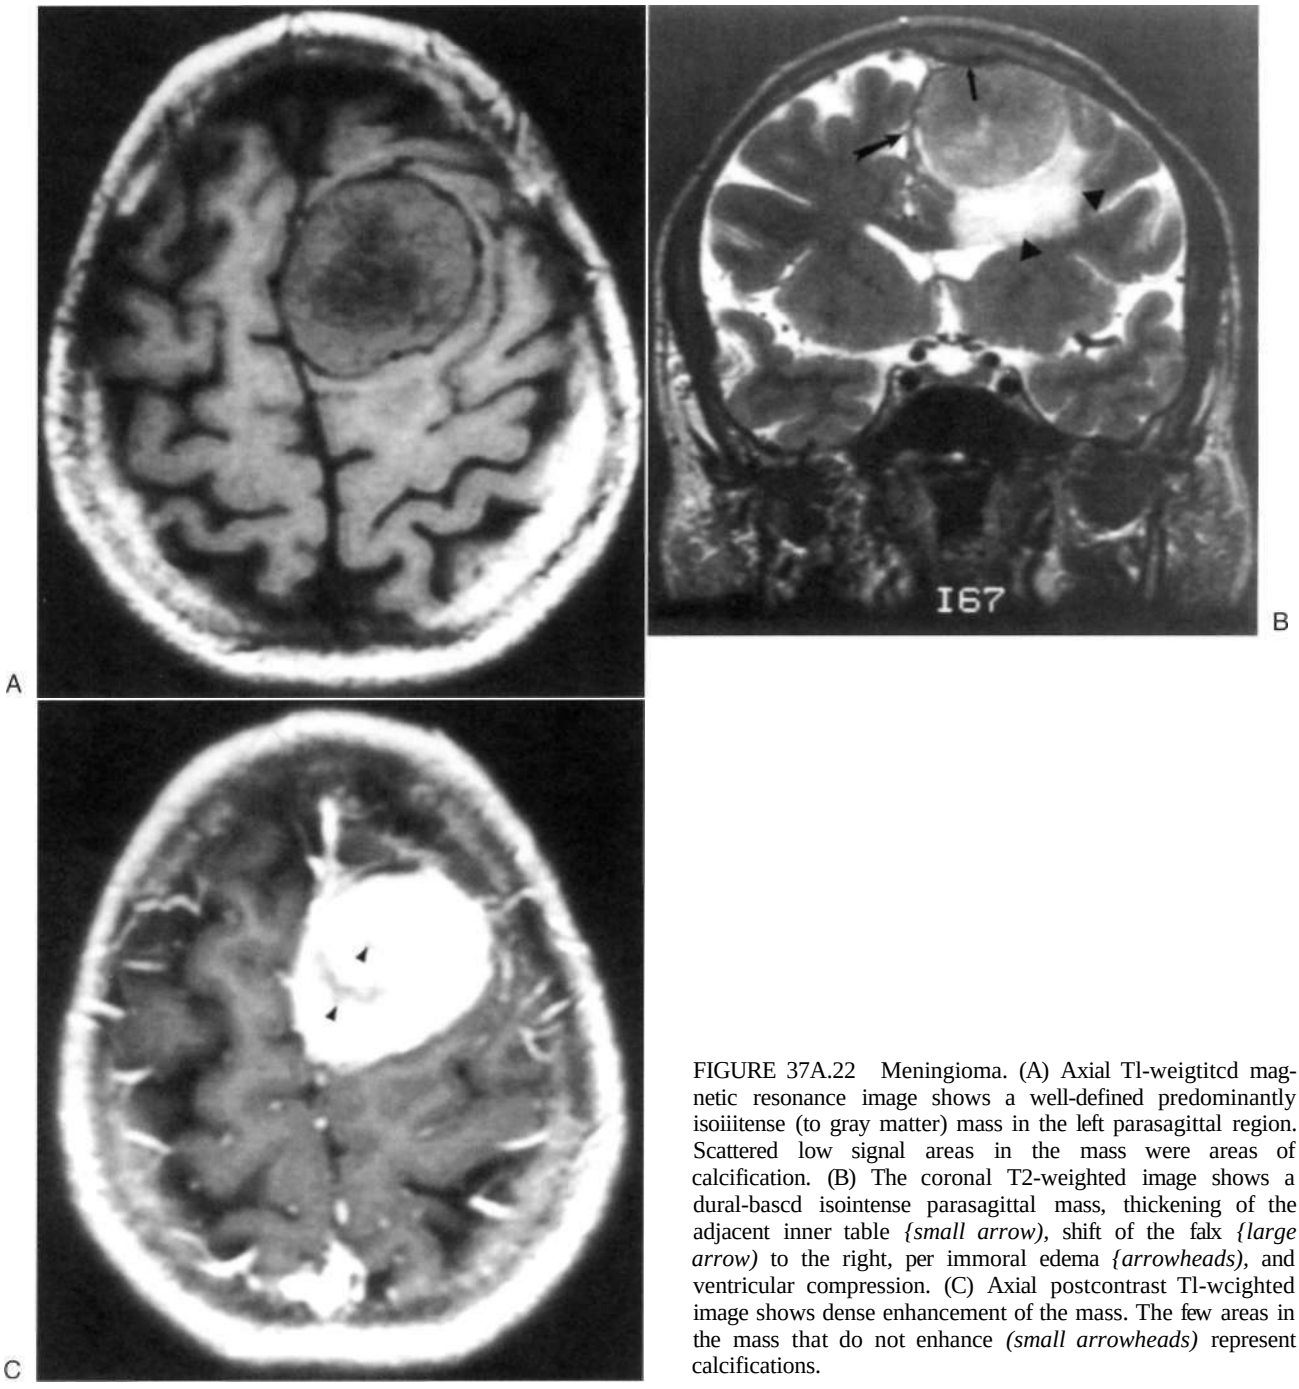

FIGURE 37A.22 Meningioma. (A) Axial Tl-weigtitcd magnetic resonance image shows a well-defined predominantly isoiiitense (to gray matter) mass in the left parasagittal region. Scattered low signal areas in the mass were areas of calcification. (B) The coronal T2-weighted image shows a dural-bascd isointense parasagittal mass, thickening of the adjacent inner table *{small arrow)*, shift of the falx *{large arrow)* to the right, per immoral edema *{arrowheads)*, and ventricular compression. (C) Axial postcontrast Tl-wcighted image shows dense enhancement of the mass. The few areas in the mass that do not enhance *(small arrowheads)* represent calcifications.

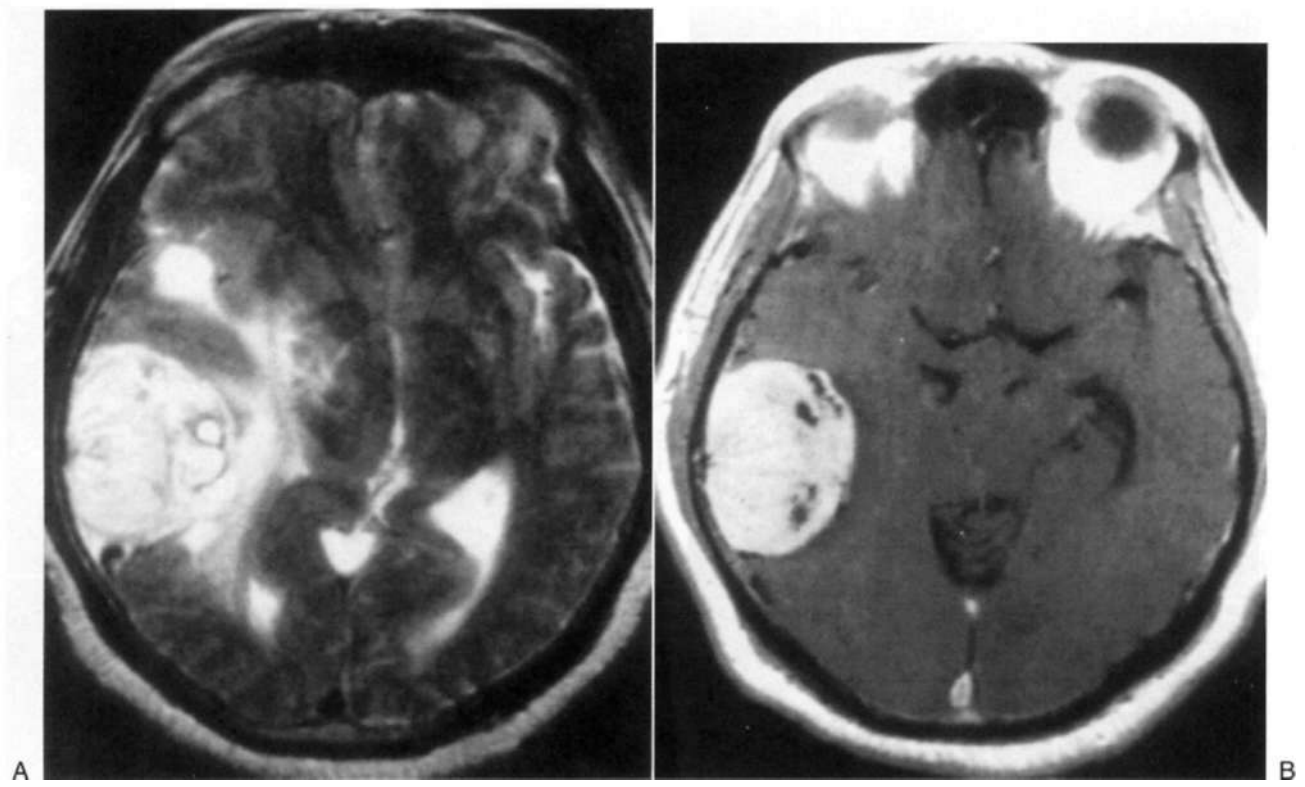

FIGURE 37A.23 Hemangiopericytoma. (A) Axial T2-wcightcd image demonstrates a right temporal extra-axial hyperintense mass containing peripheral cysts. The mass compresses the surrounding edematous brain parenchyma. (B) The tumor enhances with gadolinium.

Meningeal Sarcoma

This malignant neoplasm arises from the meninges. It is more common in children (mean age, 2 years). The lesion is not encapsulated and usually infiltrates the brain. On imaging, a large mass with intense enhancement in an extra-axial location is seen. On noncontrast CT the lesion is isodense to brain. On MRI it is isointense on Tl-weighted images and mildly hyperintense on T2-weighted images. A characteristic finding is a rapid rate of growth of the tumor in a short inrerval of rime.

Settar and Parasetlar Tumors

Pituitary Adenoma. Pituitary adenomas of less than 10 mm are called *microadenomas,* and those greater than 10 mm are called *macroadenomas.* The most common of the actively secreting adenomas is the prolactinoma. Nonfunctional pituitary adenomas present with signs and symptoms caused by compression or invasion of structures adjacent to the adenoma, such as the optic chiasm and the cavernous sinus.

Most commonly, the MRI image of the pituitary adenoma shows low signal intensity on Tl-weighted images and high signal intensity on T2-wcightcd images when compared with normal pituitary tissue. Hyperinrensity on Tl-weighted images most often represents subacute collections of blood (Figure 37A.24). This hemorrhage usually is subclinical but may indicate that a significant bleed into the pituitary tumor occurred. Gadolinium enhancement can detect adenomas that otherwise would be occult by differentially enhancing the normal gland tissue and the nonenhancing microadenoma (Figure 37A.25). Enhanced MRI is the best way to detect small adenomas found in Cushing's disease. Delayed images sometimes can demonstrate a reversal of the image contrast because of accumulation of gadolinium in the adenoma and washout from the rest of the normal gland.

A macroadenoma characteristically is seen as a hypointense mass on Tl-weighted images. The visualization of the cavernous carotid arteries and the middle and anterior cerebral arteries obviates preoperative angiography. Lateral extension of the tumor into the cavernous sinus is common and may be associated with extremely high prolactin levels. It is often impossible to determine whether the cavernous sinus is invaded or compressed by the adenoma because the medial wall of the cavernous sinus is very thin. However, the placement of abnormal tissue between the lateral wall of the cavernous sinus and the cavernous carotid is a reliable indicator of cavernous sinus invasion. Marked constriction or occlusion of the cavernous carotid artery by a pituitary adenoma is rare.

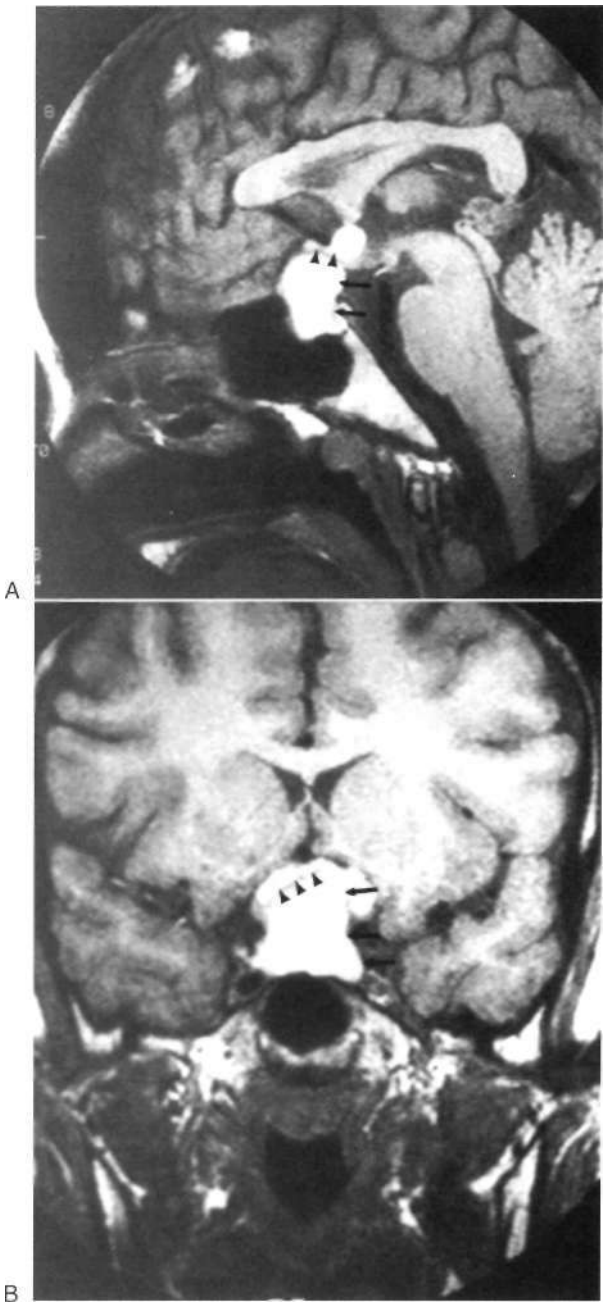

FIGURE 37A.24 Hemorrhagic pituitary macroadenoma. (A) Sagittal and (B) coronal noncontrast Tl-wcightcd images show a hyperintense signal (subacute blood) in a sellar and suprasellar mass *(arrows).* This patient presented with pituitary apoplexy and sudden vision loss, which is explained by the compression of the optic chiasm and hemorrhage into the chiasm *{arrowheads).* Incidentally noted is the multicystic pineal gland in A (pineal cyst).

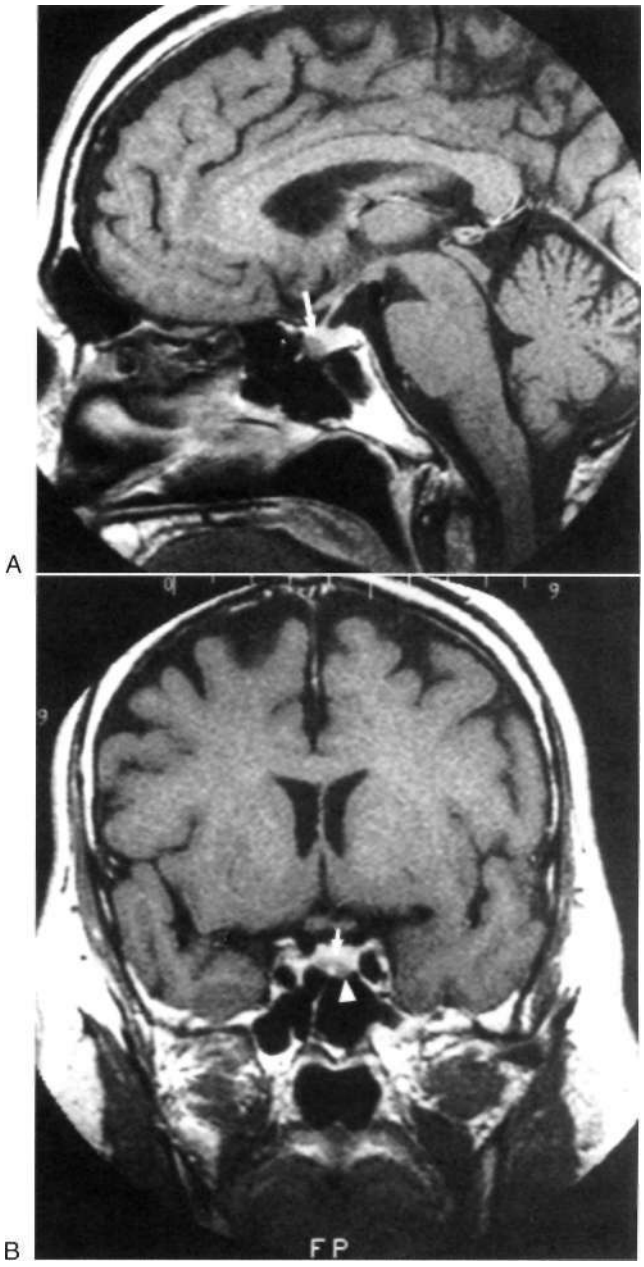

FIGURE 37A.25 Pituitary microadenoma. Postcontrast Tl-weighted images in (A) sagittal and (B) coronal planes show a nonenhancing lesion in the anterior-inferior aspect of the gland *{arrows).* Note the sloping of the floor of the sella *[arrowhead).*

Craniopharyngioma. Craniopharyngiomas commonly present in the suprasellar cistern. However, intrasellar craniopharyngiomas are found occasionally. Craniopharyngiomas may have both solid and cystic components, and calcification is seen in most tumors but is less common in adults.

On **MRI,** craniopharyngiomas are heterogeneous suprasellar masses, with components that may be hyperintense on both Tl- and T2-weighted images. If contrast is given, the solid portions usually enhance moderately (Figure 37A.26). The extension of these masses can be remarkable, growing beneath the frontal and temporal lobes and extending inferiorly along the clivus.

Meningioma. Ten percent of meningiomas occur in the parasellar region. On MRI, they are often isointense relative to gray matter on Tl-weighted images; 50% are

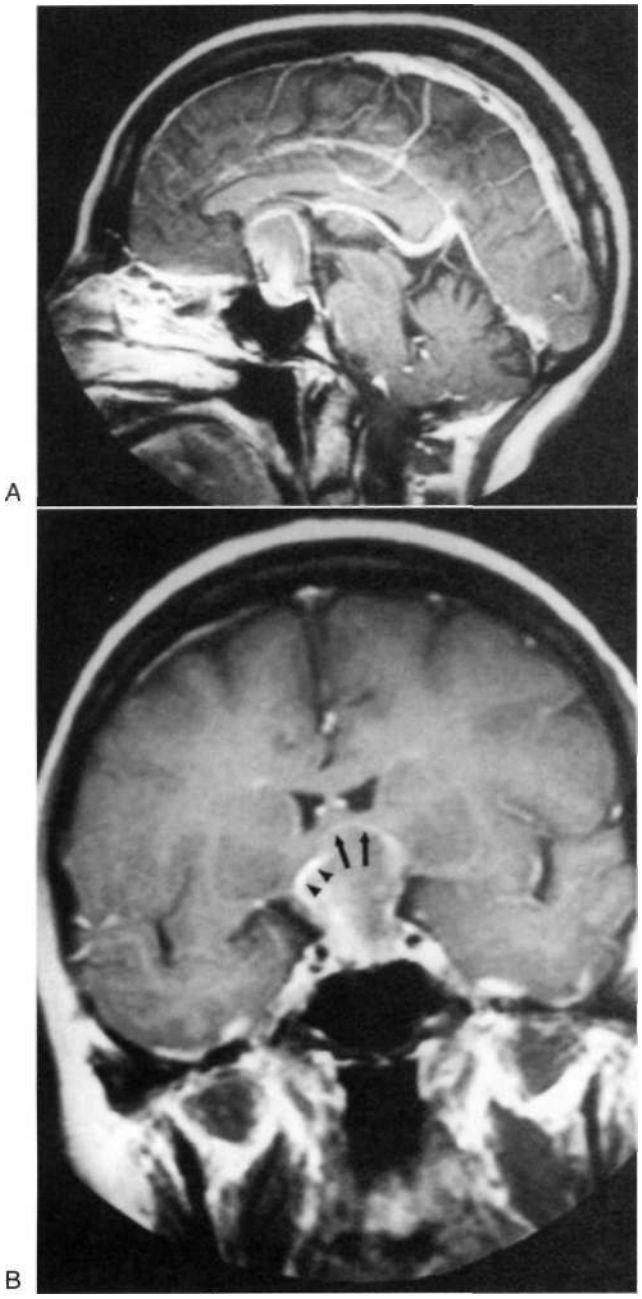

FIGURE 37A.26 Craniopharyngioma. A large suprasellar mass with nonuniform enhancement is seen on these postcontrast Tl (A) sagittal and (B) coronal images. Intense enhancement exists around the periphery of the mass *(arrows),* a portion of which may represent slowed flow in the Al segment of the right anterior cerebral artery *{arrowheads* in B). The cavernous carotid arteries are clearly separated from the mass. The major differential lies between a pituitary adenoma with suprasellar extension and craniopharyngioma. Note in both images that the sella turcica is not enlarged, ;t distinct indication that this is not a pituitary adenoma.

isointense on T2-weighted images, and 40% are hyperintense. Vascular encasement is a common finding with a meningioma in the cavernous sinus. Meningiomas enhance intensely with gadolinium, so those arising from the walls of the cavernous sinus can be difficult to separate from the enhancing venous blood in the cavernous sinus.

Chiasmatic and Hypothalamic Glioma. The distinction between gliomas that arise in the optic chiasm or hypothalamus is arbitrary because the lesion often involves both areas. These gliomas are seen mostly in children, particularly in those with neurofibromatosis (Figure .37A.27). Tumors of the chiasm are more aggressive than those arising from the optic nerves.

On Tl-weighted images, the gliomas usually are isointense and on T2-weighted images they are moderately hyperintense. Because they can extend posteriorly along the optic radiations, T2-weighted images of the entire brain are necessary. If intraorbital extension is possible, then fat-suppressed MRI is helpful.

Acoustic Neurinoma

Acoustic neurinomas (or schwannomas) arise from the vestibular portion of the eighth cranial nerve and are common with type 2 neurofibromatosis (Figure 37A.2S).

On MRI, most tumors are visualized on thin-section Tl-weighted images, where these tumors are well demarcated from CSF. On T2-weighted images the tumors are hyperintense. The signal pattern often is heterogeneous because of their internal composition, which is varied and includes different cells, mucinous and microcystic changes, regions of focal calcification, and blood vessels. Significant heterogeneity on MRI is more typical of acoustic neurinomas than meningiomas, which is the other lesion common in the cerebellopontine angle (Figure 37A.29). Acoustic neurinomas can be demonstrated on noncontrast MRI when they are 5 mm or larger. Usually, an intracanalicular portion of the tumor is associated with a cisternal mass. Approximately 2()"(J ol acoustic neurinomas have no intracanalicular component, and in those cases the differential diagnosis from meningiomas is difficult. Small intracanalicular tumors can be demonstrated with contrast enhancement.

Epidermoid Cysts

Epidermoid cysts are congenital lesions of ectodermal origin and usually do not present until the third or fourth decade of life. They are often located in the cerebellopontine angle, suprasellar and parasellar regions, and middle cranial fossa.

On CT they are hypodense, do not enhance with contrast, and may be difficult to differentiate from arachnoid cysts. However, their external surface is lobulated, unlike the smooth surface of arachnoid cysts. On Tl-weighted images epidermoid tumors arc hypointense, bur internal structure can be seen, and on T2-weighted images the tumors arc markedly hyperintense (Figure 37A.30).

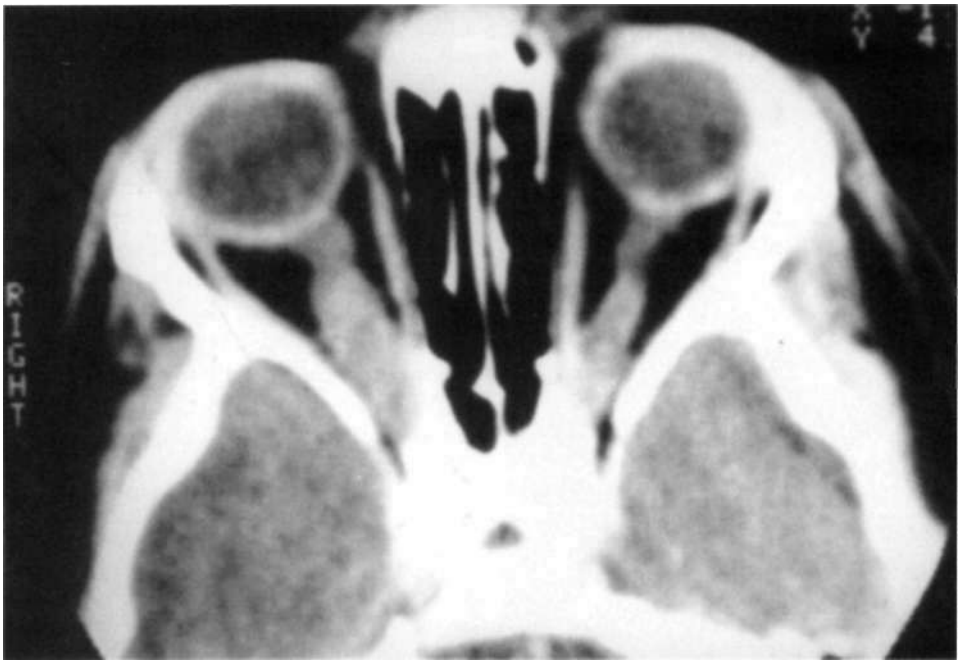

FIGURE 37A.27 Neurofibromatosis. Bilaterally enlarged optic nerves in a patient with neurofibromatosis type 1. The patient also was noted to have an optic chiasm glioma.

Neurodegenerative Disorders

Atrophy

With norma) aging, there is mild to moderate progressive enlargement of the ventricles, sulci, and cisternal spaces. In neurodegenerative disorders, atrophy is excessive and premature.

Periventricular white matter hyperintense lesions range from normal capping of the frontal horns to confluent abnormal high-signal regions extending into the deep white matter. The amount of periventricular hyp erin tensity increases with age and is higher in patients with vascular disease. Subcortical lesions, ischemic in nature, are located outside the periventricular region in the cerebral white

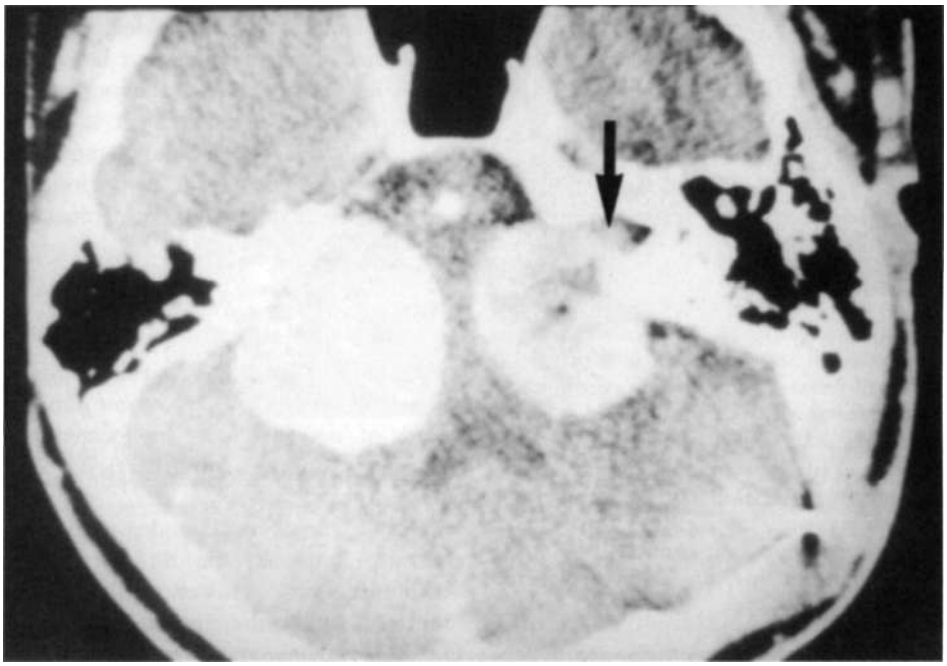

FIGURE 37A.28 Acoustic neurinomas. Bilateral acoustic neurinomas in a patient with neurofibromatosis type 2, Computed tomographic axial scan after contrast administration demonstrates bilateral rounded cerebellopontine angle masses Note the extension of the left cerebellopontine angle mass into a widened internal auditory canal *{arrow).*

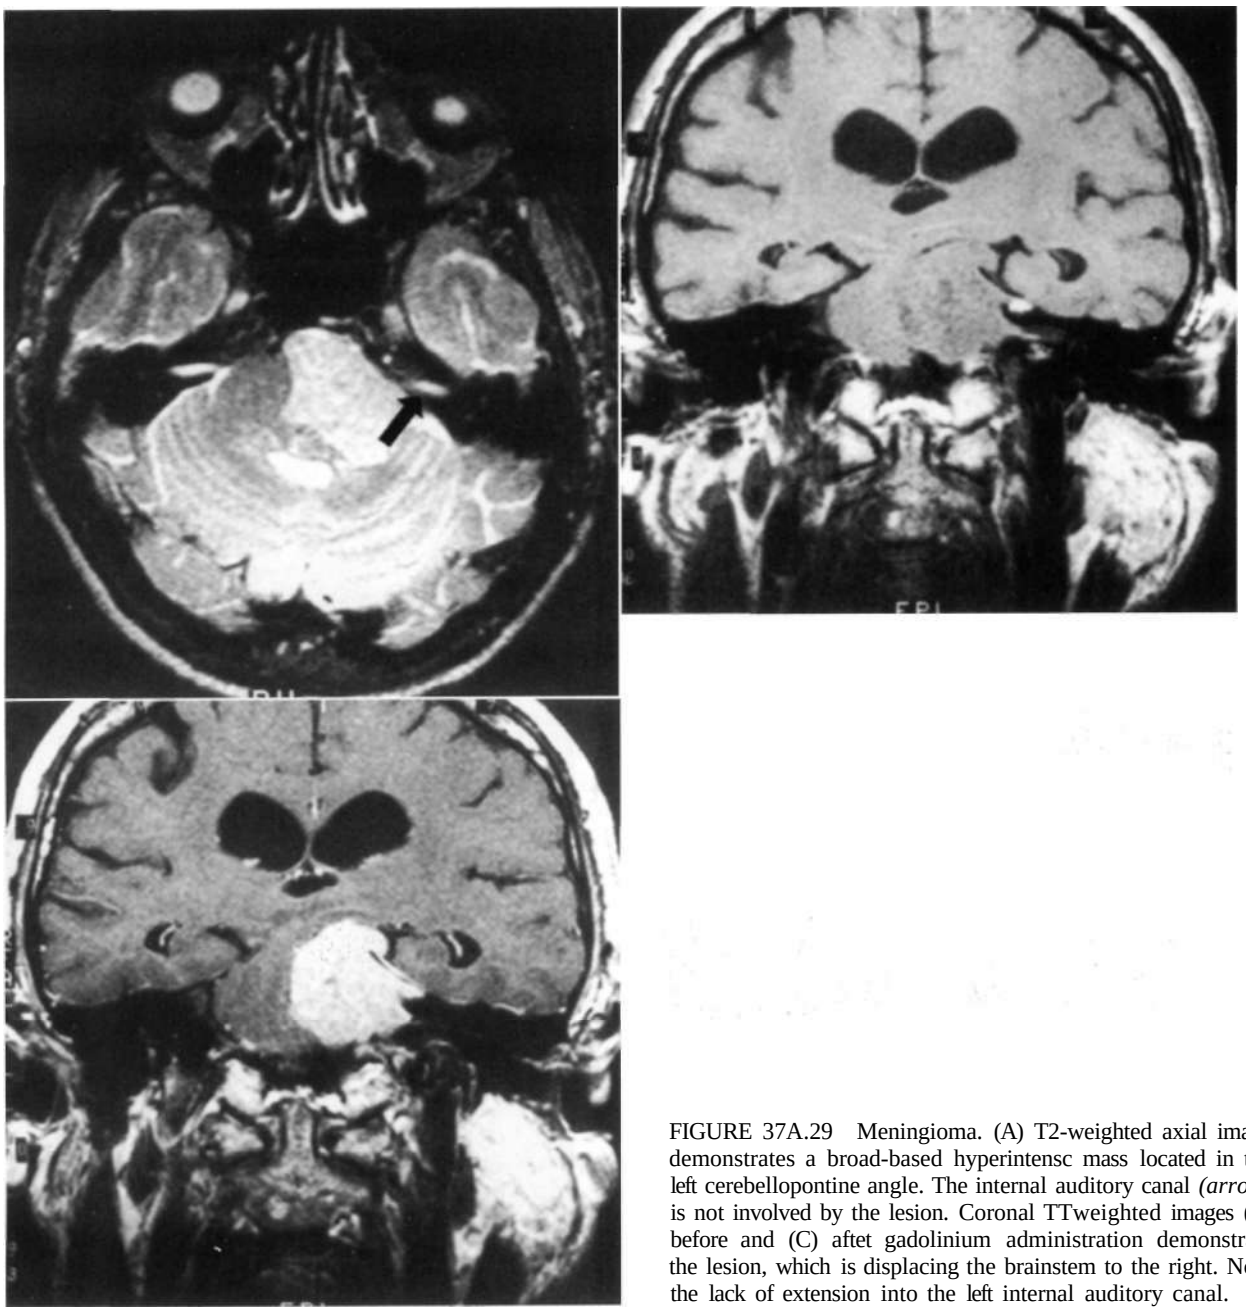

FIGURE 37A.29 Meningioma. (A) T2-weighted axial image demonstrates a broad-based hyperintensc mass located in the left cerebellopontine angle. The internal auditory canal *(arrow)* is not involved by the lesion. Coronal TTweighted images (B) before and (C) aftet gadolinium administration demonstrate the lesion, which is displacing the brainstem to the right. Note the lack of extension into the left internal auditory canal.

matter, deep gray matter (basal ganglia), or pons. The extent of these lesions also increases with age and in patients with disorders such as multi-infarct dementia (MID).

Hypoinrensiry compared with gray matter on T2-weighted images is seen normally in the globus pallidus, red nucleus, substantia nigra, and dentate nuclei because of iron deposition. With aging, a progressive decrease in signal occurs in the putamen and caudate. Many neurodegenerative disorders are associated with excessive signal loss in the extrapyramidal nuclei and thalami.

Dementia

Alzheimer's Disease. In Alzheimer's disease, generalized atrophy is seen on MRI, as is symmetrical or asymmetrical enlargement of the temporal horns, sylvian fissures, and suprasellar cistern. The degree of atrophy generally is greater than in normal aging. Medial temporal lobe atrophy and the number and size of white matter hypcrintense foci are generally greater than in normal aging,

Multi-Infarct Dementia. MID may result from cortical or multiple subcortical infarcts, or both, and is associated with hypertension. Extensive periventricular hyperintensity,

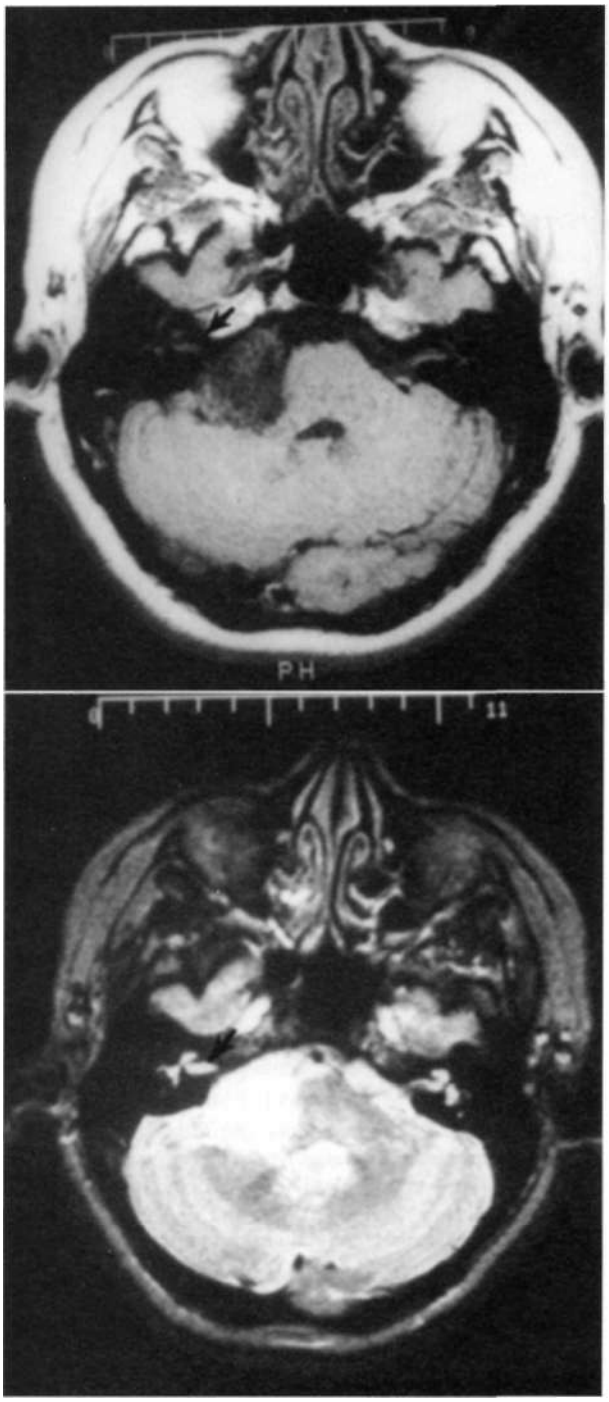

FIGURE 37A.30 Epidermoid cyst. A lesion is located in the right cerebellopontine angle, which is hypointense (slightly higher than cerebrospinal fluid) in (A) Tl-weighted image and hyperintense in (B) T2-wcighted image. The right internal auditory canal is normal *[arrows).*

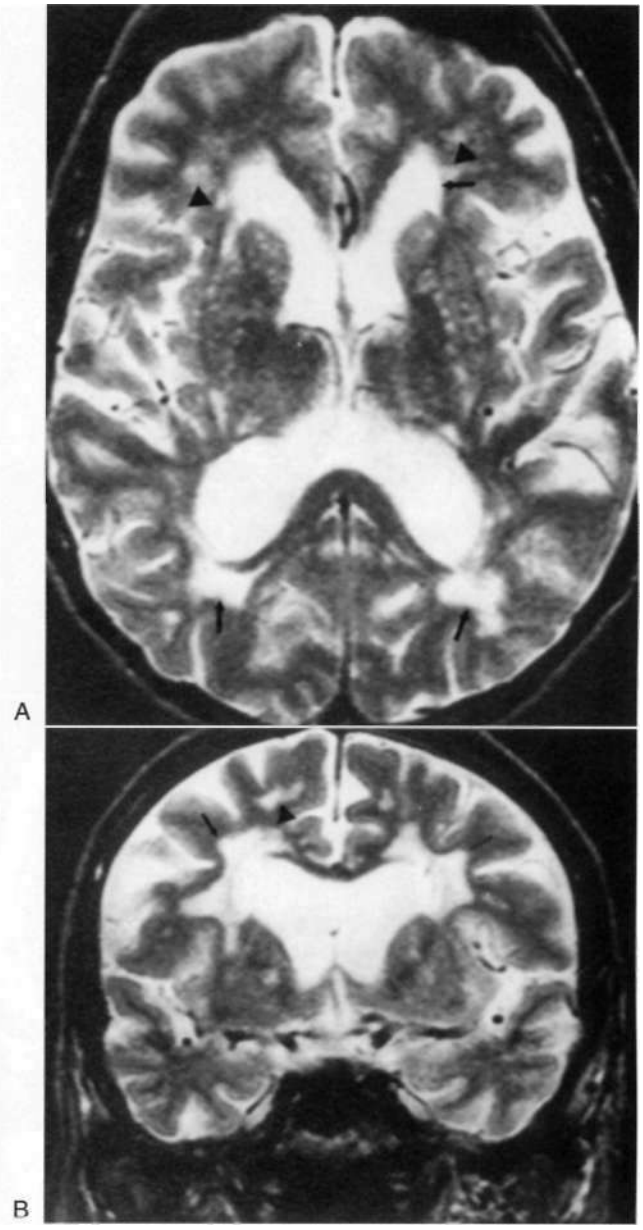

FIGURE 37A.31 Multi-infarct dementia. T2-weighted (A) axial and (B) coronal images demonstrate periventricular hyper in tensity *(arrows)* and multiple subcortical lesions *(arrowheads).* Prominent perivascular spaces are seen in the basal ganglionic region.

cortical infarcts, and basal ganglia lacunar infarcts in a patient with dementia favor a clinical diagnosis of MID or mixed MID and Alzheimer's disease. An MRI scan demonstrating prominent white matter signal changes, particularly subcortical lesions, favors MID over Alzheimer's disease (Figure 37A.31). Lacunar infarcts may be found in all forms of **MID.**

Pick's Disease. Grossly, Pick's disease is characterized by lobar atrophy that may be asymmetrical, with the **frontal** and temporal lobes most commonly affected. This atrophy is well demonstrated on CT and MRI. A similar pattern of atrophy is seen in the other forms of fron totem p oral dementia.

Creutzfeldt-Jakob Disease. CT scanning is used to exclude focal lesions as a cause for the symptoms in patients

with suspected Creutzfcidt-Jakob disease, but CT scanning rarely shows focal parenchymal abnormalities. Most often, CT scans are normal, but in approximately 20% of cases atrophy is present. Approximately one half of the cases demonstrate atrophy only on MRI, whereas in the remaining cases, abnormal high signal intensity is noted on T2-weighted images in the caudate nuclei, striatum, thalamus, cortex, basal ganglia, and periventricular white matter. Cortical gray matter involvement without diffuse cerebral atrophy may represent an early phase of the disease.

Movement Disorders

Parkinsonism. Parkinsonism includes several conditions, such as Parkinson's disease, multisystem atrophy including Shy-Drager syndrome, olivopontocerebellar atrophy, progressive supranuclear palsy, striatonigral degeneration, and corticobasal ganglionic degeneration (see Chapter 76}.

Parkinson's Disease. The imaging findings in Parkinson's disease often are indistinguishable from normal aging. There may be decreased width of the pars compacta of the substantia nigra or decreased signal in the putamen. The latter finding is more likely to be observed in patients with Parkinson's-phis syndromes. Patients with Shy-Drager syndrome associated with striatonigral degeneration have MRI findings that show this (Figure 37A.32}, whereas those with pure autonomic failure have normal MRI results. Neuroimaging and pathological examination in striatonigral degeneration show atrophy of the striatum with signal changes in the putamen. Specifically, at 1.5 T, the signal of the putamen is as hypointcnse as the globus pallidus, and the width of the pars compacta is diminished. The MRI in olivopontocerebellar atrophy shows atrophy and abnormal signal in the pons and cerebellum (Figure 37A.33). There is atrophy of the pons, middle cerebellar peduncles, cerebellum, and inferior olives. On long TR images, slight hyperintensity is seen involving the pontocerebellar pathways and olives.

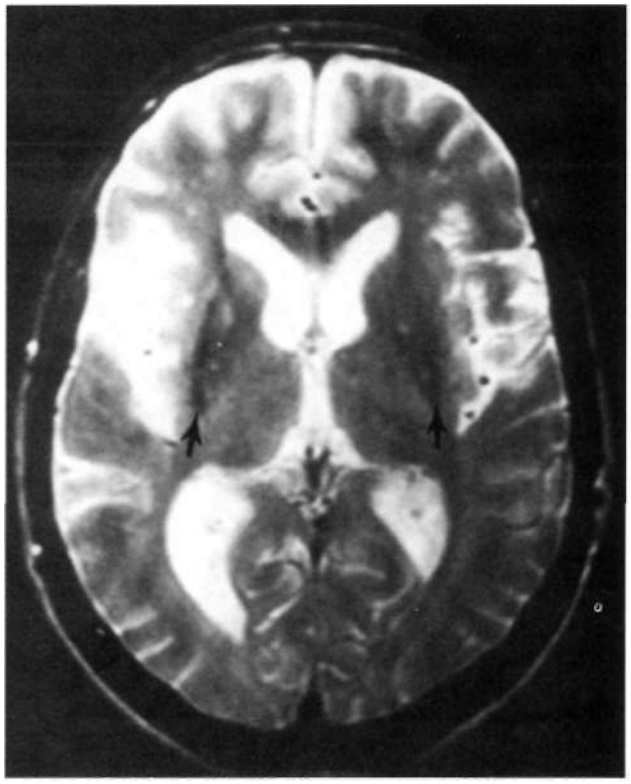

FIGURE 37A.32 Shy-Drager syndrome. This T2-weighted axial image shows hypointensity in the region of the putamen *{arrows).* Right temporal lobe atrophy (widened sylvian fissure} and ven triai I omega ly are present.

Mitochondrial Encephalopathies

Several syndromes of mitochondrial dysfunction with neurological involvement have been described, including myoclonus epilepsy with ragged-red fibers (MERRF); mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS); Kearns-Sayre syndrome; and subacute necrotizing encephalomyetopathy, or Leigh's disease, which is a severe and often fatal mitochondrial disease (see Chapter *69).* In Leigh's disease, necrosis and capillary proliferation occur in the basal ganglia, spinal cord, and brainstem. CT scans usually show low-density areas in the putamen and caudate nuclei that do not enhance after contrast administration. T2-wcightcd MRIs show striking symmetrical hyperintense foci in the globus pallidus, putamen, and caudate. The imaging changes most commonly seen in the brain in MELAS arc those of cerebral infarcts. Both large and multifocal infarcts occur, and the occipital lobes arc the most common sites of involvement. Imaging findings in MFRRF may be similar to MELAS or may show atrophic changes in the cerebral cortex, brainstem, and cerebellum.

White Matter Disease

Demyeiinating Diseases

Demyelinating diseases cause normal myelin to be destroyed. There may be additional loss of axons and secondary gliosis. MS is the most common demyelinating disease.

Multiple Sclerosis. On MRI, MS plaques appear as rounded areas of increased signal on T2-weighted images (Figure 37A.34; see Chapter 60). Gadolinium enhancement is present in many acute plaques and probably disappears within a few days. A small number of plaques show a mass effect during the acute phase. In time, the area

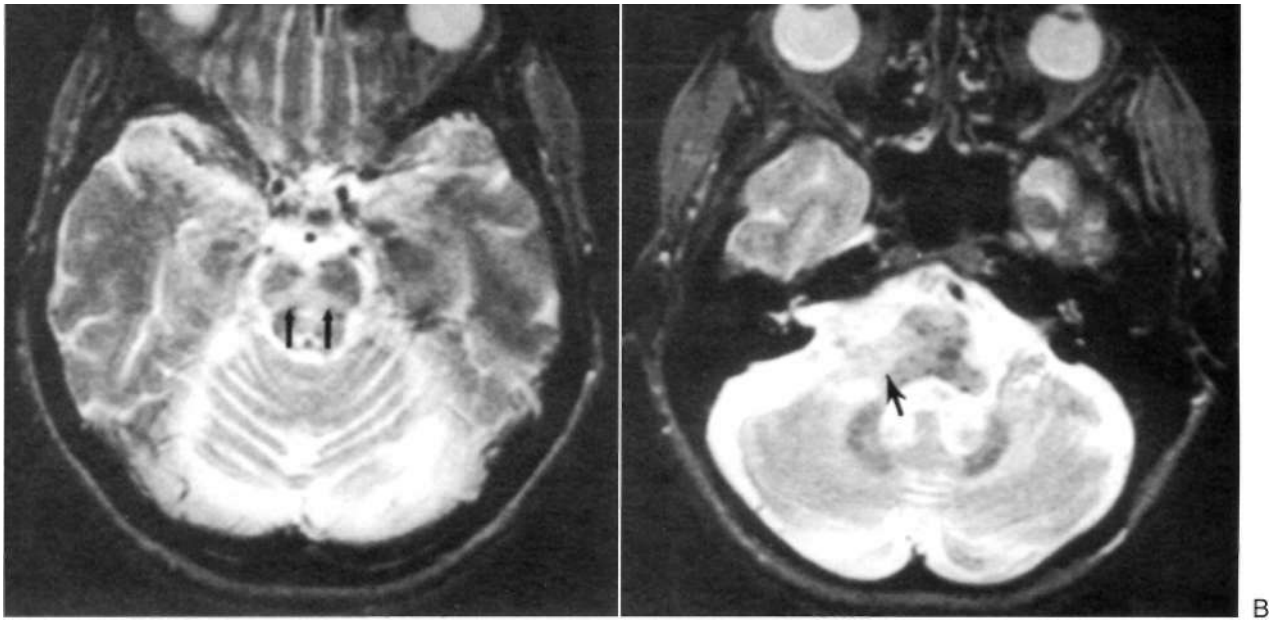

FIGURE 37A.33 Olivopontocerebellar atrophy. (A) Axial T2-weighted image through the pons shows abnormal hyperintense signal of transverse pontine fibers (between the tegmentum and the base of the pons) *(arrows).* Cerebellar atrophy is present. (B) A more inferior section shows abnormal hyperintense signal of the right middle cerebellar peduncle *(arrow).* Also note atrophy of the brainstem with enlargement of the cisterns and the fourth ventricle.

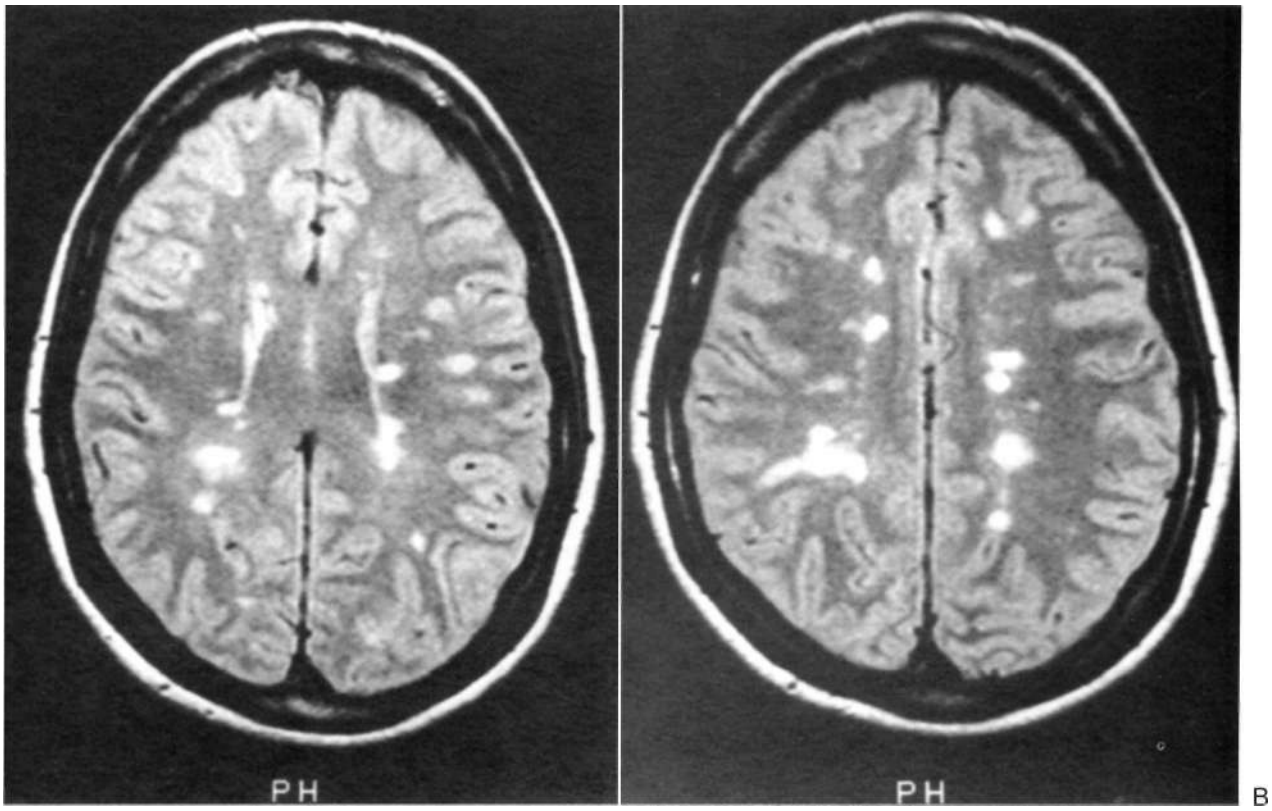

FIGURE 37A.34 Multiple sclerosis. Proton-weigh ted axial images demonstrate hyperintense lesions (A) in the periventricular region and (B) in the centrum semiovale in a patient with multiple sclerosis.

of inflammation decreases in size and leaves a plaque of high intensity on T2-weighted images. Plaques are common in the periventricular regions, internal capsule, corpus callosum, pons, and brachium pontis. Plaques located in the periventricular region may not he well seen on long 1 R-long TE images, where CSF in the ventricles is bright and may obscure the plaques. Proton density images (long TR-short TE) better define the MS lesions. Axon loss in chronic plaques is recognized by magnetic resonance spectroscopic loss of N-acety(aspartate and is responsible for the low signal in these areas in Tl-weighted images.

Acute Disseminated Encephalomyelitis. In acute disseminated encephalomyelitis, the MRI shows bright lesions on T2-weighted images, most in the subcortical white matter with relative symmetrical involvement of both hemispheres {Figure 37A.35; see Chapter 60). Enhancement can be seen with acute disseminated encephalomyelitis, and lesions usually regress in response to corticosteroid treatment.

Central Pontine Myelinolysis. On MRI, in central pontine myelinolysis the typical finding is a hyperintense lesion in T2-weighted images of the central pons, with sparing of the periphery of the pons. High-intensity lesions may also be seen more extensively throughout the brain in areas whert white and gray matter lie in proximity, including the subcortical regions and the thalamus.

Leukodystrophies

The MRI picture is that of progressive white matter lesions and diffuse cerebral atrophy (see Chapter 67), Some features distinguish between the different leukodystrophies early in the course of the disease.

Krabbe's Disease. In Krabbe's disease, on CT, increased density occurs in the thalami, caudate, and corona radiata. On MRI, lesions involve the basal ganglia and white matter in a symmetrical fashion.

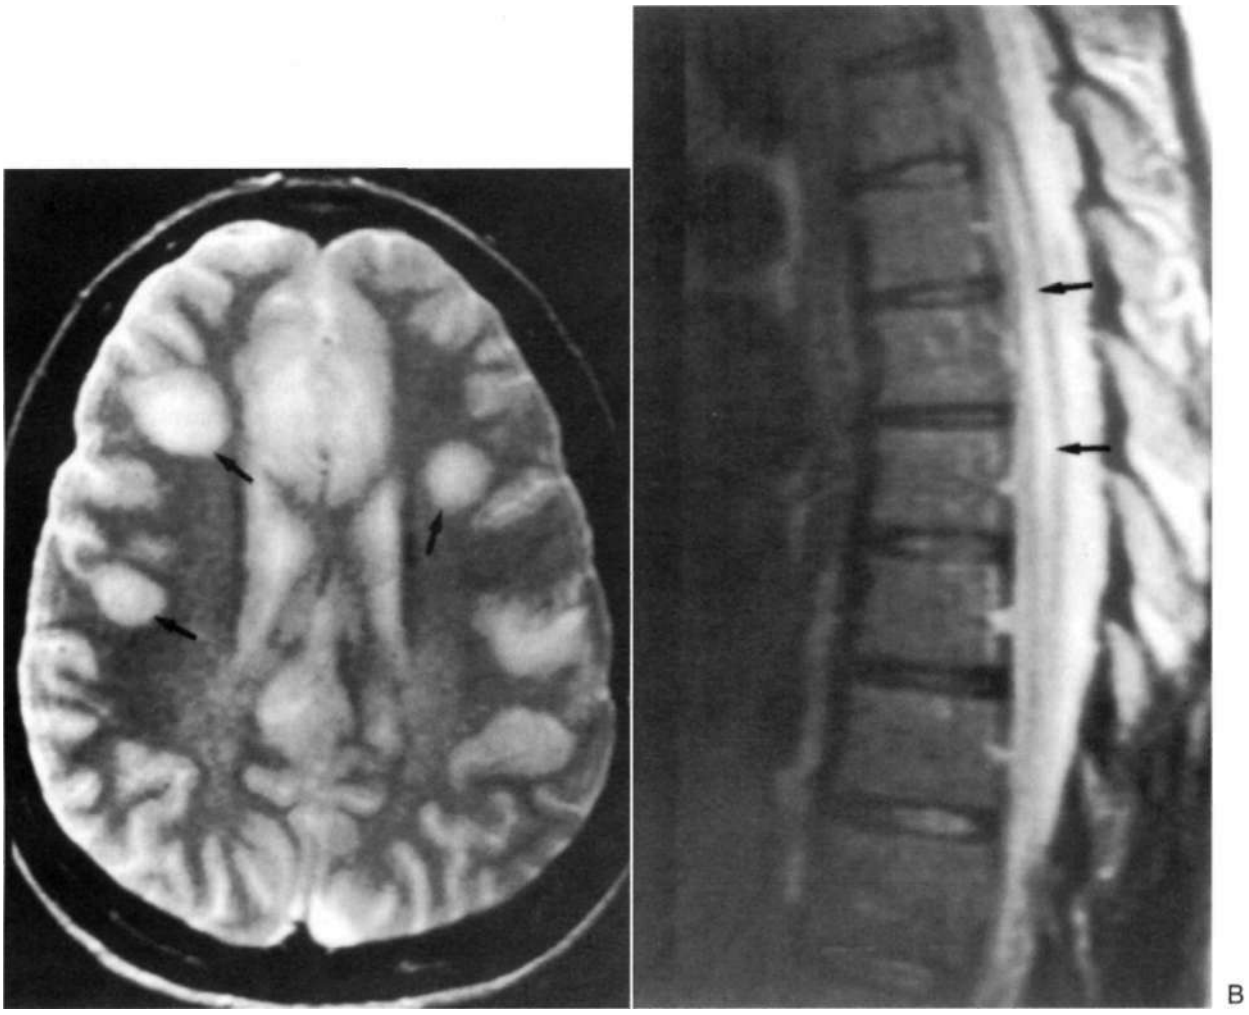

FIGURE 37A.35 Acute disseminated encephalomyelitis. (A) T2-weighted axial image shows multiple hyperintense subcortical white matter lesions *(arrows).* (B) T2-weighted sagittal image of the thoracic spine shows abnormal high signal with the cord *(arrows).*

Metachromatic Leukodystrophy. CT and MRI reveal diffuse white matter lesions (Figure 37A.36) in metachromatic leukodystrophy.

Adrenoleukodystrophy. On CT and MRI in adrenoleukodystrophy, symmetrical areas of white matter abnormality surround the atria of the lateral ventricles and span the splenium of the corpus callosum. At the lateral margin of the zones of demyelination, contrast enhancement may occur. Demyelination along certain tracts, such as the lateral lemniscus, occasionally is identified.

Miscellaneous Lesions of White Matter

Arteritis and secondary ischemic lesions of the brain may result from chemotherapy and radiation treatment. Determining whether a patient's symptoms are caused by an exacerbation of the neoplasm or the effects of treatment (i.e., radiation necrosis) can be difficult. Most recurrent or residual tumors appear as focal areas of enhancement with surrounding edema. The white matter lesions caused by radiation endarteritis may be transient or permanent

Areas of radiation necrosis can be focal or disseminated within the white matter. Radiation necrosis is seen on T2-weighted images as an area of high-intensity signal with variable gadolinium enhancement on T1-weighted images. Mass effect and edema are common early in radiation necrosis, although later atrophy predominates.

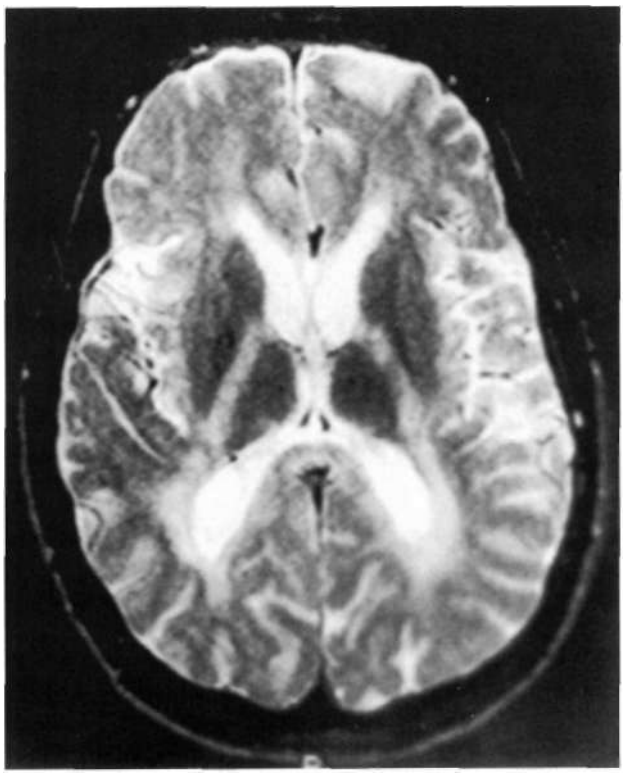

FIGURE 37A.36 Metachromatic leukodystrophy. A 26-year-old patient with progressive neurological deterioration. Diffuse high-intensity signal is noted in the periventricular white matter and internal capsule bilaterally in this T2-wcighted axial scan. The absolute symmetry of the abnormal high signals is a clue that a white matter disease other than multiple sclerosis or vascular myelopathy is responsible.

Head Trauma

CT is obtained in the initial evaluation of the acutely unstable patient who has a head injury to determine whether there is a surgical lesion, such as a subdural or epidural hematoma. However, many lesions are identified by MRI, such as cortical contusions, small subdural hematomas, and diffuse axonal injury, that may not be seen on CT examination. In addition, MRA can play an important role in evaluating trauma, identifying vascular abnormalities such as arterial occlusion and dissecrion, arteriovenous fistula (AVF), and venous sinus occlusion.

Diffuse Axonal Injury

Diffuse axonal injury occurs when the brain has been subjected to an angular acceleration force, causing the hemispheres to move in relation to more fixed structures such as the btainstem, thus tearing white matter fibers (axons). Diffuse axonal injury or shear injury is a common post-trauma tic lesion and is seen well on MRI. Lesions commonly are less than 1 cm in diameter and are seen in the lobar white matter, corpus callosum, and dorsolateral aspect of the tostral brainstem and at the corticomedullaty junction (Figure 37A.37). Patients with such injuries present with loss of consciousness and significant neurological impaitment.

The majority of shear injuries are nonhemorrhagic and MRI, especially the T2-weighted sequence, is more sensitive than CT in detecting them.

Cortical Contusion

Cortical contusions, another common type of traumatic lesion, involve the superficial cortex, tend to be multiple, usually are larger (2-4 cm) than diffuse axonal injuries, are less likely to be associated with severe impairment of consciousness, and most commonly occur in the temporal and frontal lobes. A higher percentage of cortical contusions are hemorrhagic than are those of diffuse axonal injury. MRI and CT are sensitive in detecting hemorrhagic cortical contusions, but MRI, particularly the T2-weighted sequence, is more sensitive in detecting nonhemorrhagic contusions (Figure 37A.38).

Subdural Hematoma

Subdural hematomas evolve in a pattern similar to parenchymal hematomas in the acute and subacute phase but differ from parenchymal hemaromas in the chronic

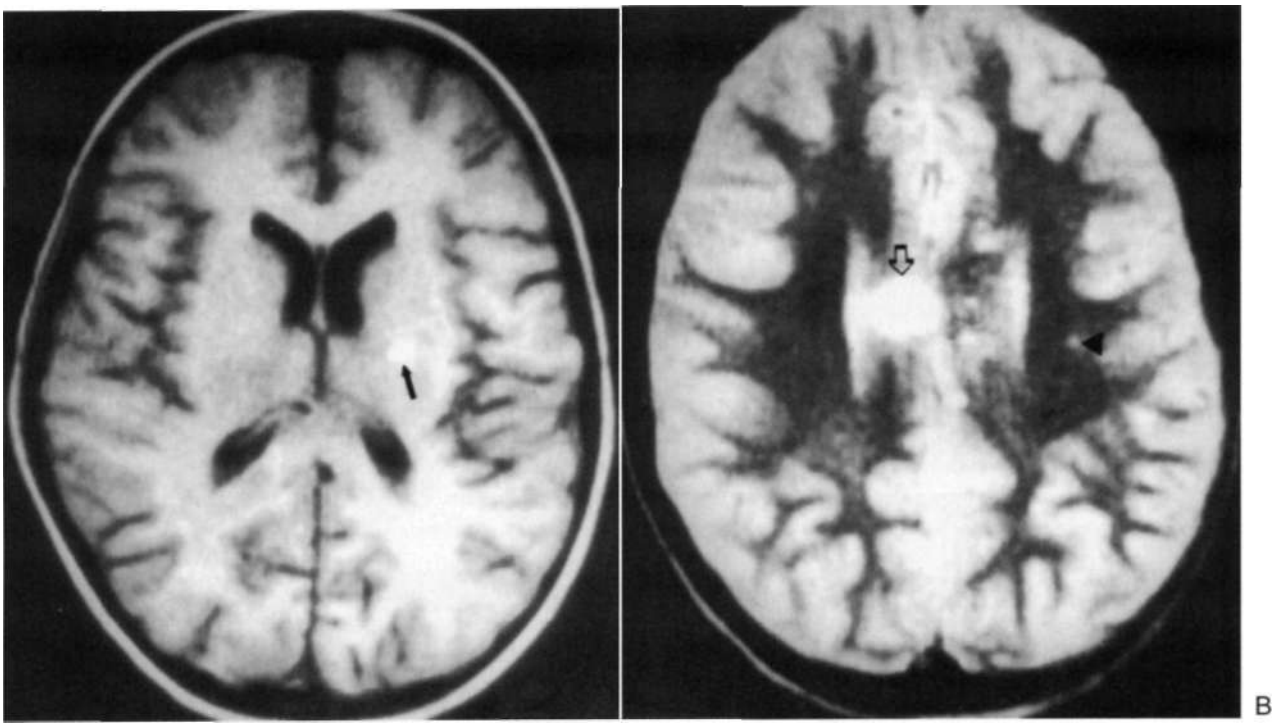

FIGURE 37A.37 Diffuse axonal injury. (A) Axial short repetition time-echo time (TR-TE) magnetic resonance scan of a patient with hemorrhage and nonhemorrhagic diffuse axonal injury. A hemorrhage is seen in the posteriot limb of the left internal capsule *(arrow).* (B) Axial long TR-TE image at a higher level shows a lesion in the corpus callosum *(open arrow)* and a smaller lesion in the left centrum scmiovale *(arrowhead),* (Reprinted with petmission from Sklar, E. M. L, Quencer, R. M., Bowen, B. C, et al. 1992, "Magnetic resonance application in cerebral injury," *Radiol Clin North Am,* vol. 30, pp. 353-366.)

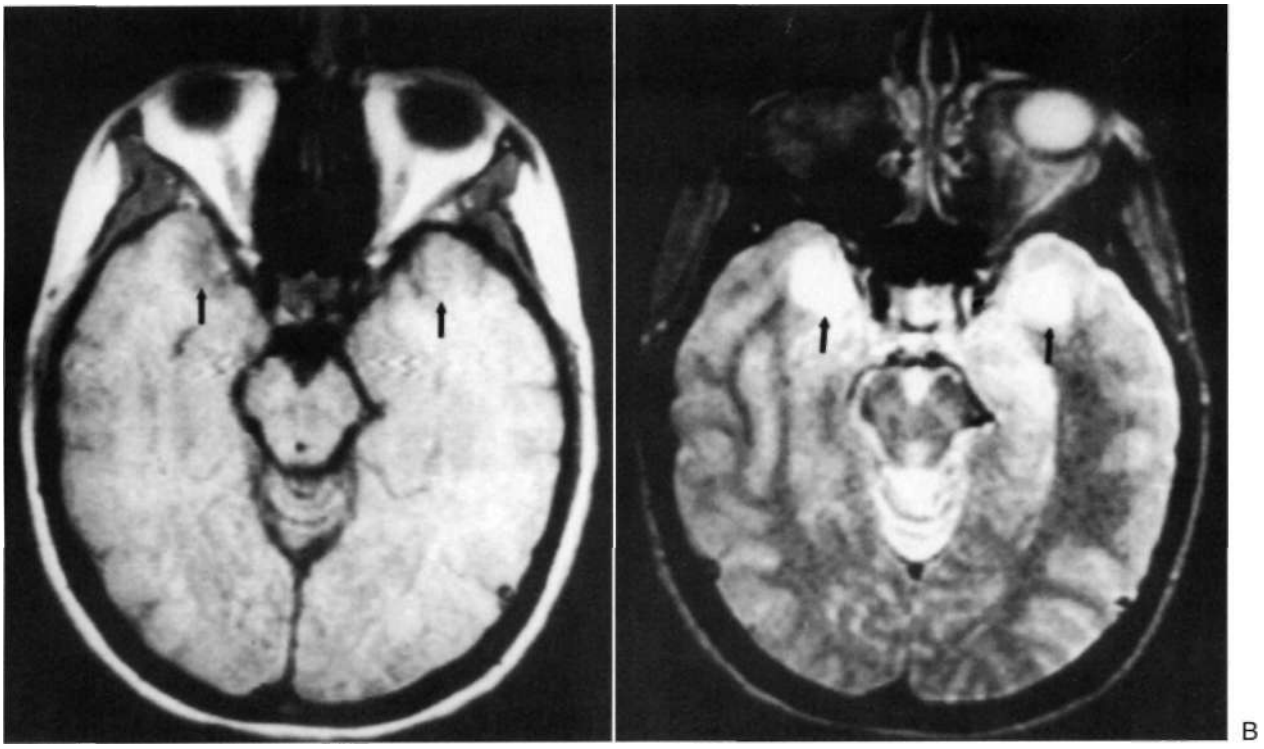

FIGURE 37AJ8 Contusion. Nonhemorrhagic cortical contusions in the temporal lobes *(arrows).* Areas are much more clearly seen in (B) T2-weighted than in (A) Tl-weighted images. (Reprinted with permission from Sklar, E. M. L, Quencer, R. M., Bowen, B. C, et al. 1992, "Magnetic resonance application in cerebral injury," *Radiol Clin North Am,* vol. 30, pp. 353-366.)

phase, as explained later. The time categories used in this discussion are as follows: *Acute* means less than 1 week old, *early subacute* indicates more than 1 week and less than 2 weeks, *late subacute* means more than 2 weeks and less than 1 month, and *chronic* indicates a duration of more than 1 month. The acute subdural hematomas are characterized by hypointensity on T2 weighted images, reflecting the presence of deoxyhemoglobin. A late subacute subdural hematoma shows high signal intensity on all pulse sequences because of the presence of extracellular methemoglobin (Figure 37A.39). Subdural hematomas in a chronic phase are hypointensc on short TR and TE images; this loss of Tl shortening results from a decrease in the concentration of methemoglobin caused by dilution, absorption, or degradation. Enhancement of the periphery of the subdural hematomas is expected in the chronic phase because of the presence of a vascular capsule.

Epidural Hematoma

Epidural (or extradural) hematomas may arise from arterial or venous bleeding. When arterial, they usually are caused by a laceration of a meningeal artery and are associated with skull fractures (Figure 37A.40). On MRI, the dura often can be seen displaced away from the inner table of the skull as a thin low-signal line between the brain and the hematoma.

Subarachnoid Hemorrhage

On CT, subarachnoid hemorrhage is seen as high density in the basal cisterns, sylvian fissures, inter hemispheric fissure, sulci, or some combination of these locations. Most of the increased density rarely lasts more than a few days because the blood becomes diluted in the subarachnoid space and

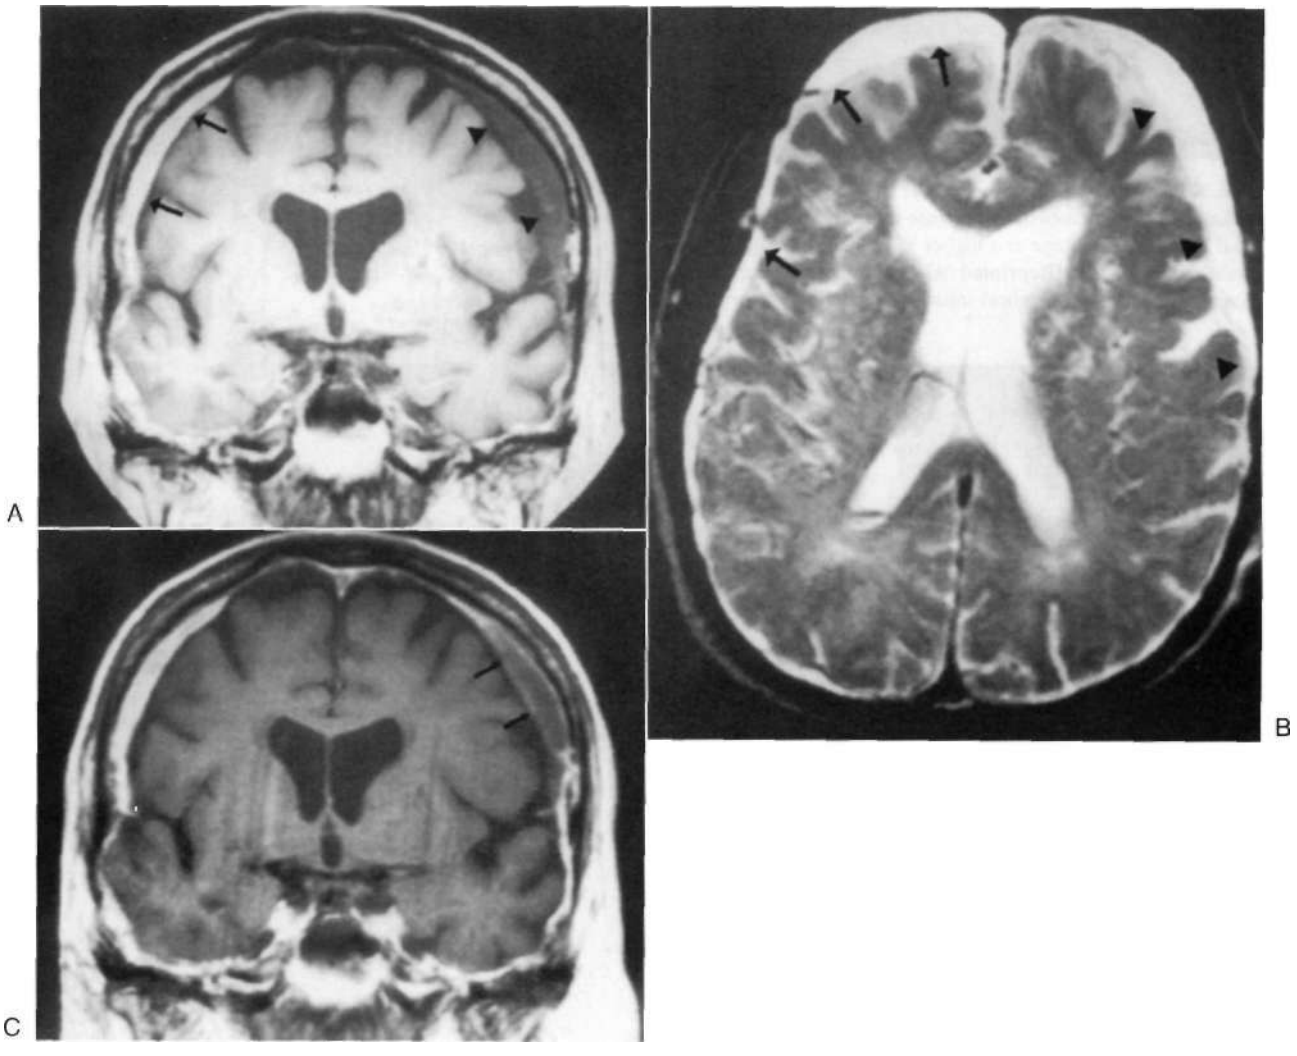

FIGURE 37A.39 Subdural hematoma (SDH). A 76-year-old man who fell 10 days before magnetic resonance imaging. (A) Subacute SDH on right *{arrows)* shows high signal on this IT-weighted coronal image. On the left side, a chronic SDH *{arrowheads)* is shown. (B) T2-weighted axial image shows high signal along the entire collection of right SDH *{arrows).* Also note the chronic SDH on the left, which is iso in tense on T1- and hyperintense on T2-weigh ted image *(arrowheads).* (C) Postcontrast-cnhanced coronal magnetic resonance innigi' liL-tnonsmucH .in enhancing membrane *(arrows)* of the chronic SDH.

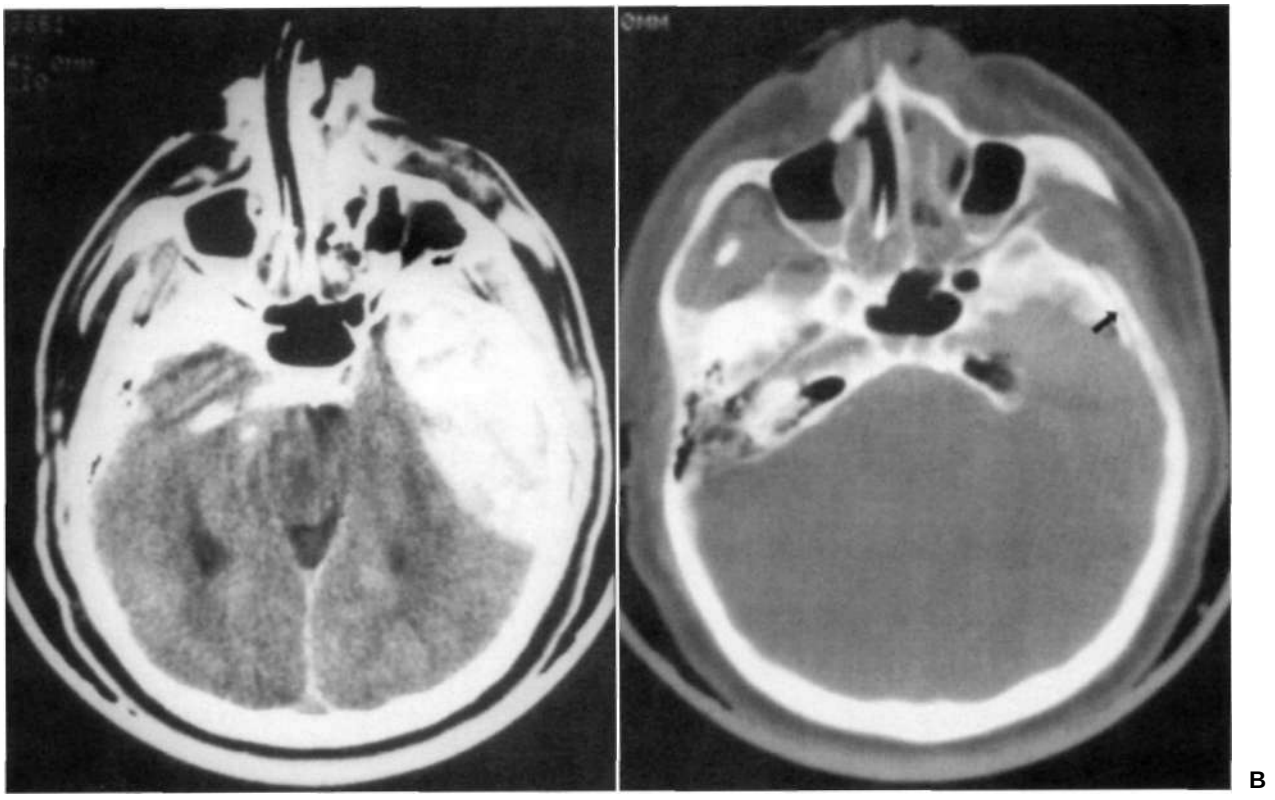

FIGURE 37A.40 Epidural hematoma. (A) Computed tomographic axial section shows a left biconvex peripheral high-density lesion consistent with an epidural hematoma. (B) A fracture *(arrow)* is seen on the bone windows of the same section.

is resorbed over the cerebral convexities. MRI is less successful in depicting acute subarachnoid hemorrhage, so CT is still the preferred study in suspected subarachnoid hemorrhage.

This inscnsitivity of MRI to blood in the subarachnoid space is related to the high Po_2 in the CSF. Conversion of oxyhemoglobin to dcoxyhemoglobin and subsequently to methemoglobin requires a narrow range of oxygen tension. In the CSK, significant quantities of methemoglobin are not formed until several days after the hemorrhage, and if the subarachnoid hemorrhage is mild the red blood cells may be resorbed before significant amounts of methemoglobin are formed. For these reasons, CT is advocated for the early diagnosis of acute subarachnoid hemorrhage. However, for subacute and chronic subarachnoid hemorrhage, MRI may be superior to CT.

Intracerebral Hematoma

Traumatic intracerebral hematomas may range from a few millimeters to several centimeters in diameter. Distinguishing hematomas from hemorrhagic contusions and shear injuries is difficult but important. Unlike intracerebral hematomas, the hemorrhage in the latter two types of injuries is interspersed between areas of edematous brain. Although most of these lesions develop immediately after trauma, some may develop in the first 48 hours after injury. This may be either because the swelling of the brain decreases, thus allowing more capillary bleeding, or because the change in oxygen tension alters the brain perfusion, thus increasing the chances of delayed hemorrhage.

Vascular Injuries: Role of Magnetic Resonance Angiography

Vascular injuries can be either arterial or venous. The most common abnormality of the major arteries after trauma is arterial occlusion, which is attributed to severe spasm and emboli from mural thrombi in areas of intimal disruption. Arterial dissections often occur near the junction of the cervical and petrous segments of the internal carotid artery where it enters the carotid canal. Arterial dissection often is idiopathic, but trauma can be the cause.

Routine spin-echo MRI is useful in imaging carotid-cavernous fistulas. The MRA findings are characteristic even though the exact site and dynamic character of the fistula arc not as well shown as on conventional angiography (Figure 37A.41). A sign of a carotid-cavernous fistula on routine MRI is significant enlargement of a draining vein, such as the superior ophthalmic vein.

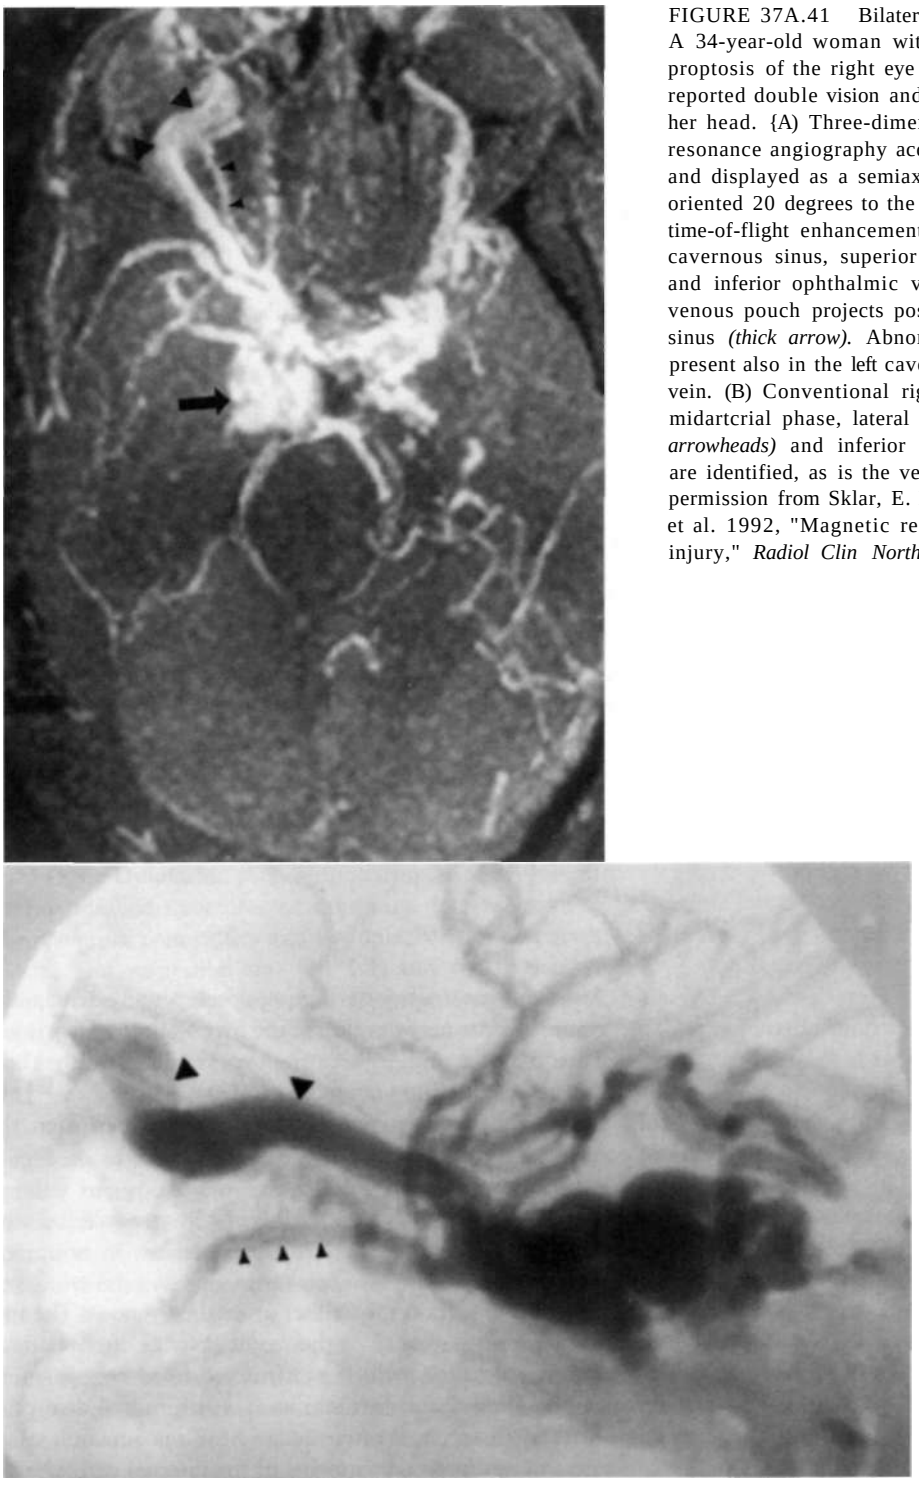

FIGURE 37A.41 Bilateral carotid cavernous fistulas, A 34-year-old woman with extensive facial injuries and proptosis of the right eye after a motor vehicle accident reported double vision and a pulsating noise in the right side of her head. {A) Three-dimensional time-of-flight magnetic resonance angiography acquired as a transaxially oriented slab and displayed as a semiaxial maximal intensity projection oriented 20 degrees to the horizontal plane. There is abnormal time-of-flight enhancement and enlargement of the right cavernous sinus, superior ophthalmic vein *(large arrowheads),* and inferior ophthalmic vein *{small arrowheads).* A large venous pouch projects posteriorly from the right cavernous sinus *(thick arrow).* Abnormal time-of-flight enhancement is present also in the left cavernous sinus and superior ophthalmic vein. (B) Conventional right internal carotid angiogram, midartcrial phase, lateral projection. The superior *[large arrowheads)* and inferior *[small arrowheads)* ophthalmic veins are identified, as is the venous pouch. (Reprinted with permission from Sklar, E. M. L, Quenccr, R. M., Bowen, B. C, et al. 1992, "Magnetic resonance application in cerebral injury," *Radiol Clin North Am,* vol. 30, pp. 353-366,)

Cerebral Infections

MRI is the imaging procedure of choice for CNS infection and inflammation. With intravenous conttast administration, areas of enhancement on MRI indicate sites of blood-brain barrier disruption and meningeal inflammation.

Viral Infections

On MRI in herpes simplex encephalitis, hyperintensiry involving the cortex and white matter in the temporal and inferior frontal lobes is noted on T2-weighted images. The areas of involvement then enlarge and coalesce, MRI often demonstrates bitemporal involvement, and hemorrhage

may be detected (Figure 37A.42). Atrophy is seen late in the course of the disease.

Bacterial Infection (see Chapter 59)

Lyme Disease. North American Lyme disease, or borreliosis, results from infection by the tickborne spirochete *Borrelia burgdorferi.* Lyme disease is endemic in the northeastern United States. Lyme disease has protean clinical manifestations, with involvement of skin, heart, and musculoskeletal and nervous systems. Neurological abnormalities develop in approximately 11% of patients with skin lesions, may occur without a histoty of skin manifestations, and typically occur months to yeats after the initial tick bite. Neurological symptoms may include aseptic meningitis, ctanial neuritis, ataxia, and encephalitis.

MRl scans may be normal or may demonstrate (in advanced stages), multiple bilateral periventricular or subcortical hyperintensc lesions on T2-weighted images without mass effect resembling MS plaques. Brainstem and basal ganglia may be involved. With gadolinium, parenchymal lesions and the meninges may be enhanced.

Cerebritis and Abscess. Cerebritis is a pootly demarcated localized area of parenchymal softening with necrosis, edema, vascular congestion, and perivascular inflammation. A focus of cerebritis may progress to abscess formation, in which a central /.one of necrosis liquefies; the lesion becomes better defined and eventually encircled by an enhancing vascularized fibrotic capsule surrounded by a zone of gliosis. Most abscesses form because of hematogenous spread of organisms at the gray matter-white matter junction, most commonly in the frontal and parietal lobes.

On MRl, an abscess on T1-weighted images has a central cavity, which is hypointensc to brain parenchyma; on T2-weighted images it is hyperintense. The rim, which is isointense to hypointense on Ti-weighted images and is hypointense on T2-wcighted images, is not identical to the ring of enhancement seen with gadolinium. The ring of enhancement usually is smooth and thin walled when compared with the peripheral enhancement seen with malignant tumors; however, occasionally the wall may be thick and simulate a necrotic neoplasm (Figure 37A.43). Edema in the white matter atound an abscess usually is greater in volume than the abscess itself. Abscesses tend to point (i.e., have a thinner wall) toward the ventricle and may ruptute into the ventricle.

Meningitis. In meningitis, unenhanced MRl scans usually show no abnormality. Gadolinium-enhanced MRl scans

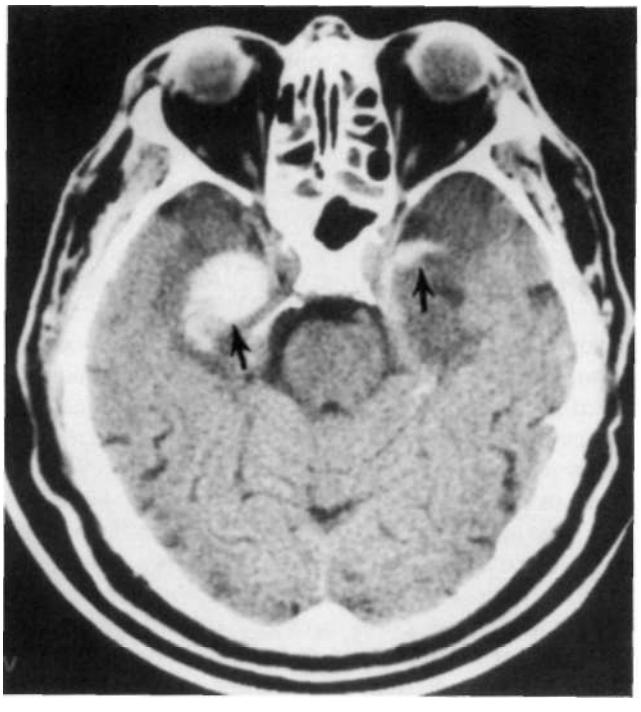

FIGURE 37A.42 Herpes encephalitis. Noncontrast axial computed tomographic scan shows bilateral hemorrhagic lesions *{arrows).* These medial and interiorly located temporal lobelesions consisting of blood, edema, and inflammatory tissue are characteristic of herpes simplex encephalitis.

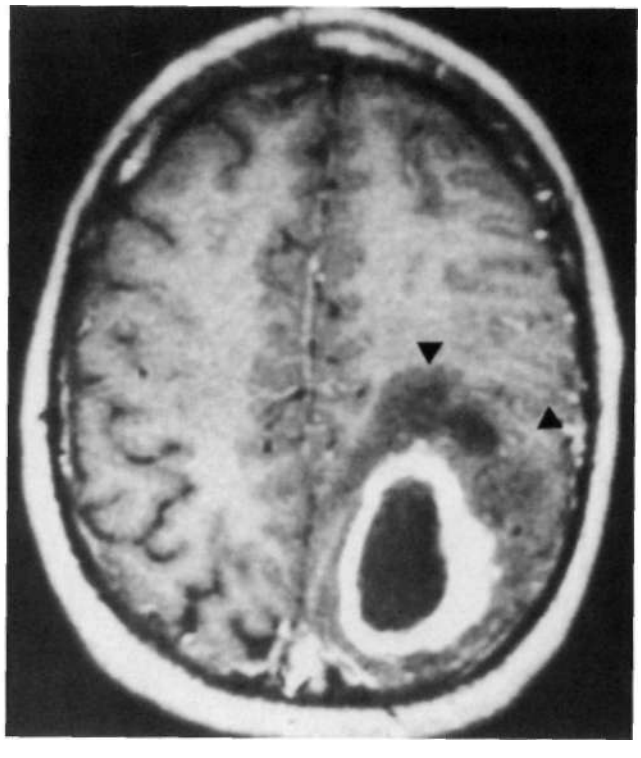

FIGURE 37A.43 Intracerebral abscess. Contrast-enhanced axial Tl-weighted magnetic resonance imaging shows a ring of enhancement surrounded by edema and hemispheric mass effect producing obliteration of sulci and crowding of the gyn *(arrowheads).* Because of the thick rim of enhancement and necrotic center, one would commonly consider a malignancy the primary diagnosis, but this was a surgically proved *Streptococcus viridans* abscess.

may show prominent leptomeningeal enhancement with a gyral pattern in severe cases. Complications of meningitis include cerebral infarction, cerebritis and abscess, subdural empyema, hydrocephalus, and ventriculitis. These complications arc best detected by **MRI.**

Mycobacterium tuberculosis. Infection by *M. tuberculosis* or certain fungi causes a granulomatous inflammatory reaction, which may involve the meninges or hrain parenchyma. Characteristically, a thick gelatinous exudate is found in the basal cisterns. The capsule of the granuloma often is thicker than that of a pyogenic abscess. Tuberculosis may produce a vasculitis due to endarteritis obliterans of the artery passing through the infection that can result in an infarction. Basal cisternal and diffuse meningeal enhancement is a predominant feature of tuberculous meningitis (Figure 37A.44).

Tuberculomas can be located anywhere in the cerebrum or cerebellum and in subarachnoid, subdural, and epidural spaces. Intraparenchymal granulomas are found at the corticomedullary junction and in the periventricular regions. In general, there is less edema in the brain surrounding a tuberculoma than that surrounding a pyogenic abscess. With intravenous contrast administration, tuberculomas enhance intensely in a nodular or ringlike fashion.

FIGURE 37A.44 Tuberculous meningitis. Postcontrast computed tomographic scan reveals diffuse cisternal enhancement *(arrows)* compatible with diffuse meningitis.

Cysticercosis

Cysticercosis is the most common parasitic infection of the human CNS worldwide. The causative agent is the pork tapeworm, *Taenia solium.* There are four types of neurocysticercosis: parenchymal, subarachnoid, intraventricular, and mixed. After initial infection, the cysticercus develops into a cyst containing the scolcx (Figure 37A.45}. As the organism dies, metabolic products leak from the wall of the cyst and incite an inflammatory reaction. Edema may then develop and the cyst becomes turbid. The cyst then collapses and calcifies. If the cyst becomes nuilriloculated, it resembles a cluster of grapes, known as the *racemose form,* which typically occurs in the basilar cisterns.

Intraventricular and subarachnoid cysts can be difficult to visualize on CT and are better seen on MRI. The fourth ventricle is the most common site of intraventricular cysticercosis (see Figure 37A.45).

Acquired Immunodeficiency Syndrome

Neuroimaging plays a crucial role in the investigation of patients with AIDS and CNS disease (see Chapter 59). CT and **MRI** are the most commonly used modalities in evaluating patients with AIDS and CNS disease; however, nuclear medicine has become an important imaging modality for differentiating inflammatory and neoplastic masses. Specifically, thallium-201 brain single photon emission CT can be used to distinguish toxoplasma encephalitis from CNS lymphoma, the two primary pathological lesions in this population (Ruiz et ai. 1994).

MRI is more sensitive than CT in detecting diffuse white matter disease, which commonly is seen in AIDS. T2-weighted images are necessary in evaluating neurologically symptomatic patients with AIDS.

Toxoplasma Encephalitis

Toxoplasma encephalitis, caused by the intracellular proto/.oan *Toxoplasma gondii,* is the most common infection to affect the brain in AIDS. In noncontrast CT, toxoplasma encephalitis is seen as multiple areas of isodensity or hypodensiry, with a predilection for the corricoiiiedullary junction and basal ganglia. The lesions may vary in size from less than 1 cm to more than 3 cm, and hemorrhage, although unusual, has been reported in both the treated and the untreated patient. Surrounding edema and mass effect occur, and postcontrast CT demonstrates ring, solid, or nodular enhancement {Figure 37A.46), although ring enhancement is most common. Double-dose delayed CT is more effective in detecting these lesions.

After the patient has begun treatment, scans should show a decrease in the number and size of the lesions and a reduction in edema and mass effect within 2-4 weeks after

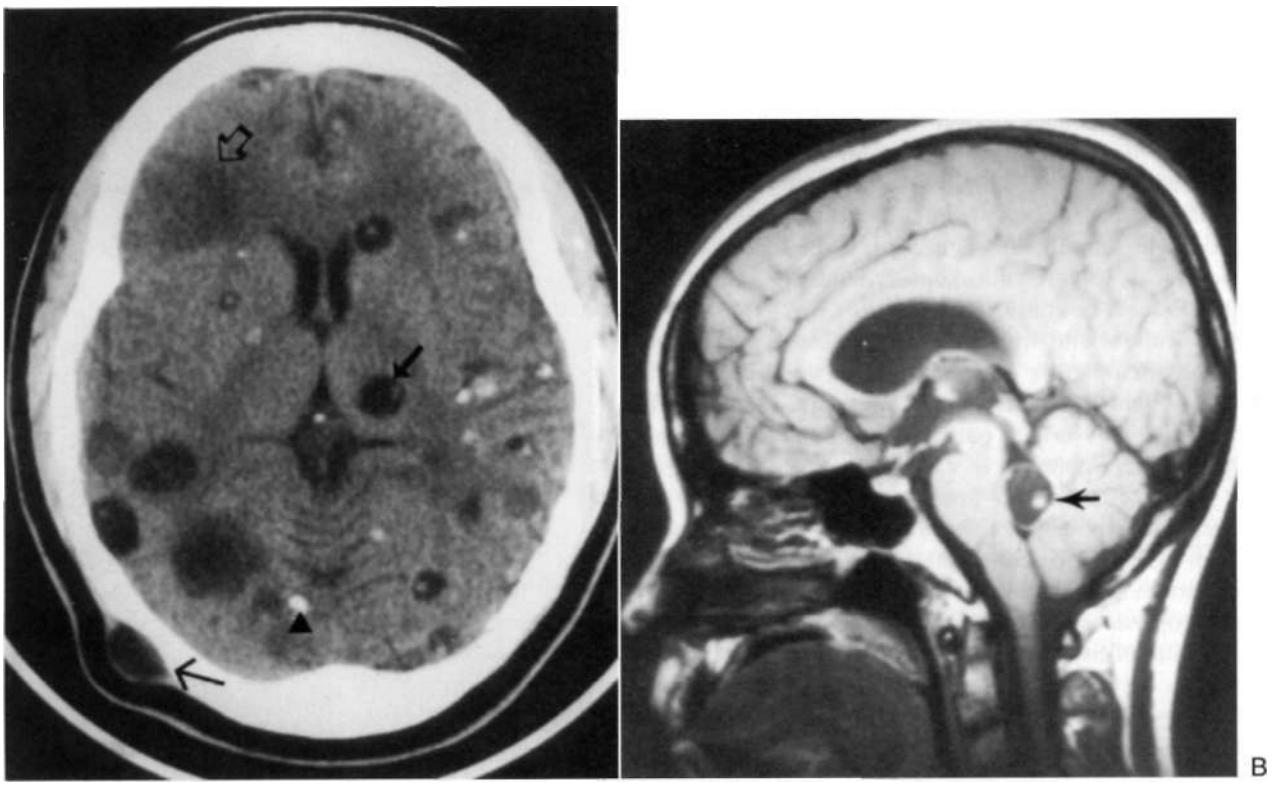

FIGURE 37A.45 Cysticercosis. (A) Noncontrast axial computed tomographic scan demonstrates multiple lesions of cysticercosis in various stages of evolution. Note the multiple cysts with scolices *{arrow)* and the calcified lesion *{arrowhead).* Also, a hypodense lesion in the right frontal lobe represents a degenerating eysticcrcus with edema *{open arrow).* Note scalp lesion *{thin arrow).* (B) Sagittal Tl-weighted magnetic resonance imaging of another patient shows a cysticercosis cyst in the fourth ventricle *{arrow).*

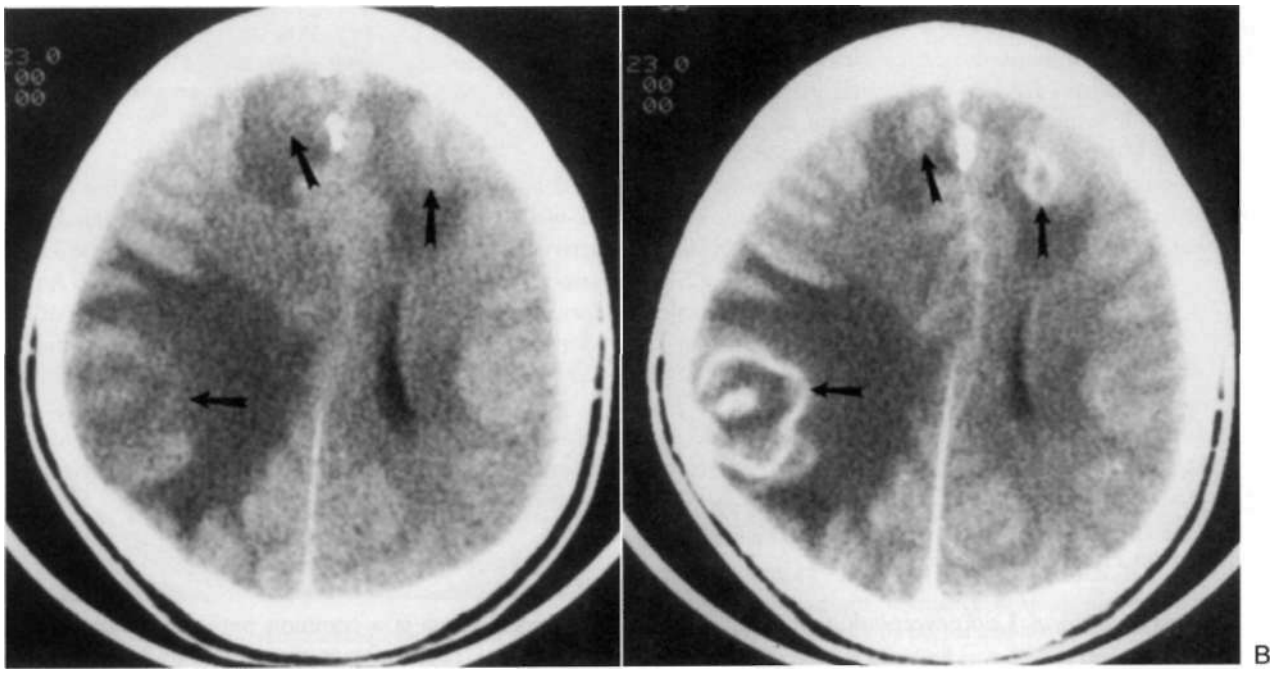

FIGURE 37A.46 Toxoplasma encephalitis. (A) Noncontrast computed tomographic scan of a patient seropositive for human immunodeficiency virus shows lesions *(arrows)* that are isodense to hypodense with extensive mass effect and edema. (B) Postcontrast computed tomographic scan (douhlc-dose delayed technique) reveals multiple enhancing lesions *(arrows).*

treatment hegins. Treated lesions have a variahle appearance on CT, The areas of prior involvement may appear normal, show cncephalomalacia, calcify, or, rarely, show areas of petechial hemorrhage. Reduction or resolution of the lesions on serial scans is presumptive evidence that toxoplasma was the causative agent for the lesions. Toxoplasma encephalitis recurs if treatment is discontinued, so lifelong therapy is needed. If the lesions do not improve with specific antitoxoplasma therapy, alternative diagnoses must be considered.

MRI without and with gadolinium is more sensitive to lesions of toxoplasma encephalitis than postcontrast CT, On Tl-weighted images, the lesions are isointense to hypointense to brain parenchyma. On T2-weighted images, active lesions are of variable intensity. The lesions may be hypcriutense to brain parenchyma or may be isointense to hypointense to brain centrally and surrounded by high-signal edema called the *target sign.* The enhancement pattern is similar to that on CT, Only 14% of patients with toxoplasmosis demonstrate a solitary lesion; therefore, lack of multiplicity should raise the possibility of a different diagnosis.

Primary CNS lymphoma and toxoplasma encephalitis may be difficult to distinguish, and because treatment is different, it is important to distinguish these two lesions. Thallium-201 brain single photon emission CT has become valuable in making this distinction because tumors have increased uptake {Figure 37A.47; Plate 37A.I), whereas infectious lesions do not {Ruiz et al, 1994).

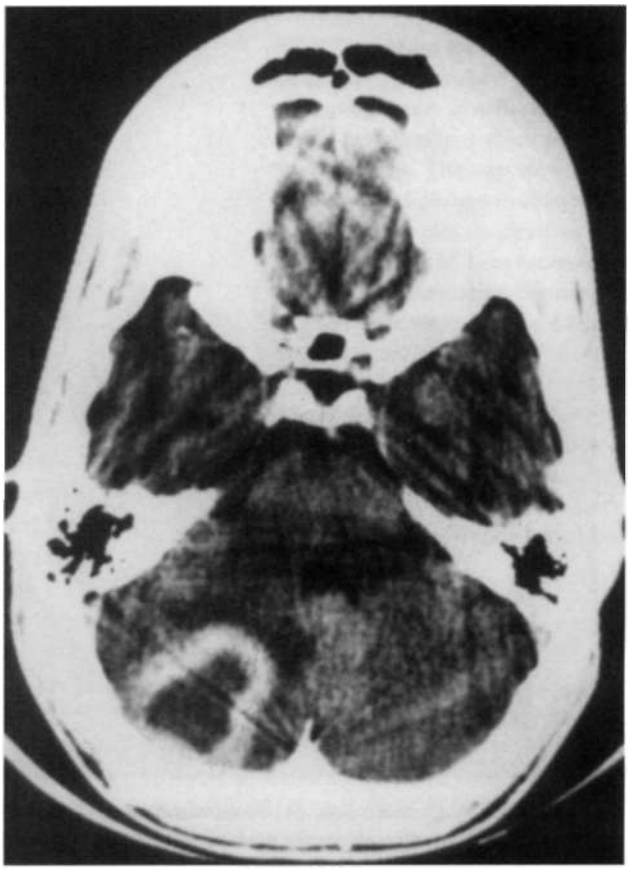

FIGURE 37A.47 Lymphoma. Postcontrast computed tomographic scan demonstrates a ring-enhancing lesion with a necrotic center in the right cerebellar hemisphere. See Plate 37A.I for brain single-photon emission computed tomography images. (Reprinted with permission from Ruiz, A., Ganz, W. L., Post, M. J. D., et al. 1994, "Use of thallium-201 brain SPECT to differentiate cerebral lymphoma from toxoplasma encephalitis in AIDS patients," *Am } Neuroradiol,* vol. 15, pp. 1885-1894. Copyright 1994, American Society of Neuroradiology.)

Human Immunodeficiency Virus Encephalitis

MRI is more sensitive than CT in demonstrating the effects of human immunodeficiency virus (HIV) infection. Hyperintense lesions are seen on T2-weighted images in the periventricular white matter and centrum semiovale and correspond to foci of dcmyelinatioti and vacuo Ian on. MRI may demonstrate atrophy and signal changes in the white matter but does not demonstrate the microglial nodules and multinucleated giant cells seen on histological sections. MRI findings are abnormal in approximately 70% of patients with AIDS, regardless of the presence of neurological symptoms,

Proton MRI spectroscopy also has been used to detect abnormalities in the brains of HIV-infected patients. One study found abnormal spectra in 10 patients with AIDS, whereas routine MRI of these same patients revealed no significant abnormalities. Therefore proton spectroscopy may hold promise of early diagnosis of biochemical alterations in HrV-infected patients.

Progressive Multifocal Leukoencephalopathy

On CT, progressive multifocal leukoencephalopathy (PML) appears as a focal area of hypodensity in the white matter without mass effect and usually without enhancement. MRI has greater sensitivity than CT in imaging PML. On T2-weighted images, PML has increased signal in the periventricular or subcortical white matter (Figure 37A.48}, sometimes with a bilateral multifocal distribution. Any lobe may be affected, but the frontal and pa ric to-occipital locations are most common. PML may be difficult to distinguish from HIV-related demyelination, but the latter is more often diffuse, symmetrical, and periventricular in location, whereas PML is more multifocal and asymmetrical and has a predilection for the subcortical white matter.

Cytom ogd lovirus

Cytomegalovirus is a common pathogen in patients with AIDS. On CT, atrophy is the most frequent finding, and hypodensity of the white matter may be seen. Periventricular and subependymal enhancement may be present, however. CT may grossly underestimate the degree of

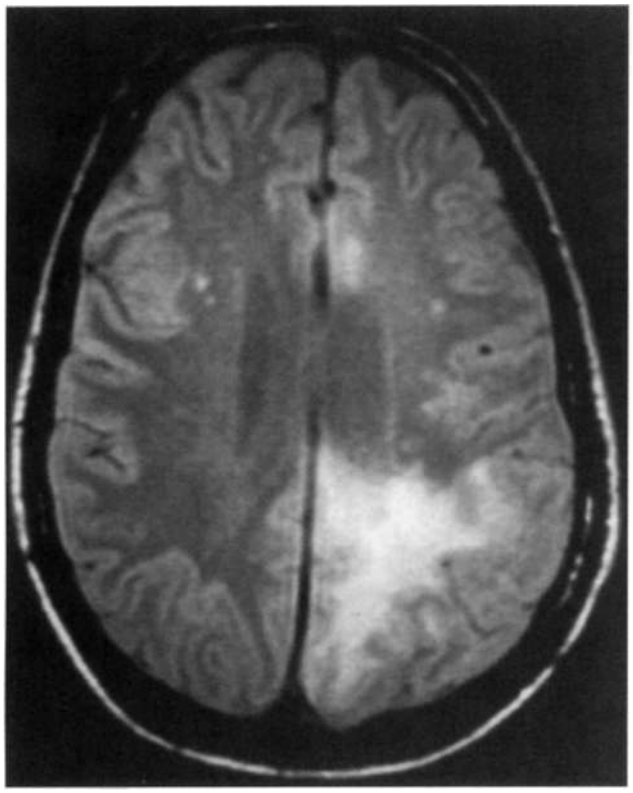

FIGURE 37A.48 Progressive multifocal leukoencephalopathy (PML). Proton density-weigh ted image shows a high-intensity lesion located in the white matter in the left posterior parietal lobe consistent with PML.

HCIJRK 37A.49 Cryprococcal gelatinous pseudocysts. Nioncori-trast computed tomographic scan shows gelatinous pseudocysts in ilu- li.i-iiI s> a nidi a in ,1 patient with acquired immunodeficiency syndrome.

involvement. **MRI** has greater sensitivity than CT in detecting CNS cytomegalovirus and its extent. MRI may demonstrate increased signal in the periventricular white matter on T2-weighted images and subependymal enhancement after contrast administtation.

Cryptococcosis

CNS cryptococcosis is caused by the saprophytic yeastlike fungus *Cryptococcus neaformans.* CNS cryptococcosis is the third most common CNS infection (after HIV encephalopathy and toxoplasma encephalitis) in patients with AIDS and is the most common fungal infection to involve the CNS in patients with AIDS. Cryptococcal meningitis is the sine qua non manifestation of CNS cryptococcosis. In addition, the perivascular (Virchow-Robin) spaces usually are dilatated by cryptococcal spread. Once the perivascular spaces become infected, they tend to become confluent. At that point cystlike lesions, hypodense on CT (Figure .V7A.49) and low on TI-weighted images and bright on T2-weighted images, may be seen in the basal ganglia, mesencephalon, and dentate nuclei. Cryptococcal involvement of the choroid plexus and pituitary gland may occur. In patients with AIDS, cryptococcal meningitis and the other lesions described rarely enhance. This is because of the inability of the patient with AIDS to mount an inflammatory response and the presence of the organism's mucoid capsule, which isolates it from the patient's inflammatory cells. CNS cryptococcomas, lesions invading the brain parenchyma, are rare in patients with AIDS.

Lymphoma

Primary CNS lymphoma is the most common CNS neoplasm seen in HIV-infected patients. AIDS-related CNS lymphomas are more often peripheral in location and tend to demonstrate necrosis more often than non-AIDS-related lymphomas. Up to 25% of CNS lymphomas occur infratentorially. Non-AIDS lymphomas appear as hyper dense masses on noncontrast CT examination, whereas AIDS-related CNS lymphoma lesions may be hypodense, probablj related to a greater degree oi necrosis. On MRI, the dense cellularity of lymphoma renders these lesions isointense to hypoin tense on all sequences. Enhancement in non-AIDS lymphoma may be homogeneous, whereas in AIDS-related lymphoma enhancement may be heterogeneous or ringlike, which again may be related to the greater degree of necrosis (see Figure 37A.47). Brain positron emission tomography and single photon emission CT studies arc helpful in differentiating AIDS-related lymphoma from non-neoplastic brain masses.

Congenital Lesions

Two major types of congenital disorders of the CNS can be described (see Chapter 66). Disorders of organogenesis are those in which an alteration of CNS development occurs. Disorders of histogenesis are those with normal development but with abnormal cell differentiation. The disorders of organogenesis include abnormalities of divcrticulation, closure migration, and CSF flow (Chapter *66).* The disorders of histogenesis include the phakomatoses (see Chapter 71).

Disorders of Diverticulation

Disorders of diverticulation are caused by failure of the primitive prosencephalon to develop into cerebral hemispheres, and various degrees of failure of separation of the brain and ventricles may occur.

Holoprosencephaly. Holoprosencephaly represents absence of cleavage of the forcbrain (prosencephalon). Three types are seen, depending on the severity of the lesion (from most severe to least severe): alobar, semilobar, and lobar. Alobar is the extreme form of holoprosencephaly, resulting in a single monoventricular cavity with thin cortical tissue (Figure 37A.50),

Septo-Optic Dysplasia. Scpto-optic dysplasia involves the anterior midline structures of the brain. It consists of an absent septum pellucidum and hypoplasia of optic nerves, chiasm, and infundibulum. On CT and MRI, there is absence of the septum pellucidum, atrophic optic nerves, and large ventricles.

Disorders of Closure

In agenesis of the corpus callosum, a large bundle of fibers (bundles of Probst) persists, passing anteroposteriorly on the medial aspect of the ventricles. On CT or MRI wide separation of the lateral ventricles occurs, occipital horns may show relative dilatation, and interposition of the third ventricle between the bodies of the lateral ventricles may occur (Figure 37A.51). On sagittal MRI, there is absence of the corpus callosum. In addition, the sulcal markings and gyri in the parasagittal area have a more vertical course.

Disorders of Cerebrospinal Fluid Flow

Chiari Malformations. In the Chiari type I malformation, the cerebellar tonsils are positioned below the foramen magnum, but the cerebellum is normal otherwise and the fourth ventricle is in a normal position. Syringohydromyelia is a common concurrent lesion, with an incidence of 20-25% in Chiari 1 malformation (Figure 37A.52).

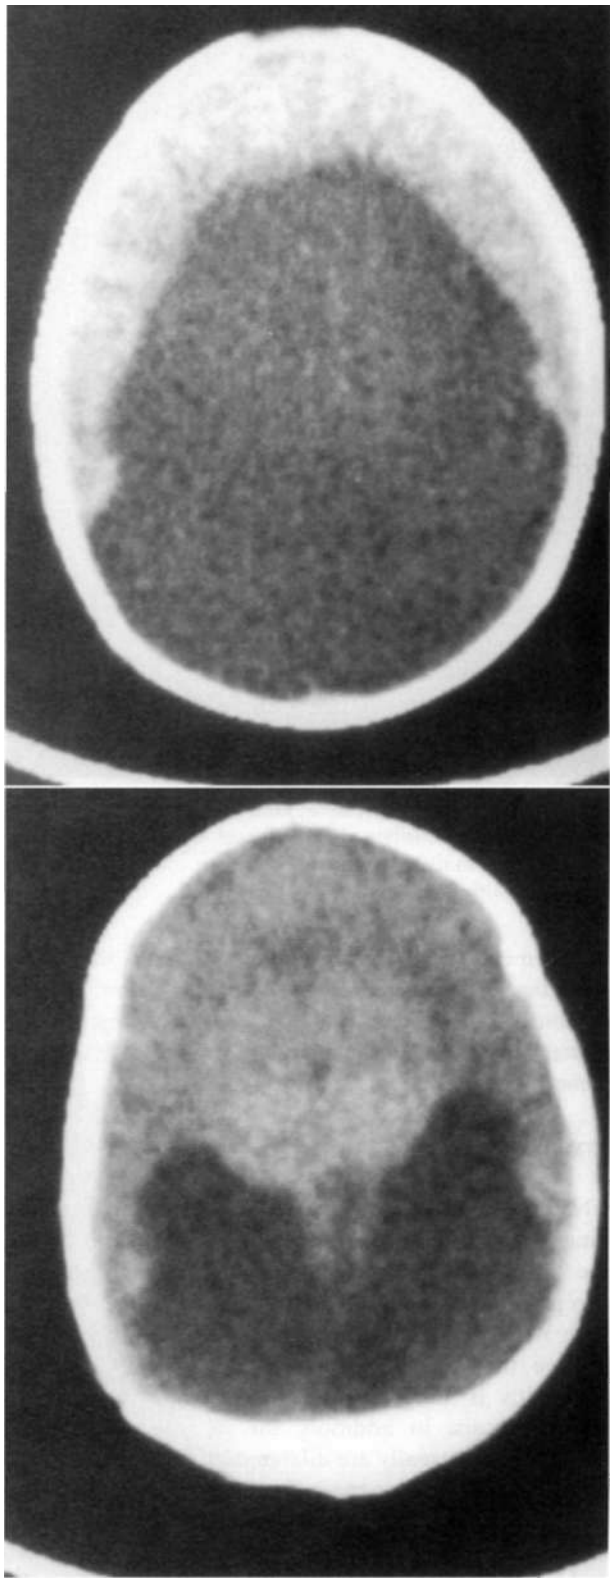

FIGURE 37A.50 Alobar holoprosencephaly. (A) Axial computed tomographic scan demonstrates a large central monoventricular cavity with a peripheral rim of cortical tissue. (B) The thalami are fused, and the third ventricle cannot be identified.

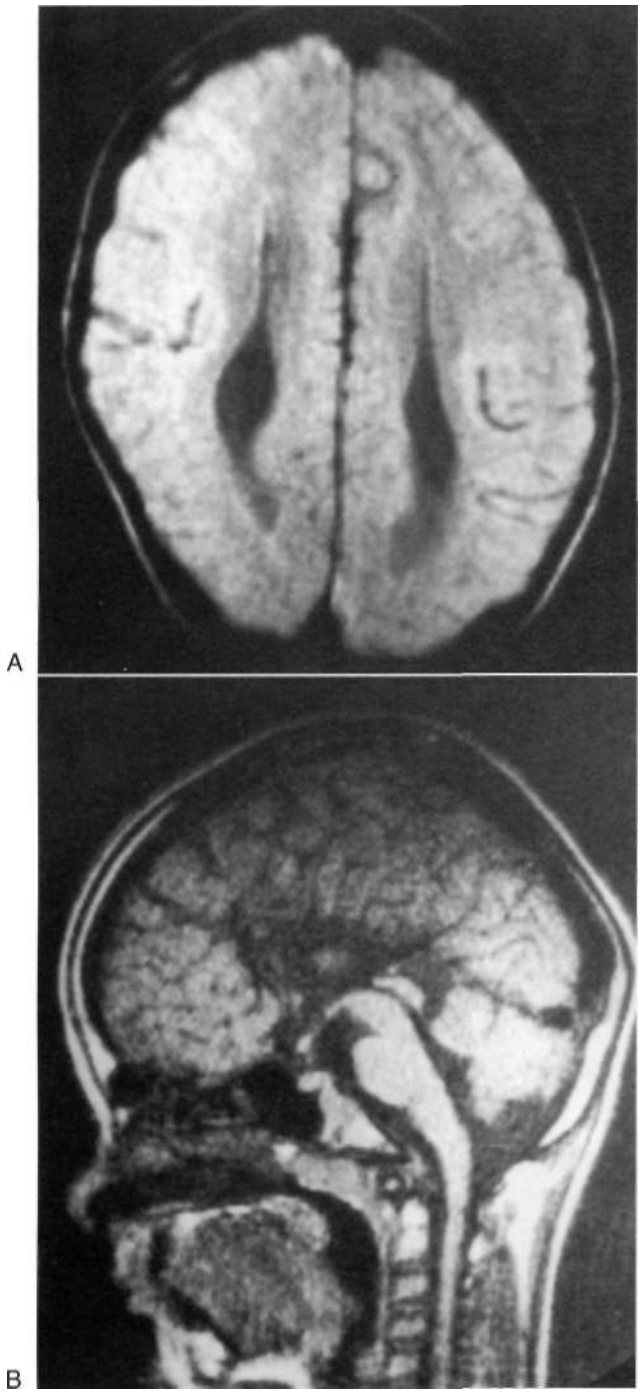

FIGURE 37A.51 Agenesis of corpus callosum. (A) Tl-weighted axial image shows separated and parallel lateral ventricles. (B) Sagittal Tl-wcightcd image shows absence of a midline corpus callosum.

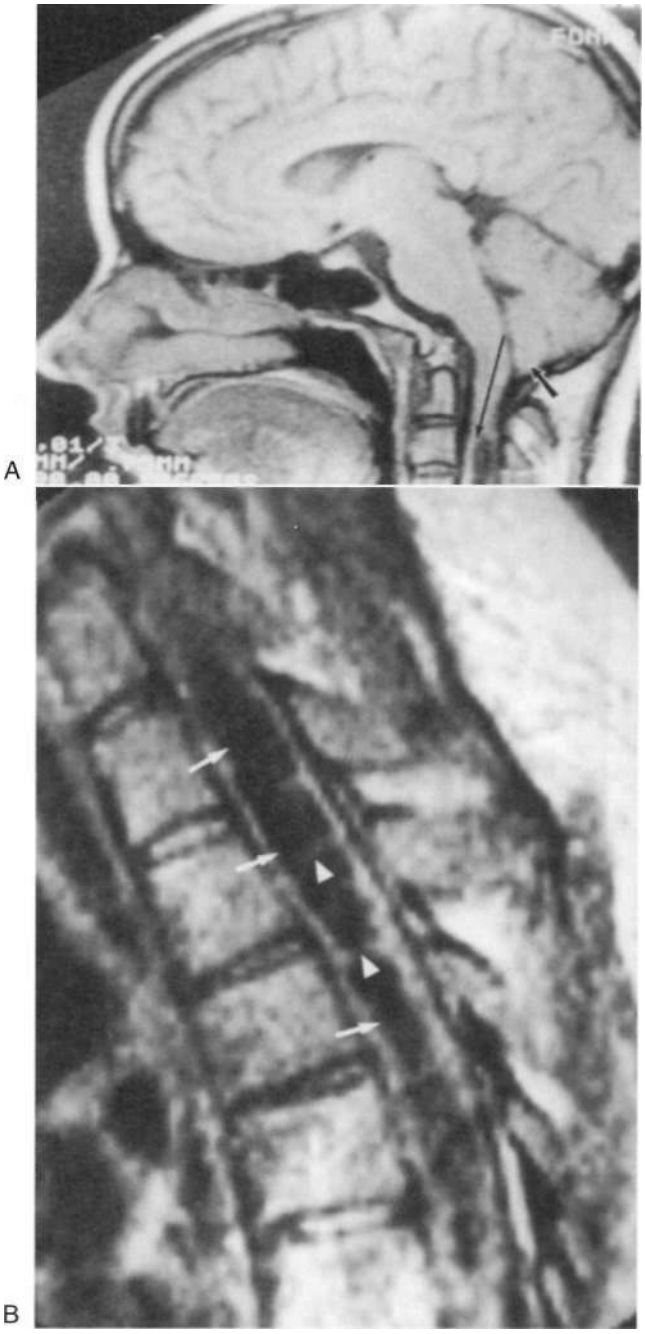

FIGURE 37A.S2 Chiari I malformation with syringohydromyelia. (A) Sagittal Tl-weighted image shows the tonsils extending below the foramen magnum *{arrow).* The very superior aspect of an intramedullary cyst is seen *(long black arrow).* (B) The sagittal T1-weighted image of the cervical spine in the same patient demonstrates a syringohydmniyeliu of the cervical spine *(arrows).* There are multiple scptations within the syrinx *(arrowheads),* and the cord is widened.

The Chiari II malformation is a dysgenesis of the hindhrain that results in a caudally displaced fourth ventricle and medulla. The essential feature is the pathologic downward displacement of the fourth ventricle extending into the cervical canal so that nonvisualization of the fourth ventricle is common. Anomalies associated with Chiari II include lukcnschadel skull (pitting of the skull), clivus and petrous scalloping, enlarged foramen magnum, myelomeningocele, dural anomalies (widened tentorial incisura), hindhrain and midhrain

anomalies (bcaking of the tectum; Figure 37A.53), and forehrain anomalies.

Dandy-Walker Syndrome. In Dandy-Walker syndrome, there is cystic enlargement of the fourth ventricle and hypoplasia of the vermis (Figure 37A.54). The tentorium, torcula, straight sinus, and vein of Galen arc displaced superiorly.

Aqucductal Stenosis. The causes of aqueductal stenosis include infection, Chiari II malformation, and neoplasm, although many cases are idiopathic. Chiari II malformation is the most common cause of hydrocephalus and aqueductal stenosis in early childhood. The lateral and third ventricles are moderately to severely enlarged (Figure 37A.55A). If Chiari II malformation is not present, the fourth ventricle usually is normal in size (Figure 37B.55B).

FIGURE 37A.53 Chiari II malformation. (A) Beaking of the tectum *(arrows)* is demonstrated in the axial computed tomographic scan of a patient with a Chiari II malformation. (BJ Tl-weighted sagittal image in another patient shows marked hydrocephalus, an enlarged massa intermedia *(arrow)*, and bcaking of the tectum *(white arroivhead)*. The fourth ventricle *(open arrow)* is not caudally displaced in this patient.

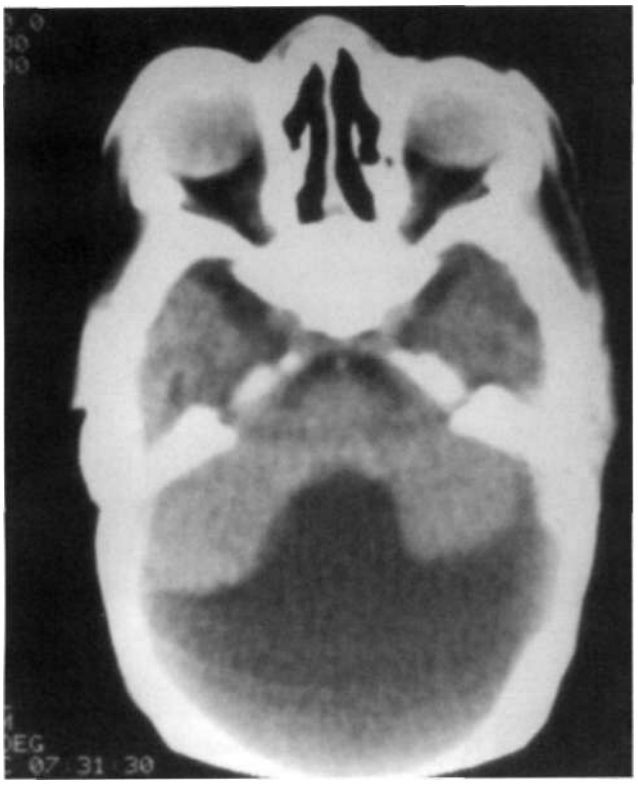

FIGURE 37A.54 Dandy-Walker syndrome. The fourth ventricle is replaced by an enlarged midline cyst in the axial computed tomographic scan. Note the hypoplasia of the vermis.

Disorders of Sulcation and Migration

Heterotopias. Heterotopias have classically been separated into three forms:

- The nodular form consists of subependymal nodules of gray matter that arc usually bilateral.
- The bulk form consists of islands of gray matter that are usually isolated in the hemispheric white matter (Figure 37A.56).
- In band heterotopia, alternating layers of gray and white matter are symmetrical throughout both hemispheres.

Schizencephaly. Schizencephaly is a disorder in which there are clefts spanning the cerebral hemispheres. Pathologically, these clefts are characterized by an infolding of the gray matter along the cleft from the cortex into the ventricles. There are two groups: those in which the walls of the cleft are fused (closed lip schizencephaly; Figure 37A.57) and those in which the walls of the cleft are separated (open lip schizencephaly).

Destructive Lesion

Hydranencephaly. In hydranencephaly, there is virtual absence of the cerebral hemispheres except for the basal ganglia. The infra tentorial structures are intact (Figure 37A.58). A severe and early intrauterine vascular accident is the presumed cause.

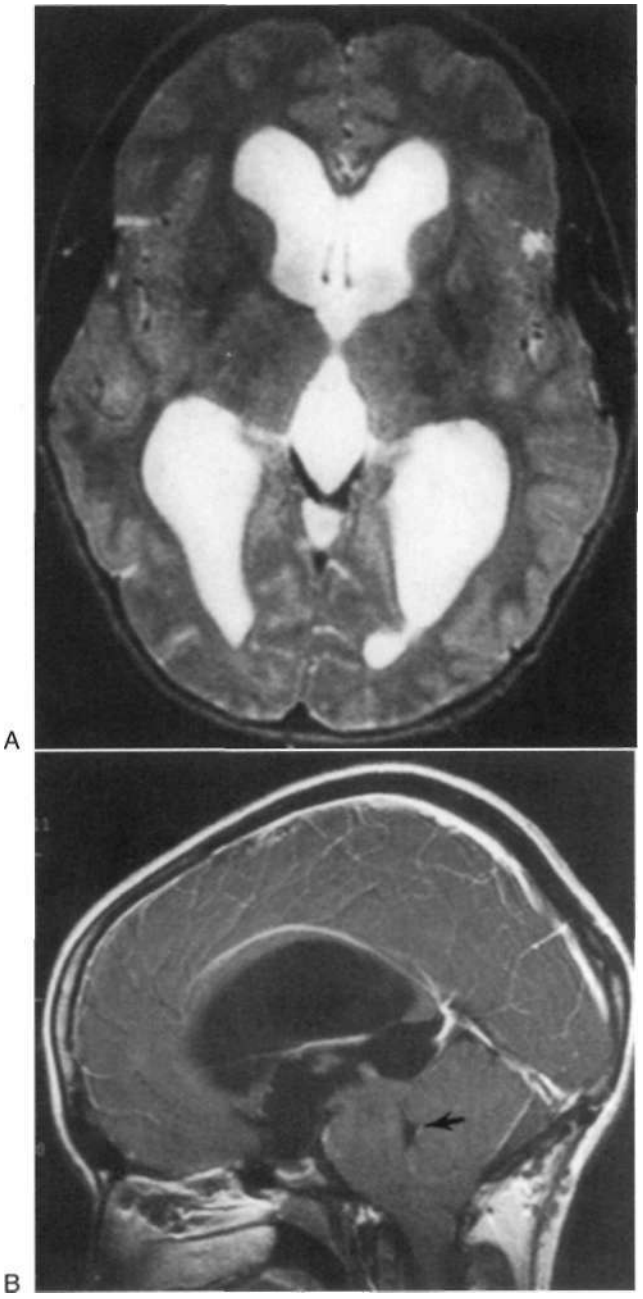

FIGURE 37A.55 Aqucductal stenosis. (A) T2-weighted axial magnetic resonance imaging demonstrates markedly dilatated lateral and third ventricles. (B) The sagittal TI-weighted image (postcontrast) shows the marked dilatation of the lateral and third ventricles hut a small fourth ventricle *{arrow).* The posterior fossa is small, and the aqueduct is not well seen.

Disorders of Histogenesis

Tuberous Sclerosis. Hamartomas, the most common lesions seen on MRI in patients with tuberous sclerosis,

FIGURE 37A.56 Heterotopia. Bulk form of heterotopia is seen as an island of gray matter that is isolated in the hemispheric white matter. This island of tissue *{arrows)* has the signal characteristics of gray matter on this T2-weighted image.

are isointense on T1- and hyperintense on T2-weightcd images (see Chapter 71). Subependymal nodules usually are multiple and bilateral; they often calcify and usually are isointense to hyperintense on Tl-weighted images and hyperintense on T2-weighted images. These subependymal hamartomas may degenerate into a giant cell astrocytoma (see Figure 37A.11), which is most often found near the foramen of Monro.

Neurofibromatosis. Neurofibromatosis is the most common of the neurocutaneous syndromes. There are two genetically distinct types: neurofibromatosis type 1 and type 2.

Neurofibromatosis Type 1. Neurofibromatosis type 1 is inherited as an autosomal dominant disease and is also called *peripheral neurofibromatosis* or *von Recklinghausen's disease.* The CNS and calvarial manifestations are diverse and include gliomas of the optic nerves and chiasm (see Figure 37A.27); gliomas in other areas of the brain; neurinomas and neurofibromas of the cranial, spinal, and peripheral nerves; dysplasia of the sphenoid bone and orbit; plexiform neurofibromas of the scalp and elsewhere; and hyperintense brain lesions demonstrated on MRI with T2-weighted images.

Neurofibromatosis Type 2. Neurofibromatosis type 2, also called *central neurofibromatosis,* is inherited as an

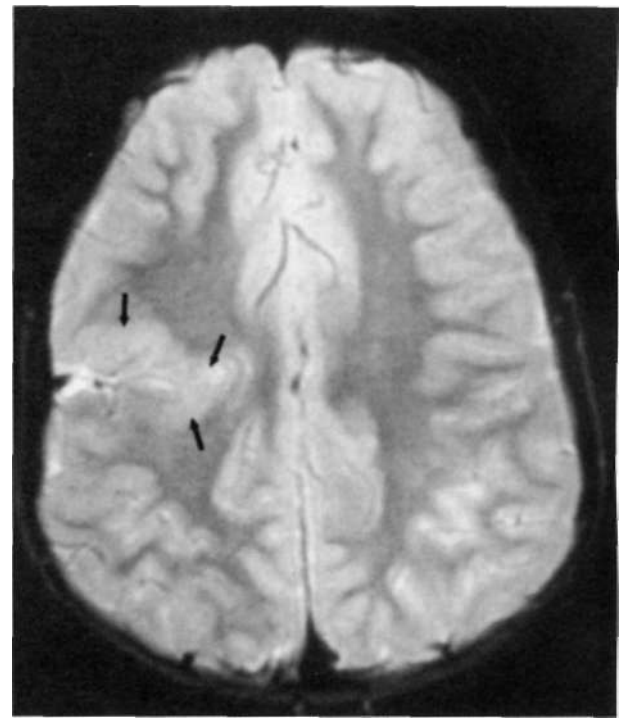

FIGURE 37A.57 Schizencephaly. Closed lip schizencephaly appears as a cleft lined by gray matter extending through the full thickness of the cerebral mantle. The island of tissue has the signal characteristics of gray matter on this T2-weighted image *(arrows).*

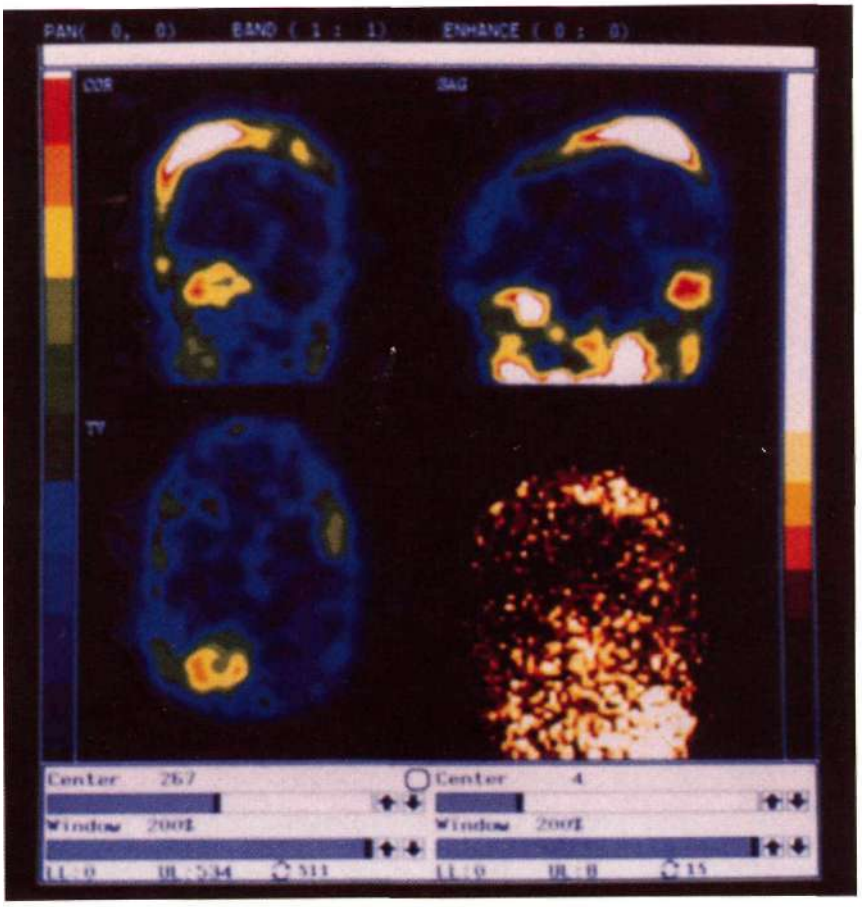
FIGURE 37A..S8 Hydranencephaly. Absence of the cerebral hemispheres, with intact basal ganglia and infratentorial structures.

PLATE 37A.I Brain single photon emission computed tomographic images with thallium-201 demonstrate a focal region of increased uptake corresponding to the same location as the lesion seen on computed tomographic scan (see Figure 37A.47). This is a biopsy-proven lymphoma. (Reprinted with permission from Ruiz, A., Ganz, W. L., Post, M. J. D., et al. 1994, "Use of thallium-201 brain SPECT to differentiate cerebral lymphoma from toxoplasma encephalitis in AIDS patients," *Am J Neuroradiol*, vol. 15, pp. 1885-1894.)



autosomal dominant disease. The diagnostic criteria for neurofibromatosis type 2 include bilateral eighth nerve schwannomas (see Figure 37A.28) or a unilateral eighth nerve schwannoma with two of the following: neurofibroma or schwannoma in a different location, meningioma, glioma, or a relative with neurofibromatosis type 2, This entity is genetically different from that of neurofibromatosis type 1 and hence optic nerve gliomas, skeletal dysplasias, and cutaneous neurofibromas are rare.

Vascular Disorders

Vascular Malformations

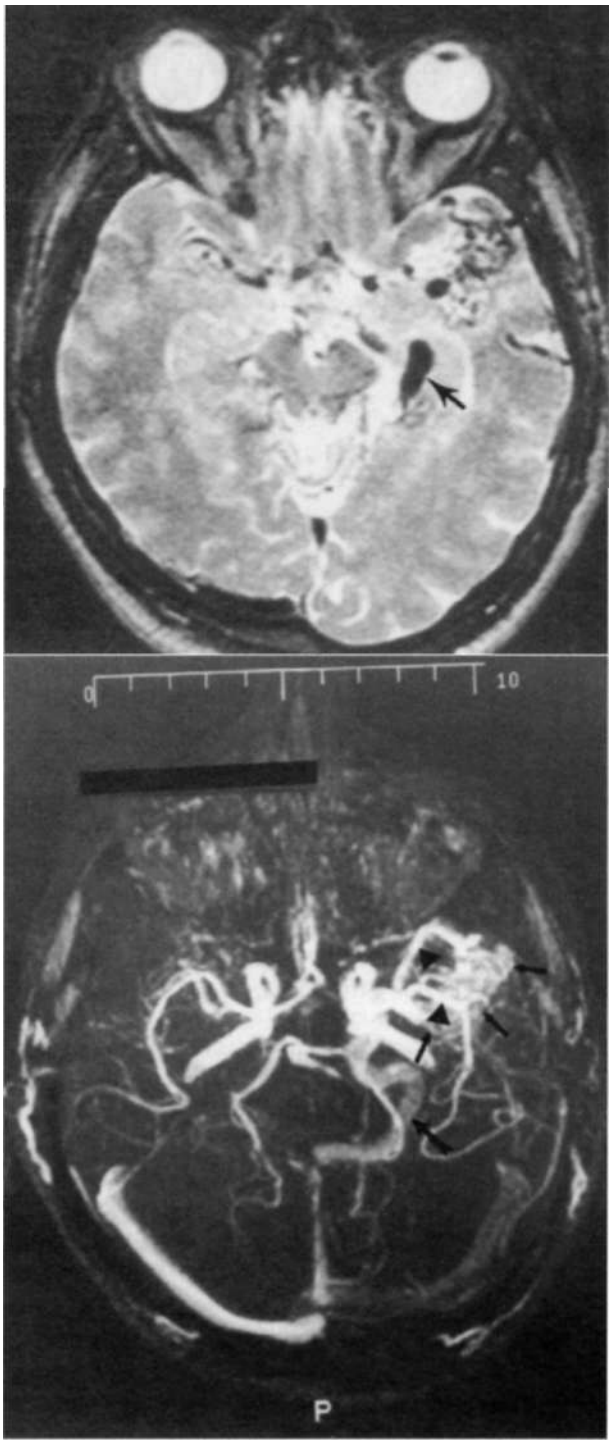
Vascular malformations have been divided into four major types: AVM, cavernous angioma, capillary telangiectasia, and venous angioma (see Chapter 57D).

Arteriovenous Malformation. Cerebral angiography is the definitive method of accurately delineating the vascular supply and venous drainage of intracranial AVMs. Morphologically, AVMs appear as wedge-shaped clusters of vessels with the apex directed toward the ventricular surface. The typical AVM appears on spin-echo MRI as a cluster of focal round lesions or serpentine areas of signal void (Figure .37A.59). At this time, conventional angiography is superior to MRA in depicting the arterial supply and venous drainage of the AVM.

Cavernous Angioma. Cavernous angiomas are discrete, multilobulated, berrylike lesions rhat contain hemorrhage in various stages of evolution. They may be found in any part of the brain; most are supra tentorial and are generally in the frontal and temporal lobes. In the posterior fossa, the pons and cerebellar hemispheres are the most common sites. Most are not detected by angiography, but occasionally a faint blush can be seen in the late capillary or venous phase. On CT, these lesions may be isodense to hyperdense in noncontrast scans, and calcification is common. MRI is the best modality for demonstrating cavernous angiomas, showing a popcorn-like lesion of mixed signal consistent with hemorrhage in different stages.

Capillary Telangiectasia. Capillary telangiectasias are small, angiographically silent or occult vascular malformations, usually revealed on magnetic resonance gradient-echo sequences by the presence of small punctate or nodular areas of dark signal ("blooming") due to the susceptibility effect caused by the presence of hemosiderin in the lesion. They may be single or multiple and may cause seizures. Capillary telangiectasias may be associated with neurocutaneous syndromes such as those of Rendu-Osler-Weber and Wyburn-Mason.

Venous Angioma. Venous angiomas are clinically silent malformations of venous drainage without an arterial



B

FIGURE .17A.59 Arteriovenous malformation (AVM). (A) Long repetition time-echo time spin-echo magnetic resonance image shows a wedge-shaped cluster of vessels in tlie left temporal lobe seen as linear and round areas of signal void. Note enlarged draining vein *{arrow).* (B) Magnetic resonance angiogram formed by a three-dimensional rime-of-flight volume slab through the base of the skull and circle of Willis shows an AVM *(small black arrows)* in the left temporal lobe. Feeding vessels arise from the left middle cerebral artery *{arrowheads).* A large medially draining vein is seen (probably a peri mesencephalic vein; *large arrow).*

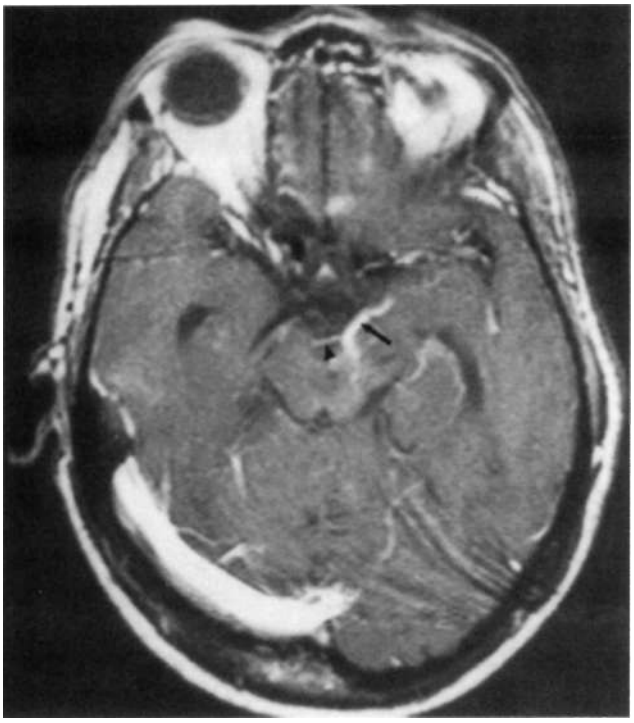


FIGURE 37A.60 Venous angioma. Postcontrast axial Tl-weighted image shows a prominent vein coursing within the left crural cistern *{arrow).* It is receiving multiple small feeding veins from within the substance of the midbrain *{arrowhead}.* These findings are typical of a venous angioma.

component. Imaging studies delineate typical curvilinear vascular channels receiving drainage from a spoke wheel-appearing collection of small tapering veins arranged in a radial pattern (Figure 37A.60). The larger draining veins empty into a targe cortical vein, a dural sinus, or a subependymal ventricular vein.

Spinal Arteriovenous Malformations

Most spinal vascular malformations are AVMs or AVFs. AVMs have a nidus of vessels and arc fed by enlarged feeding arteries and drain via large veins. AVFs drain directly into enlarged venous outflow tracts. Spinal vascular malformations have been subdivided into four groups. Type I are dural AVFs, which are found mostly in the dorsal aspect of the lower thoracic spine. Type II are intramedullary AVMs that drain into a venous plexus that surrounds the cord and usually are located in the cervicomedullary junction. Type III are larger vascular masses that involve the cord and often have extramedullary extension. Type IV are intradural extramedullary AVFs. Most are anterior to the spinal cord and occur near the conus mcdullaris.

MRI may show foci of flow void in enlarged vessels. The cord may be atrophic and often has high signal intensity on T2-weighted images. MRA is a good modality for evaluating these lesions, although spinal angiography has been the definitive diagnostic procedure for evaluating spinal AVMs. Myelography may show filling defects caused by the enlarged vessels, but since the advent of MRI, the flow voids, flow enhancement in enhanced veins, and flow-related enhancement on MRA make myelography unnecessary in the majority of cases.

Cerebral Infarction

In the first 24 hours after an arterial occlusion with infarction, 80% of **MRI** scan results are positive, compared with 50% of CT scans. These infarcts are seen as regions of subtly increased signal on T2-weighted images. At this stage the abnormalities arc mostly in the gray matter. In infarcts 2 days to 3 weeks old, the subtle signal intensity changes seen initially become more obvious with increasing signal intensity on long TR images. White matter and gray matter abnormalities then are seen. In 20% of cases there is a hemorrhagic component with increased signal seen on Tl-weighted images if the stroke is greater than approximately 48 hours old. More acute hemorrhagic strokes reveal hypointense to isointense areas on MRI, with factors such as field strength and pulse sequence playing an important role in the appearance. MRI is the most sensitive, accurate, and practical means of imaging acute strokes.

The MRI of an infarct 3-6 weeks old is characterized by a smaller and better-defined zone of signal changes. The signal intensity on T2-weighted images is greater because of cystic cavitation. Focal atrophy is also present due to a loss of tissue volume.

A crucial factor in stroke management is the determination of a hemorrhagic component in the infarct (Figure 37A.61). Acute hemorrhage may not be as obvious on MRI as on CT, especially if gradient-echo scans have not been done. Hyperacute hemorrhagic lesions may not have adequate time for the accumulation of dcoxyhcmoglobin, so CT scans may be more revealing in the early stroke period.

The pattern of cerebral infarction resulting from blood vessel occlusion depends on vascular anatomy, and the signal changes closely follow the anatomical distribution of the arteries (Figure 37A.62). In the case of proximal disease and infarcts caused by systemic hypotension, the anastomotic border zones {watershed zones) between major vascular territories are involved most severely.

MRI is superior to CT in evaluating infarcts in posterior fossa structures because CT resolution is limited by skull-base artifacts. Infarcts in the brainstem are small in relation to the extent of clinical damage. The small size of these lesions, in addition to the fact that these patients may be neurologically devastated and therefore poor candidates for MRI, sometimes make these lesions difficult to evaluate.

The vessel most often involved in embolic disease is the middle cerebral artery. Smaller, more peripheral infarcts are common with embolic disease. If emboli are multiple, more

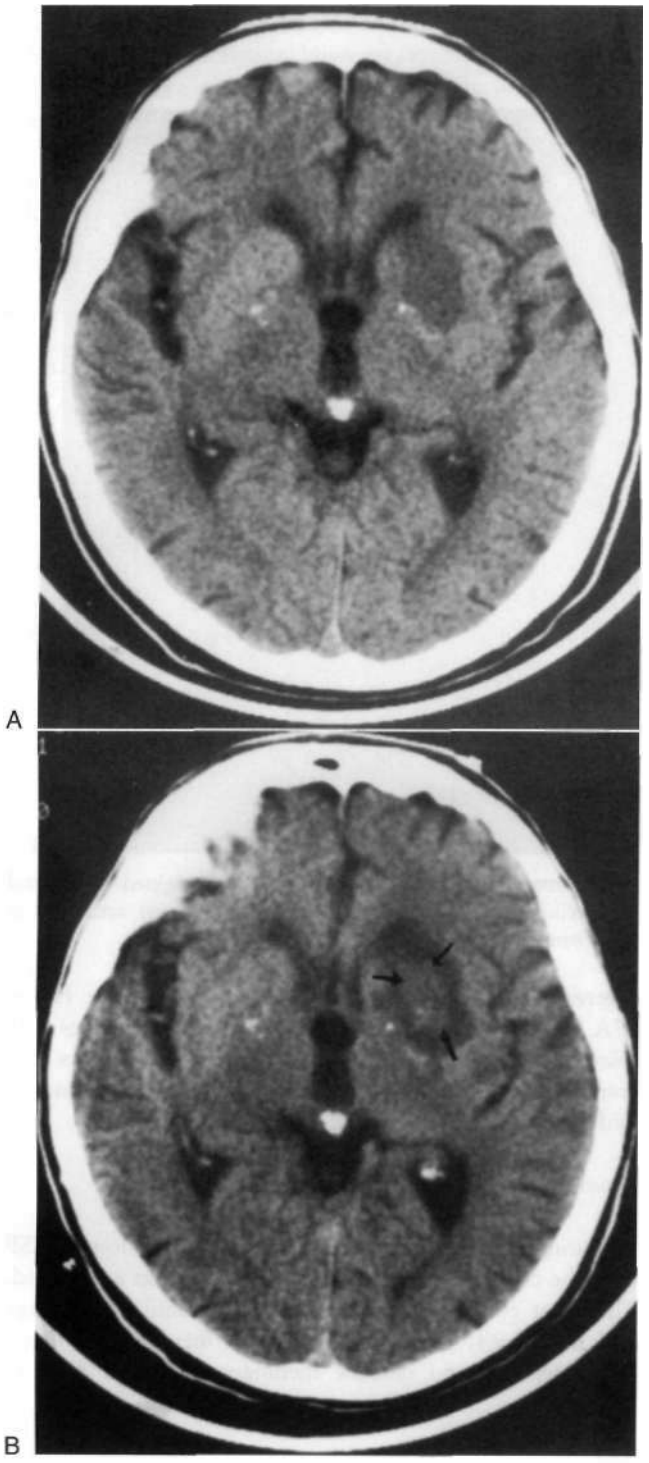

FIGURE 37A.61 Cerebral infarct. (A) Noncontrast computed tomographic scan shows infarct involving left basal ganglia. Incidental basal ganglionic calcifications are seen. (B) Three days later the computed tomographic scan shows hemorrhage (*arrows*) in the area of infarction.

than one vascular territory may be involved. The origin of small, deep infarcts in the capsular and ganglionic regions is unclear. During the chronic stage, these small infarcts resolve to become small cystic lesions, the typical lacunae.

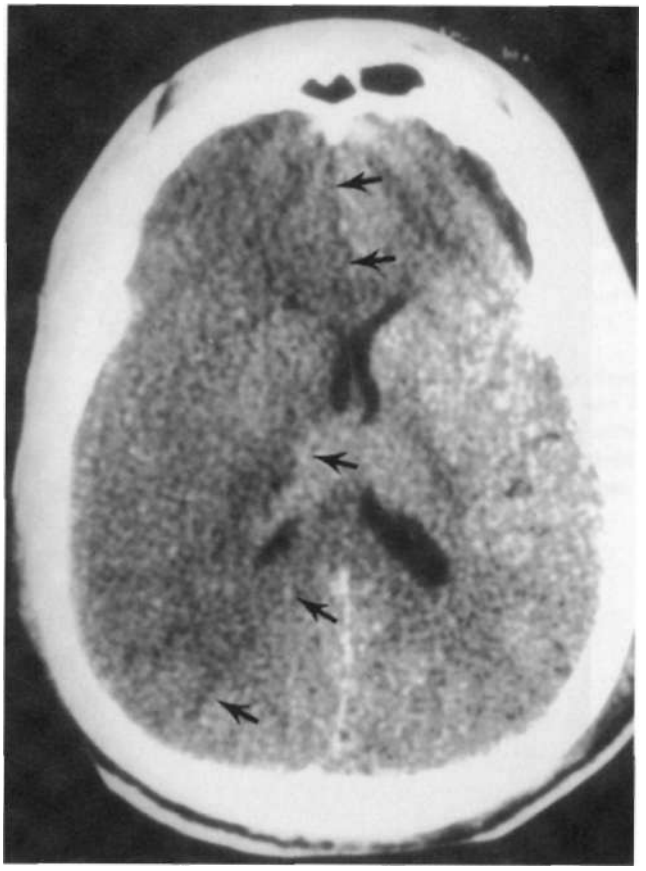

FIGURE 37A.62 Right hemisphere infarct. Noncontrast computed tomographic scan demonstrates a low-density lesion *(arrows)* involving the right frontal, temporal, and parietal lohes in a patient who sustained a hullet injury to the skull, with injury to the right internal carotid artery.

Hemorrhage and Magnetic Resonance Imaging

Acute hemorrhage consists of intact red blood cells and plasma. Intracellular oxyhemoglobin is converted to deoxyhemoglobin (Figure 37A.63), which is then oxidized to methemoglobin (from the periphery to the center). Subsequently, as a result of red blood cell lysis, intracellular methemoglobin becomes free methemoglobin, and hemosiderin concomitantly appears in the periphery. Eventually, methemoglobin is resorbed, and only a hemosiderin cleft remains. As the hemorrhage evolves, each of the stages has unique Tl and T2 relaxation times on MRI, This allows us to determine the age of the hematomas (Table 37A.1).

Hydrocephalus

Hydrocephalus is considered to be present when there are enlarged ventricles in the absence of atrophy or dysgenic brain (see Chapter 65). Therefore, a clear difference exists between hydrocephalus and ventriculomegaly

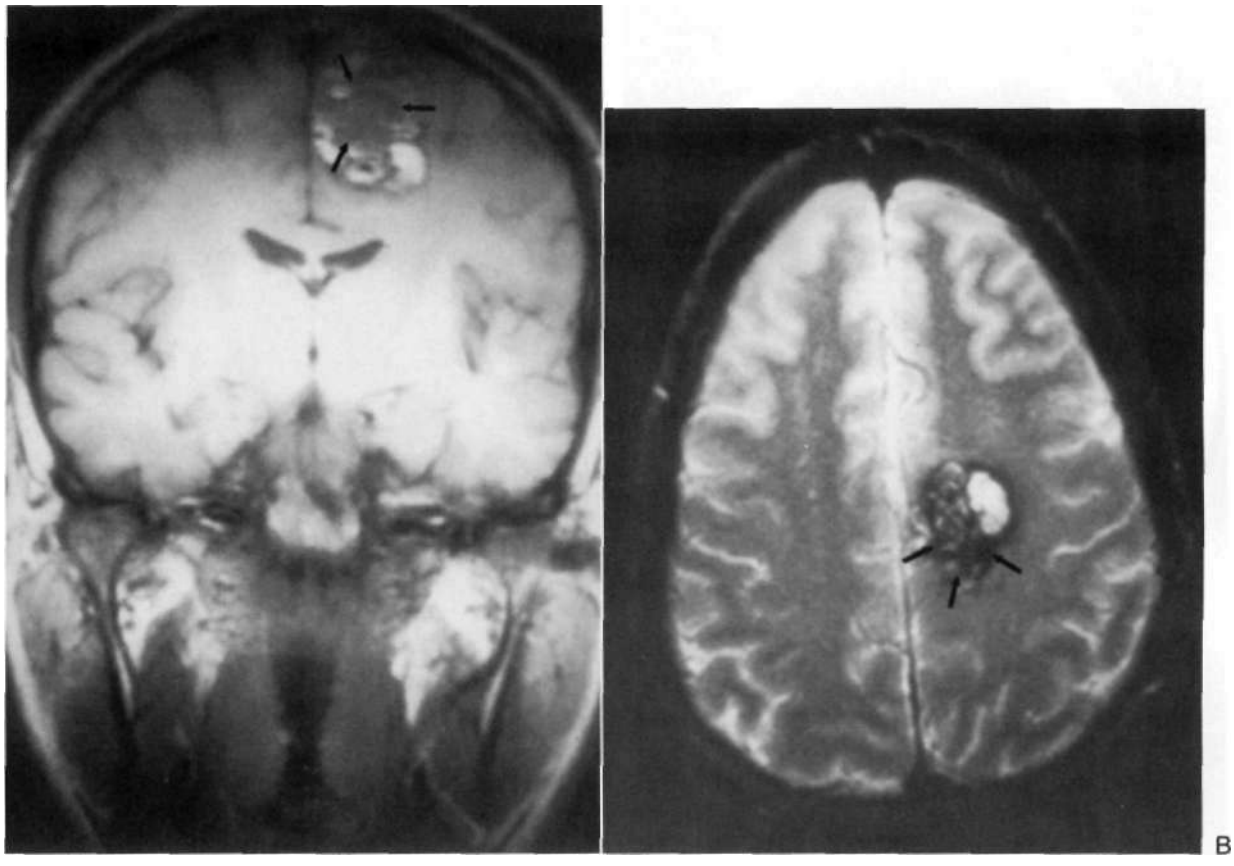

FIGURE 37A.63 Acute hematoma. There is a central area that is isointcnse to brain *{arrows)* in (A) Tl-weighted image and hypointcnsc *{arrows)* in {B) T2-weighred image, consistent with intracellular deoxy hemoglobin, and a peripheral area that is hyperintense in both Tl and T2 images, consistent with extracellular met hemoglobin,

because the latter indicates large ventricles regardless of the cause, CT and MRI can characterize the different patterns of ventricular enlargement to determine the cause,

Obstructive or Noncommunicating Hydrocephalus

The hallmark of obstructive noncommunicating hydrocephalus is ventriculomegaly proximal to the site of obstruction with the common associated finding of periventricular edema secondary to transependyma! flow of CSF. The site of obstruction is determined by the characteristic ventricular dilatation. Aqucductal obstruction produces dilatation of the third and lateral ventricles, whereas the fourth ventricle remains normal (see Figure 37A.55). A colloid cyst of the third ventricle produces only dilatation of both lateral ventricles. Cerebellar tumors may compress the fourth ventricle and cause obstructive hydrocephalus.

Communicating Hydrocephalus

In communicating hydrocephalus, the normal flow of CSF over the cerebral convexities and its resorption arc altered. The most common causes are subarachnoid hemorrhage and meningitis. However, seeding of meninges by metastatic diseases and chronic meningoencephalitic diseases

Table 37A.1: Blood breakdown products in intracerebral hemorrhages

		Signal intensity	
Time	*Type of blood product*	*T1 weighting*	*T2 weighting*
0–24 hr	Oxyhemoglobin	–/=	+
First 24 hr to 3–5 days	Deoxyhemoglobin	–/=	–
3–7 days	Intracellular methemoglobin	+	–
1 wk to months	Extracellular methemoglobin	+	+
1–2 wk to years	Hemosiderin	=	–

= decreased; – = marked decrease; + = increased; = = unchanged.

such as sarcoidosis may result also in hydrocephalus. On imaging, all the ventricles are dilatated and the sulci are effaced.

Normal Pressure Hydrocephalus

The classic clinical triad of normal pressure hydrocephalus (NPH} is dementia, gait apraxia, and urinary incontinence (see Chapter 65). Positive isotope cisternography of NPH shows reflux of the isotope into the ventricles after injection of the isotope into the lumbar thecal sac but no passage of isotope over the cerebral convexities. However, degenerative disorders also may show abnormal CSF flow, so this study is not entirely conclusive. The distinction on MRI or CT of atrophy from NPH is difficult. NPH usually causes uniform thinning and elevation of the corpus callosum and distention of the third ventricle, dilatating the optic and infundibular recesses. The normal CSF flow void in the aqueduct may be accentuated in NPH. There may or may not be periventricular transudation of fluid into the parenchyma in NPH.

SKULL BASE LESIONS

MRI has become an essential part of the evaluation of skull base lesions; it can show the margin of the tumor relative to vital structures such as the cavernous sinus and the relationship to the carotid artery. Often, it can differentiate tumor from an obstructed paranasal sinus. Fat is found between the various muscle groups beneath the skull base. As the tumor invades this fat, the normal high signal on Tl-weigbted images is obliterated by the intermediate signal of the tumor. This is especially important in detecting tumor extension through the various neural foramina. For definition of fine cortical bony erosion at the base of the skull, CT is needed.

Nasopharyngeal Carcinoma

Squamous cell carcinoma, the most malignant tumor seen in the nasopharynx, tends to be locally invasive and erode through the skull base into the intracranial cavity {Figure 37A.64). Tumor may extend through the petroclival suture and foramen lacerum into the posterior fossa and into the inferior aspect of the cavernous sinus.

Petrous Apex Lesions

The two major lesions occurring in the pettous apex are the primary cholesteatoma, or epidermoid tumor, and the granulomatous cholesterol cyst. The latter results from air cells that have been partially obstructed by chronic otitis media and filled with liquid cellular debris and hemorrhage. An epidermoid (pearly) tumor tends to be low signal on Tl-weighted images and bright on T2-wcighted images.

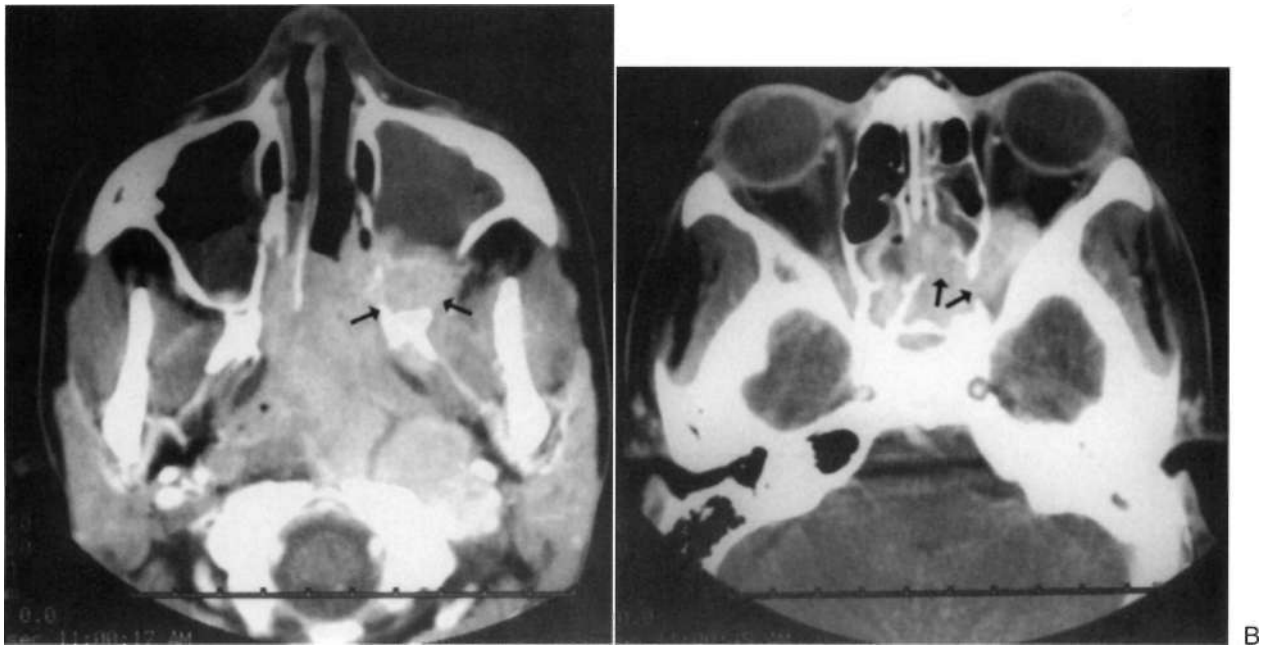

FIGURE 37A.64 Nasopharyngeal carcinoma. (A) Axial computed tomographic scan after contrast administration demonstrates a mass in the nasopharynx, which extends anteriorly to involve the nasal cavity and left maxillary sinus. The lesion is invading the left pterygopalatine fossa *{arrows).* There is bony destruction of the posterior walls of the left maxillary sinus and lateral wall of the nasal cavity. Tin.[1] IIUSS extends posteriorly to the prevertebral space and laterally involves the left carotid space. (B) The mass extends superiorly to involve the ethmoids and left orbit *(arrows).*

The granulomatous cholesterol cyst is bright on both sequences because of the tccurrcnt hemorrhage.

Signal voids representing blood flow scattered throughout the lesion arc characteristic.

Glomus Jugulate Tumor

Glomus jugulare tumor (paraganglioma) arises in the lateral portion of the jugular foramen. There can be significant extension inferiorly beneath the temporal hone and intracranially. On Tl-wcighted images these lesions usually are of intermediate signal intensity, and on Tl-wcighted images they ate hyperintense (Figure 37A.65).

Chordoma

Chordoma is a tumor of notochordal origin that is seen mainly in the sacium and the clivus. Those originating at the clivus level usually grow and spread through the duta into the middle or postetiot cranial fossa and compress the brainstem. They may extend anteriorly into the nasopharynx and often develop calcification,

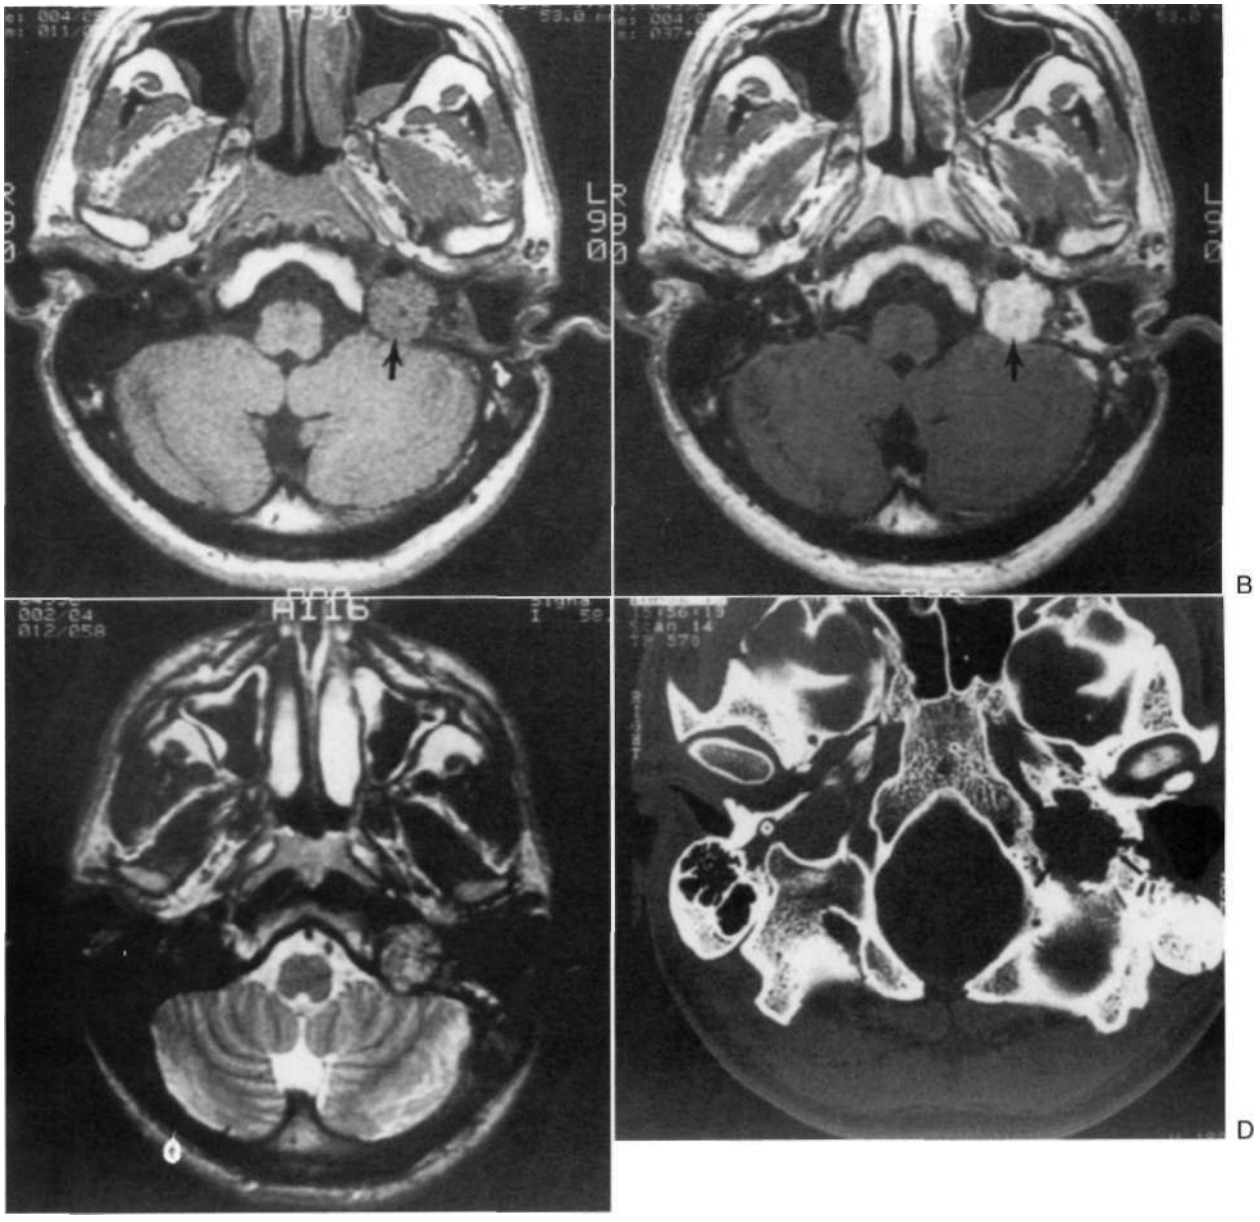

FIGURE 37A.65 Glomus jugulare tumor. Axial Tl-weighted images (A) before and (B) after intravenous administration of gadolinium show a lesion in the region of the jugular foramen, which enhances densely *(arrows).* (C) Axial T2-weighted image demonstrates an isointense to hypointcnse lesion, which has a few signal voids. (D) Computed tomographic scan using bone technique through the skull base shows erosion of the jugular foramen *(arrows).*

On Tl-weighted MRI, a chordoma is seen as a moderately hypointense lesion that replaces the hyperintense clival fat (Figure 37A.66). On T2-weighted images chordomas usually are hyperintense, and calcifications that may be present are seen as hypointensities in the mass (Figure 37A.67). CT shows the bony erosion and calcification to best advantage.

Chondrosarcoma

Chondrosarcoma may arise from the base of the skull, commonly in the region of the petroclival suture. It may have an endochondral hone, cartilaginous, or bony origin. On CT and **MRI,** an erosive, destructive lesion of the skull base or a mass compressing the brainstem may be found. Calcification due to bony lysis or calcium deposition in the tumor may be seen. The tumor spreads by local invasion and rends to recur after surgical removal. The tumor may also arise from the nasopharynx, vomer, and sphenoethmoidal regions and invade the skull base.

ORBITAL LESIONS

Orbital Tumors

Hemangiomas

Hemangiomas are the most common primary tumor of the orbit. Capillary hemangiomas are seen in childhood and cavernous hemangiomas in adults. Capillary hemangiomas appear during the neonatal period and not later than the first 2,5 years of life. They show an infiltrating gtowth (Figutc 37A.68) but may regress spontaneously. Cavernous hemangiomas have an insidious onset and never disappear on their own. They are well circumscribed and have an encapsulated pattern. On imaging, the cavernous hemangioma demonstrates a well-circumscribed intraconal orbital lesion (Figutc 37A.69). On MRI these lesions are of low intensity on Tl-weighted images, are markedly hyperintense on T2-weighted images, and enhance with contrast. With MRI the precise delineation of the mass and its relation to the optic nerve and muscle cone can be determined, which is important in the surgical planning.

Lymphangioma

Lymphangioma is a vascular lesion that is less common than hemangioma. Most of these lesions present at a young age. They show slow progressive growth without regression, and because they ate likely to hemorrhage, sudden symptoms such as proptosis are possible. On MRI these lesions ate hetctogeneous with areas of hemorrhage of varying ages and with regions of cystic change.

Dermoid Lesions

Dermoid lesions are derived from congenital epithelial cell rests. They contain sebaceous glands and other skin appendages. In their growth, they may expand the inner and outer tables of the skull and produce sharply demarcated bone defects with well-defined borders and slightly sclerotic margins. The usual site is in the orbital roof, near the orbital zygomatic suture, and the growth

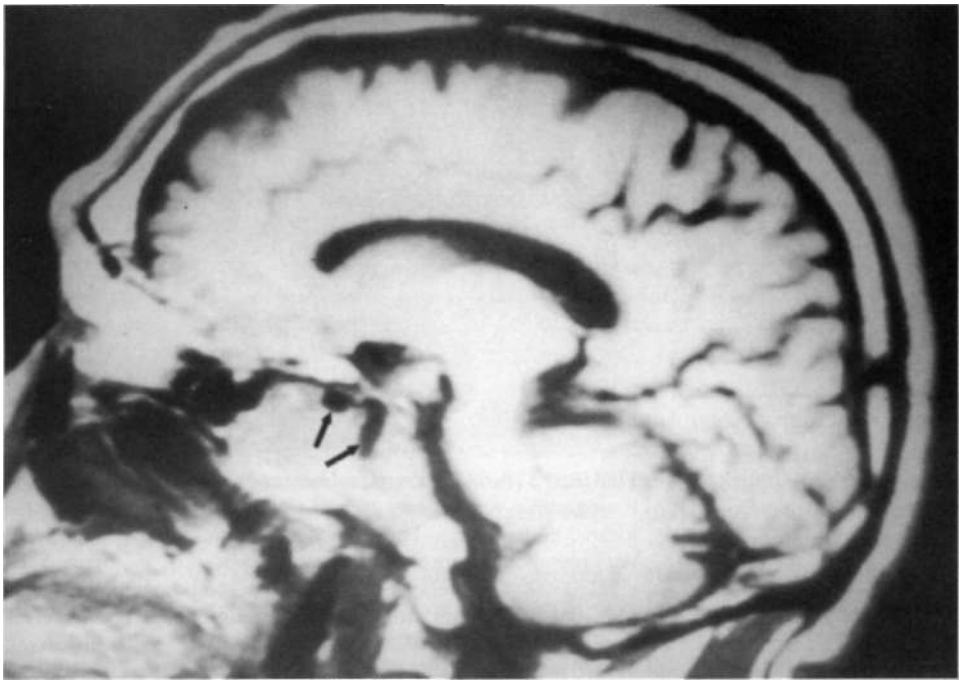

FIGURE 37A.66 Clival chordoma. Sagittal Tl-weighted image demonstrates lesion involving the clivus with destruction of the clivus and extension to the prepontine cistern and apparent encasement of the carotid artery *{arrows).*

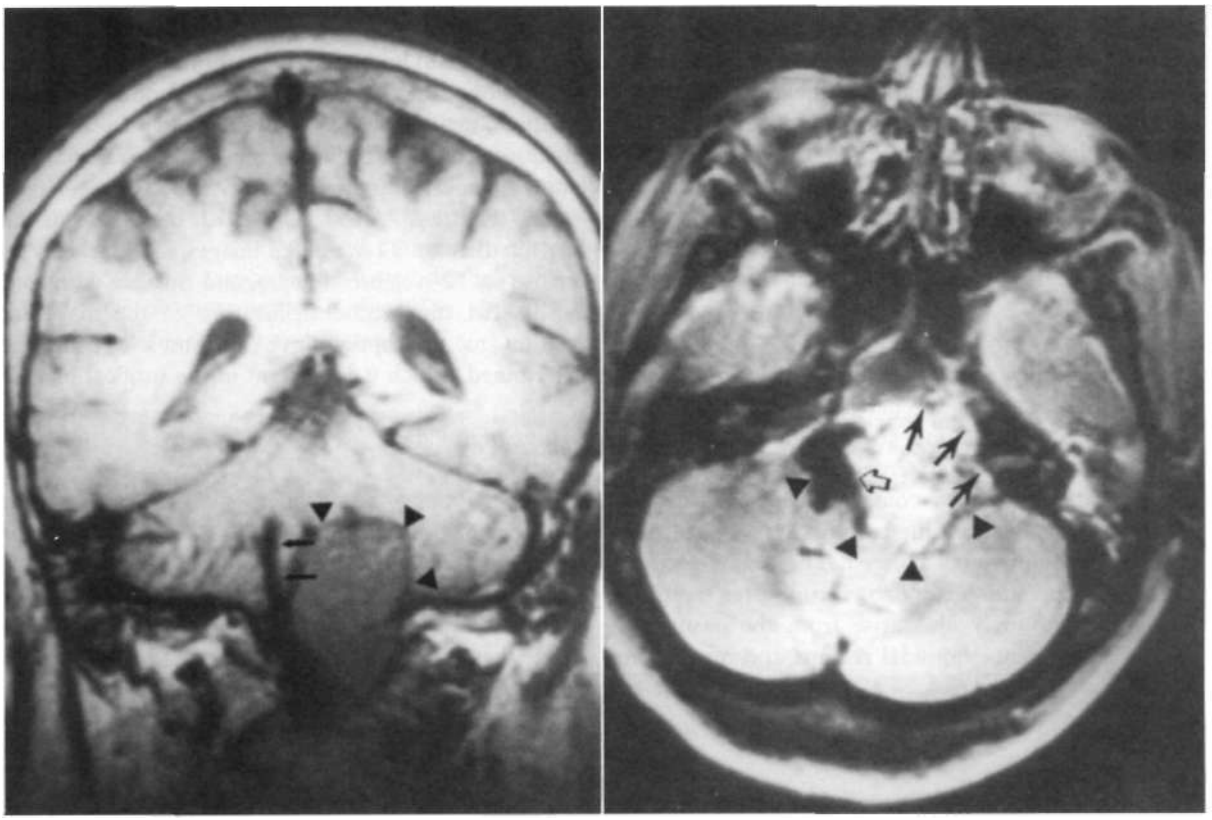

FIGURE 37A.67 Chordoma. Coronal (A) Tl-weighted and (B) T2-weighted axial images show a well-defined mass present in the prepontine cistern *{arrowheads).* Its extra-axial nature is suspected because of the presence of erosion of the clivus and petrous apex (large arrows in B). The small punctate areas that do not enhance are flecks of calcification in the tumor. The displaced basilar artery is outlined with black arrows in A *{white arrow* in B). These findings are typical for a primary clival chordoma. A meningioma is the major differential possibility for an extra-axial mass in this location, but the presence of bone erosion (B) would be atypical.

FIGURE 37A.68 Capillary hemangioma. Orbital computed tomographic scan of a capillary hemangioma after administration of contrast material. A large mass is noted, primarily in the left **orbit.** (Reprinted with permission from Sklar, E. M. L., Qucncer, R. M., Byrne, S. F., et al. 1986, "Correlative study of the computed tomographic, ultrasonographic and pathologic characteristics of cavernous versus capillary hemangiomas of the orbit,"/ *Clin NeuroOpbthalmol,* vol. 6, pp. 14-21.)

FIGURE 37A.69 Cavernous hemangioma. Orbital computed tomographic scan shows a well-circumscribed intraconal mass located in the temporal portion of the left muscle cone. (Reprinted with permission from Sklar, E. M. L., Qucncer, R. M., Byrne, S. F., et al. 1986, "Correlative study of the computed tomographic, ultrasonographic and pathologic characteristics of cavernous versus capillary hemangiomas of the orbit,'[1] / *Clin NeuroOphthalmol,* vol. 6, pp. 14-21.)

extends to involve the frontal bone. Less often they arise in the lateral wall of the orbit and rarely in the inferior wall. Focal areas of fat are identified easily on MRI. These lesions usually do not enhance.

Orbital Pseudotumor

An inflammatory lesion with acute onset usually occurring in middle age, orbital pseudotumor is difficult to differentiate clinically from a true orbital tumor. Some show spontaneous recovery, whereas others necessitate aggressive therapy, including systemic or local corticosteroid therapy or orbital decompression.

Pseudotumor causes diffuse inflammation and resultant edema. Thickening of the sclera may be seen (uveal-scleral pseudotumor), whereas in other cases there is a mass, extraocular muscle thickening, or diffuse orbital infiltration. Fluid surrounding the optic nerve may be seen as a thickened optic nerve. Obliteration of retrobulbar fat planes, an isolated lacrimal gland, or a retrobulbar mass may be seen. If the insertion of an extraocular muscle into the globe is involved, pseudotumor is a more likely diagnosis than thyroid eye disease.

On MRI, these lesions are isointense to muscle on TI-weighted images, but on T2-weighted images they are hyperintense, making a distinction between pseudotumor and lymphoma possible because orbital lymphoma is most commonly hypointense on T2-weightcd images.

Optic Nerve Glioma

Optic gliomas are low-grade pilocytic astrocytomas, which may be isolated abnormalities or may be associated with neurofibromatosis, especially if bilateral. Three fourths present by age 10 years. Some gliomas have extensive thickening of the pcrioptic meninges (peritumoral arachnoidal hyperplasia), which may be characteristic of patients with neurofibromatosis.

Optic nerve gliomas are isointense to normal white matter on Tl-weighted images, and enhancement with contrast is common. In a patient with an optic glioma, the entire visual pathway must be studied because a large number of these tumors involve the chiasm (see Figure 37A.27) and retrochiasmal pathways, extending to the level of the lateral geniculate bodies. A significant proportion of visual pathway gliomas are limited to the chiasm and retrochiasmal tracts, sparing the intraorbital optic nerve. The signal intensity varies with the site of involvement of the visual pathway. Specifically, intraorbital optic nerve masses are of low intensity on T2-weighted images, which may correlate with arachnoid hyperplasia. The chiasmal and retrochiasmal lesions tend to be hyperintense on T2-weighted images.

Optic Nerve Meningioma

Perioptic meningiomas account for one third of primary tumors of the optic nerve or sheath. Bilateral perioptic meningiomas may be associated with neurofibromatosis. In general, perioptic meningiomas arc most common in adults, and optic nerve gliomas occur in children.

These lesions often calcify and enhance markedly on CT (Figure 37A.70). MRI has a major advantage in evaluating optic nerve lesions; MRI allows visualization of the optic nerve directly and separates it from surrounding subarachnoid space and therefore distinguishes optic nerve

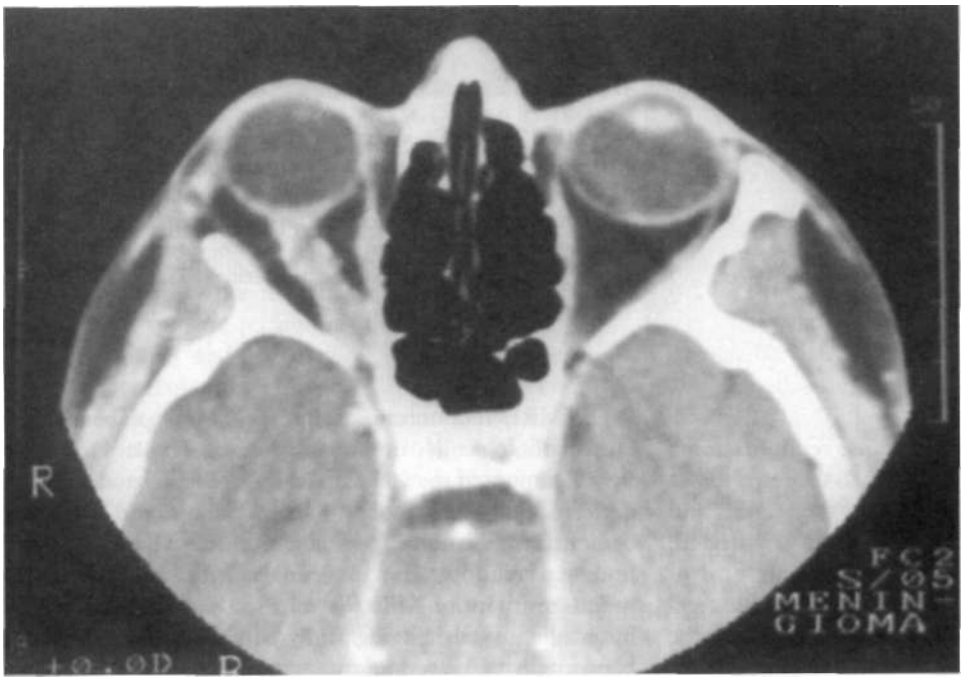

FIGURE 37A.70 Optic nerve meningioma. Con t ra st- e n h a n ccd computed tomographic scan shows the typical thickening and peripheral enhancement of the right optic nerve characteristic of a perioptic meningioma. Extension from die intrascleral portion of the optic nerve posteriorly to the orbital apex is noted.

lesions from sheath lesions. MRI can evaluate also the intracanalicular portion of the optic nerve. MRI signal intensity patterns are variable depending on the site of the lesions (i.e., perioptic versus cxtraconal intraorbital location). The majority of perioptic meningiomas enhance with contrast, and fat suppression techniques with contrast are helpful in delineating regions of gadolinium enhancement.

Ocular Lesions

Melanoma

Malignant melanoma is the most common intraocular malignancy in adults and usually is unilateral. MRI aids in the differential diagnosis of these lesions because there are other entities (such as choroidal metastases, choroidal nevi, choroidal hemangiomas, sarcoidosis, granulomas, and choroidal detachment) that can simulate a melanoma. Also, MRI helps delineate extraocular exrension, **which** occurs in 13% of cases.

On MRI, melanomas are focal masses that extend into the vitreous and enhance afrer contrast, a characteristic common to most ocular neoplasms (Figure 37A.71). In one series, the majority of melanomas were hyperintense on Tl-weighted images and were hypointense on Tl-weighted images because of their content of melanin, which has the paramagnetic characteristic of shortening of Tl and T2 relaxation times. However, melanomas may vary in their degree of pigmentation, and lesions may be amclanotic and then indistinguishable from other ocular lesions.

These lesions can be confusing because they can exhibit varying paramagnetic behavior when they are melanotic or hemorrhagic, and they are often associated with hemorrhagic retinal detachments. In general, MRI can distinguish a melanotic melanoma from an associated hemorrhagic (or nonhemorrhagic) subretinal fluid collection and from an amelanotic neoplasm on the basis of their intensity signals.

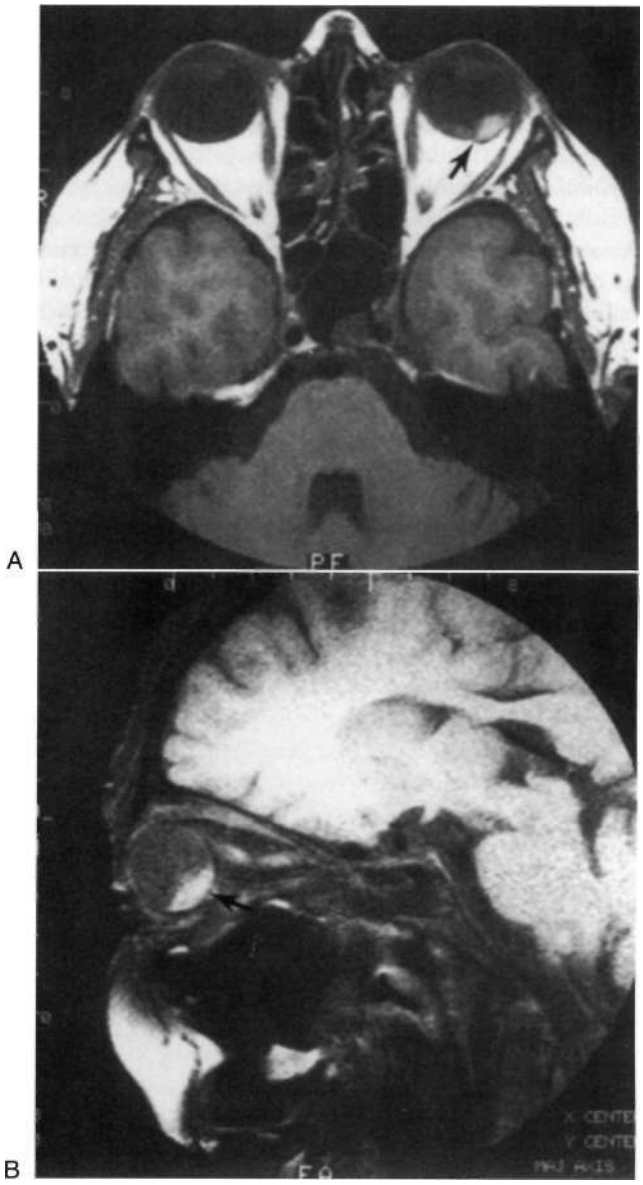

FIGURE 37A.71 Choroidal melanoma. (A) Axial Tl-weighted image demonstrates a lesion in the posterior aspect of the globe, whkh is partially hyperintense *(arrow).* This is consistent with a melanotic melanoma, (B) Sagittal fat-suppressed image shows the hyperintense lesion located in the inferior aspect of the globe *{arrow).* No retrobulbar extension is seen.

Retinoblastoma

Retinoblastoma is the most common intraocular malignancy of childhood. The average age at diagnosis is 18 months. The roles for imaging include limiting the diagnostic possibilities, because the differential diagnosis of leukokoria (reflection from a white mass in the eye, giving the appearance of a white pupil) is extensive; defining the extension of the lesion, because retinoblastoma can spread in a variety of ways, including to the retrobulbar orbit and to the CSF spaces, seeding the CNS; and determining whether the contralateral orbit is affected, because bilateral lesions are common (up to one third of patients). Also, the trilateral retinoblastoma (bilateral retinoblastoma associated with a pineal tumor) can be detected by MRI.

On MRI, retinoblastoma has variable signal intensity. Histopathologically, retinoblastoma is similar to othet PNFT tumors of the CNS and therefore has signal intensity patterns similar to those of these tumors and also may demonstrate hemoirhage and necrosis. The classic CT finding of retinoblastoma is retinal calcification. Because of the insensitivity of MRI for calcification, CT remains the initial diagnostic imaging study of choice when a retinoblastoma is suspected.

SPINAL LESIONS

Spinal Tumors

Extramedullar-)? Intradural Tumors

The two most common extramedullary intradural tumors are the neurinoma (or neurilemmoma) and meningioma. As with any other extramedullar}' intradural mass lesion, these tumors displace the spinal cord and widen the ipsilateral subarachnoid space.

Nerve Sheath Tumors. Nerve sheath tumors are the most common intraspinal neoplasm. Neurinomas can occur at any spinal level, are equally common in both sexes, and often present in the fourth decade of life. Although these tumors are most commonly extramedullary intradural in location, they also can be purely extradural or dumbbell-shaped, with both an intradural and an extradural component, the latter extending through the intervertebral foramen.

On MRI, these tumors tend to have slightly greater intensity than muscle in Tl- and T2-weighted images. These lesions enhance intensely and homogeneously (Figure 37A.72), except when there is an intratumoral cyst.

Meningiomas. Meningiomas typically are found in adults. They usually occur in the thoracic spine or at the foramen magnum and are seen more often in women than men. They are primarily extramedullary and intradural in location, but they can be also both intradural and extradural or purely extradural.

On MRI with short TR images, these lesions are hypointense to isointensc to spinal cord, and T2-weighted images show meningiomas to be slightly hypcrintcnsc to the spinal cord. These lesions enhance homogeneously and intensely after gadolinium administration.

Intramedullary Tumors

In the extradural and extramedullary intradural spaces, MRI has proved to be as effective as CT myelography while being noninvasive. However, for lesions in the cord, **MRI** is superior to CT myelography. Although noncontrast MRI

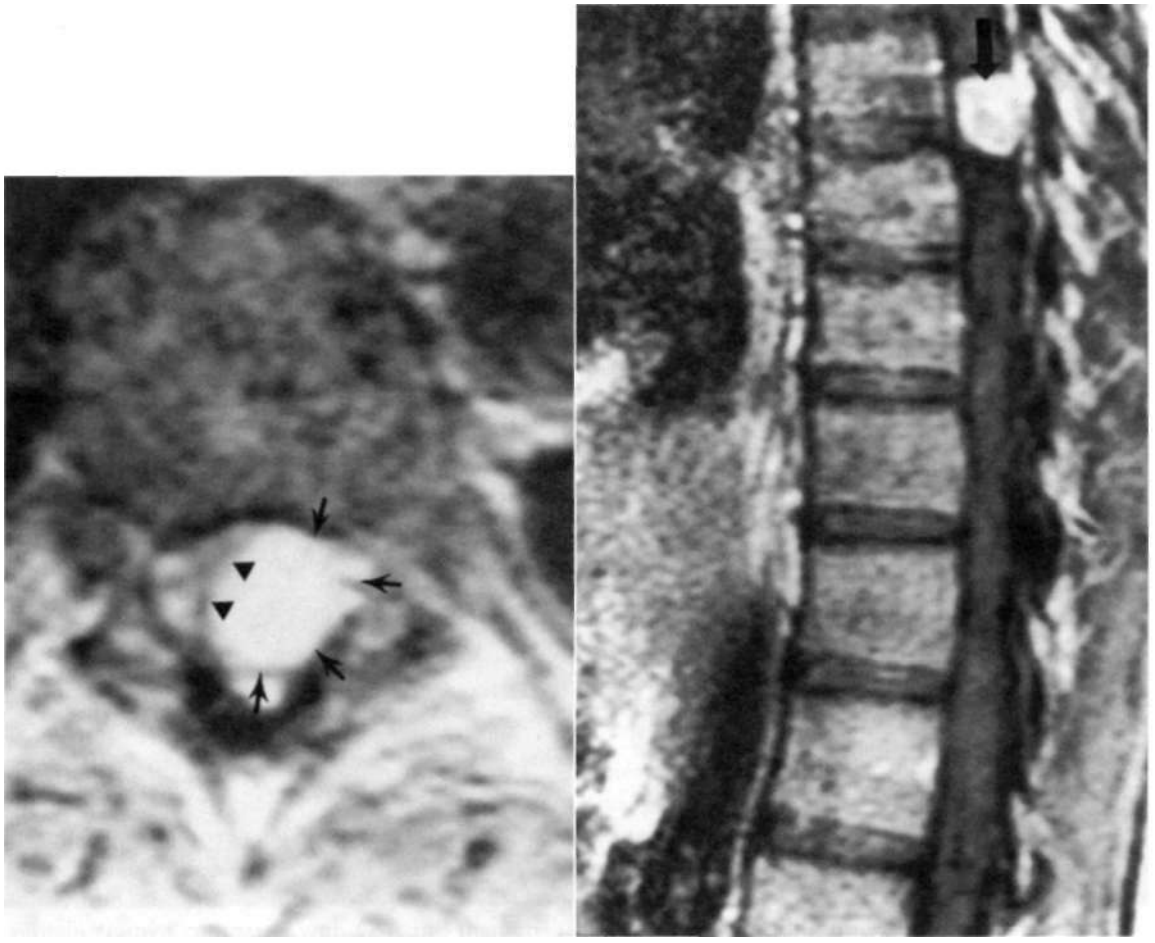

FIGURE 37A.72 Neurofibroma. Postgadolinium Tl-wcighted (A) axial and (B) sagittal images demonstrate an enhancing intradural extramedullary mass *{arrows)* on the left, displacing rhe cord *(arrowheads)* to the right. *Continued*

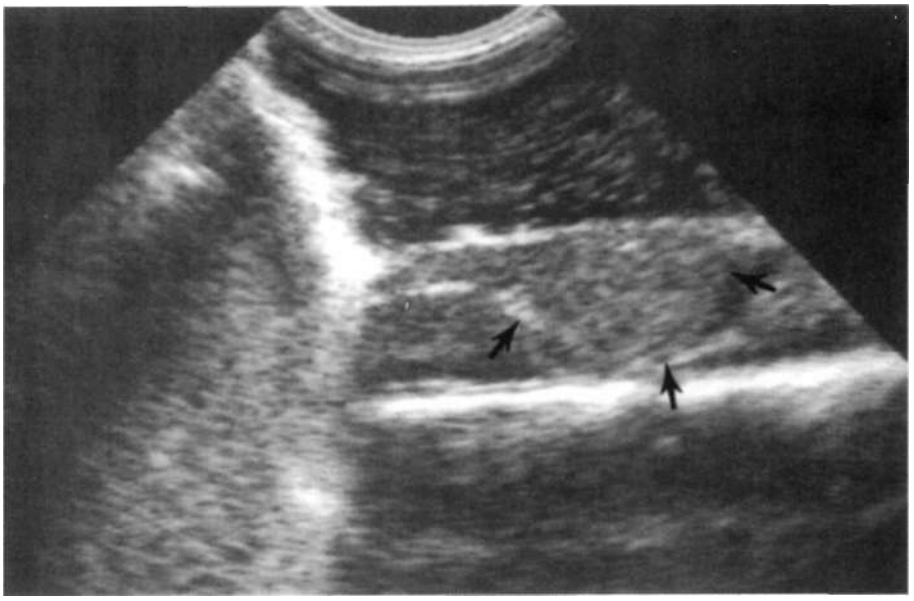

FIGURE 37A.72, cont'd. (C) On intraoperative spinal sonography in a sagittal plane, the mass is noted displacing the cord anteriorly *(arrows).*

scans generally detect lesions, gadolinium can help in further delineating them.

Astrocytomas. The peak incidence of spinal astrocytomas is in the third and fourth decades of life, but they are not uncommon in children. They are most often located in the thoracic cord, but in children holocord involvement can be found.

On MRI with Tl-weighted images astrocytomas are hypointense to normal cord, whereas on T2-weighted images they are hyperintense. The margins of the lesions are poorly defined. After intravenous contrast administration, these lesions almost always enhance, with a homogeneous or in homogeneous pattern. MRI is also helpful in distinguishing tumor cysts from benign cysts associated with tumor; tumor cysts are surrounded by enhancement, whereas the walls of benign cysts lack enhancement.

Ependymomas Ependymomas usually present in patients in the fourth and fifth decades of life, in men more often than women. It is the most common primary cord tumor of **the** lower spinal cord, conus medullaris, and filum terminalc.

Noncontrast MRI demonstrates cord widening (Figures 37A.73 and Figure 37A.74). The lesion is hypointense or hyperintense on T2-weighted images. Areas of hemorrhage may be seen, and intratumoral cysts are common. Hemosiderin deposition is common at the superior and

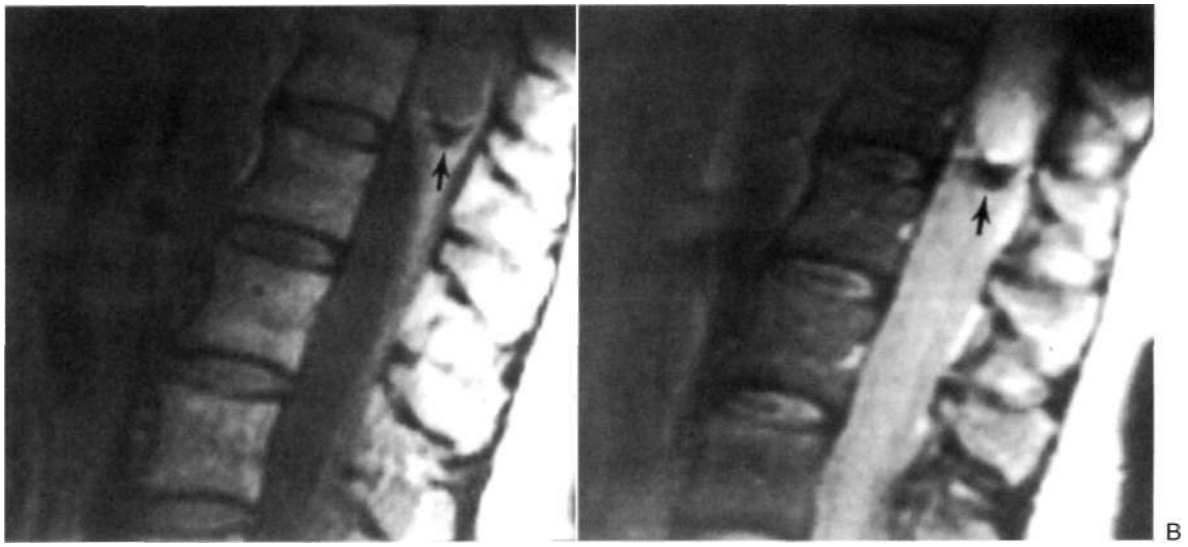

FIGURE 37A.73 Ependymoma. (A) Tl-weighted and (B) T2-weighted sagittal images demonstrate spinal cord widening at the conus. The lesion is hypointense on short repetition time (TR) images and hyperintense on long TR images. Hemosiderin deposition is noted at the inferior borders of the tumor *(arrows).*

inferior borders (see Figures 37A.73 and 37A.74}. After intravenous contrast, ependymomas tend to enhance intensely and homogeneously.

Hemangioblastoma. Hemangioblastoma is an uncommon intramedullary lesion that represents 1-5% of spinal cord tumors. Presentation usually is during the fourth or fifth decade of life, and the cervical and thoracic cord usually are affected. On MRI, a cord cyst with an enhancing nodule and, occasionally, evidence of a prominent enhancing feeding arterial vessel may be seen. Twenty percent of hemangioblastomas are associated with von Hippel-Lindau disease. The tumor may present with hemorrhage.

Extradural Tumors

Metastases are the most common of the extradural tumors. They can destroy the vertebral bodies and extend into the

spinal canal, displacing the subarachnoid space and spinal cord. The tumor and adjacent bony changes and the extent of the epidural and paraspinal involvement are well demonstrated on MRI (Figure 37A.75).

Degenerative Disease of the Spine

Degenerative Disc Disease

As an intervertebral disc degenerates, it loses water, and fibrous tissue replaces nuclear material as the disc collapses (see Chapter 77). Annular fibers weaken, resulting in disc bulging, and annular tears predispose to disc herniation.

A bulging disc extends diffusely beyond the adjacent vertebral body margins, although the concentric annular fibers are intact. An extruded disc extends through all the layers of the annulus and appears as a focal soft tissue mass (Figure 37A.76). These disc herniations may be subligamentous (anterior to the posterior longitudinal ligament} or may rupture through and be posterior to the posterior longitudinal ligament. A free disc fragment is herniated disc material that has separated from the parent disc and may migrate to a position removed from the original disc space. Approximately 90% of lumbar herniated discs occur

at L4-L5 or L5-S1, 7% at the L3-L4 level, and 3% at L1-L2 or L2-L3.

On MRI, most bulging discs extend beyond the verte bral body margin in a diffuse manner and have decreased signal intensity on T2-weighted images because of disc degeneration and loss of water, whereas a herniated disc is seen as a focal soft tissue mass displacing the epidural fat or thecal sac (see Figure 37A.76) and can show enhancement along the periphery of the disc because of the presence of reactive vascular connective tissue.

Spinal Stenosis and Spondylosis

The most common degenerative process of the spine is spondylosis deformans (osteophytosis). Osteophytes occut because of underlying disc disease. Osteoarthritis is degenerative arthritis involving the synovial joints such as the facet joints. These terms often are used synonymously because the conditions often coexist. Both lead to narrowing of the spinal canal or neural foramina and as a result can cause cord compression or root entrapment.

Lumbar Spinal Stenosis. The term *lumbar spinal stenosis* includes stenosis of the spinal canal, lateral recess, and foramina. Canal stenosis is most common at L2 to L5 levels and causes radiculopathy. Stenosis may be caused by a combination of diffuse disc bulging, facet hypertrophy, and ligamentous thickening.

Cervical Spinal Stenosis. Cervical canal stenosis is most often caused by spondylosis deformans and ligamentous thickening. Foraminal stenosis is caused by hypertrophy of

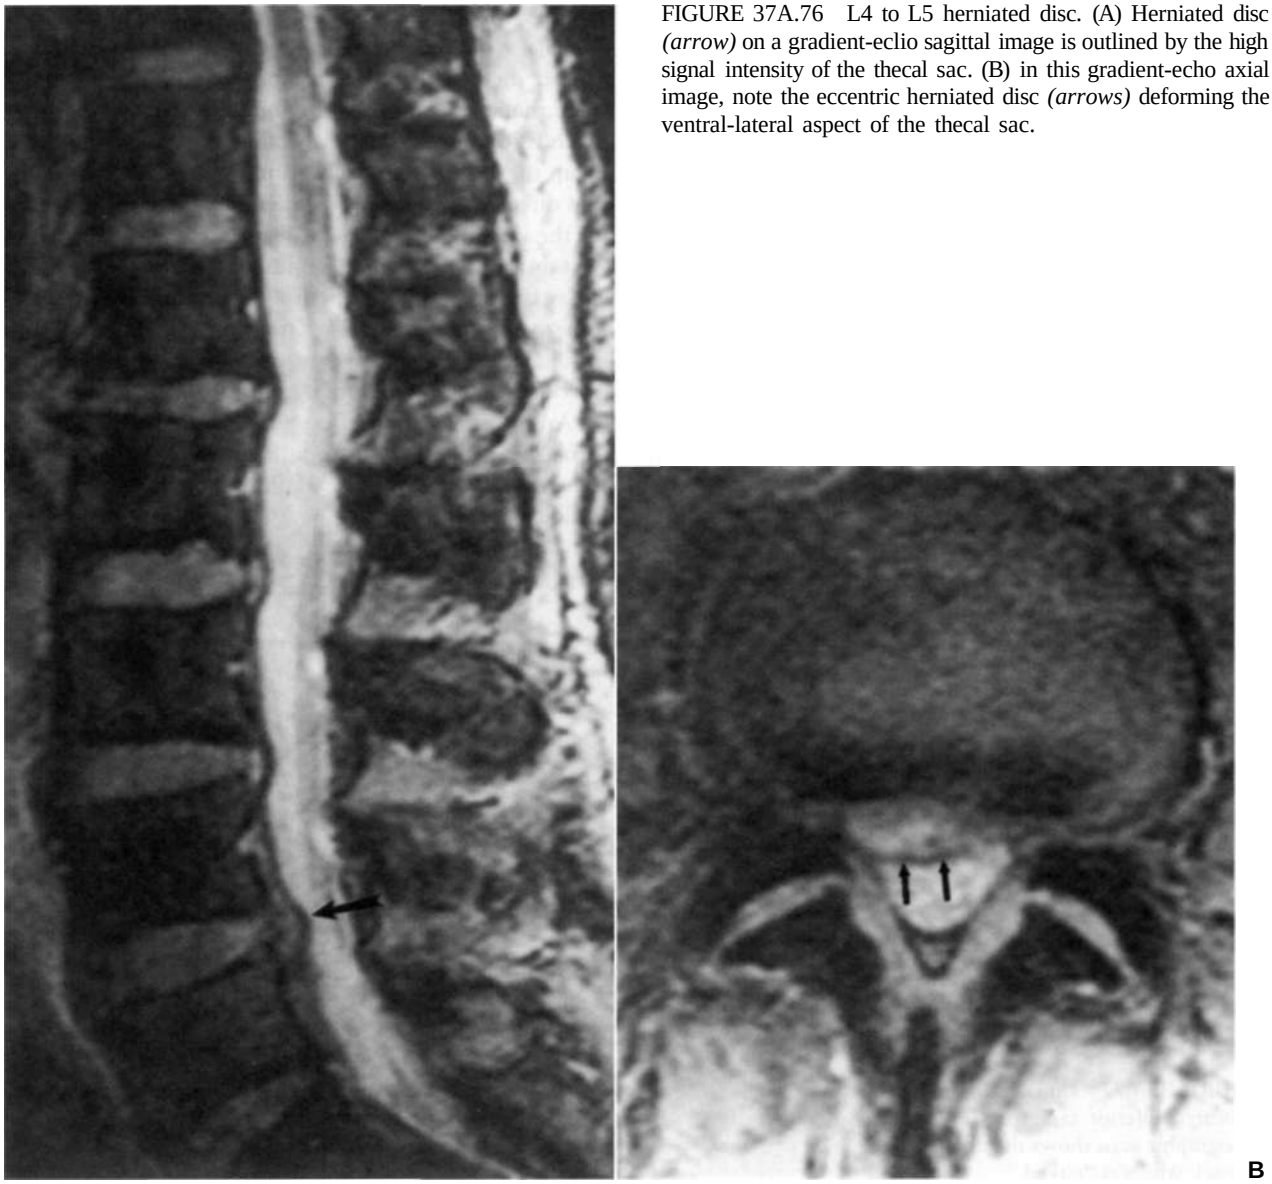

FIGURE 37A.76 L4 to L5 herniated disc. (A) Herniated disc *(arrow)* on a gradient-eclio sagittal image is outlined by the high signal intensity of the thecal sac. (B) in this gradient-echo axial image, note the eccentric herniated disc *(arrows)* deforming the ventral-lateral aspect of the thecal sac.

the uncinate process and superior articular facet. Patients are at particular risk for myelopathy or radiculopathy if the anteroposterior diameter of the cervical canal is less than 11 mm.

T2*-weighted gradient-echo images are most effective for evaluating cervical spondylosis because spurs can be distinguished from discs, and the anteroposterior diameter of the canal can be measured. CT scans have been considered the procedure of choice for diagnosing neural foramina! stenosis. However, with .3D gradient-echo techniques, thin sections may be obtained to evaluate the neural foramina, and the accuracy of these sections approaches that of high-resolution CT myelography.

Spinal Trauma

Spinal trauma is one of the leading causes of disability. Since the 1970s, important imaging developments have improved diagnosis and paralleled the development of better clinical and more aggressive surgical management of spinal injuries. In choosing a particular radiographical protocol, one must take several factors into account, including the neurological status of the patient, level of injury, age of the lesion, and potential henefit that might be derived from each of the different imaging modalities.

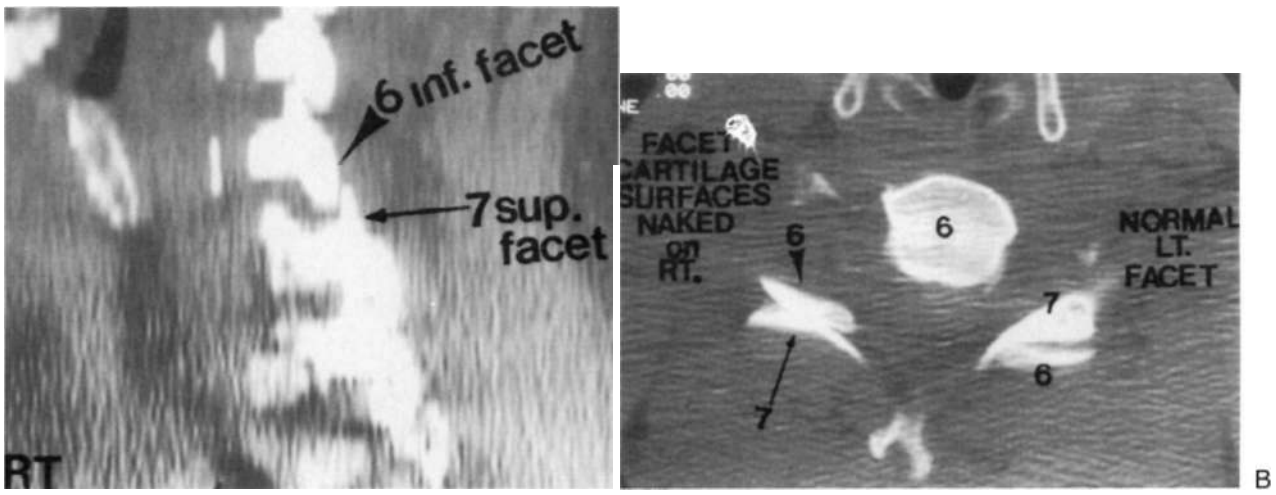
Acute Cervical Spine Trauma

Fractures

Bilateral Interfacetal Dislocation. Bilateral interfacetal dislocation is dislocation of both interfacetal joints at the same level. Interlocking of the articular facets begins with the movement of the inferior articular facets of one vertebra forward over the articular facets of the underlying vertebra. This causes the laminae and spinous processes to distract and the vertebral bodies to sublux. Radiographically, this is characterized by anterior displacement of the dislocated segment. The inferior facets of the dislocated vertebra lie anterior to the superior facets of the adjacent segment. Often this injury is called *double-locked* vertebrae. This lesion is acutely unstable because of skeletal and soft tissue disruption at the level of injury,

Unilateral Interfacetal Dislocation. Unilateral interfacetal dislocation results from simultaneous flexion and roration. The posterior ligament complex and the capsule of the dislocated facetal joint are disrupted. The interfacetal joint on the side of the direction of rotation acts as the pivotal point, whereas the contralateral side including its inferior facet rides upward and forward over the tip of the superior facet of the inferior vertebra. The dislocated facet is locked and fixed. The contiguous facets are no longer in apposition and arc uncovered, or exposed, "naked" facets. There may be fractures of either of the articular facets; tiny fragments have no clinical significance, but large fractures render the interfacetal dislocations unstable.

In the anteroposterior radiograph, unilateral interfacetal dislocation is evidenced by rotation of the spinous processes from the level of the dislocation upward off the midline in the direction of the side of the dislocated interfacetal joint. In the lateral view, forward displacement of the dislocated vertebra is seen. Although the vertebrae below are in the true lateral projection, the vertebrae above are seen obliquely because of the rotational component of the mechanism of injury. This results in a bowtie appearance of the articular pillars of the dislocated vertebra (Figure 37A.77). In the anteroposterior projection the spinous processes are displaced from the midline toward the side of the dislocated interfacetal joint at the level of the dislocation and above.



E1GURE 37A.77 Unilateral interfacetal dislocation. (A) Sagittal reformatted images of computed tomographic scanning show dislocated inferior facet of *C6 {arrowhead)* anterior to the contiguous superior facet of C7 *(arrows).* (B) The axial computed tomographic scan shows the dislocated articular mass of C6 *{arrowhead)* anterior to its subjacent counterpart, the superior facet of C7 *{arrow),* which is "naked."

Continued

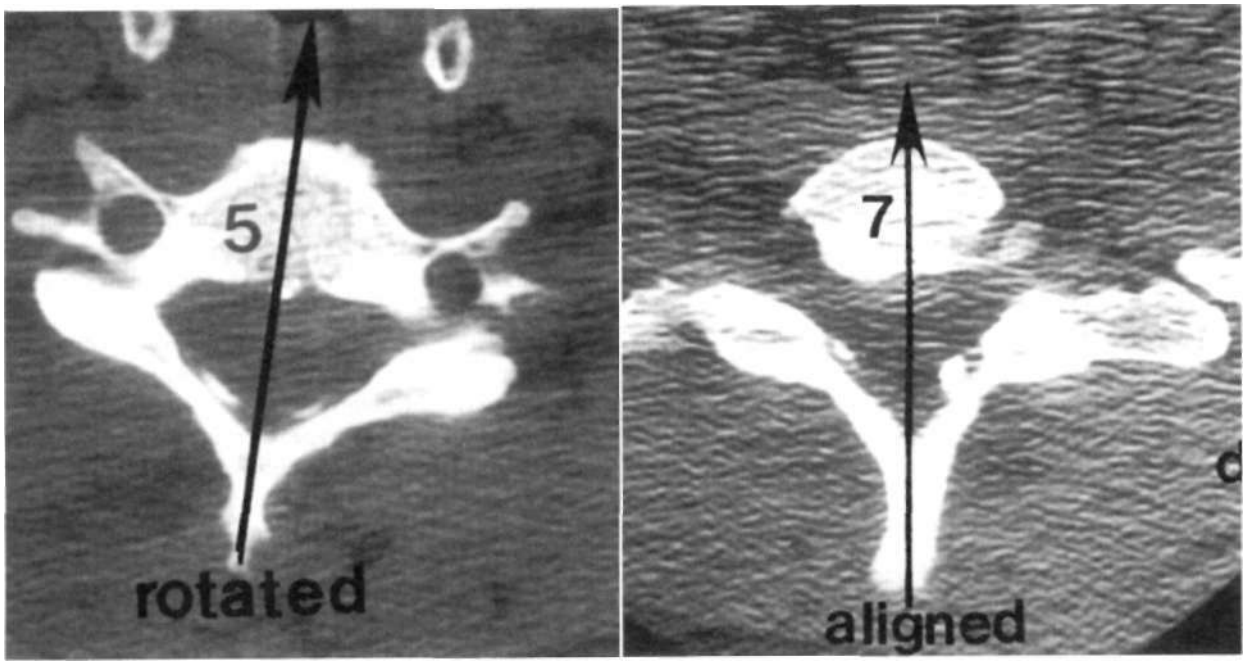


FIGURE 37A.77, cont'd. (C) Axial computed tomographic scan above the level of dislocation shows rotation of the vertebra and spinous process. (D) Axial computed tomographic scan below the level of dislocation shows no rotation.

Clay Shoueler's Fracture. Clay shovcler's fracture is an avulsion of the spinous process of C6, C7, or T1.

Hangman's Fracture. Usually, hangman's fracture represents bilateral fractures of the pars inrerarticularis of the axis. Less commonly, one or both fractures may involve the superior articulating facet or may be more anteriorly located at the junction of the posterior arch and posterior aspect of the body of C2 (Figure 37A.78).

Jefferson Bursting Fracture. The original description of the Jefferson bursting fracture was that of bilateral fractures of both the anterior and posterior arches of CI. However, the Jefferson fracture may result from a single break in each ring. In the frontal projection of plain films, there is bilateral displacement of the articular masses of CI. In the lateral projection, the anterior arch fracture is seen rarely, but the posterior arch fracture ofren is noted. On the

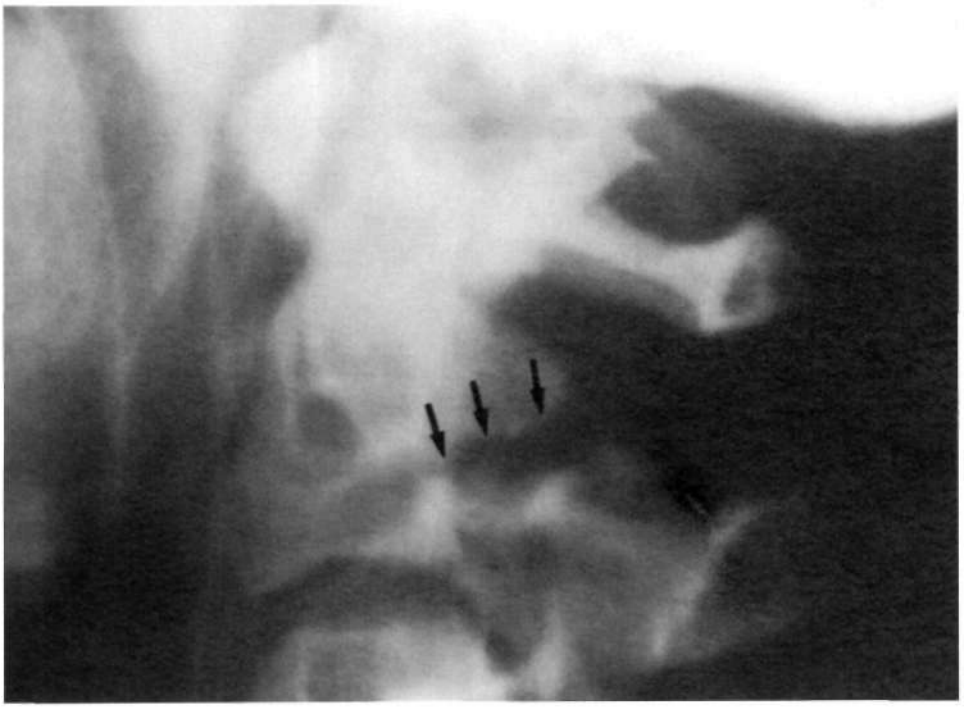

FIGURE 37A.78 Hangman's fracture. Fracture through the pars interarticularis (*arrows*).

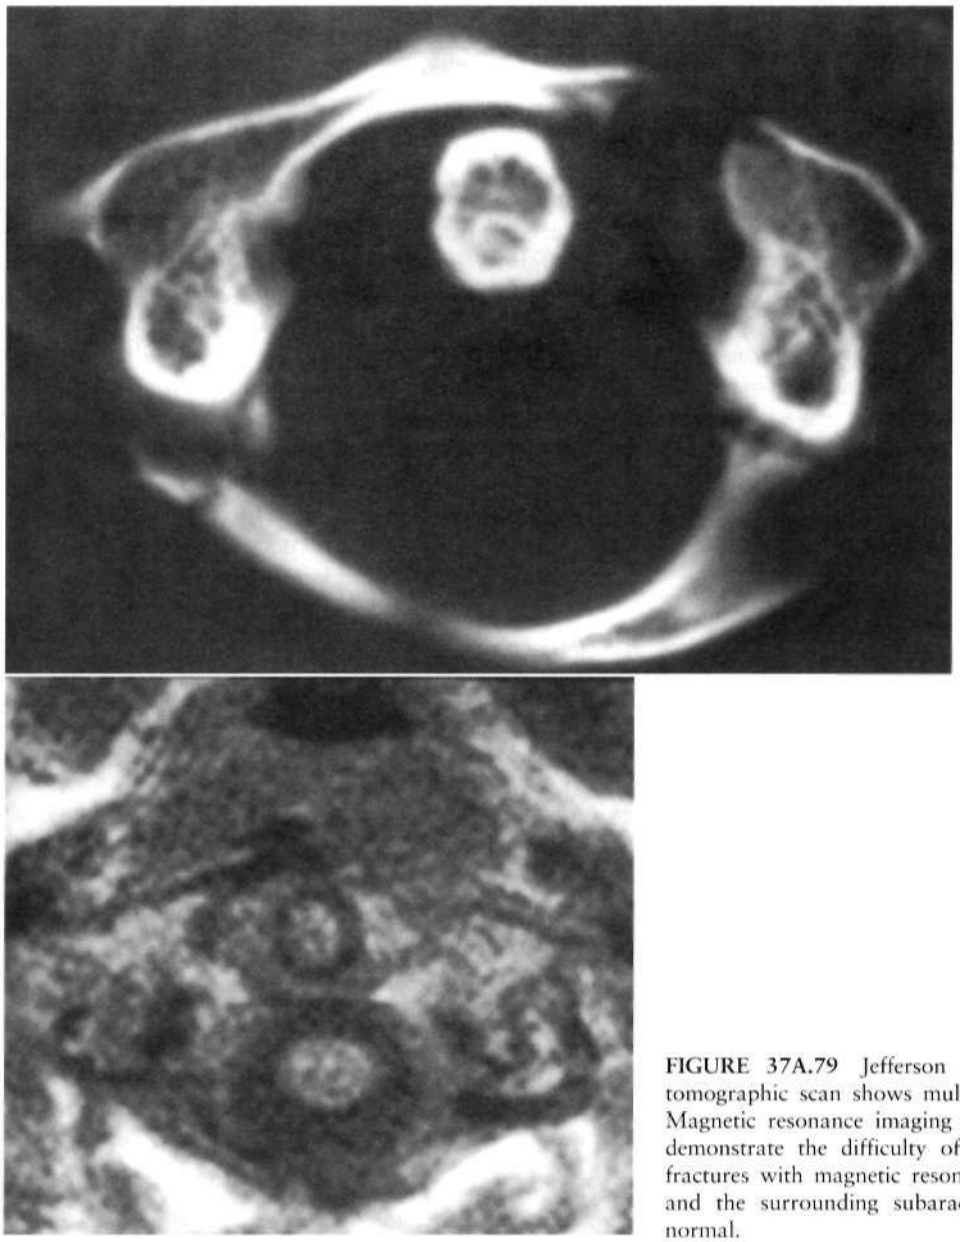
lateral projection, the Jefferson fracture cannot be distinguished from an isolated hyperextension of the posterior arch of the atlas. These fractures can be demonstrated on CT and less well on MRI (Figure 37A.79).

Burst Fracture. The burst fracture of the lower cervical spine is a comminution fracture of the vertebral body with retropulsion of bone into the spinal canal, well demonstrated on lateral radiography. CT demonstrates that a posterior arch fracture usually is present. The alignment of the posterior elements is normal. A vertical fracture of the vertebral body is seen on the frontal projection, but the posterior fracture is seen only on CT.

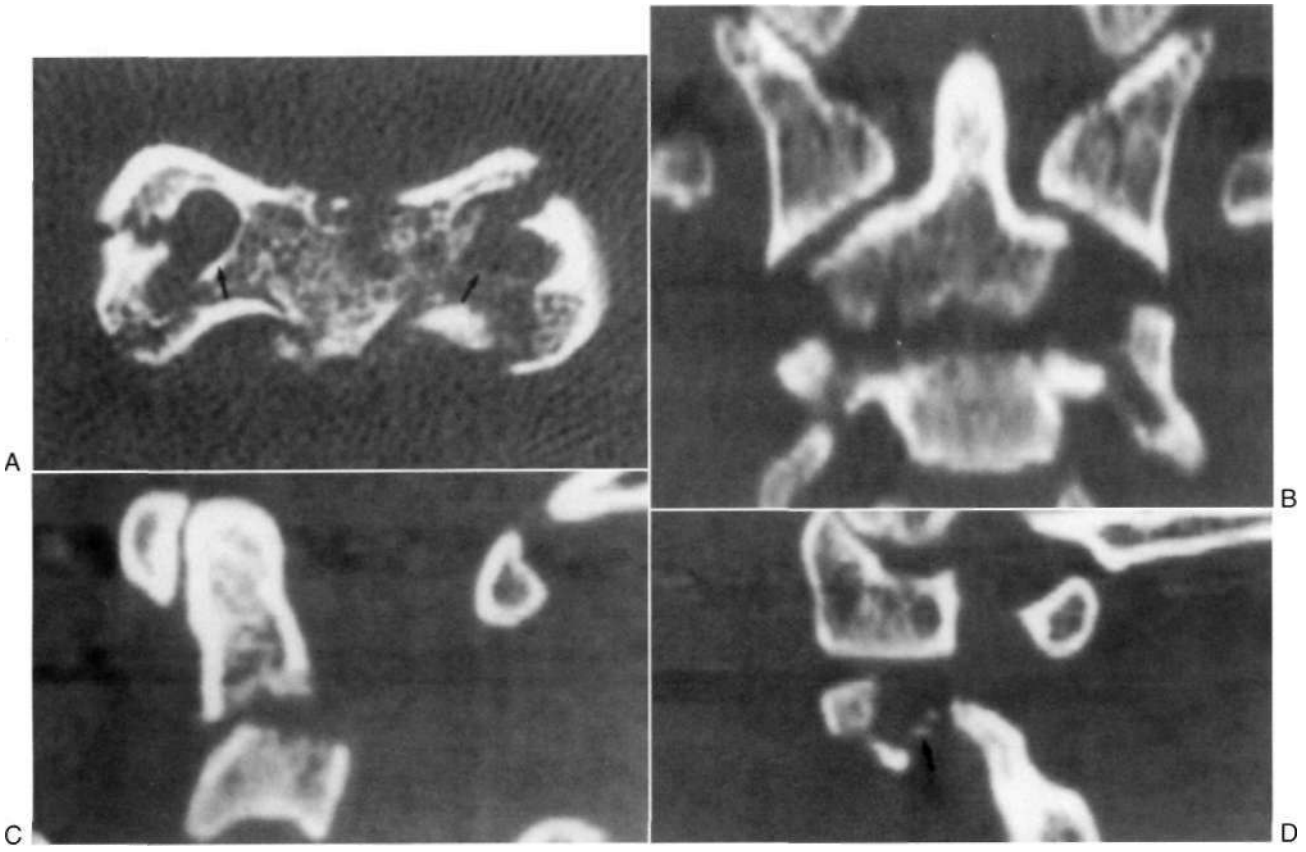
Odontoid bractures. Fractures of the dens can occur with either forced hyperflexion or forced hyperextension of the head or the neck. Hyperflexion injuries cause the dens to be displaced anteriorly, and there is forward subluxation of C1 on C2. Hyperextension injuries cause the dens to be displaced posteriorly, with posterior subluxation of CI on C2. The dens moves with CI unless the transverse ligament is ruptured. Fractures of the dens without displacement of CI on C2 can be most difficult to recognize. Polytomography of the dens may be helpful in detecting these fractures.

Odontoid fractures have been classified into three types. Type I is an avulsion fracture of the top of the dens. Type II is a transverse fracture of the dens above the body of the axis. Type III is a fracture of the superior portion of the axis body that involves one or both articulating facets (Figure 37A.80). This type of fracture is not really a fracture of the dens but a fracture of the superior portion of



B

FIGURE 37A.79 Jefferson fracture. (A) Axial computed tomographic scan shows multiple fractures through C1. (B) Magnetic resonance imaging at the same level is shown to demonstrate the difficulty often encountered in diagnosing fractures with magnetic resonance imaging. The spinal cord and the surrounding subarachnoid space at the level are normal.



HCUR1 37A.*HU* Type **III** odontoid fracture. (A) Axial computed tomographic semi rbroii^h rlu- .ixi— body shows tt-.u-inn- lines lli.n traverse both transverse foramina *{arrows).* (B) Coronal reconstructed image shows fracture through the axis body. (C) Sagittal reconstruction through the midline shows the anterior displacement of the dens. (D) Right parasagittal reconstructed image shows fractures extending through the transverse foramen and therefore not allowing posterior transarticular screw fixation *(arrow).*

the axis body. Because it involves an area of cancellous bone, it almost always heals. Type **III** fracture is considered to be mechanically unstable. The low dens fracture disrupts the axis ring. This ring is composed of the cortex of the junction of the pedicle, the vertebral body, the cortex at the junction of the axis and body superiorly, and the posterior cortex of the axis body.

Spinal Cord. The information that MRI can provide regarding the acutely injured spinal cord is unrivaled, MRI has been found to be superior in detecting spinal cord parenchymal abnormalities compared with myelography and CT myelography. **MRI** is the only imaging study that can directly image the spinal cord parenchyma with sufficient resolution and demonstrate intrinsic signal abnormality even in the absence of cord enlargement. Myelography and CT myelography can provide only information regarding spinal cord size or spinal cord compression. **MRI** can reliably determine whether acute post-traumatic cord enlargement is related to edema or hemorrhage and identify hemorrhage or contusion change in a nonenlarged cord.

Three types of MR! signal patterns in patients imaged 1 day to fi weeks after injury were reported in one study. In 19 patients who demonstrated MRI evidence of cord injury, S had evidence of cord hemorrhage with decreased T2 signal within 72 hours of injury. A peripheral hyperintense rim with persistence of central T2 hypointensity images was seen up to 7 days after injury. In a second group of 12 patients, only cord edema was appreciated (Figure 37A.81). This cord edema showed evidence of some resolution from 7 days to 3 weeks after injury, A mixture of hemorrhage and edema with central hypointensity surrounded by a rim of hyperintensity on T2-weighted images was identified as a third pattern of cord injury in two patients. Resolution of cord lesions with blood products was slower than that of cord lesions that were non hemorrhagic. In I he carh period after injury, Tl-weighred images were useful only in demonstrating cord swelling and failed to reveal significant signal change in the cord parenchyma.

Intramedullary cord hemorrhage and extensive cord edema are poor prognostic indicators for neurological recovery. T2* images are the most sensitive sequences for hemorrhage detection in the acute phase.

FIGURE 37A.81 Cord edema. Focal lesion in the cord, which is hypointense in (A) T1-weighted image and hyperinrense in (BJ T2-weighted image, is consistent with an area of edema *{arrows)* in a patient with acute spine injury. On the T2-weighted image, the markedly hypointense areas at C5-C6 and C6-C7 disc spaces represent calcified osteophytes.

Deoxyhemoglobin results in signal loss on $T2^{0,}$ images (Figure 37A.82).

Cervical Spine Trauma: Progressive Post-Traumatic Myelopathy

Spinal Cord Cysts. Post-traumatic myelopathy can occur in up to 32% of patients with chronically injured spinal cords. Post-traumatic myelopathy may present as early as 2 months after injury or as late as 36 years afrer injury. Progressive post-trauma tic myelopathy may be related to several conditions. One of the more common treatable parenchymal abnormalities is a spinal cord cyst (Figure 37A.83). Progressive myelopathy also can be seen in the presence of myelomalacia and cord tethering. Cord tethering probably plays a significant role in the development of myelomalacia and spinal cord cysts. There is also evidence that myelomalacia and spinal cord cysts are part of a continuum. Imaging plays a key role in differentiating between spinal cord cyst and myelomalacia because the two are difficult to distinguish clinically. MRI is the modaliry of choice in evaluating patients with a progressive post-traumatic myelopathy. Less common causes of post-traumatic myelopathy that are also detectable by MRI

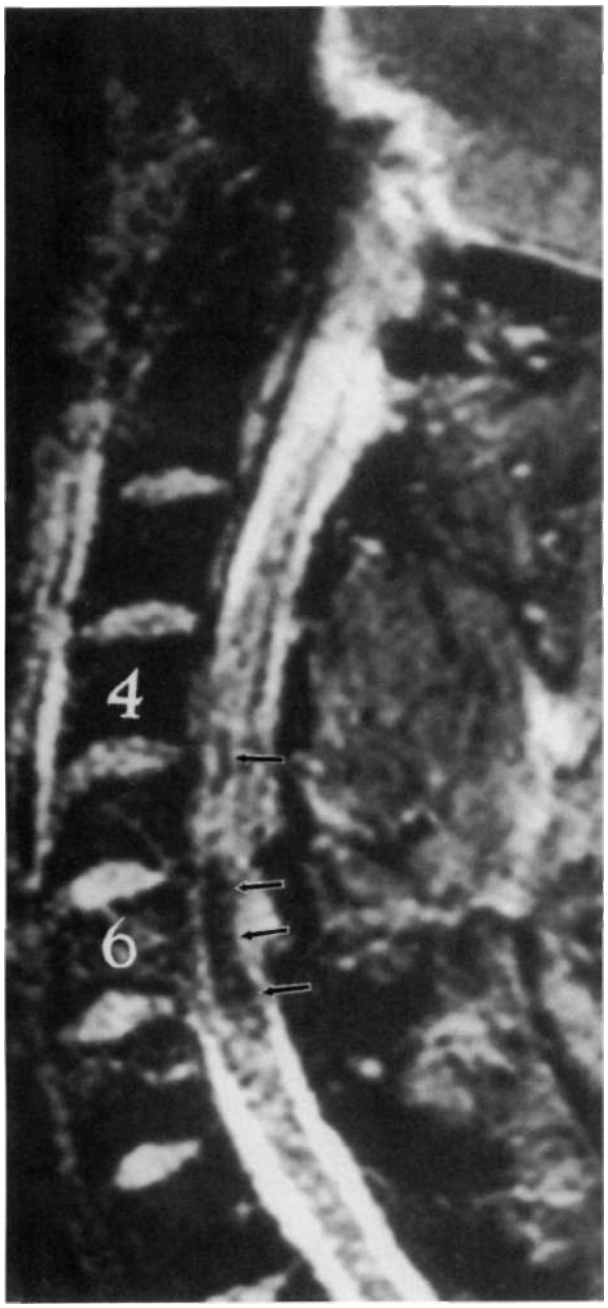


FIGURE 37A.82 Cord hematoma. T2* gradient-echo sagittal image shows hypointensity in the cord from C4 to C7 *{arrows),* consistent with acute hemorrhage (deoxyhemoglobin) in the cord.

FIGURE 37A.83 Post-traumatic intramedullary cyst. A large multisegmented intramedullary cyst is present from C1 to T1. This patient was worsening n euro logically after a fracture-subluxation in the distant past and had a prior wide posterior laminectomy. Note linear bands in the cyst, which represent fibroglial septa traversing the cyst.

include cord compression from vertebral malalignment, herniated disc or osteophytes, arachnoid cysts, and cord atrophy.

Spinal cord cysts almost always follow CSF signal intensity on MRI (see Figure 37A.83}. CSF pulsation-induced signal loss or flow-related enhancement may be seen in large pulsatile cysts and can alter the MRI appearance. Although cyst contents may contain an elevated protein content compared with CSF and theoretically shorten Tl and T2 relaxation, this is rarely a problem. A well-defined border usually can be traced around the cyst, although when a cyst develops in a region of severely damaged spinal cord tissue the entire border may not be well defined. Post-traumatic spinal cord cysts may be a single cavity or contain septations; they may occur above, below, or at a site of initial injury. Cine images may be helpful in determining cyst pulsatility. Postoperative cine evaluation may help determine whethct shunting of the cyst was successful.

Myelomalacia. Closed spinal cord trauma is a common mechanism leading to a myelomalacia or soft cord. Histologically, myelomalacia is characterized by microcysts, reactive astrocytosis, and thickening of the pia-arachnoid. Intraoperative observations at our institution have always revealed cord tethering. Untethering of the spinal cord may lead to clinical improvement.

By MRI, a myelomalacic cord typically reveals abnormal hypointcnsc signal that is greater in intensity than the CSF on Tl-weighted images (Figure 37A.84). T2-weightcd images reveal corresponding hyperintensity within the spinal cord. The proton density sequence may be helpful when there is difficulty distinguishing between myelomalacia and a spinal cord cyst. Myelomalacia does not parallel CSF and reveals isointense to hyperintcnsc signal change relative to normal spinal cord on the proton density images. The margins of a myelomalacic cord also are usually irregular and ill defined. A myelomalacic cord may be normal in size, atrophic, or expanded.

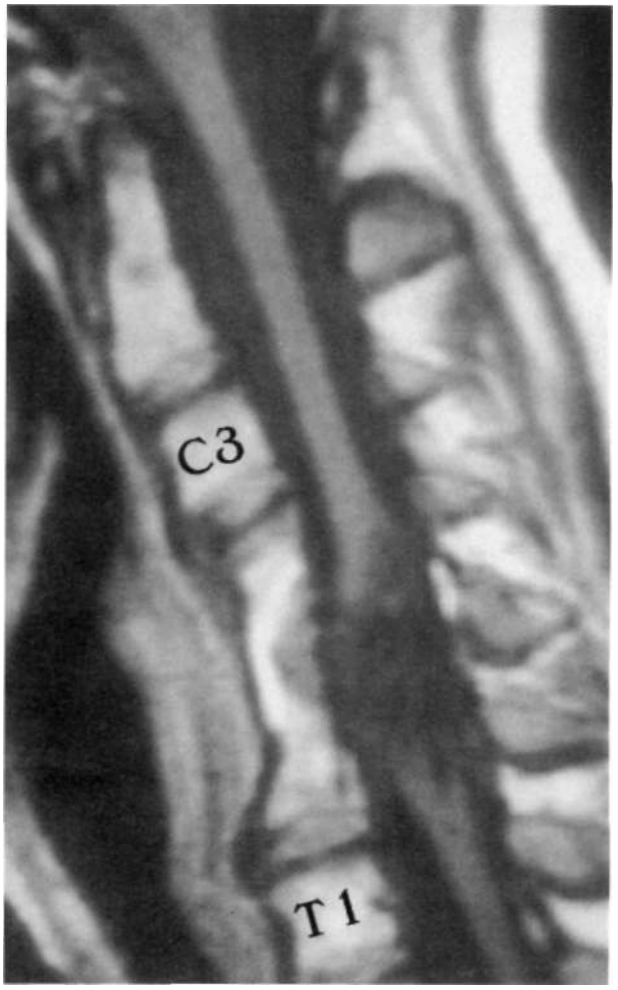

FIGURE 37A.84 Post-trauma tic myelomalacia. Sagittal Tl-weighted magnetic resonance image shows postsurgical anterior cervical decompression and fusion from C4 through C6. The cord at C5 appears expanded, with an ill-defined hypointensity. The differential diagnosis was between a post-traumatic syrinx and a microcystis myelomalacia with tethering of the cord anteriorly and posteriorly to the surrounding dura.

Thoracolumbar Trauma. Fractures of the thoracolumbar spine are second in frequency to fractures of the cervical spine. Thoracolumbar fractures make up one third of spinal fractures.

Fractures of the Upper Thoracic Spine (Tl to T10). Fractures of the upper thoracic spine are different from other levels of spinal fractures because they are stable: The rib cage and the strong attaching costovertebral ligaments limit the degree of motion of this segment of the spine. The most common type of fracture that occurs in the upper thoracic spine is the compression or axial loading fracture, which leads to different degrees of anterior wedging of the vertebral body affected. When neurological deficit occurs, it usually is caused by cord compression secondary to the presence of retropulsed bone in the spinal canal. Alternatively, the cord may be compressed by herniated nucleus pulposus or epidural hematomas.

In addition to the anterior wedging fractures, the upper thoracic spine may be affected by burst fractures, usually secondary to a severe axial loading force applied to the vertebra. Burst fractures of the upper thoracic spine may have associated fractures of the posterior neural arch {Figure 37A.85). Any comminuted retropulsed bone fragment can cause cord compression or cord maceration, a finding that is well demonstrated on MRI.

A third type of post-traumatic upper thoracic spine fracture is the sagittal slice fracture, in which the vertebra above telescopes into the vertebra below with secondary displacement of the latter.

Although most upper thoracic spine fractures are stable, instability necessitating surgical correction is seen in instances of complete dislocations, kyphosis greater than 40 degrees, progressive kyphosis, persistent pain, and progressive neurological deficits. Another indication for surgical intervention in patients with upper thoracic fractures is MRI demonstration of disruption of the spina! supporting ligaments. In the setting of acute trauma, radiographics! findings suggestive of spinal instability include vertebral subluxation, widening of the interspinous or interlaminar distance, disruption of the posterior body line, and vertebral wedging greater than 40%.

Fractures of the Thoracolumbar function (Tl 1 to L2). The thoracolumbar junction is one of the areas most commonly affected during spinal trauma. Most thoracolumbar injuries occur between T12 and L2, the area of transition between a stiff and more mobile segment of the spine. Several authors have creared a mechanistic classification for the thoracolumbar fractures. This classification divides the vertebra into three main regions: the anterior column, middle column, and posterior column (the "three-column" concept}. The anterior column is composed of the anterior longitudinal ligament, the anterior annulus fibrous, and the anterior vertebral body. The middle column

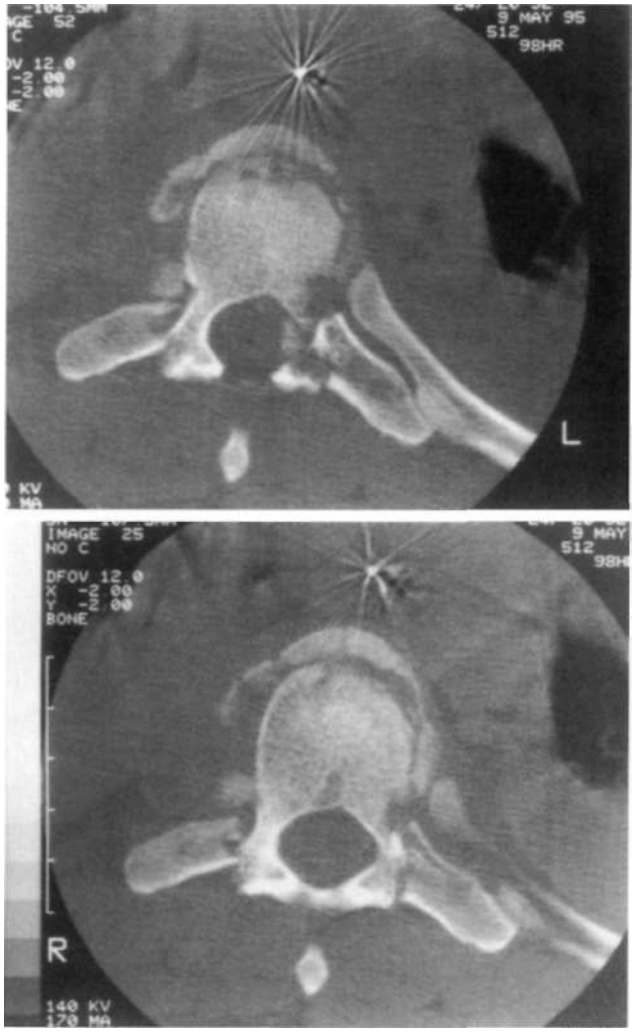

FIGURE 37A.85 Male patient involved in a motor vehicle accident. Two contiguous axial cuts (bone windows! through '17 show the severe nature of the fracture. The burst fracture is associated with fracture of the posterior arch and costotransverse process. There is mild compromise of the canal. (Reprinted with permission from Ruiz, A., Post, J. D., 8c Sklar, E. M. L. 1996, "Traumatic thoracic and lumbar fractures," *Appl Radiol,* Oct, pp. 49-57.)

consists of the posterior longitudinal ligament and the posterior annulus fibrous. The posterior column consists of all structures behind the posterior longitudinal ligament (neural arch). The main purpose of this classification is to predict the stability and neurological sequelae of the fractures of the thoracolumbar region. An intact middle column implies stability and vice versa. Fractures of the anterior column rarely are associated with a neurological deficit.

Three basic forces act to injure the middle column: axial compression, axial distraction, and lateral translation. These vectors of force are applied in the *x*-, *y*-, or ?-axis of the spine, producing the following types of injuries.

Hyperflexion Injuries, Hyperflexion injuries are the most common type of injury affecting the thoracolumbar spine. The anterior column is compressed, whereas the posterior elements arc distracted. There are several types of hypcrflcxion injuries. Hyperflexion compression fractures (Figure 37A.86) commonly affect T12, LI, and L2. The compression force can occur anteriorly or laterally, which becomes manifest on radiography or MRI by loss of height of the vertebral body anteriorly or laterally. There is focal kyphosis and scoliosis, fracture, or all three, usually of the

FIGURE 37A.86 Chronic hypcrflcxion compression fracture of T12. Sagirtal Tl- and T2-weighted images. There is severe loss of height of the T12 body anteriorly with associated endplatc disruption. Note the focal kyphos deformity and the degree of retropulsed bone compressing the sac and indenting the cord. (Reprinted with permission from Ruiz, A., Post, J. D., &: Sklar, E, M. I,, 1996, "Traumatic thoracic and lumbar fractures," *Appl Radiol,* Oct, pp. 49-57.)

anterosuperior endplate, and commonly a paraspinal hematoma.

Flexion distraction injury more often occurs from LI to L3. This injury may occur in two different ways. In one instance, the middle and posterior column may be disrupted by the tensional forces applied, with secondary rupture of the annulus fibrosus and subluxation. A second way this type of spinal injury occurs is when the hyperflexion is around an axis anterior to the anterior longitudinal ligament. When this occurs, the entire vertebra is pulled apart or distracted by the tensile force. This type of spinal injury leads then to what is known as a Chance fracture or seat belt injury (Figure 37A.87). Radiographics!ly, a split fracture through the spinous processes, pedicles, and laminae is demonstrated. The fracture line extends upward to involve the vertebral endplate anterior to the neural foramen. There is also severe disruption of the spinal ligaments and distraction of the intervertebral disc and facet joints. The fracture is unstable and usually associated with severe abdominal injuries.

Axial Compression Fracture. The characteristic fracture in this group is the burst fracture (Figure 37A.88). An axial

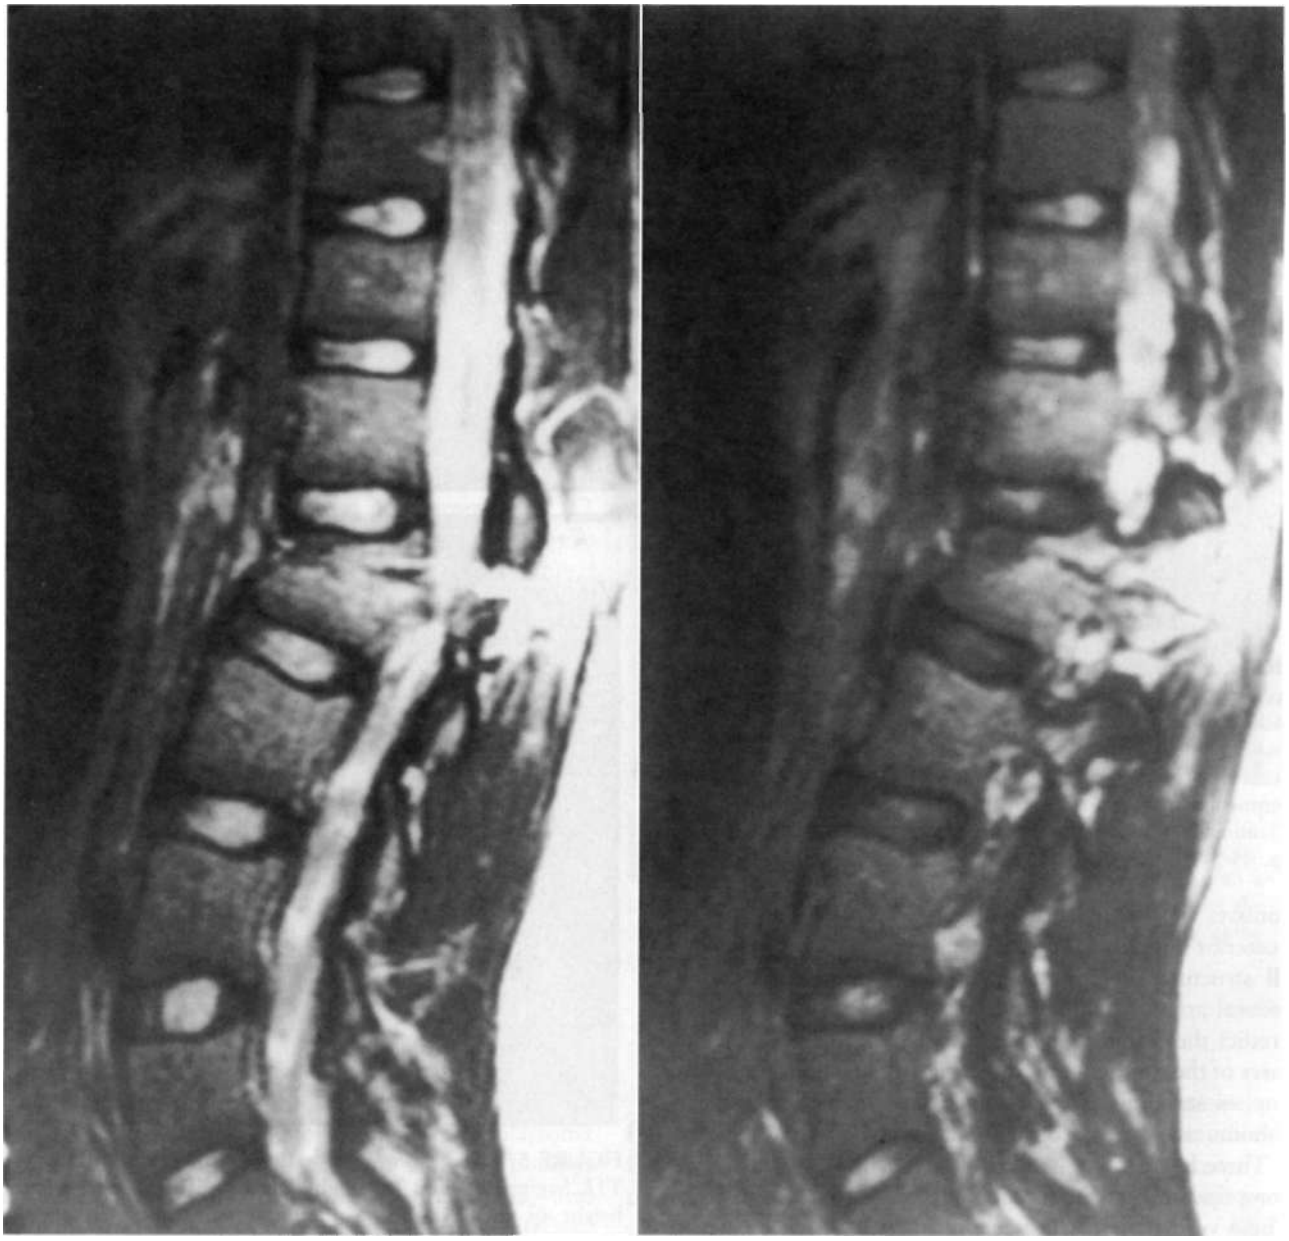

FIGURE 37A.87 Chance fractures. Female adolescent involved in a motor vehicle accident while wearing a lap seat belt. The patient sustained a flexion distraction injury. Contiguous sagittal T2-weighted images demonstrate a split fracture through the posterior elements and posterior 12 body. There is injury to the posterior spinal ligament. FIGURE 37A.88 Axial compression fracture of T12. Sagittal Tl-weighted images demonstrating superior endplate fracture, wedging deformity, and retropulsion of T12, severely compressing the cord. The decreased signal of T12 vertebra is caused by marrow edema. (Reprinted with permission from Ruiz, A., Post, J. D., 8; Sldar, E. M. L. 1996, "Traumatic thoracic and lumbar fractures," *Appl Radiol*, Oct, pp. 49-57.)

loading force pushes the intervertebral disc through the endplate inferiorly (vertical disc herniation) with secondary comminution of the vertebral body. Approximately 90% of burst fractures occur from T9 to L5. A second burst fracture is present in less than 10% of cases. Radiographic findings characteristic of this fracture are severe anterior vertebral body wedging, bone retropulsion with differenr degrees of neural canal narrowing, neural element compression, increased interpediculate distance, and a vertical fracture through the vertebral body, pedicle, or laminae. Depending on the degree of hone retropulsion and level of injury, different degrees of cord, conus, and cauda equina damage may be present. This injury is unstable. CTand MR! are the best modalities to evaluate this injury. The former demonstrates the degree of bony canal narrowing, whereas the latter provides the best information about the relationship between the retropulsed bone and neural elements, including level and degree of neural damage.

Extradural Lesions

Traumatic disc herniations can occur at the cervical, thoracic, and lumbosacral levels. The thoracic spine is not affected often because the rib cage and thoracic muscles protect this patt of the spine. A herniated disc may be unrecognized if CT or MRI is not used. In patients with fractures or dislocations who are to undergo stabilization, the discovery of one associated herniated disc may indicate the need for a prompt surgical intervention, specifically a decomptession discectomy and fusion.

Spinal epidural hematomas may produce spinal cord and or cauda equina compression. The clinical presentation is that of a sudden acute back or neck pain followed by sensory and motor deficits wirh progression to paraplegia or quadriplegia. Although epidural hemorrhage in the spinal canal has been regarded in the literature as uncommon, with the availability of MRI, this diagnosis is being made mote often. These hematomas may show some compression of the thecal sac and compression of the spinal cotd (Figutc 37A.89). They show variable signal intensity. MRI is an excellent

FIGURE 37A.89 (A) T1-weighted sagittal image shows an acute epidural hematoma (*arrows*) that is isointense relative to cord, displacing the sac anteriorly. (B) On a gradient-echo image, the lesion becomes hyperintense.

modality for making the diagnosis ol spinal epidural hematomas.

Chronic Sequelae of Trauma. Post-traumatic spinal cord cysts and myelomalacia can occur in the thoracic spine and in the cervical region. Subarachnoid cysts may follow trauma, and the definitive diagnosis is difficult. Prom our experience, MRI appears to be the most efficient study in diagnosing and characterizing acquired subarachnoid cysts and associated abnormalities.

Infection of the Spine. Infections of the spine often involve the vertebral body or disc space. The organism most often implicated is *Staphylococcus aureus,* responsible for 60% of such infections, even in patients with AIDS. Although CT is useful in detecting bone destruction associated with vertebral osteomyelitis, its depiction of the intraspinal soft tissue structures is limited. Because MRI detects bony changes earlier and shows associated soft tissue abnormalities, it is the imaging study of choice for evaluating inflammatory disease of the spine.

Discitis and Vertebral Osteomyelitis

Pyogenic Infections. Pyogenic infections have a peak incidence in the sixth to seventh decades. Infectious spondylitis involves both the vertebral body and adjacent disc space. The most common site of pyogenic infection is the cancellous bone adjacent to the endplate because of its rich vascularity. The infection then spreads into the disc space. Two thirds of patients have infection limited to the disc space and the adjacent vertebral bodies, and one fourth have involvement at more than one level. MRI detects infection earlier than other imaging modalities. The replacement of marrow by inflammatory tissue is seen as abnormally low signal intensity in the vertebral body on Tl-weighted images (Figure 37A.90). Disc space involvement usually is seen as narrowing of the disc space and a slight loss of signal of the nucleus pulposus on Tl-weighted images and high-intensity signal in the disc on T2-weigh ted images. In many patients these changes in the bone and disc are associated with adjacent inflammatory tissue anteriorly or posteriorly in the epidural space of the spinal canal. After contrast administration, enhancement is seen in the infected disc space and vertebral bodies.

Tuberculous Infections. The most common site of infection of tuberculous spondylitis is at LI; it is much less common in the cervical and sacral regions. Classically, spinal tuberculosis is thought to begin in the anteroinferior portion of the vertebral body. The infection can spread beneath the anterior longitudinal ligament involving adjacent vertebral bodies. Bone destruction typically is more extensive than in pyogenic infections. Contiguous vertebral body involvement with destruction of the disc occurs in one half of cases, and spread of infection beneath the anterior [ongirndin.il ligament may involve noncontiguous vertebral bodies. This multiplicity of vertebral body involvement sometimes makes differentiation from metastatic disease difficult. Paraspinal infection and gibbus deformity are common in tuberculous spondylitis. The size of the paraspinal lesion has been noted to be generally larger in tuberculosis than in pyogenic infections. These paravertebral ahscesses may calcify and thus may be better identified on CT.

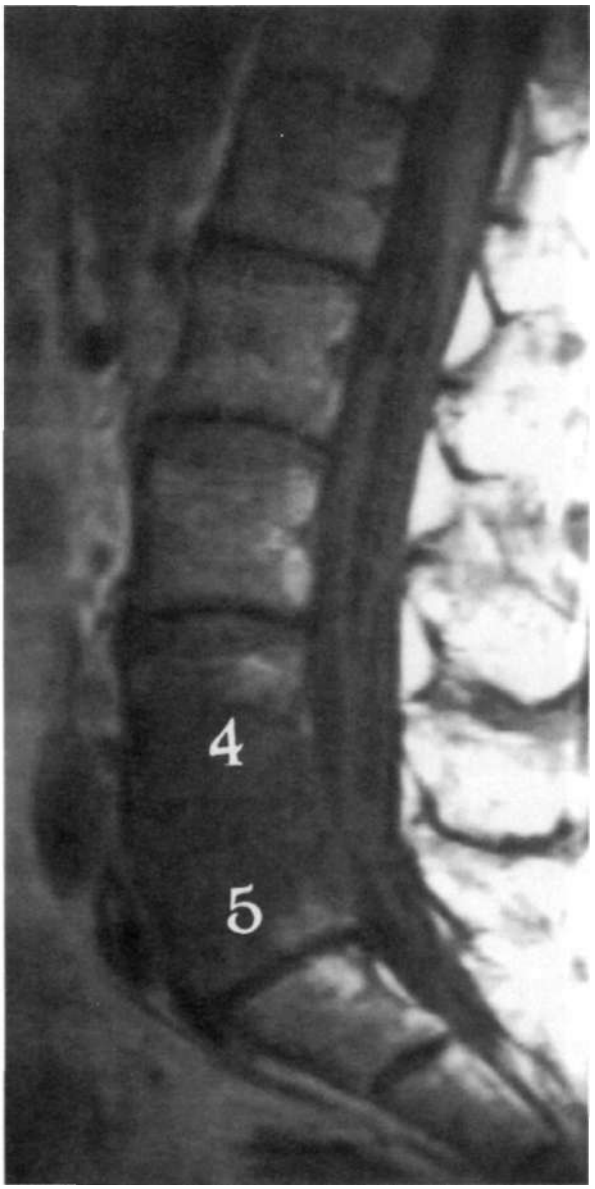

FIGURE 37A.90 Disc space infection. L4-L.S disc space infection in a 65-year-old intravenous drug abuser with blood cultures positive for *Staphylococcus aureus.* Magnetic resonance imaging scans reveal changes consistent with disc space infection and osteomyelitis at L4-L5. (A) Tl-weighted image shows abnormal low signal in the 14 and 15 bodies. *Continued*

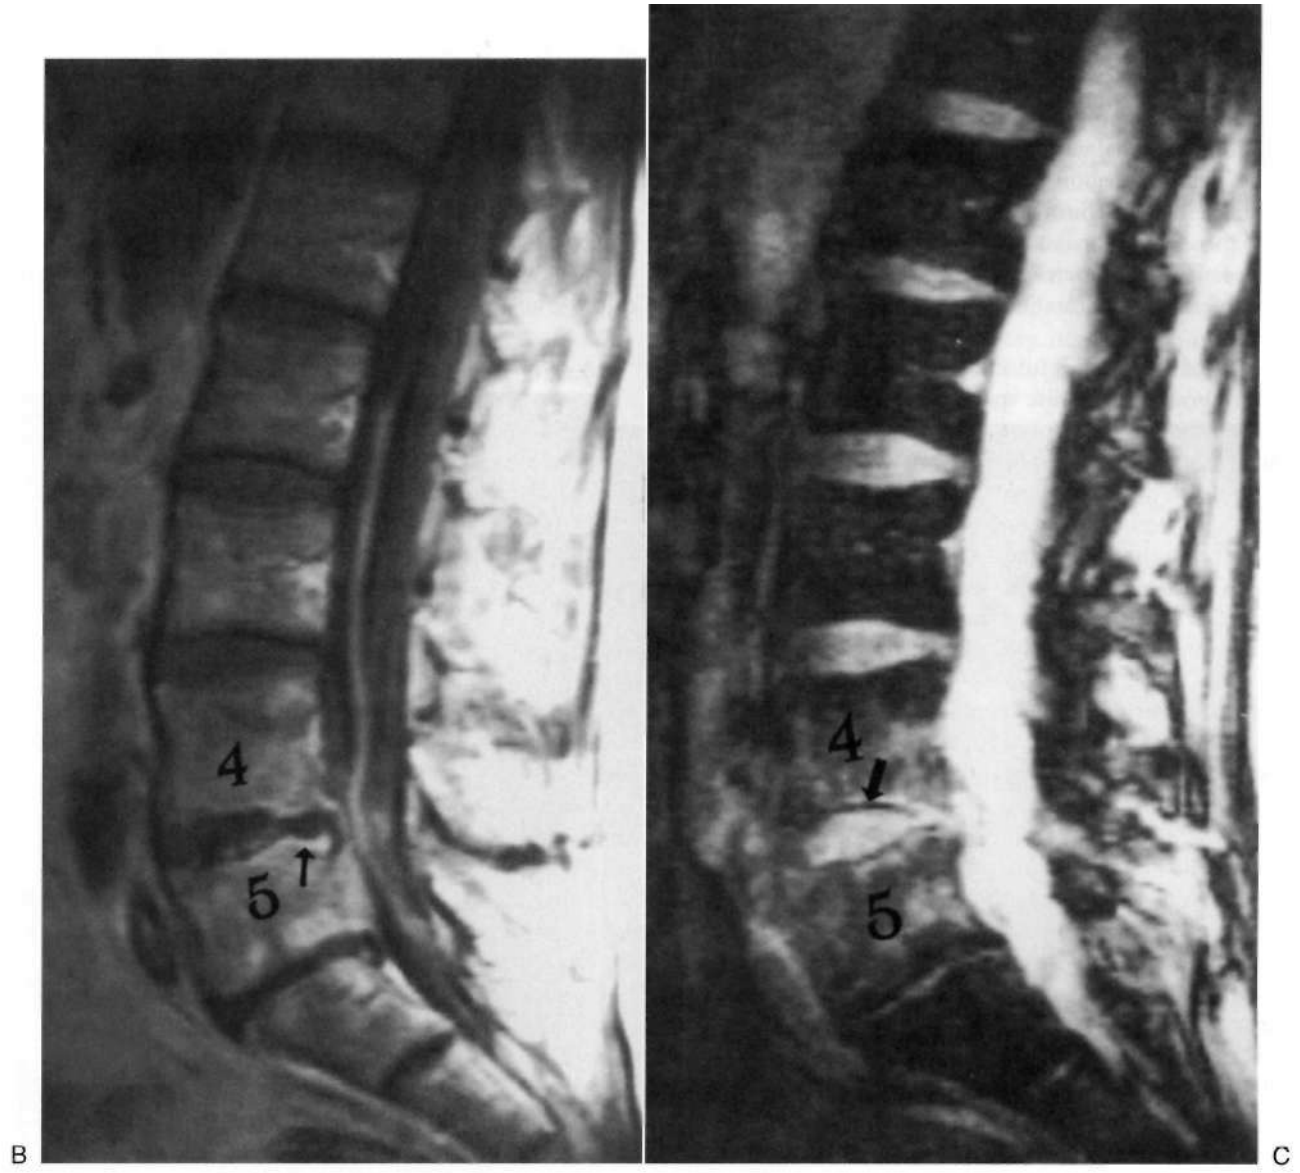

FIGURE 37A.90, cont'd. (B) Postcontrast-enhanced T1-weighted image demonstrates linear enhancement of the L4–L5 disc (*arrow*) and some epidural enhancement. (C) The T2-weighted image shows a uniform hyperintense signal in the disc (*arrow*) with absence of the normal low-signal intranuclear cleft (compare with the other disc spaces).

Epidural Abscess. An epidural abscess, although an uncommon entity when not associated with osteomyelitis or discitis, is important to recognize because early diagnosis greatly improves patient outcome. MRI generally facilitates the diagnosis and may be positive earlier than a radionuclide scan. Early diagnosis is important because timely decompression can save neurological function.

Flexion-rotation injury is unusual but very unstable and often associated with severe neurological damage and sequelae such as paraplegia. The anterior column is compressed during rotation, whereas the middle and posterior columns are disrupted by tensional forces. Subluxation and dislocation are common imaging findings as are widening of the intcrspinous distance and fractures of the laminae and transverse processes, facets, and adjacent ribs

Although MRI and CT myelography are equally sensitive (91% and 92%, respectively) in detecting epidural abscesses, MRI offers the advantage of distinguishing epidural abscesses from other entities, such as herniated discs, spinal tumor, or spinal hematoma (Sklar et al. 1993). Another advantage of MRI over CT myelography is its noninvasive nature, avoiding the potential of spreading the infection and producing meningitis via the spinal puncture needed for myelography. On plain MRI, an epidural abscess appears as a mass that is isointense to spinal cord on Tl-weighted images and often has high-intensity signal on T2-wcighrcd images. The epidural abscess may go

unrecognized if its signal is similar to that of adjacent CSF. With contrast enhancement, however, an epidural abscess can be delineated clearly on MRI. Most epidural abscesses enhance in a homogeneous fashion, occur adjacent to an infected disc space level, and involve two to four spinal segments. The organism most commonly responsible for epidural abscesses is *S, aureus,* as in vertebral osteomyelitis.

Chapter 37
Neuroimaging

B. COMPUTED TOMOGRAPHIC AND MAGNETIC RESONANCE VASCULAR IMAGING

Brian C. Bowen, Gaurav Saigal, and Armando Ruiz

For the past decade, a major focus of neuroimaging has been the development of noninvasive methods far delecting vascular disease. Three techniques, magnetic resonance angiography (MRA), computed tomographic angiography (CTA), and Doppler sonography (DS), are now used commonly in clinical practice and have progressed to the point that, individually or in combination, these techniques rival catheter angiography in accuracy of detection of certain vascular lesions, such as extracranial carotid stenosis or dural venous sinus thrombosis. Although MRA has been applied more extensively than CTA, the use of CTA is growing rapidly because of the availability of helical computed tomography (CT) scanners. CTA has achieved results comparable to those of MRA in detecting cervical carotid stenosis and intracranial aneurysms (White et ai. 2001; Randoux et al, 2001).

MAGNETIC RESONANCE ANGIOGRAPHY

Traditional Methods

In general, two methods that do not include an injectable contrast agent have been used to generate contrast between flowing blood in a vessel and surrounding stationary tissues. The first and most commonly used method is rime-of-flight (TOF) MRA, and the second is phase contrast (PC) MRA. In both methods, hydrogen nuclei (protons) in a selected volume of interest are excited using a radio-frequency (RF) pulse, which is typically part of a gradient-recalled echo pulse sequence. Before excitation, the nuclei have a net longitudinal magnetization parallel to the main magnetic field. After excitation, the magnetization has been tipped through a small angle (typically 10-40 degrees) so that it now has two components: a transverse magnetization, which produces the detectable magnetic resonance (MR) signal, and some residual longitudinal magnetization. The transverse magnetization is defined by two properties: its magnitude and its orientation (or phase angle). The magnitude produced by nuclei in flowing blood (moving or flowing nuclei) can be made to differ from that produced by nuclei in the adjacent stationary tissue (stationary nuclei). This difference is the basis for vascular contrast in TOF MRA. Alternatively, the orientation produced by flowing nuclei can be made to differ from that of stationary nuclei using a directional flow-encoding magnetic field gradient. This is the basis for vascular contrast in PC MRA.

The difference in magnitude, and hence signal, for flowing nuclei and stationary nuclei in TOF MRA results from the following effects. The stationary nuclei remain in the volume of interest throughout the time of the MR scan and arc repeatedly exposed to an RF excitation pulse at short intervals (recovery time [TR] less than 50 milli-seconds). After a few excitations, the longitudinal magnetization of the stationary nuclei is reduced significantly to a steady-state value, well below the initial value. Consequently, the magnitude of the transverse magnetization on successive excitations is small, resulting in an MR signal from stationary tissue that is markedly reduced, or saturated. Flowing nuclei, on the other hand, do not remain in the volume of interest. Because of continual wash-in and wash-out, the flowing nuclei experience only one or a few excitations (Plate 37B.I). The MR signal from flowing blood therefore is unsaturated (appearing bright on the **MRA** image) and greater than that of stationary tissue (appearing dark). The gradient-recalled echo pulse sequence

parameters that primarily affect vascular signal are the TR and the flip angle. As noted previously, the MR signal also depends on the phase of the transverse magnetization. The TOF method minimizes this dependence by using pulse sequences that compensate for the phase variation caused by position or velocity and by sampling the MR signal as soon as possible after excitation (echo delay time |TE] less than 7 milliseconds}.

In PC MRA, a magnetic field gradient is used to sensitize the phase of the transverse magnetization to the motion (velocity) of flowing nuclei. Two data sets are acquired with opposite sensitization and then subtracted to produce an image. For stationary nuclei, the net phase is zero, and their signal is eliminated in the final image. However, flowing nuclei move from one position in the field gradient to another between the time of the first sensitization and that of the second sensitization. Because phase varies with position in the field, the net phase after subtraction of the two data sets is nonzero, and there is residual signal from flowing blood (Figure 37B.1). To fully characterize the moving nuclei in three dimensions, flow-encoding (sensitizing) gradients must be applied along each of three orthogonal axes (e.g., superior-inferior, right-left, and anterior-posterior). The pulse sequences used in PC studies are designed to impart a phase shift that is proportional to the velocity of the moving nuclei. This phase shift must be between -180 and +180 degrees, and the larger the phase shift within this range, the greatet the vascular signal. Thus before PC angiography data are acquited, the anticipated maximum blood flow velocity (VENC) must be enteted into the pulse sequence protocol. If the flowing blood has velocities that ate the same as or slightly less than the selected VENC, optimal vascular signal results. Blood flow velocities gfcatet than VENC can produce aliasing artifacts, whereas velocities much smaller than VENC tcsult in a weak signal. Saturation effects are less in PC MRA than in TOF MRA because even heavily saturated nuclei in flowing blood generate a phase angle that is latget than that of stationary nuclei.

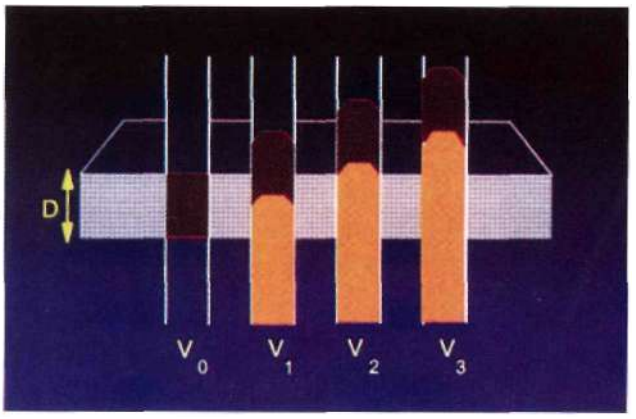
FIGURE 37B.1 Phase contrast method. Flow in the superior sagittal sinus produces bright signal against a dark background of stationary tissue. Elow-encoding gradients were applied along all three axes, with an estimated maximum blood flow velocity of 10 cm per second. The sinus, which has predominantly anterior-posterior and superior-inferior (low, and the cerebral veins, which drain into it and have predominantly right-left flow, all appear bright.

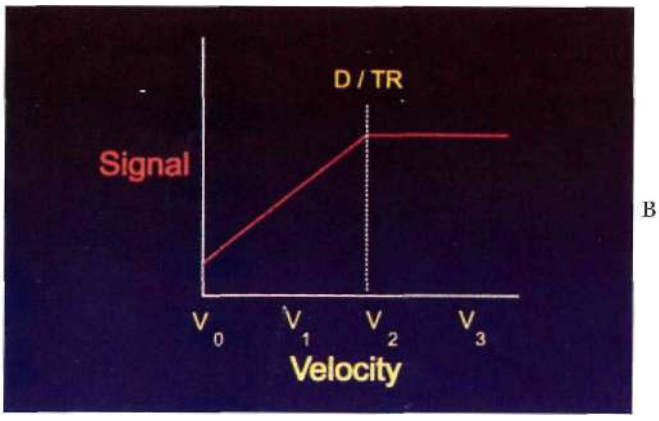
For both the TOF and PC methods, there are two apptoaches to data acquisition and image reconstruction: two-dimensional (2D) and three-dimensional (3D) Fourier transformation techniques. In 2D TOF MRA, a section (approximately 1,5 mm thick) of tissue is excited, the signal data are acquired, and the image is reconstructed. This process is tepcatcd multiple times as sequential sections (typically mote than 50 sections) are acquired, until the volume of interest has been covered (Figure 37B.2), Ideally, the plane of each section is approximately perpendicular to the vessels of interest so that there is inflow of fresh, unsaturated nuclei into each section. This results in high intravascular signal and good sensitivity to slow flow. This method is useful fot differentiating between slow flow and occlusion. If a long segment of the vessel of intetest lies in the section, however, thete can be satutation of the flowing blood and nonvisualization of the vessel.

In 3D TOF MRA, a slab that is a few centimeters thick is excited and partitioned into thin sections (approximately 0.7-0.8 mm). On reconstruction of the 3D data set, a stack of images (partitions or soutce images) is generated (Figure 37B.3). Because these sections ate thinner than the 2D sections, the 3D TOF method has better spatial resolution and is more useful for imaging tortuous and small vessels (e.g., inttactanial arteries). A disadvantage of the 3D method is that flowing blood spends more time in the slab than that in a 2D TOF individual section. Consequently, a vessel passing through the slab may have good vascular contrast on enteting the slab but become barely visible near its exit from the slab. To lessen this saturation effect, multiple thin slabs are used to covet a large region of interest. Additional modifications of the basic 3D TOF method that have been implemented on various MR scanners to improve vessel detection or reduce artifacts include magnetization transfer suppression of stationary tissue, a ramped or tilted optimized nonsaturating excitation (TONE) RF pulse (Atkinson et al. 1994), and a sliding interleaved k_Y acquisition (SLINKY; Liu et al. 1999).

Both the 2D and 3D TOF methods have the disadvantage that stationaty material with high signal intensity, such as subacute thrombus, can mimic blood flow. PC methods are useful in this situation because the high signal from stationaty tissue is eliminated when the two data sets are subtracted to produce the final flow-sensitive images.

A





B

PLATE 37B.I Time-of-flight method. (A) The section (or slab) to be imaged has thickness D. The flowing blood in a vessel that traverses the section may have a mean velocity as low as V_0 (no blood flow) or as high as V_3. At a higher velocity, there is greater wash-in of unsaturated blood *(orange)* and wash-out of partially saturated blood *(brown).* Stationary tissue *(cross-hatched region)* remains in the section and becomes saturated after several radio frequency excitations. (B) As mean blood flow velocity increases, the signal intensity of the vessel increases. Maximum signal is attained at Vi, which corresponds to complete replenishment of the blood in the section in the time (TR) between radio frequency excitations.

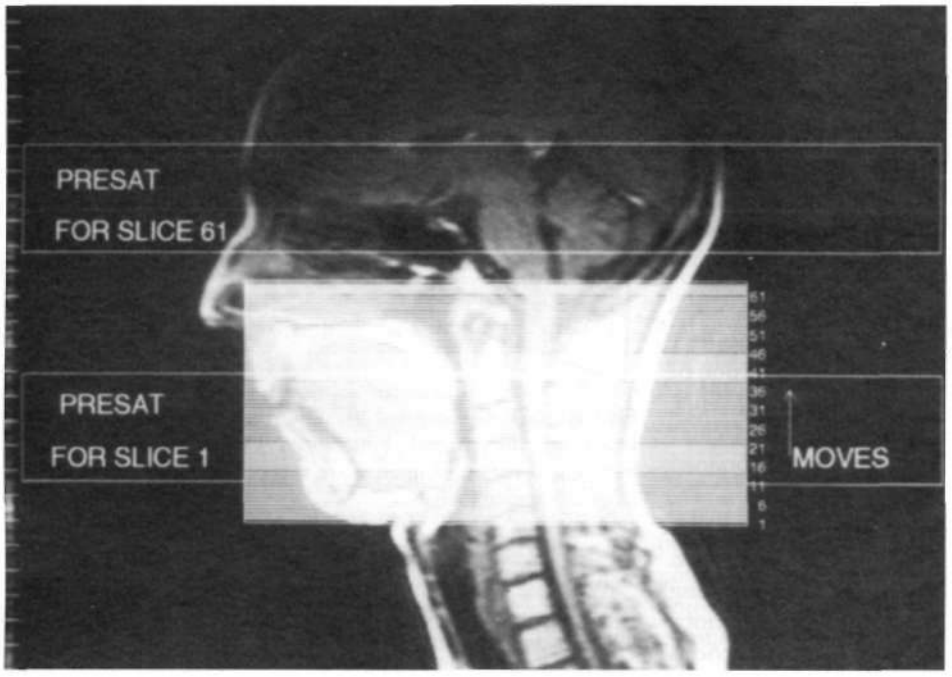


FIGURE 37B.2 Two-dimensional time-of-flight magnetic resonance angiography. Axial (transverse) sections are acquired one at a time from the region of the carotid bifurcation to the skull base. A presaturation band (PRF.SAT) is applied at a set distance above each section as it is acquired and thus "travels" with the section. Signal from the internal jugular veins is suppressed, whereas signal in the carotid and vertebtal arteries is bright.

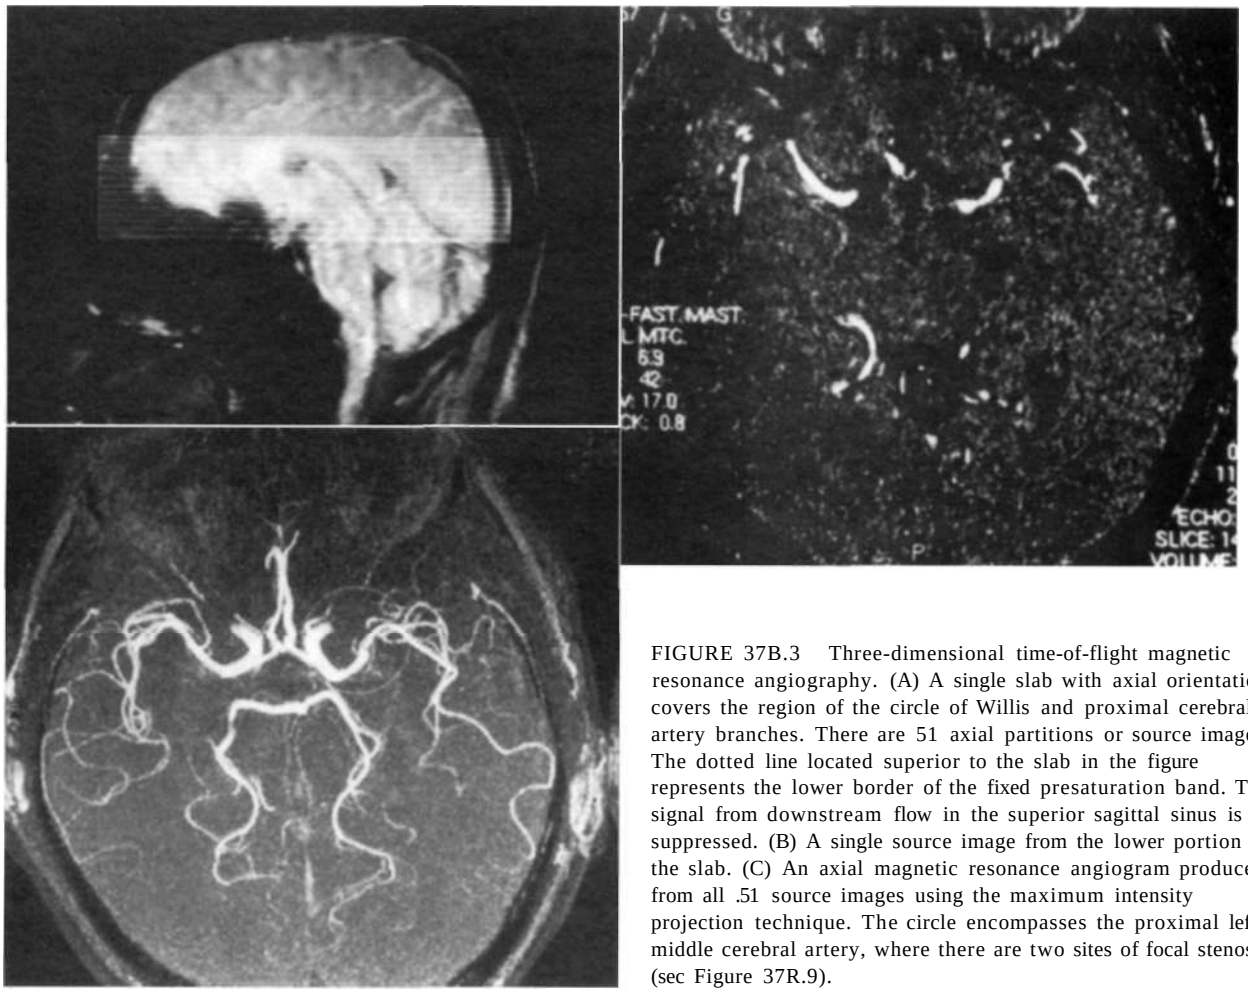

FIGURE 37B.3 Three-dimensional time-of-flight magnetic resonance angiography. (A) A single slab with axial orientation covers the region of the circle of Willis and proximal cerebral artery branches. There are 51 axial partitions or source images. The dotted line located superior to the slab in the figure represents the lower border of the fixed presaturation band. The signal from downstream flow in the superior sagittal sinus is suppressed. (B) A single source image from the lower portion of the slab. (C) An axial magnetic resonance angiogram produced from all .51 source images using the maximum intensity projection technique. The circle encompasses the proximal left middle cerebral artery, where there are two sites of focal stenosis (sec Figure 37R.9).

The PC method also incorporates 2D and 3D Fourier transformation techniques to generate images with vascular contrast. In the 2D PC technique, flow-encoding gradients are applied along two or three axes (see Figure 37B.1). A projection image displaying the vessel against a featureless hackground is produced. As described previously, PC studies are less sensitive to saturation effects than TOF studies. Therefore slow blood flow is more easily detected as long as an appropriately low VF.NC has been selected for the data acquisition. The most common applications of the 2D PC method include rapid acquisition of a localizer image of the carotid bifurcation in the neck and detection of flow in the superior sagittal (or other dural venous) sinus, or in the circle of Willis, in patients with suspected vascular occlusion. IntonthHion on flow dynamics can be obtained by acquiring cardiac-gated 2D images, called cine PC MRA. Compared with the 2D techniques, 3D PC MRA provides higher spatial resolution and information on flow directionality along each of three flow-encoding axes (superior-inferior, right-left, and anterior-posterior). The summed information from all three flow directions is displayed as a speed image, in which the signal intensity is proportional to the magnitude of the flow velocity. In general, the 3D PC method has been used less often in clinical studies than the 3D TOF method, primarily because of the longer time needed for data acquisition and uncertainties associated with the choice of VENC.

The data set that is acquired in a 3D TOF, 3D PC, or sequential 2D TOF study may be envisioned as a 3D array of pixels corresponding to the stack of partitions or sections. To display the course of a vessel, the hyperintense signal from the vessel-containing pixels is mapped onto a desired viewing plane using a maximum intensity projection (MIP) algorithm, producing a projection image. To obtain an overview of the vascular architecture, MIP images are generated in several viewing planes and then evaluated together. Targeted MIP images are produced from a region of interest within the full 3D volume (Figure 37B.4). On the MIP images, called *angiograms* because they show the courses of vessels, hyperintense signal from blood flow in both arteries and veins can cause confusion. To simplify interpretation in TOF studies, presaturation bands often are applied during data acquisition. Usually located on one side of the imaging volume, the presaturation band is a zone in which both flowing and stationary nuclei are saturated by an RF pulse that is added to the gradient-recalled echo pulse sequence. The downstream signal of a vessel that passes through the presaturation /one is suppressed because of the saturation of the flowing nuclei. In TOF studies, the location of the presaturation band may be fixed (see Figure 37B.3), or the presaturation band may travel, keeping the same distance from each imaging section or slab (see Figure 37B.2) as it is acquired. In general, the placement of presaturation bands can be chosen so as to identify flow directionality (e.g., subclavian steal),

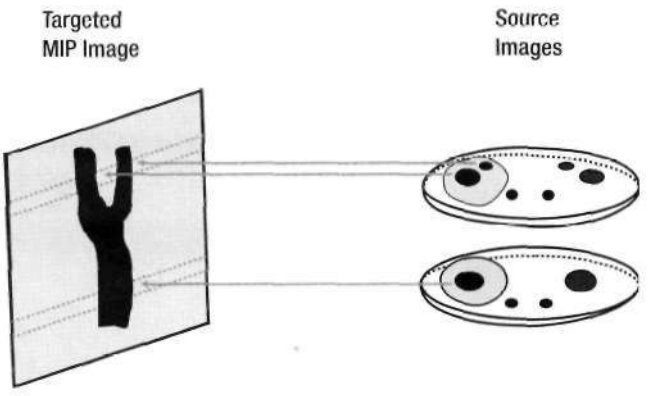

FIGURE 37B.4 Targeted maximum intensity projection (MIP) image of the carotid bifurcation. Only the vessels in the highlighted region of interest are mapped onto the viewing plane from the source images.

With the widespread clinical use of TOF MRA to assess neurovascular disease, it has become evident that two effects can limit the method's accuracy (Saloner et al. 1996}. The first effect is intravoxel phase dispersion: the presence of flowing nuclei with different phases in a single voxel. This effect is the result of a complex or disordered fluid flow pattern (acceleration, pulsatility, or turbulence). The net MR signal from the nuclei in the voxel is diminished by cancellation of the diffetcnt phases. This phenomenon is often tesponsiblc for the signal loss in an artery at a site of stenosis or marked curvature or at a bifurcation. This effect is reduced as the TE is shortened. The second effect that can limit the accuracy of the TOF method is saturation of flowing nuclei, which is most sttiking on 3D studies of small vessels. Saturation is lessened by the use of a longer TR, lower flip angle, thinner slab, or the presence of an exogenous paramagnetic contrast agent (gadolinium chelate). Gadolinium lowers the proton Tl relaxation time, preferentially increasing intravascular signal intensity for approximately 30 minutes after infusion.

3D Contrast-Enhanced MRA

The simplest type of 3D contrast-enhanced MRA (CE-MRA) uses values for TR, TE, and flip angle (e.g., 30-50 milliseconds, 5-7 milliseconds, 20 degrees) and other scan parameters that are typical of the traditional 3D TOF method and is sometimes called contrast-enhanced 3D TOF MRA. The scan time pet 3D volume is on the order of 5-10 minutes, and data are acquired in the first 10-15 minutes after the bolus infusion of a gadolinium contrasr agent (0.1-0.2 mmol per kilogram). Under these steady-state conditions, small intracranial arteries are somewhat better seen, and there is a marked improvement in the visibility of large and small veins. The use of gadolinium overcomes the problem of saturation of the slow-flowing blood in

intracranial and spinal venous structures that lie within the 3D slab. Presatu ration bands usually are ineffective at suppressing the downstream signal from vessels when gadolinium is present.

In the more technically demanding type of 3D CE-MRA (called fast, dynamic, or time-resolved CE-MRA), TR and TE are much shorter (TR less than 10 milliseconds and TF, less than 3 milliseconds), and the total scan time pet 3D volume (usually about 30-50 partitions) is reduced to 5-50 seconds, depending on hardware (gradient strength and rise time) and software (k-space sampling strategy) capabilities (Levy and Maki 1998; Melhem ct al. 1998; Golay ct al. 2001; Fain et al. 2001; Turski et al. 2001). Data are acquired as the bolus of the gadolinium contrast agent (0.2-0.3 mmol per kilogram and 2-3 mL per second infusion rate) passes through the vessels of interest, taking advantage of the marked increase in intravascular signal (first-pass method). Vessel signal is determined primarily by gadolinium concentration, analogous to conventional angiography, in which vessel detection depends on the concentration of injected contrast. Intravascular signal loss caused by phase dispersion is negligible because the TE is so short. Because the *5T*> CE-MRA method entails more tapid data acquisition, and hence higher temporal resolution, than the traditional TOF method, spatial resolution may be less; however, zero-filling of the data matrix and k-space sampling strategies, such as elliptical centric encoding with sampling of higher spatial frequencies, are used to improve vessel detail.

The 3D CE-MRA method has been applied primarily to evaluating the carotid and vertebral arteries in the neck. These ate imaged during the first pass of the gadolinium bolus, before the jugular and other neck veins are enhanced. Data acquisition in which the central lines of k space are sampled during peak arterial enhancement is key to the success of CE-MRA. The most common approaches to synchronizing the 3D data acquisition with the arrival of the gadolinium bolus in the arteries are measurement of the bolus arrival time for each patient using a small (2 mL) test dose of contrast followed by a separate 3D acquisition incorporating the appropriate time delay, automated detection of bolus attival upstream of the arterial segment of interest followed by triggering of the 3D data acquisition (Foo et al. 1997), and real-time monitoring of the bolus location by the scanner operator, who manually triggers the 3D acquisition (Fain et al. 2001). A separate approach avoids the synchronization steps by rapidly and repeatedly acquiring 3D volumes (less than 10 seconds per volume) in the neck beginning at the time of contrast bolus injection. The very rapid scan time ensures that at least one 3D volume showing only attcries will be acquired (Turski et al. 2001). For all of these techniques, both arterial and venous phase images are acquired. Subtraction of venous source images from arterial images, called digital subtraction MRA, increases vessel-to-background contrast.

APPLICATIONS

Extracranial Circulation: Carotid and Vertebral Arteries

One of the major clinical applications of MRA is the estimation of stenosis in the region of the carotid bifurcation. The attention given to this application is based primarily on the following conclusions:

- The percentage of stenosis, determined by catheter angiography using well-defined criteria, has proved effective at stratifying patients at risk for stroke in several multicentcr trials. The North American Symptomatic Carotid Endarterectomy Trial reported that recently symptomatic patients with 70-99% carotid stenosis who were treated surgically, compared with those treated medically, had an absolute risk reduction of 17% for ipsilateral stroke occurring within 2 years of treatment (Barnett et al. 1998). The European Carotid Surgery Trial showed a similar benefit (European Carotid Sutgcry Trialists Collaborative Group 1998). The Asymptomatic Carotid Atherosclerosis Study found that in asymptomatic patients with more than 60% internal carotid stenosis, carotid endarterectomy reduced stroke risk by 53% over 5 years (Executive Committee for the Asymptomatic Carotid Atherosclerosis Study 1995).
- The risks of death and disabling stroke due to catheter angiography (1.2% in the Asymptomatic Carotid Atherosclerosis Study) can exceed those of surgery itself (1.1%).
- The accuracy of the noninvasive neurovascular imaging techniques (MRA, CTA, and DS) has steadily increased in the last decade and, for concordant MRA and DS results, approaches that of catheter angiography, the gold standard.

Time-of-FUghl MRA

Based on the results of early clinical series, several conclusions may be drawn regarding carotid bifurcation stenosis estimated from TOF MRA images (Bowen et al. 1994; Norris and Rothwcll 2001). First, the degree of stenosis tends to be overestimated by the traditional 2D TOF MRA method (Figure 37B.5). A corollary of this observation is that a 2D TOF study with normal or near normal findings effectively excludes the possibility of severe (70-99%) stenosis. The most accurate results are obtained when short TE and small voxel size are used. Second, a consensus estimate of stenosis derived from a combination of the 2D and 3D TOF methods results in greater specificity than 2D TOF alone. This improvement results primarily from the inclusion of the 3D TOF method, in which stenosis is less likely to be overestimated, particularly if original (Figure 37B.6) or reformatted source images are

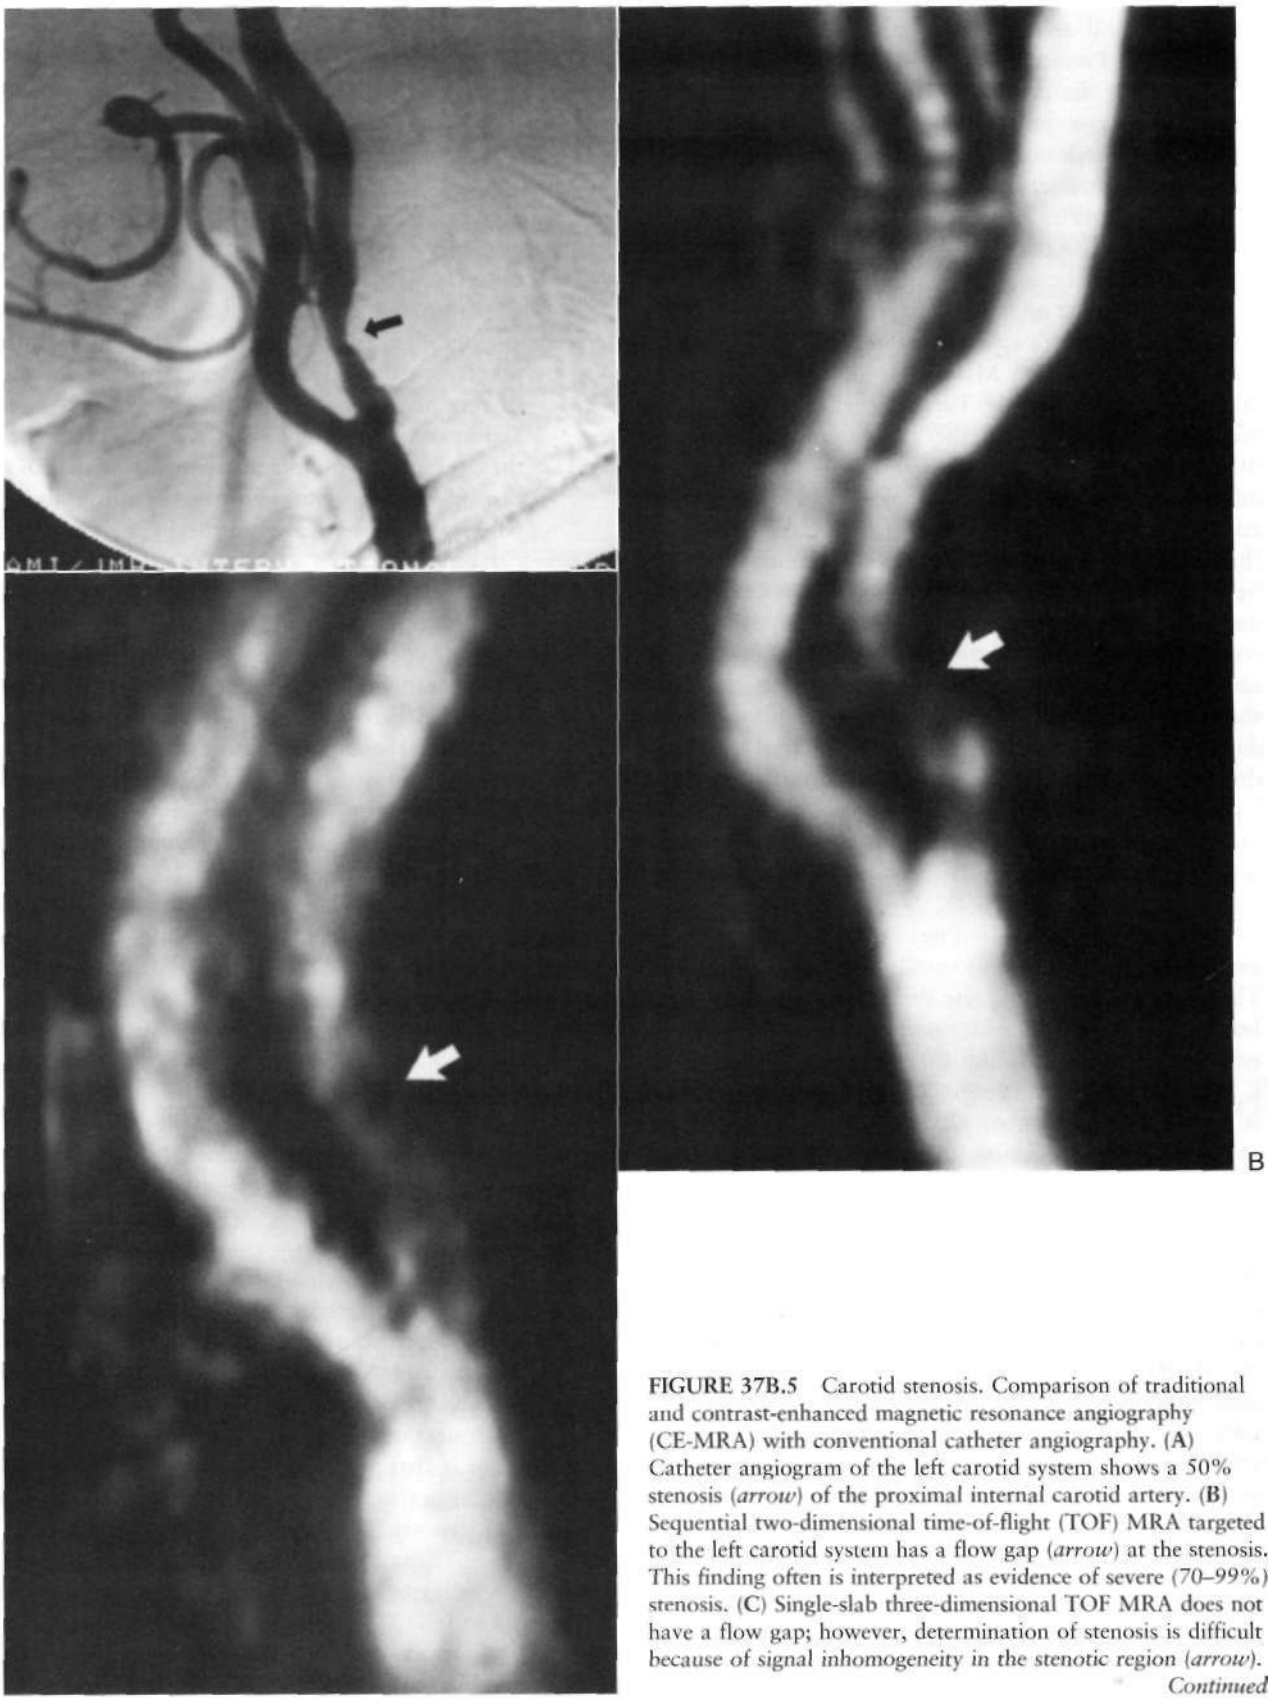

FIGURE 37B.5 Carotid stenosis. Comparison of traditional and contrast-enhanced magnetic resonance angiography (CE-MRA) with conventional catheter angiography. (**A**) Catheter angiogram of the left carotid system shows a 50% stenosis (*arrow*) of the proximal internal carotid artery. (**B**) Sequential two-dimensional time-of-flight (TOF) MRA targeted to the left carotid system has a flow gap (*arrow*) at the stenosis. This finding often is interpreted as evidence of severe (70–99%) stenosis. (**C**) Single-slab three-dimensional TOF MRA does not have a flow gap; however, determination of stenosis is difficult because of signal inhomogeneity in the stenotic region (*arrow*).

D

FIGURE 37B.5, cont'd. (D) Dynamic CE-MRA has greater vascular contrast than the two-dimensional and three-dimensional TOF techniques and demonstrates an approximately 50% stenosis *{arrow}.*

evaluated rather than the MIP images (Anderson et al. 1994). In the combined TOF approach, the 2D TOF method is used primarily to distinguish slow flow from occlusion, and in general the combined TOF approach is considered superior to DS in differentiating high-grade stenosis from occlusion. A "flow gap," which is a segmental dropout of signal from the carotid (or other vessels) caused by intravoxel phase dispersion or saturation, is often taken as a sign of stenosis measuring 70% or more. This association should be viewed with caution, however, because in one published series of patients, flow gap was observed with the 2D TOF technique at sites of 50-60% stenosis, as determined by catheter angiography (see Figure 37B.5).

Third, in detecting stenosis appropriate for carotid endarterectomy, TOF MRA is less sensitive than DS (75% MRA, 87% DS) but more specific (88% MRA, 46% DS); however, when stenosis estimates by TOF MRA and DS are concordant (Polak et al. 199.3) and then taken together, the combined MRA and DS examination is more sensitive *(96%)* and specific (85%) than either study alone. Furthermore, when patients are classified as to whether carotid endarterectomy is indicated by the noninvasive examination and then judged against the results of catheter angiography, the misclassification rate for the concordant MRA and DS results is much lower than that of cithct test alone (MRA and DS 7.9%, MRA 18%, DS 28%) (Johnston and Goldstein 2001). Therefore surgical decisions are more likely to be correct when based on concordant TOF MRA and DS results.

Three-Dimensional CE-MRA

Compared with 2D and 3D TOF MRA, 3D CE-MRA delineates carotid arterial stenosis better (Willig et al. 1998) (see Figure 37B.5). Surface morphology (e.g., ulcerated plaque) and nearly occluded vessels (e.g., "string sign") are more easily identified, and carotid arterial occlusions are more confidently identified. In recent studies, severe carotid bifurcation stenosis was detected by 3D CE-MRA with high sensitivity (93-100%) and specificity (88-96%) (Remonda et al. 2002; Johnson et al. 2000; Huston et al. 2001; Lenbart et al. 2002; Wutke et al. 2002), using conventional catheter angiography as the gold standard. Two groups of investigators have reported results for 3D CE-MRA and TOF MRA (Houston et al. 1998; Johnson et al. 2000; Huston et al. 2001). Both groups found that CE-MRA had higher sensitivity than TOF MRA in detecting severe stenosis: 93% versus 88% (Houston et al. 2001) and 94% versus 82% (Johnson et al. 2000), respectively. Specificity of CE-MRA was slightly lower thanthatofTOFMRA:88% versus 89% and 95% versus 100%, respectively. Although we are unaware of any published reports of the sensitivity, specificity, or misclassification rate (for carotid endarterectomy) based on concordant results of 3D CE-MRA and DS, such an investigation seems a likely next step in the process of evaluating noninvasive carotid imaging techniques as alternatives to conventional catheter angiography.

Atherosclerotic narrowing of the carotid system less commonly involves the intracranial carotid siphon and the origin of the common carotid artery. Tandem stenosis occurs in approximately 5% of patients with significant bifurcation disease, and the second site usually is the siphon. Although there have been no published reports documenting the accuracy with which MRA detects tandem bifurcation-siphon stenoses, it is sensible to cover the siphon in addition to the bifurcation and cervical internal

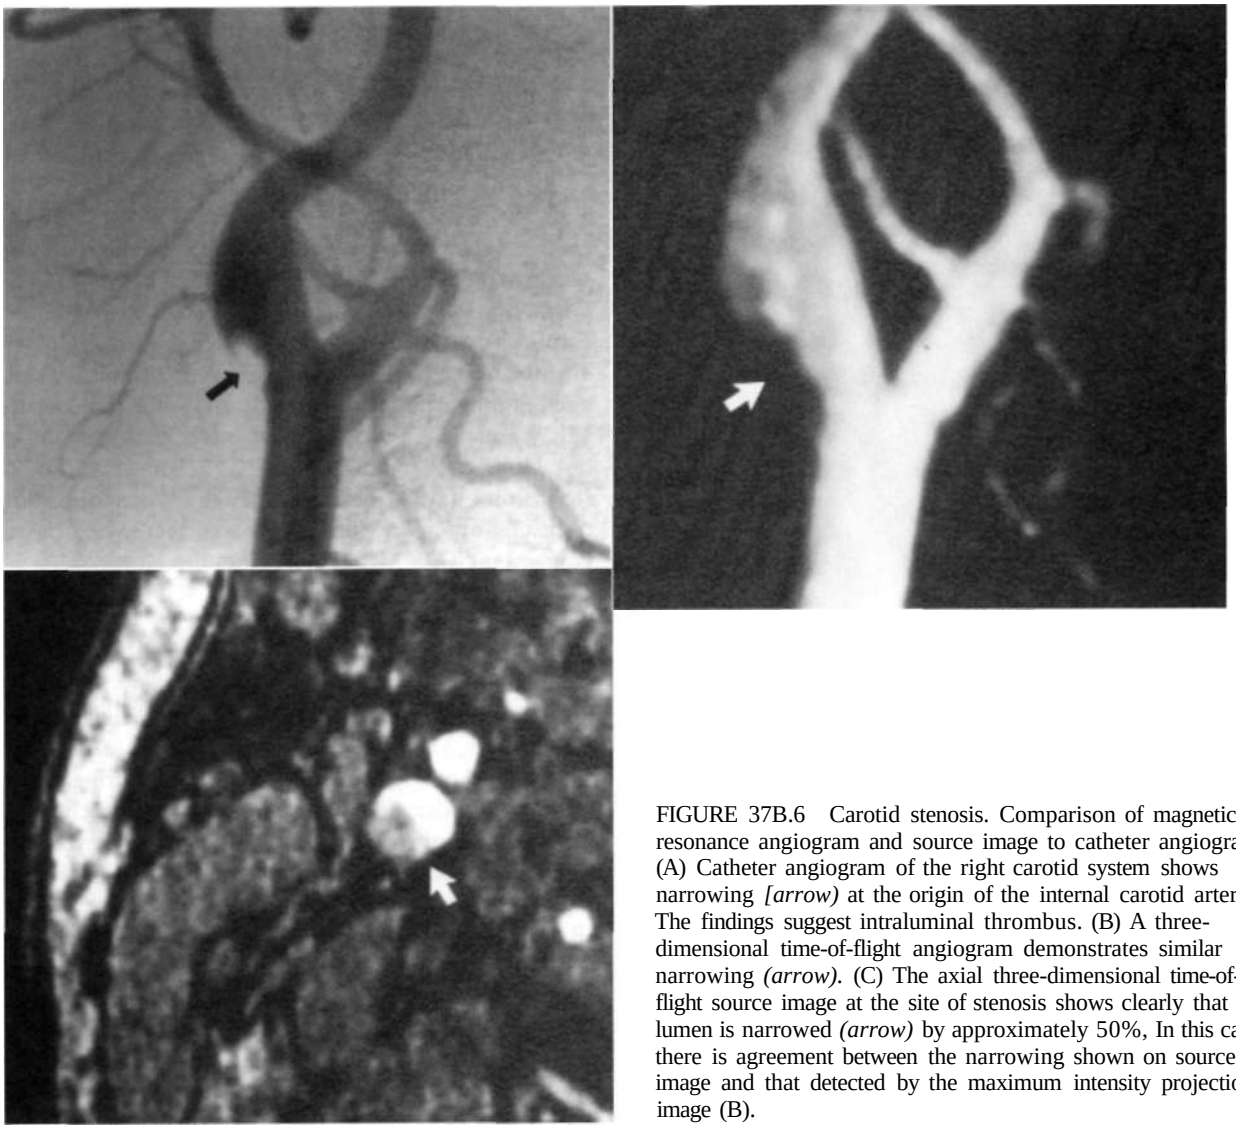

FIGURE 37B.6 Carotid stenosis. Comparison of magnetic resonance angiogram and source image to catheter angiogram. (A) Catheter angiogram of the right carotid system shows narrowing *[arrow)* at the origin of the internal carotid artery. The findings suggest intraluminal thrombus. (B) A three-dimensional time-of-flight angiogram demonstrates similar narrowing *(arrow).* (C) The axial three-dimensional time-of-flight source image at the site of stenosis shows clearly that the lumen is narrowed *(arrow)* by approximately 50%, In this case, there is agreement between the narrowing shown on source image and that detected by the maximum intensity projection image (B).

carotid artery (ICA) during preoperative screening. For 3D TOP MRA with pulse sequences designed to limit saturation effects (described earlier}, the carotid arteries may be satisfactorily imaged from the level of the midportion of rhe common carotid to the circle of Willis. The origin of the common carotid typically is omitted for several reasons, including inadequate RF coil coverage and respiratory motion artifacts. With CE-MRA the entire length of each carotid can be imaged; however, the spatial resolution may be inadequate to allow confident evaluation of even moderate stenosis of the siphons. At our institution, evaluation of the carotid system by MRA involves a 3D TOF study, using SLINKY, from the common carotid bifurcation to the circle of Willis, and a sequential 2D TOF study from the carotid bifurcation to the skull base (see Figure 37B.2). If there is a flow gap, poorly shown surface morphology, or findings indeterminate for near occlusion versus occlusion involving the bifurcation and cervical internal carotid, then a time-resolved 3D CE-MRA is done.

Atherosclerotic narrowing of the vertebral artery commonly involves the origin or distal intracranial portion. For TOF MRA evaluation of posterior circulation cerebrovascular disease, the vertebral origins usually are not evaluated, for the same reasons that the common carotid origins are nor evaluated. Typically, a 3D TOF study covering the vertebral-basilar system from the C2 level to the tip of the basilar artery is done (Wentz et al. 1994). However, sequential 2D TOF MRA of the neck is useful in determining whether proximal occlusion is present and in demonstrating flow direction in the vertebral arteries in patients with suspected subclavian steal. A 2D TOF study obtained with no presaturation band shows flow enhancement in both vertebral arteries, whereas a study obtained with a superiorly located, walking presaturation band

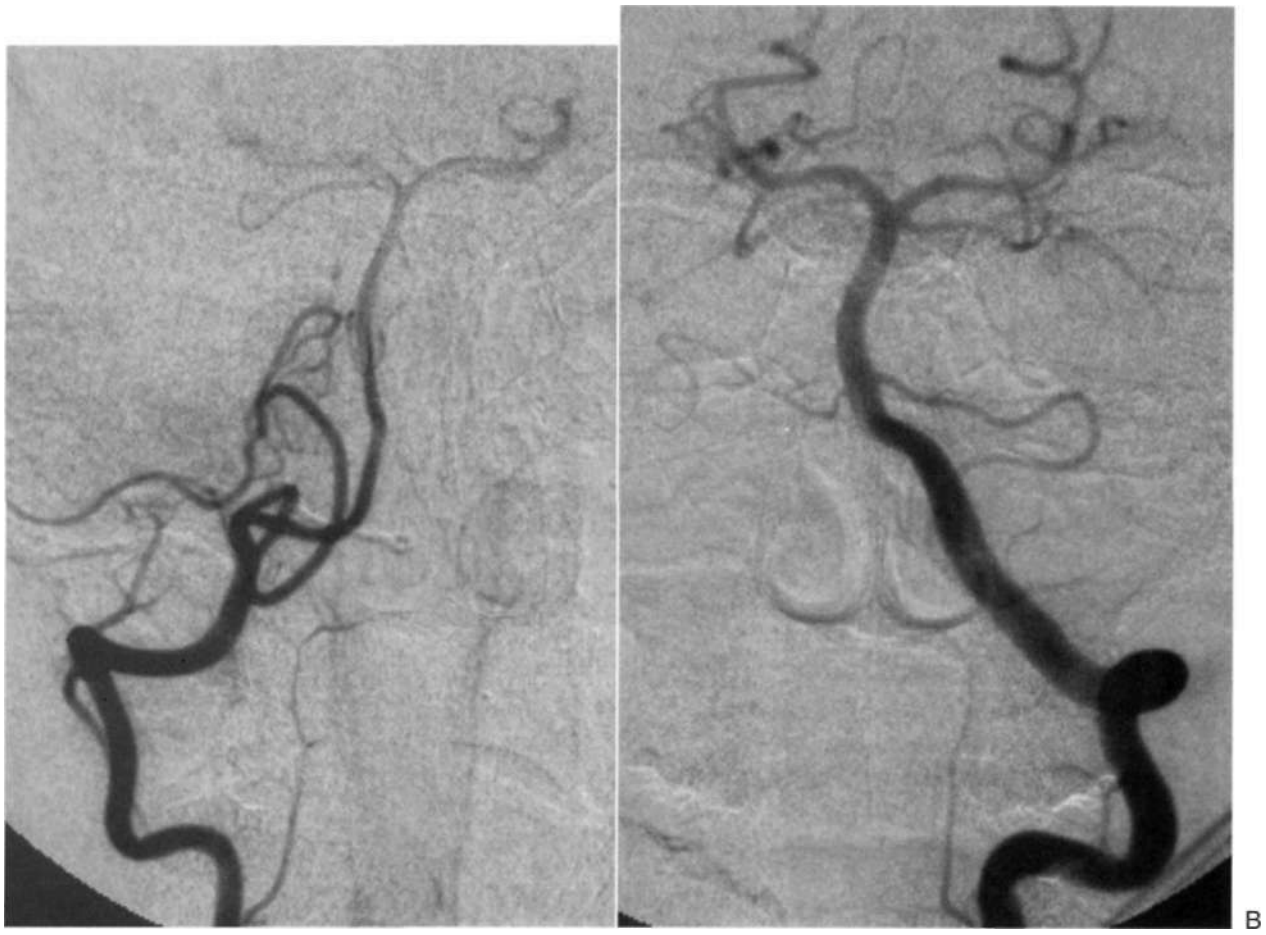

FIGURE 37B.7 Vertebral artery arrifactual signal loss. Comparison of traditional magnetic resonance angiography (MRA) and contra st-en ha need MRA (CE-MRA) with conventional catheter angiography. (A and B) Normal catheter angiograms of the right (A) and left (B) vertebral arteries. The left vertebral artery is dominant in this patient with a history of resection of a foramen magnum meningioma. *Continued*

shows flow only in the vertebral artery with normal antegrade flow. The 3D CE-MRA techniques can display both the origins and distal intracranial portions of the vertebrals in a single acquisition and are particularly useful in evaluating vertebral artery segments with partial or complete signal loss caused by slow flow and in-plane saturation effects (Figure 37B.7). The accuracy of 3D CE-MRA measurements of stenosis at the vertebral artery origin has yet to be reported, although the accuracy is unlikely to equal that of carotid bifurcation measurements because of the smaller size of the vertebral origins (Koliias et al. 1999). Nevertheless, an analysis of the elliptical centric encoding technique predicts that it can achieve an isotropic spatial resolution of 1 mm (before zero filling) in a field of view (FOV) typically used for bilateral carotid and vertebral imaging (Fain et al. 1999). Stenosis or occlusion of the subclavian artery is now routinely evaluated with 3D CE-MRA.

Carotid or vertebral artery dissection may be delected adequately using routine T1- and T2-weighted images; however, subacute, hyper intense thrombus is better seen if fat suppression is implemented on Tl-weigbted acquisitions to eliminate the high signal intensity from perivascular adipose tissue. When the evaluation includes a 2D or 3D TOF combined study or 3D CE-MRA (Koliias et al. 1999), the detection of stenosis (Figure 37B.8), pseudoaneurysm, or occlusion is improved. Also, the presence of a thrombosed false lumen is more convincingly demonstrated when spin-echo images are supplemented with PC or TOF images showing absence of flow in the false lumen.

Intracranial Circulation

Arteries

The accuracy of TOE MRA in detecting stenosis or occlusion of **the** larger intracranial vessels, compared with that of conventional catheter angiography, has been determined by several investigators (Furst ct al. 1996; Stock et a I. 1995). Initially, accuracy was limited by technical shortcomings, such as long TE, lower spatial resolution, and single slab acquisition, that permitted greater loss of vascular signal caused by inrravoxel phase dispersion,

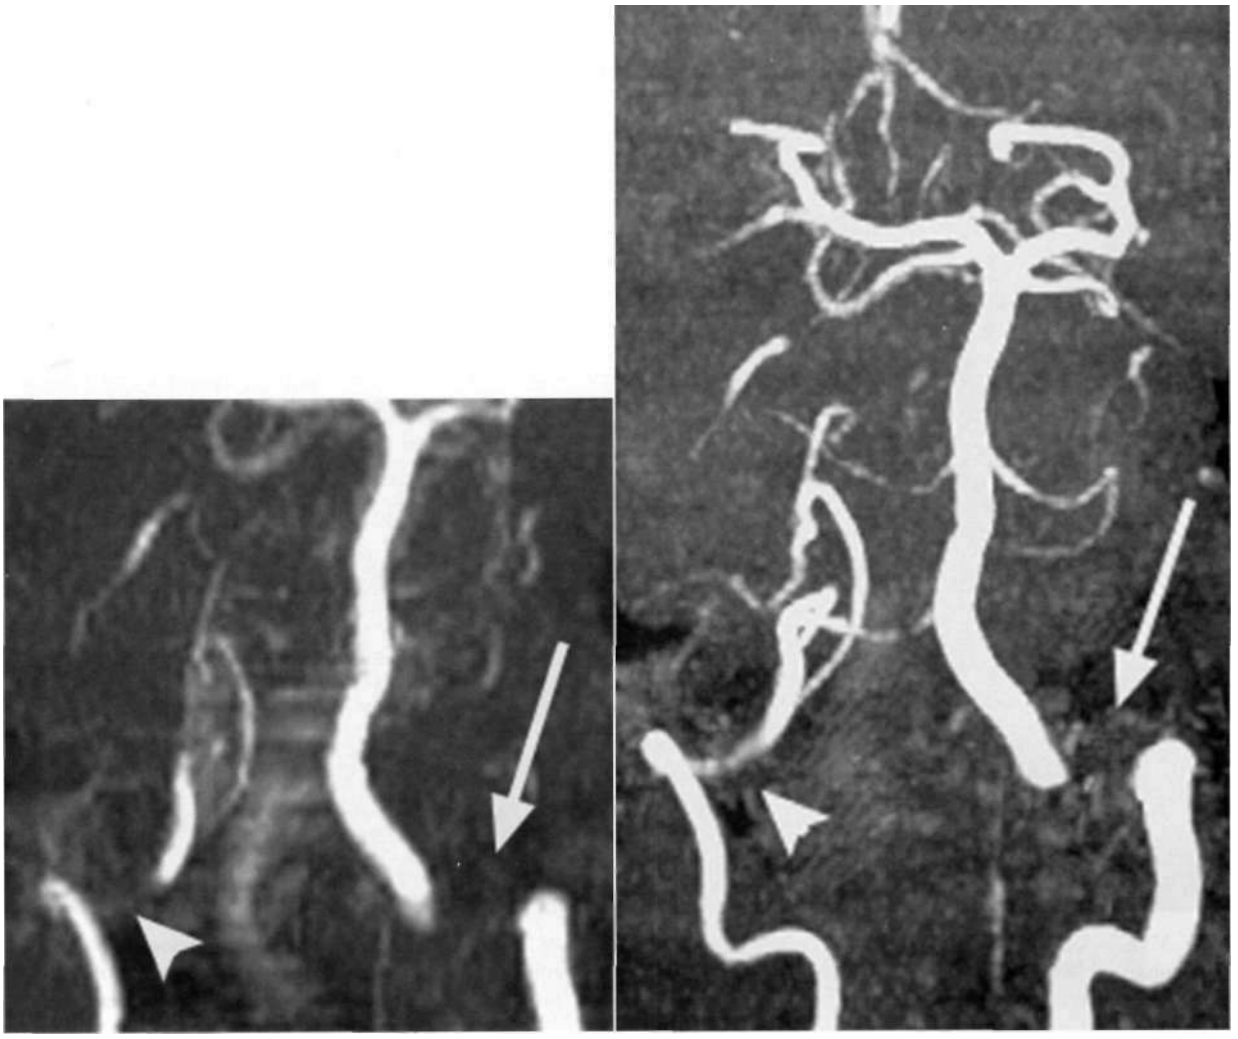

FIGURE 37B.7, cont'd. (C) Two-dimensional time of flight (TOF) MRA shows extensive signal loss involving the horizontal portions of the right *{arrowhead)* and left *(arrow*) vertebral arteries at the level of the foramen magnum. Ill-defined background hyper in ten shy medial to the arrowhead results from cerebrospinal fluid flow in the subarachnoid space. (D) Three-dimensional TOF MRA with higher spatial resolution provides better depiction of small arteries and continuity of the right vertebral artery *{arrowhead),* yet marked signal loss *(arrow)* in the left vertebral artery persists. *Continued*

susceptibility effects, and salutation effects. Signal loss was typically evident in the petrous, cavernous, and supraclinoid segments of the ICA and in the proximal Ml segment of the middle cerebral artery (MCA), Second- and third-order btanches of the cerebral arteries were poorly shown. Later, investigators reported that normal vessels and completely occluded vessels could be graded correctly, when compared with catheter angiogtaphy results; however, stenotic segments wete correctly graded (as cither less than ot more than 50% narrowing) in only about 60% of stenoses. Subsequently, technical improvements in the .3D TOF method (variable flip angle, magnetization transfer suppression, multiple thin-slab acquisitions, and higher spatial resolution [512 matrix or greatet]) improved the accuracy of stenosis grading, with investigators reporting that 80% of stenoses gteater than 70% and 88% of stenoses less than 70% are quantified correctly at MRA. The current approach to evaluating the inttactanial arteries is a multislab 3D TOF acquisition that covets the head from the foramen magnum to the roof of the thitd ventricle. Each slab has a transaxial orientation and may or may not have a superiorly located presaturation band. The axial source images and the rcprojected MIP images (Figure 37B.9) arc reviewed in conjunction with other MR images (e.g., Tl-weightcd, T2-weighted, fluid-attenuated inversion recovery, diffusion-weighted, and susceptibility-weighted [perfusion| images) in an integtated approach to characterizing brain infarction (Wittsack et al. 2002). In the setting of acute infarction with the potential for thrombolytic treatment, protocols often include a rapidly acquired

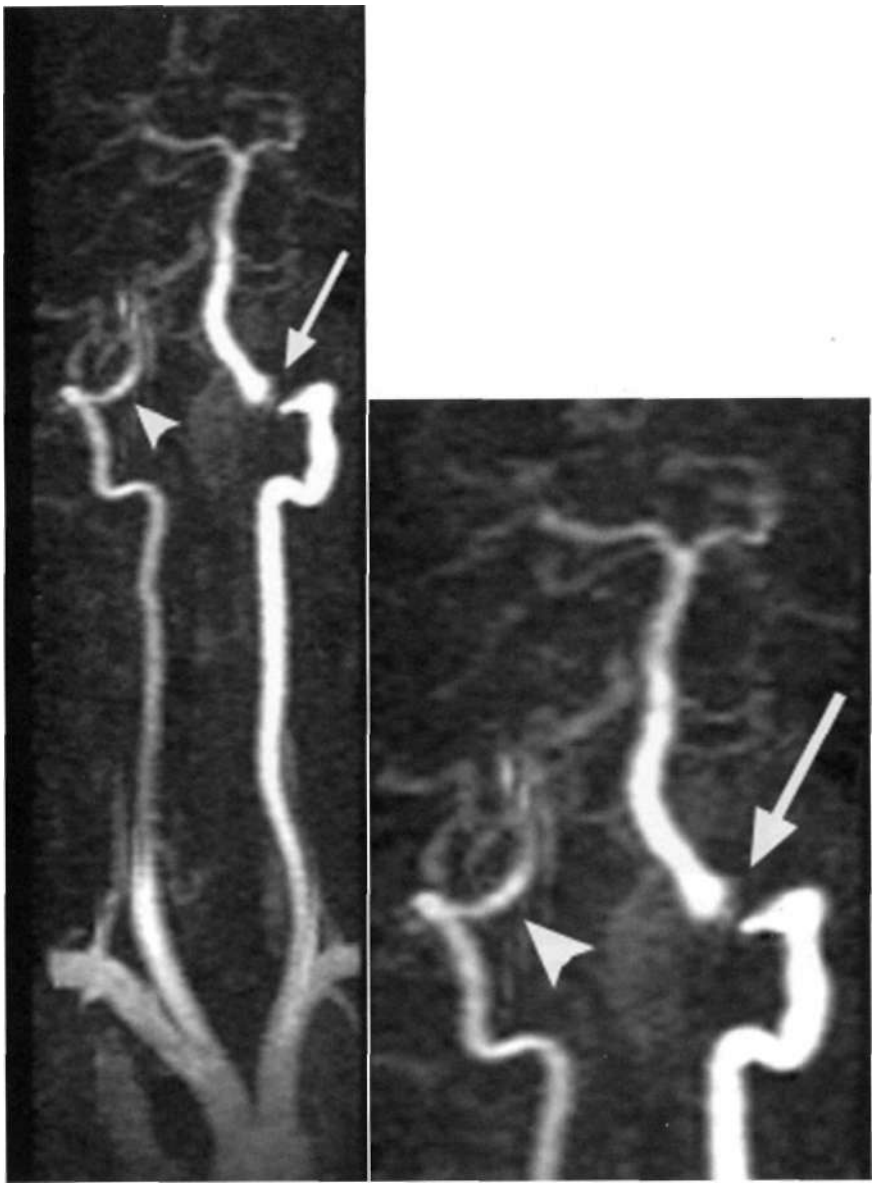

FIGURE 37B.7, cont'd. (E) CE-MRA shows the entire vertebro-basilar arterial system. Spatial resolution is less than in (D). (F) Zoomed view of the distal vertebral arteries from (E) reveals complete restoration of signal in the right vertebral artery *(arrowhead)* and nearly complete restoration of signal in the left vertebral artery *[arrow),* Persistent focal signal loss resulted from a small metal surgical clip adjacent to the left vertebral artery; the clip is obscured by contrast in (B). All MR angiograms were produced with the targeted maximum (pixel) intensity projection technique.

2D PC MR study of the circle of Willis instead of the more time-consuming 3D TOP study. Other clinical settings in which MRA reportedly complements routine MR imaging include sickle cell disease, moyamoya disease, and hemi-facial spasm and ttigeminal neutalgia. **Flow** dynamics (magnitude and direction) in the circle of Willis are more easily determined with the PC method, especially when vessel diameters are 1 mm or more.

As described earlier, the simplest type of 3D CE-MRA technique uses scan parameters typical of 3D TOP MRA acquisitions with scan times on the otder of 5-10 minutes per 3D volume. Under these steady-state conditions, visibility of the small intracranial arteries is greater after intravenous gadolinium administration; however, a much greater increase in visibility occurs for the intracranial veins. Consequently, the MIP images become cluttered with veins, resulting in greater difficulty in identifying and delineating specific arteries. With dynamic 3D CE-MRA, as used for extracranial catotid imaging, temporal resolution is improved, and visibility of arteries is greater than that of veins. However, vascular image detail is variably diminished depending on CE-MRA technique, and temporal resolution usually is incomplete because only about 5 seconds separates the onset of intracranial arterial enhancement from venous enhancement. Some investigators have suggested using careful region-of-intetest MIP postprocessing to further exclude veins from intracranial artery displays. Despite the limits placed on spatial resolution by **the** dynamic 3D CE-MRA technique, Parker and colleagues (1998} have shown that, in theory, imaging with a TR of 7-10 milliseconds (e.g., scan time approximately 1 minute per 3D volume} and a Tl relaxation time of 2.S-50 milliseconds for flowing blood containing gadolinium (first-pass arterial concentration of approximately 5-10 mM) can produce

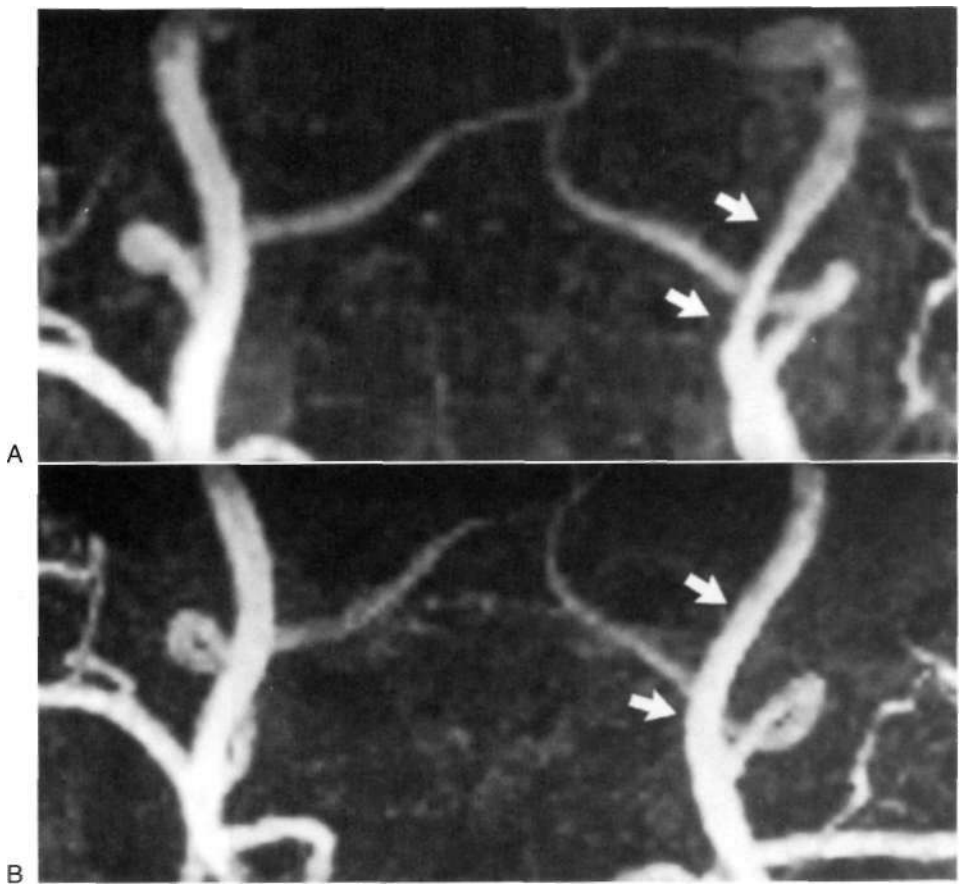

FIGURE 37B.8 Resolution of carotid dissection followed with magnetic resonance angiography. (A) Magnetic resonance angiogram produced by the three-dimensional time-of-flight technique shows a segmental stenosis *[arrows)* involving the distal cervical portion of the left internal carotid artery. (B) A repeat study, obtained after anticoagulant therapy, demonstrates a return to normal caliber of the internal carotid artery segment *(arrows).*

images of the intracranial arteries (approximately 0..S mm diameter) with vascular contrast comparable to that produced by the steady-state 3D CE-MRA technique. Investigational studies indicate that dynamic 3D CE-MRA will play a significant role in evaluating intracranial arterial steno-occlusive disease, but the accuracy, reproducibility, and reliability of CE-MRA measurements compared with those of catheter angiography and TOF MRA in controlled clinical trials have not yet been reported.

3D TOF MRA is now readily accepted as a noninvasive screening tool for familial aneurysmal disease. It has also been used as an alternative to catheter angiography (intra-arterial digital subtraction angiography [IA-DSA]) for the surgical management of ruptured aneurysms. A review of the relevant literature for 1988-1998 found that TOF MRA (and CTA) depicted aneurysms with an accuracy of about 90% (White, Wardlaw, and Easton 2000). Sensitivity was much greater for detection of aneurysms larger than 3 mm (94%) than for detection of aneurysms 3 mm or smaller (38%). Diagnostic accuracy was similar for anterior and posterior circulation aneurysms {Figure 37B.10). In general, noninvasive imaging evaluation includes a review of T1- and T2-weighted (fast) spin-echo images and T2'*-weightcd gradient-echo images, in addition to the source images and MIP images from the MRA acquisition.

The role of 3D TOF MRA in assessing intracranial aneurysms before endovascular treatment is adjunctive to the definitive IA-DSA study (Adams, Lait, and Jackson 2000). Based on a composite assessment that included aneurysm detection rate, aneurysm morphology, neck interpretation, and branch vessel relationship to the aneurysm, Adams and colleagues found MRA to be inferior to IA-DSA overall and to have missed aneurysms smaller than 3 mm. Nevertheless, MRA provided complementary information to IA-DSA in anatomically complex areas or in the presence of intramural thrombus. The authors applied the assessment to four different types of image data display: axial source images, multiplanar reconstruction (MPR) of the source image data, MIP images, and 3D isosurface-rendered images. Among these types of images, the MPR and 3D isosurface images were comparable to the IA-DSA images in all categories of the composite assessment, whereas the MIP images scored poorly in all categories

FIGURE 37B.9 Proximal middle cerebral artery (MCAJ stenosis (same patient as in Figure 37B.3). (A) Coronal reprojection magnetic resonance angiogram was produced from die axial source images shown in Figure 37B.3. The coronal view shows better than the axial view (Figure 37B.3C) that there is stenosis *(arrows)* involving both M2 branches of the MCA. (B) Catheter angiography confirms the presence of both stenoses (arrows).

except aneurysm detection. These findings indicate that better noninvasive characterization of aneurysms with TOF MRA can be achieved by adding MPR or 3D isosurface-rendered images to the source and MIP images that are now routinely reviewed in clinical practice.

Although there is no conclusive evidence that CE-MRA is superior to TOF MRA in depicting intracranial aneurysms in general, Jager and colleagues (2000) have shown that 3D CE-MRA is the method of choice for detecting the lumen and connecting vessels of giant cerebral aneurysms {aneurysms larger than 25 mm), Although both the simple steady-state and the dynamic CE-MRA techniques reliably showed the lumen and exiting vessels, the dynamic MRA technique provided superior contrast between flow and background and eliminated the short Tl contamination artifact caused by subacute intraluminal or extraluminal blood clot. Another application of MRA in which CE-MRA shows promise is in the follow-up of intracranial aneurysms treated with detachable coils. In a prospective study of 68 patients, boulin and Pierot (2001) found that the steady-state 3D CE-MRA technique correlated with DSA regarding the presence or absence of residual aneurysm in 90% of cases. In the remaining cases, the primary difference was that MRA failed to detect a remnant lumen measuring less than 3 mm. Because small aneurysm remnants or recurrences were thought not to be clinically significant, the authors concluded that CE-MRA is an option for post-tteatment follow-up and may partly replace IA-DSA.

Veins and Venous Sinuses

The approach to evaluating the intracranial veins and dural venous sinuses differs from that of arteries because of the lower velocity of venous flow and the morphology of the venous sinuses. For suspected dural sinus occlusion resulting from thrombosis or tumor invasion, the primary technique is 2D TOF MRA in conjunction with spin-echo imaging. To establish the diagnosis of venous thrombosis, lack of visualization of a vein or sinus on the source images

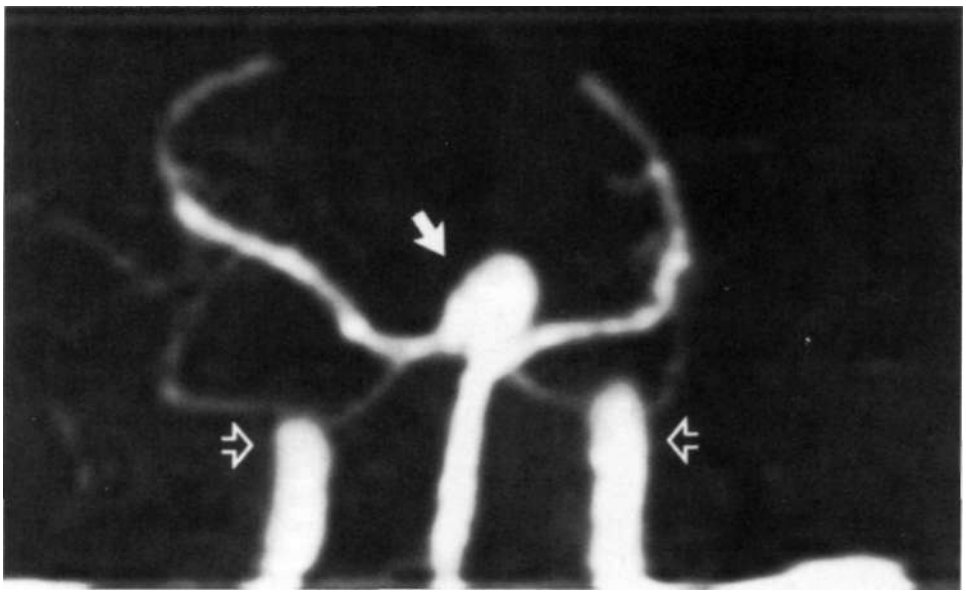

FIGURE 37B.10 Basilar tip aneurysm. Magnetic resonance angiogram (frontal view), produced from a three-dimensional rime-of-flight axial slab acquisition, shows an aneurysm *(closed arrow)* arising from the basilar artery terminus and measuring 9 mm in longitudinal diameter. Although targeted to the posterior circulation primarily, the maximum intensity projection image includes portions of the precavernous internal carotid arteries *{open arrows).*

and angiogram must ⊳L- accompanied by identification of the clot on the spin-echo images at the location of the suspected occlusion (Figure 37B.11). With the 2D TOF technique, optimal flow enhancement is achieved when a section is perpendicular to the flow direction. This condition is best approximated using coronal sections to image the sagittal, straight, and transverse sinuses (as well as the internal cerebral veins, basal veins of Rosenthal, and, to a lesser degree, the vein of Galen). The acquisition of coronal sections can be augmented by the acquisition of oblique sagittal sections to allow better flow enhancement in the postetior portions of the transverse sinuses and the cortical veins draining into the superior sagittal sinus. With the 2D TOF MR venography technique, arterial signal is reduced or eliminated by an axial presaturation band placed across the upper neck below the skull base. A common diagnostic pitfall of the technique is the presence of flow gaps in the transverse sinus. Ayanzen and colleagues (2000) observed these gaps in 31 % of patients with normal MR imaging findings. Flow gaps were not observed in the superior sagittal, straight, or dominant transverse sinuses, so gaps occurring in these locations should raise suspicion of venous obstruction. The authors found that the nondominant transverse sinuses (90% of gaps) or codominant transverse sinuses (10%) that demonstrated the flow gaps were hypoplastic yet patent by conventional catheter angiography,

Alternative techniques for demonstrating intracranial veins and dutal venous sinuses lack the robustness of the 2D TOF technique. The 3D TOF technique suffers from saturation effects and hence frequent signal loss in the veins and dural sinuses. The 2D PC technique is limited by gradient imperfections, eddy currents, aliasing artifacts, and lower spatial resolution. Although the PC technique can be useful in differentiating very slow flow in the dural sinuses from thrombosis, it was recently found to be inferior to the 2D TOF technique and a contrast-enhanced 3D FLASH (fast low-angle shot) MRA technique in displaying the normal septal veins, internal cerebral veins, and the basal veins (Kitchhof er al. 2002), Both the 3D FLASH technique and a 3D magnetization-prepared, rapid-acquisition gradient echo MR imaging technique (Liang et al. 2001) are contrast-enhanced (CE) methods and reportedly are superior to the 2D TOF technique in depicting normal venous structures, especially in overcoming the flow gap artifact. However, these CE techniques have two fundamental limitations: Both techniques involve tapid acquisition (1-2 minutes per 3D volume), so that the intensity of the intravascular signal depends on the timing of the contrast infusion relative to data acquisition, and chronic thrombus enhances with gadolinium and can mimic a patent lumen. Consequently, these two CE techniques should be viewed as adjuncts to the 2D TOF technique.

Vascular Malformations and Tumors

Traditional MRA methods (2D and 3D TOF and PC MRA) have played a secondary role to IA-DSA in evaluating inttactanial arteriovenous malformations (AVMs) because of a lack of consistent and complete demonstration of all components of an AVM: feeding attcrics, nidus, and draining veins. For this reason, and

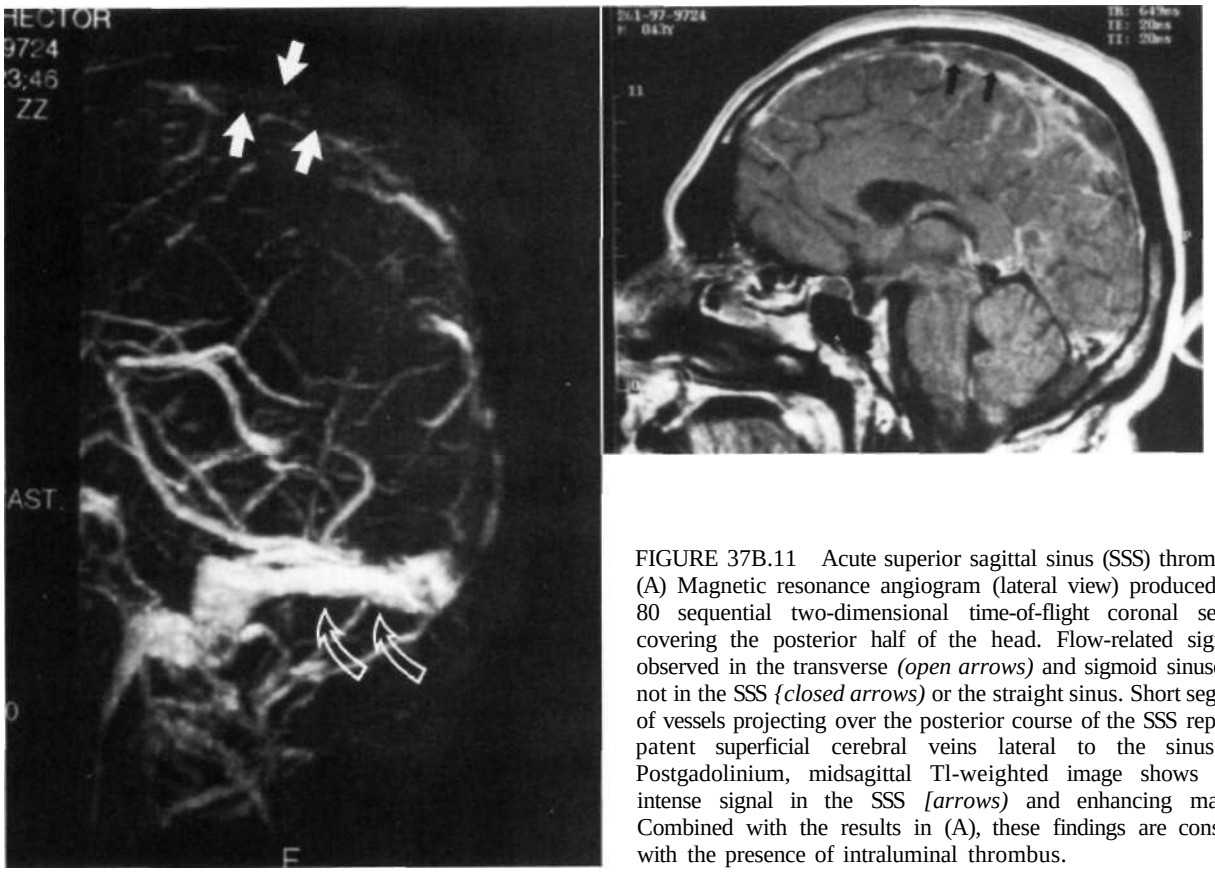

FIGURE 37B.11 Acute superior sagittal sinus (SSS) thrombosis. (A) Magnetic resonance angiogram (lateral view) produced from 80 sequential two-dimensional time-of-flight coronal sections covering the posterior half of the head. Flow-related signal is observed in the transverse *(open arrows)* and sigmoid sinuses but not in the SSS *{closed arrows)* or the straight sinus. Short segments of vessels projecting over the posterior course of the SSS represent patent superficial cerebral veins lateral to the sinus. (B) Postgadolinium, midsagittal Tl-weighted image shows hypo-intense signal in the SSS *[arrows)* and enhancing margins. Combined with the results in (A), these findings are consistent with the presence of intraluminal thrombus.

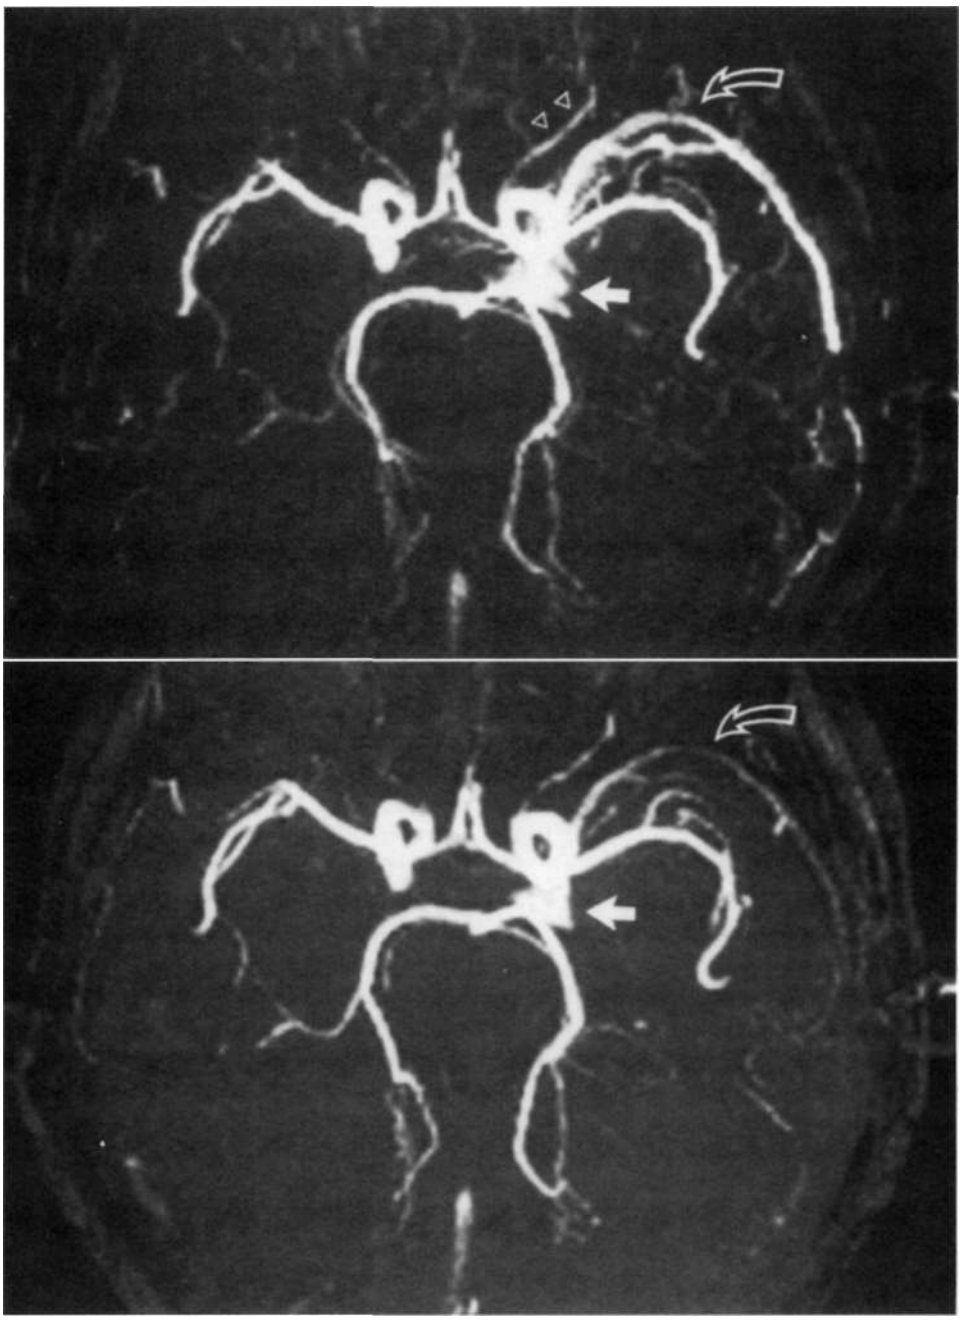
because of the general impression that TOF MRA adds little to the spin-echo MR imaging findings useful for preliminary staging of an AVM (nidus size and location and central versus peripheral pattern of venous drainage in the Spetzler and Martin criteria) before definitive IA-DSA, many investigators have considered TOF MRA of AVMs superfluous. PC techniques have been used by some investigators to estimate blood flow velocities and volume flow rates in the largest arteries supplying the AVM. A high-resolution 3D gradient-echo technique based on the paramagnetic property of deoxyhemoglobin has been used to detect cerebral veins with submillimeter resolution, resulting in greater sensitivity in identifying the presence of small AVMs compared with TOF MRA; however, the technique provides poorer detection of feeding arteries and is markedly limited in its delineation of nidus size and shape when there are susceptibility artifacts from nearby bone, air, or blood products (hemosiderin) (Essig et al. 1999).

More recently, high-resolution real-time auto-triggered elliptic centtic-ordered 3D CE-MRA (Farb et al. 2001) and lower-resolution time-resolved 2D CF-MRA (Klisch et al. 2000) have been applied to the evaluation of AVMs and the results compared with those of TOP MRA and IA-DSA, In an initial investigation, Farb and colleagues found that their 3D CE-MRA technique was superior to 3D TOF MRA, particularly in depicting nidus and draining veins. The 3D CE-MRA technique consistently showed AVM components and their spatial relationships on MIP images and was equivalent to IA-DSA in depicting AVM components in 70-90% of cases (total patients = 10), based on blinded, independent assessments by two experienced neuroradiol-ogists.

Dural arteriovenous fistulas (AVFs) most commonly involve the cavernous, transverse, and sigmoid sinuses along the skull base. Arterial feeders not seen on spin-echo MR sometimes are detected on 3D TOF MRA but much less often than on catheter angiography. Transverse and sigmoid sinus occlusion and dilated cortical veins are detected better by MRA than spin-echo imaging, yet neither technique achieves the accuracy of carheter angiography. Traditional 3D TOF MRA is useful in detecting cavernous sinus fistulas because flow enhancement in the cavernous sinus and contiguous veins can provide evidence of the fistula (Figure 37B.12). This finding must be regarded with caution because venous flow signal has been observed in the cavernous sinus and inferior pettosal sinus in a variable percentage (from 4% to 36%, depending on unspecified technical differences between MR scanners) of patients without clinical evidence of carotid cavernous fistula (Ouanounou et al. 1999).

The diagnostic imaging features of venous malformations (angiomas, developmental venous anomalies) are well shown on postgadolinium Tl-weighted spin-echo images.



B

FIGURE 37B.12 Spontaneous resolution of a left carotid-cavernous dural arteriovenous fistula. Magnetic resonance angiograms (axial maximum intensity projection images) of the sellar region and the circle of Willis were acquired with rhe three-dimensional time-of-flight technique (no gadolinium enhancement). The studies, performed (A) at the time of clinical presentation, (B) *i* months later, (C) 3 years later, show progressive resolution of the venous drainage from the fistula. Flow-related signal in the left cavernous sinus *[closed arrow),* sphenoparietal sinus *{open arrow),* and cerebral veins results from shunting of high flow rate arterial blood through the fistula. Note the progressive decrease in signal in the sphenoparietal sinus. Flow-related signal in the left orbit is caused by the ophthalmic artery *(arrowheads),* not the superior ophthalmic vein, which was found by catheter angiography to be thromhosed at the time of presentation.

Continued

These features include rhe radially oriented collection of small vessels (medullary veins) that produce a caput medusa or spoke-wheel configuration. This is contiguous with a large trunk vein that drains into cither subependymal or superficial cerebral veins or a dural sinus. The 2D TOF technique and the PC method with low VENC often display these slow-flow malformations without the use of gadolinium and allow determination of flow direction; however, the 3D TOF technique, which provides greater spatial resolution, requires gadolinium to avoid saturation effects. Cavernous malformations and capillary telangiectasias do not show flow enhancement on MRA studies, and

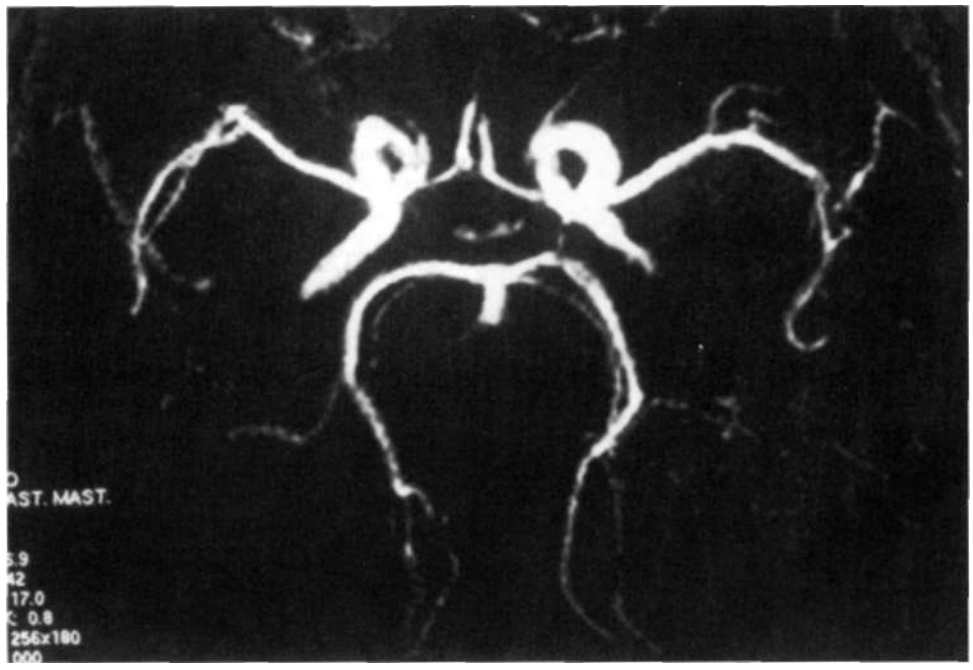


FIGURE 37B.12, cont'd.

the former usually are identified on spin-echo and gradient-echo images by the heterogeneous signal intensity caused hy blood products from prior hemorrhage.

The role of MRA in diagnosing intracranial tumors has yet to be defined, and evaluation more commonly involves bolus-chase susceptibility-weigh ted ("perfusion") MR imaging. In general, tumor-associated neovascularity consists of numerous small vessels, which are poorly delineated on traditional MRA compared with catheter angiography. The 2D TOF technique has been used to document dural sinus invasion or displacement by a neoplasm, and the 3D TOF technique is helpful in distinguishing a parasellar tumor from a patent aneurysm. Steady-state CE-MRA delineates small superficial and deep cerebral veins and has been used for preoperative planning in patients with a proven intracerebral mass.

Extracranial Circulation: Spine

Spinal MRA is used as an adjunct to MR imaging to improve the visibility of the millimeter-sized intradural vessels and to help differentiate abnormal from normal ones. The combined MR examination provides better characterization of spinal vessels and thus more effective noninvasive screening for vascular lesions, such as dural AVFs, than MR imaging alone (Saraf-Lavi et al. 2002). The improved screening facilitates decisions regarding invasive catheter angiography for definitive diagnosis and endovascular treatment. The combined MR examination also allows the largest normal vessels to be localized noninvasively before surgical or endovascular procedures that carry a risk of cord injury (Yamada et al. 2000).

Enhancement of the intradural vessels with gadolinium contrast agents has been found necessary for optimal detection on MRA. The 3D CE-MRA technique with steady-state conditions (i.e., TOF pulse sequence parameters) has been shown to detect the largest intradural veins in healrhy volunteers: the posterior and anterior median veins and the great medullary veins draining from the surface of the cord to the epidural space. This technique, and to a lesser extent the 3D PC technique, also detects the abnormally enlarged and tortuous veins draining dural AVFs (figure 37B.13) and intramedullary AVMs. In detecting the presence of dural AVFs, the steady-state 3D CE-MRA technique combined with spin-echo MR imaging had a sensitivity ranging from 80% to 100%, specificity of 82%, and accuracy of 81-94% in a randomized, blinded review by three neuroradiologists of 11 control subjects and 20 patients with proven dural AVFs (Saraf-Lavi et al. 2002). More importantly, in determining the vertebral level of the fistula, the correct level ± one level was predicted in 73% cases by combined MRA and MRI, representing a significant improvement over MRI alone. Improved noninvasive localization of the fistula level potentially expedites the subsequent invasive catheter angiography study. Preliminary studies of spinal vascular malformations using time-resolved or fast 3D CE-MRA indicate that such first-pass studies may provide better depiction of the dural AVF in the neural foramen because of diminished extradural venous enhancement and improved visibility of the feeding arteries of AVMs (Binkert, Kollias, and Valavanis 1999).

Although intraspinal vascular tumors such as hemangioblasroma, paraganglioma, hemangiopericytoma, and angioblastic meningioma are rare, preoperative imaging findings that suggest this differential diagnosis arc

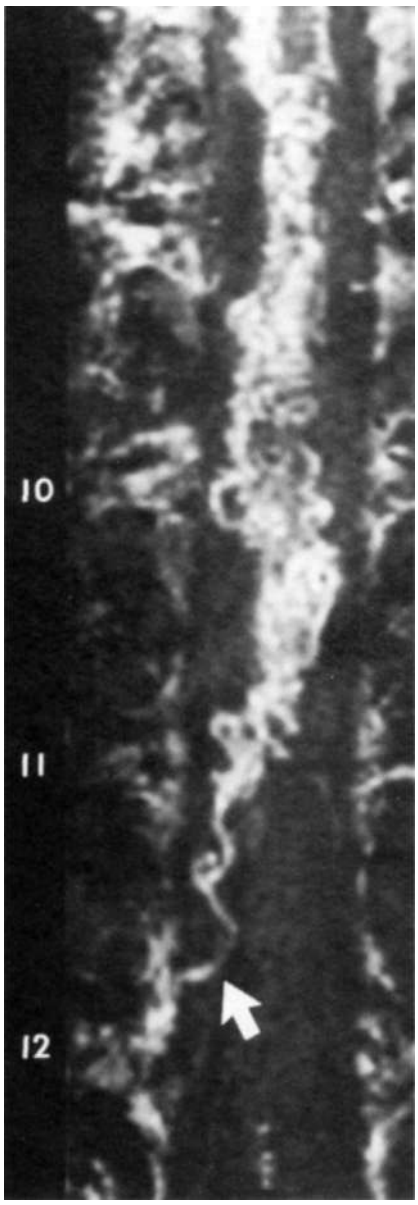

FIGURE 37B.13 Spinal dura] arteriovenous fistula. Gadolinium-enhanced magnetic resonance angiogram (frontal view), targeted to the posterior half of the lower thoracic canal, demonstrates an enlarged and tortuous vessel *(arroiv)* that courses from the region of the right T12 neural foramen to the posterior surface of the spinal cord, where there are numerous abnormal vessels. The enlarged vessel is the right Tl 2 posterior medullary vein, and it is contiguous with the coronal venous plexus around the cord. The veins are enlarged and tortuous because of retrograde filling by the shunted arterial blood from a fistula in the Tl 2 foramen. The right vertebral foramina at T10, Tl 1, and T12 are labeled.

important tor surgical planning and evaluation. In the few cases that have been reported, the steady-state 3D CH-MRA technique detected abnormal intradural vessels (primarily perimedullary veins) associated with these tumors better than did routine spm-echo imaging (Bowen and Pattany 2000). In cases of lumbar paraganglioma or hemangiopericytoma, in which the mass can mimic ependymoma or schwannoma on routine MR imaging, MRA findings suggesting vascular tumor can lead to the performance of catheter angiography and, if indicated, preoperative embolization.

COMPUTED TOMOGRAPHIC ANGIOGRAPHY

Methods

With the advent of helical CT scanning, uninterrupted volume acquisition of data from the head and neck region can easily be obtained in less than 1 minute. In general, data are acquired using a slice (collimated) thickness of 1-3 mm and a pitch of 1-2 as a bolus of iodinated contrast traverses the arteries of interest. For CTA of the carotid and vertebral arteries in the neck, the helical volume extends from the aortic arch to the skull base. Typical acquisition parameters are 7.5 images per rotation of the x-ray tube, 2.5 mm slice thickness, and a reconstruction interval (distance between the centers of two consecutively reconstructed images) of 1.25 mm. For the circle of Willis and proximal cerebral arteries, the helical volume extends from the skull base to the roofs of the lateral ventricles and has a smaller field of view than the neck study. Typical acquisition parameters for this higher spatial resolution scan are 3.75 images per rotation, 1.25 mm slice thickness, and an interval of 0.5 mm,

To produce intravascular enhancement, a volume of contrast ranging from 100 to 150 mL is injected into a peripheral vein at a rate of 2-3 mL per second and followed by a saline chase or flush (20-50 mL). Adequate enhancement of the arteries in the neck or head is obtained approximately 15-20 seconds after injection of the contrast. Most helical scanners have a special feature that allows visual and analytical monitoring of contrast in a chosen vessel upstream from the 3D volume to be scanned. As with CE-MRA, the most common approaches to synchronizing the 3D CT helical data acquisition with the arrival of the contrast bolus are determination of the bolus arrival time using a preliminary test dose, automated detection of bolus arrival and subsequent triggering of data acquisition, and real-time monitoring of bolus arrival and operator-triggered data acquisition. Data from the axial source images typically are postproccssed using one or more of the following techniques: multiplanar reformatting, MIP, and 3D volume rendering.

Applications

Extracranial Circulation

Carotid Artery Stenosis. In evaluating occlusive disease of the carotid bifurcation, CTA complements conventional angiography and is an alternative to DS and MRA

(Figure 37B.14). In the grading of carotid stenosis using North American Symptomatic Carotid Endarterectomy Trial criteria, Randoux and colleagues (2001) found that the rate of agreement between 3D CTA and IA-DSA was 95%. Relative to IA-DSA (the gold standard), severe stenosis (70-99%) was detected with a sensitivity and specificity of 100% and 100% for CTA and 93% and 100% for CE-MRA, respectively. In addition, CTA and CH-MRA were significantly correlated with IA-DSA in depicting the length of the stenotic segment.

Other investigators have reported lower sensitivity (range of 80-89%) yet comparable specificity (range of 96-100%) for CTA in detecting severe stenosis (Magarelli et al. 1998; Binaghi et al. 2001). Those investigatots found that TOF MRA had higher sensitivity (92-93%) than CTA and similar specificity (98-100%). Binaghi and colleagues also compared CTA with DS and showed that the sensitivity was the same *(89%),* whereas specificity was higher fot CTA (100%) than for DS (81%).

CTA has several advantages and disadvantages in comparison to the other techniques. Investigators have noted the following advantages:

- Better visualization of calcifications compared with **IA-DSA**
- Images less affected by carotid kinks and loops compared with TOP MRA, which may show false stenotic lesions or flow gaps at such sites (Link et al. 1995)
- Better localization of the level of carotid bifurcation by including reference points such as the cervical spine and mandible in the image volume
- Better delineation of plaque irregularities and ulceration compared with IA-DSA (Randoux et al. 2001)

Disadvantages of CTA include the following:

- Use of an iodinated contrast agent with its associated risks
- Inability to show the carotid siphon adequately so as to exclude tandem stenosis, which may preclude surgery

Currently, either CTA or MRA is used to evaluate suspected carotid occlusive disease, with the choice of method determined by clinical conditions (e.g., pacemaker), accessibility of CT and MR scanners, and additional imaging capabilities (CT or MR perfusion brain imaging). The advantages of MRA are the availability of both TOF and CE-MRA techniques and the more extensive history of clinical testing, including the validation of combined DS and TOF MRA examinations in which concotdant results correlated highly with IA-DSA results.

Carotid Dissection. Dissections of the extracranial ICA account for up to 20% of ischemic strokes in young adults (Leys et al. 1995). Although catheter angiography has been considered the gold standard for diagnosing ICA dissections, MRI, MRA, and CTA (Leclerc et al. 1996, 1998) have emerged as alternative, noninvasive approaches to the diagnosis and monitoring of acute ICA dissection.

The CTA findings include demonstration of a narrowed eccentric arterial lumen in the presence of a thickened vessel

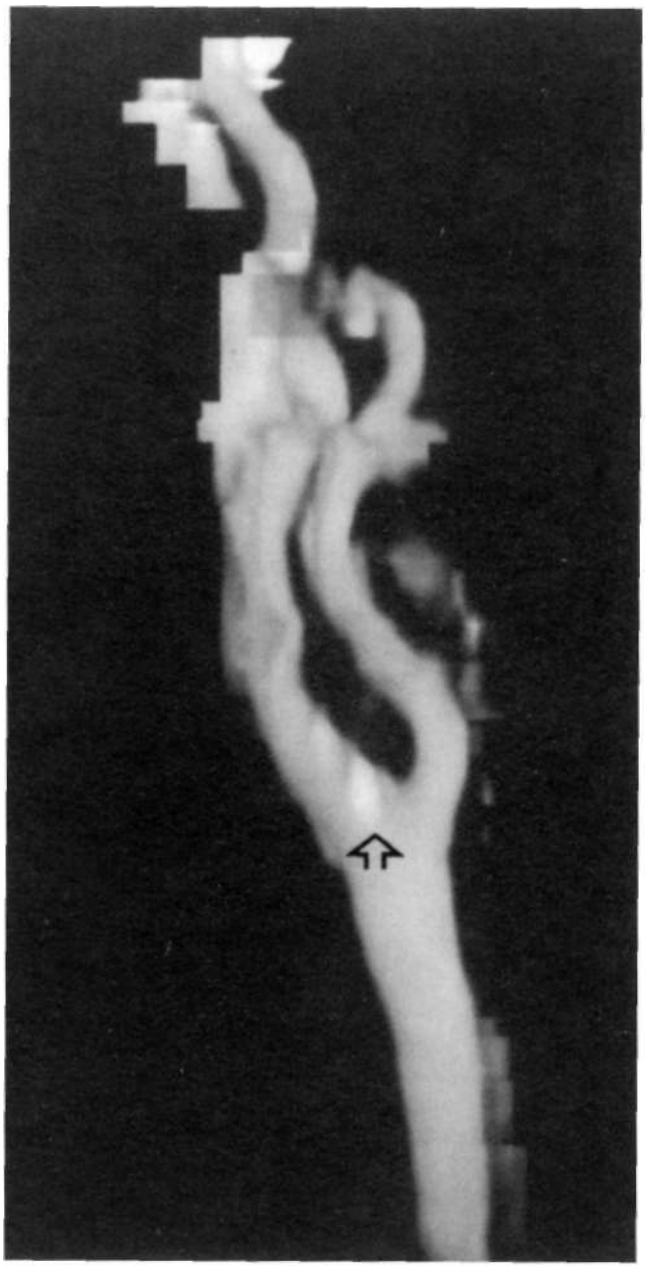

FIGURE 37B.14 Computed tomographic angiography of the cervical internal carotid artery in a patient with a history of transient ischemic attacks. Maximum intensity projection image shows no evidence of stenosis; however, a calcified plaque is demonstrated at the origin of the internal carotid artery *{arrow}.* Large plaques may obscure the arterial lumen. Improved assessment is possible with a virtual endoscopic view of the affected lumen.

wall and occasionally pseudoaneurysm. In subacute and chronic dissection, CTA has been shown to detect a reduction in the thickness of the arterial wall, rccanalization of the arterial lumen, and reduction in size or resolution of pseudoaneurysm. CTA (or MRA) is superior to DS in depicting the middle to distal portions of the cervical ICA, which are commonly involved in dissections (sec Figure 37B.8). CTA is likely to be superior to MR imaging alone in evaluating pseudoaneurysms because MR findings often ate complicated by the presence of flow-related artifacts. CTA usually is inferior to MRI and MRA in depicting dissections at the level of the skull base because CT findings can be masked by beam hardening and other artifacrs and by similarities in the densities of the tempotal and sphenoid bones and the dissected ICA on source and reformatted images.

Intracranial Circulation

Acute Ischemic Stroke. Reports by several investigators (Shrier et al. 1997; Knauth et al. 1997) have shown that CTA is a reliable alternative to MRA in evaluating arterial occlusive disease near the circle of Willis in patients with symptoms of acute stroke (Figure 37B.15). CTA shows clinically televant occlusions of major cerebral arteries and enhancement caused by collateral flow distal to the site of

FIGURE 37B.15 Maximum intensity projection (MIP) images. (A) Axial MIP image. (B and C) Oblique MIP images were obtained to improve display of each of the MCA trifurcations. MCA stenosis is ruled out. Note the excellent resolution and anatomical detail of the major circle of Willis vessels and second-arid third-order vessels in the posterior cerebral artery and anterior eerebral artery distributions.

occlusion. In the diagnosis of MCA occlusion, CTA has shown good correlation with transcranial Doppler (TCD) sonography but is inferior to MRA. More recently, CTA was found to be superior to TCD in diagnosing atherothromboric MCA disease in Asian patients presenting with MCA stroke (Suwanwela, Phanthumchinda, and Suwanwela 2002), CTA detected MCA stenosis measuring more than 50% in twice as many patients as TCD. The difference resulted primarily from the improved detection by CTA of distal Ml and M2 stenosis. Because half of the patients studied by Suwanwela and colleagues had distal Ml and M2 disease, the authors concluded that TCD sonography should not be used to screen for MCA stenosis.

In the detection of inttacranial steno-occlusive disease, Hirai and colleagues (2002) have shown that combined CTA and MRA provide substantially higher sensitivity, specificity, and accuracy than MRA alone. Review of the CTA depiction of vessels in conjunction with the 3D TOF MRA display reduced the ftequency of overestimation of stenosis when compared with MRA alone. In the identification of 50% or greater stenosis, the sensitivity, specificity, and accuracy for the combined CTA and MRA evaluation were 100%, 99%, and 99%, respectively, and the values for 3D TOF MRA alone were 92%, 91%, and 91%, respectively. The grading of stenosis by the combined approach agreed with the IA-DSA grading in 98% of cases. In a retrospective review of their cases, the authors found that CTA did not always correctly delineate arterial lumina with circumferential calcification and the cavernous portion of the ICA.

Cerebral Aneurysms. Catheter angiography has been the gold standatd for imaging diagnosis and preoperative evaluation of ruptured and unruptured cerebral aneurysms; however IA-DSA is invasive and subject to complications tesulting from catheter manipulation. Thus in asymptomatic patients at greater risk for cerebral aneurysms, the use of noninvasive techniques such as MRA and CTA to screen for aneurysms is particularly attractive. These techniques have advantages and disadvantages. The most thoroughly investigated MRA technique is 3D TOF MRA, and its main disadvantages arc long scanning times, difficulty in detecting very small aneurysms, difficulty in establishing the relationship of the aneurysm to adjacent (and surgically important) osseous anatomy, and occasional difficulty in distinguishing between patent lumen and thrombus. The main disadvantages of CTA are radiation exposure, the use of iodinated contrast material, and difficulty in detecting very small aneutysms. In a prospective blinded comparison between CTA and 3D TOF MRA (142 patients), White and colleagues (2001) found no significant difference in diagnostic performance between the two techniques. The sensitivity for detecting aneurysms smaller than 5 mm was 57% for CTA and 35% for MRA, compared with 94% and 86%, tespectively, for aneurysms 5 mm or larger (Figures 37B.16 and 37B.17). This is somewhat discouraging because the critical size at which aneurysms are at a significant risk of rupture has been reported to be 4 mm (Crompton 1996). The limited sensitivity of CTA and MRA in detecting small aneurysms has prevented the more widespread application of these techniques for screening

FIGURK 37B.16 Proximal left middle cerebral artery aneurysm. Comparison of computed tomographic angiography (CTA) with conventional catheter angiography, (A) Maximum intensity projection image from CTA of the circle of Willis shows a berry aneurysm of the Ml segment. (B) Catheter angiography submentovertex view, following left internal carotid artery injection, shows excellent correlation,

FIGURE 37B.17 Left internal carotid artery aneurysm. Comparison of computed tomographic angiography (CTA) postprocessed images with catheter angiography. (A) Catheter angiography lateral view, following left internal carotid artery (ICA) injection, shows aneurysm originating from the supraclinoid portion of the ICA. (B) CTA axial source image reveals tabulated aneurysm (arrow), (C, D, and E) CTA 3D vol time-rendered images with transparency feature for user-selected tissue regions (called "4D angiography"). (C) Lateral view from the left side of the patient demonstrates the relationship of the aneurysm, measuring 14 mm from neck to dome, to the anterior clinoid process.

or pretreatment evaluation of aneurysms (Adams, Laitt, and Jackson 2000).

Villablanca and colleagues (2002) have presented promising CTA results for detecting and characterizing very small (less than 5 mm) intracranial aneurysms. Using optimized helical CTA acquisition and postprocessing protocols, which included 3D perspective volume rendered images, 3D thick slab and gray scale 2D single-section images, and thick slab multiplanar reformatted 2D images, the authors reported a sensitivity of CTA for very small aneurysm detection that ranged from 98% to 100%, compared with *95%* for IA-DSA. The specificity of CTA and of IA-DSA was 100%. CTA image analysis times ranged from 6 to 36 minutes (mean = 16 minutes). The smallest aneurysm detected was 1,9 x 1.6 x 1.3 mm', and 48% of aneurysms were detected in the presence of subarachnoid hemorrhage. The sensitivity of CTA exceeded that of IA-DSA primarily because the optimal projection necessary to visualize some aneurysms could be displayed on the postprocessed CTA images but was not or could not be displayed by IA-DSA. Other disadvantages of IA-DSA that have been noted by investigators include superimposition of normal vessels obscuring a small aneurysm and the lack of an internal image scale for estimating the aneurysm sac and neck dimensions. Villablanca and colleagues showed that CTA can provide quantitative information, such as dome-to-neck ratios, and aneurysm characterization, such as the presence of mural thrombi or calcium, branching pattern at the neck, and the incorporation of arterial segments in the aneurysm. The 3D images in particular provided a surgically useful display of the aneurysm sac in relation to skull base structures (see Figure 37B.17). The authors concluded that with adequate attention to detail, all clinically relevant aneurysms can he detected by CTA using routine scanners, protocols similar to those described in the article, and commercially available image-processing workstations. Furthermore, CTA can be a reliable source of information for treatment planning.

Cerebral veins show much more anatomical variation than arteries. The presence of an unexpected vein, or the lack of collateral drainage from a region drained by a vein that may need to be sacrificed during surgery, can alter the approach to resection of an aneurysm. Kaminogo and colleagues (2002) used 3D CTA to demonstrate the venous anatomy accurately. They showed the usefulness of this information in selecting a therapeutic procedure (surgery versus endovascular coiling) and in planning the approach for surgical treatment.

CONCLUSION

Noninvasive imaging of neurovascular disease has progressed greatly in the past decade and is gaining acceptance as the primary approach to screening for several different types of vascular lesions, including atherosclerotic narrowing of the cervical ICA, carotid or vertebral dissection, cerebral aneurysm in the asymptomatic patient at risk, dural venous sinus thrombosis, and spinal dural fistula. The number of indications for noninvasive screening is likely to increase as improvements in MRA (increased field strength to 3 Tesla or more, faster gradient rise times, and improved phased-array technology and k-space sampling techniques) and CTA (greater heat storage capacity and multidetector array helical scanning) result in greater accuracy and reliability of these methods. What remains to be elucidated

are the algorithms that will be followed to diagnose a vascular lesion or category of lesions in the most timely and cost-effective manner for a given clinical presentation. As these algorithms are developed, it seems certain that **MRA** and CTA will play large and complementary roles, with catheter studies reserved for endovascular or intraoperative intervention and evaluation.

Chapter 37
Neuroimaging

C. NEUROANGIOGRAPHIC ANATOMY AND COMMON CEREBROVASCULAR DISEASES

Johnny S. Sandhu and Ajay K. Wakhloo

Neuroangiography remains the gold standard for diagnostic imaging for most cerebrovascular disorders, even with the advent of magnetic resonance imaging (MRI), magnetic resonance angiography (MRA), and three-dimensional (3D) computed tomography (CT) angiography. Despite great advancements in CT and MRA, there are limitations in their sensitivity to detect vascular abnormalities, Although these modalities will undoubtedly improve soon, current indications for diagnostic (catheter) angiography remain extensive (Citron et a). 2000). Furthermore, as other imaging modalities assume a larger role in diagnostic neuroangiography, the applications of neuroendovascular interventions are increasing. Road mapping, digital subtraction angiography, high-resolution flat-panel systems, data acquirement and analysis, and 3D reconstruction (Culham 1996) have all replaced previous methods of acquiring contrast-enhanced images. The importance of understanding normal neurovascular anatomy from an angiographic standpoint remains essential in the diagnosis of neurovascular abnormalities, classification of cerebrovascular pathology, and treatment of disease.

The reported success rate of neuroangiography is 9H% (Vitck 1973; Dion et al. 1987; Citron et al. 2000). The potential risks of angiography and interventional procedures include minor and major stroke (<0.05%, institution dependent) through vessel occlusion and embolic events, contrasr reaction, vessel damage (arterial dissection, pseudoaneurysm, perforation), renal failure, and groin hematoma. Risks increase in patients with severe atherosclerosis, advanced age, pre-existing vascular disease, collagen diseases, dysplasias, and acute subarachnoid hemorrhage, as well as with the length of the procedure, quality of catheters, and the amount of contrast used. Relative contraindications are lodinatcd contrast media allergy, hypotension, severe hypertension, coagulopathy, renal insufficiency, and congestive heart failure. A thorough history and physical examination should precede angiography to allow correction of important pre-existing medical conditions. For example, patients with diabetes mcllitus should discontinue metformin 24 hours befotc undergoing angiography to avoid lactic acidosis. Ir should be withheld for 48 hours after the procedure until their renal function test results return to baseline. Informed consent should be obtained and necessary laboratory work should be documented before performing angiography (Wallace 2000).

FUNCTIONAL NEUROVASCULAR ANATOMY

A thorough understanding of the normal human vasculature and common anomalies is paramount in the practice of safe and effective ncurointervcntional angiography and procedures.

Branches of the Aortic Arch

Generally, three major vessels arise from the aortic arch. The first branch is the *innominate artery* (IA) or *brachiocephalic trunk,* which then branches into the right subclavian artery (SCA) and right common carotid artery

(CCA). The major branches of the right SCA include the right vertebral artery (VA) (dominant vertebral in 25%), the right internal mammary artery, the thyrocervical trunk, and the costoccrvical trunk. An aberrant right SCA arises directly from the aortic arch in 0.5-1.0% of all cases. An irregular right SCA usually presents as the last vessel that arises from the arch (Osborn 1994) and is commonly associated with a right CCA that originates directly from the aortic arch.

The second branch off the aortic arch is the *left* CCA. The most common anatomical variant is a common origin from the aortic arch with the IA (25%). In 5-10% of cases, the left CCA will branch off the proximal IA, termed as the *bovine origin* of the left CCA because of its similarity to bovine anatomy (Figure 37C.1). The left CCA may also be absent, in which case the left external and internal arteries rise directly from the arch.

Finally, the third and usually last branch is the *left* SCA. Major branches of the left SCA include the left VA (dominant in 50-60%), the thyrocervical trunk, and the costocervical trunk. The left VA may originate directly from the arch (5%).

Common Carotid Arteries

The right CCA typically arises from the IA; the left CCA usually originates from the aortic arch. The CCA branches into the external and internal carotid arteries approximately at the level of the fourth cervical body (C4). The proximal portion of the internal carotid artery (ICA) runs posterior and lateral to the proximal portion of the external carotid artery (ECA). The carotid bulb is the relatively dilatated proximal portion of the ICA and is significant for disturbed flow that is thought to contribute to endothelial cell damage and subsequent carotid artery plaque formation. There are no significant cervical branches of the ICA.

External Carotid Artery

The smaller ECA in humans, however, gives rise to many hranches of the craniofacial region (Table 37C.1}. Great variability exists in the branches of the ECA, the vascular territories supplied, and the functional significances of those diffetcnecs (Russell 1986; Osborn 1994). Most

FIGURE 37C.1 (A) Digital subtraction angiogram of the aortic arch in anteroposterior projection. Note: The left vertebral artery is a variant that originates directly from the aortic arch. CCA = common carotid artery; IMA = internal mammary artery; SCA = subclavian artery; VA — vertebral artery.

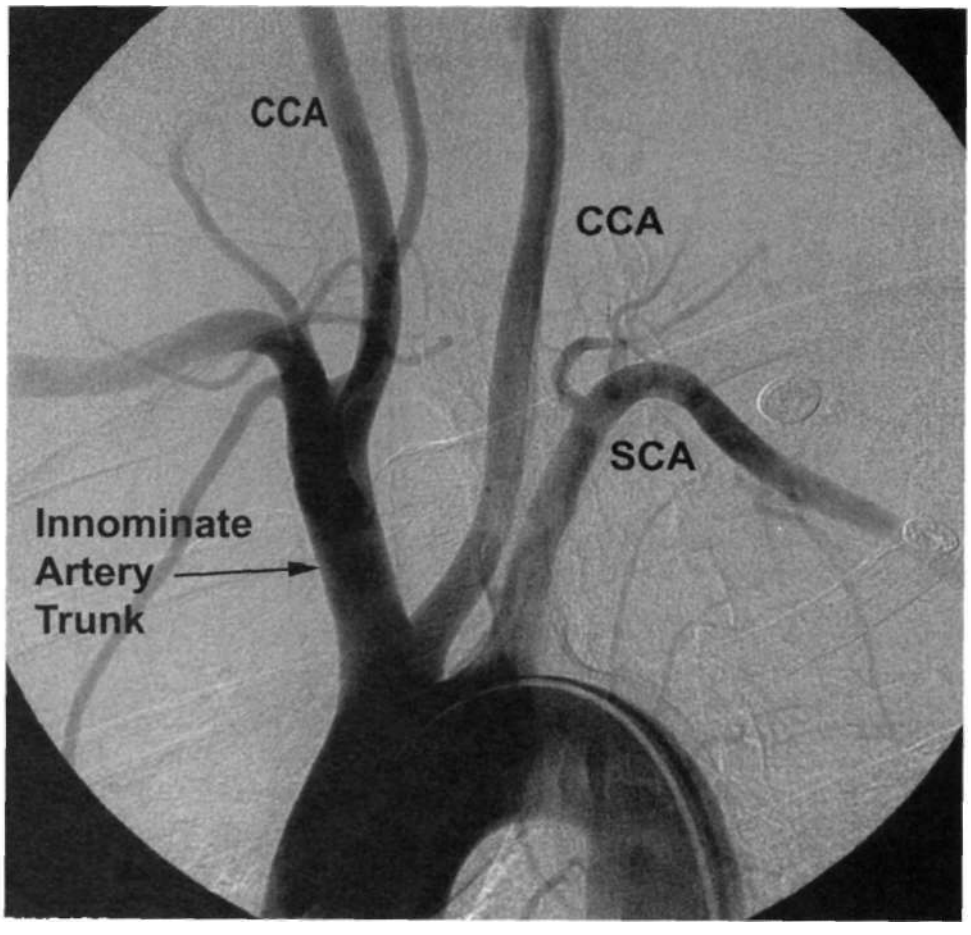

FIGURE 37C.1, cont'd. (B) I.eft antero-oblique (LAO 30-degree) view of the aortic arch. Note the bovine origin of the left common carotid artery.

commonly, the arterial branches of the external carotid are the following in proximal to distal order: superior thyroidal, ascending pharyngeal, lingual, facial, occipital, posterior auricular, superficial temporal, and internal maxillary. In the case of a variant CCA without a bifurcation, all branches may be supplied by the ICA. Key anastomoses of the external and internal carotid arteries are listed because of their significance for embolization in ECA territories and the risk of inadvertent brain stroke resulting from these "dangerous" anastomoses (see Table 37C.1). The maxillary artery has several anastomoses with the ICA. These include the following: infraorbital branch, sphenopalatine artery, middle meningeal artery (meningo-ophthalamic, recurrent meningeal, cavernous ramus), accessory meningeal artery (cavernous ramus), artery of foramen rotundum, anterior deep temporal (orbital branch), anterior tympanic artery, and vidian artery. The ascending pharyngeal artery anastomoses with the petrous ICA through the superior pharyngeal (mandibular anastomosis) and the inferior tympanic artery. The ascending pharyngeal artery anastomoses with the carotid siphon through the superior pharyngeal (carotid branch), the jugular artery (lateral clival branch), and the hypoglossal artery (medial clival branch). The ascending pharyngeal anastomoses with the VA through the hypoglossal artery (odontoid arterial arch), muscular spinal, and lateral spinal artery. The occipital artery meets the VA through CI and C2 anastomotic branches. The posterior cervical artery meets the VA through C2, C3, and C4 anastomotic branches. The ascending cervical meets the VA through C3 and C4 anastomotic branches. The external carotid and vertebral arteries may communicate through C4 collaterals and a type II proatlantal artery.

Commonly associated disorders of the ECA include vascular tumors. Meningiomas, glomus tumors, and juvenile nasopharyngeal angiofibromas are the most commonly discovered vascular tumors supplied by the ECA. The most significant vascular lesions that are supplied by the ECA include pial arteriovenous malformations (AVMs), dural AVMs, capillary telangiectasias, venous angiomas, hemangiomas, carotid-cavernous fistulas, rare aneurysms, and atherosclerotic disease. Commonly, the locus of Kiesselbach that supplies the nasal mucosa will be the source of epistaxis. Traumatic lacctation of the ECA or its branches may also be a source of intractable bleeding.

Table 37C.1: Branches of the external carotid artery, territories supplied, and dangerous anastomoses

	Branch (proximal to distal)	*Territory supplied*	*Cranial nerves*	*Anatomical variants*	*Notes*	*Anastomoses*
1	Superior thyroidal artery	Upper thyroid/larynx		Separate branches for larynx and thyroid directly from ECA		With inferior thyroidal artery
2	Ascending pharyngeal artery	Naso-oropharynx, tympanic membrane, middle ear, some meningeal	V, IX, X, XI, XII: from hypoglossal and jugular branches	Common trunk with occipital artery, also variant branch off ICA		With VA branches through odontoid arcade and neuromeningeal branches
3	Lingual artery	Tongue, floor of mouth, submandibular gland, part of mandible		Common lingual-facial trunk		
4	Facial artery	Face, palate, pharynx, cheek, lip				Angular branch with orbital branches of ophthalmic artery (ICA-ECA)
5	Occipital artery	Posterior scalp, upper cervical musculature, posterior fossa meninges		Variant branch off ICA	Facial nerve palsy not uncommon with embolization of branches of stylomastoid foramen	Numerous with VA branches through distal muscular branches
6	Posterior auricular artery	Scalp, pinna, external auditory canal				With ICA through stylomastoid artery
7	Superficial temporal artery	Scalp, ear, face, buccal		Transverse facial (branch that supplies deep face and cheek) may directly arise from ECA	One of two distal terminal branches, distinguished from middle meningeal artery by hairpin turn across zygomatic arch	
8	Internal maxillary artery	Major distal internal maxillary branches include: Sphenopalatine, descending palatine, and infraorbital arteries. These supply deep facial (muscles of mastication, palate, maxilla, sinuses, teeth, partial nose and orbit including mucous membranes) meninges	Facial nerve through a branch that traverses the petrous bone, also branches with V2		Gives rise to middle meningeal and accessory meningeal branches	With ICA through ethmoidal branches with ophthalmic artery, vidian artery (with petrous ICA), artery of the foramen rotundum (with inferolateral trunk and lateral mainstem in cavernous ICA)

ECA = external carotid artery; ICA = internal carotid artery; VA = vertebral artery.

Internal Carotid Artery

The ICA arises from the bifurcation of the CCA. It consists of four general segments: the *cervical* portion (extracranial), the *petrous* portion (extracranial), the *cavernous* portion (intracranial), and the *cerebral* or *supraclinoid* (intracranial) portion (Hubcr 1982; de Olivcira et al. 1995). The ICA has a typical angiographic appearance (Figure 37C.2) with visible branches that include (proximal to distal) the meningohypophyseal trunk, infcrolateral trunk (lateral mainstem artery), ophthalmic artery (OA), superior hypophyseal artery, posterior communicating artery (PComA), anterior choroidal artery (AChA), anterior cerebral artery (ACA), and middle cerebral artery (MCA), which is the continuation of the ICA.

The *cervical portion* of the ICA includes the carotid bulb and extends to the entrance into the carotid foramen of the petrous temporal bone. Most commonly, the ICA is initially posterolateral to the ECA at the bifurcation; however, the cervical segment subsequently passes medially to the ECA. As stated earlier, anomalous ECA branches may arise from the ICA. Furthermore, persistent embryonic vessels may give rise to vertebrobasilar anastomoses (see Typical Fetal Remnants, later in this chapter).

The *petrous portion* runs within the carotid canal of the petrous bone and ends where the artery enters the cavernous sinus. The petrous portion bends upward toward its posterior bend, or genu, and forms the ascending or vertical segment. The vertical segment runs along the tympanic bone. At the genu, the artery curves anteromedially to the petrous apex and forms the horizontal segment. The distal portion of the horizontal segment runs upward and medially and fills the foramen lacerum to become intracranial. During its run through the petrous, the ICA has several tympanic branches to the middle ear. It is here that the vidian artery, also known as the *artery of the pterygoid canal,* anastomoses with branches of the ECA. Another branch, the caroticotympanic artery, supplies both the middle and the inner ear. It is worthwhile to point out that an aberrant petrous ICA may run posterolaterally rather than anteromedially. It may present in patients as a pulsatile retrotympanic mass.

The *cavernous portion* or the carotid cavernous segment begins at the exit of the JCA from the petrous apex, runs through the cavernous sinus, ends where it exits at the base of the skull, and enters the subarachnoid space near the anterior clinoid. After it leaves the carotid canal, the ICA curves anteriorly and medially to follow the lateral surface

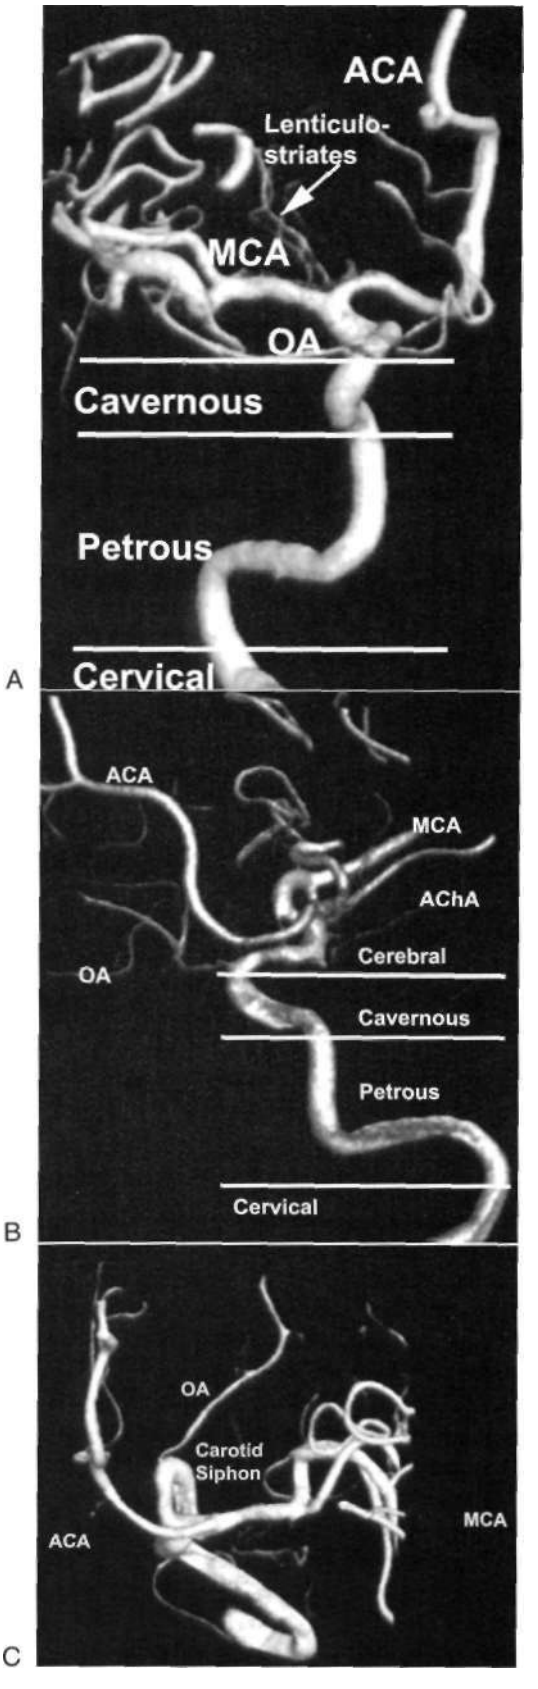

FIGURE 37C.2 Rotational angiogram of the right internal carotid artery with three-dimensional reconstruction. Cervical, petrous, and cavernous segments are demarcated in (A) anteroposterior, (B) lateral, and (C) craniocaudal plane. ACA = anterior cerebral artery; MCA = middlc cerebral artery; OA, ophthalmic artery.

Table 37C.2: Segments of the internal carotid artery and associated branches

Fischer segment (ascending proximal to distal from aorta)	*Named*	*Boundary*	*Common disease findings*	*Branches and vascular territory*	*Anastomoses*
C5 "gassenan segment"	Cavernous between the apex of petrosal pyramid and posreroinferior aspect of the sellar region	Endocranial opening of carotid canal to the beginning of the first (posterior) ICA genu		.\U'Eiiiij;()hypophyseal artery (posterior trunk) (near C4 and C5) Inferior hypophyseal (pituitary gland) Marginal tentorial or Bernasconi and Cassinari (tentorium) Clival dural branch (cavernous sinus, cranial nerves III through VI)	
C4 "cavernous segment"	[ntracavernous Juxtasellar segment	End of ascending portion and beginning of the horizontal segment	Engorgement of ILT with vascular neoplasms or AVM	lnferolateral trunk—ILT (lateral mainstem artery) supplies cranial nerves III, IV, VI, and gasserian ganglion (cranial nerve V) and cavernous sinus dura, foramen of rotundum	ILT with internal maxillary artery
C3 "carotid knee"	]ntracavernous	Posterior 90-degree bend to anterior *90*-degree bend		Capsular branches (distal C3) supplies pituitary gland	
C2 "cisternal segment"	Cerebral portion	End of horizontal segment to end of cavernous segment CI		Capsular branches (proximal C2) supplies pituitary gland	
C1 "terminal segment": supra clinoid	Cerebral portion			Superior hypophyseal, perforating, ophthalmic, PComA, AChA	

AChA = anterior choroidal artery; AVM = arteriovenous malformation; ICA = internal carotid artery; ILT = inferolateral trunk; PComA = posterior communicating artery.

of the sphenoid. It is separated from the trigeminal ganglion laterally and above. The artery runs vertically above the foramen lacerum within a groove along the lateral surface of the sphenoid body near the frontal pole of the trigeminal ganglion, which may be tefetred to as the *ganglion segment* (i.e., the C5 Fischer classification segment) (Fischer 1938) (Table 37C.2).

The artery then tuns anteriorly as it ascends to the base of the anterior clinoid process that displaces the ICA slightly laterally. This segment is referred to as the *C4 Fischer classification segment,* which is la fetal to the pituitary fossa. Below the base of the anterior clinoid process, the carotid makes a sharp bend that is anterior. This segment is known as the *carotid knee* ot *segment C3,* which is still patt of the inttacavernous portion.

The sinusoidal shape of the ICA and the beginning of the final *intracranial or mpraclinoid segment* make up the carotid siphon. The C2-C4 portion was named the "carotid siphon" by Moniz, a term that is well accepted (Huber 1982). In 90% of patients, the OA is the fitst btanch of the intradural portion of the ICA and serves as the demarcation between the *cavernous* and *cerebral* segments of the ICA. The OA is intradural in 90% of patients and arises from the cavernous segment of the ICA in the other 10%. The OA supplies the globe and the tetina via the central retinal artery. It also supplies the orbit and its contents in conjunction with ECA branches. It may receive important collaterals from the orbital branches of the facial and internal maxillary arteries. Proximal occlusion of the OA is associated with little risk to vision because of these ECA collaterals. Visual acuity can be compromised in the case of central tetinal artety embolization, either through the OA or the ECA collaterals to the OA.

The *cerebral* or *supraclinoid portion* of the ICA begins above the antetior clinoid process and ends at the bifurcation to give rise to the ACA and the MCA. The

artery penetrates the dura and arachnoid membrane at the level of the OA, which is usually located intradurally. The carotid artery then runs posteriorly along the medial margin of the anterior clinoid process and beneath the optic nerve, which is known as the *cisternal segment,* or C2, The terminal carotid segment, or CI, ascends and then divides at the circle of Willis.

The PComA is a collateral pathway of the circle of Willis that connects the internal carotid and vertebrobasilar circulations. It originates between the supraclinoid portion of the ICA and the PI segment of the ipsilateral posterior cerebral artety (PCA). The PComA supplies petforating branches to the thalamus, hypothalamus, and optic chiasm. Anomalies of the PComA include hypoplasia, which is seen in one third of anatomical dissections (Sacki and Rhoton 1977; Osborn 1994}. Another anatomical variant is the fetal origin of the PCA that is seen in 20-25% of all patients.

The AChA originates from the ICA distal to the PComA. It is distinguished into two segments. The proximal or cistern segment travels posteriorly in the crural cistern subjacent to the optic tract and medial to the uncus of the temporal lobe. It then enters the choroidal fissure of the temporal horn of the lateral ventricle where there is a slight kink in its contour that is known as the *plexal point.* Distal to the kink, the second segment is known as the *distal* or *plexal (intraventricular) segment.* This segment runs into the choroid plexus of the temporal horn and curves posterolaterally around the thalamus. It supplies the choroid plexus of the lateral ventricle and anastomoses with the la tero posted or choroidal artery. There are several branches that also anastomose with branches of the PComA, PCA, and MCA. Perforators serve the retrolenticular fibers of the internal capsule, optic tract, globus pallidus, thalamus, hypothalamus, caudate nucleus, red nucleus, parts of the temporal lobe, basal ganglia, a portion of the cerebral peduncle, and substantia nigra. Proximal occlusion of the cisternal part of the AChA may cause hemiplegia, hemiparesis, or homonymous quadrant or hemianopia by thrombosis of minute petforators that arise proximal to the plexal point. Also, patients may present with hemianesthesia, or memory deficits. Embolizations performed distally to the plexal point are considered safe. However, because of flow reduction, retrograde thrombosis of the entire AChA may occur.

The cavernous and *cerebral* (supraclinoid) segments of the ICA may undergo distal narrowing secondary to athetosclerotic disease. Other nondegenerative disorders that may cause arterial narrowing include spasm, tumor encasement, dissection, and radiation-induced vasculitis. The most important vascular lesions in this area are aneurysms, carotid-cavernous fistulas, dural fistulas, moyamoya disease, fibromuscular dysplasia (FMD), and AVM. Highly vascularized tumors that may present in this area include meningiomas, juvenile nasopharyngeal angiofibromas, and pituitary adenomas.

The terminal ICA bifurcates into the MCA and the ACA. The PCAs typically originate from the basilar artery but rarely branch off the ICA, which is known as a *fetal origin* (see Typical Fetal Remnants, later in this chapter).

The ACA supplies the anterior two thirds of the medial portions of the cetebral hemispheres and approximately 1 cm of the superolateral surface of the brain convexity. Its caliber is smaller than the MCA (Muller et al. 1991) and it provides several vital branches. The ACA major branches include the following: orhitofrontal, frontopolar, callosomarginal, pcricallosal, anterior (internal) frontal, middle (internal) frontal, posterior (internal) frontal, paracentral, parietal (internal) superior, parietal (internal) inferior, and splenial arteries (Figure 37C.3).

The Al or horizontal segment is the first branch of the ACA and runs medially from its origin, giving rise to the medial lcnticulostriate arteties, which are deep perforating branches that supply the head of the caudate nucleus and the anterior limb of the internal capsule (Ghika, Bogousslavsky, and Regli 1990). The ACA then joins the anterior communicating artery (AComA). The AComA is actually a part of the circle of Willis but is usually considered part of one complex with the ACA (Damasio 1983; van der Zwan et al. 1992; Osborn 1994). Small perforating branches of the AComA may supply the following structures: lamina terminalis and hypothalamus, anterior commissure, fornix, septum pcllucidum, paraolfactory gyrus, the subcallosal region, and the anterior part of the cingulate gyrus.

The A2 segment is the ACA from its connection to the AComA to its bifurcation into the pericallosal and callosomarginal arteries. It runs cephalad in the cistern of the lamina terminalis and courses around the corpus callosum genu. One of the lenticulostriate branches that commonly arise from the proximal A2 segment is the recurrent artery of Heubner (50%), which may originate from the Al segment (44%) and infrequently from the AComA. It supplies the caudate nucleus, the rostral putamen, and the anterior limb of the internal capsule. Infarctions in the vascular territory of the recurrent artery of Heubner result in clinical syndtomes that present with contralateral hemiplegia of face and arm, transcortical motor aphasia, or crural monoplegia.

The medial lenticulostriate arteries from the Al segment supply the basal ganglia, anterior limb of the internal capsule, hypothalamus, optic chiasm, and inmndibulum. The AComA perforators supply the corpus callosum genu, the head of the caudate nucleus, and the basal ganglia. These perforators may be injured during a frontal approach to surgical clipping of AComA aneurysms. Patients may experience short-term memory deficits and complex neuropsychological impairments.

The next two branches of the A2 segment ate the orhitofrontal and frontopolar arteries. The A2 segment runs superiorly within the interhemispheric fissure and ends with the pericallosal and callosomarginal arteries. Table 37C.3 provides an overview of common

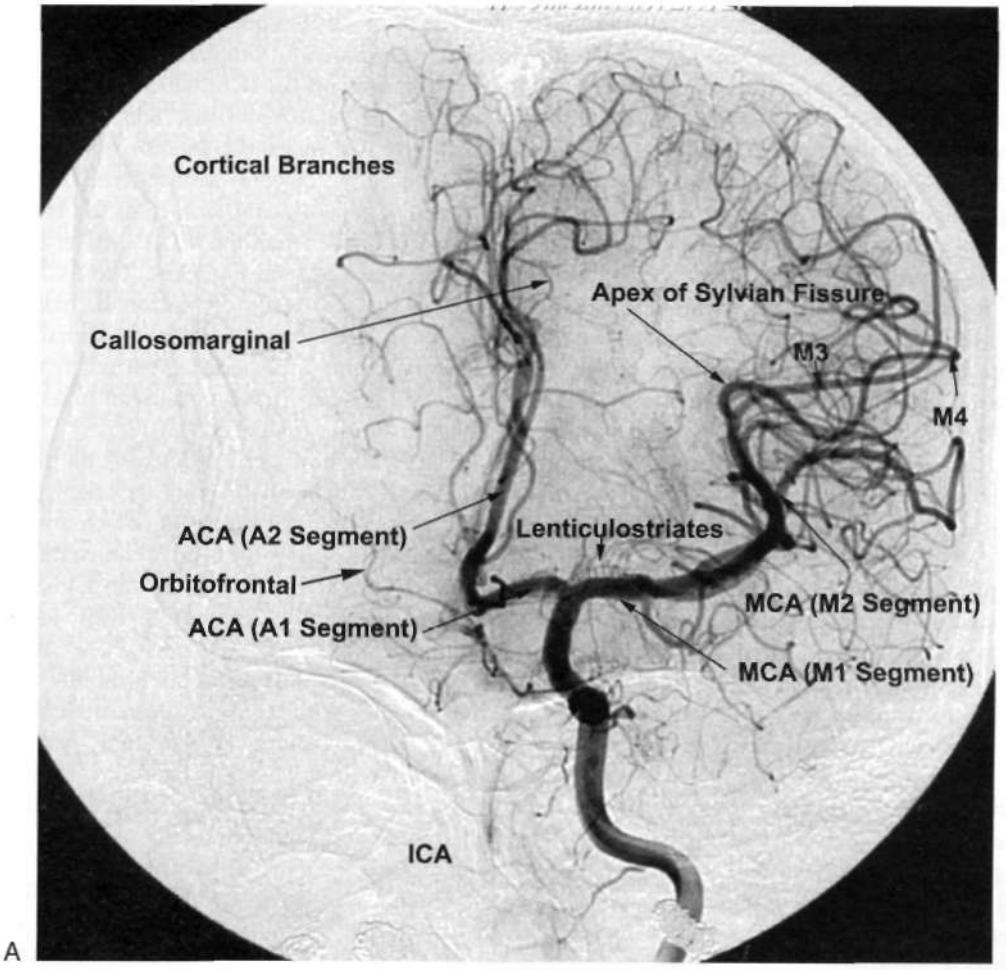

FIGURE 37C3 Anterior (A) and lateral (B and C) views of anterior circulation after contrast injection into the left internal carotid artery. For the purpose of clarity, the middle cerebral artery (MCA) and the anterior cerebral artery (ACA) branches are labeled separately in (B) and (C).

neurological symptoms observed with interruption of blood flow from particular branches. The A3 branches refer to cortical suppliers and have classically been regarded to vascularize the anterior two thirds of the medial hemispheric surfaces in addition to a small area that extends over the convexities. However, variability is common and normal.

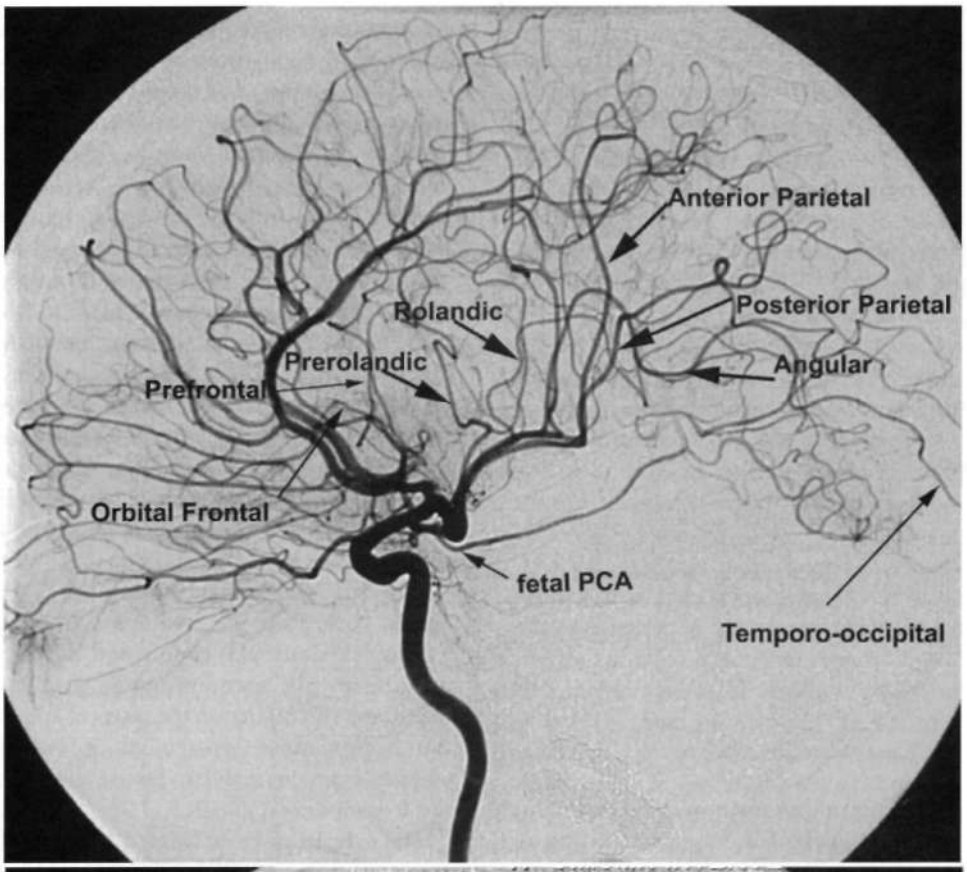
Common anatomical variants include hypoplastic or absent Al (5-18%). Yasargil and Smith (1982) reported that as many as 50% of these patients develop a contralateral Al intracranial aneurysm. A duplicated Al is also seen in approximately 10% of patients. An azygous ACA refers to a solitary and unpaired vessel that arises from the confluence of the Al segments from the left and right ACAs. However, true azygous ACAs are rare and are associated with lobar holoproscnccphaly and saccular aneurysms {Osborn 1994). A bihemispheric ACA sends a variable number of branches to the contralateral side {separate left and right arc present, but one is dominant and sends to both sides). Other ACA variants include infra-optic origin, duplicated ACA, and fusion of associated aneurysms,

Neurological symptoms in the ACA territory include slight impairment of superficial sensation and severe impairment of deep sensation in the contralateral lower limb. If the dominant hemisphere is involved, aphasia resulting from infarction of the supplementary speech areas will occur, although it is usually transient. There may be loss of control of urinary and rectal sphincters. Psychomotor phenomena include catatonic posturing, hypokinesia, and memory loss.

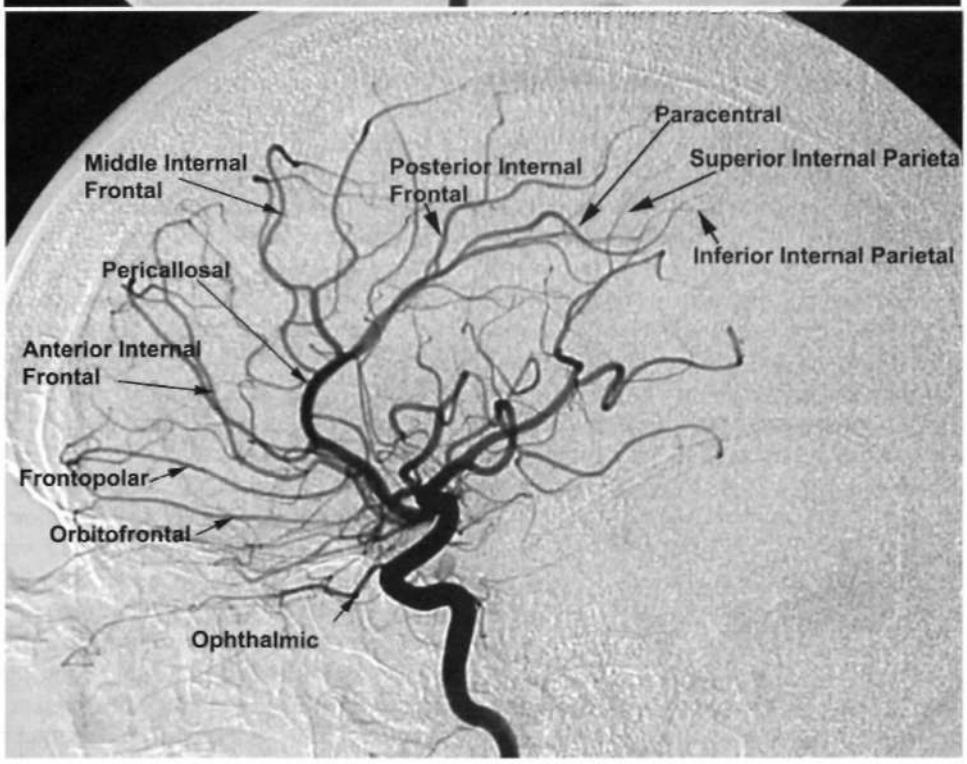
Finally, issues to consider in the endovascular approach of the ACA include recognition of a hypoplastic A1, the hair-pinned origin A1, access through the posterior circulation, and variations of the distal A2 through AComA variations,

The Middle Cerebral Artery

The MCA is the other of two branches of the ICA. It is the larger diameter vessel and is divided into several major segments. Table 37C.4 details its complex course and the large, deep, and cortical territories that are supplied.



B



C

FIGURE 37C.3, cont'd.

Tabic 37C.3: Clinical presentation associated with vascular compromise of various anterior cerebral artery territories

Artery	*Associated symptoms*
Orbito frontal	Confabulation, amnesia, cardiovascular instability
Fronto polar	
Callosomarginal	
Pcricallosal	
Anterior (internal) frontal	Eye deviation toward lesions, loss of interest (abulia), and reflex grasping
Middle (internal) frontal	Transcortical motor aphasia (dominant hemisphere), tnniMnii contralateral akinesia, contralateral alien hand syndrome, and contralateral dyspraxia
Posterior (internal) frontal	
Paracentral	Contralateral weakness, numbness of lower extremities, loss of discriminative sensoty modalities, bowel and bladder incontinence
Parietal (internal) superior	
Parietal (internal) inferior	
Splenial	

Great variability exists within the branching of the MCA as it supplies structures in the frontal, parietal, temporal, and lateral occipital lobes. The MCA is the most common site for embolic stroke because it carries almost two thirds of the blood flow from the ICA and presents morphologically a continuation of the ICA. Its branches supply most of the lateral surface of the hemisphere, insula, and anrerior and lateral aspects of the temporal lobe. The variability of the MCA, the bifurcation, and its branches are less frequently seen when compared with rhe other cerebral arteries.

The MCA has been classically described in two major ways: the functional branching approach and the segmental approach. The segmental approach divides the MCA into four major segments according to brain landmarks (Chyatte and Porterfield 2001). The major segments of the MCA are the Ml or sphenoidal segment (origin to limen insulae), M2 or insular segment (runs along the insula), M3 or opercular segment (operculum superior to the insula), and M4 or terminal segment (convex surfaces). The Ml segment is the largest in diameter and gives rise to the lateral lenticulostriate arteries that supply the basal ganglia and the anterior limb of the internal capsule. The Ml segment extends laterally and horizontally for 1-2 cm from its origin at the terminal ICA to the sylvian or lateral cerebral fissure. The lateral lenticulostriate arteries penetrate the inferior surface of the frontal lobe to supply the basal ganglia, caudate nucleus, and internal capsule. The Ml segment may also provide anterior temporal branches that sometimes originate from the proximal M2 segment. The anterior temporal branches supply the temporal tip cortex. At **its** distal portion, the Ml segment curves posterosuperiorly to the insular cortex (island of Reil), where it bifurcates into major anrerior and posterior cortical branches. Between 20% and 30% of all intracranial aneurysms are found at the Ml bifurcation,

Table 37C.4: Branches of the middle cerebral artery and its anatomical course

Segment	*Course*
MCA	
(Ml) sphenoidal	Extends laterally and horizontally from its origin at ICA to sylvian fissure
(M2) insular	At its genu, M2 loops over insula and passes laterally to exit from sylvian fissure
(M4) terminal	Hemispheric surface

ICA = internal carotid arrery; MCA = middle cerebral artery,

The M2 segment has branches that course over the insular cortex and the frontoparietal operculum. It follows a complex sinusoidal course and moves posterosuperiorly to the superior margins of the insular cortex and then passes inferolaterally on the internal and inferior surfaces of the frontoparietal operculum. These multiple branches emerge from the sylvian fissure and run superiorly over the frontoparietal cortex.

The sylvian point is formed by a branch of the angular artery and is the most superior M2 arterial loop on anteroposterior angiographic images. It is at the superior margin of the insula. The sylvian triangle can be noted on lateral angiographic images and is distinguished by the complex array of MCA cortical branches extending over the insular and opercular cortices. Its base is in the frontosellar region and its apex is in the parietal region. Distortions or displacement of the sylvian triangle can be induced by mass effect of intracranial lesions.

The anterior cortical branches of the M2 portion follow the common order: lateral orbito frontal, operculofrontal {ascending frontal or candelabra branch), and central sulcus arteries. The central sulcus arteries are usually called the *precentrai* or *prerolandic* and *central* or *roiandic* branches. They supply the motor and sensory cortical strips. The posterior M2 cortical branches include the anteriot and posterior parietal, angular, and posterior temporal arteries. The M2 cortical branches provide vascular supply to cerebral centers of speech, comprehension, and calculating ability {for the dominant hemi-sphere). It also supplies motor and sensory function of the contralateral face, neck, upper extremities, thorax, and abdomen. Many strokes and transient ischemic events will present with an MCA syndrome with symptoms that reflect consequences of embolic or occlusive events in this vascular territory.

The M4 terminal segment supplies rhe cortex of the frontal and parietal lobes. The superior division includes the orbitofrontal, prefrontal, precentrai, postcentral, anterior and posterior parietal, and angular arteries. The inferior

division supplies the temporal lobe and part of the occipital lobe. Its branches include the temporopolar, anterotemporal, middle temporal, posterotemporal, and tempo ro-occi pita I arteries. Table .>7C..S displays the common neurological presentation of patients with disruption of blood flow from the inferior and superior division,

Aneurysms of the MCA make up approximately 20-25% of all aneurysms and are typically located at the M1-M2 bifurcation. Mycotic aneurysms are generally located in the distal MCA territory, or the M4 branch. Other disorders within the territory of the MCA are commonly seen and include AVM, atherosclerosis, vasculitis, arteritis, and mass effect on the MCA with displacement of the sylvian triangle and point.

Endovascular considerations specific to the MCA include navigation of catheters and devices beyond tin- sylvian triangle where the MCA loops over the surface of the insula, en passage vessels of AVMs, and dominant hemisphere with eloquent brain areas.

VERTEBROBASILAR SYSTEM

The VAs originate from the subclavian arteries adjacent to the origins of the internal maxillary arteries proximal to the thyrocervical and costocervical trunks. In 5% of patients, the VA arises directly from the aortic arch, usually the left side. Also, the thyrocervical and costocervical trunks may anastomose with the extracranial portion of the VA, which may provide branches to the anterior and posterolateral spinal arteries. One of the two vertebral arteries, again usually the left, may be dominant in size. The VA ascends through the transverse foramen of the vertebral body of C6 and passes superiorly through the transverse foramina of C5-C1. The VA then runs posteriorly around the atlanto-occipital joint and ascends through the foramen magnum. This point may be apparent on angiographic images as a decrease in vessel caliber where it penetrates the foramen magnum membrane and the dura, where the origin of the posterior meningeal artery is usually located. The intradural VA travels superiorly and around the lateral aspect of the medulla (Figure 37C.4).

Table 37G5: Clinical presentations associated with vascular compromise of various middle cerebral artery territories

Vessel	*Side*	*Symptoms*
Middle cerebral artery	Dominant hemisphere	Contralateral hemiplegia Hemianesthesia Homonymous hemianopia Conjugate ocular deviation toward the affected side
	Nondominant hemisphere	Contralateral hemineglect, global aphasia
M4 superior		Contralateral sensorimotor deficit and ipsilateral deviation of head and eyes Broca's aphasia in dominant hemisphere (motor)
M4 inferior		Wernicke's aphasia in dominant hemisphere with possible homonymous hemianopia Gerstmann's syndrome (agraphia, acalculia, finger agnosia and right-1 eft confusion, hemisensory deficit if dominant parietal lobe affected) Nondominant hemisphere infarct results in hemineglect and agitated delirium

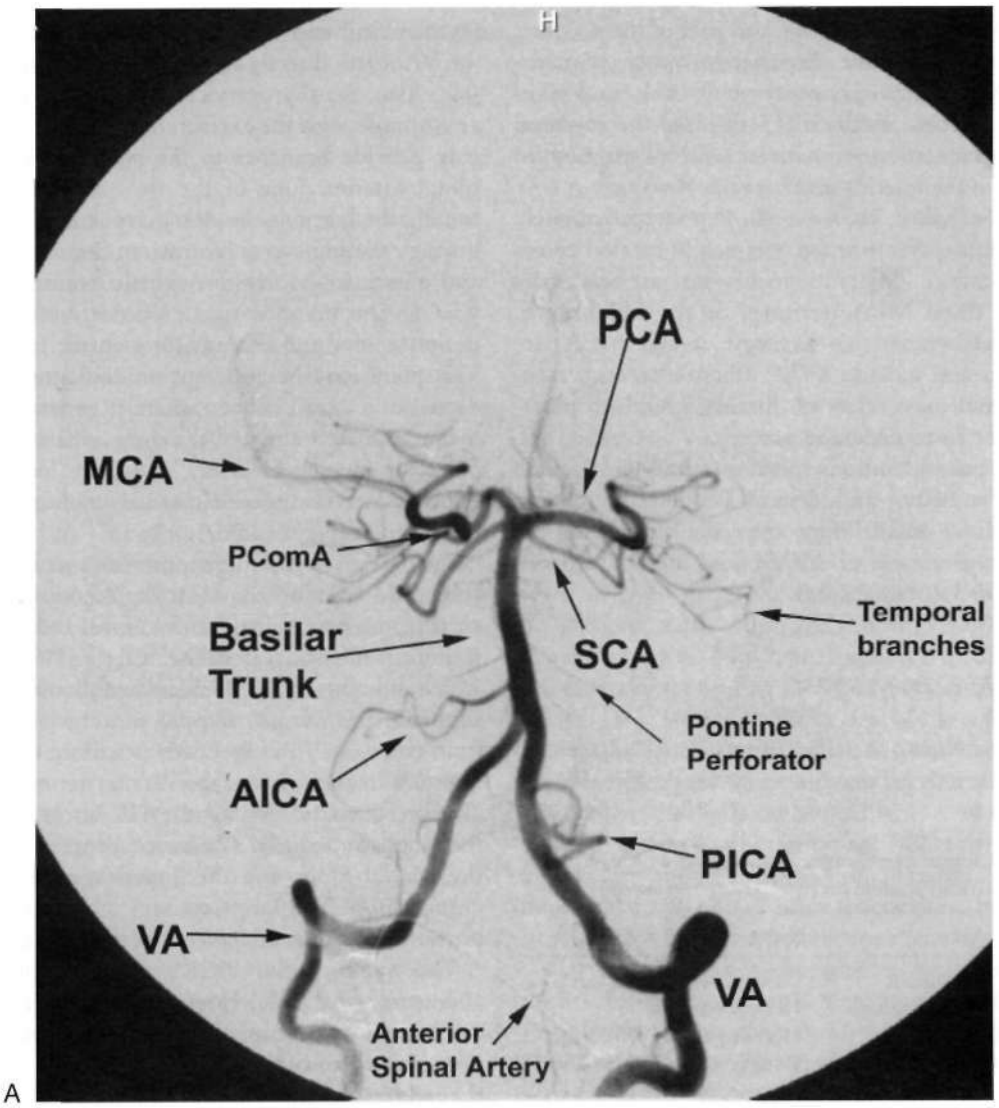
The VA gives rise to the posterior meningeal artery (falx cerebelli), anterior spinal artery (cervical anterior spinal cord), posterior spinal artery (rare and may arise from posterior inferior cerebellar artery [PICA]), and PICA, which runs around the medulla and over the tonsil and supplies the inferior vermis, the choroid plexus of the fourth ventricle, and the inferior surface of the cerebellum.

In 1% of angiograms, the VA may terminate in the PICA. The proximal portion of the PICA travels inferiorly and then loops superiorly. The inferior portion is also known as the *caudal loop,* and the superior portion is called the *cranial loop.* The loops contain the anterior, lateral, and posterior medullary segments of the proximal PICA.

The apex of the PICA'S cranial loop is called the *choroidal point* and defines the floor of the fourth ventricle on lateral angiographic images. It provides the fourth ventricular choroidal branches. After the choroidal point, the supra ton si liar segment of the PICA gives rise to the tonsillohemispheric and inferior vermian branches. The inferior vermian artery anastomoses distally with the superior vermian branch of the superior cerebellar artery and provides a major posterior fossa collateral pathway.

Occlusion of the PICA results in a range of consequences from no symptoms to cerebellar or brainstem infarction that results in severe neurological deficits or even death. Infarction of the lateral medullary segment lying posterior to the inferior olivary nucleus leads to the classic lateral medullary syndrome (Wallenberg's) with nystagmus, ipsilateral ataxia, asynergia, vomiting, dysarthria, dysphonia, singultus, contralateral impairment of pain and thermal sense, hypoacusis, ipsilateral numbness of the face, loss of taste, ipsilateral Horner's syndrome, hoarseness, and dysphagia.

The anterior spinal arteries originate from the VA distal to the PICA origin and course inferomedially in 50% of cases to join the contralateral side along the anterior cord. Normally, a variable degree of hypoplasia may exist distal to the origin of the PICA. Near the pontomedullary junction, the two vertebral arteries join to make up the basilar artery. The basilar artery runs antcrosupcriorly over



FIGUKE 37C.4 (A) Anteroposterior view of the posterior circulation, the left vertebral artery has been injected with contrast. AICA = anterior inferior cerebellar artery; MCA = middle cerebral artery; PCA = posterior cerebral artery; PComA = posterior communicating artery; PICA = posterior inferior cerebellar artery; SCA = superior cerebellar artery; VA = vertebral artery.

the ventral pons. The vertebral arteries and the basilar artery may be fenestrated where they divide into two parallel channels over short distances. Many small pontine perforating branches arise from the basilar artery and supply the following structures: pyramidal tracts, medial Iemnisci, red nuclei, respiratory centers, and all nuclei to cranial nerves II, VI, VII, and XII.

The first major branches of the basilar artery distal to the joining of the vertebral arteries are the paired anterior inferior cerebellar arteries (AICA) that course around the pons and toward the cerebellopontine angle and the internal auditory canal meatus to supply the anterior cerebellar hemispheres, cranial nerve VII, and cranial nerve VIII. The AICA supplies la total pontine structures and gives rise to the labyrinthine artery, which arises directly from the basilar artery in 15% of cases. The PICA and AICA occasionally may originate from the basilar within a common trunk. The labyrinthine artery runs along cranial nerve VIII through the internal auditory canal and supplies the inner ear. Other important basilar artery branches include small pontine perforators that supply the brainstem. The last infratentorial branches of the basilar are the paired superior cerebellar arteries. The superior cerebellar artery runs around the brainstem in the pontomesencephalic groove in the perhne-sencephalic cistern below the oculomotor and trochlear nerves and above the trigeminal nerve to supply the supero-lateral surface of the cerebellar hemisphere. Proximally, it supplies the lateral pontine structures and the sympathetic and spinothalamic tracts. Distally, it branches into the superior vermian artery and cerebellar hemispheric branches, which supply portions of the cerebellar peduncles, dentate nucleus, and superolateral aspects of the cerebellar

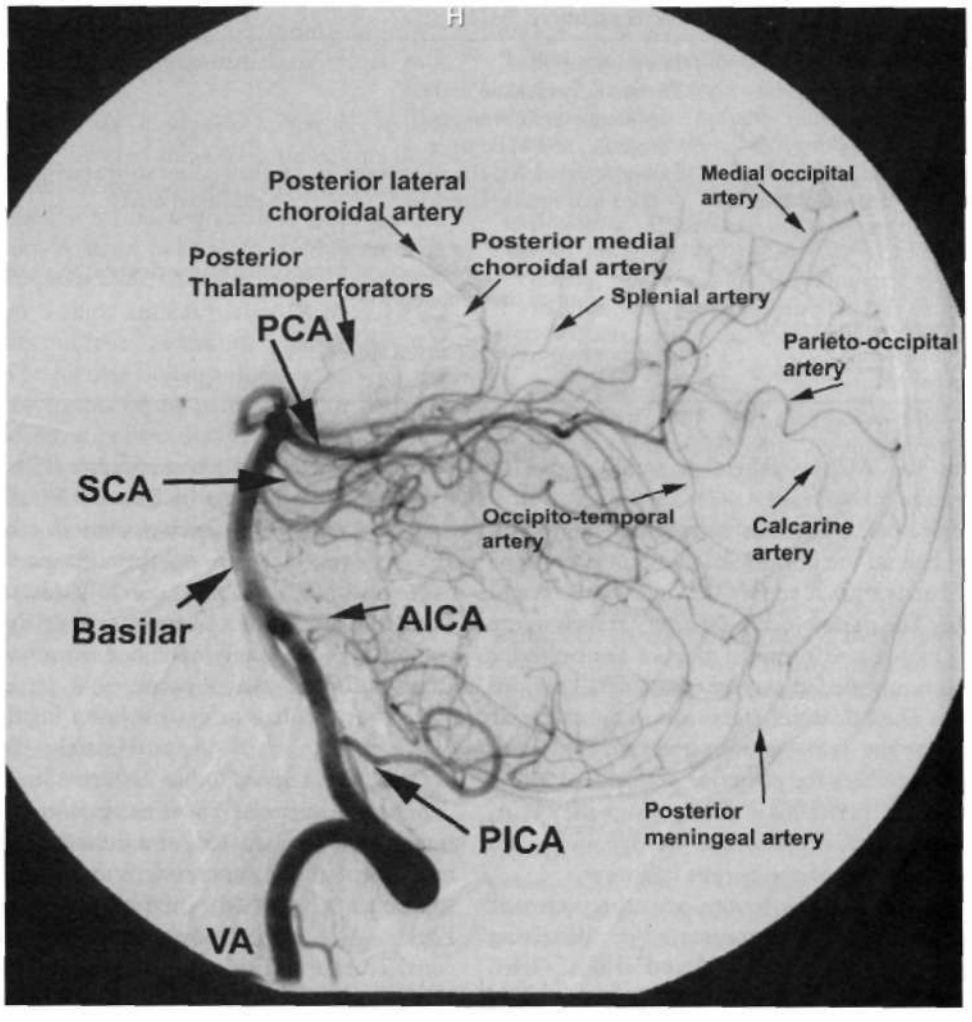


FIGURE 37C.4, cont'd. (B) Lateral view of the posterior circulation.

hemispheres. Duplication of one or both superior cerebellar arteries may be present infrequently.

The distal basilar trunk generally bifurcates into the left and right PCAs at the level of the pontomesencephalic junction, which is superior to the oculomotor nerve and the tentorium. The tentorium separates the proximal PCA from the superior cerebellar artery on both anteroposterior and lateral angiographic images. The proximal PCA is divided into P1 and P2 segments. PI and P2 can often be distinguished during angiography when nonopacified flow fills the transition zone from the ipsilateral PComA. The PCA directly arises from the ipsilateral ICA in approximately 20% of patients, which is also known as the *fetal origin of the PCA.* There is usually marked hypoplasia or complete absence of the PI segment in those cases. Vertebral angiography that reveals unilateral or bilateral absence of the PCA may be due to occlusion of the PCA or secondary to a fetal origin of the PCA. The P2 segment provides many branches with supply to a number of structures (Table 37C.6).

The PCA runs posteriorly around the brainstem in the ambient cistern and then travels medially in the quadrigcminal plate cistern. The distal calcarine cortical branches of the PCAs converge toward the midline on a Towne's projection (caudad angulation of the vertebral angiogram) and arc separated by the falx cerebri.

The PCA has branches that supply the diencephalon, midbrain, posterior one third of the medial hemisphere surface, and occipital lobe.

The peduncular or PI segment is the first part of the PCA. It is characterized as a short segment from the basilar top to the PComA and travels above the third cranial nerve, The thalamoperforating arteries arise from the PComA and PI segment and supply the diencephalon and midbrain. The P2 or ambient segment runs in the ambient cistern from the PComA to the posterior aspect of the midbrain. **Its** branches are the medial PChAs (proximal P2) and supply the colliculi, posterior thalamus, pineal gland, and part of the midbrain. The lateral posterior choroidal arteries pass into the choroid plexus of the lateral ventricle and

Table 37C.6; Branches of the posterior cerebral artery

Proximal segment of P2	*Territory supplied*	*Anastomosis*
Posterior thai a mop erf orating and thalamogeniculate arteries	Thalamus, geniculate body, posterior limb of internal capsule, and optic tract	
Minute branches, medial and lateral posterior choroidal arteries	Cerebral peduncles, choroid plexus of third and fourth ventricles	Collateralizes with anterior choroidal artery
Distal segment of P2		
Splenial artery	Splenium of the corpus callosum	Collatetal with distal ipsilateral pericallosal
Antetiot, middle, and posterior temporal arteries	Undersurface of the temporal lobe	
Parieto-occipital artery	Inner posterior cerebrocortical sutface	
Calcarine artery		Visual cortex

anastomose with the AChAs. There is some degree of variability of supply.

The P3 (quadrigeminal) segment runs within the quadrigeminal cistern behind the brainstem. Its branches are the inferior temporal arteries that supply the inferior surface of the temporal lobe. The parieto-occipital artery travels in the parieto-occipital fissure and supplies most of the posterior one third of the brain's medial surface and a small area of the Literal surface. The calcarine artery runs in the calcarine fissure and supplies the visual cortex and occipital pole. The splenial artery is where the posterior pericallosal artery anastomoses with the pericallosal artery from the ACA, runs adjacent to the corpus callosum at the splenium, and supplies the posterior part of the corpus callosum.

The most important vascular lesions are atherosclerotic changes, rare cases of FMD, traumatic or dissecting aneurysms, moyamoya disease, AVMs, and vein of Galen malformations. Important mass effects and encasements of PCA branches include displacements with brainstem mass, posterior temporal mass, caudal transtentorial herniation, tentorial meningiomas, thalamic mass, suprasellar mass, and posterior fossa mass.

Occlusion of thalamoperforators (P2) results in contralateral hemiplegia, cerebellar ataxia, and rubral tremor associated with ipsilateral oculomotor nerve paresis (Nothnagel's syndrome) (Table 37C.7). If the subthalamus is affected, hemiballism on the contralateral side may result. Occlusion of the thalamogeniculate (P2) arteries results in the thalamic syndrome of Dejerine-Roussy (loss of superficial and particularly deep sensation, with intense intractable hyperpathic pain on the affected side and extreme hypersensitivity to mild touch pain and temperature). Transient contralateral hemiparesis or dystonic movement with possible homonymous hemianopsia may be present. Distortion of taste may occur.

The vertebrobasilar system has a highly variable course of the basilar artery. Approximately 10% of aneurysms occur in this tegion. Other abnormalities include fusiform dilatation (otherwise know as *vertebrobasilar dolichoectasia:* distorted, elongated, and dilatated artery compressing neural structures), atherosclerotic disease, thrombosis with subsequent brainstem infarction, traumatic dissections, FMD, AVM, and metastatic lesions. Endovascular considerations include the tortuosity of the vertebrobasilar system, perforating branches, eloquent areas of the brain supplied, risk of perforation with subsequent hemorrhage, embolic events, en passage vessels, and the proximity of the vascular system to the cranial nerves.

TYPICAL FETAL REMNANTS

Typical fetal remnants include the following vessels: fetal PCA, trigeminal, hypoglossal, otic, proatlamal I, and

Table 37C.7: Clinical presentation associated with vascular compromise of various posterior circulation territories

Vessel	*Clinical symptoms*
P2 peduncular perforators	Contralateral rigor, tremor, chorea, athetosis, ipsilateral oculomotor paresis, and contralateral hemiplegia (Weber's syndrome)
Long circumflex branches (PI, P2)	Damage of oculomotor nuclei and other tectal structures (I'arinaud's syndrome}
Bilateral occlusion of inferior temporal arteries (P2)	Memory loss and Korsakoff-like syndrome, endocrine disturbances
Calcarine	Homonymous hemianopia with central vision pares
Splenial artery (P3)	Dominant occipital lobe leads to dyslexia without dysgraphia
Anterior inferior cerebellar artery	Variable extent of potential infarct dependent on size and territory supplied; large anterior inferior cerebellar artery occlusion can lead to death or infarction of the lateral pons, tegmentum, or medulla
Superior cerebellar artery	Ipsilateral cerebellar ataxia, nausea and vomiting, pseudobulbar speech, contralateral loss of pain and thermal sensation, partial deafness, ipsilateral static tremor, ipsilateral Horner's syndrome, and palatal myoclonus

proatlantal II. Also, a persistent stapedial artery may present as an intra tympanic vascular anomaly that usually ends as a connection to the middle meningeal artery. The fetal PCA may be present in nearly 15% of patients. It originates from the ICA but diminishes in size during development to become the PComA to connect the ICA with the basilar artery. A persistent trigeminal artery may be seen on less than 1% of angiograms and connects the petrous ICA with the distal third of the basilar artery. This embryonic vessel is the most common anastomosis of the carotid to vertebral system caudal to the circle of Willis. The persistent primitive hypoglossal artery connects the cervical ICA to the basilar artery after traversing the hypoglossal canal. The VA is often hypoplastic on the ipsilateral side. The presence of a persistent otic artery is rare. It connects the AICA to the intrapetrous ICA. Intersegmental proatlantal arteries maybe present and connect the cervical ICA {proatlantal I) or the ECA (proatlantal II) to the distal VA before its passage through the foramen magnum. The ipsilateral VA is usually hypoplastic in those cases.

THE CIRCLE OF WILLIS

The circle of Willis connects the anterior and posterior circulations. It has a significant physiological role in providing collateral blood flow to vital brain structures. It is located at the base of the brain, surrounding the optic chiasm and the pituitary stalk. However, there are a large number of bifurcations, multiple flow impingement points, complex flow patterns, and increased wall shear stress within this small region. The higher incidence of cerebral aneurysms within the circle of Willis suggests a strong correlation to these hemodynamic factors (Wakhloo et al. 2003). Most intracranial aneurysms occur within the circle of Willis, with 30% at the AComA and 20-30% at the PComA.

The circle of Willis is composed of the following vessels (posterior to anterior): the basilar artery bifurcation or top, paired proximal PI segments of the PC As proximal to the junction with the PComAs, paired PComAs, paired distal or terminal ICA, paired proximal Al segments of the ACAs, and AComA (Table 37C.8). A complete circle of Willis is present in only 25% of patients, with 75% of patients having hypoplastic or absent segments. Variants include fetal origin of the PCA, hypoplastic or absent Al segments of the ACA, and hypoplastic PComAs.

Branches of the basilar top, PI segments, and the PComAs supply vital structures that include the thalamus, limbic system, reticular activating system, cerebral peduncles, posterior limb of the internal capsule, and oculomotor nerve nucleus.

Other vascular abnormalities that occur at the circle of Willis include atherosclerosis, moyamoya disease, and AVMs. Tumor encasement and displacement of the circle of Willis are also frequently seen. Many facets must be considered in the endovascular treatment of circle of Willis lesions, including the following: obtaining access to the lesion, avoiding perforators, recognizing collateral blood supply, using cross compression or balloon test occlusion, protecting sensitive and eloquent brain areas, and recognizing anatomical variants.

INTRACRANIAL VENOUS DRAINAGE PATHWAYS

The cerebral venous system is highly variable with common anomalies, Ir is composed of Jural sinuses, superficial cortical veins, and deep cerebral and transmedullary veins. It is important to recognize the potential collateral drainage pathways. Cerebral vein and sinus thrombosis can result from, but are not limited to, dehydration, infectious disease, hypcrcoagulable states, and trauma. The venous system of the brain can be fundamentally separated into the supratentorial and infratentorial systems. From there, divisions may be made at deep versus superficial drainage: supratentoiial, infratentorial, deep drainage (including transmedullary veins), cortical drainage, and dural drainage (Figure 37C.5).

Cerebral Cortical Veins

The cerebral cortical veins are highly variable and run in superficial paths along the cortical sulci to drain the cerebral cortex and white matter via transmedullary veins. Multiple cortical veins drain superiorly into the superior sagittal sinus. The superficial middle cerebral vein is within the sylvian fissure and receives drainage from the surrounding opercular cortical regions. It usually runs anteromedially around the temporal tip to empty into the sphenoparietal or cavernous sinus. It may have anastomotic communications with the deep cerebral venous system, the extracranial pterygoid venous plexus, and facial veins.

The posterior portion of the superficial middle cerebral vein communicates with the veins of Trolard (superiorly drains toward the superior sagittal sinus) and Labbe (inferoposteriorly drains toward the ipsilateral transverse sinus). Both of these veins cross the subdural space and enter the dural sinuses. Occlusion of cortical veins during surgical or endovascular procedures may lead to cerebral venous infarction.

Deep Cerebral Veins

Supratentorially, the deep cerebral veins receive their blood supply from white matter, basal ganglia, and thalamus via transmedullary veins. The paired septal veins run posteriorly near the midline along the septum pellucidum. They arc responsible for drainage of the deep white matter of the anterior portions of the frontal lobes. The pair of thalamostriate veins run in a subependymal course

Tabic 37C.8 Vascular components of the circle of Willis territories supplied and clinical symptoms associated with occlusion

Artery	*Variants*	*Branches*	*Neurological deficit*
A Com A		Small perforatots supply the limbic system and optic chiasm	Akinetic mutism, bitemporal hemianopia
Proximal Al	Hypoplasia or absence in Al segment is not uncommon; multiple AComAs in up to 40%, origin of recurrent artery of Heubner (14%)	Medial lenticulostriate branches supply the internal capsule, hypothalamus, and basal ganglia, optic chiasm, and infundibulum Heubner-anterior limb of internal capsule, globus pallidus, and head of caudate nucleus	Motor aphasia, facial weakness, mood changes, impaired judgement
PComA	Hypoplastic in 30% of population, perforators may supply optic chiasm and pituitary stalk	PComA, PI, and basilar provide thalamoperforators: limbic system, midbrain, hypothalamus, reticular activating system, cerebral peduncles, posterior limb of the internal capsule, and the oculomotot nerve nucleus	No specific isolated clinical presentation
Proximal PI	Arises from supraclinoid ICA in 20%, fetal origin, thalamoperforators and thalamogeniculate arteries supply the posterior and lateral thalamus		Memory deficits, homonymous hemianopia, anterolateral and posterolateral thalamic syndromes, contralateral sensory loss
Basilar top			I.ocked-in syndrome, ventral and lateral pontine syndromes, ataxic hemiparesis, cortical blindness

ACA = antcrior cerebral artery; AComA = anterior communicating artery; ICA = internal carotid artery; PCA = posterior cerebral artery; PComA = posterior communicating artety.

anteriorly and medially along the floor of the lateral ventricles. The veins pass between the body of the caudate nucleus and thalamus. They drain the caudate nucleus, the deep white matter of the parietal and posterior frontal lobes, and the internal capsule, and pass anteriorly through the foramina of Monro, where they join with the septal veins to form the paired paramedian internal cerebral veins. The internal cerebral veins run posteriorly within the velum intcrpositum and define the roof of the third ventricle.

The paired basal veins of Rosenthal are formed by the confluence of the deep middle and anterior cerebral veins on the ventral surface of the brain and continue posteriorly around the cerebral peduncles. The basal veins also receive venous drainage from the insula and cerebral peduncles. The basal veins travel posteromedial^ and superiorly, coalescing with the internal cerebral veins (subjacent to the splenium of the cotpus callosum) to form the vein of Galen (great cerebral vein), The midline vein of Galen travels posteriorly approximately 2 cm under the splenium of the corpus callosum within the quadrigeminal plate cistern. It receives the posterior pericallosal, posterior mesencephalic, lateral mesencephalic, internal occipital, and several posterior fossa veins before it joins with the inferior sagittal sinus to form the straight sinus at the junction of the falx and tentorial incisura.

Posterior Fossa Veins

[lu- posterior tossa veins have been divided into four groups: superficial, deep, brainstem, and bridging veins (Rhoton 2000}, The pons is drained by the anterior pontomesencephalic vein and a network of small veins along its ventral surface. Superiorly, the pons drains toward either the basal vein of Rosenthal or the posterior mesencephalic vein. The precentral vein drains a portion of the cerebellar hemispheres and travels posterior to the roof of the fourth ventricle, then superiorly behind the inferior colliculi to drain the vein of Galen. The superior and inferior vermian veins run along the superior and inferior surfaces of the vermis, respectively. These veins

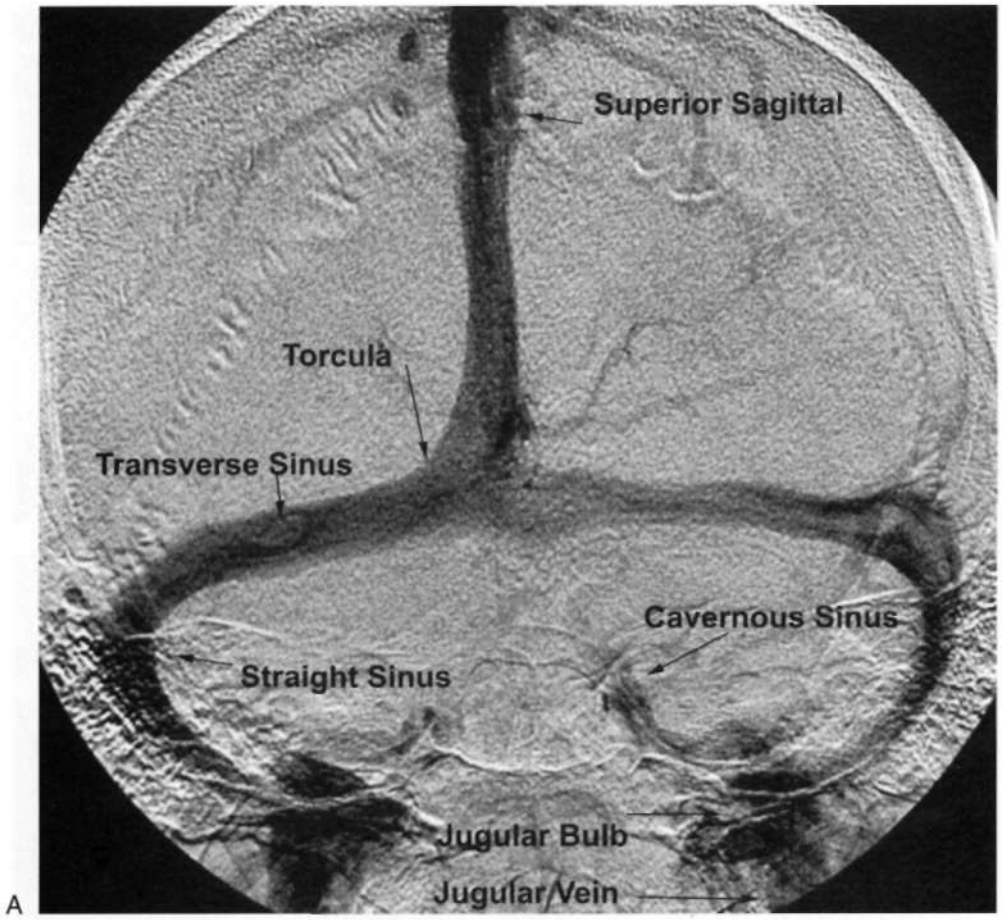

FIGURE 37C.5 Late venous-phase angiogram in anteroposterior (A) and lateral (B) plane. *Continued*

drain the cerebellar vermis and hemispheres. The superior vermian vein drains antcrosupcriorly toward the vein of Galen. The paramedian inferior veins usually drain posteriorly into the straight sinus.

Dural Sinus Network

The dura mater covers the central nervous system and has two layers. The periosteal and meningeal layers of the dura separate to form venous drainage channels or dural sinuses for the brain. The inner meningeal layer forms a reflection onto itself that is known as the falx cerebri {separating the cerebral hemispheres), tentorium (separating the cerebrum from cerebellum), and the falx cerebelli (separating cerebellar hemispheres). Dural sinuses may communicate with veins in the scalp and the diploic space of the calvarium via emissary veins.

The superior sagittal sinus travels along the superior margin of the falx cerebri and receives venous drainage from multiple cerebral cortical veins, the vein of Trolard, and emissary veins. The anterior one third of the superior sagittal sinus may not opacify during late-phase cerebral angiography or may be cnngenitally absent. This midline sinus carries blood flow posteriorly and infcriorly in a creseentie course to the posterior junction point between falx and tentorium containing the confluence of sinuses (also known as the *torcular Heropbili* or *torcuh)* near the occipital protuberance (Table 37C.9),

The inferior sagittal sinus is contained within the lower curvilinear edge of the falx, where it receives venous drainage from the falx and the cerebral hemispheres. This dural channel drains posteriorly in the midline to join with the vein of Galen to form the straight sinus within the intersection between the falx cerebri and the tentorium. The straight sinus drains posteriorly toward the torcula. Occipital sinuses, of variable caliber, are often visualized during cerebral angiography, coursing supramedially within the dura of the posterior fossa, just lateral to the foramen magnum, and draining toward the torcula.

The paired transverse sinuses follow a creseentie course, within the periphery of the tentorium, laterally and anteriorly from the torcula. Usually, the right transverse sinus is dominant or larger than the left. Occasionally, one may be extremely hypoplastic. The transverse sinuses receive drainage from the inferior cerebral veins and vein

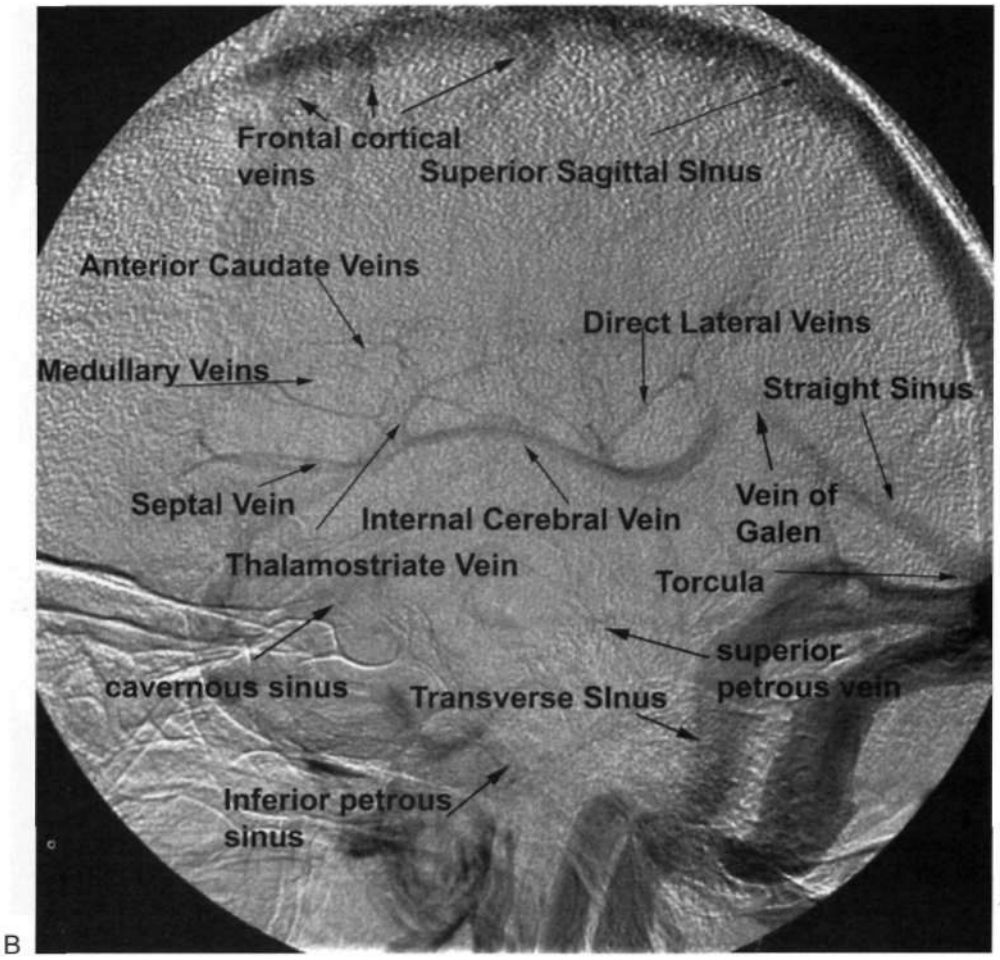

FIGURE 37C.5, cont'd.

Table 37C.9: Major vessels of the venous circulation

Major veins			
Dural sinuses		Deep cerebral vein	
	Superior sagittal sinus		Subependymal veins
	Inferior sagittal sinus		Thalamostriate veins
	Straight sinus		Septal veins
	Torcular herophili (sinus confluens)		Internal cerebral veins
	Transverse sinus		Basal vein of Rosenthal
	Sigmoid sinus		Vein of Galen
	Occipital sinus		Anterior pontomesencephalic veins
	Inferior petrous sinus		Precentral cerebellar vein
	Superior petrous sinus		Superior and inferior vermian veins
	Cavernous sinus	Dural veins	Meningeal vein
Superficial cortical			Emissary veins (connection between sinus and scalp)
	Sylvian veins		
	Veins of Trolard and Labbe	Scalp veins	Occipital vein
	Frontal ascending/descending cortical veins		Temporal vein
	Occipital cortical veins	Cervical veins	Jugular bulb
	Sphenoparietal vein		Internal/external jugular veins

of Labbe, and communicate with the cavernous sinuses via the superior petrosal sinuses, which run along the petrous ridges.

The transverse sinus, as it travels sub]acent to the tentorium, becomes the sigmoid sinus. This sinus, contained within the dura of the posterior fossa, follows a curved course toward the jugular foramen where it empties into the internal jugular vein. A bend in contour at this junction point is termed the *jugular bulb.* Other structures traversing the jugular foramen include cranial nerves IX through XI and small branches of the ascending pharyngeal and occipital arteries. The jugular bulbs communicate with the cavernous sinuses by means of the paired inferior petrosal sinuses, which ascend superomedially from the jugular foramen within the dural flanking the clivus. The inferior petrosal sinuses interconnect through a clival venous plexus.

The cavernous sinuses receive venous drainage from the orbits and their contents via the superior and inferior ophthalmic veins (which in turn communicate with the angular, frontal scalp, and anterior facial veins). This venous drainage pattern may allow intracranial spread of central and deep facial infectious processes.

Arachnoid Granulations

Multiple arachnoid invaginations present along the superior sagittal and the transverse sinuses are known as *arachnoid granulations,* which serve as the sites of cerebrospinal fluid resorption from the subarachnoid space. These structures may appear as filling defects during the venous phase of cerebral angiograms and should not be mistaken for intraluminal thrombi.

Common congenital anomalies found in the venous system include Chiari II malformations with low-lying torcular and transverse sinus, Dandy-Walker malformations with the torcular displaced above lambda, Sturge-Weber syndrome with the lack of superficial cortical veins with dilatated medullary and subependymal veins, and high riding jugular bulb. Variants include venous angiomas (developmental venous anomalies), AVMs, and sinus pericranii (an abnormal communicarion between the intracranial and extracranial venous circulation). Tumor and thrombosis can cause occlusions and displacements.

Chapter 37
Neuroimaging

D. ULTRASOUND IMAGING OF THE CEREBRAL VASCULATURE

Viken L. Babikian and Charles H. Tegeler

Inttoduced to the clinical neurosciences more than 30 years ago, ultrasound technology is widely used today as a diagnostic modality. Its clinical applications include imaging of the brain parenchyma and assessment of blood flow in the cerebral vasculature in children and adults. Technological advances and a lack of radiation exposure have facilitated this evolution and made it possible for ultrasound to be used not only in the outpatient laboratory hut also at the bedside and in the operating room. The introduction of newer developments is expected to further expand these applications.

A comprehensive review of the principles of physics and the clinical and research applications of ultrasound technology in neurology and neurosurgery can be found in textbooks (Kremkau 2002; Tegeler, Babikian, and Gomez 1997). This chapter presents an outline of ultrasound imaging of the cerebral vasculature.

ULTRASOUND PHYSICS AND PRINCIPLES

Although the end product of ultrasound testing often is condensed into a short report indicating whether a flow velocity measurement suggests the presence of significant vascular stenosis, the clinician must know some basic principles and physics to understand what velocity measurements mean for a specific patient. Even minimal knowledge of these concepts provides valuable insight into the technique's strengths and limitations. This section addresses **the** basic principles and physics of ultrasound that form the basis for understanding its many applications (Kremkau 2002; Tegeler and Ratanakorn 1999a).

Ultrasound Transducers, Frequency, and Units of Measure

All ultrasound devices have a crystal in the transducer that has piezoelectric properties; it rapidly contracts and expands when an alternating electrical current is applied. The rapid expansion and contraction cycle converts electrical energy into acoustic energy, or sound waves. Conversely, when acoustic energy strikes the transducer element, as when sound waves reflected or scattered from the insonated tissues return to the transducer, the conformational change causes the crystal to give off a small electrical current rhat can be analyzed by the instrument. Sound waves are described in terms of their frequency (i.e., the number of cycles per second). The unit used to describe one cycle per second is the Hertz (Hz). The human ear can potentially hear sound at frequencies between 20 and 20,000 Hz. Therefore the term *ultrasound* implies frequencies higher than the human audible range (more than 20,000 1 1/, or 20 kl 1/1. Most diagnostic ultrasound devices operate at frequencies of 2-10 million Hz (2-10 MHz). Ultrasound transducers can have a single crystal or element or many individual elements (up to 256), organized in a variety of arrays. Conventional transcranial Dopplcr (TCD) transducers use a single element, whereas most duplex or color flow transducers are linear arrays in which the

elements fire in specific sequences to steer or focus the ultrasound beam as desired.

Doppler Ultrasonography

Diagnostic ultrasound provides an evaluation of cerebrovascular hemodynamics, structure, and anatomy. Hemodynamic information usually is obtained using Doppler ultrasonography, or derivatives thereof, such as color flow or power Doppler imaging (PDI). Structural and anatomical information is provided by gray-scale B-mode imaging. Doppler ultrasonography often is combined with B-mode imaging as duplex sonography, or duplex color flow imaging (CFI).

The key principle on which vascular ultrasound rests was initially described by Christian Andreas Doppler in 1842. The Doppler effect is the change or shift in the frequency (and thus of the wavelength) of a wave caused by relative movement between the sound source or scattcrer and the receiver (Figure 37D.1). As used in vascular ultrasound, in which moving blood components act as scatterers, this principle holds that the Doppler frequency shift (Fs) depends on the speed of blood flow (v in meters per second), the angle that occurs between the sound beam and the direction of blood flow (angle of insonation, *8),* the transmitted frequency (f[t]), and the speed of sound in soft tissue {C in meters per second).

$$Fs(MHz) = 2 \times v(m/s) \times f(t)(MHz) \times \cos 0/C(m/s)$$

According to the Doppler principle, the change or shift in frequency equals the difference between the transmitted frequency and the frequency that is received by the transducer, having been modified according to the factors in the equation. By convention, blood flowing toward the transducer produces a positive Doppler frequency shift, whereas flow that is farther away from the transducer results in a negative shift.

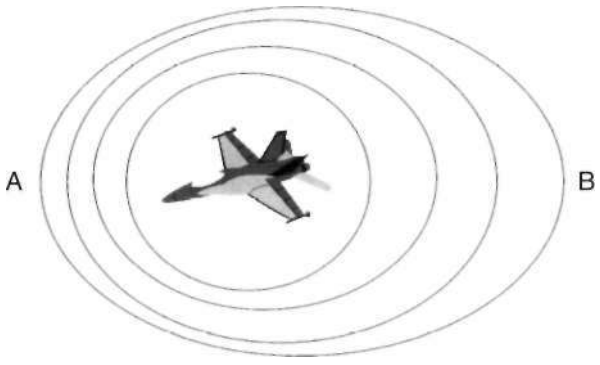

FIGURE 37D.1: Doppler principle. More sound waves per second (higher frequency, higher pitch) hit receiver A than B because of the relative movement of the jet (sound source) toward A and away from B.

$$v\{m/s) = Fs(MHz) \times C\ (m/s)/2 \times f(t)(MHz) \times costf$$

As implemented routinely on newer ultrasound instruments, when both the frequency of the transducer and the angle of insonation arc known, the velocity of the scatterer (flowing blood) can be calculated. For vascular ultrasound, this is the blood flow velocity.

Sound travels through the soft tissues of the body at a speed of 1540 m per second. Thus, the equation is expressed as:

$$v(cm/s) = Fs(kHz) \times 77/f\{t)(MHz) \times \cos 0$$

Because the cosine of the angle of insonation is used in the equation, Fs is greatest as the Doppler angle approaches 0 degrees (direction of the sound beam parallel to the direction of blood flow), and lowest when the angle approaches 90 degrees (right angle to the direction of flow), at which point there is no relative movement toward or away from the transducer and therefore there is no Doppler shift. Although the ideal Doppler angle is 0 degrees, in the body the angle of insonation changes dramatically depending on in situ anatomy.

Use of a standard range for an acceptable angle of insonation increases the reliability and reproducibility of the results. As discussed later in this chapter, carotid ultrasound usually is performed with a 60 degree angle of insonation, whereas conventional TCD instruments assume a 0-degree angle of insonation. Transcranial color flow duplex devices allow angle correction, but criteria and experience with this alternate approach are still emerging.

Current instrumentation almost exclusively uses blood flow velocity {v in centimeters per second) rather than Doppler frequency shift (Fs in kilohertz) to show results. This avoids potential confusion related to variation in f(t) between instruments and laboratories, or cos ft, by correcting for the transducer frequency and the angle of insonation. This approach provides a common language and a measure with which to compare results between different studies. Blood flow velocity is now the most commonly used ultrasound parameter by which to diagnose vascular stenosis and to assess vascular hemodynamics.

Transducers for Doppler ultrasonography can be divided into two broad categories: those that continuously transmit and receive (continuous-wave Doppler) and those that intermittently emit and receive a series of short pulses of sound (pulsed-wave Doppler). The continuous-wave Doppler transducer is sensitive to any moving target along the path of the sound beam. It can accurately identify extremely high-flow velocities. However, continuous-wave Doppler cannot localize the specific depth of the reflector (scatterer) from which a signal arose. Pulsed Doppler transducers emit brief pulses of sound and wait for any scattered signals to return before sending the next pulse. The pulsed-wave Doppler method allows manipulation of the time of sampling to choose a specific depth or a time window for recording. This allows sampling from a specific region or volume of tissue

(sample volume). In addition, because sound travels in soft tissue at a constant speed, the depth of a reflector can be determined, or a desired depth of sampling can be chosen.

Pulsed-wave Doppler uses a series of sound pulses emitted at a fixed rate (pulse repetition frequency) rather than continuous sampling. It may not be able to accurately assess very high frequency shifts generated by high blood flow velocities. When the frequency shift being sampled exceeds one half the pulse repetition rate, also known as the Nyquist limit, the velocity information is recorded erroneously. The highest velocities, corresponding to frequency shifts higher than one half the pulse repetition frequency, are displayed as flow in the opposite direction, a pattern known as aliasing.

Doppler Spectral Display and Analysis

Because red blood cells flowing in vessels move at a variety of speeds and directions, there is a spectrum of different **blood flow velocities** within any given sample volume at any time. With the hemodynamic changes that occur throughout the cardiac cycle, the spectrum of velocities also changes over time. This diversity of flow velocities within the vessel is displayed visually by use of the fast Fourier transform (FFT) display. Many hemodynamic parameters are derived from analysis of the **FFT** display of the Doppler velocity data. Analysis includes specific objective parameters such as flow direction, peak systolic velocity, and end-diastolic flow velocity, as well as several indirect or derived parameters such as width or spread of the spectral band of velocities, flow acceleration time (systolic acceleration slope), pulsatility, or resistivity index. These latter parameters for spectral analysis provide additional insights into flow characteristics not only at the site of sampling but also proximally and distally.

Norma! vessels have a compact, narrow, smooth flow velocity envelope on **FFT** display of the Doppler velocity data (Figure 37D.2). With arterial stenosis and turbulence, flow is distributed across a broader spectrum of velocities (spectral broadening), reflecting a greater variety of speeds and directions. Turbulent flow, as occurs distal to a tight stenosis, may also produce an irregular margin to the acoustic envelope, resulting in a bubbling or gurgling sound or even flow reversal, displayed below baseline on the **FFT** display, light stenosis can cause vibration of the vessel walls to produce an audible bruit, and the Doppler spectrum can show the ultrasonic equivalent as a low-velocity, turbulent, high-intensity signal on the FFT display. There are also other events, such as cerebral embolism, in which it is crucial to display the intensity of the signals within the Doppler spectrum. An embolic particle passing through **the** Doppler sample volume has a much greater reflectivity or acoustic impedance than the surrounding blood, causing more energy to be scattered back to the transducer. This phenomenon results in transient high-intensity signals, also called microcmbolic signals, to appear in the Doppler spectral display with an accompanying audible sound. These have also been called high intensity transient signals.

Individual vessels also have characteristic spectral appearances, created primarily by the distal peripheral resistance. The internal carotid artery (ICA), supplying a low-resistance vascular system in the brain, has a very different appearance from the external carotid artery, which feeds a high-resistance vascular bed in the face and scalp. The ICA velocity waveform typically has a more gentle systolic upslope, a more rounded peak in systole, a more gradual decrease in velocity, and persistent diastolic

flow. The extracranial carotid artery has a sharp upslope, a sharp peak in systole, a rapid fall-off, and little (if any) flow in diastole. Specific spectral patterns, particularly very high- or low-resistance signals, provide indirect clues about hemodynamics and potential pathological conditions both proxiinally and distally.

Brightness-Mode Imaging

B-mode, or brightness-mode, imaging allows anatomical interrogation based on the acoustic properties of the tissue being studied. When an ultrasound beam traverses the tissues, it may be transmitted largely unaltered, or it may be scattered, bent, absorbed as beat, or reflected. The outcome depends on several factors, including the acoustic impedance of the tissue, the differences in acoustic impedance between adjacent tissues, and the angle at which the sound beam strikes the interface. Greater differences in acoustic imped ance between adjacent tissues at an interface or boundary result in greater reflection or scattering. The transducer converts the returning ultrasound energy into electrical impulses that arc then encoded in a digital memory, based on the signal intensity at each point along the ultrasound beam. These data can be displayed visually as varying shades of gray, depending on the signal intensity at each point. When the transducer is mechanically or electronically swept actoss the tissue, in a single plane, the resulting series of scan lines can be used to create a two-dimensional, gray-scale B-mode image. This provides a two-dimensional visual display of a slice of tissue based on the acoustic properties of the tissue (Figure 37D.3). These are static images, but the image can be updated 15-30 times per second so that it appears to be moving in real time. This is the same principle used in making movies: Single frames are displayed in rapid succession to appear as moving reality.

A variety of factors determine the appearance of the B-mode image and the ability to identify structures in the soft tissue. The ability to clearly distinguish two points on the image is called *detail resolution.* This depends on both axial and lateral resolution. Separation of points along the axis of the sound beam (axial resolution) depends mostly on transducer frequency, which improves with higher-frequency transducers. Separation of points perpendicular to the direction of the sound beam (lateral resolution) depends on the width and focusing of the sound beam. Narrower, better-foe used sound beams allow better lateral resolution of points that are side by side. In general, higher

transducer frequencies, with better axial resolution, are desirable to achieve better images. However, attenuation (loss of acoustic energy as sound moves through tissues) is greater with higher frequency transducers, which limits the depth of penetration. Thus, the choice of the best transducer for a specific task must balance the desired depth of penetration against the need for resolution. Modern transducers for extracranial high-resolution B-mode carotid imaging operate ar frequencies of 7.5-10.0 MHz, whereas those used for transcranial CFI operate at 2-3 MHz.

Duplex Imaging

Duplex ultrasonography makes use of both pulsed-wavc Doppler ultrasound and B-modc imaging to obtain both hemodynamic and anatomical information (Figure 37D.4). Now the standard for vascular ultrasound, duplex ultrasound overcomes many prior shortcomings of ultrasound testing by offering image-guided placement of the Doppler interrogation, with correction for the angle of insonation, resulting in more accurate and site-specific velocity measurements.

Color Flow Imaging

CFI uses Doppler flow velocity information obtained from many points (multiple sample volumes) within the image, which is then color coded based on the speed and direction of flow and overlaid onto the appropriate anatomical site in the gray-scale B-mode image {Plate 37D.I). The Doppler data on the color flow image typically represent the mean velocity at each point. This, along with the longer processing time needed to display both Doppler and B-modc data and the resulting slower frame rates, causes CFI to lack the real-time, quantitative hemodynamic accuracy of regular duplex Doppler spectral analysis. However, CFI has many potential advantages compared with conventional duplex ultrasound and is becoming the standard. At least one instrument has used time domain processing, rather than Doppler frequency shift data, to obtain and display velocity information. This approach, known as color velocity imaging, uses the patterns of echoes in the B-modc scan lines, which are cross-correlated with echo patterns from adjacent scan lines, to determine the velocity vector. Although limited in availability, this approach offers several potential advantages over conventional CFI, wirh lower power use, high time and spatial resolution, and the ability to display peak velocity in the color image (Knappertz, Tcgeler, and Myers 1996).

Power Doppler Imaging

Another variation on CFI is PDI, which uses the integrated intensity or amplitude of power in the Doppler spectrum as the basis for displaying color-coded flow on the B-mode

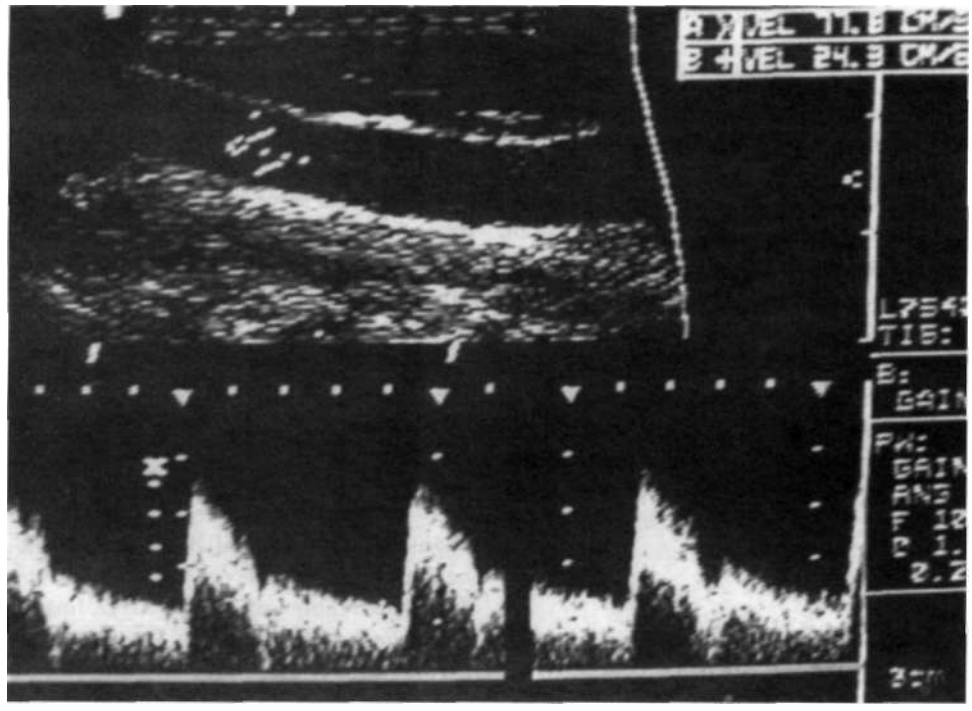

FIGURE 37D.4 Duplex ultrasonography. Combined Doppler velocity spectral display and brightness-mode image guided placement of the sample volume.

image. The data presented on the PDI color display reflect the amount of blood flow detected at each point rather than the mean Doppler velocity (Rubin et al. 1994). PDI is less angle dependent, is not affected by aliasing, and may be more sensitive to flow than conventional CFI, especially with very poor angles of insonation or very little flow in the vessel. Typically, PDI does not display the direction or velocity of flow, so it cannot be used independently to grade stenosis. However, it is complementary to duplex ultrasound and CFI, may improve accuracy in some difficult patients, may be quite useful for screening examinations, and may be particularly helpful with transcranial applications of CFI (Criewing et al. 1996; Bluth et al. 2000).

TECHNICAL CONSIDERATIONS

Extracranial Cerebrovascular Ultrasonography

Interrogation of the carotid arteries is the most common and arguably the most clinically important current application of cerebrovascular ultrasound. Any evaluation of the extracranial cerebral vessels must also include study of the vertebral arteries and usually should be combined with intracranial ultrasound to evaluate the entire cerebral circulation rather than any segment in isolation. As outlined earlier in this chapter, a variety of methods can be used to study the carotid and vertebral arteries. There is great variation across laboratories in the techniques used and in the quality of extracranial testing. This section discusses the essential components for such testing, some additional methods, and the need for quality assurance, certification, and aceteditation.

Any protocol for a carotid or vertebral artery ultrasound study should include duplex ultrasound to evaluate hemodynamic and structural changes, with or without CH. The only exception might be screening situations in which continuous-wave Doppler or PDI might be used alone to assess for hemodynamic changes indicative of significant disease that warrants further study. Real-time recording of the results with videotape is strongly recommended, as opposed to saving only a scries of frozen images. It is important for the reading physician to teview the real-time results to get the most information possible, taking advantage of the real-time capability of ultrasound. CFI, PDI, and volume flow rate measurements provide valuable adjunctive information that can improve understanding and accuracy of interpretation.

Carotid Duplex Examination

Duplex examination of the carotids must include Doppler flow velocity sampling of the proximal, mid-, and distal common carotid (CCA) arteries, proximal and distal ICAs, and external carotid arrerics, bilaterally. The proximal great vessels (innominate and subclavian arteries) are also studied if they can he visualized. If disease is detected, then additional Doppler sampling of the vessel proximal to, at the point of, and distal to the stenosis should be included. Sampling should be across the entire vessel diameter to avoid missing a high-velocity jet along the vessel wall. Sampling should be done using a standard angle of insonation, or at least within a standard range of angles. Most sonographers try to sample at a 60-degree angle, but 45-60 degrees is acceptable. Enough of the study should be videotaped to allow review of both the spectral display and the audible signals from all of rhe target vessels or regions of abnormality. Transducer frequencies for Doppler interrogation usually are between 4.0 and 7.5 MH/..

Because of predictable hemodynamic changes as stenosis develops, duplex Doppler ultrasound can be used to estimate the severity of the stenosis. Very mild degrees of stenosis have little hemodynamic effect and cause little change in flow velocity or in the Doppler spectral waveform. Progressive stenosis first causes increased peak systolic velocity across the narrowed segment. Additional narrow ing causes further increase in the peak systolic velocity, and a disturbed flow pattern, or turbulence, emerges (Figure 37D.5). Severe stenosis prevents adequate blood flow volume across the lesion; despite higher peak systolic velocity values, the end-diastolic velocity also increases. In very tight carotid stenosis approaching occlusion, peak systolic and end-diastolic velocity values may increase even further or may begin to decrease as critical narrowing is reached.

These changes in velocity and flow pattern are used to estimate the severity of stenosis. Most criteria used for interpretation are based primarily on the peak systolic velocity, end-diastolic velocity, and ratios of velocities in the ICA and CCA (Table 37D.1). The ratio of velocities is helpful because the velocity in the stenotic segment remains high when compared with the velocity proximal to the stenosis, even when cardiac dysfunction exists. Any set of criteria should serve as a guideline for interpreting velocity data and should not be considered hard, inflexible rules. Inrerpreters also must consider the overall clinical picture in every patient and exercise judgment and flexibility in reaching conclusions. Current ultrasound laborarories should srrive for an accuracy of approximately 90% for identification of tight carotid stenosis, as documented by a program of ongoing quality assurance.

Carotid B-Mode Imaging

High-resolution carotid B-mode real-time imaging should be done with transducers having frequencies greater than 5 MHz, preferably exceeding 7 MHz. Imaging should include visualization of the CCA; CCA bifurcation; ICA; external carotid artery including anterior, lateral, posterior, and transverse views; or a circumferential scan at each level to include all of these views. Real-time recording of these images allows study of pulsation patterns and movement of

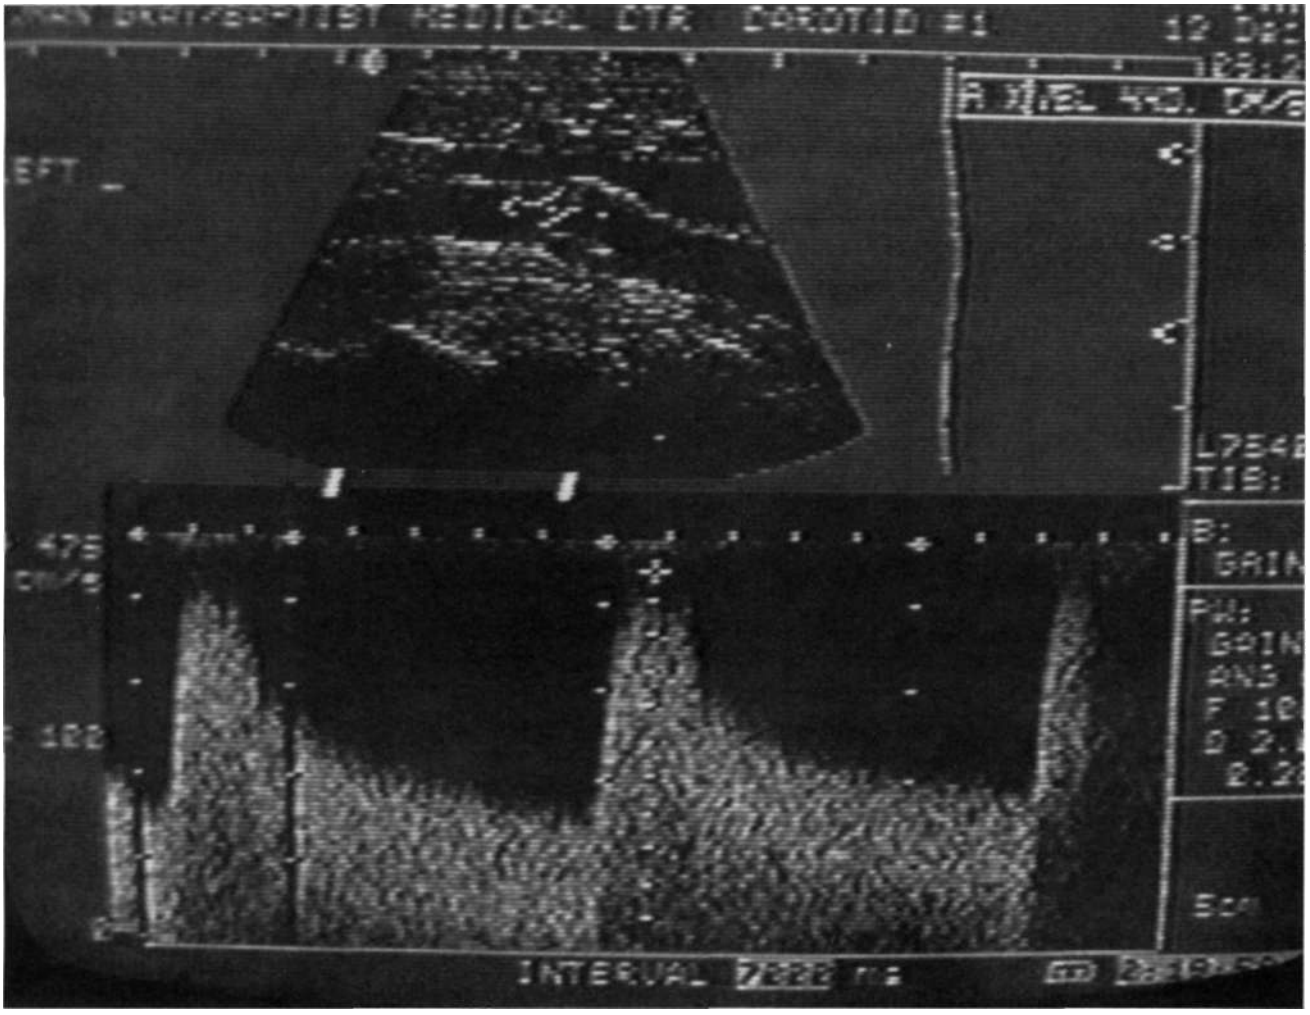

FIGURE 37D.5 Doppter ultrasound with tight stenosis. Spectral display of Doppler flow velocities distal to 75-90% internal carotid artery stenosis, with high systolic (440 cm per second) and diastolic velocities and spectral broadening.

intimal flaps or complex plaques. Measurements of the plaque thickness and residual lumen are performed frequently. Plaque severity can be classified by thickness, with minimal (1.1-2.0 mm), moderate (2.1—4.0 mm), and severe (more than 4.0 mm) categories. The posterolateral approach usually is optimal for measurements of plaque formation and residual lumen because plaques most often occur on the posterior wall of the carotid bifurcation and ICA, and B-mode imaging is most accurate when the sound beam is perpendicular to the interface being imaged.

High-resolution B-mode imaging also has a unique ability to evaluate the specific features of atherosclerotic plaques (Figure 37D.6). Identifiable characteristics include the distribution of plaque (concentric, eccentric; length), the

surface features (smooth, irregular, crater), the echodensity and presence of any calcification producing acoustic shadowing, and the texture (homogeneous, heterogeneous; intraplaque hemorrhage). Hypoechoic plaques and those that are heterogeneous, with prominent hypoechoic regions (complex plaque), indicate an elevated risk of stroke (Polak et al. 1998). High-resolution B-mode imaging is more accurate for defining atherosclerosis of the vessel wall early in the course of the disease than is Dopplcr ultrasound testing. Measurement of the intima-media thickness, **which** increases in the early stages of plaque formation, is used as a surrogate endpoint for clinical trials assessing whether lipid-lowering medications might slow or reverse atherosclerosis. The sensitivity of B-mode imaging for detecting surface ulceration is estimated at 77% in plaques causing less than 50% linear stenosis and 41% for plaques causing more than 50% linear stenosis, with no significant differences between B-mode carotid imaging and arteriography, Although associated with a somewhat worse outcome, surface irregularity or crater formation appears to be a less important morphological risk factor than echodensity and heterogeneity,

Color Plow and Power Doppler Imaging

There is now widespread use of CFI as part of carotid ultrasound testing. Advantages of CFI include rapid determination of the presence and direction of blood flow, with more accurate placement of the Doppler sample volume and determination of the angle of insonation. Absence of color filling in what appears Co be the vessel lumen provides clues about the presence of a hypoechoic plaque, and the contour of the color column can provide information about surface features. If a crater or ulcer is open to the lumen, it is filled in by color. Newer instruments with sensitive CFI designed to detect very low flow velocities are able to accurately differentiate critical stenosis from total occlusion (87-100% sensitivity, 84% specificity compared with angiography), obviating the need for conventional angiography (Sitzer, Siebler, and Steinmetz 1996). The addition of CFI improves understanding of many unusual anatomical configurations such as kinks or coils. Although its contribution is difficult to quantify accurately, CFI probably adds approximately 5% to the overall diagnostic accuracy of carotid duplex ultrasound.

The addition of PDI offers more potential to improve accuracy in some difficult situations. In the setting of high-grade stenosis, PDI improves identification of stenosis and measurement of residual lumen and may improve visualization of plaque surface features, even in the presence of calcification.

Volume Plow Rate Determination

Conventional criteria for reporting carotid stenosis use flow velocity to estimate the linear percentage of stenosis. But flow velocity may be affected by many other factors besides percentage of stenosis. For example, hyper per fusion can

increase flow velocity and might be misconstrued as stenosis. Measurement of actual volume flow rate could help avoid mistakes in such situations, and it is the parameter in which most clinicians treating neurological disorders are interested. Color velocity imaging, as previously described, uses time-domain processing to determine flow velocity. With assumption of a circular vessel and flow symmetrical around the axis of its own direction, the data are integrated to yield the volume flow rate in milliliters per minute. It has been shown to be valid and reliable in vitro and reproducible for studying the CCA in volunteers, and expected normal values have been defined (330 ± 60 mL per minute for women and 375 ± 70 mL per minute for men). Use of the CCA volume flow rate in patients with carotid stenosis reveals characteristic decreases in the rate with progressive stenosis. Measurement of CCA volume flow rate is a standard part of the carotid evaluation in some laboratories, being obtained in patients in whom flow velocity suggests 50% or greater carotid stenosis (Plate 37D.II). This method is also being used in other clinical cerebrovascular diseases and offers a new window for understanding cerebral hemodynamic changes (Knappertz, Tegelcr, and Myers 1996; Tan et al. 2002). Other strategies for measuring volume flow rate are available using traditional Doppler ultrasound instruments.

Vertebral Ultrasonography

Because posterior circulation cerebrovascular disease is common, study of the vertebral arteries is considered a part of the routine extracranial duplex examination. The same techniques described for use in the carotid arteries can be used to study the vertebral arteries and the proximal subclavian or innominate arteries. Therefore duplex Doppler and B-mode imaging of these arterial segments should be performed. CFI is also helpful for visualizing the vertebral arteries. The vertebral artery can almost always be evaluated in the pretransverse and intertransverse cervical segment of C5-C6, whereas the origin can be studied on the right in only 81% and on the left in only *65%* of patients. Because there is mostly a low-resistance distal vascular bed, the vertebral artery usually shows a low-resistance pattern Doppler spectral pattern, similar to that of the ICA. There are no widely accepted criteria for stenosis in the extracranial vertebral artery. As with the carotid system, spectral analysis provides insight into proximal and distal disease.

Technical Limitations

Potentially important limitations of carotid duplex sonography are relared to the patient, instrumentation, sonographer, and interpreter. Patient factors that can preclude an adequate study include the inability to cooperate, neck swelling or other conditions that limit access to the neck, a high carotid bifurcarion, deeply situated vessels, and calcification with acoustic shadowing that blocks the sound beam.

Intracranial Cerebrovascular Ultrasonography

Transcranial Doppler Ultrasonography

Most commercially available TCD instruments use a 2-MHz probe to allow insonation through the cranium. These pulsed-Doppler instruments have an effective insonation depth range of 3.0-12.0 cm or more that can be evaluated by increments of 2 or 5 mm. At an insonation depth of 50 mm, the sample volume usually is 8-10 mm axially and 5 mm laterally. TCD probes differ from the 4- to 10-MHz transducers used to monitor the progress of intraoperative neurosurgical procedures (Unsgaard et al. 2002). Advantages of TCD include the maneuverability of the small probes, the Doppler sensitivity, and, especially when compared with transcranial color-coded duplex and magnetic resonance angiography, the low price of instruments.

Routine TCD testing relies on three natural acoustic windows to study the basal segments of the main cerehral arteries. Insonarion through the temporal bone window allows detection of flow through the middle cerebral artery (MCA) Ml and anterior cerebral artery Al segments. Normal blood flow direction is toward the probe in the MCA and away from it in the anterior cerebral artery. The supraclinoid ICA is also detected, but it may be difficult to distinguish from the MCA. Depending on the position of the window, the probe usually has to be tilted frontally to detect these vessels. A posterior (or occipital) tilt of the probe enables insonarion of the posterior cerebral artery's first segment.

The occipital window takes advantage of the foramen magnum's opening into the skull. Flow in the distal vertebral artery and proximal to midporrions of the basilar artery can be detected; it is away from the probe in these arterial segments. The position and caliber of these arteries vary widely, making insonation occasionally difficult.

The ophthalmic artery and carotid siphon can be studied through the orbital window. Flow in the ophthalmic artery-is toward the probe and has a high resistance pattern. Flow in the ICA siphon can be either toward or away from the probe, depending on the insonated segment of the siphon. The instrument's power output must be decreased when it is insonating through the orbital window because prolonged exposure to high-intensity ultrasound has been associated with cataract formation.

Flow velocities change with age and differ between men and women. Normal values have been reported by several authors. Repeated measurements of flow velocities are highly reproducible.

Based on rhe general knowledge of the location of intracranial arteries and flow direction, a comprehensive map of the basal arteries can be generated. This map is

clinically useful because common pathological conditions affecting the intracranial arteries, such as atherosclerosis, sickle cell disease, and vasospasm associated with aneurysmal subarachnoid hemorrhage, often affect arterial segments that can be insonated. Convexity branches of the cerebral arteries arc beyond the reach of TCD.

Transcranial Color-Coded Duplex Ultrasonography

Examinations performed with 2.25-MHz phased array and 2.5-MHz 90-dcgrcc sector transducers enable color-coded imaging of intracranial arterial blood flow in red *Aiid* blue, respectively, indicating flow toward and away from the probe (Plate 37D.III). The main advantages of transcranial color-coded duplex are the ability to visualize and positively identify the insonated vessel, thus increasing the ultrasonographer's confidence, and the ability to correct for the angle of insonation. In addition, transcranial color-coded duplex provides a limited B-mode image of intracranial structures.

Technical Limitations

A technically adequate study of the anterior circle of Willis cannot be obtained in 2.5-20% of patients studied with TCD. This is due to several factors, including the thickness of the temporal bone. The rate of unsatisfactory studies varies between medical centers and probably relates to the characteristics of the population tested at each neurovascular laboratory. Failure rates are higher in older adults and in African American patients. Restrictions in the emitted power of TCD instruments and limitations secondary to transmission through the skull hone can also result in technically unsatisfactory studies. The immediate cause of this limitation often is an inadequate signal-to-noise ratio. The latter can he improved by enhancing the reflected ultrasound waves with the use of contrast agents. Several echocontrast agents, including lipid-coated microbubbles and galactose microparticlcs, enhance the ultrasound signal in a clinically useful way. A commercially available agent is in use in Germany. Although available for echocardiography, commercial agents are not yet available for **TCD** testing in the United States. Echocontrast agents are especially useful in patients with inadequate temporal bone windows.

Certification and Accreditation

An ongoing program of quality assurance is basic to maintaining the highest quality of testing. Quality assurance is vital to ensure that for specific sonographcrs, using specific equipment, interpreted by specific readers, the criteria arc performing as expected (Gomez et al. 1997; Masdeu 1997; Smith, Anderson, and Gramith 1993). Formal correlation should be sought using any other modalities available, including catheter angiography, magnetic resonance angiography, pathological specimens, clinical outcomes, and repeat examinations.

Certification of sonographcrs and physicians and accreditation of neurovascular laboratories is desirable. In the United States, sonographcrs have access to several certifications that help to demonstrate expertise, The most widely accepted is the registered vascular technologist certification, which requires documented experience in the field, completion of rigorous examinations, and practical application of vascular ultrasound. Guidelines for training physicians have been established by the American Academy of Neurology, the American Society of Ncuroimaging, and other organizations. The Neurosonology Certification offered by the American Society of Neuroimaging is an important mechanism to show additional expertise. It requires documented background training and practical experience. The accreditation offered by the Intersocietal Commission for Accreditation of Vascular Laboratories is the recommended accreditation for neurovascular laboratories and remains the most rigorous of those available. Accreditation is offered for both cerebrovascular extracranial and intracranial testing.

CLINICAL APPLICATIONS

Acute **Stroke**

The 1995 introduction of tissue plasminogen activator (t-PA) to treat acute ischemic stroke (National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group 1995) focused the attention of the medical community on acute cerebral ischemia as a treatable emetgency. In the National Institute of Neurological Disorders and Stroke trial, all clinically diagnosed subtypes of stroke benefited from t-PA, and brain computed tomography was the only neuroimaging test obtained to rule out intracranial hemorrhage or other unexpected diagnoses. As a result, imaging of the cerebral vasculature is not currently a prerequisite in initiate intravenous t-PA thrombolytic therapy, although perhaps it should be.

The association of thrombolytic therapy with a 6.4% (National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group 1995) or higher risk of symptomatic intracerebral hemorrhage has led some investigators to argue for better patient selection. A belief that the treatment of patients with cerebrovascular disease should be specific to **the** cause of the stroke has prompted the use of technologies such as single photon emission computed tomography, perfusion and diffusion-weighted magnetic resonance imaging, and TCD to better characterize the cause of acute cerebral infarction.

TCD studies obtained within hours from the onset of symptoms of cerebral infarction along the vascular territory of the ICA show stenosis or occlusion of the distal

intracranial ICA or proximal MCA in 70% of patients. **When** compared with cerebral angiography, TCD is more than 90% sensitive and specific in detecting supraclinoid **ICA** or MCA Ml segment lesions. Contrast-enhanced color-coded duplex sonography can he especially useful in this context. Approximately 30% of **TCD** and cerebral angiography studies show no evidence of arterial occlusions during this acute stage, and it is unlikely that this subgroup of patients benefits from thrombolysis.

TCD can monitor the effect of thrombolytic agents. Testing before and after the administration of streptokinase or t-PA o.ni J^SI-SS iIK- agent's efficacy in obtaining arterial patency or ascertain continued patency in the days after treatment (Yasaka et al. 1998). In addition, investigators have adjusted the dosage and duration of intravenous thrombolytic agent administration based on information provided by continuous TCI) monitoring. Rapid arterial I'Lcanalization is associated with better short-term improvement (Alexandrov et al. 2001).

Although the current use of thrombolytic therapy in acute stroke does not necessitate rapid evaluation of the carotid arteries, testing might provide information that would alter therapy. Urgent carotid testing has not been widely available, and the exact clinical utility remains to be defined.

Recent Transient Ischemic Attack or Stroke

Beyond the 3-hour window, t-PA is not an established treatment option for patients with acute or subacute stroke. Antiplatelet agents and heparin or warfarin anticoagulation are prescribed depending on the immediate cause of cerebral ischemia. Atherosclerotic plaques causing moderate or severe stenosis of the ICA origin and siphon; the proximal segments of middle, anterior, and posterior cerebral arteries; the distal vertebral artery; and the basilat artery constitute approximately 20-30% of the causes of cetebral infarction. These lesions can be detected with ultrasound techniques.

Extracranial Internal Carotid Artery

Estimates of how often carotid disease is the primary cause of cerebral infarction vary from 15% to 40%. Although atherosclerosis is by far the most common cause of carotid stenosis or occlusion, other disorders, such as dissection, congenital anomalies, and thrombus that formed locally or arrived from proximal sources, must be sought. In patients with tecent transient ischemic attack or stroke, it is important to identify those with significant carotid stenosis. Not only is carotid endarterectomy (CEA) more effective than the best medical therapy for preventing subsequent stroke in patients with symptomatic tight carotid stenosis (70-99% linear stenosis), but also the absence of significant carotid disease is important in directing further diagnostic testing and treatment. The North **American** Symptomatic Carotid Endarterectomy Trial investigators also showed that patients with 50-69% linear stenosis also have **a** significant but much lower magnitude of benefit from CEA compared with medical therapy (Barnett et al. 1998). Clearly, although every patient with transient ischemic **attack** or stroke is not a candidate for CEA, the treating physician must identify those who might reasonably benefit from such treatment. In addition, new treatments, such as angioplasty with stenting, may offer attractive alternatives, even for those who are not good surgical candidates.

In the setting of recent transient ischemic attack or stroke, as with other cerebrovascular diseases, several key principles should guide the diagnostic evaluation. The physician must first determine whether any testing is warranted. The basic question is whether testing will help with the diagnosis or affect management. If so, safe, accurate, and less costly modalities should be used first, and more risky, invasive, costly methods should be used only when needed. Physicians also must be aware that the services, resources, expertise, and quality of all types of testing available locally may drastically yet appropriately alter the algorithm for evaluating cetebrovascular disease.

Ultrasound testing offers a safe, accurate, noninvasive, and inexpensive way to evaluate for extracranial cerebrovascular disease. It is considered the initial test of choice for identifying significant carotid stenosis in patients with recent transient ischemic attack or stroke (Figure 37D.7; Tegcler and Ratanakorn 1998). For the carotid territory, this should include duplex ultrasonography, with or without CFI. Reports should address the severity of stenosis based on Doppler velocity measurements. They also include information about the presence of any plaque and the morphology, based on high-resolution B-mode imaging. Additional helpful ultrasound tools include PDI and volume flow rate measurement.

Results of carotid ultrasound testing must then be integrated with other available testing modalities if additional information is needed. At present, this often means a combination of ultrasound and magnetic resonance angiography or compured tomographical angiography, with conventional angiography reserved for those in whom the noninvasive testing is technically inadequate, equivocal, or contradictory. The combination of ultrasound and magnetic resonance angiography is more cost-effective than the use of routine conventional angiography in this setting. However, the best algorithm for evaluation may vary depending on the services and expertise available at each medical center.

Intracranial Circulation

Intracranial atherosclerotic lesions account for approximately 5-10% of all cerebral infarcts. They tend to be more common in African Americans and in Japanese and Chinese populations. Intracranial atherosclerotic lesions are

Extracranial Carotid Ultrasonography in Practice

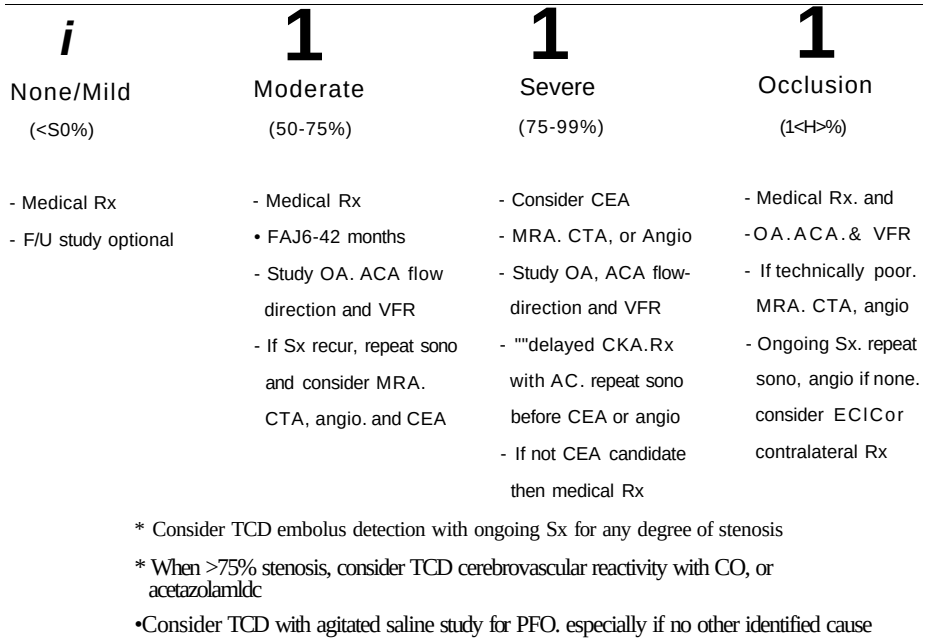

FIGURE 37D.7 Extracranial carotid ultrasonography in practice. Practical importance of carotid ultrasound. The category of stenosis severity influences treatment decisions and provides additional diagnostic information. associated with a high risk of cerebral infarction, which varies depending on the location of the lesion. The annual rate of stroke ipsilateral to MCA stenosis is approximately 6-10%. Brain infarction in this setting is caused by occlusion of penetrating arterioles and artery-to-artery embolism {Wong et al. 2002). Pharmacological treatment of vascular risk factors, antiplatelet agents, and anticoagulants often are prescribed to patients with these lesions, but there are no prospective studies showing the efficacy of these regimens. A 1995 retrospective study of symptomatic patients with angiographically demonstrated lesions causing more than 50% stenosis showed that warfarin anticoagulation reduces the risk of recurrent cerebral infarction and has a more favorable risk-to-benefit ratio than aspirin (Chimowitz et al. 1995}. Angioplasty is performed at some centers.

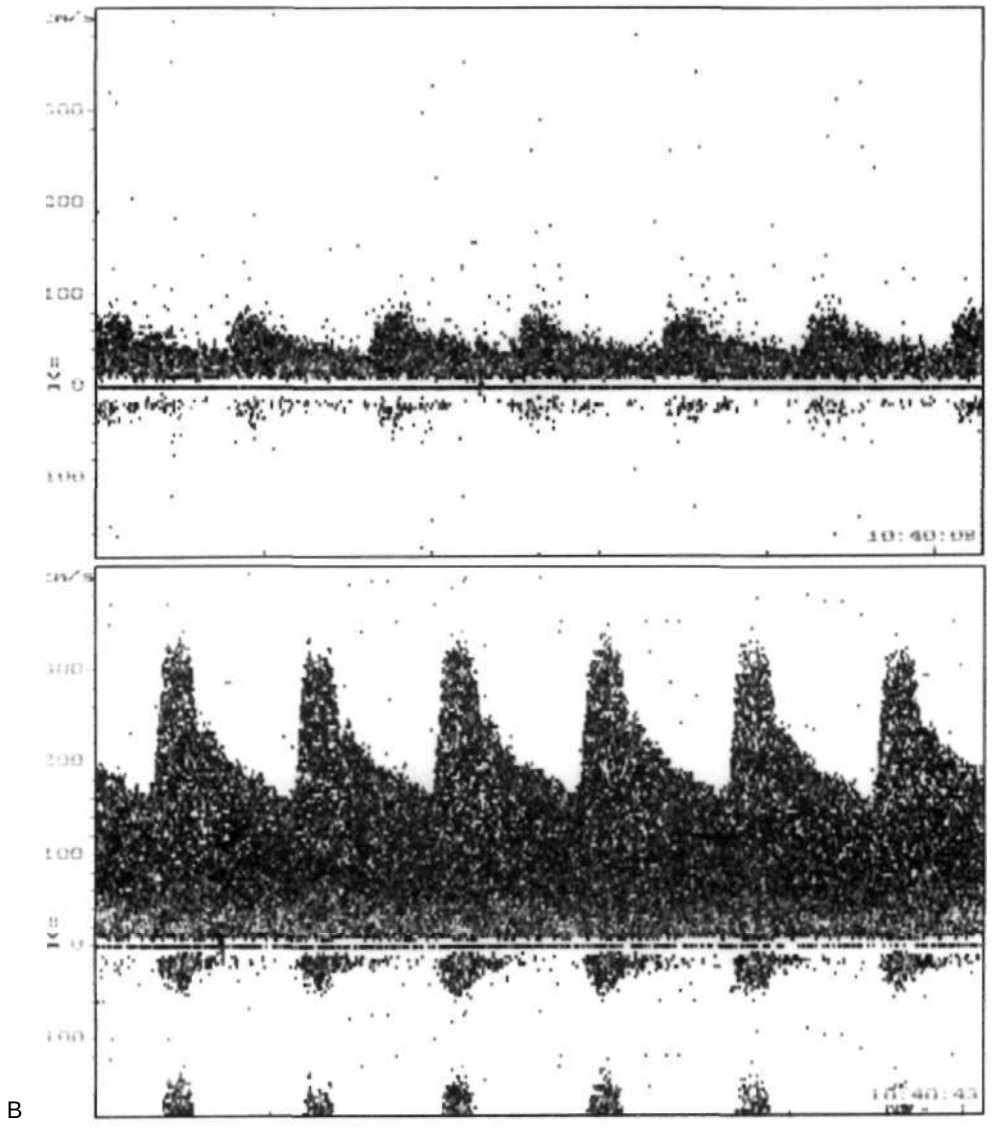
ICA distribution stenoses secondary to atherosclerosis, sickle cell disease, moyamoya disease, and dissection are reliably detected by TCD. As in other arteries, a focal increase of flow velocity is the characteristic finding of ICA siphon and supraclinoid segment as well as MCA Ml stenoses (Figure 37D.8). It is often associated with a decrease in velocity in the arterial segment distal to the stenotic lesion, in addition to low-frequency bidirectional signals during systole and arterial wall covibrations. The diagnostically relevant minimal increase in velocity remains a matter of debate, but most investigators concur that MCA peak systolic and mean velocities exceeding 140 cm per second and 80 cm per second, respectively, are significant. When compared with those of cerebral angiography, TCD findings provide an approximate sensitivity of 85% and specificity of 95% in detecting these lesions. Lower velocity values improve sensitivity, whereas higher values enhance specificity. TCD's accuracy is highest in detecting lesions causing more than 50% stenosis. The technique is less reliable in detecting lesions in the proximal anterior and posterior cerebral arteries, and the MCA M2 segment usually is beyond its reach. The accuracy of cerebral catheter angiography in detecting some itirracranial lesions and in estimating the degree of stenosis has been questioned, however.

MCA or basilar artery occlusion is associated with an absence or severe reduction of the Doppler signal at the appropriate depth of insonation at a time when signals from the other ipsilateral basal cerebral arteries arc detectable. Follow-up studies often show spontaneous recanalization of previously occluded segments. The latter can be detected within hours of the onset of symptoms; the majority of symptomatic occlusions are recanalized within *2* days, followed by a period of hyperpcrfusion.

Collateral flow patterns associated with severe cervical carotid stenosis or occlusion also can be detected. They include retrograde flow of the ophthalmic artery and



B

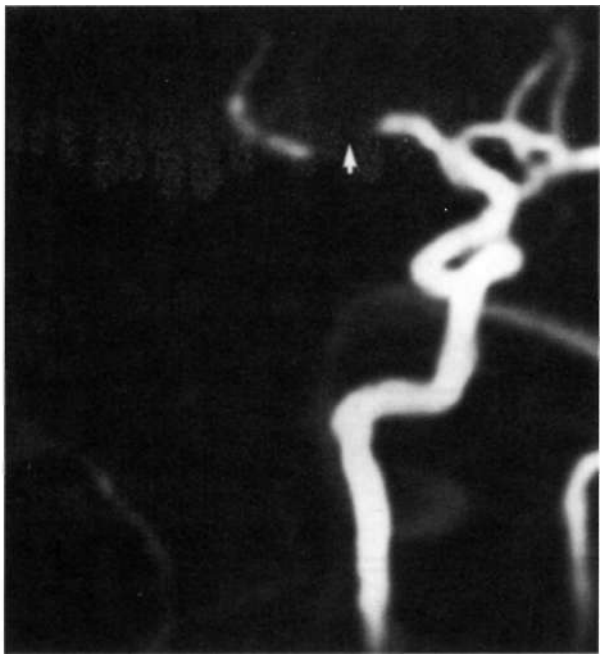
FIGURE 37D.8 Middle cerebral artery stenosis. Focal increase in flow velocities. (A) The peak systolic flow velocity is only 82 em per second, a value within the normal range, at a depth of insonation of 56 mm. (B) At 48 mm, however, the peak systolic velocity is markedly increased at approximately 330 cm per second, indicating a severely stenotic lesion of the Ml segment. *Continued*

anterior or posterior communicating artery flow toward the hemisphere distal to stenosed or occluded ICAs.

Lesions causing stenosis of the V4 segment of vertebral artery and the proximal basilar artery also can be imaged by TCD. Focal increases of the peak systolic and mean velocities to, respectively, 120 cm per second and 80 cm per second or more at depths of insonation corresponding to these arterial segments is considered significant (Figure 37D.9). Velocities often exceed 200 cm per second with lesions causing more than 50% stenosis. When compared with angiography, the sensitivity of TCD is approximately 75% in detecting vertebrobasilar stenotic lesions, and its specificity exceeds 85%. The frequent variation in the size and course of the vertebrobasilar trunk and its contribution of collateral flow to the anterior cerebral circulation are the main reasons for these low figures. Contrast media and transcranial color-coded imaging can be particularly helpful in this setting {Stolz et al. 2002),

Usually a benign condition, the subclavian steal syndrome is characterized by the triad of retrograde flow in one vertebral artery, anterograde flow in the other, and biphasic or retrograde flow in the basilar artery (Figure 37D.10), The surge in interest in this condition stems from the use of angioplasty to treat selected patients with severe symptoms.

Microemholic signals (Plate 371X1V) detected by 1 CI) correspond to gaseous microbubbles or emboli composed of platelets, fibrinogen, or cholesterol moving in intracranial arteries. In patients with extracranial carotid disease, these signals are associated with a history of recent



C

FIGURE 37D.8, cont'd. (C) The magnetic resonance angiogram confirms the presence of the stenotic lesion *{arrowhead}*.

transient ischemic attacks or cerebral infarction in the distribution of the insonatcd artery, and they correlate with the presence of ipsilateral severe stenosis and plaque ulceration. They are detected mainly during the week after symptoms of cerebral ischemia and resolve afterward. Microembolic signals also can be detected in subjects with cardiac prosthetic valves but often correspond to gaseous micro bubbles in that setting. They are less common in adequately anticoagulatcd patients with atrial fibrillation.

The clinical impact of microembolus detection studies remains limited. The presence of these signals in an arterial territory is useful in identifying active lesions. This is especially relevant when a symptomatic patient has more than one potential lesion, such as cervical carotid stenosis and atrial fibrillation, or a suboptimal history. In this situation, laboratory data can help identify the specific cause of cerebral infarction. In addition, because the presence of microembolic signals predicts future cerebral ischemic events in the insonated artery's territory (Babikian et al. 1997), the detection of these signals may tilt therapeutic decisions. In the future, microembolus detection studies may be useful in monitoring the effect of antiplatelet agents or anticoagulation. Microemboli monitoring is also useful in the context of CFA and coronary artery bypass surgery.

Although at some medical cenrers carotid duplex and TCD testing are performed in different laboratories, they are complementary. The accuracy of TCD studies is improved when the condition of the extracranial carotid and vertebral arteries is known. Similarly, in endarterectomy candidates with symptomatic extracranial carotid stenosis diagnosed by duplex scanning, tandem lesions can occasionally coexist and should be ruled out. Therefore duplex and TCD testing should often be obtained together, or in an organized sequence, to answer specific questions or hypotheses developed by the treating physician.

Chronic Ischemic Cerebrovascular Disease

Extracranial Stenotic Lesions

Ultrasound offers a safe, noninvasive way to serially follow patients with carotid or vertebral artery disorders. Periodic evaluation can be helpful for assessing the progression or regression of existing plaques or the development of new lesions, whether symptomatic or asymptomatic. The timing of follow-up carotid testing must be individualized depending on the severity and types of lesions and the onset of new or recurrent symptoms. Asymptomatic stenosis of less than 50% might be initially restudied in 12-24 months, whereas lesions with 50-75% stenosis and uncomplicated plaques might wait 6-12 months. For 50-75% stenosis with complicated plaque features, or for more rh.m 75% stenosis, initial restudy at 3-6 months seems appropriate if CEA is not performed. Lack of progression for several years allows lengthened intervals before restudy. When evidence of asymptomatic progression is present, a shorter interval is recommended. Development of new symptoms should prompt urgent reevaluation. After CEA, repear ultrasound often is done approximately 1 month after surgery and then yearly to look for restenosis.

The identification of asymptomatic carotid stenosis has become an important clinical mandate since the Asymptomatic Carotid Atherosclerosis Study showed the benefit of CEA in asymptomatic individuals with 60-99% stenosis when compared with treatment with 325 mg of aspirin daily (Executive Committee for the Asymptomatic Carotid Atherosclerosis Study 1995). Yet it is not cost-effective to screen the entire population, even with ultrasound. Asymptomatic individuals with cervical bruits should be studied, even though bruits often are due to another cause. Patients with multiple risk factors probably warrant study, but the clinical utility of this has not yet been confirmed. If stenosis is identified, intervals for restudy should be similar to those outlined previously,

Large population studies, such as the Atherosclerosis Risk in Communities and the Cardiovascular Health Study, have documented the association between risk factors and mtima-media thickening in the wall of the carotid artery on B-mode imaging (Howard et al. 1993; Polak et al. 1998). This may be an early stage in the development of atherosclerosis, and the presence of significant thickening correlates with risk of heart attack and with abnormalities

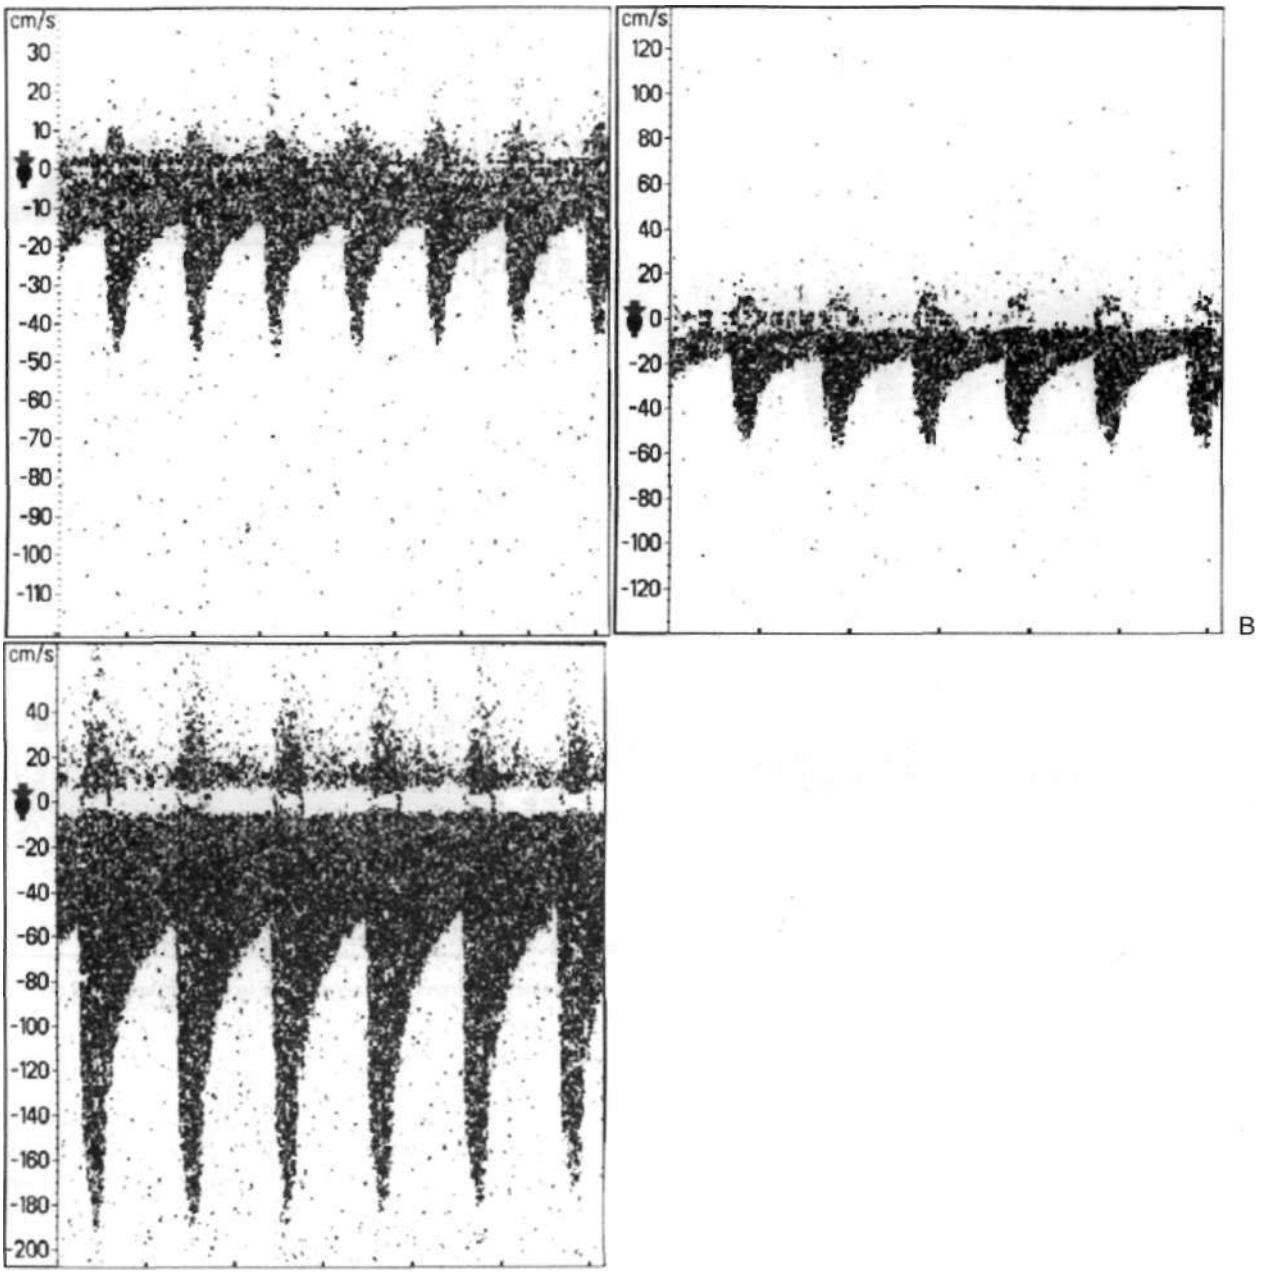


FIGURE 37D.9 Basilar artery stenosis. {A, B) The flow velocities are within the normal range in the vertebral arteries. (C) The peak systolic velocity exceeds ISO cm per second, and the end-diastolic velocity exceeds 45 cm per second at an insonation depth of 100 mm, indicating proximal Basilar artery stenosis.

on magnetic resonance imaging of the htain. Although extensive data to confirm the clinical utility of identifying increased intima-media thickness values are lacking, it has been suggested that B-mode imaging to evaluate intima-media thickness should be used clinically to identify patients with high risk for coronary or cerebrovascular events or to assess responses to risk factor modification (Greenland et al. 2000). It is hoped that such early identification of atherosclerotic changes will allow intervention to prevent later development of clinical events.

Intracranial Stenotic Lesions

Intracranial atherosclerotic plaques are dynamic lesions. Although some lesions progress, causing increasing degrees of stenosis, others may tegress over short periods of time. TCD enables the noninvasive monitoring of the progtession of these lesions. It is often obtained at baseline, in conjunction with cerebral catheter angiogtaphy or magnetic resonance angiography, and is subsequently repeated during the follow-up period (Figure 37D.11), Monitoring also enables detection of new atherosclerotic plaques.

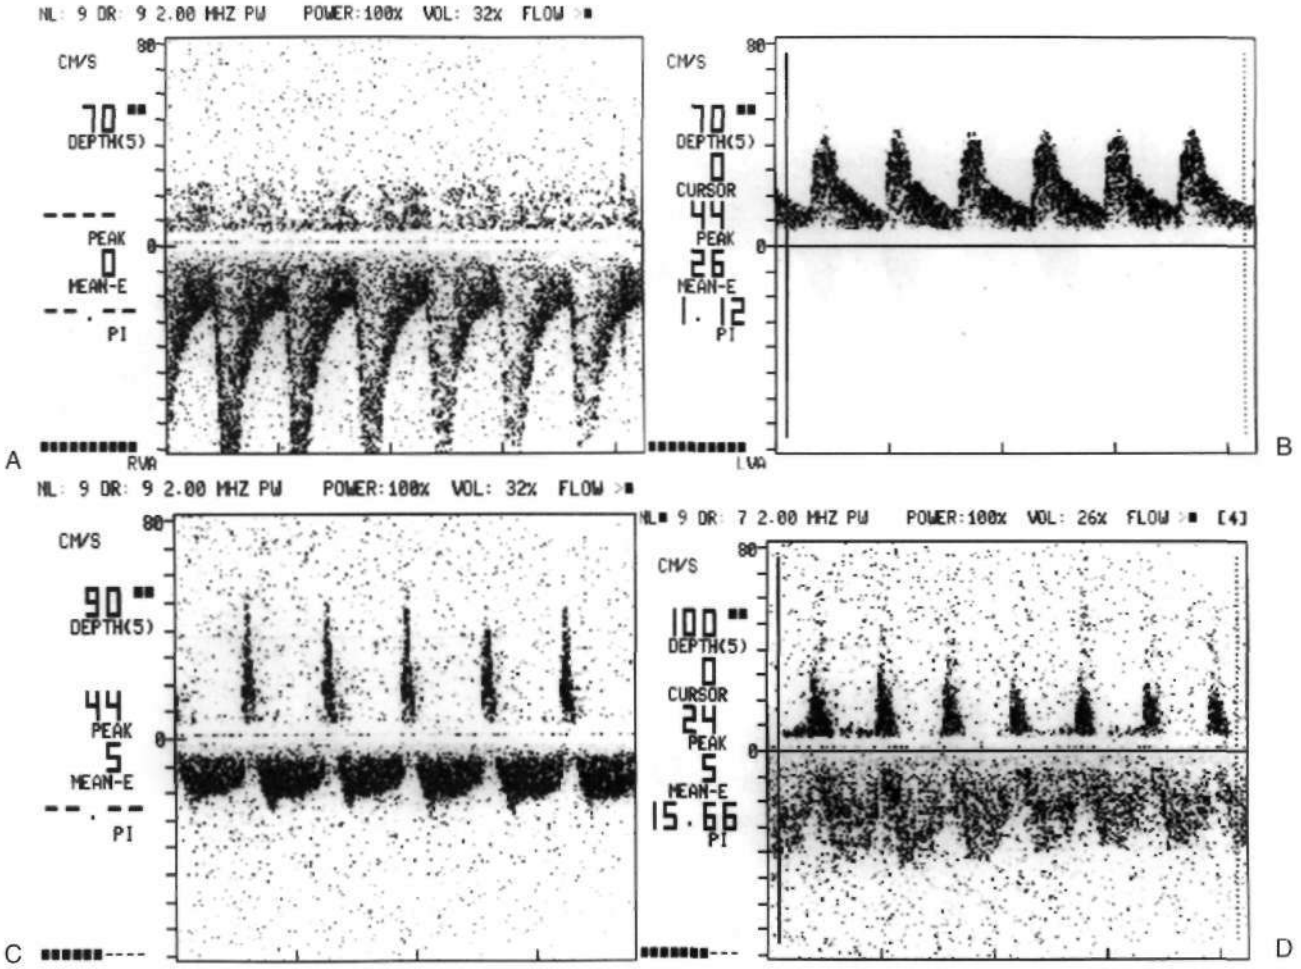

FIGURE 37D.10 Subclavian steal. The flow is anterograde in the right vertebral artery (A), retrograde in the left vertebral artery (B), and biphasic in the basilar artery (C, D).

However, clinical experience is limited, and no published prospective studies exist to make recommendations regarding the frequency and timing of follow-up studies.

Cerebrovascular Reactivity

The annual stroke rate distal to carotid occlusion is approximately 2-5%. Cerebral embolism and hypoperfusion are considered the main causes of recurrent symptoms of cerebral ischemia. Although the ability of abnormal cerebral hemodynamic changes to identify patients at an increased risk of recurrent stroke has been questioned, more recent studies suggest that hemodynamic impairment can be a major cause of cerebral ischemia. In patients with ICA occlusion and impaired cerebrovascular reactivity determined by TCD or xenon computed tomography, the annual rate of distal cerebral ischemic events is approximately 10%. Because a subgroup of patients with impaired cerebrovascular reactivity may benefit from a bypass procedure, a new randomized clinical trial has been organized (Adams et al. 2001).

Both intravenous acetazolamide administration and carbon dioxide inhalation methods are used to assess cerebrovascular reactivity. In patients with exhausted cerebrovascular reactivity, flow velocities fail to adequately increase after the intravenous administration of acetazolamide or have a decreased response to hypercapnia and hypocapnia. TCD testing can provide an estimate of the stroke risk in patients with ICA occlusion. However, the ability of testing to reliably identify patients who might benefit from a revascularization procedure has not been shown.

Sickle Cell Disease

An occlusive vasculopathy characterized by a fibrous proliferation of the intima often involves the basal cerebral arteries of patients with sickle cell disease. Cerebral infarction is a common complication of this vasculopathy and has a frequency of approximately 5-15%.

As in all patients with anemia, flow velocities are diffusely increased in patients with sickle cell anemia.

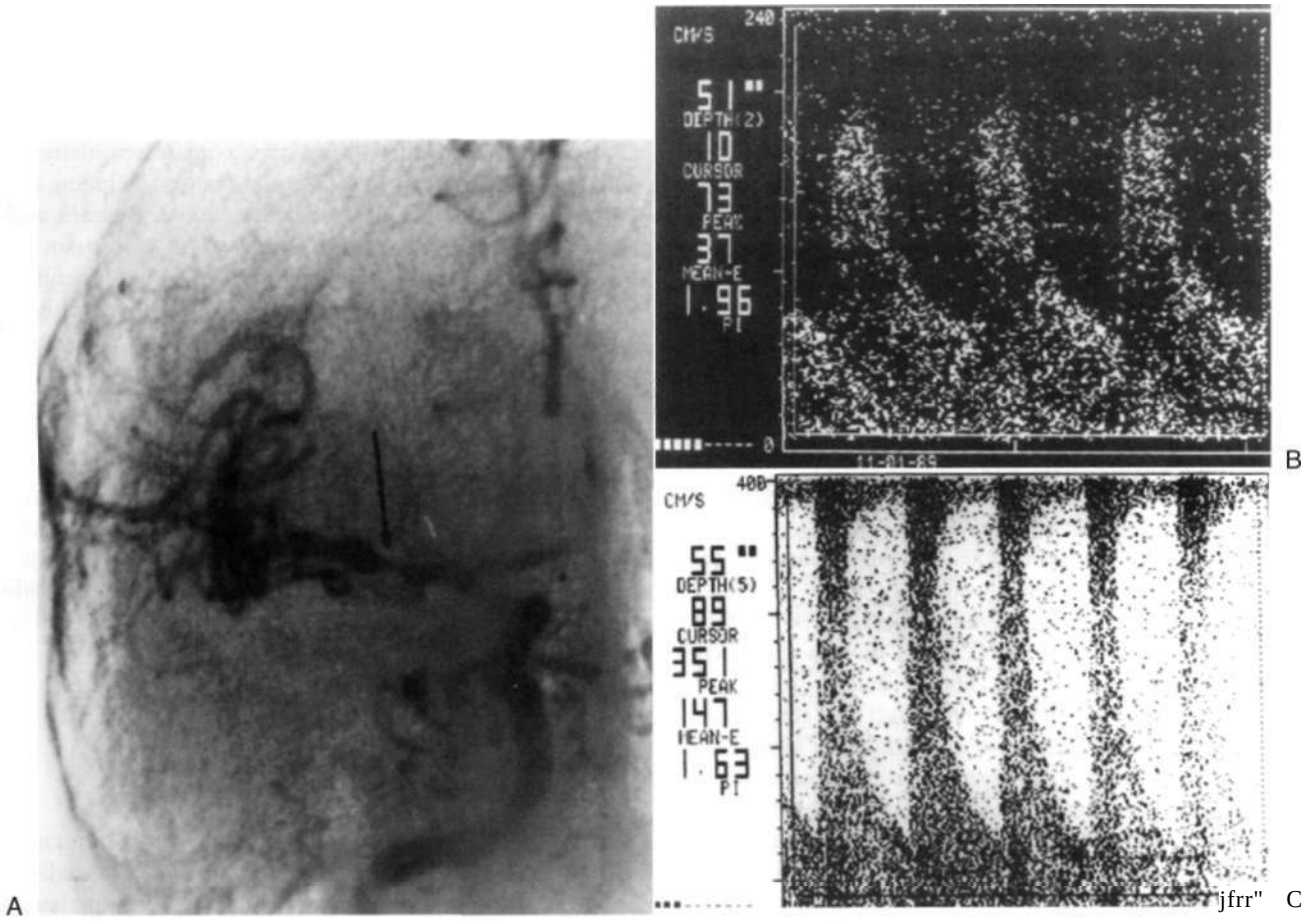

FIGURE 37D.11 Monitoring of intracranial atherosclerotic lesions. (A) Cerebral angiogram shows an area of stenosis *{arrow)* in the Ml segment of the right middle cerebral artery, (B) The first transcranial Doppler study obtained within 48 hours of angiography shows a corresponding peak systolic velocity of 188 cm per second. (C) Repeat transcranial Doppler study .34 months later shows a further increase of the peak systolic velocity to approximately 350 cm per second. (Reprinted with permission from Schwarzc, J. J., Babikian, V., DeWitt, L. D., ct al., 1994, "Longitudinal monitoring of intracranial arterial stenoses with transcranial Doppler ultrasonography," *] Neuroimaging,* vol. 4, pp. 182-187.)

Additional focal velocity increases in the basal cerebral arteries can be detected in some patients (Plate 37D.V}. These increases correlate with 90% sensitivity and more than 95% specificity with stenotic lesions demonstrated by cerebral catheter or magnetic resonance angiography. A time-averaged mean of the maximum velocity of 200 cm per second or greater in the distal ICA and proximal MCA identifies neurologically asymptomatic children at an increased risk for first-time stroke {Adams et al. 1998). Periodic red blood cell transfusion is associated with a 90% reduction in the rate of stroke. A Clinical Alert from the National Heart, Lung and Blood Institute recommended that children with sickle cell disease between ages 2 and 16 receive baseline TCD testing and that those with normal study results be restudied every *6* months {National Heart, Lung and Blood Institute 1997). Red blood cell transfusions reduce some of the abnormalities seen on cerebral angiography.

Aneurysmal Subarachnoid Hemorrhage

Vasoconstriction of intracerebral arteries is the leading cause of delayed cerebral infarction and mortality after aneurysmal subarachnoid hemorrhage. Vasospasm is clinically detected 3 or 4 days after the hemorrhage and usually resolves after day 12. Although the exact cause of vasospasm remains unknown, its presence correlates with the volume and duration of exposure of an intracranial artery to the blood clot. Laboratory and animal models indicate that blood breakdown products can lead to vasoconstriction.

The detection of vasospasm is important because it can be treated. Nimodipine, intravascular volume expansion, and pharmacologically induced relative hypertension are some of the prescribed therapies, and balloon angioplasty and intra-arterial papaverine are experimental therapies increasingly provided at some medical centers.

These treatments are not innocuous, and the ability to noninvasively detect and monitor vasospasm is of clinical interest.

Although vasospasm can he angiographically detected in 30-70% of patients with aneurysmal subarachnoid hemorrhage, only 2CMK)% develop clinical signs of cerebral ischemia. Therefore the presence of vasospasm is not a sufficient condition for developing a clinical focal ischemic deficit, and several factors, including the severity of spasm, presence of collateral flow, condition of patient's intravascular volume, and cerebral perfusion pressure, are considered mitigating factors.

TCD studies show an increase in the flow velocities of basal cerebral arteries, usually starting on day 4 after subarachnoid hemorrhage and peaking by days 7-14 (Plate 37D.VI). Although a diffuse increase in velocities often is detected in patients with severe hemorrhage, arterial segments in close proximity to the subarachnoid blood clot usually have the highest velocities.

Severe vasospasm in an arterial segment can be associated with reduced regional cerebral blood flow in the artery's distal territory. There is a linear, inverse relationship between the severity of vasospasm and the amplitude of flow velocity increase in an arterial segment. It is valid until the vasoconstriction is so severe that the flow volume is reduced, flow velocities drop, and the TCD signal becomes difficult to detect. The linear relationship can also be affected by several factors including the presence of hyperperfusion. Whether there is a critical threshold of flow velocity for cerebral ischemia remains a matter of debate. Angiographic studies confirm the presence of at least some degree of MCA vasospasm when the mean flow velocities are higher than 100 cm per second, but values below 120 cm per second are considered clinically insignificant. Mean velocities between 120 and 200 cm per second correspond to 25-50% angiographically determined diameter reduction, and values exceeding 200 cm per second correspond to more than 50% luminal narrowing (Sloan, Wozniak, and Macko 1999). Based on these and other considerations, some investigators initiate hypertensive therapy at a mean velocity threshold of 120 cm per second, but this is not standard practice. The 200 cm per second threshold and rapid flow velocity increases exceeding 50 cm per second on consecutive days are associated with subsequent infarction. The effect of orally administered nimodipine on flow velocities appears to be minimal.

TCD is used also to monitor the effects of endovascular treatment of vasospasm. Flow velocities decrease after successful angioplasty or papaverine infusion. Persistent increases after treatment indicate either extension of vasospasm to new arterial segments or hyperemia in the treated arterial segment and may constitute a valid reason for repeat cerebral angiography.

The accuracy of TCD in detecting vasospasm depends to some degree on the location of the involved arterial segment. Although TCD criteria are more than 90% specific in detecting MCA and anterior cerebral artery vasospasm, they are, respectively, 80% and less than 50% sensitive in detecting disease in these arterial segments (Sloan, Wozniak, and Macko 1999). Basilar artery vasospasm is detected with an approximate sensitivity of 75% and specificity of 80%. Several factors, including the effects of hyperemia, increased intracranial pressure and blood pressure changes, the presence of vasospasm in convexity branches not accessible by TCD, and difficulties in assessing vasospasm by angiography, contribute to these findings.

Because of these limitations in accuracy, the combined use of TCD and single photon emission computed tomography or xenon-enhanced computed tomography has been advocated, with the expectation that it will provide a more comprehensive and accurate assessment of the clinical condition. Overall, however, TCD is considered to have acceptable accuracy for evaluating vasospasm in aneurysmal subarachnoid hemorrhage. It is a useful tool with limitations that must be taken into consideration in the clinical setting.

Intensive Care Unit and Perioperative Monitoring

Cerebral Circulatory Arrest

A characteristic pattern of changes can be detected by TCD in patients with increased intracranial pressure. Early findings consist of a mild decrease in the diastolic flow velocity and an increase in the difference between peak systolic and end-diastolic velocities. When the intracranial pressure increases further and reaches the diastolic blood pressure level, flow stops during diastole, and the corresponding flow velocity drops to zero; flow continues during systole, and spiky systolic peaks are observed. A further increase of the intracranial pressure is **associated** with a reverberating flow pattern, with forward flow in systole and retrograde flow in diastole (Figure **37D.12).** The net volume of flow decreases and can reach zero. At cerebral perfusion pressure values close to zero, either small systolic spikes are observed (Figure 37D. 12), or no signal at all is detected. This corresponds to a complete arrest of flow as demonstrated by cerebral angiography. The pattern of TCD changes is not specific to a particular neurological disease and can occur in a **variety** of conditions associated with increased intracranial pressure.

The changes described in the preceding paragraphs are also observed in patients clinically diagnosed as brain dead. In one study, a high-resistance waveform pattern consisting of absent or reversed diastolic flow and small early systolic spikes, when present in at least two intracranial arteries, was more than 90% sensitive and 100% specific for brain death. Experience at other centers has been more variable, with some investigators reporting patients who do not

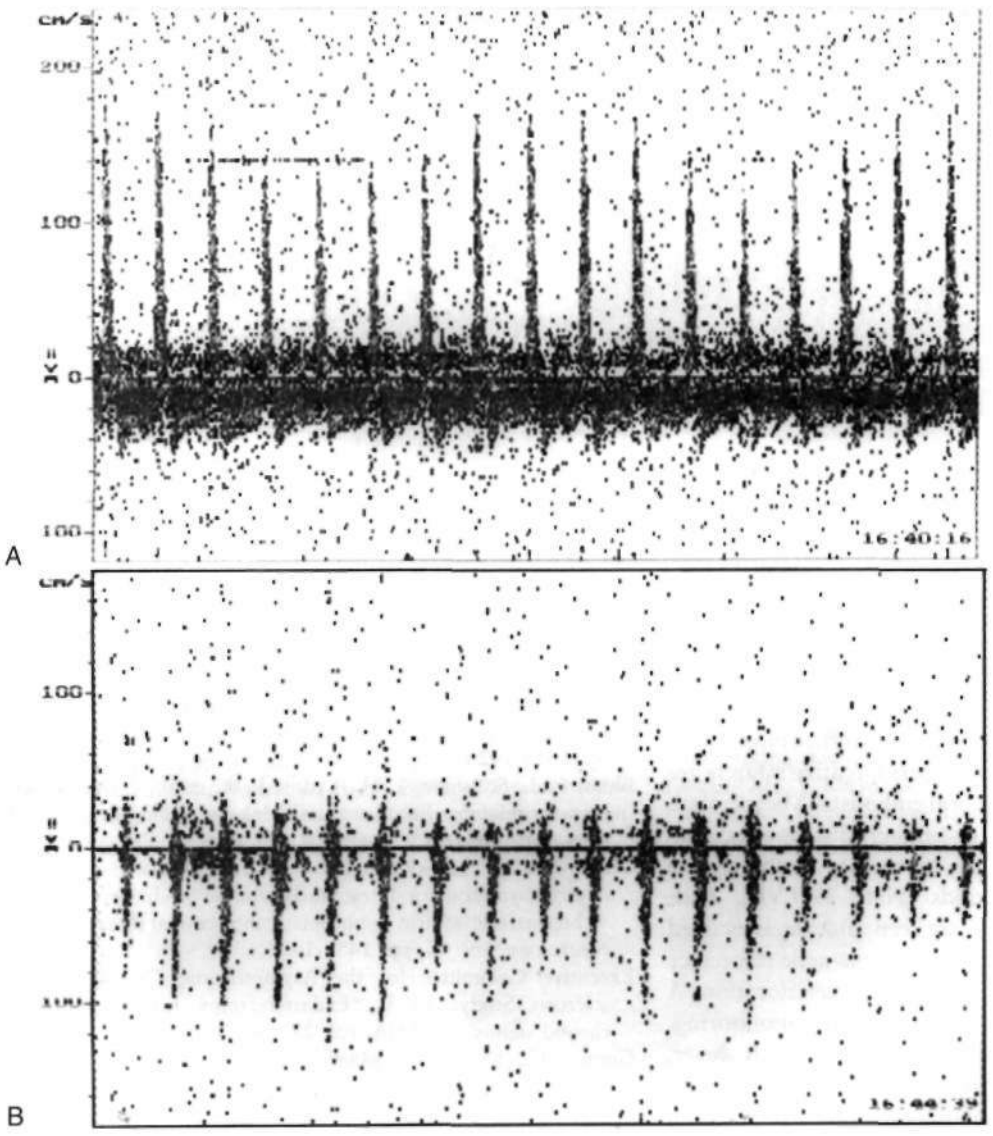

FIGURE 37D.12 Raised intracranial pressure. Reverberating flow pattern (**A**) and small systolic spikes (**B**) seen in a patient with markedly increased intracranial pressure.

satisfy clinical criteria for brain death, even though their TCD studies indicate circulatory arrest in some cerebral vessels. This is not totally unexpected because preserved intracranial circulation has been demonstrated previously in brain-dead patients. Thus although TCD is useful in detecting cerebral circulatory arrest, it cannot be recommended as the sole diagnostic test for diagnosing brain death. The latter must be established based on the clinical presentation and neurological examination findings. TCD and other laboratory tests can help confirm the clinical impression.

Carotid Endarterectomy

As indicated earlier in this chapter, CEA is more effective than medical therapy when it can be performed with a combined mortality and morbidity of less than 6% for symptomatic and 3% for asymptomatic patients. Unfortunately, these results are not achieved at all medical centers (Wennberg et al. 1998).

Monitoring is performed to identify and correct surgical events that can lead to cerebrovascular complications. Monitoring tests currently in use include electroencephalography and stump pressure measurement. These tests are useful in detecting cerebral hypoperfusion or its consequence, cerebral ischemia, but their effectiveness in reducing the perioperative stroke rate has not been demonstrated in prospective studies.

TCD monitoring during CEA shows a consistent pattern of flow velocity changes during endarterectomy, The most significant changes occur at the time of carotid clamping, with persistent and severe velocity decreases to less than 15% of prcclamp values in up to 10% of patients (Figure 37D.13). Patients with velocities decreasing to this level usually are considered candidates for shunting. Although definitive TCD criteria for shunting have not yet been established, a postclamp peak systolic

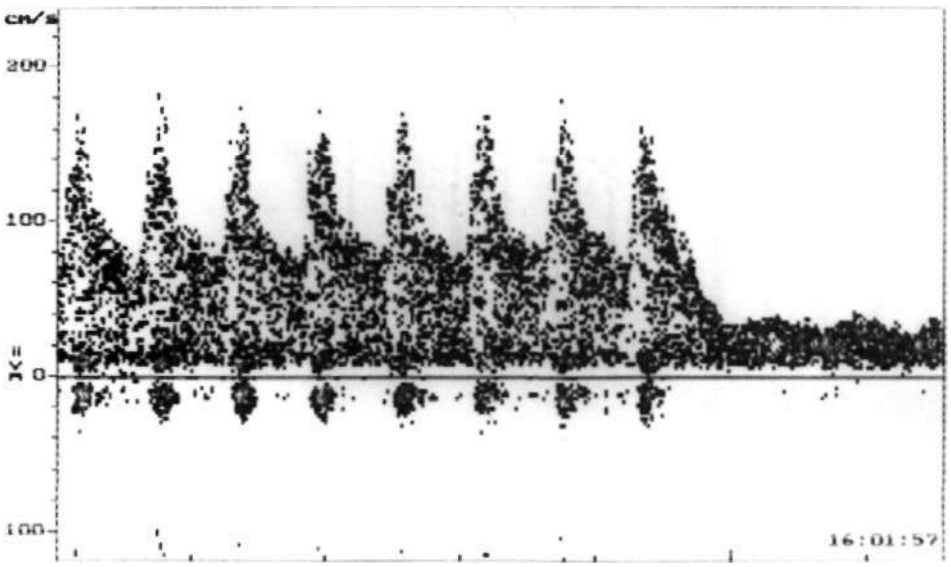

FIGURE 37D.13 Carotid endarterectomy. At clamp insertion, the peak systolic flow velocity decreases from approximately 175 to 35 cm per second.

or mean flow velocity decrease to less than 30% of the preclamp value often is considered an acceptable criterion.

TCD also has the unique ability to detect microembolism as it occurs. This gives TCD an edge over other monitoring techniques because the majority of perioperative infarcts are thought to be secondary to cerebral embolism, Mtcroemholi are detected at specific stages of surgery; dissection, clamp insertion and release, and the immediate postoperative period are rhe high-risk periods (Plate 37D.VII). Roth gaseous and particulate emboli are seen and are associated with small cerebral infarcts detected by magnetic resonance imaging and with postoperative cognitive deterioration. A relative newcomet to the field of intraoperative monitoring, TCD provides useful information to rhe surgeon. However, the characteristics of microembolism associated with cerebral infarction, such as emboli count and composition, remain to be determined. A prospective study to assess the technique's effectiveness is needed.

Chapter 37
Neuroimaging

E. FUNCTIONAL NEUROIMAGING

Darin D. Dougherty, Alan J. Fischman, and Scott L. Rauch

Structural neuroimaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI) have been available for several decades and have become invaluable tools in the evaluation of central nervous system (CNS) disease. Functional neuroimaging modalities have been developed more recently. Although CT and MRI provide static, high-resolution images ol die CNS, functional neuroimaging modalities such as positron emission tomography (PET), single-photon emission CT (SPECT), and functional MRI {fMRI) provide dynamic images of brain function. This chapter reviews the various functional neuroimaging modalities. In addition, the clinical utility of these techniques is reviewed and potential clinical and research applications arc discussed.

FUNCTIONAL NEUROIMAGING MODALITIES

Positron Emission Tomography and Single-Photon Emission Tomography

PET and SPECT are radiotracer imaging modalities. A biologically relevant radiotracer is introduced into the subject and its actions can be measured *in vivo.* For example, $^{15}0$ can be incorporated into either CO2 or H2O, The $'^{5}0$ radiotracer can be introduced to the subject cither by inhalation or intravenous injection and serves as an *in vivo* dynamic marker of regional cerebral blood flow (rCBF) in PET studies. PET and SPECT cameras are designed to measure the radiation emitted from radiotracers in a manner that allows for reconstruction of spatial images (tomographs) that provide both qualitative and quantitative measures of brain function. The typical spatial resolution of these images is 3-5 mm for PET and 7-10 mm for SPECT (although advances in technology may ultimately result in comparable spatial resolutions for both modalities). Single functional images may be collected (i.e., "snapshots" of brain function} or multiple serial images may be acquired (i.e., dynamic, "filmstrip-like" images of brain function). However, the temporal resolution of PET and SPECT docs not approach that of fMRI (discussed later in this chapter).

PET and SPECT are primarily used to measure indices of neuronal activity. Regional cerebral metabolic rate (rCMR) and rCBF can be assessed using PET, whereas SPECT can measure only rCBF. ^{IK}F-fluorodeoxygIucosc (FDG) is used to measure rCMR and ^{ts}O is used to measure rCBF with PET. A number of SPECT radiotracers are available to measure rCBE including ^{yym}Tc-hcxamerhylpropyIenearnine oxime (HMPAO), ^{99m}Tc-ethylene cysteinate dimer (ECD), and ^{12}*I-isopropyl iodoamphetamiuc (IMP). Of note, the shorter half-life of $^{15}0$ (about 2 minutes) allows for multiple measures of rCBE during a single PET study, whereas the longer half-life of the SPECT radiotracers typically allows for only one measure of rCBE during a single SPECT session. Thus paradigms requiring multiple acquisitions require multiple visits on separate days if SPECT is to be used.

In addition to the radiotracers designed to measure rCMR and rCBF, there are also a number of agents

Tabic 37E.1: Representative radiotracers

Radiotracer	*What it measures*
Single-photon emission computed tomography

F-setoperone	Type 2 serotonin (5-HT2) receptor
C-flumazenil	Benzodiazepine receptor
C-diprenorphine	Opioid receptor (nonselective)
"C-carfentanil	Opioid receptor (mu selective)

designed to measure various aspects of neurochemistry (Table 37E.1). These radiotracers allow for quantification of presynaptic and postsynaptic neuroreceptors and neurotransmitter synthesis. Such neurochemistry studies show promise for assessing conditions in which abnormalities of a single neurotransmitter play a prominent role in the pathophysiology of the disease (e.g., dopamine abnormalities in Parkinson's disease).

Functional Magnetic Resonance Imaging

fMRI studies use unique data-acquisition parameters that differ from those used for conducting structural MRI studies. Structural MRI studies involve placing the subject in a strong magnetic field (see Chapter 37A). This strong magnetic field aligns the resonant spin of a fraction of the hydrogen nuclei in the body. Then, the application of a radiofrequency pulse results in these nuclei changing orientation relative to the pre-existing magnetic field. In time, the hydrogen nuclei begin to return to their initial alignment. It is this relaxation of the hydrogen nuclei that provides the data necessary for construction of structural images, fMRI exploits the fact that deoxyhcmoglobin distorts the magnetic field. Because the local concentration of deoxyhemoglobin varies, the amount of distortion also varies. The local concentrations of deoxyhemoglobin provide an indirect measure of oxygen use. These changes in localized blood oxygenation give rise to the fMRI blood oxygen level-dependent (BOLD) signal change that is related to CBE and cerebral blood volume.

Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) also exploits the behavior of endogenous compounds in a magnetic field to measure underlying biological processes. The nuclei of a number of atoms ('H, ^{1y}F, ^{7}Li, ^{2i}Na, and ^{M}P) are excited by the magnetic field. As the energy of these nuclei returns to a baseline state, a "frequency signature" particular to each nucleus can be measured. Simply put, the magnitude of each peak in this "frequency signature" corresponds to the concentration of a particular atom in the brain region being assessed.

MRS studies of the different nuclei allow for quantification of a number of compounds in the brain. MRS studies of the hydrogen nucleus allow for the semiquantitative measurement of a number of endogenous compounds including N-acetyl-aspartate (NAA}, choline, creatine, *y*-aminobutyric acid (GABA), glutamate, glutamine, inositol, and phosphocrcatinc. NAA is purportedly a marker of viable neurons. GABA and glutamate are the main inhibitory and excitatory neurotransmitters, respectively, in the human brain. Creatine and phosphocreatine are involved in neuronal energy metabolism. Choline is involved in membrane metabolism, and inositol is involved 111 second-messenger neurotransmission.

Phosphorus MRS allows for measurement of molecules involved in energy metabolism such as adenosine triphosphate (ATP) and adenosine diphosphate (ADP). Components of neuronal membranes such as phosphomonoesters (PMEs) and phosphodiesters (PDEs) can also be measured using phosphorus MRS. Fluorine MRS and lithium MRS can be used to measure concentrations of exogenous substances (e.g., drugs) in the brain, i.irhium MRS can be used to measure brain lithium levels, and fluorine MRS can be used to measure the concenttation of fluorinated compounds {e.g., fluoxetine).

MRS is being increasingly used to identify neoplasms of brain and to localize areas of tumor involvement (Figure 37E.1).

Electroencephalography and Magneto encephalography

Electroencephalography (EEG) involves measurement of cortical activity via scalp electrodes. Conventional EEG has a multitude of clinical applications and is discussed in detail in Chapter 36A. Other EEG-related methodologies include event-related potentials (ERP) and quantitative EEG (QEEG). *ERP* refers to event-related waveforms in the EEG data that atisc following sensory, motor, or cognitive events. Although HRP lias a wide range ot applications in the research setting, there are currently three major uses of

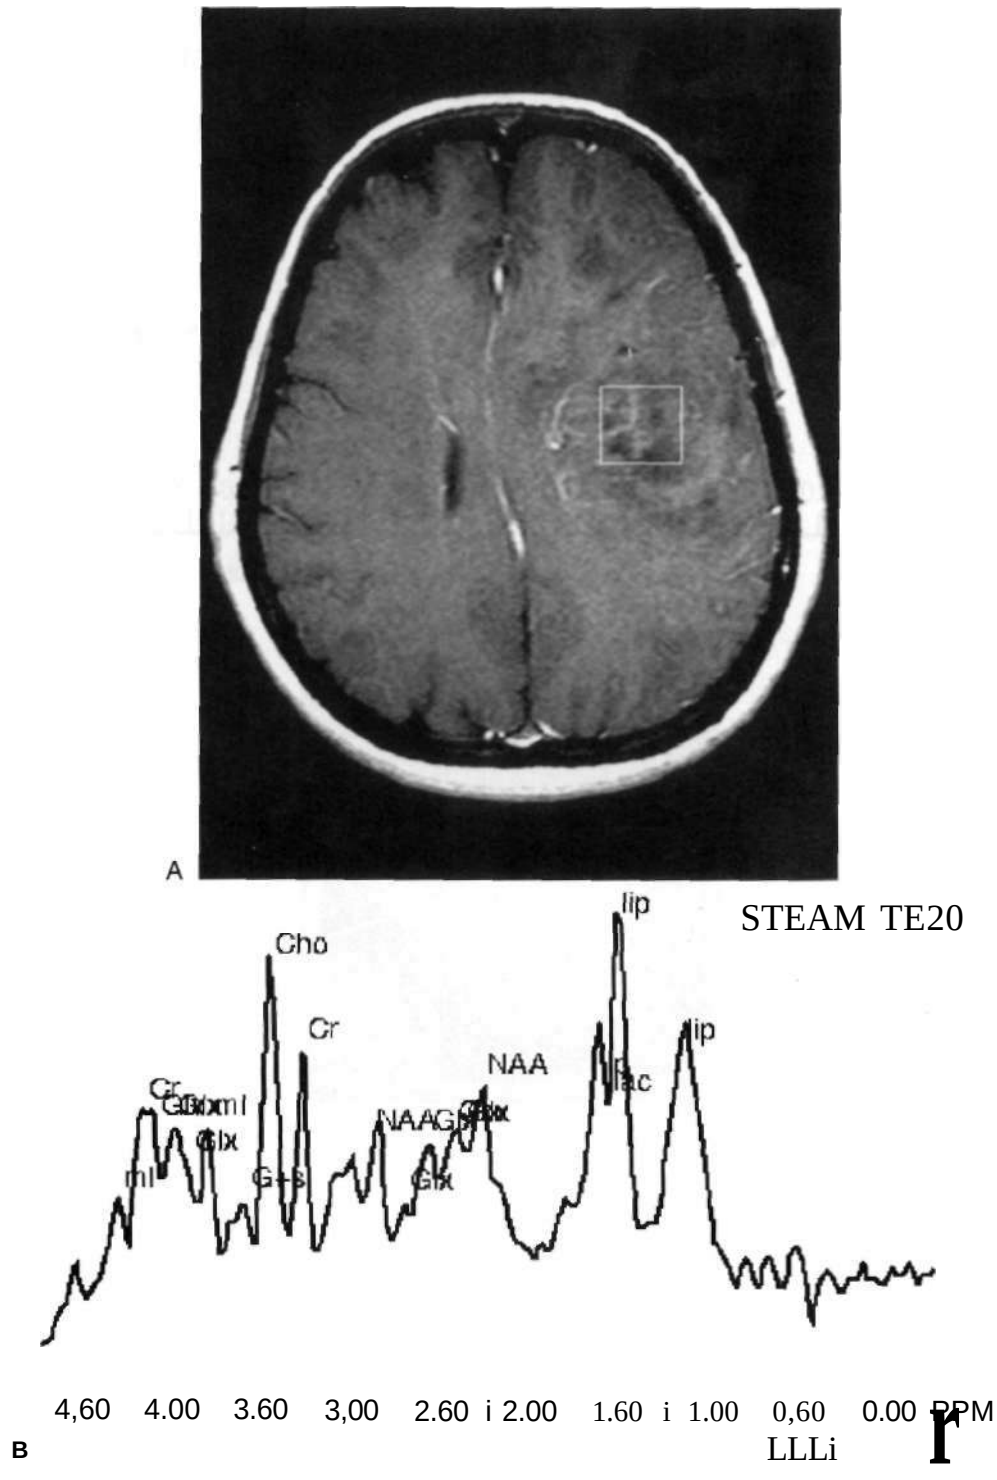

FIGURE 37E.1 Grade III astrocytoma, left frontal lobe, evaluated with single-voxel spectroscopy (SVS) and magnetic resonance spectroscopic imaging (MRSI). The results are typical of a high-grade astrocytoma. (A) Postcontrast Tl-weighted axial image used for localization of an 8-mL single voxel (2 x 2 x 2 cm) in the left frontal lobe. The voxel is positioned in a region of heterogeneous signal intensity with mild enhancement. There is moderate compression and displacement of adjacent brain, (B) SVS at echo time (TF.) of 135 ms: Point-resolved spectroscopy (PRESS) spectrum demonstrates decreased N-acetyl-aspartate (NAA), increased level of choline-con raining small molecules (Cho), and increased lactate (Lac, appears as inverted doublet). Compare the peak heights and areas to those in (E), which were acquired from a region of normal-appearing brain. *Continued*

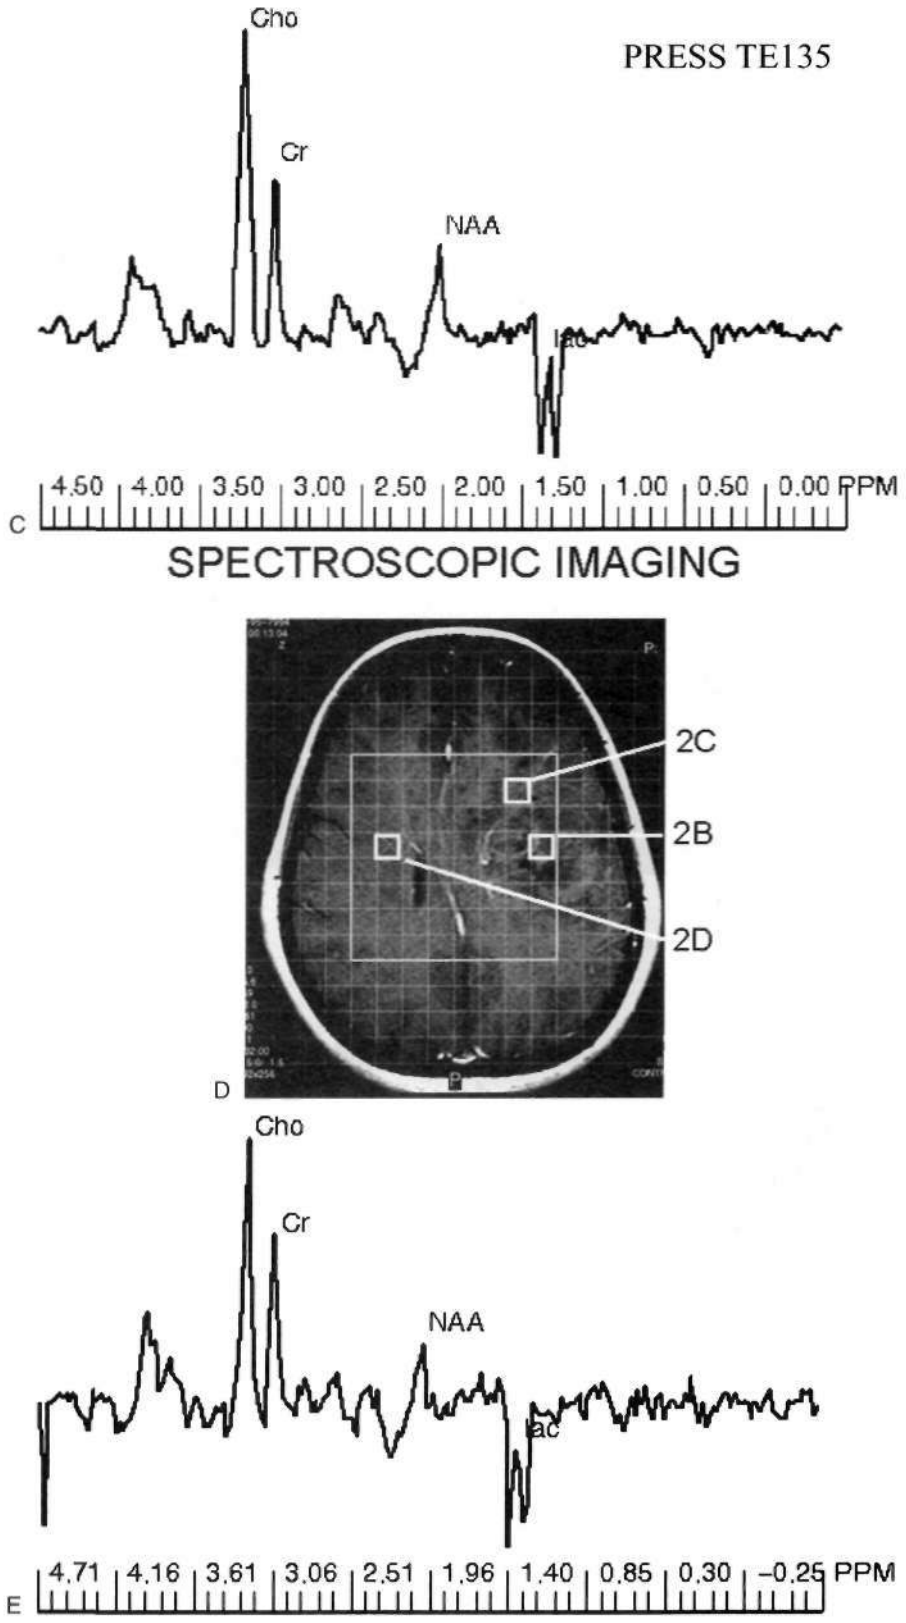

FIGURE 37E.1, cont'd. (C) SVS at TE of 20 ms: Stimulated acquisition mode (STEAM) spectrum acquired with shott TE confirms PRESS findings and reveals prominent lipid (Lip) peaks in the 0.6-1.6 ppm region of the spectrum. (D) Same image as in (A) was also used for placement of a 2-cm thick, single-section, mul ti voxel (16 x 16) grid encompassing the brain at this level. Spectra were generated from the center 8 x 8 subvoxels (each 2.5 ml.) and 3 of the 64 spectra are shown in (E), (F), and (G). (E) MRS! at TE of 135 ms; PRESS specttum from a subvoxel located in the same region as used in (B}. Note the similarity in the MRS] spectra and the SVS spectra in (B).

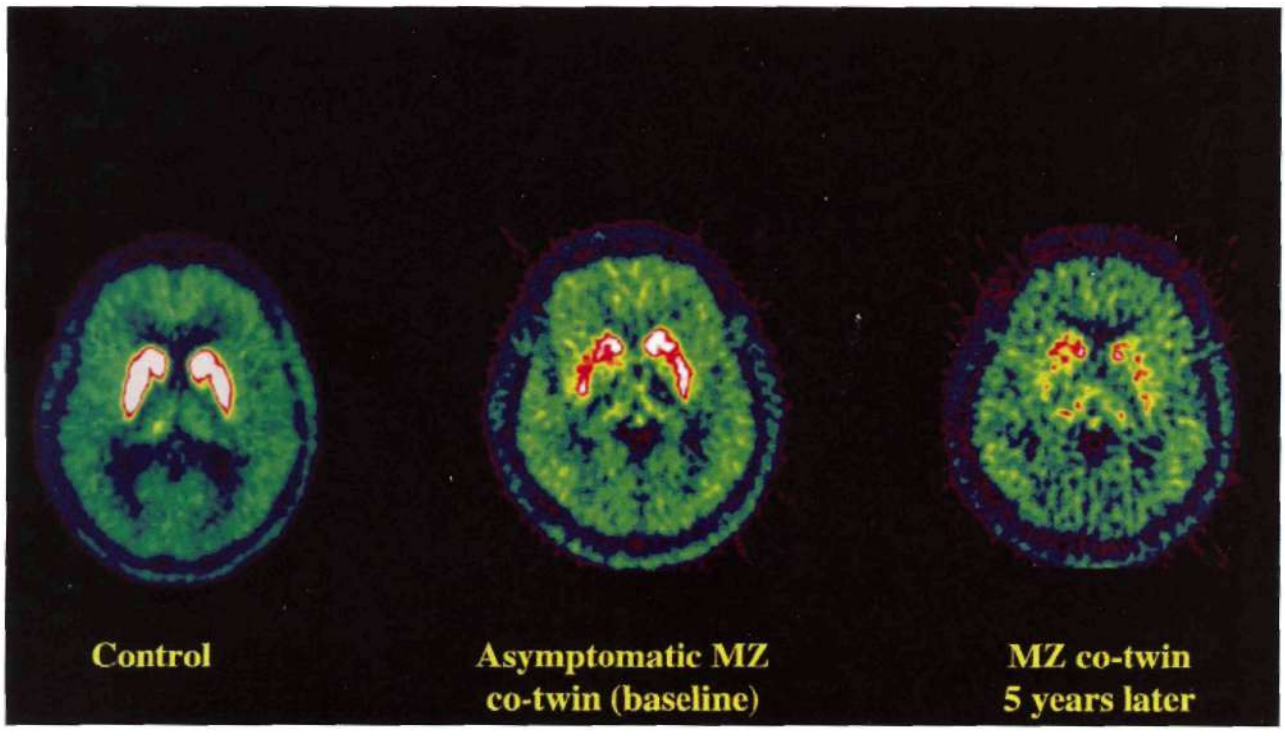

PLATE 37E.I Positron emission tomography images of striatal ^{18}F-dopa uptake in a healthy subject and an asymptomatic monozygotic co-twin of a patient with Parkinson's disease. The co-twin shows reduced putamen ^{18}F-dopa uptake at baseline and more severely 5 years later when symptomatic. (Courtesy Paola Piccini. From Brooks, D. J. 2000, "Morphological and functional imaging studies on the diagnosis and progression of Parkinson's disease," *J Neurol*, vol. 247, suppl. 2, pp. II/11-II/18.)

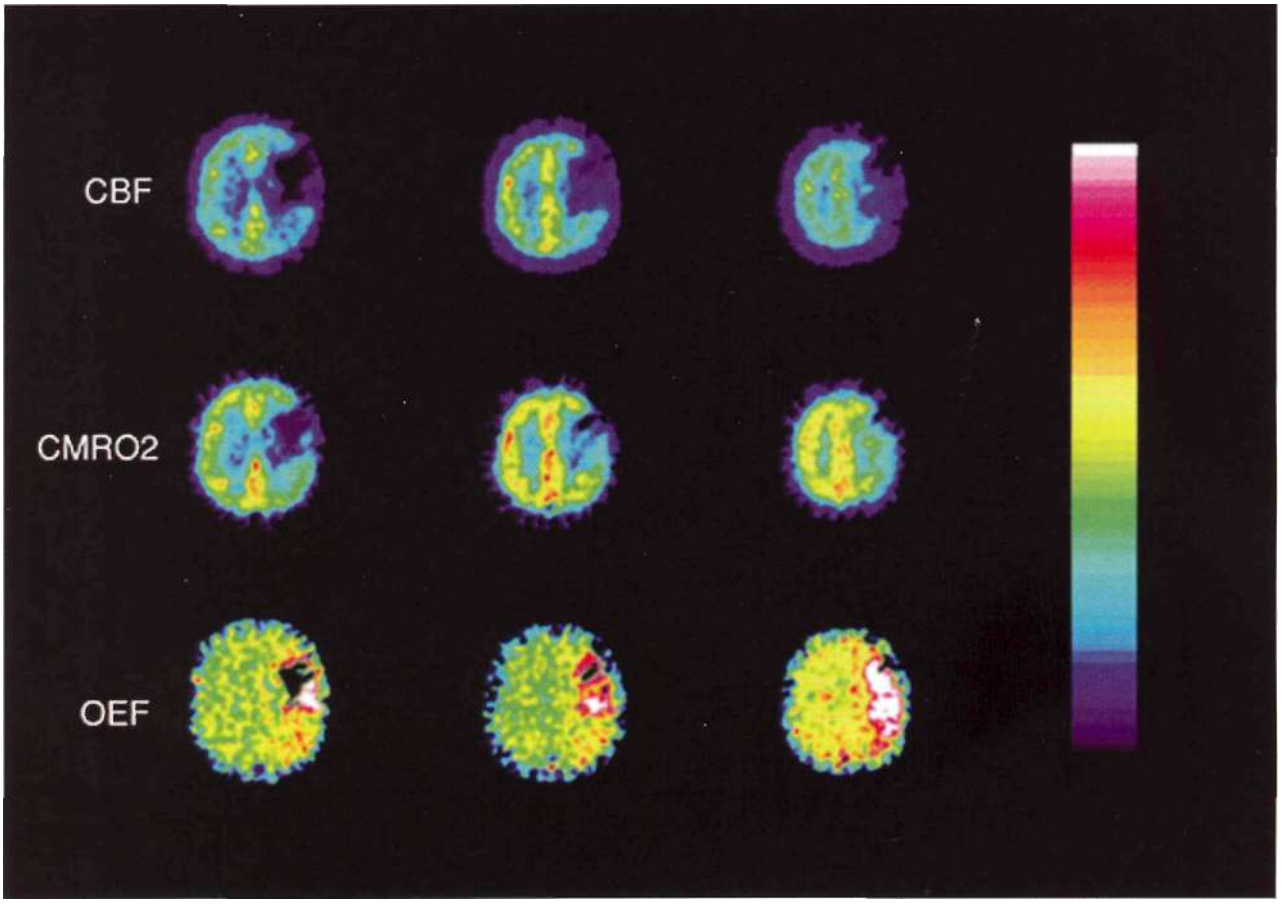

PLATE 37E.I1 $^{L5}0$ positron emission tomography (PET) images of a patient experiencing an acute ischemic event. Note that cerebral blood flow (CBF), cerebral metabolic rate of oxygen (CMRO,), and oxygen extraction fraction (OEF) are all decreased at the site of the ischemic event. These are all indices of neuronal activity that can be measured using "0 PET techniques. (Used with permission from Dougherty, D. D., Rauch, S. L., 8c Fischman, A. J. 2003, "Neuropsychiatric applications of PET and SPECT," in *Essentials of Nmroimaging for the Practitioner,* eds D. **D.** Dougherty, S. L. Rauch, *tk.* J. F. Rosenbaum, American Psychiatric Publishing, Washington, DC.)

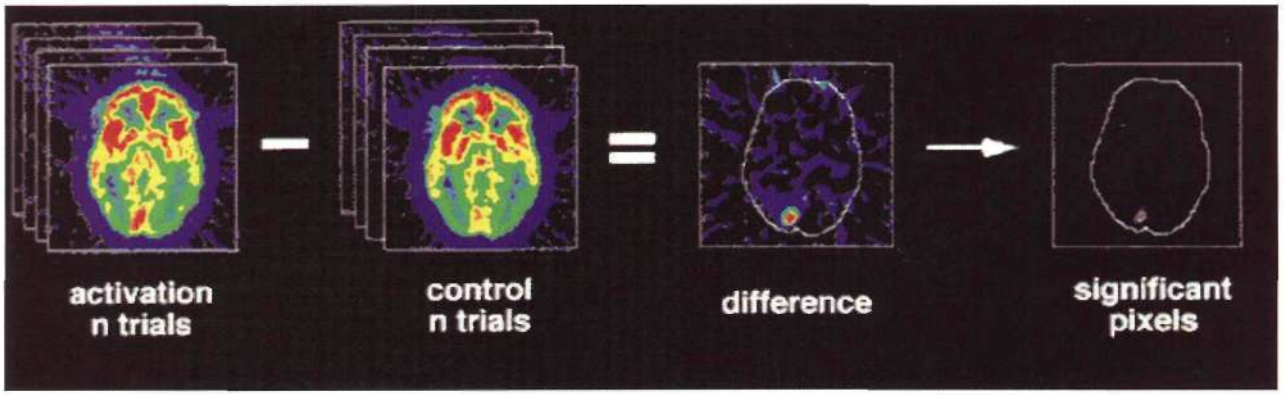

PLATE 37E.III Illustration of the methodology used for functional neuroimaging activation studies. Data are acquired in a serial manner in both activated and control states. By grouping the activation and control data, one can produce a difference image. Statistical tests can be used to determine which differences are statistically significant. This example shows a robust response to a hemifield stimulation of the visual system with a reversing checkerboard pattern using $H_2{}^{15}0$ as the tracer. The activated visual cortex can be clearly seen, even before subtraction. (Used with permission from Cherry, S. R. & Phelps, M. E. 1996, "Imaging brain function with positron emission tomography," in *Brain Mapping: The Methods,* eds A. W. Toga & J. C. Mazziotta, Academic Press, San Diego, Calif.)

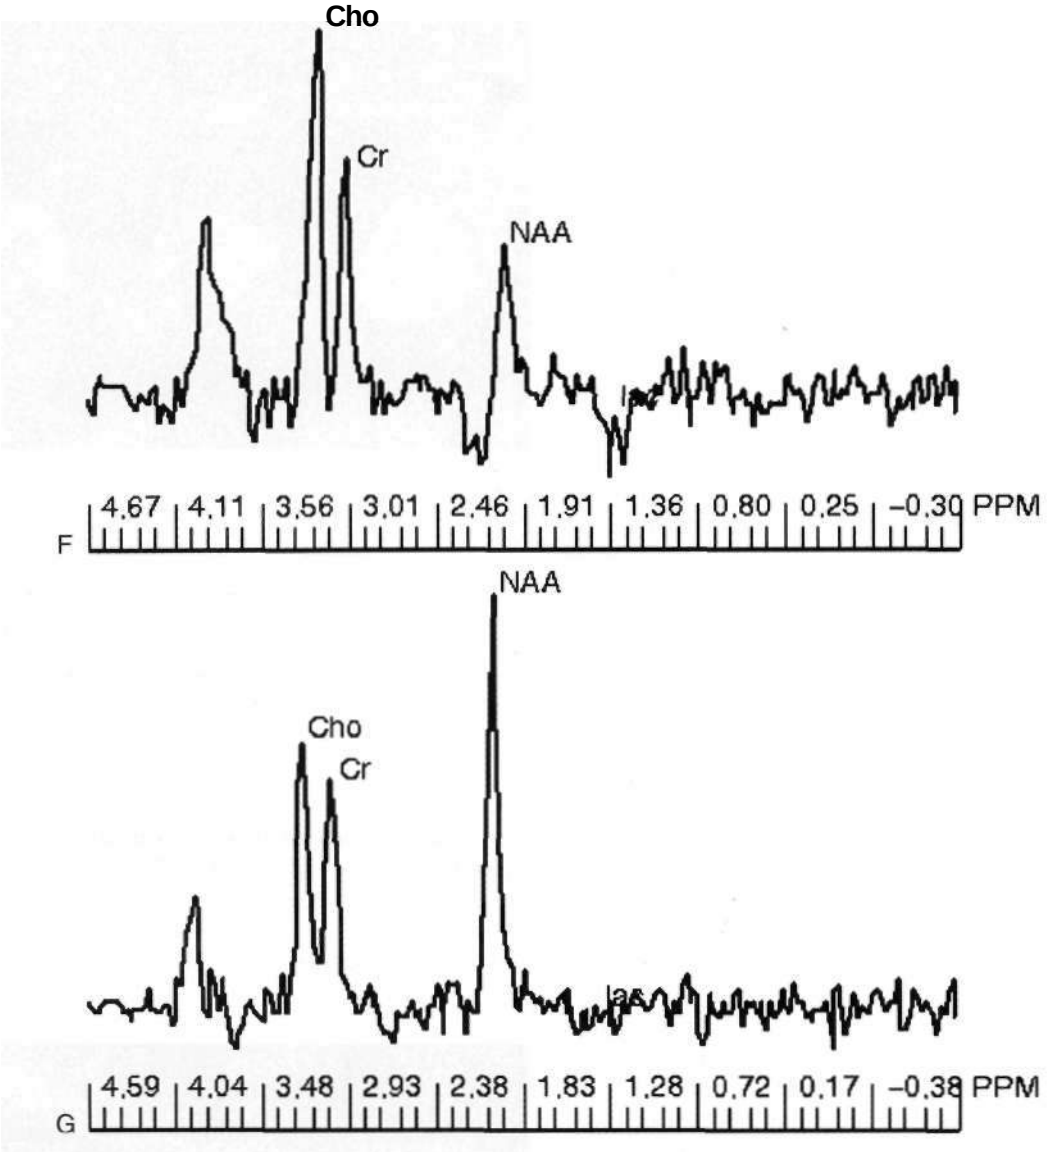

FIGURE 37E.1, cont'd. (F) MRSI at TE of 135 ms: PRESS spectrum from a subvoxel located slightly outside the region of enhancement and necrosis. On routine magnetic resonance imaging (MRI), this area of the hrain might he interpreted as "edema"; however, the elevated Cho, decreased NAA, and evidence of Lac on MRSI suggest that there is tumor infiltration. (G) MRSI at TE of 135 ms: PRESS spectrum from a suhvoxel located in an area of normal-appearing brain. This spectrum serves as a control to which the spectra from abnormal brain can he compared. Note the dominant NAA peak and the similarity of the Cho and Cr peaks in this area of normal brain. (Courtesy Dr. Brian Bowen.)

ERP in the clinical setting. These include brainstem auditory evoked potential, somatosensory evoked potential, and pattern reversal visual evoked potential. QEEG, currently used only in the research setting, involves transforming the LEG data in a manner thai allows for quantitative analysis. Detailed discussion of QEEG and ERP are heyond the scope of this chapter. They are mentioned here because they ate, technically, functional neuroimaging modalities and because they arc increasingly used in conjunction with other functional neutoimaging techniques for research purposes.

Magnetoencephalogtaphy (MEG) is similar to EEG in that it measures surface cortical activity. However, MEG detects the magnetic signal that arises from the electrical current that is measured by EEG. Quantitative and ERP techniques can be applied to MEG data as well. Although fMRI has much better spatial resolution than MEG, the temporal resolution of MEG vastly exceeds that of **fMRI.** Thus fMRI provides spatial information that allows for refinement of MEG data analysis, whereas MEG provides temporal information that allows for tcfinement of **fMRI** data analysis. For these reasons, MEG and fMRI

techniques are increasingly being used in conjunction with each another in the research setting.

CLINICAL UTILITY

Although a number of functional neuroimaging modalities are available for assessing the CNS, currently only PET and SPECT have clinical utility. As such, this section focuses on the clinical uses of PET and SPECT. Potential uses for the remaining functional neuroimaging modalities are currently under investigation.

Dementia

The potential of PET and SPECT in the diagnosis of Alzheimer's disease and other dementias continues to evolve. In fact, recent studies demonstrate that PET and SPECT have sensitivities and specificities of 90% or more in differentiating Alzheimer's disease from other types of dementia. Typically SPECT studies using a variety of blood flow tracers and/or FDG PET studies are ordered as part of a dementia workup. The characteristic "earmuff" pattern of decreased metabolism or blood flow in bilateral temporoparietal and frontal regions with sparing of the somatosensory cortex is associated with the diagnosis of advanced Alzheimer's disease (Figure 37E.2).

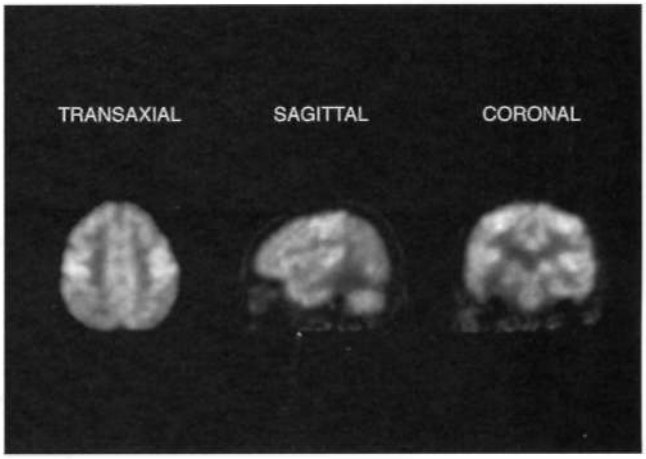

FIGURE 37E.2 Fluorodeoxyglucose positron emission tomography (PET) images of a patient with advanced Alzheimer's disease. Note the characteristic pattern of decreased glucose metabolism in all cortical regions except the somatosensory cortex (the "earmuff" pattern). (Used with permission from Dougherty, D. D., Ranch, S. L„ & Fischman, A. J. 2003, "Neuropsychiatry: applications of PET and SPECT," in *Essentials of Neuroimaging for the Practitioner,* eds D. D. Dougherty, S. L. Rauch, & J. F. Rosenbaum, American Psychiatric Publishing, Washington, DC.)

Seizures

Although EEG is the mainstay for detecting seizure foci, this technique is somewhat limited in that EEG is able to measure only corneal surface electrical activity. **PET** and SPECT are able to measure glucose metabolism or blood flow throughout the brain. Seizure foci demonstrate increased metabolism or blood flow during a seizure and decreased metabolism or blood flow during the interictal period (Figure 37E.3). Thus these functional neuroimaging modalities can be useful in cases with an unclear diagnostic picture, for localization of the seizure focus, and preoperative^ in cases in which neurosurgery is indicated.

Parkinson's Disease

Because Parkinson's disease is caused by degeneration of dopaminergic neurons in the substantia nigra, a means for *in vivo* assessment of dopaminergic function may be of diagnostic value. A number of **PET** and SPECT radiopharmaceuticals arc available to measure presynaptic dopamine synthesis (^{ls}E-dopa) and dopamine transporter density (^{12,}I-/SCIT, "C-CFT, ''C-altropane). These measures serve as markers for the number of intact dopaminergic neurons in the striatum. As Parkinson's disease progresses, binding of these radiopharmaceuticals in the striatum decreases {Plate 37E.I). The clinical use of these techniques is just beginning to emerge. These techniques ultimately may be diagnostically useful not only in situations in which the patient is clinically symptomatic,

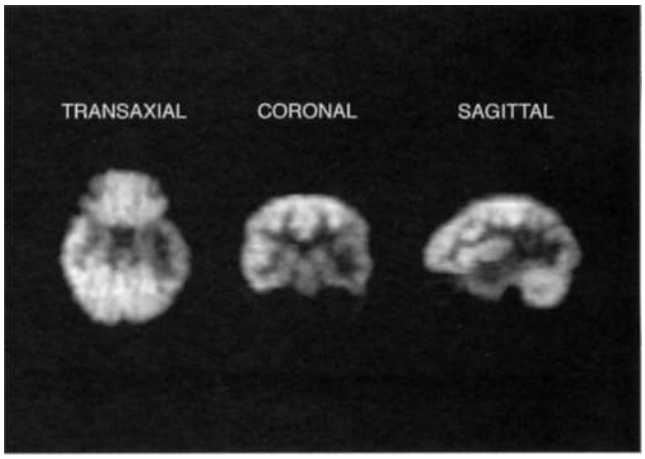

FIGURE 37E.3 Fluorodeoxyglucose positron emission tomography images ol a patient with temporal lobe epilepsy, fk'tausi' this image was acquired during the interictal period, glucose metabolism is decreased at the site of the seizure focus. (Used with permission from Dougherty, D. D., Rauch, S. L., & Fischman, A. J. 2003, "Neuropsychiatric applications of PET and SPECT," in *Essentials of Neuroimaging for the Practitioner,* eds D. D. Dougherty, S. L. Rauch, *&c* J. F. Rosenbaum, American Psychiatric Publishing, Washington, DC.)

but perhaps even for early diagnosis (before symptoms emerge) so appropriate therapeutic interventions may be initiated earlier in the course of the disease. Another potential use is for quantitative measurement of disease progression, both in the standard clinical setting and in the context of clinical trials.

Cerebral Ischemia

Although PET and SPECT are still not widely used in the evaluation of acute cerebral ischemia, there is growing evidence that PET and SPECT may have significant diagnostic value in these clinical situations. In addition, whereas CT and MRI detect structural changes associated with an ischemic event, PET and SPECT can directly measure cerebral perfusion. Thus PET and SPECT can detect hypoperfusion following an acute ischemic event almost immediately, whereas it may take several hours before corresponding structural changes are detected by CT or MRI (Plate 37E.II). Ongoing studies are being conducted that may help define the role of PET and SPECT in the clinical evaluation of cerebral ischemia.

Neoplasms

Most cerebral neoplasms can be detected using CT or MRI. However, because neoplasms typically demonstrate greater metabolism or blood flow than surrounding tissue (Figure 37E.4), PET and/or SPECT studies of glucose metabolism or CBF can provide complementary information in the clinical evaluation of cerebral neoplasms. Importantly, tumor metabolism is thought to be proportional to tumor cell proliferation. Thus PET and SPECT studies provide information thai may be used for rumor classification. Lastly, PET and SPECT data may also be used to follow therapeutic response of cerebral neoplasms, as well as for differentiating radionecrosis from tumor recurrence.

RESEARCH APPLICATIONS

All of the functional neuroimaging modalities discussed in this chapter are being used extensively in neuroscience research. Although each of these modalities is capable of measuring different aspects of brain function, the research paradigms used are relatively universal. In this section, we provide a brief description of some of the ways these functional neuroimaging modalities may be used in the research setting.

Neutral State

The simplest type of functional neuroimaging studies involves comparing populations during a resting, or neutral, state. For example, FDG PET studies have been conducted in groups of patients with major depression and in healthy control subjects. These studies have demonstrated that anterior frontal regions, especially on the left side, are hypometabolic in patients with major depression when compared with healthy control subjects. Comparable neutral state functional neuroimaging studies have been conducted in patients with many disorders, including obsessive-compulsive disorder, schizophrenia, and chronic fatigue syndrome.

Activation Studies

Although neutral state functional neuroimaging studies have provided valuable information regarding the pathophysiology of a number of disorders, functional neuroimaging studies conducted during specific tasks may have even greater research use. In functional neuroimaging activation studies, individuals perform tasks designed to assess a particular function (e.g., cognitive, affective, and visual) or to probe the functional integrity of a specific brain region. Brain function during the performance of these tasks is compared with brain function during a neutral condition and the difference is attributed to the performance of the task (Plate 37E.III). This methodology may be more robust than neutral state functional neuroimaging studies. For example, although neutral state functional neuroimaging studies demonstrate minimal abnormalities in patients with attention-deficit/hyper-

activity disorder (ADHD), functional neuroimaging activation studies assessing attention in patients with this condition have demonstrated marked abnormalities in patients with ADHD when compared with healthy control subjects.

Treatment Studies

Functional neuroimaging techniques (eirher neutral state or activation studies) can also be used to assess treatment. There are generally two approaches to these types of studies. The first type, predictors of treatment response studies, involves performing functional neuroimaging studies in patients before initiating a course of treatment. After treatment, correlates between baseline brain function and subsequent treatment response can be ascertained. In this ni.miu • ;, iv possibk' to detect baseline brain function profiles that predict subsequent treatment response. Secondly, functional neuroimaging studies can be performed before and after treatment. Predictors of trearment response analyses can be performed using the baseline functional neuroimaging data. Moreover, a comparison of pretreatment and posttreatment functional neuroimaging data may help to elucidate the mechanism of action of the treatment in question.

Neurochemistry

As described previously PET, SPECT, and MRS can be used to assess neurochemistry *in vivo.* Essentially any functional neuroimaging paradigm that assesses neuronal activity (e.g., neutral state studies, activation studies, and treatment studies) can also be performed using these neurochemistry imaging techniques. Thus dopamine function, for example, can be measured at rest, before and during a specific task, or before and after treatment, and the data can be analyzed using methods similar to those described earlier in this chapter. Thus functional neuroimaging technologies can be used to study indices of neuronal activity, as well as neurochemistry using any of these paradigms.

CONCLUSION

In summary, the application of functional neuroimaging technologies in the clinical evaluation of patients continues to evolve. In addition, functional neuroimaging is a powerful tool for neuroscience research. In the coming years, rhe clinical use of functional neuroimaging technology should continue to expand rapidly.

Chapter 38
Neuropsychology

Jane S. Paulsen and Karin Ferneyhough Hoth

The assessment of cognitive functioning is a critical part of a complete neurological examination. Whereas the cluneal neurological examination often focuses on the motor and sensory system, the neuropsychological examination focuses on the psychometric assessment of cognition and behavior. The cognitive evaluation can significantly contribute to neurological diagnosis, treatment planning, and monitoring over time. A wide range of intellectual abilities are assessed, and neuropsychological information complements information from electrophysiological techniques and neuroimaging.

In this chapter we describe the neuropsychological evaluation process, including methodological issues that must he considered in test administration, examine the contribution of a comprehensive neuropsychological assessment, and describe the typical patterns of cognitive impairments that are associated with a variety of neurological disorders. Guidelines for brief mental status assessment are also included.

GOALS OF NEUROPSYCHOLOGY

When potential cognitive deficits are noted clinically or during a brief mental status examination, an extended neuropsychology assessment is appropriate. Although the specific goals of a neuropsychological assessment differ depending on the referral question and the context in which the examination is given, several overarching aims can be identified {Table 38.1).

The primary goal oi neuropsychological assessment is to identify and describe the patient's cognitive strengths and weaknesses and characterize impairments and deficits in patients with brain damage. Approximately 30 years ago, the main role of neuropsychology was lesion localization. Although this remains useful, the advent of neuroimaging techniques in the 1970s and 1980s shifted the emphasis of neuropsychology toward describing the patient's cognitive and behavioral profile. Nonetheless, tests of neuropsychological functioning often are able to detect subtle cognitive deficits that are undetected by electrophysiological or neuroimaging methods. Other major goals of neuropsychological assessment concern differentiation between intellectual changes associated with brain damage, cognitive and behavioral impairments resulting from psychiatric illness, and cognitive changes secondary to normal aging.

In addition to offering information regarding diagnosis and neuroanatomical localization of dysfunction, the neuropsychological assessment is unique in its ability to address the patient's functional abilities. Clinicians often are called on to assess a patient's ability to make financial and health care decisions, to drive a car, and to live independently. These decisions can also determine when a patient is able to return to work after injury or what type of job the patient is suited for. A neuropsychological assessment may be used to determine appropriate adjustments to the patient's treatment and develop recommendations regarding activities of daily living.

Repeated neuropsychological evaluation can be invaluable in monitoring cognitive change over time. Repeated assessments can track cognitive decline in a progressive illness, such as dementia or multiple sclerosis, or monitor recovery after acute injury, such as stroke or traumatic brain injury. Evaluating the effectiveness of medical procedures and neurological surgery also entails repeated comprehensive assessment ot cognitive abilities. A comparison ol pre- and post-treatment data offers information about changes in the patient's level of functioning after medical intervention.

NEUROPSYCHOLOGICAL ASSESSMENT

The neuropsychological assessment generally involves a clinical interview, review of patient records, test selection, test administration and scoring, test interpretation, diagnosis, and treatment and rehabilitation recommendations. The clinical interview may vary in length given the presenting concerns of the patient. However, a complete interview typically covers the patient's developmental background, personal medical and psychiatric history, family medical history, academic performance, vocational achievements, psychosocial functioning, and activities of daily living. Information obtained from collateral sources such as caregivers or spouses about the patient's medical and psychosocial history often is critical. Behavioral observations of the patient during the examination are an important source of information that can influence test selection and the interpretation of test scores. One of the primary goals of the interview is to develop hypotheses about the patient's cognitive status and guide test selection. Many measures of cognitive functioning are available, and they differ in format, length, complexity, standardization, and quality of normative data. Different tests may be appropriate in different cases, and the test selection process is essential in gathering meaningful information about the patient. In the fixed battery approach, the same tests are given to every patient in a standardized manner. One of the most commonly used fixed batteries is the Halstead-Reitan Battery (Table 38.2}, for which comprehensive norms were published by Heaton and colleagues. An advantage of the **fixed** battery is that the information gathered is comprehensive and systematically assesses multiple domains of cognitive functioning. Additionally, if repeated assessments are available, test scores can be directly compared with baseline information. Drawbacks of the fixed battery approach involve its length (typically *X* hours! because it may be too long for some patients to tolerate and is difficult to afford with limited reirnbursement schedules in managed care. Finally, a comprehensive assessment may not be necessary to address the referral question.

In contrast with a fixed battery, in the flexible (or hypothesis-driven) approach, test selection differs based on the referral question, the patient's history, and the clinical interview. Most neuropsychologists' approach falls somewhere between the use of a set battery and a completely individualized examination. Often called the flexible battery, a brief set of basic tests is initially administered and additional tests of more specific abilities are used to meet each particular patient's needs.

Test interpretation requires the integration of neuropsychological test scores with findings from the clinical interview, the patient's history, the neurological examination, and neurophysiology and neuroimaging data. Before this can be accomplished, however, the raw test scores must be interpreted in the context of an appropriate comparison standard. Several approaches are used in interpreting neuropsychological test scores including the use of normative data, cutting scores, and comparisons with baseline data. Neuropsychological test scores are interpreted most often through the use of normative data obtained by collecting information about test performance from a standardization sample. For instance, Table 38.3 shows the percentage of variance in test raw scores accounted for by the demographic variables age, education, and sex. The test chosen for this example is the Wechsler Adult Intelligence Scale (WAIS), one of the most commonly administered assessments of intellect. As shown in the table, some tests share 38% variance with age (Digit Symbol), others share 4.)'X> variance with education (Information), and others differ with sex (Arithmetic). Interpreting **performances** on these tests without correcting for demographic characteristics of the person of interest would result in inappropriate conclusions.

Normative data provide information about the expected test performance of individuals within a particular group, often stratified based on age or level of education. An individual raw score is compared with the distribution of scores from the person's peer group to determine where it falls within the range of performances. Figure 38.1 and Table 38.4 show guidelines for use in neuropsychological interpretation. The usefulness of normative data depends

strongly on the size and representativeness of the standardisation sample. Clinical utility can be greatly affected by the goodness of the fit between the individual and the sample and the extent to which the norms take demographic factors into account. For example, it would not be appropriate to make determinations about the test performance of an 82-year-old man with 8 years of education by comparing his test score with those of a group of 40-year-olds with an average of 12 years of education. .Significant limitations exist in some normative data including the absence of suitable norms for older adults and heterogeneity of education, ethnicity, and health variables among some standardization samples. Furthermore, it is important to use the most recent norms available because cohort effects may lead to differences between current patients and those from whom data were collected years ago. When appropriate norms are not available, there is a danger of overdiagnosis or undcrdiagnosis of cognitive impairment. Thus the accurate intetprctation of neuropsychological test performance necessarily incorporates information about the sample from which the norms for each test were developed.

Another approach to test interpretation is the use of cutting scores to identify people who demonstrate pathological cognitive symptoms. Some tests ate designed to measure abilities that are largely intact in normal subjects but are impaired in disordered patients. For example, most people are able to bisect a line without difficulty, but patients with left-sided visuospatial neglect typically identify the midpoint of the line to be to the right of the centet. Tests that rely on cutting scores tend to measure performances with low base rates or deficits that very few people demonstrate.

An important component of test interpretation is the comparison of current performance with past test scores. Often no previous data have been collected. Clearly, when one is attempting to identify cognitive decline, a patient's

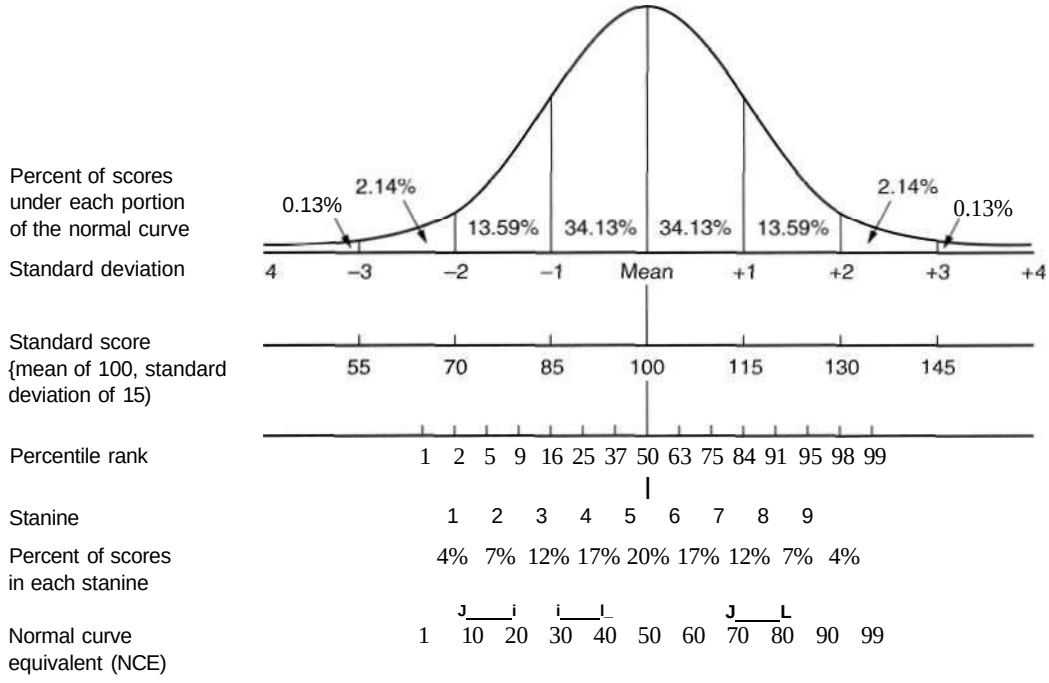

FIGURE 38.1 The normal curve and its relationship to derived scores.

Note: The patient's educational history and premorbid level of functioning should be taken into consideration in applying any qualitative label.

previous performance is an ideal comparison standard. When no previous test scores are available, evidence of the patient's premorbid intellectual functioning is used to make an estimate. Demographic factors such as education level can he useful indicators of premorbid level of ability. One rural neuropsychologist used number of acres owned to estimate IQ. A common approach to estimating premorbid intellectual functioning is to rely on specific characteristics of the patient's neuropsychological test performance that arc considered stable, or "hold" tests. Reading ability often is used as an estimate of overall premorbid intellectual ability because it is thought to be resistant to many processes that cause declines in cognitive functioning. Some common measures of reading ability arc the National American Adult Reading Test (Nelson 1982), which measures the ability to read irregularly spelled words, and the Wide Range Achievement Tcst-3 (Wilkinson 1V93), which measures the ability to read aloud. Because demographic variables account for a significant proportion of the variance in neuropsychological test performance, a number of regression equations have been developed using intelligence test standardization samples. Table .38.5 lists some of the demographic regression models used to estimate premorbid intellect. Contemporary neuropsychologists use a combination of these strategies to arrive at the best estimate of premorbid ability.

Factors other than the cognitive ability of interest, including demographic and clinical characteristics, can influence a patient's test scores. Subject characteristics such as age, education, sex, and ethnicity have been shown to affect test behavior (see Table 38.3). Overall, increasing age is associated with more adverse consequences of brain damage, although the relationship is complicated. In terms of test performance, aging has different effects on different cognitive domains. Aging has its most pronounced effects on nonverbal, timed tests, and although ovcrlearned material typically is stable into late life, a generalized slowing of response is the most ubiquitous change. Education level can also influence test performance, which is not surprising given that several neuropsychological tests were developed with the intent to measure intelligence and predict academic success. As mentioned earlier, norms are commonly divided based on age and education. Sex differences on neuropsychological tests of spatial abilities, strength, motor speed, and certain verbal abilities have been observed, although males and females appear to be equivalent in general intelligence. Finally, although research suggests that ethnicity influences performance on some neuropsychological tests, it is clear that more research on the topic is warranted. The clinical myth that ethnicity is important only on verbal or knowledge based tests and not on "culture free" tests such as some abstract reasoning measures is outdated. More recent evidence suggests that this distinction is unclear, and although research on the effect of ethnicity on test performance has been increasing, we still do not understand the complex relationship.

Medication and treatment side effects can complicate the interpretation of test scores. Often patients who are referred for neuropsychological assessment are taking medications or are being treated for a medical disorder. In fact, the action of some drugs or treatments can be the source of a patient's presenting cognitive problems. Gathering treatment information and assessing the potential influence of medications or other inrerventions on cognitive functioning is essential. Older adults and patients with brain damage

Table 38.5: Premorbid verbal IQ estimations

Wilson: V1Q = 0.18 (age) - 2.02 (sex) - 8.99 (race) + 3.09 (education) + 0.97 (occupation) + 70.8

Barona: VIQ = 54.23 + 0.49 (age) + 1.92 (sex) + 4.24 (race) + 5.25 (education) + 1.89 (occupation) + 1.29 (region)

Reynolds: VIQ = 127.85 - 3.7 (parental SES) - 8.86 (race) - 2.40 (sex) - 0.16 (region) - 1.16 (urban or rural residence)

may he particularly susceptible to adverse drug reactions, winch can impair cognitive functioning. For example, anticholinergic drugs used to treat Parkinson's disease can interfere with memory functions and present as exaggerated cognitive dysfunction. When relevant, a neuropsychological examination can help to elucidate potential interactions between brain damage and treatment effects.

THE BRIEF MENTAL STATUS EXAMINATION

zBefore neuropsychological referral the neurologist typically has either clinical or historical evidence of cognitive concerns. The ability to rapidly and reliably assess the nature and extent of cognitive impairments is important in all clinical settings. An important component of the neurological examination is the brief mental status examination. Although the mental status examination often is conducted in a nonstandard manner, neurologists are encouraged to develop a standardized method of mental status examination so that interpretations across time and patients can be made reliably (Table 38.6). Recommended standard examinations arc briefly described in this section.

Mini-Mental State Examination

Although a variety of standardized mental status examinations have been used, a few scales are used more widely than others. One popular mental status examination often administered by neurologists is the Mim-Mcntal State Examination (MMSE; Folstein et al. 1975), an 11-item standardized method assessing orientation, attention, immediate and short-term recall, naming, and the ability to follow simple verbal and written commands. The MMSE has been used with different cultural and ethnic subgroups and has been translated into several different languages. Using a cutoff of 23, the sensitivity and specificity of the MMSE have been reported to he 87% and 82%, respectively, for detecting delirium or dementia in hospitalized patients (Anthony et al. 1982), More recent research has documented the significant associations between MMSE performances and age *[r* — -.38) and education *(r* = .50), suggesting that the utility of the instrument varies greatly depending on demographic factors. The best norms published to dare involve dara from rhc Epidemiologic Catchment Area household surveys and are presented in Table 38.7. Longitudinal studies suggest that people with Alzheimer's disease (AD) show an average annual rate of change of 2.81 points, although change rates are not uniform across illness stages. The item most often missed by people with AD is item 5 (recall three items), whereas the most sensitive item for "subcortical" dementias is item 4 (serial 7s) (Figure 38.2).

Tabic 38.6: Utility of menta! status assessments

Benefits	*Drawbacks*
Standardized format	Reliance on total score
Brevity	Emphasis on verbal tasks
Sensitivity to advanced dementia	Disproportionate weight orinitiition
Test-retest reliability	In sensitivity with above average IQ
	Perceptual deficits = wrong answers
	No consideration of gender, education, or ethnicity

Despite its widespread use, the validity and reliability of MMSE administration and interpretation have received little attention. There are three primary threats to the internal validity of the MMSE: nonorthogonal wotd stimuli allowed fot recall, nonstandard scoring of serial 7s, and nonstandard inclusion of spelling *world* backwards in MMSE total. Because learning and then teaching standard scoring instructions can alleviate the latter two threats, we have included structured scoring criteria in the MMSE shown in Figure 38.3. The primary threat to the internal validity of the MMSE is that most practitioners simply use whatever words come to mind or whatever words they were trained with for the recall of three items. Even the standard MMSE sold by Psychological Assessment Resources (PAR) has only two sets of words. This practice is unsatisfactory for several reasons. Firsr, older adults in a community or hospital quickly learn the local stimuli. For instance, all residents at one university teaching hospital were using "apple, orange, airplane," and many patients had been examined by a medical student, a resident, a fellow, and an attending physician at various times throughout their care. The test is not a measure of learning **and** memory if the patient has **heard it** before. In addition, the wotd stimuli used cannot be associated with one another. For instance, the words in the aforementioned example can easily be associated with one another, such as "orange and apple" (both fruits) or "orange airplane" (a color modifying the airplane). The rest is not a uniform measure of three items if some items are associated with others. Another common problem is the use of words with varying degrees of imageability. For instance, the words "red," "ball," and "happy" are not equivalent in their evocation of images. It may be easy to picture a red ball but more difficult to recall that it is happy. In an effort to encourage residents to vary the word stimuli and avoid "chunked" or "grouped" stimuli, we have selected a list from which words can be selected. We have selected imageablc words with a standard frequency index of U > 60 (approximately 100 per million) that require a reading level not greater than sixth grade. We encourage practitionets to return to the list petiodically and select a new version of three unrelated words to practice standard administration of the MMSE (Table 38.8).

Dementia Rating Scale

The Dementia Rating Scale (DRS; Mattis 1976) is a 36-item measure of cognitive status with five subscales: Attention, Initiation, Construction, Conceptualization, and Memory. Although administration of the DRS can take 15 minutes for healthy older adults (and up to 40 minutes for people with severe impairment), the scale has clear advantages over the MMSE in some situations. The DRS assesses a greater number of cognitive domains and is less likely to miss impairment. The DRS has a greater range, so measures of change are better documented and interpreted. Finally, the DRS is successful in differentiating between various types of dementia, even in later stages of disease (Paulsen etal. 1995; Figure 38.4).

Using a cutoff of 129, the sensitivity and specificity of the DRS have been reported to he 98% and 97%, respectively, for detecting AD (Monsch et al. 1995). To better account for demographic influences, the following formula is used to determine whether performance is impaired: 0.09 (age) - 0.06 (education) + 0.59 (initialion/petseveration subscale score) + 1.25 (memory subscale score) = *x*. A value of *x* below zero suggests impairment (98% of AD), whereas a score value above zero suggests normal performance (98% of normal controls [NC]). Norms for older adults are provided in Table 38.9. Longitudinal studies suggest that people with AD show an avetage annual rate of DRS change of 11.38 points. The Initiation/ Perseveration subscale is most sensitive for subcortical and white matter dementias, whereas the Memory subscale is most sensitive for AD.

Additional Bedside Evaluation

Despite its advantages, the DRS takes longer to administer and is unlikely to be used at the bedside by neurologists. The 5-minute MMSE is more likely to remain the scale of choice for cognitive screening. Although the MMSE identifies AD, the most prevalent cause of dementia, it does not identify subtle cognitive impairments associated with white matter, subcortical, and cerebellar changes. Because the executive functions involve the most complex forms of human behavior, mild disturbances in their resolution can have significant impact on daily living. It is recommended that bedside executive tasks and careful

clinical interview accompany the MMSE to provide a comprehensive cognitive screening. Any indication of poor decision making, disinhibition, inflexibility, or slowed processing may warrant a complete neuropsychological assessment. To identify possible weaknesses in this area, many neurologists use fluency, clock drawing, or an evaluation of alternating sets. Healthy older adults should be able to produce about 20 first names in 1 minute, and performances below this cutoff watrant additional evaluation by a neuropsychologist. The alternating patterns shown in Figure 38.5 may be used to document inability to smoothly switch sets. Other bedside mental status examinations include executive items such as proverb interpretation and conceptual teasoning. For example, patients are asked to interpret the meaning of "Rome wasn't built in a day" and "A golden hammer can break down an iron door,"

Draw a Clock

The clock drawing test (CDT) is widely used as a clinical screening tool for cognitive decline in late life. Research indicates that patients with AD commit a greater proportion of conceptual, visuospatial, perseverative, and

FIGURE 38.5 Alternating patterns for bedside cognitive assessment.

stimulus-bound errors while demonstrating better performance when asked to copy a drawing of a clock rather than construct a clock on command (Figure 38.6; Rouleau et al. 1996). Longitudinal study of CDT performance in AD indicates that stimulus-hound errors increase with disease progression. The CDT can effectively differentiate between certain types of dementia syndromes. For instance, people with Huntington's disease (HD) commit more planning errors and tend to have more graphic difficulties than patients with AD (Figure 38.7), whereas people with Parkinson's disease (PD) make a greater proportion of visuospatial errors. Although bedside cognitive examinations have included the clock drawing test for years, little use has been made of the clocks produced in terms of scoring and interpretation. Although originally conceived as a specific test of visuospatial and constructional ability, the CDT has recently gained favor as a quick and easily administered screening instrument for general cognitive dysfunction. The use of the CDT emerged from the realization that the test is sensitive to many fotms of brain dysfunction because it draws on multiple cognitive processes, including auditory comprehension of the instructions, access to the semantic reptesentation of a clock, conceptualization and planning abilities, and visuoperceptual, visuospatial, and visuomotor skills. Numerous studies uniformly demonstrate that patients with AD perform significantly worse than control subjects on the CDT and that the test has clinical utility for detecting dementia. Qualitative analysis of the performance of mildly demented patients indicates that poor performance may be mediated by semantic knowledge deficits tesulting in conceptual errors in AD (e.g., misrepresenting the clock by drawing a face without numbers or with an incorrect use of numbers,

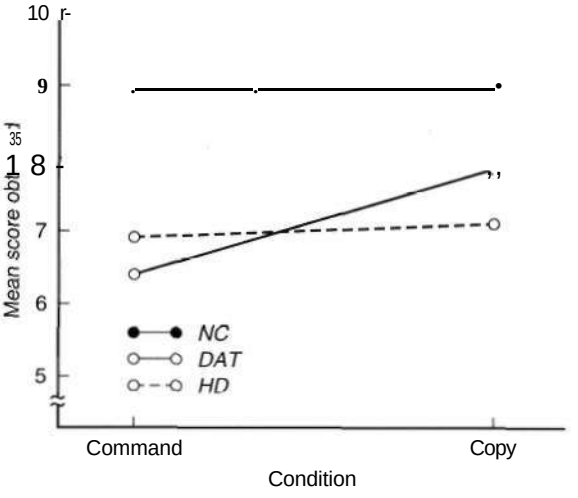

FIGURE 38.6 Scores obtained in the command and copy conditions as a function of diagnostic groups. NC = normal controls; DAT = dementia of the Alzheimer's type; HD = Huntington's disease. misrepresenting the time by failing to include the hands, incorrectly using the hands, or writing the time in the clock face; Figure 38.8) or planning or graphic errors in subcortical dementias (Figure 38.9). Conceptual errors on the CDT occur early in AD and increase over time. In addition, the performance of patients with AD often is much worse when they are asked to draw a clock from memory than when they are asked to copy a drawing of a clock.

NEUROPSYCHOLOGICAL CHARACTERISTICS OF NEUROLOGICAL DISEASE

In this section we briefly address the ncuroeognitive sequelae of some of the major neurological disorders. Reference is made to appropriate chapters in this text and to other review articles where appropriate.

Mild Cognitive Impairment

The field of aging and dementia research is increasingly focusing on characterizing the earliest period of cognitive impairment before the development of dementia. Growing evidence points to a long prodromal period in the development of disease, with research suggesting that biochemical and neuropathological changes may occur up to 20 years before the clinical manifestation of disease. Mild to moderate impairment in cognitive functioning, typically memory, with otherwise intact performance has been called mild cognitive impairment (MCI; Petersen et al. 1999). MCI typically refers to a clinical presentation between normal aging and dementia, with greater than expected memory loss in the absence of other cognitive deficits (Figure 38.10). MCI should be differentiated from normal aging and other terms such as "age-associated memory impairment" and "age-associated memory decline," which generally refer to extremes of normal aging rather than a precursor to a pathological condition. Diagnostic criteria for MCI have been formulated by the Mayo Clinic Alzheimer's Research Center (Table 38.10). Estimates of the prevalence of MCI suggest that approximately 5-8% of people in community samples meet criteria for MCI. Several large-scale clinical trials arc under way to identify drugs that can slow cognitive decline among people with MCI, so identifying patients with MCI is imperative.

The clinical outcome of patients with MCI has been investigated in longitudinal follow-up studies. Several reviews of the literature have concluded that patients with MCI are at an elevated risk for developing clinically

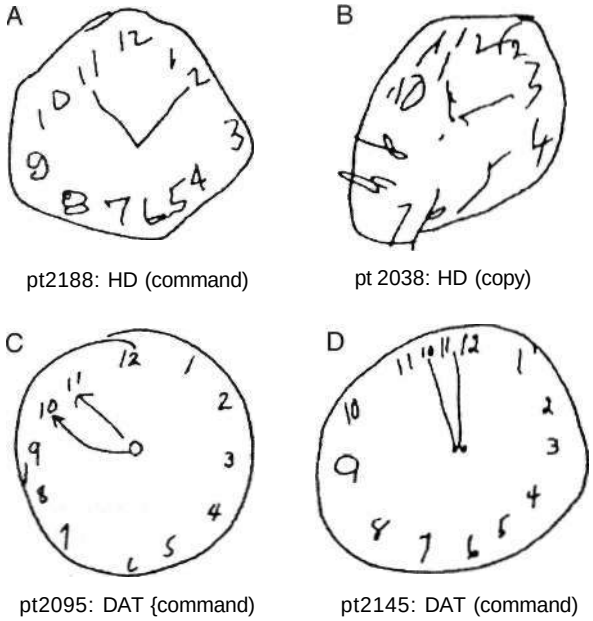

FIGURE 38.8 Sample of command and copy errors observed on the Clock Drawing Test in patients with Alzheimer's disease (dementia of the Alzheimer's type [DAT]) and Huntington's disease (HD). Graphic difficulties; (A) moderate; (B) severe, stimulus-bound response, (C) associated with visuospatial deficit; (D) associated with a conceptual deficit in representing the time on the clock. (Adapted from Rouleau, I., Salmon, D. P., & Butters, N. *1996,* "Longitudinal analysis of clock drawing in Alzheimer's disease patients," *Brain Cogn,* vol. 31, pp. 17-34.)

diagnosed AD. Estimates suggest that approximately 10-15% of patients with MCI will progress to AD per year. Studies have also found that MCI is associated with increased morbidity and a decline in selected cognitive abilities including episodic memory, semantic memory, and perceptual speed.

The heterogeneity of MCI has been acknowledged in the literature. Recently, several subtypes of MCI have been proposed including an amnestic subtype, which emphasizes memory loss, a subtype in which a single nonmemory domain is affected, and a subtype in which multiple domains arc slightly affected (Figure 38.11).

The criteria for MCI require both subjective and objective memory impairment in the presence of normal general cognitive functioning. Overall, deficits on measures of verbal episodic memory and new learning arc reported in patients with MCI, whereas other cognitive functions including language and executive functioning are largely intact (Petersen et al. 2001). The objective memory impairment typically is documented with neuropsychological testing using a cutoff of performance approximately 1.5 standard deviations below the average performance of people of a similar age and education. However, although other aspects of cognitive functioning in these people are largely intact, they may not be completely normal. A study comparing patients with MCI, normal control subjects, and patients with mild AD (characterized by a clinical dementia rating of 0.5 and 1) demonstrated that although the jyucral cognitive function of these subjects was normal, the level of cognitive functioning in other nonmemory domains was somewhat below normal (Petersen 2000).

Several predictors of subsequent cognitive decline among people with MCI and mild AD have been examined. An investigation at the Mayo Alzheimer's Disease Research Center longitudinally examined 155 people with MCI and found that apolipoprotein E4 carrier status, poor performance on a cued recall test, and atrophic hippocampi on magnetic resonance imaging (MRI) predicted more rapid

declines (Petersen et al. 2001). Impairment in cognitive domains other than memory may also predict subsequent decline in performance.

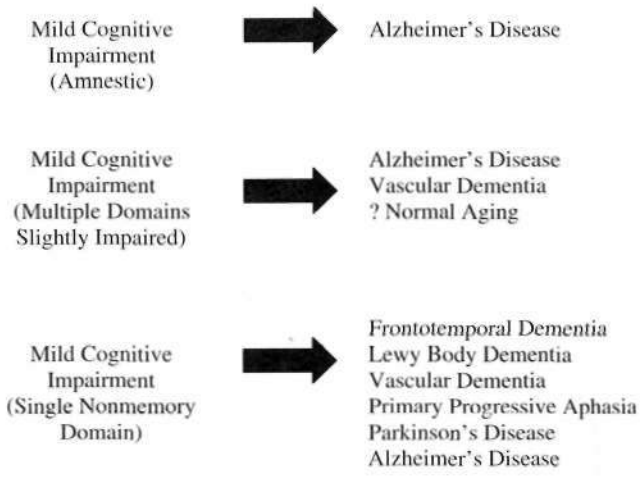

FIGURE 38.11 Heterogeneity of the term *mild cognitive impairment.* (Adapted from Peterson, R. C., Doody, R., et al. 2001, "Current concepts in mild cognitive impairment," *Arch Neurol*, vol. 58, pp. 1985-1992.)

Alzheimer's Disease

Neuropsychological tests, formal or informal, have always been the hallmark of the clinical diagnosis of AD. The recent development of pharmacological treatments for AD and the introduction of new therapies make assessing dementia at its different stages an even greater scientific and public health challenge. Neuropsychological tests at present are the only in vivo screening and diagnostic tools fot AD and related disorders that can establish deficits in more than one domain of cognition. This is required for the diagnosis of dementia and AD by the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (American Psychiattic Association 1994) and the National Institute of Neurological and Communicative Disorders and Srroke/Alzheimer's Disease and Relared Disorders Association (NINCDS-ADRDA) (McKhann et al. 1984) criteria. Although the MMSE is excellent fot identifying AD in mid-stages (i.e., total score of 23), it is insufficient to identify early AD. Several cognitive tasks have been developed to sctccn for AD. Among these additional tests are the Neurobehavioral Cognitive Status Examination (Kiernan et al. 1997) and the 7 Minute Screen (Solomon etal. 1998).

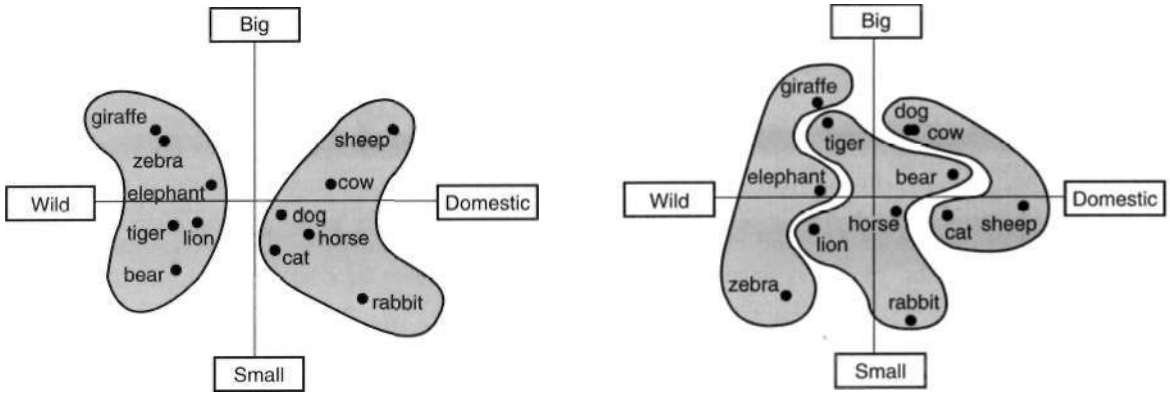
Tabic 38.10: Criteria for amnestic mild cognitive impairment

Memory complaint, preferably corroborated by an informant
impaired memory function for age and education
Preserved general cognitive function
Intact activities of daily living
Not demented

Source; Peterson, R. C, Doody, R., et al. 2001, "Current concepts in mild cognitive impairment," *Arch Neurol*, vol. 58, pp. 1985-1992.

AD results in a global disorder of intellectual functioning that affects a wide variety of cognitive processes. Memory impairment usually is the earliest and most salient fcatute of the disorder, but the particular cognitive processes that are initially affected and the relative seventy of various cognitive impairments can vary from patient to patient. The neuropsychological evaluarion of AD must include a thorough assessment of a wide range of cognitive abilities, including verbal and nonverbal memory, language and semantic knowledge, attention and executive functions, visual perception, and spatial abilities. Numerous studies have shown that measures of the ability to learn and retain new information arc effective in differentiating between mildly demented patients with AD and normal adults. For example, Welsh and colleagues (1991) found that the accuracy of word list recall after a 10-minute delay differentiated patients with very early AD (MMSE > 25) from healthy controls with bettet than 90% accutacy. The abnormally rapid forgetting exhibited by patients with AD on clinical memoty tests suggests that their memory impairment is caused by ineffective consolidation of information (i.e., difficulty transferring information from short-term to long-term memoty).

Because AD results in widespread cortical damage and affects a wide variety of cognitive functions, the memory impairment of these patients may be exacerbated by a number of ancillary deficits. For example, poor attention and weakened semantic memory associations may adversely affect memory performances. One recent report suggests that attention is the first nonmemory domain to be affected in AD, before language and visuospatial functions. Divided attention and aspects of selective attention, such as set-shifting and response selection, are particularly vulnerable, whereas sustained attention is largely preserved in the early stages of AD.



NORMAL ELDERLY CONTROLS ALZHEIMER'S DISEASE PATIENTS

FIGURE 38.12 The cognitive map of normal older adults *{left)* and patients with Alzheimer's disease *(right)* obtained from multidimensional scaling analysis and clustering analysis. (Adapted from Chan, A., Butters, N., Paulsen, J. S., et al. 1993, "An assessment of the semantic network in patients with Alzheimer's disease," *J Cogn Neurosci,* vol. 5, pp. 254-261.)

The nature of language deficits exhibited by patients with Al) Mifi^ests thai these patients MI iter deterioration in the organization of semantic knowledge or a degradation of the knowledge itself. For example, several studies using verbal fluency tests have shown that patients with AD are more impaired when required to generate exemplars from a particular category (e.g., animals) than words beginning with a particular phoneme (e.g., FAS). Chan and her colleagues (1993) used multidimensional scaling analyses to show the distorted semantic network of the patient with AD (Figure 38.12).

Deficits in visuoperceptual abilities and constructional praxis occur in patients with AD, although they usually emerge after the early stages of the disease and may have little to contribute to the differentiation of early dementia from normal aging. Convergent findings from neuropathology, neuroimaging, and neuropsychology indicate that early memory impairments in AD are specifically related to early stage limbic-diencephalic pathology and that nonmnemonic impairment is specifically related to later-stage tcmporal-neocortical pathology.

Vascular Dementia and Vascular Cognitive Impairment

Current estimates of the prevalence of vascular dementia suggest that it accounts for 10-50% of all dementia cases, making it the second most common cause of dementia after AD {see Chapter 72 for a review of the clinical aspects of vascular dementia). The development of the diagnostic criteria for vascular dementia has been heavily based on AD research. This has resulted in a focus on symptoms of memory impairment, progression, and severity of symptoms. Vascular dementia is treated as a largely unitary condition and either implicitly or explicitly includes dementia caused by stroke {see Chapter 72). Several authors argue that this focus is inadequate to capture the range of cognitive impairments that can result from cardiovascular disease (Bowler and Hachinski 2002).

Bowler and Hachinski proposed the broader term *vascular cognitive impairment* (VCI) to encompass the array of cognitive deficits resulting from cerebrovascular disease. Those who may be diagnosed with VCI include patients with early cases of cognitive impairment associated with cardiovascular disease and exclude those with nonischemic cases and major stroke. Future research on VCI may help characterize the range of cognitive impairments that are typically associated with cerebrovascular disease. In the meantime, it is important to recognize that vascular lesions that produce cognitive impairments can have many different origins, including ischemia, incomplete infarction, and major stroke.

Although numerous studies have attempted to identify patterns of cognitive deficits that arc typically associated with cerebrovascular disease, the recognition of characteristic cognitive impairments is influenced by the manner in which the patients are diagnosed. The particular pattern of cognitive deficits varies with the subtypes of vascular dementia, which include subcortical vascular dementia, multi-infarct dementia, hypoperfusion dementia, and single cortical or subcortical infarcts {Desmond and Pasquicr 2002).

Given such a wide range of dementias, a comprehensive description of the corresponding deficits is beyond the scope of this chapter (see Chapter 72). Nonetheless, several commonalities, including an emphasis on impairment of executive functioning with largely intact performance in several aspects of memory, have emerged in the literature.

The most common neuropsychological impairment in patients with cerebrovascular disease, particularly those without a history of major stroke, is subcortical and frontal lobe functioning deficits. Planning and sequencing, speed of mental processing, performance on unstructured tasks, and attention tend to be impaired in vascular dementia

(Desmond and Pasquier 2002). Subcortical lacunar infarctions in the territory near the thalamus, caudate, and globus pallidus may disrupt frontal-subcortical circuits and account for the prevalence of executive dysfunction in these patients.

The presence of memory impairment in vascular dementia is somewhat controversial. Memory impairment is considered a defining feature of AD, and many studies have found more significant memory impairments in AD than in vascular dementia. However, several studies have found evidence of memory impairment in vascular dementia as well. For example, one study found that tests of memory were among those that differentiated between patients with ischemic stroke and control participants.

Findings of memory impairment associated with cerebrovascular disease may result from comorbid cerebrovascular disease and Alzheimer's dementia. Memory impairment may also be a secondary manifestation of cerebrovascular disease from infarcts in the medial temporal lobe or a consequence of executive functioning deficits such as inattention and disorganization (Desmond and Pasquier 2002), Using positron emission tomography, Reed et al. (2000) found that episodic memory failure in patients with subcortical cerebrovascular disease was associated with prefrontal lobe metabolism, whereas memory performance in patients with AD was correlated with left hippocampal and temporal lobe metabolism. The authors suggest that different pathogenic mechanisms underlie episodic memory failure in subcortical vascular disease and AD. Given the current criteria for vascular dementia, which emphasize memory impairment and global cognitive deterioration, it has also been suggested the observed memory deficits in patients diagnosed with vascular dementia may be influenced by selection bias.

A recent review of the literature indicated that patients with AD have greater deficits than patients with vascular dementia in functions mediated by posterior cortical areas including memory deficits (e.g., faster rate of information decay, reduced ability to benefit from retrieval cues, and greater intrusion errors) and particular language deficits such as naming impairment (Desmond and Pasquier 2002). Greater deficits in syntax in vascular dementia, and in accessing lexicon in AD, have also been reported. One study examined the performance of 114 people with probable AD and subcortical ischemic vascular dementia on a variety of tests purported to measure executive abilities. The authors found that patients with AD had more self-monitoring problems than patients with subcortical vascular disease, whereas patients with subcortical vascular disease demonstrated more executive memory search deficits, pointing to differences in the types of executive functioning deficits manifested by the dementia groups (Yuspeh et al. 2002). Despite these observed differences, other recent research has found evidence of similar patterns of deficits when comparing patients with AD and vascular dementia on several neuropsychological tests.

Historically, a patchy, stepwise pattern of cognitive deficits has been associated with vascular dementia, particularly multi-infarct dementia. There is recent evidence that patients with vascular dementia have a higher prevalence of fluctuating cognitive functioning than those with AD. Although this may be the case in some instances, it is clear that the course of cognitive decline may also be continuous and slowly progressive in many patients with multiple vascular disorders,

Fro n to temp oral Dementia

Focal degeneration of the frontotemporal lobes is a common cause of dementia, accounting for about 20% of cases of dementia with presenile onset. Frontotemporal dementia (FTD) encompasses a clinically heterogeneous group of syndromes determined by the distribution of pathological change within the brain. Cases of FTD do not have a common molecular basis, however, and highlight the importance of defining patients on clinical, anatomical, histological, and biological grounds. Three ma]or syndromes can be identified: (1) frontal lobe degeneration of non-Alzheimer type, in which changes in social behavior and personality predominate, reflecting the orbitobasal frontal lobe focus of the pathology; (2) semantic dementia, also known a progressive fluent aphasia, in which there is a breakdown in the conceptual database that underlies language production and comprehension and is associated with asymmetrical anterolateral temporal atrophy with relative sparing of the hippocampal formation; and (3) progressive nonfluent aphasia, the most rare of these syndromes, in which the phonological and syntactic components of language are affected in association with left perisylvian atrophy.

There are three main histological types: microvacuolar, Pick's, or motor neuron disease. It is important to note that each of these FTD syndromes can be associated with motor neuron disease (amyotrophic lateral sclerosis), although the neurological symptoms and signs commence after the development of the dementia and lead to death within 3 years. Although it has been suggested that FTD disorders should be regarded as tauopathies on the basis of the tau pathology seen in a number of cases and the mutations in the tau gene in some familial cases, recent studies have documented only 37% of FTD with tau pathology and 10% with mutations in the tau gene, suggesting that FTD is not a unitary etiological disorder.

Simple cognitive screening tests, such as the MMSF, are unreliable for detecting and monitoring FTD. Performance on the MMSE can remain intact even when institutionalization is needed. Early personality or functioning complaints must be regarded seriously, and a neuropsychological assessment should emphasize executive and social tasks,

The clinical presentation of primary FTD is one of profound alteration in social conduct and personality.

Patients may show a disinhibited, overactive, and restless change reminiscent of orbitofrontal dysfunction or akinesia and apathy accompanied by a lack of concern and insight (Table 38.11). In many patients, stereotypic, ritualistic behaviors are the dominant clinical feature. Such patients may develop elaborate rituals for dressing or toileting, adhere to a rigid daily routine, and experience significant difficulty shifting from one activity to the next. Performances on executive tasks reveal profound abnormalities in abstraction, planning, sequencing, organization, and regulation.

Patients with semantic dementia typically complain of loss of memory for words. They are often painfully aware of their shrinking expressive vocabulary but are strangely oblivious to their impaired comprehension. Caregivers note the increased use of substitute words and phrases such as "thing" and "you know." Patients with primary right-sided atrophy may present with difficulty recognizing and naming faces and become severely prosopagnostic. Day-to-day episodic memory and orientation remain intact.

Progressive nonfluent aphasia presents with a decline in language expression in the relative absence of other cognitive deficits. Speech becomes nonfluent and effortful and may involve stuttering. Word retrieval difficulties are prominent, and repetition is impaired. Spoken and written comprehension remains largely preserved, as do visual perception, spatial abilities, and memory. Social skills typically are well preserved in the early stages, although behavioral changes akin to frontal lobe degeneration emerge later in the disease.

Parkinson's Disease

In addition to motor symptoms, PD is associated with elevated levels of depression and cognitive impairments, Clinical ratings based on the level of clinical disability have become the standard method of measuring PD-related functioning. The Unified Parkinson's Disease Rating Scale {Fahn et al. 1987) is the most widely used scale today and incorporates the Hoehn-Yahr clinical disability stages and the Schwab and Kngland activities of daily living into scores that are used to assess treatments and measure disease stages. Because cognitive and emotional functioning can have a significant impact on functional capacity, these assessments must be a central component of the PD evaluation.

Although cognitive impairment is the rule rather than the exception in PD, there is heterogeneity in presentation and progression of cognitive deficits. The neuropsychological profile of PD includes cognitive slowing, memory impairment, visuospatial deficits (e.g., problems with pattern completion and facial recognition), and a range of executive deficits including impairments in decision making, planning, shifting, and monitoring of goal-directed behaviors. Nearly all patients with PD suffer from a general cognitive slowing, or bradyphrenia.

Several studies suggest that changes in executive functioning may be one of the earliest signs of cognitive decline in PD. Patients with PD often report problems with decision making, planning, and monitoring of goal-directed behaviors. On traditional and computerized neuropsychological tests, even nondemented patients with PD show impaired ability to shift between sets.

Up to 80% of patients with PD experience speech problems beyond production problems related to motor symptoms. They experience problems comprehending and producing syntactically complex sentences. Unlike patients with AD, those with PD generally do not experience problems with name finding.

Memory problems are also commonly reported among patients with PD. In particular, they report difficulty in recalling effortful information but exhibit intact recognition. Several studies have demonstrated that learning and retrieval deficits exist in patients with PD without frank dementia.

Dementia occurs in up to 25% of patients with PD. A number of factors have been implicated as risk factors for dementia in PD, including older age, lower education, and the presence of depression and confusion or psychosis after levodopa treatment.

There is no consensus regarding the effect of pharmacological treatment on cognition in PD. It is clear that for some patients with PD, the gold standard treatment, levodopa, may exert a highly selective and deleterious effect on cognitive function. This is particularly salient given that the cognitive decline observed in PD remains a major source of disability and mortality in PD.

Tabic .18.11: Differentiating Alzheimer-type dementia from frontal lobe dementia

CI mica I variables	*Alzheimer's disease*	*frontal lobe dementia*
Personality	Passive, largely intact	Apathetic, disinhibited, sometimes eccentric
Social skills	Spared early	Early deterioration
Kliivcr-Bucy syndrome	Late	Early
Language	Fluent aphasias	Decreased output, mute
Naming	Lexical anomia	Semantic anomia
Drawing	Impaired early	Largely spared
Calculation	Impaired early	Largely spared
Memory	Impaired early, not helped by cues	Variable, helped by cues

Huntington's Disease

HD is a genetically transmitted neurodegenerative disease of the basal ganglia that is characterized by a triad of clinical symptoms: choreoathctosis, cognitive decline, and psychiatric features. The diagnosis of HD is based on a neurological evaluation and requires the presence of an unequivocal movement disorder, although the cognitive and behavioral alterations are the most debilitating aspect of the disease and place the greatest burden on HD families.

In manifest HD, the most striking cognitive deficit is executive dysfunction (e.g., strategies in planning and problem solving, self-monitoring, and attentional and cognitive flexibility). As expected, cognitive deficits reported in people who are presymptomatic for HD but have the gene mutation also emphasize executive dysfunction. In a meta-analytic review, Zakzanis (1998) concluded that patients with HD are most deficient in the acquisition of new information, delayed recall, cognitive flexibility, manual dexterity, attention, speed of processing, and verbal skill.

Several studies have demonstrated that patients with HD are impaired on tests that require executive functions, such as the Wisconsin Card Sorting Test, the Stroop Color Word Test, and clinical rating scales of executive dyscontrol. In fact, brief tests of executive functions have been suggested as sensitive tools for identifying subcortical dysfunction. That is, the Serial Sevens item on the Mini-Mental State Examination, the Initiation and Perseveration subtest of the Dementia Rating Scale (Mattis 1976), and an abbreviated battery of frontal lobe tests have been demonstrated to be distinctly sensitive to patients with HD.

Some recent research has evaluated the performance of patients with HD on clinically relevant, face-valid tests of judgment and decision making. Stout and colleagues (2001) used a simulated gambling task to quantify decision-making deficits in patients with I ID, Findings showed that patients with HD made fewer advantageous selections than age- and education-matched healthy controls and dementi a-severity-matched patients with PD. Impairments on tasks requiring decision making may result from various cognitive decrements, including learning, attention, inhibition, and appreciation for future consequences. Findings can also be interpreted as further evidence that patients with HD are less able to benefit from feedback and have difficulty varying output based on performance. Despite evidence of explicit knowledge for the tasks, patients with HD were unable to update existing programs based on new experience and to alter their responses. Numerous wide-ranging consequences of these types of executive deficits are self-evident.

Early neuropsychological studies reported that patients with HD perform poorly on subtests requiring attention and working memory. More recent studies have emphasized dysfunction in unique aspects of attention, including resource allocation, response flexibility, and vigilance. For instance, one study reported that patients with HD are able to maintain attention for a previously learned response set but have difficulty shifting attention to a new set. Others have reported that patients with HD are able to maintain alertness when the task involves an external cue but fail when internal self-generated vigilance is required. The clinical implications of the attentional impairment in HD are significant. Many people with HD perform better when they avoid tasks involving divided attention. Patients and families agree that trying to divide the already-compromised attentional resources can contribute to discomfort and increase safety risks. For instance, driving a car while listening to the radio, talking to people in the back seat, or talking on the cell phone is not recommended. To reduce choking risk, the environment should be quiet and calm at mealtimes to emphasize concentration on chewing and swallowing.

Deficits in learning and memory are the most frequently reported cognitive complaints from people with HD and their family members. Patients with HD exhibit verbal learning deficits even in the earliest stages of the illness. The majority of studies describe the memory impairment as a primary encoding and retrieval deficit because recognition memory often is preserved. That is, most studies show that people with HD consistently have problems learning new information and also experience difficulty when asked to use free recall to remember what they have learned; in contrast, they perform near normal when a less-effortful memory strategy is used, such as offering choices of or recognizing possible learned items. Patients with HD manifest intact retention over a delay period, indicating no abnormal forgetting or rapid loss of information. When tested on memory for information acquired long ago, they demonstrate no temporal gradient in performance, indicating that memory performance is equivalent for all periods of their lives.

The memory impairment of HD is characterized by a mild encoding deficit (probably caused by impaired organization of the to-be-learned information and ineffective working memory) and moderately impaired retrieval in the context of largely intact memory storage when measured with a less-effortful strategy (i.e., recognirion). Skill learning can be acquired when external feedback is allowed, but motor programs are not stored for later use, possibly because of the dependence of the striatum in "chunking" components of the motor program.

Several studies have shown olfaction impairments in HD using the University of Pennsylvania Smell Identification Test (Doty 1991). The most comprehensive research to date assessed absolute detection, intensity discrimination, quality discrimination, short-term recognition memory, and lexical- and picture-based identification for odor, using taste and vision as comparison modalities. Results suggested that although odor recognition memory is not affected in patients with I ID, absolute detection, intensity discrimination, quality discrimination, and identification

were significantly impaired. Poor detection sensitivity explained performance on several other olfactory tasks where odor identification was the function most impaired.

Deficits in the ability to copy simple geometric designs, to copy block designs, and to put together puzzles are evident in HD. Although some of these impairments probably reflect motor abnormalities, performance is also impaired on motor-free untimed perceptual tasks. Mohr and colleagues (1997) recently examined whether visuospatial deficits in basal ganglia disease are a nonspecific function of dementia severity or whether they reflect disease-specific impairments. Findings suggested that general visuospatial processing capacity is impaired as a nonspecific dementia effect in both HD and PD, whereas only patients with HD showed specific impairment in person-centered spatial judgment. For instance, people with HI) (but not PD) experience difficulty with map reading, directional sense, and varying their motor responses after alterations in space. People with HD typically misjudge distances and the relationship of their body to walls, curbs, and other potential obstacles.

One of the most prominent features of HD is the motor speech impairment, or dysarthria, that is characteristic of the illness. Early speech changes may include insufficient breath support, varying prosody, increased response latencies, and mild misarticulations. As HD progresses, phrase length decreases, and pauses in speech output lengthen. Performances on tasks of letter and category fluency are impaired early in the disease, although the integrity of word associations remains largely intact, with little evidence of intrusion or perseveration errors. Despite significant impairments in verbal fluency, speed of output, and complexity, syntactic structure remains intact, and speech content usually is appropriate. Although there are some reports in late-stage HD of mild deterioration in semantic knowledge structure, several other studies have shown that errors in confrontation naming are more likely to be caused by visual-perceptual deficits and retrieval slowing. Speech output becomes severely impaired as the disease progresses, typically resulting in a profound communication deficit.

Several studies have relied on the Total Functional Capacity (TFC) scale to quantify disease stages and functional dependence associated with HD. Research has been largely consistent, with most studies demonstrating an average decline of 0.63 ± 0.75 units/year on the TFC. Although controversial, there is some evidence that rate of progression is more rapid in juvenile onset and more gradual in late onset. Marder and colleagues (2000) recently examined the annual rate of functional decline in 960 prospective patients with HD followed an average of 18 months at 43 sites in the Huntington Study Group. Findings were consistent with previous research, suggesting TFC decline of 0.72 units per year and independent-scale decline of 4.52 units per year. Better cognitive status at baseline, lower baseline TFC, and longer disease duration were associated with a less rapid rate of decline, whereas depressive symptoms were associated with more rapid functional decline. Rich and colleagues (1999) assessed flexibility and language functions over 5 years and reported stable semantic clustering (language) performances in patients with HD despite a progressive reduction in shifting. Findings are consistent with a cross-sectional study of 75 patients with HD divided into three stages of illness: early, middle, and advanced. These findings suggested that memory, receptive language, and simple attention remain largely intact throughout the stages of HD. It is important for professionals and family members to educate staff at care facilities regarding the pattern of impaired and preserved cognitive functions in later stages of HD, when verbal output is severely limited.

Tourette's Syndrome

Tourctte's syndrome (TS) is an inherited neuropsychiatric disorder characterized by motor and phonic tics (Jankovic 2001). Diagnostic criteria for TS include the presence of multiple motor tics and one or more vocal tics, both of which must exceed a year's duration. Onset of this disorder occurs in childhood, with an average onset age of 6 to 7 years. AI tin High evidence suggests a genetic transmission of TS, a gene has not yet been identified. Illness course is variable, with some patients experiencing spontaneous remission or significant decrease of symptom severity whereas others experience lifelong presence of symptoms.

Up to 68% of children with TS function below expectations in school. The neuropsychology of TS is incomplete, however, in part because there have been insufficient experimental studies of primary psychological systems and in part because most studies that have been carried out have included a mix of subjects. Because comorbidity in TS is high, subject samples often are heterogeneous with regard to obsessive-compulsive symptoms, attention deficit hyperactivity disorders, mood disorders, coprolalia, age, medication usage, illness duration, and age of onset. In addition, TS children sometimes are distracted by their various motor and vocal tics or use a great deal of resources to suppress these tics, taking attention from their studies. Motor tics may interfere with homework, note taking, or performance on written examinations. Children with TS are clearly seen as different from other children in the classroom and often experience psychological and emotional burdens associated with being perceived as different. Despite these iinutations, some preliminary conclusions may be drawn.

Although some findings suggest that children with TS have executive dysfunction, other reports show that children with pure TS (no comorbid diagnoses) have normal performances on neuropsychological measures or **nearly** normal performances with only subtle slowing or disinhibition. When considered together, findings suggest

that cognitive impairments in pure TS are mild and not easily captured with gross measures. More comprehensive executive evaluations and novel study designs (Cirino et al. 2000) probably are needed to better differentiate the core cognitive component of TS from the cognitive deficits associated with its comorbid disorders.

Children with TS and a comorbid diagnosis of attention deficit hyperactivity disorder (ADHD) demonstrate dysexecutive performances and increased perseverative errors as well as increased incidence of learning disability. Primary cognitive dysfunction associated with frontal systems may impait the planning, organization, and execution of behavioral output for children with TS and ADHD. Compensatory sttategics that might be useful involve increased structure fot problem solving. Children with TS and comorbid obsessive-compulsive symptoms show dysexecutive petformances as well, but performance is mosr severely impaired in children with TS, ADHD, and obsessive-compulsive symptoms. Even after controlling for tic severity, IS children with comorbid ADHD and obsessive-compulsive disorder demonsrrated the most severe cognitive impairments and poorer academic achievement.

Table 38.12: Relative frequency of cognitive deficits in multiple sclerosis

Cognitive deficits	*Frequency \n multiple sclerosis*
Attention	+-H-
Information processing	+++
Encoding memory	+ 4....
Free recall memory	+++
Verbal fluency	+++
Auditory and visual span	++
Recognition memory	++
Executive function	++

Multiple Sclerosis

Cognitive dysfunction is a significant cause of disability in patients with multiple sclerosis (MS). Estimates of the prevalence of cognitive impairment in MS range from 45% to 65%. Cognitive deficits can develop at any time during the course of the disease and can occur in the presence or absence of neurological disability. Although some research suggests that only certain domains of cognition are initially affected and that more widespread cognitive deficits emerge later in the disease, the course of cognitive impairment in MS remains controversial. Although cognitive deficits vary among patients with MS, perhaps because of the inter-individual variability in the nature of the microscopic and macroscopic pathology of MS, several patterns of impairment are evident in the literature {Table 38.12). Patients with MS who have cognitive impairmenr mosr commonly have deficits in memoty, learning, attention, speed of information processing, and verbal fluency. Deficits in conceptual thinking and problem solving, functional language abilities, and spatial reasoning have also been reported in the literature.

As mentioned earlier, memory deficits are one of the most commonly observed cognitive impairments in MS. A meta-analysis of 36 published papets on memoty impairment in MS suggested that patients had significant abnormalities in all aspects of memory functioning, Nonetheless, individual studies have focused on different aspects of the memory deficit. Early studies of memory impairmenr in MS identified rettieval deficits as being important. More recently, several studies have suggested that the memory impairment in MS results primarily from deficits in acquisition rather than recall per se. For example, although people with MS need significantly more learning trials to meet criteria on memory tasks, after a delay they recall similar amounts of information to healthy controls (Demaree et al. 2000). Other studies have suggested that deficits in working memory underlie the short-term memory deficits and verbal dysfluency observed in MS (Janculjak et al. 1999).

Slowed information processing speed among patients with MS has been observed in several studies independent of slowed sensorimotor processing. A recent study compared the neuropsychological performance of 55 inpatients with MS with that of 42 norma) controls (Janculjak et al. 2002). Findings suggested that the major cognitive deficit in MS caused by demyclination is the slowing of information processing, which was found to be related to focused attention and the simplest forms of explicit memory. The transfer of information between hemispheres has also been shown to be slow in patients with MS, and imaging studies have revealed corpus callosum atrophy in MS.

Four subtypes of MS have been defined based on an international survey of specialists: (1) relapsing-remitting, (2) secondary progressive, (3) primary progressive, and (4) progressive-relapsing courses. Primary progressive MS involves continual progression from the onset of the disorder, whereas the relapsing-remitting subtype involves initial petiods of remission that later develop into secondary progressive MS. Some studies on the neuropsychology of MS have attempted to identify differing patterns of cognirive deficits among the subtypes. For example, a study examining explicit and implicit memory found that patients with primary progressive MS exhibited a pattern of memory impairment that was distinct from that of patients

with relapsing-remitting and secondary progressive MS (Figure 38.13}.

Furthermore, a recent meta-analysis of 34 studies comparing patients with MS and healthy controls found that cognitive impairment was evident generally and that distinct patterns of neurocognitive deficits characterized chronic progressive and relapse-remitting subtypes of MS (Kakzanis 2000). Patients with chronic progressive MS presented with more frontal executive impairment, whereas patients with relapsing-remitting MS presented with more memory-related dysfunction.

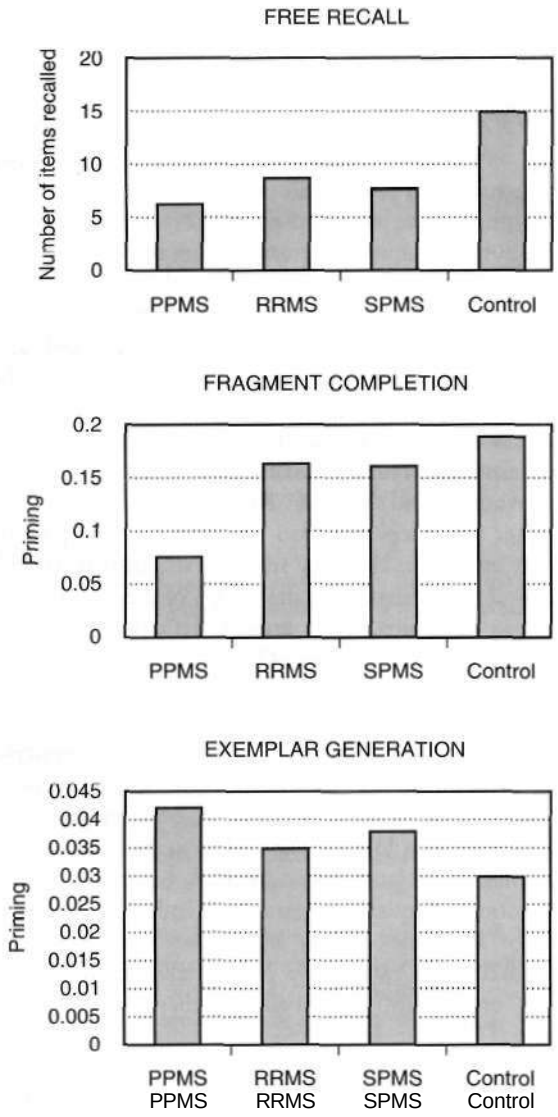

FIGURE 38.13 Free recall performance, word fragment completion priming, and exemplar generation priming in primary progressive multiple sclerosis (PPMS), relapsing-remitting multiple sclerosis (RRMS), secondary progressive multiple sclerosis (SPMS), and control subjects. (Adapted from Blum, D,, Yonelinas, A. P., Luks, T., et al. 2002, "Dissociating perceptual and conceptual implicit memory in multiple sclerosis patients," *Brain Cogn,* vol. 50, pp, 51-61.)

A meta-analysis of research on neuropsychological functioning in patients with MS over a 20-year period suggested that interhemispheric transfer, general cognitive ability, and learning and memory were more highly associated with MS than visuoperceptual, visuospatial, and visuoconstructional ability, language, and conceptual ability (Table 38.13). Effect sizes comparing MS and healthy control groups on variables grouped by neuropsychological domain were generally small to moderate. However, in contrast with many previous reports, disease subtype was not related to neuropsychological functioning,

Several studies suggest that lesion burden as measured by brain imaging, including MRI, correlate with cognitive disability. Deficits on neuropsychological measures have been correlated with lesion load, atrophy of the corpus callosum, and magnetization transfer ratio. One study that used MRI found that right and left superior frontal lobes arc the regions of the cortex most susceptible to atrophy and resulting cognitive changes in verbal and spatial learning, attention, and conceptual reasoning (Benedict et al. 2002). Another study examined 28 patients with MS and matched healthy controls using MRI and neuropsychological testing at baseline and 1-year and 4-year follow-up (Sperling et al. 2001). Results of this study suggest that MS lesions demonstrate a propensity for frontal and parietal white matter. Patients with MS showed significant impairments on tasks of sustained attention, processing speed, and verbal memory as compared with the control subjects, which was correlated with MS lesion volume in frontal and parietal regions. The authors concluded that disruption of fronto-parietal subcortical networks might underlie the observed pattern of neuropsychological impairment observed in these patients. In contrast, the authors of a study of cognition using MRI in patients with rare forms of MS (primary progressive and transitional progressive MS) observed modest correlations between MRI lesion measures and a global cognitive impairment index. They concluded that cognitive functioning in primary progressive and transitional progressive MS is multifactorial and is not adequately explained by pathology as demonstrated by conventional MRI (Camp et al. 1999). These authors suggest that advances in imaging and the development of more sensitive cognitive tests will help elucidate the pathophysiology of MS in these subtypes of the disease.

Epilepsy

An epileptic seizure, by definition, involves abnormal activity of the brain; therefore it is commonly acknowledged that the ictal period, before, during, and immediately after a seizure, is associated with cognitive changes including confusion and alterations of consciousness. However, it is important to recognize that epilepsy is also associated with interictal alterations in cognitive abilities {see Chapter 73 for a review of epilepsy).

Table 3S.13: Effect sizes of differences between patients with multiple sclerosis and control subjects

Neuropsychological domain	***k***	N	M_r *(SD)*	$r_{,r}$	$Q_{„}$
Interhemispheric transfer	*7*	798	.46 (.15)	.43*	23.8
Mood Lind psychological status	14	1157	.37 (.21)	.3-1	71.9[s]
General cognitive ability	29	3269	*36* (.20}	.33*	182.7*

Language	45	4736	.26 (.21)	.23*	S0.6*
Conceptual ability	22	2733	.22 (.13)	.23*	42.4*

k — number of effect si7.es; N = number of subjects per effect size; M_r — effect size; r_{su} — weighted *r; Q* — homogeneity statistic; Q_w — Q within.

Source: Adapted from Wish art, H. *&c* Sharpc, D. 1997, "Neuropsychological aspects of multiple sclerosis: A quantitative review," *} Clin Exp Ncuropsychol,* vol. 19, pp. 810-824.

There is no one cognitive profile associated with epilepsy, perhaps because the condition has a variety of origins and clinical manifestations. Nonetheless, a substantial body of research suggests that a range of cognitive deficits is related to epilepsy and its treatment,

One of the most often studied neuropsychological variables in epilepsy is overall intellectual functioning. The early clinical literature suggested that epilepsy was commonly associated with overall cognitive deterioration, and several recent studies have also found evidence of overall decrements in intellectual functioning in patients with epilepsy. However, other research suggests that epilepsy does not necessarily lead to overall reductions in cognitive functioning. Research examining the relationship between overall cognitive status and particular clinical characteristics has provided useful information. For example, patients with more generalized seizure activity tend to show more significant and widespread cognitive deficits, There is evidence that people with convulsive seizures have poorer cognitive functioning, whereas generalized non-convulsive and partial seizures are not associated with significant losses in overall intellect. Research on the age of onset shows that the earlier the epilepsy begins, the greater the impact on cognitive abilities. Furthermore, the longer the duration of epilepsy, the lower the patient's overall cognitive functioning. Findings regarding the relationship between the frequency of seizures and cognitive functioning have yielded mixed results. It appears that the type of seizures experienced by the patient, including their cause and whether the patient experiences status epilepticus with repeated seizures concentrated in time, may be more predictive of losses in overall cognitive functioning than seizure frequency alone. Focal seizures typically involve just one side of the brain and are more likely to show a circumscribed pattern of cognitive deficits than more generalized epilepsy. Focal seizures usually are associated with patterns of cognitive performance typically seen with damage to the area of the seizure focus in the absence of epileptic activity.

Memory dysfunction is the most commonly reported cognitive complaint associated with temporal lobe epilepsy (TLE; Ogden-F.pker and Cullum **2001).** Verbal memory deficits typically are reported to be associated with left temporal lobe epilepsy, whereas verbal memory deficits have been emphasized in association with right temporal lobe epilepsy. However, findings regarding the relationship between epilepsy and memory functioning are mixed, and some studies have not found a relationship between the laterality of TLE and material specific memory deficits. Nonetheless, there is evidence that self-reported memory is an important predictor of quality of life in patients with TLE (Giovagnoli and Avanzini 2000).

Language disorders are also associated with epilepsy. One study examined language function in 60 patients with epilepsy and found that more than 30% of the patients had language impairments, with greater deficits in receptive than in expressive abilities. The language abilities of patients with unilateral TLE were studied using a large battery of neuropsychological language tests. Results showed that patients with left temporal lobe epilepsy performed significantly worse on tests of naming, repetition, and language comprehension than patients with right temporal lobe epilepsy. The authors concluded that language problems occur in TLE generally but are more pronounced in left temporal lobe epilepsy. Deficits of the ability to name objects have also been shown to be associated with intractable mesial temporal lobe. For example, one study examined whether object-naming deficits in **TLE** were associated with semantic knowledge deficits (Bell et al. 2001; Figure 38.14). The findings suggested that patients with early-onset TLE have a semantic knowledge deficit that contributes to their confrontation naming problems.

Several studies have demonstrated that deficits in executive functioning are associated with frontal lobe epilepsy. Recently, one study compared the neuropsychological profiles of children with frontal lobe epilepsy and TLE (Culhane Shelburne et al. 2002), Children with frontal lobe

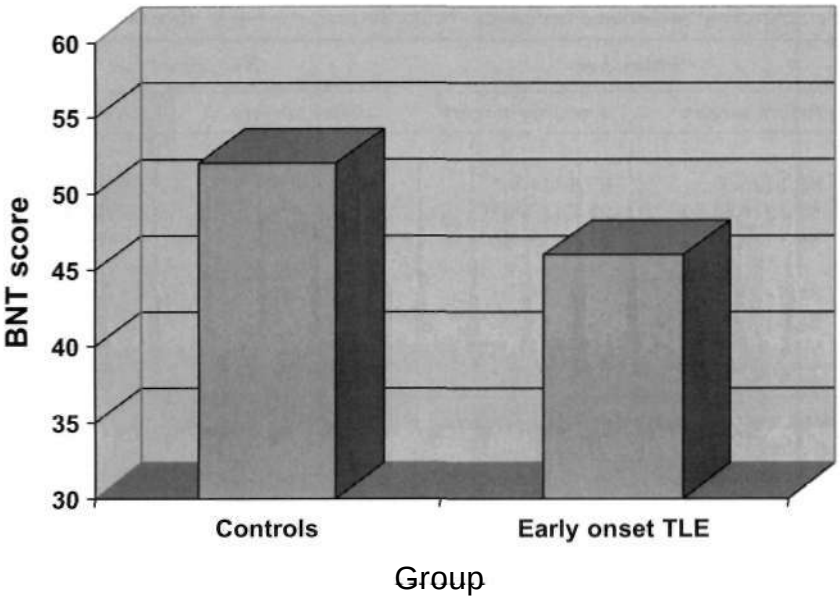

FIGURE 38.14 Boston Naming Test (BNT) results by group (temporal lobe epilepsy [TLF.| versus normal controls). (Adapted from Bell, B. D., Hermann, B. P., Woodard, A. R. 1997, "Object naming and semantic knowledge in temporal lobe epilepsy," *Neuropsychology,* vol. 15, pp. 434-443.)

epilepsy had deficits with planning and executive functions with intact verbal and nonverbal memory, whereas the children with TLE showed the opposite pattern. Another study examined children with TLE, frontal lobe epilepsy, and generalized epilepsy (Hernandez et al. 2002). Findings indicated that children with frontal lobe epilepsy had deficits in planning and impulse control and more coordination problems and motor rigidity than children in the other groups.

A complicating issue in identifying cognitive deficits associated with epilepsy is the fact that the main treatment approaches, including anticonvulsant medications and neurosurgery for intractable seizures, commonly have additional, independent effects on neuropsychological functioning. Therefore treatment must balance seizure relief with adverse side effects of the treatment.

Many patients with epilepsy remain on antiepileptic medication for years. Awareness of the potentially harmful effects of anticonvulsant medications on cognitive functioning is increasing. Many of the older anticonvulsants have been associated with adverse effects on cognition, although their specific patterns of impairments may vary. Reviews of the literature suggest that antiepileptic drugs can decrease performance on tests of motor speed, attention, memory, perceptual functions, and motor coordination. Antiepileptics can also affect cognition by increasing drowsiness and dizziness. However, there is some suggestion in the literature that newer antiepileptic medications such as oxcarbazepinc and vigabatrin have less of an impact on cognitive functioning than older drugs, although this has not been comprehensively studied (see Brunbech and Sabers 2002 for a review). Historically, several methodological problems including selection factors, statistical problems, and inappropriate use of cognitive tests complicate the research. However, it is clear that the consideration of potential side effects of antiepileptic medication is important in treatmenr and that further research as new medications arc developed will be valuable.

The surgical resection of epileptogenic brain tissue can be an effective treatment for inrractable epilepsy; however, preoperative localization of the seizure origin and assessment of cognitive abilities are essential to minimize the adverse consequences that can be associated with the surgery. Surgical resection typically is performed to treat TLE that is resistant to pharmacotherapy and is used less commonly for intractable frontal lobe epilepsy. Neuropsychological evaluation provides important information about localization of seizure onset, lateralization of important cognitive functions, and the risks of surgery to essential psychological functions such as language and memory. Neuropsychological assessment also provides information about psychosocial and cognitive changes after surgery.

The most common neuropsychological finding after surgical resection is a decline in verbal memory after dominant temporal lobe resection and deficits in visual memory after nondominant temporal lobe resection. However, some research suggests that the neuropsychological performance of many patients improves after surgical treatment for TLE. Postoperative improvement appears to be influenced by the reduction in the frequency of seizures after surgery (Wachi et al. 2001; Table 38.14). Engman et al. (2001) found significant variability between individuals in their postoperative cognitive change. The authors point to the importance of considering interindividual and ultraindividual variability. Several factors have been shown to be associated with favorable postoperative outcomes, including interictal electroencephalographic localization to the operated lobe and the absence of secondarily generalized seizures.

Table 38.14: Neuropsychological results of seizure-free and not-seizure-free groups before surgery and 1 year after surgery

	Seizure free		*Not seizure free*	
Test	*Before surgery*	*1 yr after surgery*	*Before surgery*	*1 yr after surgery*
Wechsler Adult Intelligence Scale-Revised				
Verbal IQ	86.1 (15.3)	87.8 (14.8)*	83.4 (10.9)	82.8 (13.3)
Performance IQ	89.2(16.8)	98.7(17.8)**	88.6(14.9)	89.7(18.0)
Full-Scale IQ	86.3(15.9)	91.4(15.4)**	84.1(12.5)	84.1(16.2)
Wechsler Memory Scale-Revised				
Verbal	81.4 (14.7)	91.3 (14.9)**	80.4 (17.3)	88.4 (20.6)
General	88.6 (16.3)	96.1 (18.2)**	85.9 (11.2)	92.0(18.0)
Delayed Paired Associates	90.6 (17.7)	103.7 (17.7)**	89.9 (11.0)	97.7 (18.3)
Raven Progressive Matrices	32.6(3.7)	34.3(2.3)**	32.8(2.4)	34.2 (1.9)[1]

Human Immunodeficiency Virus

Overall estimates of the number of people infected with human immunodeficiency virus (HIV) who experience neurocognitive complications of infection range from approximately 30% to 50%. Neuropsychological impairment in HIV-infected patients can be classified into three subgroups (Grant et al. 1999). Patients with subsyndromic neuropsychological impairment show deficits in at least two neuropsychological domains with no evidence of functional impairment. A second ncurobehavioral disorder in HIV has been called mild neurocognitive disorder or minor cognitive/motor disorder and involves deficits in at least two ability domains, confirmed by neuropsychological testing, and impairment sufficient to affect the patient's daily functioning. The most severe neurocognitive manifestation of infection is HIV-1-associated dementia, which is characterized by moderate to severe cognitive and psychomotor slowing, impaired concentration and attention, memory disturbances, and often motor incoordination and weakness.

The neuropsychological profile of patients with HIV, particularly in the later stages of the disease, has been associated with the deficits seen in subcortical dementias (e.g., Huntington's disease), including slowed information processing, reduced fluency, impaired motor skills, and impaired free recall of recently learned information. Indeed, there is evidence that the greatest brain abnormalities occur in subcortical structures and white matter regions. However, the neuropsychological deficits observed in HIV can vary greatly across individuals. Cognitive impairment can be associated with the direct effects of HIV infection or secondary complications, including those resulting from immunodeficiency (e.g., opportunistic infections) and the treatment of the disease.

Although the majority of studies provide evidence of neuropsychological impairments in a subset of patients in the later stages of HIV infection, the prevalence of cognitive symptoms early in the course of HIV infection is more controversial. A meta-analysis of 41 studies examining the neuropsychological sequelae of HIV infection found that cognitive deficits in the early stages of HIV are small and increase in the later phases of the illness (Reger et al. 2002). Overall, the authors concluded that the cognitive decline with disease progression resembled a subcortical pattern; the greatest declines were in motor functioning, executive skills, and information-processing speed.

A literature review of 57 articles on neuropsychological functioning in asymptomatic HIV-infected patients points to inconsistencies in the literature (White et al. 1995). Thirty-two percent of the studies reported increased neuropsychological impairment in HIV-positive subjects, 21% had equivocal results, and 47% found no significant differences in neuropsychological functioning between HIV-infected subjects and seronegative controls. Interestingly, the authors of the review article found that the comprehensiveness of the neuropsychological battery used in the studies was strongly associated with the likelihood of finding group differences, underscoring the importance of a comprehensive assessment approach. The domains of neuropsychological functioning that were most often impaired were attention and speed of information processing, learning, verbal abilities, and motor functioning.

Researchers at the San Diego HIV Neurobehavioral Research Center (HNRC) have been longitudinally assessing the neurocognitive functioning of over 500 HIV-positive men. Findings ftom this group suggest that asymptomatic HIV-positive men have twice the rate of neuropsychological impairment of HIV-negative control subjects and that cognitive impairment increases with disease progression (Figure 38.15). Neuropsychological impairment was found to be more prevalent in later stages of infection, and when it occurred, it affected more cognitive domains than in the asymptomatic stage. Additional research from the HNRC group suggests that

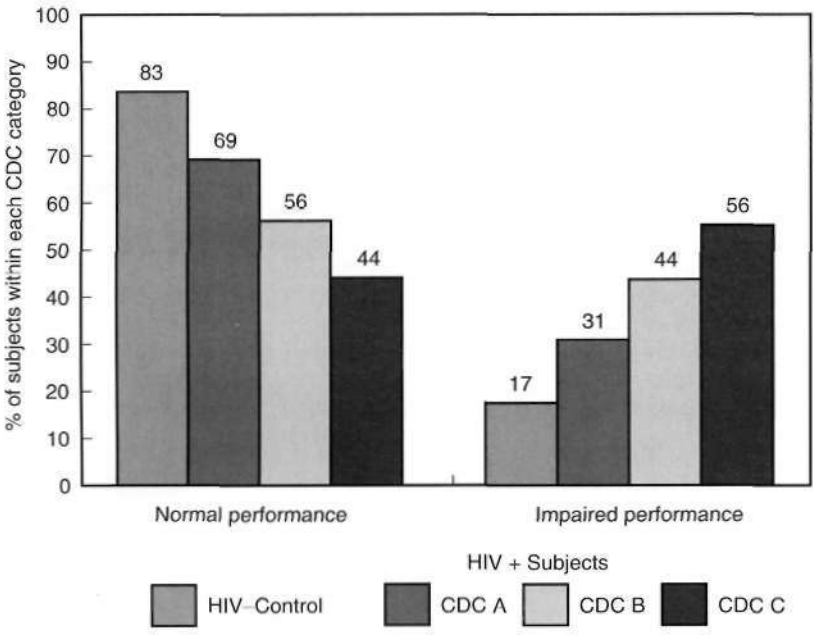

FIGURE 38.15 Clinical rating scores for patients with human immunodeficiency virus (HIV) grouped according to U.S. Centers for Disease Control (CDC) category. Categories **A**, **B**, and **C** refer to clinical levels of HIV infection: asymptomatic, minor symptoms, and AIDS-defining conditions, respectively. (From Kelly, M. D., Grant, I., Heaton, R. K., et al. 1996, "Neuropsychological findings in HIV infection and AIDS," in *Neuropsychological Assessment of Neuropsychiatric Disorders*, eds Grant and Adams, Oxford University Press, New York.)

attention and learning arc the areas impaired in the greatest proportion of HIV-positive men, a finding that is consistent with previous research (Figure 38.16).

Traumatic Brain Injury

Traumatic brain injury (TBI) is one of the most common forms of acquired neurological damage in the United States, particularly in young adults. Cognitive deficits after injury are common. In cases of moderate to severe injury, where head trauma is sufficient to cause loss of consciousness and post-traumatic amnesia, impairment in several cognitive domains including attention, memory, communication skills, and executive functioning may occur. Although more controversial, in some cases mild head injury can also produce alterations in cognitive status (see van der Naalt 2001 for a review of recovery after mild to moderate TBI).

The psychological consequences of injury depend on how the injury occurred, the severity of the injury, the site of the lesion, premorbid personality, and the treatment received after the injury. Therefore the range of deficits that can result from brain injury vary significantly. Brain damage after trauma may involves penetrating or closed injuries, and consequences of both the primary injury and secondary effects influence the clinical presentation. The fact that

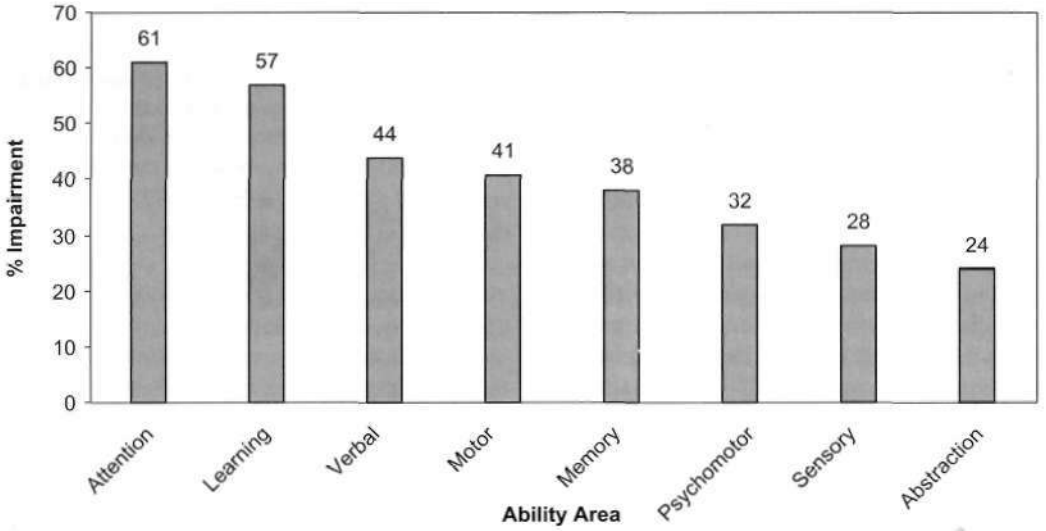

FIGURE 38.16 Prevalence of deficits in each ability area for human immunodeficiency virus–positive subjects rated as neuropsychologically impaired. (Adapted from Heaton, R. K., Grant, I., Butters, N., et al. 1995, "The HNRC 500: Neuropsychology of HIV infection at different disease stages," *J Int Neuropsychol Soc*, vol. 1, pp. 231-251.)

Table 38.15: Common neurocognitive sequelae of moderate to severe traumatic brain injury

Cognitive domain	*Clinical manifestation of the impairment*
Attention	Difficulty with sustained attention
	Poor concentration
	Psychomotor impersistence
Memory	Problems with acquiring and retaining new verbal or nonverbal information
	Problems in retrieving verbal and nonverbal memories
Speed of information processing	Slowed sensorimotor skills and information processing
Executive functioning	Problems in convergent and divergent reasoning
	Poor judgment
	Difficulty planning
	Problems in self-monitoring and self-correcting behavior
Awareness of symptoms	Difficulty recognizing deficits
	Unrealistic expectations concerning the recovery of functions
	Problems related to poor treatment compliance
Language and communication	Problems in word comprehension
	Impaired reading, spelling, and writing ability
	Tendency to become fragmented in free speech
Impaired integrative functions	Problems in adequate or time efficient execution of various pcrccptual-motor-spatial-sequential tasks

brain injury often involves both focal injuries to the brain and diffuse damage (e.g., shearing effects and edema} contributes to variability in the presentation of cognitive impairment.

Despite individual clinical variability, several common neurobehavioral sequelae of moderate to severe TBI can be identified (Table 38.15).

For example, damage to the orbital and polar aspects of the frontal lobe and the temporal poles is likely to result from head trauma given the anatomy of the skull (e.g., orbital plate of the frontal bone and sphenoidal ridge). These injuries can be associated with executive dysfunction and memory deficits.

Immediately after injury, patients may experience loss of consciousness and post-traumatic amnesia. Early recovery is characterized by resumption of basic attentional processes and a return of speech. Patients may go through a period nt confusion during which they confabulate and tail to retrieve new, and often remote, memories. Although attention gradually improves, mental slowness with decreased information-processing speed often persists. Patients may complain of confusion, inability to think clearly, and disorientation. They tend to be distractiblc and unable to maintain focused attention.

After the acute confusional state and post-traumatic amnesia ends, the most common cognitive deficits that persist include disturbances of memory, attention, language, and executive dysfunction. Memory disturbance is one of the most common complaints of patients after TBI and is related to the severity of TBI and the diffuse nature of the injuty. Patients may show problems with acquisition and retention of new verbal and nonverbal information and problems with retrieval. Retrograde memory deficits, for events occurring before the injury, often show a memory gradient so that the most temporally proximate events are the most likely to be forgotten.

After frontal lobe damage, deficits in judgment, planning, organizing and sequencing, concept formation, set shifting, self-monitoring, and self-correcting behavior may occur. The sequelae of moderate to severe traumatic brain injury can also include disturbances in the balance between excitatory and inhibitory processes including impulse control problems, reduced stamina or energy levels, and lowered tolerance for frustration and irritability. Inadequate awareness of deficits may be present such that the patient has difficulty assessing the severity of his or her deficirs, sometimes leading to unrealistic expectations for recovery and poor treatment compliance.

Chapter 39
Neuro-Ophthalmology: Ocular Motor System

Patrick J. M. Lavin and Sean P. Donahue

Neuro-ophthalmology bridges the disciplines of ophthalmology and neurology. Despite sophisticated technological advances in neuroimaging, competence in neuro-ophthalmological diagnosis still requires basic clinical skills. These include attentive listening; timely, probing questions; knowledge of neuroanatomy and of disorders that affect the afferent and efferent visual pathways; skill in examination of the visual system and the cranial nerves; and experience and expertise in evaluating supplementary investigations, including perimetry, fluorescein angiography, and neuroimaging. Often, a thorough clinical examination and careful thought preempt uncomfortable, invasive, and expensive procedures. The old adage "ears and eyes first and most, hands least and last," still holds true.

This chapter discusses central control mechanisms and disorders of the ocular motor system. Diplopia, nystagmus, and other ocular oscillations are discussed in Chapter 16, and disorders of the ocular motor nerves are discussed in Chapter *76.*

GENERATION AND CONTROL OF EYE MOVEMENTS

A reasonable understanding and interpretation of gaze disorders require an appreciation of the anatomy and physiology of eye movement control. In the words of Hughlmgs Jackson, "The study of the cause of things must be preceded by the study of things caused."

Normal visual behavior is accomplished by a continuous cycle of visual fixation and visual analysis interrupted by saccades (Schall and Thompson 1999). Individuals with intact sensory visual systems (optical and afferent) are capable of discerning small details, comparable to Snellen acuity of 20/13, provided the fovea is maintained on target. However, 10 degrees from fixation, the resolving power of the retina drops to 20/200. Although the peripheral retina has poor spatial resolution capabilities, it is exquisitely sensitive to movement (temporal resolution). The image of an object entering the peripheral visual field stimulates the retina to signal the ocular motor system to make a rapid eye movement (saccade) and fixate it on the fovea: In the words of the American psychologist, William James "The peripheral retina is like a sentinel and when an object of regard falls upon it, it shouts 'hark, who goes there' and calls the fovea to the spot," Visual information concerning spatial resolution (fine detail) and color travels via retinal ganglion (P) cells to the parvocellular layers of the lateral geniculate nucleus (LGN), whereas information concerning temporal resolution (movement) travels via retinal ganglion (M) cells to the magnocellular layer of the LGN. In turn, neurons in the LGN project via the optic radiations to the primary visual area (VI), the striate cortex (area 17). Visual processing in the cortex begins in the primary visual area from which issues two processing streams (Figure 39.1A). One stream (ventral), responsible for form and object recognition and emphasizing foveal representation, projects to the temporal lobe via occipital areas V2 and V4. The second stream (dorsal), responsible for movement recognition, guiding actions in space, and emphasizing peripheral visual field representation, projects to the prestriate cortex. It then relays to the superior temporal sulcus region, which contains cortical areas MT (middle temporal) and MST (middle superior temporal) in monkeys, roughly equivalent

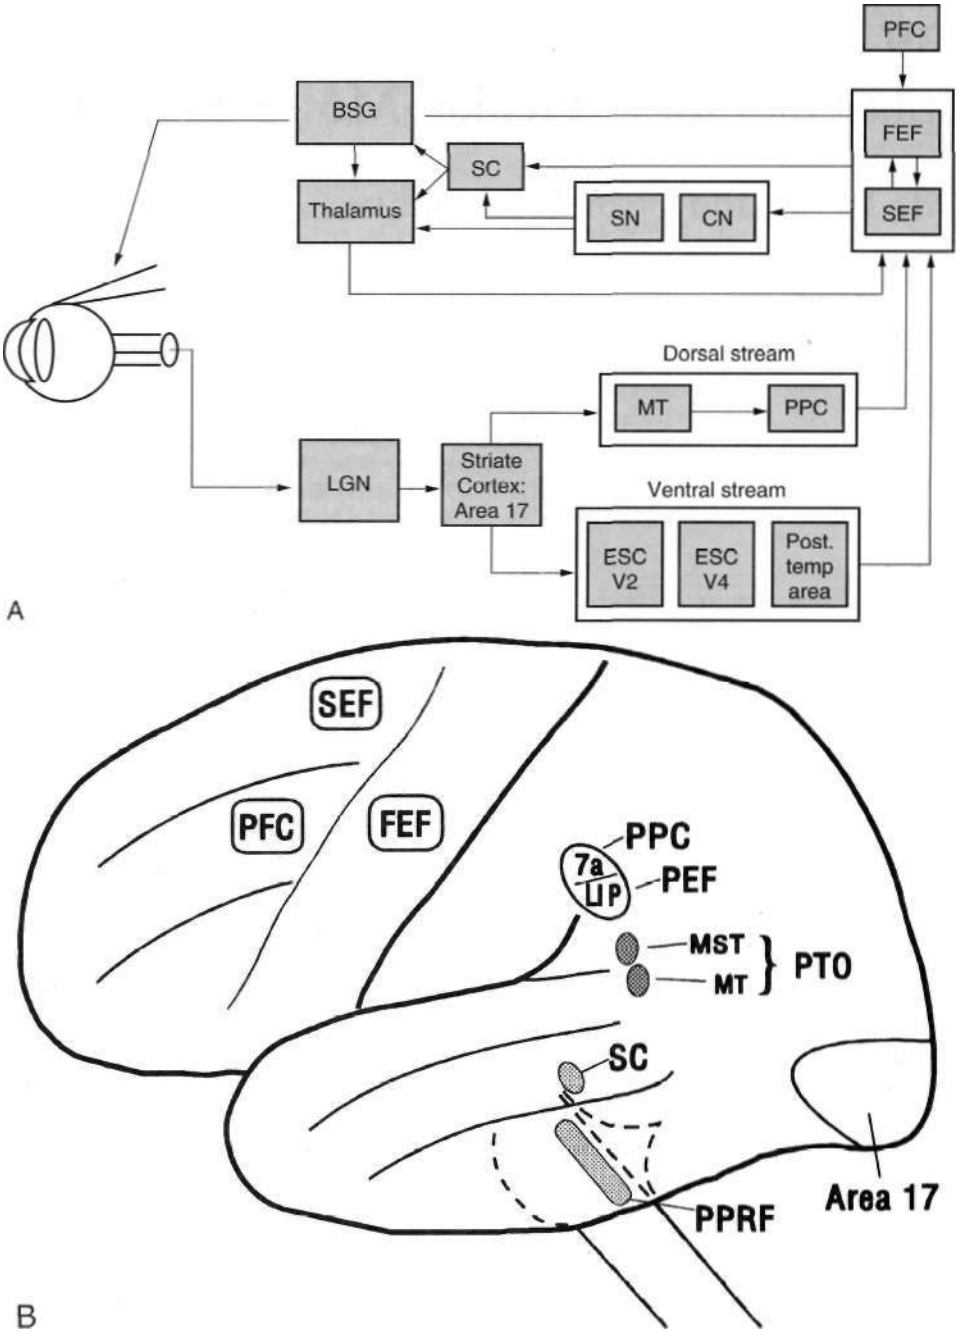

FIGURE 39.1 (A) Overview of the visuo-ocular motor system, (Redrawn from Sruphorn and Schall 2002.) (B) Areas in the human brain that are believed to be important in generating saccades and pursuit. BSG = brainstem saccadic generator; CN = caudate nucleus; ESC = extra striate cortex; FFF = frontal eye field; LGN = lateral geniculate nucleus; IJP = lateral intraparietal area; MST —medial superior temporal visual area; MT = middle temporal visual area; PEF = parietal eye field; PFC = prefrontal cortex; PPC = posterior parietal cortex area; PPRF = paramedian pontine reticular formation; PTO = pa rie to-tempore-occipital junction; SC = superior colliculus; SEF = supplementary eye fields in the supplementary motor area; 7a = area 7a; SN = substantia nigra.

to the parieto-temporo-occipital junction (PTO) in humans, and encodes for location, direction, and velocity of objects. Both streams converge on the FEF (frontal eye field) and are involved in controlling saccades (see later).

The prcmotor substrates for conjugate gaze and vergence eye movements are in the brainstem. The substrates specific for vertical gaze, vergence, and ocular counter-rolling are in the mesodiencephalic region, whereas those for horizontal eye movements are mainly in the pons. The mechanisms for horizontal eye movements are better understood than those for vertical eye movements and are based on clinicoparhological and radiological correlation as well as animal and bioengi nee ring experiments. With the exception of reflexive movements, such as the

vestibulo-ocular reflex (VOR) and fast phases of nystagmus, cerebral structures determine *when* and *where* the eyes move, whereas brainstem mechanisms determine *how* they move: in other words, voluntary eye movements are generated in the brainstem, but are triggered by the cerebral cortex.

Ocular Motor Subsystems

Six ocular motor subsystems enable the fovea to find and fixate a target, stabilize an image of the target on each retina, and maintain binocular foveation during head or target movement, or both. The saccadic system moves the eyes rapidly (up to 800 degrees per second) to fixate new targets (Figure 39.2A). Saccades may be generated voluntarily or in response to verbal commands in the absence of a visible target. Reflex saccades may occur in response to peripheral retinal stimuli, such as visual threat or retinal error signals, or to sound. Saccades are also the fast components of nystagmus.

The pursuit system enables the eyes to track slowly moving targets (up ro 70 degrees per second) to maintain the image stable on the fovea. Specially trained subjects are capable of smooth pursuit eye movements as fast as 100 degrees per second. Pursuit eye movements are limited more by the target's acceleration than by its velocity. If the target moves too quickly or abruptly changes direction, or if the pursuit system is impaired, the eyes are unable to maintain pace with the target and fall behind. Consequently, the image moves off the fovea, producing a retinal error signal that provokes the saccadic system to make a catch-up saccade to refixate the target. The cycle then repeats itself, resulting in saccadic ("cogwheel") pursuit (see Figure 39.2B).

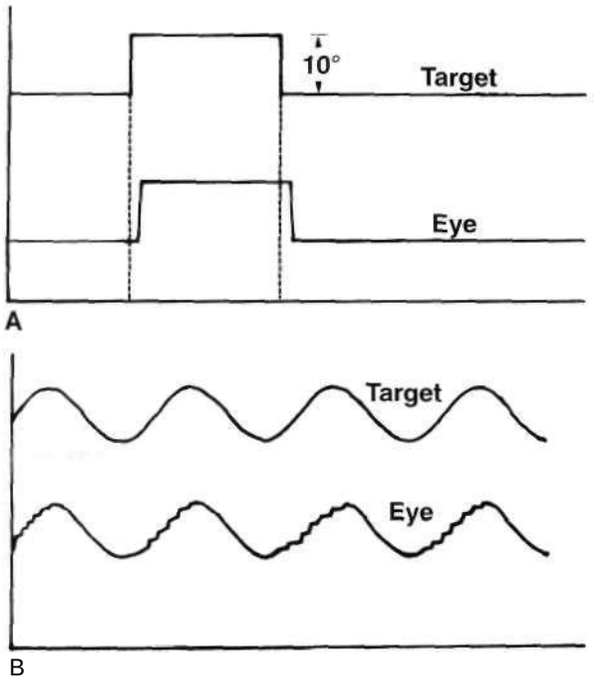

FIGURE 39.2 Simulated eye movement recordings, By convention for horizontal movements, upward deflections represent rightward eye movements, and downward deflections represent leftward eye movements. (A) Saccades. A target moves rapidly 10 degrees to the right. After a latency of about 200 ms, the eye follows. When the target returns to the center, the sequence is repeated in the opposite direction. (B) Pursuit. The target moves in a sinusoidal pattern in front of the patient. The eye follows the target after a latency of about 120 ms, but pursuit movements to the right are defective, resulting in the rightward "cogwheel" (saccadic) pursuit. Pursuit to the left is normal.

Bidircctionally defective pursuit eye movements, a normal finding in infants, are nonspecific and occur under conditions of stress or fatigue, or with sedative medication. Impaired tracking in one direction, however, suggests a structural lesion of the ipsi lateral pursuit system (see Figure 39.2B).

Fixation allows the eyes to maintain an image of a stationary target on each fovea at rest. The fixation subsystem shares neural circuitry with the optokinetic (OKN) and pursuit systems (Leigh and Zee 1999).

The vestibular eye movement subsystem maintains a stable image on the retina during head movements. The semicircular canals respond to rotational acceleration of the head by driving the VOR to maintain the eyes in the same direction in space during head movements. The otoliths (utricle and saccule} are gravity receptors that respond to linear acceleration and static head tilt (gravity), that is, with ocular counter-rolling. The vestibular system is discussed further in Chapter 41.

The optokinetic system uses visual reference points in the environment to maintain orientation. It complements the vestibulo-ocular system, which becomes less responsive during slow or sustained head movements, to stabilize images on the retina in situations such as spinning. When the eyes reach their limit of movement in the orbits, a reflex saccade allows refixation to a point further forward in the direction of bead rotation. The sequence repeats itself, resulting in OKN (see Chapter 16).

In humans, the optokinetic system responds predominantly to fixation and pursuit of a moving target (immediate component), and to a lesser extent velocity storage (delayed component), which involves neural circuitry in the vestibular system. (Velocity storage is a mechanism by which the central nervous system, predominantly the vestibular system including the vestibulo-eerebellum, prolongs or perseverates short signals generated by the vestibular end-organ to enhance orientation in space. Velocity storage is largely involuntary.)

The vergence system enables the eyes to move disconjugarely (converge and diverge) in the horizontal plane to maintain binocular fixation on a rarget moving toward or away from the Subject. Vergence movements are essential for binocular single vision and stereoscopic depth perception.

The different types of eye movements are listed in Table 39.1.

Horizontal Eye Movements

When gaze is redirected from one point to another, a saccade moves the eyes conjugatcly. To enable the small, strap-like extraocular muscles to move the relatively large globes and overcome the elastic recoil of the viscous orbital contents, the yoked agonist muscles require a surge or hurst of innervation (pulse) at the same time their yoked antagonists are reciprocally inhibited (Figure 39.3A). For a leftward saccade, rhe left lateral rectus and the right medial rectus muscles each receive a pulse of innervation while their antagonists, the left medial and right lateral rectus muscles, are reciprocally inhibited. Excitatory burst neurons (EBNs) contained in the ipsilateral paramedian pontine reticular formation (PPRF), just rostral to the abducens nucleus, generate the pulse to initiate the saccade. The EBNs are medium- lead hurst cells that discharge about 10 ms before, and during, all horizontal saccadic eye movements; they preferentially discharge for ipsilateral saccades and create the immediate premotor command generating pulse activity for saccades.

About half the neurons in the abducens nucleus are interneurons (with different morphological and pharmacological features than the neurons of the abducens nerve) that relay, via the medial longitudinal fasciculus

Tabic 39.1: Types of eye movements

A. Saccades (moving eyes from one target to another)
- Intentional saccades (internally triggered, with a goal)
  - Visually guided saccades
  - Memory-guided saccades (with visual/vestibular input)
  - Predictive saccades
  - Target-searching saccades
  - Antisaccades"'
- Reflexive saccades (externally triggered)
  - Visually guided saccades
  - Auditory saccades
- Spontaneous saccades (internally triggered, without a goal)
  - During another motor activity
  - At rest
  - When sleeping
- Quick phases of nystagmus
  - Physiological nystagmus
    - Vestibular nystagmus
    - Optokinetic nystagmus
  - End-point nystagmus
  - Pathological nystagmus (see Chapter 16)

B. Eye movements stabilizing the image of the target on the fovea
- Smooth pursuit
  - Eoveal pursuit
  - Full-Held pursuit (slow phase of optokinetic nystagmus)
- Vesti bu I o-ocular reflex (horizontal, vertical, torsional)
- Convergence

C. Ocular oscillations that may interfere with vision
- Double saccadic pulses
- Macrosaccadic oscillations
- Ocular bobbing
- Ocular dysmetria
  - Ocular hypometria
  - Ocular by per m err ia
  - Ocular lateropnlsioii
  - Ocular torsi pulsion
- Ocular flutter
- Ocular neuromyotonia
- Ocular tics (myoclonic jerks)
- Oculogyric crisis
- Opsoclonus
- Saccadic pulses
- Square wave pulses (previously designated macrosquare wave jerks)
- Square wave jerks
- Superior oblique myokymia
- Torsional saccades (blips)

* Antisaccades are fast eye movements deliberately made away from a new target. It is a laboratory procedure used to investigate frontal lobe or cognitive function.

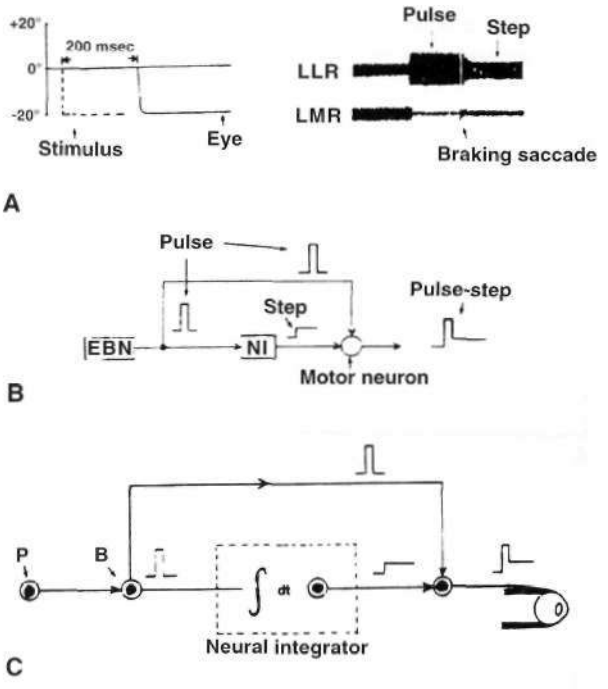

FIGURE 39,3 Ocular motor events on gaze left. (A) After the appearance of a stimulus 20 degrees to the left of fixation (-20 degrees), the eyes move to the target with a saccade after a latency of 200 ms. Idealized electromyography of the left extraocular muscles shows the activity of the agonist (the left lateral rectus [LLR|), and the antagonist (the left medial rectus |I.MR] muscles). (B) The pulse originates in the excitatory burst neurons (EBNs) and is mathematically integrated by the neural integrator (NI); both signals are added to produce the pulse-step of the innervation to the ocular motor neurons. (C) The pause cells (P) discharge continuously, suppressing the hurst cells (B), except during a saccade, when they "pause," allowing the burst cells to discharge and generate a pulse. (Reprinted with permission from P. j. M. Lavin. 1985, "Conjugate and disconjugate eye movements," in *Neitro-opbthaimofoxy: Clinical signs and symptoms,* ed T. J. Walsh, Lea &c Febiger, Philadelphia.)

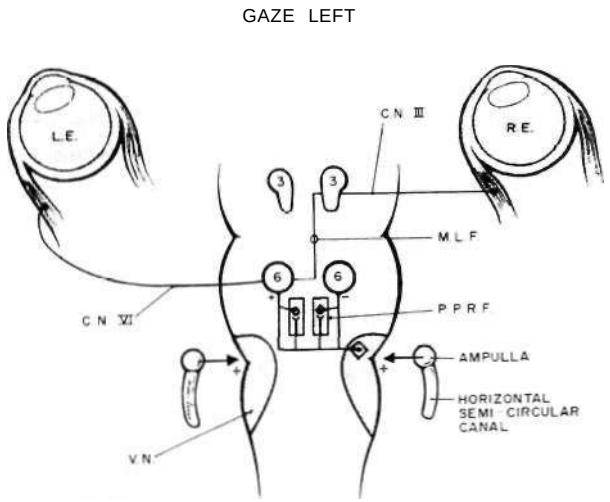

FIGURE 39.4 A lateral head turn induces movement of the cndolymph, in the ipsilatcral horizontal semicircular canal, toward the ampulla (as would warm water caloric stimulation of an ear), and thus excites the contralateral abducens nucleus and inhibits the ipsilateral abducens nucleus via the vestibular nuclei (VN). Each abducens nucleus innervates the ipsilateral lateral rectus muscle via the abducens nerve and the contralateral medial rectus muscle via the abducens nucleus inremeurons, the medial longitudinal fasciculus (MLF), and the neurons for the medial rectus (part of cranial nerve [CN] ill nucleus). Neurons in each paramedian pontine reticular formation (PPRF) also have an excitatory input to the ipsilateral abducens nucleus and an inhibitory input to the contralateral abducens nucleus, for saccades and quick phases of nystagmus, (LE = left eye; RE = right eye. (Adapted from Lavin, P. J. M. 1985, "Conjugate and disconjugate eye movements," in *Neuro-opbtbalmvlogy; Clinical signs and symptoms,* cd T. j. Walsh, Lea *Sc* Febiger, Philadelphia.)

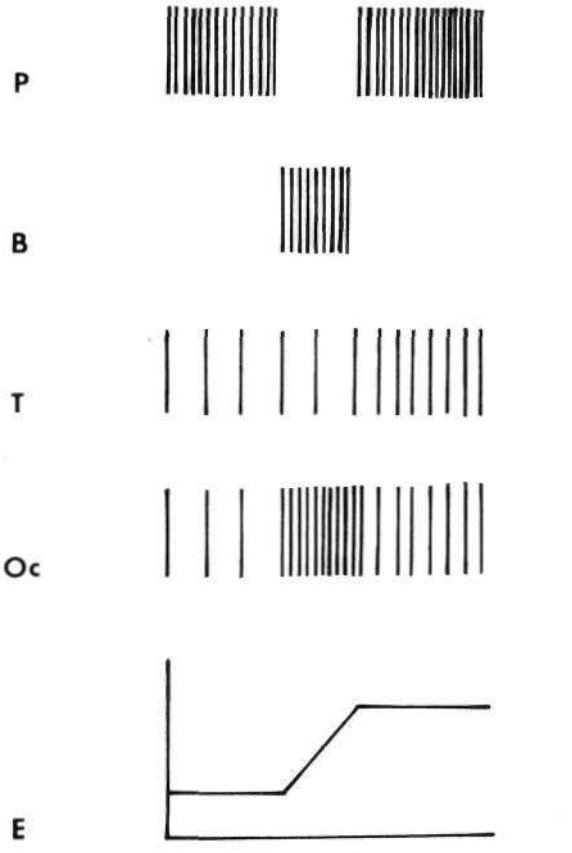

FIGURE 39.5 Electrophysiological events during an eye movement. P represents an intraneuronal recording from a pause cell and demonstrates a constant discharge, which ceases, allowing an excitatory burst neuron (iJ) to discharge during pulse. T represents the discharge in a tonic neuron, which increases after the pulse as a result of integration of the pulse to a step. Both the pulse *[P)* and the tonic output (T) of burst-tonic neurons inncrvare the ocularmoror neurons *(Oc).* The rcsuir is a rapid contraction of the extraocular muscle, which moves the eye from primary position and holds it in an eccentric position (£).

(MLF), to the contralateral medial rectus neurons in the oculomotor nuclear complex (Figure 39.4). The KBNs are tonically suppressed, except just before and during a saccade, by pause cells located in the nucleus raphe inter - positus rostral to the abducens nucleus. Thus the pause cells, which receive input ftom the cerebrum, cerebellum, and superior colliculus (SC), mediate the command for a saccade when they cease discharging and allow the burst cells to fire (Figure 39.5). At the same time the EBNs discharge, a group of inhibitory cell-burst neurons that lie caudal to the abducens nucleus in the medial rostral medulla and project across the midline to the contralateral abducens nucleus, discharge during the saccade to reciprocally inhibit the yoked antagonist muscles (Leigh and Zee 1999).

To maintain the eyes on target in an eccentric position at the end of a saccade, the agonist muscles for a leftward movement (left lateral and right medial recti) now require a new level of tonic innervation—a position command—achieved by a gtoup of neurons referred to as the *neural integrator* (NI). (An integrator converts phasic input to tonic output, mathematically, by using reverberating collateral circuits to rc-excite neurons. The efficiency of an integrator depends on its time constant, that is, the duration it can prolong the activity of the input. The effective time constant is the period necessary for the output to decay to 37% of its initial value after the input signal stops.)

The NI for horizontal gaze, thought to be partly in the rostral perihypoglossal nuclear complex and the adjacent rostral medial vestibular nucleus {Leigh and Zee 1999), receives the velocity command signal (pulse) from the EBNs. The NI then mathematically integrates the pulse to a "tonic" position command (step) before relaying it to the ipsilateral abducens nucleus (see Figures 39.3B and 39,4).

The cerebellum and the PPRF maintain the output of this NI by controlling the gain, via a positive feedback loop, to keep the eyes on target (Figure 39.6). The gain of a system is the ratio of its output to its input. In this case, the output is the innervation required to maintain eccentric fixation, and the input is the pulse signal (see Figure 39.3C). If the NI is unable to maintain the gain at unity (output/input = 1),

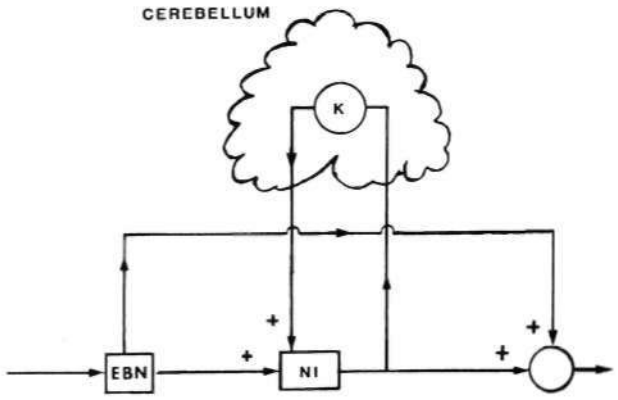

FIGURE 39.6 The time constant of the brainstem neural integrator (Nf), and therefore the fidelity of its output (innervation for gaze holding), is controlled predominantly by the cerebellum. Dysfunction of the gain control *(K)* may cause the integrator output to fall (a shortened time constant causes the signal to decay), allowing the eyes to drift back toward primary position. Conversely, an increase in K may result in an unstable integrator and Cause the eye to drift eccentrically with an increasing velocity waveform. EBN = excitatory burst neuron. (Adapted from Lavin, P.J. M. 1985, "Conjugate and disconjugate eye movements," in *Neuro-ophtbalmology: Clinical signs and symptoms,* eds T. J. Walsh, Lea *&c* Fchigcr, Philadelphia. Reprinted by permission of the author and the publisher.)

the output falls, causing the eyes to drift off target toward primary position. A corrective saccade then refixates the target, resulting in gaze-evoked (gaze-paretic) nystagmus (see Chapter 16). Current evidence suggests that all conjugate eye-movement commands, including saccades, pursuit, the slow phases of OKN, and the VOR, are initiated as velocity commands and mediated by a final common integrator (Figure 39.7),

Although its anatomical borders are not clear, the PPRF is defined functionally with the medial aspects of the nuclei gigantoeellularis, or pontis centralis oralis and caudalis, and is located just ventral and lateral to the MLF, extending from the level of the abducens nucleus almost to the trochlear nucleus. The PPRF innervates the ipsilateral abducens nucleus, the rostral medulla (part of the NI),

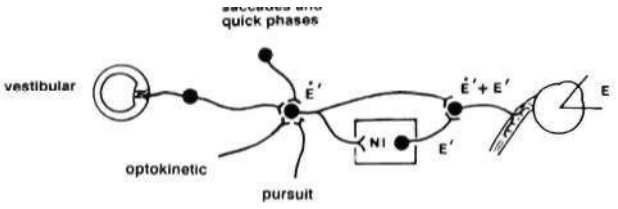

FIGURE 39.7 The final common integrator hypothesis. All conjugate eye movements (£) are initiated as eye, velocity commands (£') that are converted to eye position *(E)* by the neural integrator (N/). Both eye velocity and eye position commands arc relayed to the motor neurons, (Adapted from Cannon, S. C. & Zee, D. S. 1988, "The neural integrator of the oculomotor system," in *Current Neuro-ophthalmalogy,* eds S. Lessell & J. T W. van Dalen, Year Book, Chicago.)

and the midbrain reticular formation (MRF) to coordinate horizontal and vertical eye movements. The PPRF receives direct input from the medial vestibular nucleus, the contralateral frontal eye fields (FEFs), the ipsilateral posterior parietal region, the SC, and the cerebellum.

A lesion of the abducens nucleus produces paralysis of all ipsilateral versional eye movements. Pontine lesions outside the abducens nucleus may selectively involve certain classes of eye movements while sparing others, demonstrating that the neural signals encoding subclasses of eye movements (e.g., saccades, pursuit, VOR, tonic position) project independently to the abducens nucleus (Halmagyi 1994). The PPRF also plays a role in generating vertical eye movements; acute bilateral injury may cause a transient vertical and horizontal gaze palsy. A unilateral lesion, in addition to impairing ipsilateral horizontal saccades, may also cause slowing and oblique misdirection of vertical saccades away from the side of injury (Johnston et al. 1993). With rare exceptions (Miller et al. 2002), lesions of the abducens nucleus that cause an acquired ipsilateral gaze palsy almost always involve the facia! nerve fasciculus as it loops around the abducens nucleus, and result in an associated facial nerve palsy.

The vestibular system stabilizes the direction of gaze during head movements by virtue of changes in its tonic input to the ocular motor nuclei. This is most clearly illustrated by the horizontal VOR (see Figure 39.4). Each horizontal semicircular canal innervates the ipsilateral medial vestibular nucleus to inhibit the ipsilateral and excite the contralateral abducens nucleus. The ampulla of the right horizontal semicircular canal is stimulated by turning the head to the right (or warm caloric stimulation). This mechanical information is transduced by the vestibular end organ to electrical signals and transmitted to the ipsilateral vestibular nucleus. Excitatory information is then relayed to the contralateral abducens nucleus, and inhibitory information to the ipsilateral abducens nucleus, causing the eyes to deviate in the direction opposite to head rotation, thus maintaining the direction of gaze.

Saccades (sec Tabic 39.1), or fast eye movements, are iniriated mainly in the contralateral frontal lobe and may be classified into four broad groups:

1. Internally triggered saccades, which are voluntary (intentional) and include target-searching, memory-guided, predictive (where the appearance of the target is anticipated), intentional visually guided saccades to an existing target in the peripheral visual field, and antisaccades.
2. Externally triggered saccades are reflexively activated by the appearance of a new target or a sound.
3. Spontaneous saccades, which occur in the absence of a target and are triggered internally, by both the FEF and the SC, to repetitively scan the environment; they occur at rest, during other motor activities, and during rapid-eye-movemenr sleep.

4. The quick phases of nystagmus (see Chapter 16).

A number of specialized areas in the cerebral cortex, identified by both experimental and pathologic lesions, and by neurophysiological studies, particularly in monkeys, and by transcranial magnetic stimulation, play a major role in controlling saccades (see Figure 39.IB):

1. The FEF, in the prcccntral gyrus and sulcus (Brodmann's area 6 in humans, and area 8 in monkeys).
2. The supplementary eye field (SEF) on rhe dorsomedial aspect of rhe superior frontal gyrus is anterior to the supplementary motor area.
3. The parietal eye field (PEF), in the lateral intraparietal area (LIP) in monkeys, is equivalent to an area in the intraparietal sulcus near the angular gyrus region (Brodmann's areas 39 and 40) in humans.

Other cortical areas that have a role in controlling saccades include the posterior parietal cortex (PPC), located in Brodmann's area 39 in the upper angular gyrus in humans, equivalent to 7a in monkeys; the prefrontal cortex (PFC), area 46; the vestibular cortex in the posterior aspect of the superior temporal gyrus; and the hippocampus in the medial temporal lobe (Pierrot-Dcscilligny et al. 1995). These cortical areas, and the superior colliculus, are parts of a network that collectively produce saccades and determine when different types of saccades occur and where they go; that is, they calculate their direction and amplitude (accuracy). In summary, this network determines where potential targets for orienting are located; where, whether, and when gaze will shift; and coordinates saccades with visually guided reaching and head movement-,.

The FEF is heavily interconnected, topographically, with areas in both the dorsal and ventral streams of the extrastriate visual cortex (see Figure 39.1A) and participates in the transformation of visual signals into saccadic motor commands (Schall et al. 1995). Being extensively connected with extrastriate visual cortical areas, many neurons in the FEF respond to visual stimuli. The FEF and SC are both activated in the same way at the same time in response to visual stimuli before and during saccades.

The FEF also plays a direct role in producing saccades. Low-intensity microstimulation of the FEF" elicits saccades; this direct influence is mediated by a subpopulation of neurons in FEF that discharge specifically before and during saccades. These neurons that trigger movement-related activity innervate the deeper layers of the SC and neural circuits in the brainstem that generate saccades.

The FEF projects to the SC mainly by three pathways: a direct pathway through the posterior aspect of the anterior limb of the internal capsule near the genu, an indirect pathway via the thalamus, and another indirect pathway via the caudate nucleus to neurons in the substantia nigra pars reticulata (SNr), These neurons in the SNr project, in turn, to the SC and tonically suppress saccades by a *y*-aminobutyric add (GABA)-ergic mechanism. Controlled d is inhibition of this basal ganglia system is important for normal visually and auditory-guided saccades and is probably essential for saccades to remembered targets (Stell and Bronstein 1994). Saccades of different amplitudes and directions are encoded in neurons in the FEF and SC in a retinotopic fashion (i.e., rhe size and direction of a saccade is determined by which neurons are stimulated). The SC also has some role in reflexive and orienting saccades. The basal ganglia are involved in sequencing complex memory-guided saccades and perhaps predictive saccades (Picrrot-Deseilligny et al. 1995).

The SEF parallels the FEF in several respects, and also innervates ocular motor centers in the SC and brainstem. However, the SEF seems to play a less essential or less potent role in saccade production, as ablation of SEF causes only minimal and short-lasting gaze impairment.

The role of the PEF (area LIP in monkeys) is uncertain. Although neural activity in the PEF precedes saccades, the PEF docs not directly control the initiation of saccades, but signals areas such ay the FEE and SC with the location of potential targets for orienting {Colby and Goldberg 1999; Snyder et al. 2000).

The SC has seven alternating fibrous and cellular layers that are broadly divided into a superficial sensory (dorsal) and a deep, predominantly motor (ventral) division. The superficial sensory division receives a direct orderly input from the retina via the accessory optic tract, bypassing the lateral geniculate body, such that the visual field may be mapped on the surface of the SC (retinotopic). Only about 10% of the retinal ganglion cells project to the SC, the remainder project to rhe lateral geniculate bod\ to subserve conscious vision. The deep motor division receives visual input from the striate cortex (area 17) and projects to motor areas in the subthalamic region and brainstem. The deeper division also receives input directly from the FEE and PPC and indirectly via the basal ganglia, as well as somatosensory and auditory input. Stimulation of the SC drives the eyes contralateral^ to a point in the visual field corresponding to the retinal projection lo that site. Thus the SC is essentially a sensory map overlying a corresponding motor map and represents the visual fields (Leigh and Zee 1999). The SC may also play a role in relaying excitatory information from part of the inferior parietal lobule (1PL), which has some influence in initiating saccades. Isolated lesions of the SC produce minimal, but specific, defects of saccades; when combined with experimental lesions of the FEFs; however, significant contralateral saccadic defects result. Purely vertical saccades require bilateral, simultaneous stimulation of corresponding points of the SC or of the FEFs.

Control of smooth pursuit eye movements is also complex (see Figure 39.1) but essentially consists of three components: sensory, motor, and attcntional-spatial. The stimulus for pursuit is movement of an image across the

fovea at velocities greater than 3-5 degrees per second. The sensory component includes the striate cortex (area 17), which receives information from the retinal ganglion (M) cells via the magnocellular layer of the lateral geniculate body (nucleus) and the optic radiations. The striate cortex projects to the prestriate cortex (parieto-occipital areas 18 and 19) and then to the superior temporal sulcus region, which contains cortical areas MT (middle temporal) and MST (middle superior temporal) in monkeys, equivalent to the pariero-temporo-occipital junction (PTO) in humans (Barton et al. 1995). This sensory subsystem encodes for location, direction, and velocity of objects moving in the contralateral visual field and is the major afferent input driving smooth pursuit; it projects bilaterally to the pursuit motor subsystem, which is also located in the PTO region, as well as to the FEF and SFF. This pursuit pathway is indirect and focuses attention on small moving targets. A direct pathway, bypassing the attentional-spatial subsystem, enables large, moving objects, such as full-field OKN stimuli, to generate smooth pursuit contralaterally even when the subject is inattentive. The SC also contributes to pursuit drive. The PTO projects via the internal sagittal stratum and the posterior limb of the internal capsule to the ipsilateral dorsolateral and lateral pontine nuclei (Gaymard et al. 1993). The pursuit pathways control ipsilateral tracking and so must either remain on the same side or undergo a double decussation at least once. In 1992, Johnston and coworkers suggested the pursuit pathways project from the pontine nuclei to the contralateral flocculus and medial vestibular nucleus and then back to the ipsilateral abducens nucleus (Figure 39.8).

Pursuit defects fall into four categories (Morrow and Sharpe 1993):

1, Retinotopic defects: Lesions of the geniculostriatc pathway cause impaired pursuit in both directions in the contralateral visual field defect. Defects also occur with lesions of areas MST or MT; these patients have apparently normal visual fields but selective "blindness" for motion.
2. Impaired pursuit, worse in the ipsilateral direction in both hemifields, occurs with lesions in the lateral aspect of area MST and the foveal representation of area MT in monkeys, similar to a focal PTO lesion in humans. Lesions in the FEFs, posterior thalamus, midbrain, ipsilateral pons, contralateral cerebellum, contralateral pontomedullary junction, and the ipsilateral abducens nucleus can also impair pursuit in both hemifields worse in the ipsilateral direction.

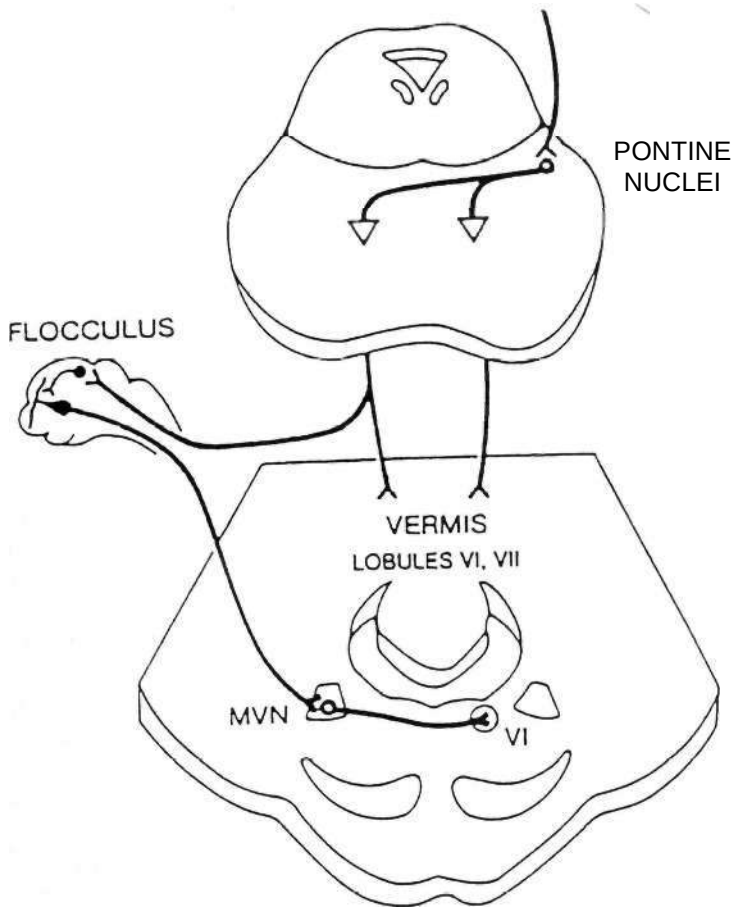

FIGURE 39.8 Postulated double decussation of pursuit pathways in the brainstem and cerebellum. The first decussation consists of excitatory mossy fiber projections from the pontine nuclei to granule cells, which excite basket cells and stellate cells in the contralateral cerebellar flocculus. The basket and stellate cells inhibit Purkinje cells, which in turn inhibit neurons in the medial vestibular nucleus (MVN). The second decussation consists of excitatory projections from the MVN to the opposite abducens nucleus (VI). (Reprinted with permission from Johnston, J. L., Sharpe, J. A., Et Morrow, M. J. 1992, "Paresis of contralateral smooth pursuit and normal vestibulat smooth eye movements after unilateral brainstem lesions," *Ann Neurol,* vol. 31, pp. 495-502.)

3. Symmetrically impaired pursuit in both horizontal directions occurs with focal lesions in the parieto-occipital region {area 39). Medication (e.g., anticonvulsants, sedatives, and psychotropic agents), alcohol, fatigue, inattention, schizophrenia, encephalopathy, a variety of neurodegenerative disorders, and age (infants and the elderly) also cause symmetrically impaired pursuit.
4. An acute nondominant (e.g., parietal or frontal) hemisphere lesion associated with a hemispatial neglect syndrome causes transient loss of pursuit beyond the midline into contralateral hemispace.

The cerebellum coordinates the ocular motor system to drive the eyes smoothly and accurately and is richly supplied by afferent fibers conveying ocular information (such as velocity, position, and neural integration) from the vestibular system, the afferent visual system, the PPRF, and the MRF. The dorsal vermis and fastigial nuclei determine the accuracy of saccades by modulating saccadic amplitude; they also adjust the innervation to each eye selectively to ensure precise conjugate movements. Lesions of the dorsal vermis and fastigial nuclei result in saccadic dysmctna (often, overshoot dysmetria that is greater centripetally) and macrosaccadic oscillations (see Chapter 16).

Selective cerebellar lesions have differential effects on eye movements. Bilateral lesions of the fastigial and globose (interpositus) nuclei cause hypermetria of externally triggered saccades but do not affect internally triggered saccades (Straube et al. 1995). Bilateral lesions of the posterior vermis (lobules VI and VII) cause hypomctric horizontal and vertical saccades and impaired pursuit. Unilateral lesions of the posterior vermis cause hypometric ipsilateral and hypermetric contralateral saccades, whereas unilateral lesions of the caudal fastigial nucleus cause hypermetric ipsilateral and hypometric contralateral saccades (Biittner and Straube 1995; Vahedi et al. 1995).

The flocculus, part of the vestibulocerebellum, is responsible for matching the saccadic pulse and step appropriately and for stabilizing images on the fovea. It adjusts the output of the NI and participates in long-term adaptive processing to ensure that eye movements remain appropriate to the stimulus. For example, the amplitude (gain) and even the direction of the slow phases of the VOR are adjusted by the flocculus. Lesions of the flocculus result in gaze-holding deficits, such as gaze-evoked, rebound, and downbeat nystagmus. Floccular lesions also impair smooth pursuit, cancellation (suppression) of the VOR by the pursuit system during combined head and eye tracking, and the ability to suppress nystagmus (and vertigo) by fixation. The nodulus, also part of the vestibulocerebellum, influences vestibular eye movements and vestibular optokinetic interaction. Lesions of the nodulus in monkeys and humans produce periodic alternating nystagmus (PAN).

Vergence Eye Movements

In humans and other animals capable of binocular fusional vision, dysconjugatc (vergence) eye movements are necessary to maintain ocular alignment on an approaching or retreating object (convergence and divergence, respectively). Electromyography demonstrates that divergence is an active movement, although not as dynamic or as much under voluntary control as convergence. The principal driving stimuli for vergence movements, relayed from the occipital cortex, are accommodative retinal blur (unfocused) and fusional disparity (diplopia). Each of these stimuli can operate independently. During convergence, each eye also extorts, more so in downgaze, to facilitate stereoscopic perception (Brodsky 2002), In addition, the pupils change size, synkinetically, as part of the near reflex to increase the depth of field and to improve the focus of the optical system.

Although the precise locations of the convergence and divergence centers are unknown, two areas, the midbrain prctcctum and the nucleus reticularis teg men ti pontis (NRTP), are important. Lesions in the pretectal region cause accommodative and vergence abnormalities (Ohsuka et al. 2002), and there is a group of neurons that fire in relation to the angle of convergence just lateral ro the third cranial nerve nuclear complex. The NRTP is contiguous with the PPRF and forms part of a feedback loop by relaying visual information to the cerebellum via a cerebro-ponto-ccrcbellar pathway; the NRTP may also function as a vergence integrator. Experimental lesions of the NRTP in monkeys can cause sustained convergence or pendular convergence-divergence oscillations.

Unilateral stimulation of areas 19 and 22 of the preoccipital cortex caused bilateral convergence, accommodation, and miosis in macaque monkeys. The occipito-mesencephalic pathway, involved in vergence, travels more vcntrally in the dienccphalon and midbrain than does the light reflex pathway and is less susceptible to compression by extrinsic lesions (dorsal midbrain syndrome) (see Chapter 22).

Vertical Eye Movements

The pathways involved in controlling vertical gaze arc not fully known, and some of the neural connections discussed below arc speculative.

The third and fourth cranial nerves innervate the extraocular muscles responsible for both vertical and torsional eye movements (see Chapter 16). The pre motor substrate for vertical and torsional eye movements lies in the midbrain reticular formation (MRF); however, some vertical saccades are programmed in the PPRF and relayed to the MRF via a juxta-MLF pathway, presumably to coordinate horizontal, vertical, and oblique trajectories, and head movement. The rostral interstitial nucleus of the medial longitudinal

fasciculus (riMLF) on each side contains EBNS for both upward and downward saccades but only for ipsilateral torsional saccades. The KBNs for upward saccades are probably caudal, ventral, and medial in the riMLF and project to the elevator muscles (superior rectus and inferior oblique) bilaterally, with axons crossing within the oculomotor nucleus (Figure 39.9A) and not in the posterior commissure (PC) as previously thought (Bhidayasiri et al. 2000). The EBNs for downward saccades are more rostral, dorsal, and lateral in the riMLF, and project only to the ipsilateral depressor muscles (inferior rectus and superior oblique) (Figure 39.9B). The EBNs for vertical saccades also project to the interstitial nucleus of Cajal (INC), which plays a major role in neural integration for vertical and torsional gaze (see below) (Bhidayasiri ct al. 2002). From the INC, the pathways project dorsally and laterally to cross in the PC before turning vcntrally to the oculomotor and trochlear nerve nuclei (see Figure 39.9). The axons to the elevator muscles travel more dorsally and thus are more susceptible to extrinsic compression, such as from a pinealoma.

While the riMLF is key for vertical saccades, the MRF also has a role because of its reciprocal connections with the SC. Each riMLF also receives input from the nucleus of the posterior commissure, the FEF, the SC, the fastigial nucleus of the cerebellum and the contralateral riMLF; the latter fibers cross in a commissure ventral to the aqueduct (see Figure 39,9). Each riMLF is supplied by a branch of the proximal posterior cerebral artery, the posterior thalamo-subrhalamic paramedian artery; a single anomalous posterior thalamo-subthalamic paramedian artery (the arrery of Pcrchcron) may supply the riMLF bilaterally. Vertical saccades require bilateral supranuclear innervation from the FEF or SC, or both.

The neural integrator (NI) for vertical and torsional eye movements (Halmagyi et al. 1994) is located in the interstitial nucleus of Cajal (INC). Burst-tonic and tonic neurons in the region of the INC discharge in relation to vertical eye position and play a role in vertical pursuit and eye position. These neurons project to the contralateral INC and the ocular motor nuclei via the PC, which plays a critical role in vertical gaze (see Figure 39.9). Injury to the PC limits all types of vertical eye movements, particularly upward movements, although the vertical VORs and Bell's phenomenon may be relatively spared.

Retinal slip, the sensory stimulus for vertical pursuit, is encoded by the dorsolateral pontine nuclei and relayed to the flocculus and posterior vermis before converging, via the INC, on the midbrain (see Figures 39.8 and 39.9). The commands for vertical pursuit pass through the pons and cerebellum before turning rostrally to reach the relevant ocular motor neurons in the midbrain.

DEVELOPMENT OF **THE** OCULAR MOTOR SYSTEM

At birth, the vestibular system is the most developed of the ocular motor subsystems and is easily tested by rotating the infant, held at arm's length, with the head tilted 30 degrees forward. In normal neonates, the eyes tonically deviate in the same direction as head movement; reflex saccades develop by 2-3 weeks. Smooth pursuit movemenrs may be detected in neonates but only with large targets (such as a human face) at low velocities. These findings, although not well quantified, are consistent with histological maturation of the fovea after at least 8 weeks of age. Neonates can also generate the smooth pursuit component of OKN with full-field stimulation.

Fixation is not well developed until about two months, although some infants younger than 1 month can fixate

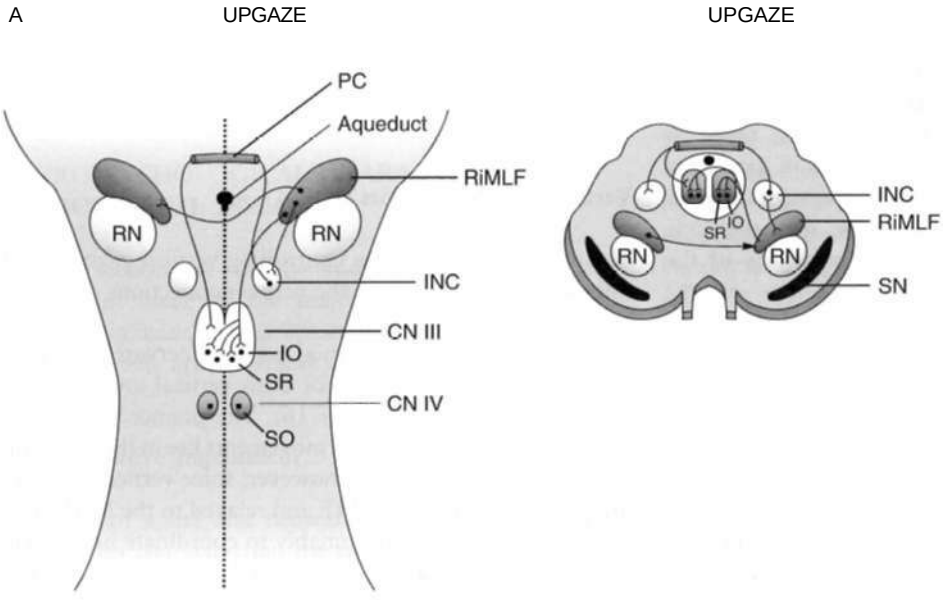

FIGURE 39.9 Hypothetical pathways involved in controlling vertical eye movements, (A) Upward eye movements. Burst neurons for upward saccades are shown projecting from the medial rostra] interstitial nucleus of the medial longitudinal fasciculus (riMLF) to the elevator muscles, superior recti and inferior obliques bilaterally, with axons crossing within the oculomotor nucleus. *Continued*

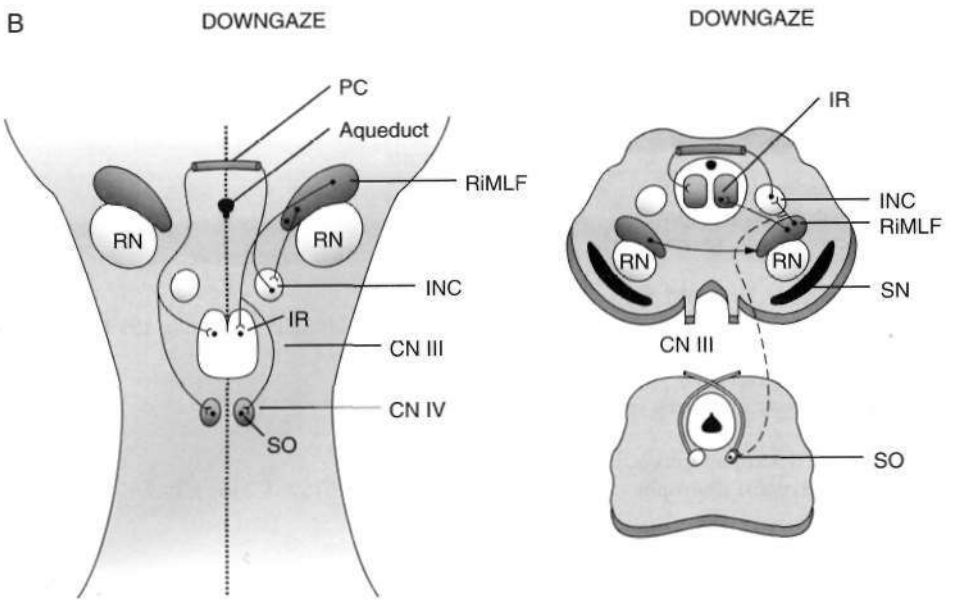

FIGURE 39.9, cont'd. (B) Burst neurons for downward saccades are shown projecting only to the ipsilateral depressor muscles, the inferior rectus and superior ohlique. The axons of the burst neurons for upward saccades also project to the interstitial nucleus of Cajal (INC), which plays a role in tun nil integration tor vertical and torsional gaze. From the INC, the axons project dorsally and laterally to cross in the posterior commissure before turning ventrally to the oculomotor and trochlear nerve nuclei. (CN-II1 = third nerve nuclear complex; CN-IV = fourth nerve nucleus; INC = interstitial nucleus of Cajal; IO — inferior oblique subnucleus; IR = inferior rectus subnucleus; PC = posterior commissure; nMLF = rostral interstitial nucleus of the medial longitudinal fasciculus; RN = red nucleus; SN = substantia nigra; SO = superior oblique nucleus; SR = superior rectus subnucleus.) (Redrawn from Bhidayasiri, R., Plant, G. T,, & Leigh, R. J. 2000, "A hypothetical scheme for the brainstem control of vertical gaze," *Neurology,* vol. 54, pp. 1985-1993.)

targets, provided the stimuli are engaging and the infant is alert. By nine weeks, 90% of full-term infants can fixate and follow the human face. Full-field OKN and larger targets stimulate the parafoveal retina, which matures earlier than the fovea. Stimulation of the saccadic system, also immature in the neonate, is influenced by the infant's attention as well as by the size and appropriateness of the target. Vertical saccades mature more slowly than horizontal saccades and may not he detected for the first month after birth. Vergence movements are also slow to mature but are seen after about the first month.

Ocular alignment in the newborn is usually poor, with transient shifts from esotropia to exotropia during the first few weeks. In most infants, ocular alignment is established by 3-4 weeks but may be delayed as late as five months. Small angle esotropia and intermittent esotropia may spontaneously resolve in infants less than 20 weeks of age; constant esotropia greater than 40 prism diopters is unlikely to resolve spontaneously. Esotropia after 3 months and exotropia after 5 months are considered abnormal and require appropriate evaluation. Large-angle exotropia may be associated with craniofacial, genetic, or other neurological abnormalities.

Paroxysmal phenomena are common in infancy and may be as widespread as one in four (Reerink et al. 1995). Ocular motor anomalies may occur in the neonate without any pathological significance. About 2% of newborns have a tendency for tonic downward deviation of the eyes in the waking state; during sleep, however, the eyes assume the normal position, and the VORs are intact. Other uncommon abnormalities seen in newborns include opsoclonus, which may regress through a phase of ocular flutter, skew deviation, apparent bilateral internuclear ophthalmoplegia; transient downbeat nystagmus; and tonic upward deviation. These findings likely represent delayed maturity of the ocular motor system in neonates.

SUPRANUCLEAR. GAZE DISTURBANCES

Interruption of the saccadic and pursuit pathways before they reach the eye-movement generators in the MRF and PPRF results in a loss of voluntary eye movements but relatively spares reflex movements, such as VOR, optokinetic response and Bell's phenomenon. This constellation of findings is referred to as a *supranuclear gaze palsy* and occurs classically in progressive supranuclear palsy (PSP) as well as a variety of disorders listed in Table 39.2. Technically, skew deviation and the ocular tilt reaction (OTR), which spare the final common efferent pathway

	Paraneoplastic disorders
	Parkinson's disease (transient gaze palsy with intercurrent infection)
	Pelizaeus-Merzbacher disease (H>V)
	Pick's disease (impaired saccades)
	Progressive multifocal leukoencephalopathy
	Tay-Sachs disease (infantile GM_2 gangliosidosis) (V>H)
	Wernicke's encephalopathy
	Whipple's disease (V>H)

AIDS = acquired immunodeficiency syndrome; D = loss of downgaze; FLOM = extraocular muscles; g1oba1 = loss of horizontal and vertical gaze; H = loss of horizontal gaze; MNCIE = mitochondrial neurogastrointestinal encephalomyopathy syndrome; OPCA = olivopontocerebellar atrophy; U = loss of upgaze; V = loss of vertical gaze.

for eye movements, are also supranuclear, but because they are dy scon jugate, they are referred to here as prenuclear.

Bilateral lesions of the fronto-mesencephalic pathways cause loss of horizontal saccades in both directions and impair vertical saccades (particularly upward) but spare pursuit, VORs, and the slow phases of OKN. Focal lesions in the PPRF can also cause selective saccadic defects (see Horizontal Eye Movements, earlier in this chapter).

To evaluate disorders of gaze, first determine the range of versions (conjugate eye movements) to a slowly moving target, and then test saccades, as described in Chapter 16. If a dysconjugate defect is observed, check ductions, ocular alignment, and comitance. If a conjugate defect (i.e., a gaze palsy) is present, determine if the eyes move reflexively by testing for the oculoccphalic reflex (doll's eye maneuver) or VOR (calorics), and Bell's phenomenon (ocular deviation, usually upward, on forced eyelid closure); their presence indicates supranuclear dysfunction. With suptanuclcar gaze disorders, saccades may be impaired firsr, then pursuit, followed by loss of VORs. Causes of gaze palsies and ophthalmoplegias are outlined in Table 39.2.

Ocular Motor Apraxia

Ocular motor apraxia is the inability to perform voluntary saccades; spontaneous saccades and reflex eye movements (vestibular and OKN slow phases) are preserved. The term is sometimes used loosely and incorrectly (see below),

Congenital ocular motor apraxia (COMA) is more common in boys than in girls and is characterized by impaired voluntary horizontal pursuit and saccadic movements but preservation of vertical eye movements (Leigh and Zee 1999); teflex saccades may be partly retained. Because random eye movements are also absent in many of these children, the term *apraxia* is strictly incorrect; *congenital saccadic palsy* or *congenital gaze palsy* is more accurate (Leigh et al. 1997), but the term COMA is now established in the literatute. By 4-8 months of age, the child develops a thrusting head-movement strategy, often with ptominent blinking, to ovetcome the eye-movement deficit (see Figure 24.3). Because the VOR prevents a change in direction of gaze on head turning, the child closes the eyes to reduce the degree of reflex eye movement (the gain of the VOR falls with the eyes closed) while thrusting the head beyond the range of the VOR arc to bring the eyes in line with the target. Then, with the eyes open, the child slowly straightens the head while the contralateral VOR maintains fixation. Some patients may use the dynamic head thrust to facilitate saccadic eye movements or reflexively to induce fast phases of vestibular nystagmus.

Because children with COMA cannot easily refixate or pursue new targets, particularly in the first 6 months of life, before they develop the head-thrusting strategy, they arc sometimes initially misdiagnosed as being blind. After *6* months of age, children with COMA present because of the head thrusts. The diagnosis of COMA can be confirmed by demonstrating the inability to make saccades; this is most easily done by spinning the infant, as described in Development of the Ocular Motor System, earlier in this chapter. In normal infants, the eyes tonically deviate in the same direction as head movement; absence of reflex saccades (fast phases in the opposite direction) after 2-3 weeks of age is abnormal and indicates saccadic palsy.

As children with COMA reach school age, pursuit and voluntary saccades variably improve. However, the condition does not completely resolve and can be detected in adulthood. COMA may be associated with hypoplasia of the cotpus callosum, hypoplasia of the cerebellar vermis in as many as 53% of patients (Sargent et al. 1997), occipital porencephalic cysts, and bilateral cortical lesions. It may occasionally be familial. Strabismus, psychomotor developmental delay (particularly reading and expressive language ability), clumsiness, and gait disturbances are often associated.

A similat ocular motor disordet occurs in children with Aicardi's syndrome, ataxia telangiectasia (80%), Cockayne's syndrome, Joubert's syndrome, Pelizaeus-Merzbacher disease, succinic semi-aldehyde dehydrogenase deficiency (Eustace et al. 1994), Wieacker's syndtome, carbohydrate deficient glycoprotein syndrome type la (Stark et al. 2000), and ataxia-oculomotor apraxia syndrome (which mimics ataxia telangiectasia, without the extraneurological features, and is probably autosomal recessive) (Gascon et al. 1995).

Congenital vertical ocular motor apraxia is rare and must be differentiated from metabolic and degenerative disotdets that cause ptogtessive neurological dysfunction, such as neurovisceral lipidosis, and from stable disorders, such as birth injury, perinatal hypoxia, and Leber's congenital amaurosis.

Acquired ocular motor aptaxia occuts in patients with bilateral parietal damage and with diffuse bilateral cerebral disease (see Table 39.2); the head thrusts are not as conspicuous as in the congenital vatiety.

Spasm of Fixation

Spasm of fixation, a term introduced by Gordon Holmes in 1930, describes patients who have difficulty shifting visual attention because of impaired initiation of voluntary saccades when looking at a fixation target but normal initiation of saccades in the absence of such a target. Their saccades have a prolonged latency and may be hypometric in the presence of u a/urr.il visual rarurt; however, Minks or combined eye and head movements may sometimes facilitate normal saccades. Holmes stressed that fixation was an active process and attributed spasm of fixation to "exaggerated" fixation; evidence from other studies supports this concept.

The lesions that cause spasm of fixation may be bi hemispheric and interrupt indirect FEF projections via the caudate nucleus and SNr (see Horizontal Eye Movements, earlier in this chapter) to the SC. Normally, during saccades to auditory, visual, and remembered targets, neurons in the FEFs discharge via these pathways and disinhibit the SC to allow the saccades and disengage fixation. Interruption of these, and perhaps oilier path ways, might contribute to spasm of fixation by maintaining tonic inhibitory suppression of saccades by the SC (Leigh and Zee 1999).

Familial Horizontal Gaze Palsy

Familial horizontal gaze palsy with scoliosis (HGPS) is an autosomal recessive disorder characterized by paralysis of horizontal gaze from birth, impaired OKN and VORs but intact convergence, vertical eye movements, and progressive scoliosis (Leigh and Zee 1999). HGPS maps to chromosome llq23-25 in some kindreds (Jen et al. 2002). Types of nystagmus described in HGPS include a fine pendular horizontal nystagmus, upbeat nystagmus, and see-saw nystagmus (Pieh et al. 2002). Individuals in some families may also have facial myokymia, facial twitching, hemifacial atrophy, and situs invetsus of the optic discs. Neutoimaging may demonstrate brainstem dysplasia, particularly pontine hypoplasia (Pieh et al. 2002). HGPS is one of a spectrum of disorders of maldevelopment of cranial nerve nuclei that include Duane's syndrome (see Chaprer 16), Mobius syndrome, the congenital fibrosis of the extraocular muscles syndromes, and congenital ptosis (Engle and Leigh 2002),

Acquired Horizontal Gaze Palsy

Transient gaze deviation, usually of the head and eyes, occurs in about 20% of patients with acute hemisphere stroke and other insults. The eyes are usually deviated toward the side of the lesion (ipsiversive gaze deviation} because of gaze paresis to the hemiplegic side (i.e., paralysis of gaze and limbs is on the same side). In stroke patients, right-sided lesions are more common but smallet; consequently, patients with left-sided lesions (gaze deviation to the left) have a worse prognosis. Ipsiversive gaze deviation occurs more often when the inferior parietal lobule (IPL) or circuits between the FEFs and the IPL or their projections to the brainstem (SC or PPRF) are involved; the FEFs are usually spared. After about 5 days, the intact hemisphere, which contains neurons for bilareral gaze, takes over; thereafter, subtle abnormalities such as prolonged saccadic latencies and impaired saccadic suppression can be detected only by quantitative oculography.

Because the premotor neural network for voluntary horizontal eye movements in the PPRF is composed of subclasses of neurons with different functions, selective lesions may affect some types of eye movement while sparing others (see Horizontal Eye Movements, earlier in this chapter). A lesion affecting the ipsilateral abducens nucleus or PPRF causes ipsilateral gaze palsy; a rostral PPRF lesion spares the VOR, whereas a caudal lesion does not. Paraneoplastic brainstem encephalitis can cause supranuclear, internuclear, or nuclear damage, resulting in selective loss of voluntary horizontal and vertical saccades (Crino et al. 1996). Patients with prostatic adenocarcinoma may, after an interval of 3–4 years, develop paraneoplastic gaze palsies followed by severe facial and bulbar muscle spasms (probable sustained myoclonus), diplopia, and respiratory insufficiency (Baloh et al. 1993). Other neurological features that may be associated with such paraneoplastic disorders include ataxia, hypcracusis, muscle spasms, myoclonus, periodic alternating gaze deviation (PAGD), and vertigo. Magnetic resonance imaging is often unrevealing, particularly in the early stages, but auditory evoked potentials and cerebrospinal fluid analysis may be abnormal. Clonazepam, valproic acid, and botulinum may help the myoclonus and muscle spasms.

Other causes of horizontal gaze palsies are listed in Table 39.2,

Wrong-Way Eyes

Conjugate eye deviation to the "wrong" side (i.e., away from the lesion and toward the hemiplegia [contraversive gaze deviation]) may occur with supratentorial lesions, particularly thalamic hemorrhage, and, rarely, large perisylvian or lobar hemorrhage. The mechanism is unclear, but possibilities include the following:

1. An irritative or seizure focus causing "contraversive ocular deviation" is unlikely because neither clinical nor electrical seizure activity has been reported in these patients.
2. Because eye movements are represented bilaterally in each frontal lobe, it is conceivable that the center for ipsilateral gaze alone may be damaged, resulting in contraversive ocular deviation.
3. An irritative lesion of the intralaminar thalamic neurons, which discharge for contralateral saccades, could theoretically cause contraversive ocular deviation (Leigh and Zee 1999).
4. Damage to the contralateral inhibitory center could also be responsible.

Postictal "paralytic" conjugate ocular deviation occurs after adversive seizures as part of Todd's paralysis.

Spasticity ol conjugate gaze (lateral deviation ot both eyes away from the lesion) during forced eyelid closure, a variant of Bell's phenomenon, can occur in patients with large, deep parietotemporal lesions; eye

movements are otherwise normal except for ipsilateral saccadic pursuit.

Psychogenic ocular deviation can occur in patients feigning unconsciousness; the eyes are directed toward the ground irrespective of which way the patient is turned.

Periodic Alternating Gaze Deviation

Periodic Alternating Gaze Deviation (PAGD) is a rare cyclical ocular motor disorder in which the direction of gaze alternates every few minutes. Lateral deviation can he sustained for up to \5 minutes; gaze then returns to the midline for 10-20 seconds before changing to the other side. Occasionally, PAGD is associated with structural lesions, such as pontine vascular disorders; Chiari malformations; congenital absence or abnormalities of the inferior cerebellar vermis, the uvula, and nodulus; Creutzfeldt-Jakob disease involving the flocculonodular lobe; spinocerebellar degeneration; occipital cnccphaloceles; and paraneoplastic brainstem encephalitis (Baloh et al. 1993). A reversible form of PAGD occurs with hepatic encephalopathy and is attributed to derangement of GABA metabolism (Averhuch-Heller and Meiner 1995}.

PAN (sec Chapter 16) has a similar time cycle to PAGD and also results from lesions of the uvular and nodular regions. Indeed, PAGD may be PAN with loss of corrective saccades because of concomitant saccadic palsy or immaturity of the saccadic system in infants.

Other cyclical ocular motor phenomena, including cyclical esotropia, cyclical oculomotor palsy, springing pupil, alternating skew deviation, and PAN, are discussed in the appropriate sections.

Ping-Pong Gaze

Ping-pong gaze is a conjugate horizontal rhythmic oscillation that cycles every 4-8 seconds (short-cycle PAGD) and occurs in comatose patients as a result of bilateral cerebral or upper brainstem damage (e.g., disconnection) or metabolic dysfunction. Ping-pong gaze implies that the horizontal gaze centers in the pons are intact. The prognosis for recovery is poor except in patients with a toxic or metabolic cause (Johkura et al. 1998).

Saccadic Lateropulsion

Saccadic lateropulsion is characterized by hypermetric (overshoot) saccades (see Chapter 16, Figure 16.1 SB) to the side of the lesion (ipsipulsion) and hypometric (undershoot) saccades (see Chapter 16, Figure 16.18C) to the opposite side. In darkness or with the eyelids closed, the patient may have conjugate deviation toward the side of the lesion. Saccadic lateropulsion occurs with lesions of the lateral medulla (most commonly ischemic) involving cerebellar inflow (inferior cerebellar peduncle).

Saccadic lateropulsion with a bias away from the side of the lesion (contrapulsion) may occur with lesions involving the region of the superior cerebellar peduncle (outflow tract) and adjacent cerebellum (superior cerebellar artery territory) (Halmagyi 1994),

Pulsion of vertical saccades, with a parabolic trajectory, occurs in patients with lateral medullary injury. Both upward and downward saccades deviate toward the side of the lesion, with corrective oblique saccades, whereas in those with lesions involving cerebellar outflow, vertical saccades deviate away from the side of the injury (Halmagyi 1994).

Torsional Saccades

Pathological rapid torsional eye deviation during voluntary saccades may occur with large lesions involving the midline cerebellum, deep cerebellar nuclei, and dorsolateral medulla. The amplitudes of these torsional saccades (blips) are larger for ipsilesional (hypermetric) than for contralesional (hypometric) horizontal saccades. Eye movement recordings using a scleral search coil (see Eye Movement Recording Techniques, later in this chapter) demonstrated that the "blips" are followed by an exponenrially slow (see Chapter 16) torsional drift toward the initial torsional eye position. These blips may be a form of torsional saccadic dysmetria (Helmchen et al. 1997).

Slow Saccades

Saccades of low velocity result from pontine disease, presumably because of burst cell dysfunction. They occur in patients with olivopontocerebellar degeneration and other disorders listed in Table 39,3. Some patients with hypometric saccades (see Chapter 16, Figure 16.18C), composed of multiple small-amplitude steps (as in myasthenia, Huntington's disease, brainstem encephalitis, and srriatonigral degeneration) appear to have slow saccades clinically (pseudo-slow saccades), but each small saccadc has a normal velocity-amplitude relationship.

Prolonged Saccadic Latency

Disorders of saccadic initiation, resulting in prolonged latencies for voluntary saccades, occur in patients with inattention acquired immunodeficiency syndrome (AIDS)-dementia complex and a variety of encephalopathies and degenerative disorders of the nervous system, such as Alzheimer's, Huntington's, and Parkinson's disease.

Table 39.3; Slow saccades

AIDS-dementi a complex
Amyotrophic lateral sclerosis
Anticonvulsant toxicity (consciousness usually impaired)
Ataxia-telangiectasia
Hexosaminidase A deficiency
Huntington's disease
Internuclear ophthalmoplegia (slow abduction)
Joseph's disease
Lesions of the paramedian pontine reticular formation
Lipid storage diseases
Long-standing cholestasis (proba hie vitamin E deficiency)
Lytico-Bodig disease (Guamanian ALS-PD-dementia complex)
Myotonic dystrophy
Nephropathy cystinosis
Ocular motor apraxia
Ocular motor nerve or muscle weakness
Olivopontocerebellar degeneration (ADCA type I)
Progressive supranuclear palsy
Wernicke's encephalopathy-
Whipple's disease
Wilson's disease

ADCA = autosomal dominant cerebellar ataxia; AIDS = aequired immunodeficiency syndrome; ALS-PD = amyotrophic lateral sclerosis-Parkinson'sdisease.

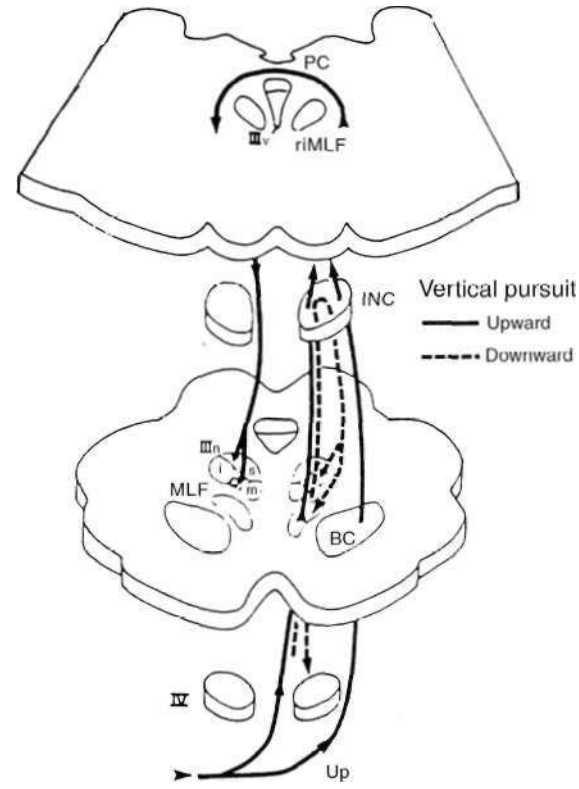

FIGURE 39.10 Vertical pursuit. The hypothetical pathways for pursuit reach the midbrain via the dorsal lateral pontine nuclei and travel upward in the brachium conjunctivum (BQ and the medial longitudinal fasciculus (MLF). The interstitial nucleus of Cajal (INC) is involved in pursuit and may also be the neural integrator for vertical position commands. (Reprinted with permission from Ranalli, P. J., Sharpe, J. A., & Fletcher, W. A. 1998, "Palsy of upward and downward saccadic, pursuit, and vestibular movements with a unilateral midbrain lesion: Pathophysiologic correlations," *Neurology,* vol. 38, pp. 114-123.)

Square Wave Jerks

Square wave jerks (SWJs) (Table 39.4) are spontaneous, small-amplitude paired saccades with an intersaccadic latency of 150-200 ms tbat briefly interrupts fixation (Figure 39.10). They may occur physiologically in normal subjects (particularly in darkness) without fixation and are usually about 2 degrees in amplitude. They are more common in the elderly (Halmagyi 1994) and in carriers of blue-cone monochromatism (Gottlob 1994). SWJs are prominent in PSP, multiple system atrophy, and cerebellar disease; the increased frequency of SWJs in these less dopamine-responsive parkinsonian syndromes, such as olivopontocerebellar atrophy (autosomal dominant cerebellar atrophy), PSP, Lewy body disease, and multiple system atrophy, may distinguish them from Parkinson's disease.

Table 39.4: Square wave jerks

Normal subjects (<2 degrees)
Excitement in normals
Catecholamine depletion in normals
Aging
Carriers of blue-cone monochromatism
Strabismus
Congenital nystagmus
Latent nystagmus
Dyslexia (suppressed by methylphenidate)
Progressive supranuclear palsy
Schizophrenia
Cerebral hemisphere tumors and stroke
Parkinson's disease
Wernicke's encephalopathy
Friedreich's ataxia
Joseph's disease
Gerstmann-Straussler-Scheinker disease
Lithium
Tobacco
AIDS-dementia complex (HIV encephalitis)
Square wave pulses (macrosquare wave jerks)
  Olivopontoccrcbellat atrophy
  Multiple sclerosis (cerebellar dysfunction)

AIDS = acquired immunodeficiency syndrome; HIV = human immunodeficiency virus.

Because of the intersaccadic interval (latency), SWJs arc thought to be triggered supratentorially, whereas other saccadic intrusions (e.g., saccadic pulses) and oscillations (e.g., flutter and opsoclonus) are caused by dysfunction of the pause cells in the brainstem (see Chapter 16).

Square wave pulses (SWPs), previously termed *macro-square wave jerks,* also interrupt fixation but differ from SWJs with larger amplitudes (10-40[11]) and shorter latencies (about 80 ms) before the eyes return to the target; they occur in patients with multiple sclerosis,

olivopontocerebellar degeneration and may accompany rubral tremor. SWJs and SWPs should be distinguished from macrosaccadic oscillations, which wax and wane-across fixation {Figure 39.11), are not present in darkness, and occur with midline cerebellar lesions. These and other saccadic oscillations are discussed in detail elsewhere (Dell'Osso and Daroff 1999a; Leigh and Zee 1999).

In ternu el car Ophthalmoplegia

Damage to the MLF between the third and sixth cranial nerve nuclei impairs transmission of neural impulses to the ipsilateral medial rectus muscle (see Figure 39.4). Adducting saccades of the ipsilateral eye are impaired (either slow or absent), depending on the severity of the lesion. The nystagmus-like movement of the abducting eye typically seen gives the appearance of dissociated nystagmus (see Chapter 16) but is in fact overshoot dysmctria (Halmagyi 1994). Upward-heating and torsional nystagmus is often present. Convergence may be preserved with an INO, but because the patient's attention and effort are necessary for its evaluation, it is not a particularly helpful sign. Patients with bilateral INO may be exotropic, designated the WEBINO (wall-eyed bilateral INO) syndrome (Komiyama et al. 1998), and have slow-abducting saccades because of impaired inhibition of tone in the medial recti. Other clinical features associated with INO include skew deviation (usually ipsilateral hypertropia), and defective vertical smooth pursuit, OKN, and vertical VORs.

A subtle INO may be demonstrated by having the patient make repetitive horizontal saccades, which often discloses slow adduction of the ipsilateral eye. Alternatively, an optokinetic tape may be used to induce repetitive saccades in the direction of action of the suspected weak medial rectus muscle, by moving the tape in the opposite direction and observing for smaller-amplitude adducting saccades.

INO may occur with a variety of disorders affecting the brainstem and must be distinguished from the many, primarily peripheral, causes of pseudo-INO (Table 39.5).

Rarely, patients with small lesions in the rostra! pons or midbrain, remote from the abducens nerve and nucleus, may have a Lutz posterior INO. In this condition, abduction is impaired, but the adducting eye has nystagmus. The mechanism is attributed to impaired inhibition of the antagonist medial rectus muscle because of damage to uncrossed fibers, from the PPRF to the oculomotor nucleus, running close to but separate from the MLF (as discussed by Thomke et al. 1992).

Tabic 39.5: Causes of internuclear ophthalmoplegia

- Brainstem (pontine) stroke—unilateral
- Multiple sclerosis—unilateral or bilateral
- Intrinsic tumor—primary or metastatic
- Meningitis (especially tuberculosis)
- Brainstem eiia/phalim (infective, paraneoplastic)
- Chemotherapy with radiation therapy
- Drug intoxication:
  - (Comatose)—anticonvulsants, phenothiazincs, tricyclics
  - (Awake)—lithium
- Spinocerebellar degeneration
- Fabry's disease (vascular)
- Wernicke's encephalopathy
- Progressive supranuclear palsy
- Syringobulbia associated with a Chiari malformation
- Trauma (closed head injury)
- Hexosaminidase A deficiency
- Maple syrup urine disease
- Cerebral air embolism
- Pseudointernuclear ophthalmoplegia
  - Long-standing exotropia
  - .Myasthenia
  - Myotonic dystrophy

One-and-a-Half Syndrome

A lesion in the caudal dorsal pontine tegmentum involving the ipsilateral PPRF, or the abducens nucleus, and the ipsilateral MLF results in an ipsilateral gaze palsy with an ipsilateral INO (see Figure 39.3) (Komiyama et al. 1998). This is known as the *one-and-a-half syndrome.* Abduction of the contralateral eye is the only intact horizontal movement. Patients who also have facial nerve palsy may later develop oculopalatal myoclonus (see Chapter 16), probably because of the proximity of the central tegmental tract to the facial nerve (Wolin et al. 1996). Ocular myasthenia may cause a pseudo-one-and a-half syndrome.

Disorders of Vertical Gaze

A variety of disorders of conjugate vertical gaze result from discretely placed lesions in the midbrain pretectal region (see Figure 39.9). However, selective deficits of vertical gaze may be overlooked unless the examiner specifically tests for different types of eye movements, particularly saccades.

Paralysis of vertical saccades usually involves loss of downward saccades or combined upward and downward saccades and is often caused by bilateral ischemia of the riMLF, Selective paralysis of downward saccades may occur because the depressor muscles are innervated just unilaterally, whereas the elevator muscles are innervated bilaterally; thus partial riMLF lesions affect the depressor muscles disproportionately (Bhidayasiri et al. 2000).

A unilateral lesion, in the midbrain tegmentum, involving the riMLF can cause impairment of both upward and downward saccades by injuring ipsilateral butst cells, crossing fibers from the contralateral burst cells, and probably neighboring inhibitory pathways. In addition, a unilateral lesion of the riMLF can cause loss of ipsilateral torsional saccades, detected by tilting the patient's head to the shoulder, i.e., in the roll plane. A lesion of the PC limits all types of vertical eye movements, particularly upgaze.

Upgaze paralysis occurs with lesions at or near the posterior commissure, or bilaterally in the pretectal area (see Figure *19.9).*

Downgaze paralysis occurs with bilatetal lesions of the riMLF (Figure 39.11) or its projections, which course caudally and dorsally, bilaterally (see Figure *59.9).* In humans, with the exception of occlusion of the posterior thalamosubthalamic branch of the posterior cerebral artery, such isolated lesions are rare (Green et al. 1993). More commonly, bilatetal involvement of the pathways for downgaze (as well as upgaze) occurs as a part of diffuse disorders, such as P5P, Whipple's disease, neurovisceral lipid storage disorders, and complications of AIDS (see Table 39.2).

Patients with impaired vertical gaze as a result of extrinsic compression of the posterior commissure or pretectal tegion ate more likely to have pupillary light-near dissociation (loss of the pupillary light reflex but preservation of the near reflex) because the light-reflex pathways are more superficial. Intrinsic midbrain lesions cause impairment of convergence and accommodation (the near reflex) while sparing the light reflex. With supranuclear disorders of vertical gaze, saccades are impaired initially, followed by pursuit, and then by loss of verticil VORs. Paralysis of upga/c, light-near dissociation of the pupils, impaired convergence, lid rettaction, and convergence-retraction nystagmus are features of the dorsal midbrain (Parinaud's) pretectal syndrome (see Chaptet 22), which occurs with injury to the PC or both INCs.

Disorders of vertical gaze (see Table 39,2), particularly downgaze and combined upgaze and downgaze paresis, may be overlooked in patients with brainstem vascular disease because of impaired consciousness as a result of concomitant damage to the reticular activating system.

Two forms of the vertical one-and-a-half syndrome occur with discrete lesions in the upper midbrain. One, which consists of bilatetal upgaze palsy associated with monocular paresis of downward movement, can occur with either ipsilateral or contralateral thalamomesencephalic infarctions; the other consists of a downgaze palsy associated with monocular elevator paresis that can occur with bilateral mesodiencephalic lesions.

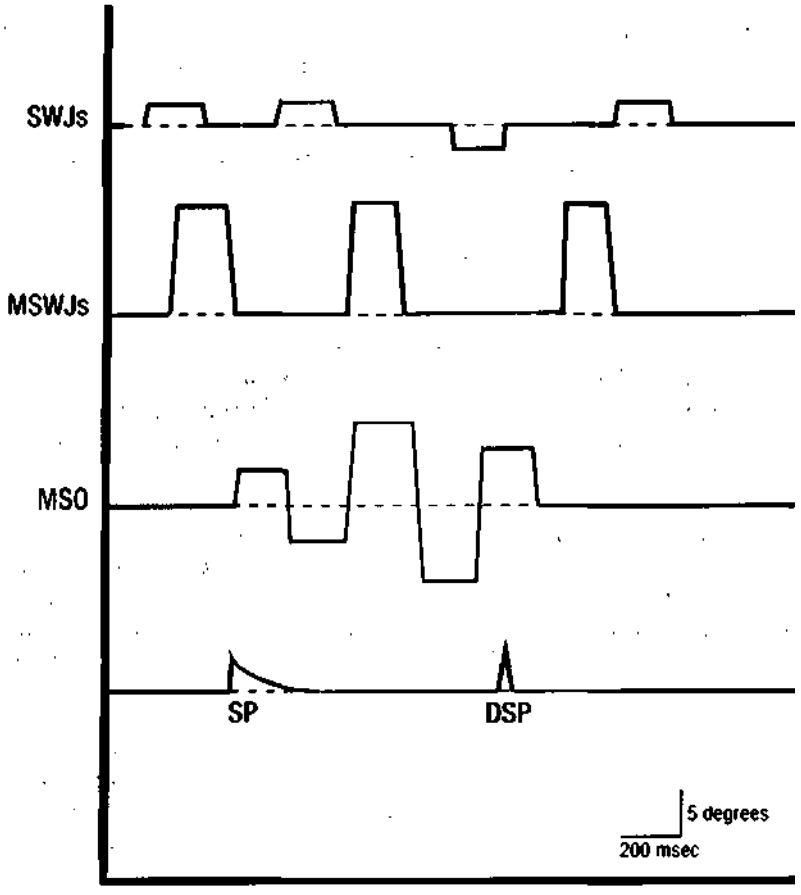

FIGURE 39.11 Simulated eye movement recordings of square wave jerks (SWJs), macrosquare wave jerks or square wave pulses (MSWJs), macrosaccadic oscillations (MSO), a saccadic pulse (SP), and a double saccadic pulse (DSP).

A crossed vertical gaze paresis, with supranuclear weakness of elevation of the contralateral eye and weakness of depression of the ipsilatcral eye, may occur with a lesion involving the me sod i encephalic junction and medial thalamus (Wiest et al. 1996).

Monocular elevator deficiency, also termed *monocular elevator palsy* or *double elevator palsy,* is characterized by limitation of elevation of one eye. The limitation is the same in both adduction and abduction, unlike Brown's superior oblique tendon sheath syndrome, in which rhe limitation is predominantly in adduction. Monocular elevator deficiency can result from paretic or restrictive disorders of the extraocular muscles, such as muscle fibrosis, myositis, myasthenia, infiltrative disease (thyroid orbitopathy, neoplasia), orbital floor fractures, and fascicular lesions of the oculomotor nerve (Gauntt et al. 1995). Some cases may be supranuclear, particularly those with normal ocular alignment in primary position (see below).

When monocular elevator deficiency is congenital, or occurs early in life, it may be associated with abnormalities of convergence, amblyopia, a chin-up head position, and ptosis or pseudoptosis. (Pseudoptosis occurs when a patient with a hypotropic eye fixates with the other eye; the upper lid follows the hypotropic eye and appears ptotic; when the patient fixates with the hypotropic eye the apparent ptosis disappears. Some patients may have both a true ptosis and a superimposed pseudoptosis.) Some congenital cases are supranuclear as a result of congenital unilateral midbrain lesions (e.g., Ziffer et al. 1992) when they are long-standing inferior rectus restriction and fibrosis prevents reflex elevation of the eye (Bell's phenomena). In those cases, primary orbital disorders, such as myositis, thyroid orbitopathy, orbital floor fractures, and infiltrative disease, must be excluded. Corrective surgery is sometimes helpful.

Acquired supranuclear monocular elevator palsy results in limitation of elevation of one eye on attempted upgaze, despite intact downgaze and orthotropia in primary position (unlike patients with monocular elevator deficiency, who have an abnormal head posture). This rare condition occurs with unilateral vascular or neoplastic lesions involving either the ipsilateral or contralateral midbrain. The affected eye can usually be elevated in response to vestibular stimulation or Bell's phenomenon, and ptosis is usually absent.

Tonic upward deviation of gaze {forced upgaze), a rare sign, is seen in unconscious patienrs and must be distinguished from oculogyric crises, petit mal seizures, and psychogenic coma. Comatose patients with sustained upgaze after diffuse brain injury (e.g., hypotension, cardiac arrest, and heatstroke) usually have cerebral and cerebellar hypoxic damage, with relative sparing of the brainstem. **Some of** these patients later develop myoclonic jerks and large-amplitude downbeat nystagmus; their prognosis is extremely poor. Rarely, tonic upward gaze deviation may he psychogenic but can be overcome, indeed cured, by cold caloric stimulation of the eardrums.

"Benign" paroxysmal tonic upward gaze (PTU) may occur in association with ataxia in young children who have downbeat nystagmus on attempted downgaze. The duration of the deviation is variable (seconds to hours) but is usually short, and it occurs frequently throughout the day. PTU usually starts in the first year of life and lasts about 2 years; the onset may be during or shortly after an infection or vaccination. PTU may be exacerbated by fatigue, relieved by sleep, and sometimes provoked by car travel; there is no evidence rhar the episodes are seizures or oculogyric crises. The cause of PTU is unknown, but at follow-up, a significant number of patients have developmental delay, intellectual disability, language delay, or ocular motility disorders; these findings imply that PTU is a marker for underlying neurological or developmental abnormalities (Hayman et al. 1998). The condition is reminiscent of the intermittent or periodic ataxias, which may respond to drugs such as acerazolamide (see Chapter 70).

Tonic downward deviation of gaze (forced downgaze) is associated with impaired consciousness in patients with medial thalamic hemorrhage, acute obstructive hydrocephalus, severe metabolic or hypoxic encephalopathy, or massive subarachnoid hemorrhage. The eyes may also converge, as if looking at the nose. Tonic downward gaze deviation may also occur in psychogenic illness, especially feigned coma, but also can be overcome by caloric stimulation. In young children with acute hydrocephalus, tonic downward deviation may be associated with upper lid retraction; because of its appearance, this is called the *setting sun sign,*

In otherwise healthy neonates, downward deviation of the eyes or tonic upgaze while awake may occur as a transient phenomenon (see Development of the Ocular Motor System, earlier in this chapter); these phenomena may be caused by uneven, delayed development in the vertical otolithic-ocular pathways (Brodsky and Donahue 200 I !. Tonic vertical deviation as a result of ictal activity is rare. A form of paroxysmal ocular downward deviation that lasts seconds and occurs in neurologically impaired infants with poor vision may also be seen in preterm infants with bronchopulmonary dysplasia but subsequent normal development (Kleiman et al. 1994).

Torsional nystagmus with a jerk waveform may be evoked during vertical pursuit eye movements in patients with lesions of the middle cerebellar peduncle {see Chapter 16). The direction of the fast phase is usually toward the side of the lesion on downward pursuit and away from the side of the lesion on upward pursuit {FitzGibbon et al. 1996).

In normal circumstances, a synkinetic movement, ocular counter-rolling, allows people to maintain horizontal orientation of the environment while tilting the head to either side (Figure 39.12A). When the head is tilted to the left, the left eye rises and intorts as the right eye falls and extorts, within the range of the ocular tilt reflex (approximately

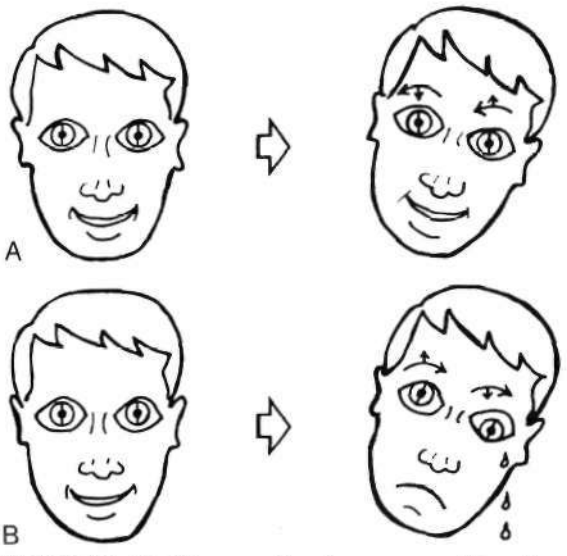

FIGURE 39.12 (A) The normal ocular counter-rolling phenom enon during head tilt. (B) The ocular tilt reaction is a triad o spontaneous skew deviation, cyclotorsion of the eyes, and heac tilt toward the side of the lower eye.

10 degrees from the vertical). The initial transient dynamic (phasic) counter-rolling response results from stimulation of the semicircular canals, whereas the sustained (tonic) response is mediated by the otolith organs and holds the eyes in their new position. Lesions of these pathways result in skew deviation.

Skew deviation is a vertical divergence of the ocular axes caused by a "prenuclear" lesion in the brainstem or cerebellum involving the vertical vestibulo-ocular pathways or, occasionally, the vestibular nerve or end organ. In about 12% of patients, the skew alternates on lateral gaze, or spontaneously. A skew deviation is usually, but not always, comitant (see Chapter 16); when noncomitant, it may mimic a partial third cranial nerve or a fourth cranial nerve palsy. Skew deviation occurs most commonly with vascular lesions of the pons or lateral medulla (Wallenberg's syndrome), presumably because of injury to the vestibular nuclei or their projections. Brandt and Diererich (1998) demonstrated ocular torsion of one or both eyes associated with subjective tilting of the visual vertical toward the lower eye in most patients with skew deviations. With lesions caudal to the lower pons, the ipsilatcral eye was lower (ipsiversive skew), but with lesions rostral to the midpontine level, the contralateral eye was lower (contra-vcrsive skew). Ocular torsion may be present without a vertical deviation and, in either situation, can be detected by blind spot mapping, indirect ophthalmoscopy, fundus photography, or settings of the visual vertical (Halmagyi 1994; Mossman and Halmagyi 1997). Skew deviation with ocular torsion (skew torsion) is a tesult of an imbalance in the tonic vestibulo-oculat pathways, in both the vertical and coronal (roll) planes, which normally stabilize the eyes and head in an upright position to maintain horizontal and vertical orientation.

Alternating skew deviation, in which the hypertropia changes sides, results from vascular or demyelinating lesions at the pretcctal-mesodiencephalic junction, usually involving the INC. This phenomenon, also referred to as *paroxysmal skew deviation* and *periodic alternating skew*, may change spontaneously or with the direction of gaze, in a regular or irregular manner over periods of seconds to minutes. Disorders affecting the cerebellar pathways or cervicomedullary junction cause alternating skew deviation on lateral gaze, in which the abducting eye is hypertropic as a result of presumed superior oblique overaction (Hamed et a I, 1993). This is probably the result of asymmetrical vestibular input to the yoked superiot oblique and contralateral inferior rectus muscles (see Chapter 16, Table 16.2) as a tesult of increased centra) otolithic tone for downgaze (Brodsky and Donahue 2001). Congenital superior oblique overaction causes an A-pattern exotropia (eyes diverge on downgaze) and abducting hypertropia on lateral gaze; it is often associated with disorders of the posterior fossa, such as hydrocephalus and meningomye-locele, and Chiari II malformations. Congenital inferior oblique overaction causes a V-pattern esotropia (eyes converge on downgaze) and is otherwise benign (Brodsky and Donahue 2001).

Bilateral fourth cranial nerve palsies may mimic gaze-dependent alternating skew, in which the adducting eye is hypertropic; however, diplopia is worse on downgaze, with significant excyclotorsion and a V-pattern esotropia,

The OTR consists of the triad of spontaneous skew deviation, cyclotorsion of both eyes, and paradoxical head tilting toward the side of the lower eye (Figure 39.12B) (Arbusow et al. 1998; Ohashi et al. 1998). A tonic (sustained) OTR may occur with a lesion of the ipsilateral utricle, vestibulat nerve, nuclei, or a lesion in the tegion of the contralateral INC and medial thalamus {Halmagyi 1994). A phasic (paroxysmal) OTR occurs with a lesion in the region of the INC, and it may respond to baclofen; when multiple sclerosis is responsible, the OTR also may respond to catbamazepine. An OTR can be induced by sound in patients with perilymph fistulas of the vestibular end organ (Tullio's phenomenon) (Halmagyi 1994).

A partial OTR, in which there is no head tilt, or there is merely ocular torsion, can occur with lesions of the cerebellar nodulus and uvula. This is attributed to an increase in the tonic resting activity of secondary otolithic neutons in the ipsilcsional vestibular nucleus as a result of loss of inhibition from the injured nodulus (Mossman and Halmagyi 1997).

Oculogyric crises are spasmodic conjugate ocular deviations, usually in an upward direction. They occurred in the late stages of postencephalitic Parkinson's disease, aftet the 1918 influenza epidemic, but now are most often caused by neuroleptic medication, particularly halopetidol. They may also occur in patients with head injury,

neurosyphilis, and carbamazepine or lithium carbonate toxicity. Oculogyric crises can also occur in the early stages of autosomal dominant "rapid-onset dystonia-parkinsonism" (Dobyns et al. 1993). A typical attack or crisis lasts about 2 hours, during which the eyes are tonically deviated upward, repetitively, for periods of seconds to minutes. The spasms may be preceded or accompanied by disturbing emotional symptoms, including anxiety, restlessness, compulsive thinking, and sensations of increased brightness or distortions of visual background (similar to occipital lobe seizures). The patient may be able to force the eyes back to the ptimary position temporarily by using voluntary saccades, optokinetic tracking, head rotation, or blinking. Electroencephalograph recordings during the attacks show no epileptiform activity. The eyelids are usually open, although they may rhythmically jerk at times from twitching of the orbicularis oculi. The pupils are not usually involved with mydriasis or aniso-coria. Attacks may be precipitated by excitement. They should be differentiated from benign paroxysmal tonic upward ga2e (see Disorders of Vertical Gaze, earlier in this chapter). Treatment for oculogyric crises includes diphenhydramine, i-dopa, and high-dose trihexyphenidyl.

Disorders of Convergence

Convergence paralysis is usually associated with other features of the dorsal midbrain syndrome (see Chapter 22). Patients with psychogenic convergence paralysis may be distinguished from those with organic disease by absence of pupillary constriction during attempted convergence and preservation of upgaze. Lack of effort is the most common cause of poor convergence, which becomes more difficult with age. Degenerative disorders, such as Parkinson's disease and PSP, are often associated with poor convergence and can be helped with prisms.

Convergence insufficiency, an idiopathic condition that may be partly psychogenic, occurs most commonly in women between the ages of 15 and 45 years (Waltz and Lavin 1993). Symptoms include words running together when reading, occasionally **frank** diplopia at near, and vague symptoms, such as eyestrain, headache, and burning eyes, that are often associated with asthenopia (see Chapter 16). Convergence insufficiency may also be seen after head injury. Because the mechanism of convergence insufficiency is an imbalance between accommodation and convergence, orthoptic exercises (pencil pushups), less commonly prisms, and myopic correction are useful in management.

Spasm of the near reflex, a disorder characterized by intermittent episodes of convergence, miosis, and accommodation, may mimic bilateral, and occasionally unilateral, abducens paresis. The patient may complain of double or blurred vision and is esotropic, particularly at distance; prominent miosis, however, is the due. Spasm of the near reflex may occasionally occur in patients with organic disorders (Goldstein and Schneekloth 1996) but is more commonly psychogenic, either in patients with conversion reactions or in anxious patients in whom the "spasm" is a manifestation of misdirected effort. The differential diagnosis is that of esotropia (Table 39.6). Miosis on gaze testing generally establishes the diagnosis but can be difficult to discern. Accomodative esotropia and latent hypottopia must be excluded by obtaining cydoplegic refraction. Patients with "psychogenic" spasm of the near reflex have associated somatic complaints and behaviotal abnormalities. Blepharoclonus on persistent lateral gaze and poor cooperation in performing motor tasks, such as smiling, opening the mouth, protruding the tongue, and the like (features of neurasthenia and asthenopia), are often found during examination (Table 39.7). Management should focus on identifying the source of the psycho pathology and may require psychiatric evaluation. Strategies such as the use of cycloplegia (homatropine eye drops) to prevent accommodative spasm, thus inhibiting the near triad, are helpful.

Table 39.6: Causes of esotropia

Congenital esotropia (also acquired, cyclic)
Duane's syndrome
Accommodative esotropia
Abducens palsy (unilateral or bilateral)
Spasm of the near reflex
Tonic convergence spasm (part of dorsal midbrain syndrome)
Pseudo-sixth cranial nerve palsy of Fisher
Acute thalamic esotropia
Posterior inrernuclear ophthalmoplegia of Lutz (pseudo-sixth)
Neuromyotonia
Divergence insufficiency
Divergence paralysis
Cyclical oculomotor palsy (spastic phase)
Nystagmus blockage syndrome
Abducens palsy with contracture of antagonist (ipsilatcral medial rectus) during recovery
Myasthenia
Medial rectus entrapment (blowout fracture)
Thyroid myopathy (rare, at presentation)
Orbital disorders (orbital varix, infiltrative lesions)
Wernicke's encephalopathy (bilateral abducens palsies)
Chiari malformation
Rippling muscle disease

Disorders of Divergence

Divergence insufficiency is characterized by sudden-onset esotropia and uncrossed horizontal diplopia at distance, in the absence of other neurologic symptoms or signs. The esotropia may be intermittent or constant, but the patients can fuse at near. The esodeviation (see Chapter 16) is greater at distance than near but is comitant in all directions. Versions and ductions are full, and saccadic velocities, if measured quantitatively, appear normal.

Table 39.7: Features of spasm of the near reflex (psychogenic)

Near tetrad
Convergence
Miosis
Accommodation (blur at distance, myopia by retinoscopy)
Extorsion (exeyclotorsion)
Neurasthenic symptoms
Rlcpharoelonus (frequent blink rate)
Poor cooperation in other motor tasks
Other behavioral changes, such as tunnel vision
May disappear with rapid saccades
Full range of eye movement
With pursuit of own hand
With one eye covered
Doll's eyes with fixation
lee-cold calorics
Normal response
liizarre bL-havior.il response
Normal optokinetic nystagmus if patient encouraged or distracted (e.g., count stripes)
Demeanor
Affective disorder
Tinted glasses or sunglasses
Excessive makeup

Fusional divergence is reduced. The origin of divergence insufficiency is unclear, but it may result from a break in fusion in a patient with a congenital esophoria, usually coming on later in life; it also occurs in patients with midline cerebellar disease. The condition is easily treated with base-out prisms for the distance correction and rarely requires extraocular muscle surgery.

Divergence paralysis, a controversial entity that may be difficult to distinguish from divergence insufficiency, usually occurs in the context of a severe head injury or other cause of raised intracranial pressure. Such patients also have horizontal diplopia at distance, but quantitatively, abducting saccades are slow. Patients with bilateral palsies of the sixth cranial nerve who recover gradually may go through a phase in which the esotropia becomes comitant with full ductions, mimicking divergence paralysis. Divergence paralysis can also occur with Fisher's syndrome, Chiari malformations, pontine tumors, and excessive sedation from drugs.

Central disruption of fusion, or post-trauma tic fusion deficiency, can occur after moderate head injury and causes intractable diplopia, despite the patient's ability to intermittently fuse and even briefly achieve stereopsis. The diplopia fluctuates and varies among crossed, uncrossed, and vertical. Versions and ductions may be full, but vergence amplitudes (see Chapter 16} arc greatly reduced. Prism therapy or surgery is ineffective, but an eye patch may provide symptomatic relief. The location of injury is presumed to be in the midbrain. Central disruption of fusion has also been associated with brainstem tumors, stroke, removal of long-standing cataracts or uncorrected aphakia, and neurosurgical procedures. This condition must be distinguished from bilateral fourth cranial nerve palsies, when diplopia is constant and associated with eyclodiplopia and excyclotropia (>12 degrees), and also from psychogenic disorders of vergence (see Disorders of Convergence, earlier in this chapter).

A congenital inability to fuse is associated with amblyopia or congenital esotropia (see Chapter 16).

The hemislidc (hemifield slip) phenomenon causes diplopia in patients with large visual field defects, particularly dense bitemporal hemianopias or, occasionally, heteronymous altitudinal defects (Borchert et al. 19%). Because of loss of overlapping areas of visual field, patients have difficulty maintaining fusion and can no longer suppress any latent ocular deviation (see Chapter 16).

Cyclical esotropia, also called *circadian, alternate-day,* or *clock-mechanism esotropia,* usually begins in childhood, although it can occur at any age; it can also follow surgery for intermittent esotropia. The cycles of orthotropia and esotropia may run 24-96 hours and parallel many other cyclical or periodic biological phenomena of obscure mechanisms. Patients with cyclical esotropia can decompensate into a constant esotropia that can be corrected surgically.

Ocular ncuromyotonia is a brief episodic myotonic contraction of one or more muscles supplied by the ocular motor nerves, most commonly the oculomotor nerve (Yee and Purvin 1998). It may occur spontaneously or be provoked by prolonged gaze in a particular direction. It usually results in esotropia of the affected eye accompanied by failure of elevation and depression of the globe. When the oculomotor nerve is affected, there may be associated signs of aberrant reinnervation (see Chapter 76). The pupil may be fixed to both light and near stimuli or become myotonic (Abulia and Eustace 1999). Ocular ncuromyotonia occurs most often after radiation therapy tor sellar region tumors; less often it is associated with compressive lesions, such as pituitary adenomas, cavernous sinus meningiomas or aneurysms, thyroid orbitopathy, and occasionally following myelography with thorium dioxide (Yee and Purvin 1998), with Paget's disease of the skull base, or neurovascular compression by a dolichoectatic basilar artery (Tilikete et al. 2000). Demyelinating lesions in the region of the third cranial nerve fascicle can also cause "paroxysmal spasm" of the muscles innervated by the oculomotor nerve (Ezra and Plant 1996) but are usually accompanied by other findings, such as eyelid retraction or paroxysmal limb dystonia (Sethi K, personal communication, 1998). Occasionally no cause can be found. Ocular ncuromyotonia may respond to carbamazepinc or other antiepilcptic drugs. It should be distinguished from superior oblique myokymia (see Chapter 16) and the spasms of cyclical oculomotor palsy.

Cyclical oculomotor palsy is characterized by paresis alternating with "cyclic" spasms of both the extra- and intraocular muscles supplied by the oculomotor nerve. It is a rare condition usually noted in the first 2 years of life,

Table 39,8; Gazc-cvokcd phenomena

1, Physiological phenomena
- Blinks
- End-point nystagmus
- Flaring of the nostrils during vertical saccades
- Mentalis contraction during horizontal saccades (personal observation)
- Oculo-auricular phenomenon: retraction of ear during lateral gaze (or convergence)
- Orbicularis oculi myokymia
- Phosphenes (more intense in patients with optic neuritis, retinal/vitreous detachment: Moore's lightning streaks)

II. Pathological sensory phenomena
- Gaze-evoked amaurosis in the eye ipsilateral to an orbital apex tumor
- Gaze-evoked tinnitus with cerebellopontine angle tumors or Following posterior lossa surgery
- Reverse-Tullio's phenomenon (gaze-evoked swooshing sound) caused by end-organ damage in a patient with Tullio's phenomenon (sound-evoked nystagmus and vertigo) (personal observation)
- SUNCT (Sudden Unilateral Conjunctival injection and Tearing) syndrome with saccades (Pareja et al. 1994)
- Tinnitus with periodic saccadic oscillations
- Vertigo

III. Pathological motor phenomena
- Convergence retraction nystagmus on attempted upgaze (dorsal midbrain syndrome)
- Facial twitching, clonic limb movements, blepharoclonus, lid nystagmus, involuntary laughter and seizures
- Gaze-evoked nystagmus (see Chapter 16)
- Neuro myotonia
- Retraction of the globe in Duane's syndrome
- Superior oblique myokymia (see Chapter 16)
- Synkinetic movements with cyclical oculomotor palsy and with aberrant reinnervation of the oculomotor nerve (see Chapter 77)

although the majority of cases are believed to be congenital and are often associated with other features of birth trauma. During the spasms, which last 10-30 seconds, the upper eyelid elevates, the globe adducts, and the pupil and ciliary muscle constrict, causing miosis and increased accommodation (Loewenfeld 1999); the paretic phase usually lasts longer. Signs of aberrant oculomotor reinnervation (see Chapter *76)* are usually present. Spasms, often heralded by twitching of the upper lid, may be precipitated by intentional accommodation or adduction. Cycles occur irregularly, vary from 1.5 to 3 minutes in duration, persist during sleep, may be suppressed by topical cholinergic agents (eserine, pilocarpine), and are abolished by topical anticholinergic agents (atropine, homatropine) or general anesthesia. The cycles usually persist throughout life, but the spasms of the extraocular muscles may abate, leaving only intermittent miosis.

Symptomatic cyclical oculomotor palsy may occur in later life in patients with underlying lesions involving the third cranial nerve, but the features and cycles are atypical. The mechanism of cyclical spasms is unclear but is well discussed elsewhere (Loewenfeld 1999).

Gaze-evoked phenomena, such as end-point nystagmus, the oculo-auricular phenomenon (Urban et al. 1993), and orbicularis oculi myokymia (Jacome 1997), are physiological, or benign; others, such as gaze evoked nystagmus or tinnitus, are pathological (Table 39.8) and may be the result of damage to the horizontal neural integrator (Lockwood er al. 2001).

Eye Movement Recording Techniques

Oculographic techniques provide clinicians and researchers with objective and quantitative means of analysis that have led to a better understanding of eye movement neurophysiology and ocular motility disorders. Quantitative oculography can measure saccadic latency, velocity, accuracy, pursuit and VOR gain, and nystagmus slow-phase velocity; it can detect unsuspected oscillations and intrusions and identify different nystagmus waveforms. Oculography is used to record both spontaneous and induced eye movements to a target, such as a projected light in front of the subject, or to vestibular and optokinetic stimuli.

Electro-oculography, also known as *electronystagmography* (Chapter 41), is a popular method of quantitative oculography but has a limited range and is unreliable for vertical eye movements because of eyelid artifact. Infrared oculography is more accurate but is also not ideal for vertical eye movements. The most quantitatively accurate technique involves the scleral search coil. Details of all the recording techniques are found in Dcll'Osso and Daroff (1999b).

Chapter 40
Neuro-Ophthalmology: Afferent Visual System

Robert L. Tomsak

From a conceptual standpoint, it is useful to considet vision as having two components: central vision (macular vision, high acuity, color perception, light adapted) and peripheral vision (ambulatory vision, low acuity, poor color perception, dark adapted). Light is refracted by the cornea and lens and focused on the retina, which is analogous to photographic film. For the best possible vision, the object of tegard must be focused on the most sensitive part of the macular retina, called the *fovea.* Central vision and colot vision are mediated mainly by the cone photoreceptors, which ate of highest density in the foveal region. The cone system functions optimally in conditions of light adaptation. Visual acuity and cone density fall off rapidly as the distance from the fovea inctcascs. For example, the retina that is 20 degtecs eccentric to the fovea is capable only of resolving objects equal to Snellen 20/200 (6/60 metric) optotypes or larger. Rod phototeceptors are present in highest numbers approximately 20 degrees from the fovea and are more abundant than cones in the more peripheral retina; rods function best in dim illumination. The total extent of the normal peripheral visual field in each eye is approximately 60 degtces superior, 60 degrees nasal, 70-75 degrees inferior, and 100 degrees temporal (Figure 40.1; see Chapter 14). Information transduced by the retina is sent from each eye to both hemisphctes of the brain by the optic nerves, each of which contains approximately 1.2 million axons. Axons that atisc from the ganglion cells of the nasal retinas of each eye cross in the optic chiasm to the contralateral optic tract. Axons from the temporal retinas do not decussate at the chiasm. The percentages of crossed and uncrossed axons in the human optic chiasm ate approximately 53% and 47%, respectively. Because of the optical properties of the eye, the nasal retina teceives visual information from the temporal visual field, and the temporal retina teceives information from the nasal visual field (see Figure 40.1). Similarly, the retina supetior to the fovea sees the inferior visual field and vice versa. These points ate clinically impottant in evaluating visual loss {see Chapter 14).

Visual information is further sttatified in the lateral geniculate body (LGB), which is the only way station between the retinal ganglion cells and the primary visual cortex. The LGB is a portion of the thalamus with six layers. Axons from ipsilateral retinal ganglion cells synapse in layers 2, 3, and 5; conttalateral axons synapse in layers 1, 4, and 6. Layers 1 and 2 of the LGB are called *magnocellular layers;* they receive input from M retinal ganglion cells. The magnocellulat pathway is concerned mainly with movement detection, detection of low contrast, and dynamic form perception. After projecting to the ptimaty visual cortex (visual atea 1, VI, or Brodmann's area 17), information from the M pathway is distributed to V2 (part of area 18) and V5 (junction of areas 19 and 37). Layers 3-6 of the LGB are called *parvacellular* and receive input ftom retinal P cells, which are color selective and respond to high contrast. These cells project to a teas V2 and V4 (fusiform gyrus) (Zeki 1993). Superior fibers that leave the LGB go straight back to the primary visual cortex; inferior fibers loop antetiotly around the superior tempotal horn of the lateral ventricles (Meyer's loop). Because these fibers are approximately 5 cm from the tip of the temporal lobe, they are sometimes damaged during temporal lobectomy, resulting in a "pie in the sky" homonymous visual field defect.

The ptimaty visual cortex (striate cottcx, atea VI, or Brodmann's area 17) is in the occipital lobe of the btain. Macular vision is represented most posteriorly at the

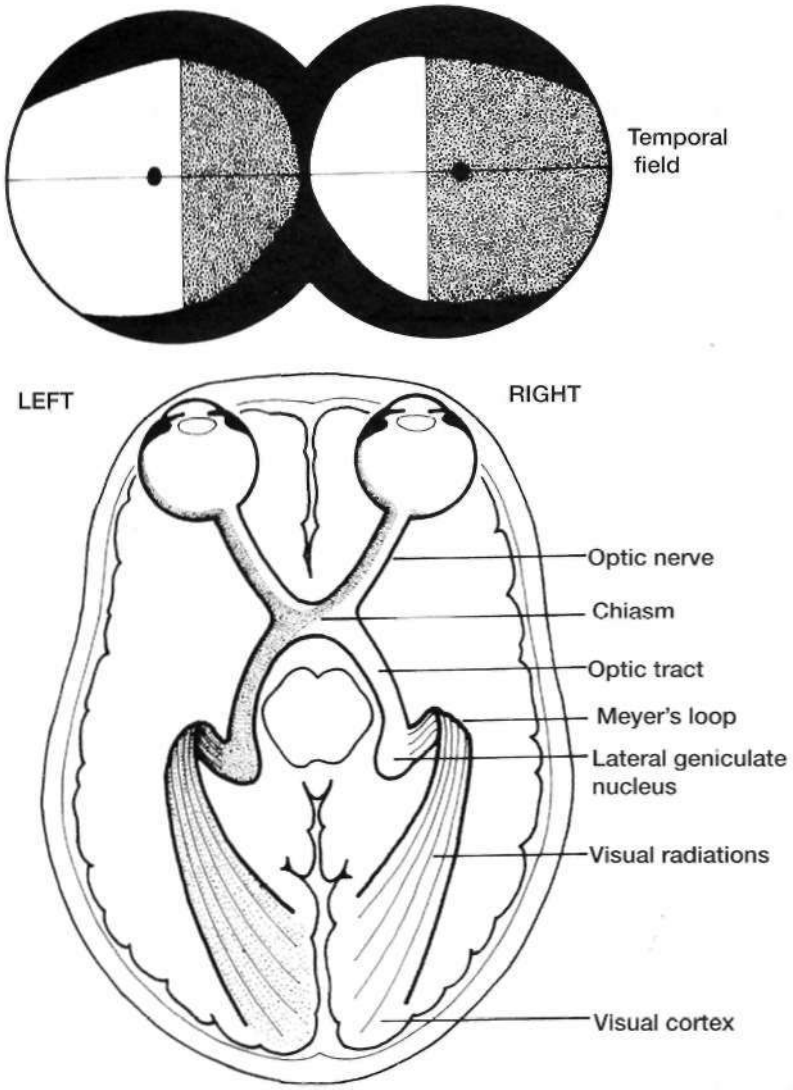

FIGURE 40.1 Visual pathways.

occipital tips. Each fovea appears to project to both occipital lobes. The peripheral visual field projects to the visual cortex that lies more anteriorly. The nonoverlapping part of the most peripheral temporal field (monocular temporal crescent) represents unpaired crossed axons from the nasal retina, which project to the most anteromedial part of the visual cortex. The primary visual cortex has interconnections with numerous visual association areas (Zeki 1993).

NEURO-OPHTHALMOLOGICAL EXAMINATION OF THE AFFERENT VISUAL SYSTEM

The neuro-ophthalmological examination makes use of ophthalmic tools and techniques but aims at neurological diagnosis. It therefore provides a bridge between neurology and ophthalmology. Many neurologists are unfamiliar with detailed ophthatmological methods, and ophthalmologists often are not facile with neurological localization.

Examination of Visual Acuity

Visual acuity describes the spatial limit of visual discrimination. Visual acuity always should be measured with each eye individually and with the best possible optical correction (i.e., using the patient's glasses); other optical means such as the pinhole device or a refraction may be needed (Clascr *1999).* The resultant response, called *best corrected* visual acuity, is the only universally interpretablc measurement of central visual function. Ideally, vision should be measured both at a standard distance (usually 20 ft, or *6* m) and also at a near distance (usually *0.33* nil- The notation 20/20 *{6/6* metric) means that the patient (numerator) is able to see the same optotypes at 20 ft as would a normal

subject (denominator). A vision of 20/60 (6/18 metric) means that the patient sees a standard optotype at 20 ft that a normal person sees at 60 ft.

A disparity between the best corrected distance and near visual acuity often indicates a specific problem. For example, the most common cause of distance acuity being better than near acuity is uncorrected presbyopia. Other conditions in which distance vision often is better than near vision include Parkinson's disease and progressive supranuclear palsy. Common causes of near acuity being better than distance acuity are myopia and congenital nystagmus. In the latter disorder, convergence needed for near vision damps the nystagmus amplitude, resulting in more consistent foveation and better binocular near acuity than distance acuity.

When measuring near vision, the reading card should be held at the specified distance of 14 in., or 0.33 m, to control for image size variation on the retina. If a nonstandard distance is used, it should be specified clearly in the medical record.

Two types of near cards are readily available; one has numbers and the other type has written text (Figure 40.2). Both are useful, but in neurological or neuro-ophthalmological practice, a near card with text measures not only visual acuity hut also reading ability. A disparity between these measurements may reveal a disturbance of cortical functions, specifically language and visual perception (see Chapter UB).

Contrast Sensitivity Testing

Contrast sensitivity testing measures the perception of lines of different width (spatial frequency) and varying degrees of

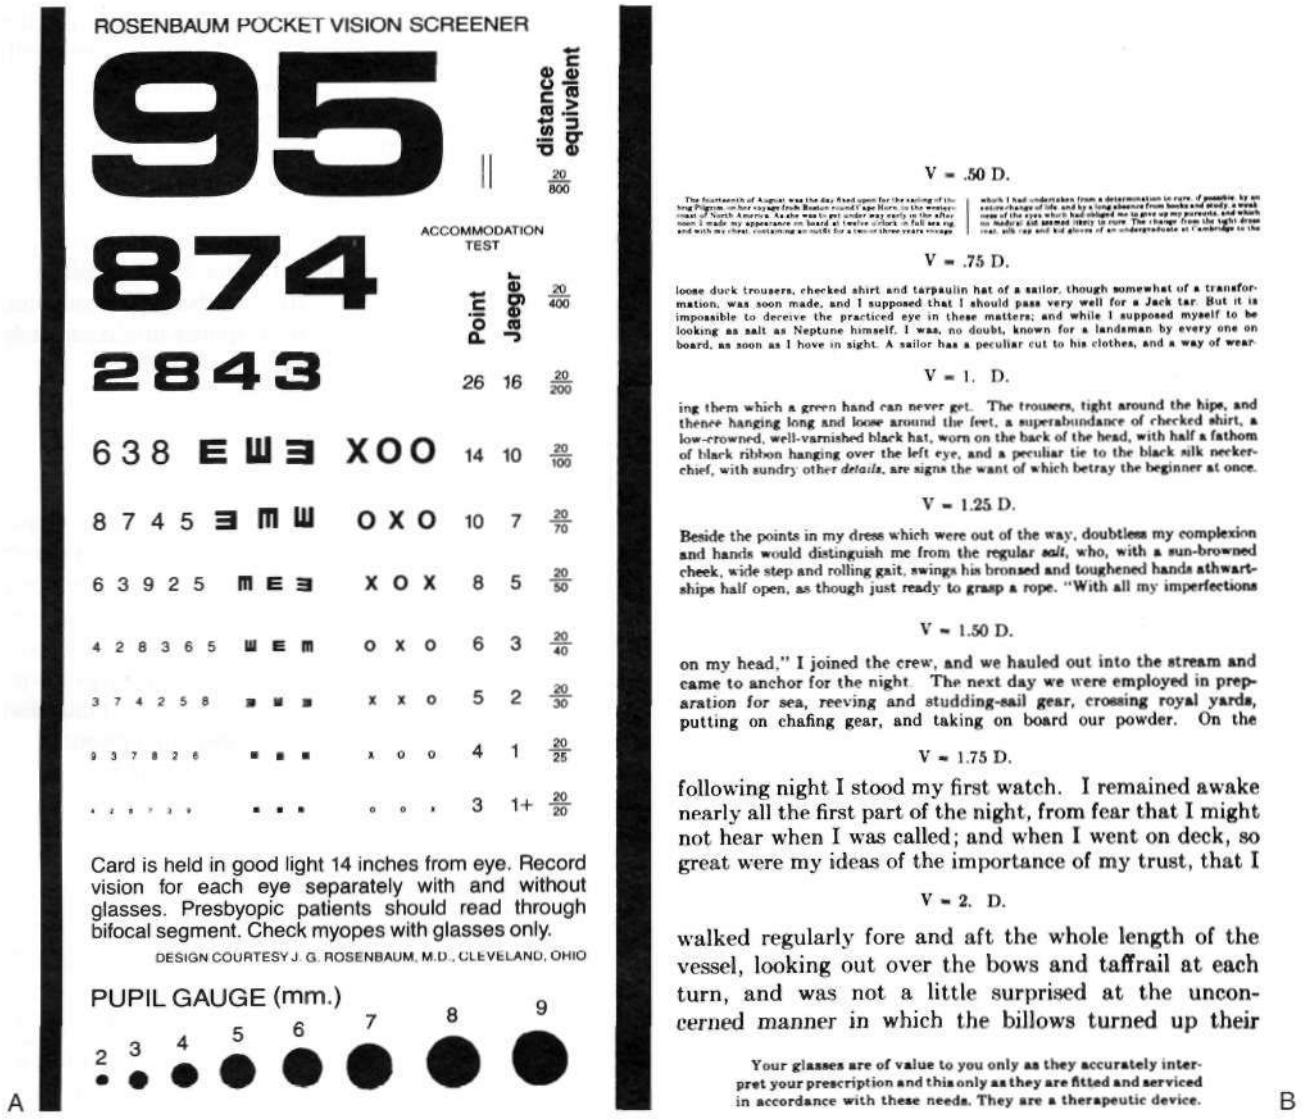

FIGURE 40.2 (A) Rosenbaum-style near vision card. (B) Near vision card with written text.

contrast. This visual function is different from visual acuity and is abnormal in numerous diseases of the eye and retrobulbar visual pathways. Measurement of contrast sensitivity in the office setting requires a special series of test plates (e.g., Atden gratings or Peli Robson chart). More complex testing is possible with computer-generated sine wave gratings.

Light Stress Test

Some disorders that affect the macula are difficult to observe with the direct ophthalmoscope. Fortunately, the light stress (or photo stress) test is an excellent method for determining whether a reduction in visual acuity is caused by an abnormality in central retinal function (Glaser 1999). The test is performed by first measuring the best corrected visual acuity with each eye. Then die eye with faulty vision is occluded and the normal eye is subjected to a bright light for 10 seconds. Immediately thereafter the patient is instructed to read the next, larger line, and the recovery period is timed. The same procedure is done with the other eye. and the results are compared. Fift; seconds is the upper limit of normal for visual recovery. In diseases that affect the macula, it is not unusual for the recovery period to take several minutes.

Color Vision Testing

Disordered color perception, especially if asymmetrical between the eyes, is a good indication of optic nerve dysfunction; symmcttical acquired color vision defects should raise the possibility of a retinal degeneration such as cone-rod dystrophy. Congenital color vision anomalies occur in approximately 8% of men and 0.5% of women. Techniques for measuring color vision range from the simple to the sophisticated. Holding a brightly colored object in front of each of the patient's eyes individually and asking for a comparison of both brightness and color intensity is a useful office and bedside technique for detecting central color defects. Also, testing with colored objects on each side of fixation often can detect a subtle hemianopia.

More formal estimates of color vision can be made with standard pseudoisochromatic color charts (Ishihara's or Hardy-Rand-Rittler) or with sorting tests such as the Farnsworth-Munsell or Sahlgren's saturation tesr.

Examination of the Pupils

Examination should include measurement of pupil size, the direct and consensual reaction to light, the accommodative reaction, and the presence or absence of an afferent pupillary defect. If anisocoria is found, ptosis should be looked for, keeping in mind the possibility of Horner's syndrome or third cranial nerve paresis. This information should be recorded in an easily understood format; for one example, see Table 40.1.

The measurement of pupil size and light reaction should be made in constant dim illumination with the patient fixating an immobile distance target. At times it is useful to measure pupil sine in the dark and also in bright ambient light. For example, anisocoria caused by oculosympathetic paresis (Horner's syndrome) often is more pronounced in the dark because the affected pupil does not dilate well. Conversely, a pupil with parasympathetic denervation (e.g., Adie's tonic pupil) often is more evident in bright light because of abnormal constriction (see Chapter 17).

When one is measuring the light reaction or looking for the afferent pupillary defect, the brightest light available should be used. The reaction to a near object is best brought out by having the subject look at his or her own finger or thumb at a distance of 15-30 cm. Using this method, one can observe a near pupillary response in a completely blind person because of proprioceptive influences.

The observation of a relative afferent pupillary defect (Gunn's pupil or Marcus Gunn's pupil) is an invaluable indication of a conduction defect in the optic nerve. Indeed, many neuro-ophtbalmologists regard this as the most important pupillary abnormality. This difference in pupillary reaction is best brought out by alternately illuminating one pupil and then the other, hence the name *swinging flashlight test.* The swinging flashlight test also can be thought of as a comparison of the direct and consensual response in the same eye. Normally, these pupillary responses are equal; in an eye with an optic nerve conduction defect the direct response is less than the consensual response.

The test for a relative afferent pupillary defect should be performed as described in Table 40.2 and shown in

Tabic 40.1: Simple method of record "::ipillary examination

	Size (mm)	*Direct light reaction*	*Comemua! reaction*	*Near response*
Right eye	4,0	+4	+2	+4
Left eye	4.0	+2	+4	+4

Note: In this example, the resting pupil size is equal in the two eyes at 4 mm. The pupillary reactions can he estimated using 1+ to *4+* scale, as shown here, or by actually recording the pupil sixe before and after the light or near response. In the example shown, the direct response is better in the right eye than in the left eye, and the reverse is true for the consensual reaction. This table illustrates a left relative afferent pupillary defect.

Tabic 40.2: Testing for the relative afferent pupillary defect

1. The patient should fixate at a distance to minimize fluctuation in pupillary size and accommodative miosis.
2. A light bright enough to cause maximum pupillary constriction should be used.
3. Each pupil should be checked individually for its direct light response, which can be graded on a scale of 1-4 (see Table 40.1).
4. The light should be moved quickly to illuminate each eye alternately every 1-2 sec (the swinging flashlight test of Levitan).
5. The initial constriction of the pupil and the presence or absence of pupillary escape should be observed.
6. Only 3 or 4 swings of the light should be made to minimize bleaching of the retina with subsequent slowing of the pupillary reaction.

Figure 40.3. There is one caveat: The swinging light test brings out an asymmetry of optic nerve conduction. Therefore if both nerves are injured to the same extent, no obvious telative afferent pupillary defect is observed. Furthermore, severe macular or retinal disease can produce Marcus Gunn's pupil, but these problems are almost always apparenr on funduscopic examination. By contrast, minimal optic nerve disease commonly yields an obvious relative afferent pupillary defect. See Chapter 17 for a more complete discussion of pupillary abnormalities.

Light Brightness Comparison

Light brightness comparison can be considered as a subjective swinging flashlight test. The subjective appreciation of light intensity often is impaited in optic nerve disease but not in macular problems. The test is done by directing a bright light into both eyes in succession, and the patient is asked to estimate the difference in subjective brightness as a percentage. For example, the examinet might ask, "If this light [normal eye illuminated] were worrh $1, in terms of light brightness or intensity, what would this one be worth [abnormal eye illuminated]?" The patient often is able to estimate the difference in perceived brightness.

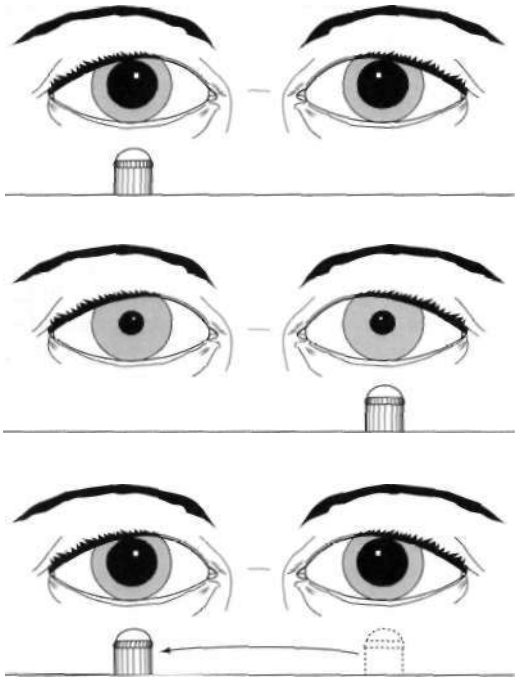

FIGURE 40.3 Right relative afferent pupillary defect (Marcus Gunn's pupil) from right optic nerve lesion. (A) Right eye illuminated. Poor direct and consensual reaction. (B) Excellent direct and consensual response. (C) Light swung from left to right with redilatation of both pupils.

Visual Field Testing

Evaluation of the visual fields is vital in everyone with unexplained visual loss. Confrontation testing should be part of the routine neurological examination. Numerous techniques are available for visual field examination, ranging from simple confrontation testing to sophisticated thteshold static perimetry. For the purposes of this discussion, simple, practical techniques adapted from the teachings of J. Lawton Smith are emphasized, and the mote complicated methods are summarized briefly.

The first assessment involves asking the patient to observe the examinet's face or another part of the environment with each eye and to report whether anything is missing or blurred; Smith called this step the "history field." For example, a patient with optic neuritis and a centtal scotoma might look at a face and report that the eyes and nose are missing. Another patient with ischemic optic neuropathy and an inferior altitudinal visual field defect might not see anything below the nose. Similarly, to a patient with a homonymous hemianopia, one half of the face would appear to be missing.

Confrontation testing should follow. Although there are many methods, a simple, thorough examination can be done by finger counting in quadrants coupled with hand comparison. The steps are as follows:

1. The physician has the patient cover one eye and fixate on the center of the examiner's face.
2. *dinger counting in the quadrants:* The physician holds up fingers sequentially in each of the four quadrants of the visual field and asks the patient to count how many are seen.
3. *Simultaneous finger counting using both hands:* If step 2 is completed normally, the physician asks the patient to count the number of fingers he or she is displaying with both hands, first in both the right and left upper quadrants of the patient's visual field, then in both the right and left lower quadrants. The patient is then asked to add the total number of fingers shown with

both hands. This stage of confrontation testing often brings out evidence of extinction, hemineglect, or problems with calculation. It also has the effect of stabilizing wandering visual fixation.

4. *Simultaneous band comparison:* Finally, both hands are held open in the right and left upper and lower quadrants, and the patient is asked to compare the quality of the images. For example, a patient with a •subtle bitemporal hemianopia might be able to pass steps 1 through 3, but when shown hands on either side of the vertical midline the patient might state that the hands in the temporal hemifields arc not as clear as the ones held in the nasal hemifields.

A major advantage to the finger counting method over kinetic methods of confrontation testing is that the potential for Riddoch's phenomenon is minimized. Riddoch's phenomenon is a dissociation between the visual perception of form and movement so that the patient can perceive only moving targets in a hemianopic visual field (Zeki and Ffytche 1998). This phenomenon occurs in homonymous hemianopias that have resulted from injuries to the occipital cortex. Therefore a hemianopia may be missed if the examiner uses only a moving target, such as wiggling fingers in the far periphery.

Confrontation methods using colored objects can be effective in detecting visual field abnormalities. Confrontation testing is useful for patients with constricted visual fields. Normally, as the distance from the examiner to the patient increases, the visual field expands, or funnels; with psychogenic visual field constriction, the field remains the same size even at longer distances, or it tunnels (Figure 40.4).

Measurement of the central 20 degrees of visual field (in each eye separately) can be done using Amsler's grid chart (Figure 40.5). The chart is held in good light at a distance of 30 cm from the eye, with the patient wearing reading glasses, if needed. The following questions are asked:

Can you sec the spot in the center of the square?
"While looking at the center, can you see the entire square, or are any sides or corners missing?
While you are looking at the center, are any small squares missing or distorted?

If any abnormal responses to these questions arc given, the examiner should ask the patient to draw the abnormal areas on the chart. This can then be kept in the patient's medical record.

Patients with a central scotoma often report that the center of the grid is missing or blurred, those with hemianopic defects say one half of the grid is missing, and those with macular disease may report that some of the lines are wavy or distorted (see Chapter 14).

Numerous other methods for examining the visual field are available (Glaser 1999) but are beyond the scope of this chapter and the expertise of most neurologists. This section provides only an overview.

Examination of the entire field of vision requires a perimeter; the tangent screen measures only the central 30 degrees of visual field at a distance of 1 m. Perimeters can be divided into those that use a moving stimulus (kinetic) and those in which individual spots in the visual field are tested statically. Most static perimeters available today are automated and driven by computerized examination strategies. Static perimeters may measure the actual visual threshold at defined points in space (threshold static perimetry) or may test these points with light of preset luminance (suprathreshold static perimetry). A commonly used kinetic machine is the Goldmann instrument; popular automated perimeters include the Octopus and Humphrey

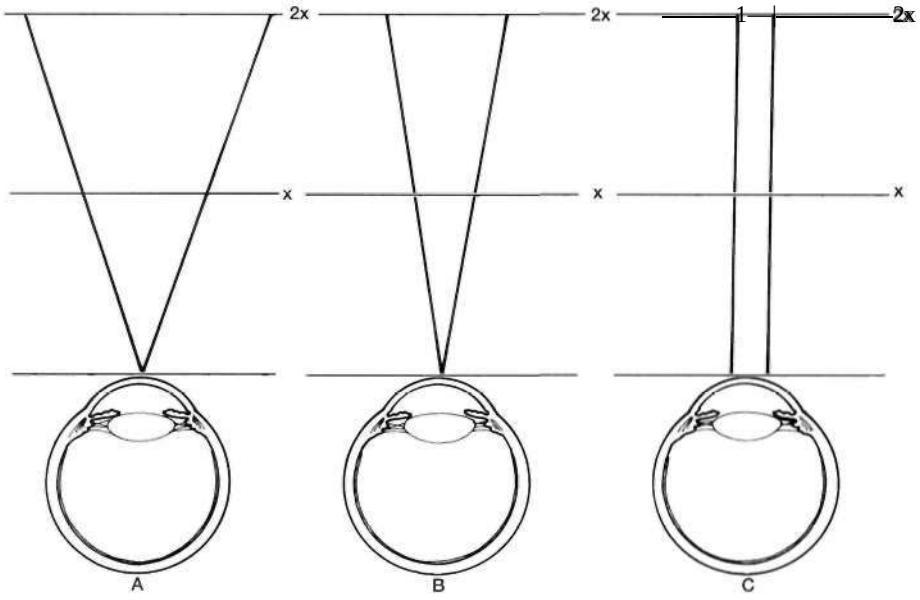

FIGURE 40.4 (A) Normal visual field enlarges with increase in testing distance; it "funnels." (B) Constricted visual field from organic disease also proportionally enlarges. (C) Constricted visual field of psychogenic origin usually docs not enlarge as testing distance increases; it "tunnels." (Data from Trobc, J. D. & Glaser, J. S. 1983, *The Visual Fields Manual: A Practical Guide to Testing and interpretation*, Triad, Gainesville, Fla., p. 135.)

units (threshold static perimeters). On theoretical grounds, threshold static perimeters are the most sensitive and quantitative, but the examination is time consuming and tiring for the subject. Many patients with neurological disorders are unable to sit for an examination that may take as long as 45 minutes per eye and requires intense concentration and alertness. Therefore, many neuro-ophthalmologists rely on kinetic perimeters of the basic Goldmann design because of their versatility.

VISUAL FIELD ABNORMALITIES

Eight general rules for visual field interpretation are summarized in Table 40.3. Comments about six of these general rules are discussed in the following sections.

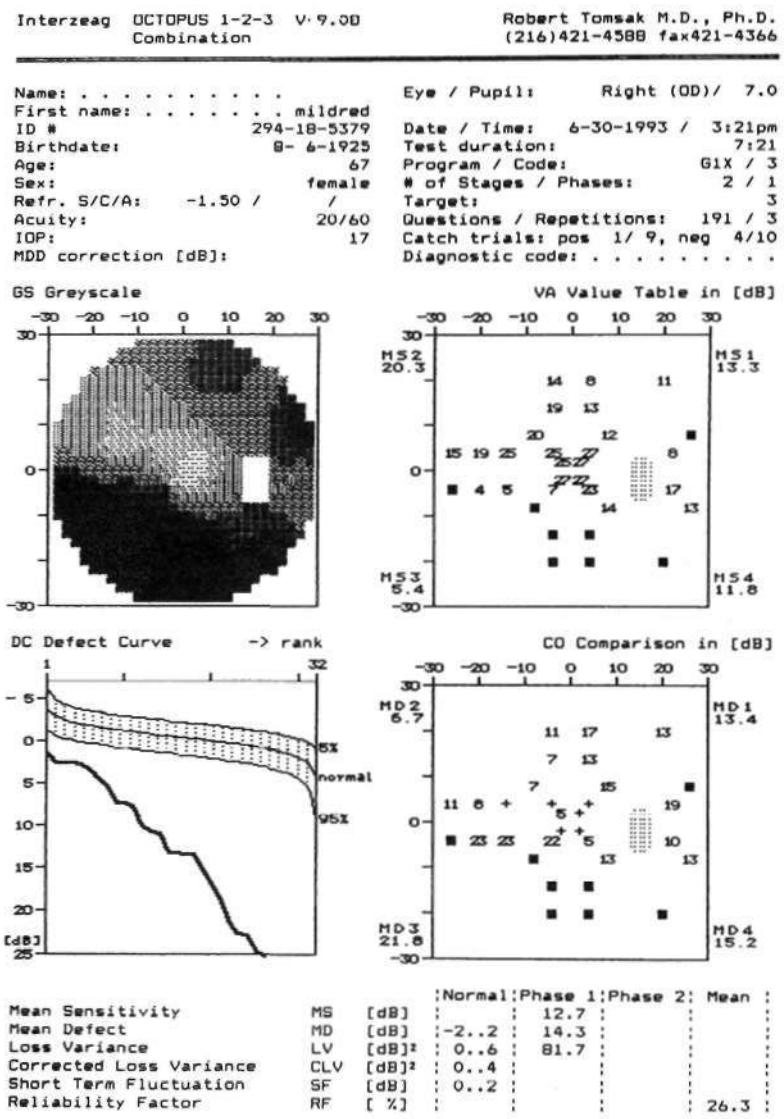
Rule 1

Optic nerve lesions produce prechiasmal visual field abnormalities that are often characteristic. Ischemic optic neuropathy usually leads to inferior altitudinal defects (Eigure 40.6A), optic neuritis usually manifests as a cecocentral scotoma (Figure 40.6B), and compressive lesions cause abnormalities in the peripheral field as well as centrally (Eigure 40.7).

A lesion involving the posterior optic nerve and anterior chiasm results in a junctional scotoma (i.e., ipsilateral cecocentral scotoma and contralateral upper temporal defect) from involvement of ipsilateral and crossing fibers from the opposite inferonasal retinal (Willbrand's anterior knee). Binasal hemianopias usually are the result of local ocular disease {Figure 40.8); these diseases include papilledema, ischemic optic neuropathy, glaucoma, optic

Tabic 40.3: General rules of visual field interpretation

1. Lesions of the retina and optic nerve produce field defects in the ipsilateral eye only, unless the lesions are bilateral.
2. True hitemporal hemianopia is caused only by a lesion at the optic chiasm.
3. Retrochiasmal lesions produce homonymous visual field defects.
4. Anterior retrochiasmal lesions produce incongruous homonymous visual field defects.
5. Posterior retrochiasmal lesions produce congruous visual held defects.
6. Temporal lobe lesions give slightly incongruous homonymous hemianopias involving the upper quadrant,
7. There is no localizing value to a complete homonymous hemianopia except that the lesion is retrochiasmal and contralateral to the visual field defect.
8. A unilatetal homonymous hemianopia does not reduce visual acuity.



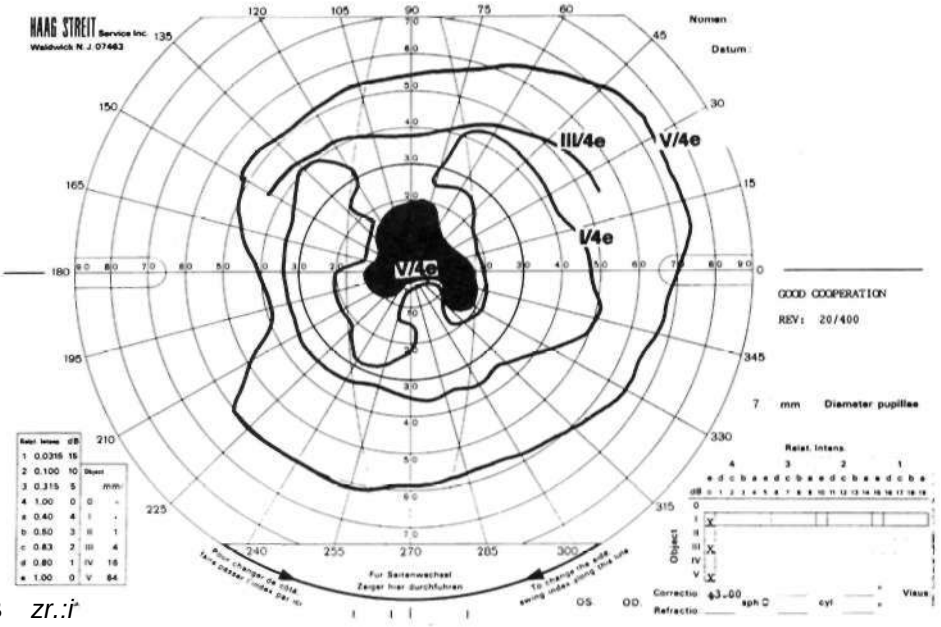


FIGURE 40.6 (A) Threshold static measurement of central 30 degrees of right visual field (Octopus 1-2-3 perimeter; G1X program). Sixty-seven-year-old woman with anterior ischemic optic neuropathy OD and inferior altitudinal visual field defect. Upper left: Gray-scale measurement; darker areas correspond to abnormal areas of visual field (displays measured and interpolated data). Area of blind spot is not investigated and therefore is reproduced as white, not black. Upper right: Mean sensitivity (MS) display in decibels. The decibel (dB) is a logarithmic relative scale to quantify differential light sensitivity (dB = 0.1 log-unit of stimulus intensity). Lower right: Mean defect (MD) display (MD = mean of the deviation of measured dB from age-matched normal values). Positive values indicate decreased sensitivity. Lower left: Cumulative defect curve (Bebie curve) arranges test locations with the least difference on the left side. This curve helps differentiate local from diffuse damage. (B) Kinetic perimetry of right visual field by Goldmann's technique.

B *zr..ir*

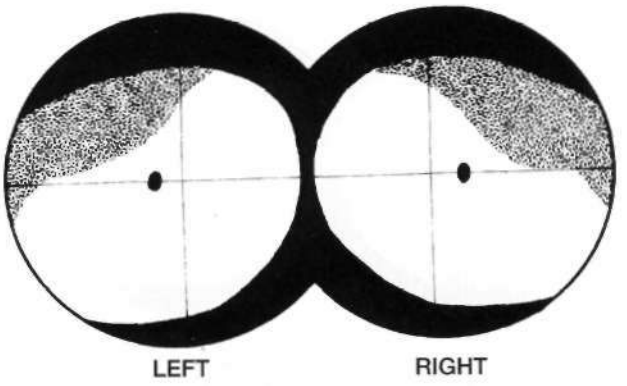

FIGURE 40.9 Pseudobitemporal hemianopia. Note that vertical midline is not respected.

nerve drusen, congenital optic nerve pits, optic nerve hypoplasia, and sectoral retinitis pigmentosa. Less often, hydrocephalus, ectatic parasellar arteries, and basal tumors cause binasal field defects. Binasal visual field defects of organic causes do not respect the vertical visual field meridian, whereas psychogenic binasal defects may.

Rule 2

True bitemporal hemianopias are the hallmark of chiasmal disease; the common causes are discussed in Chapter 14. Less commonly, ischemia, radiotherapy, and demyelination can cause chiasmal syndromes. Bitemporal defects that cross the vertical midline (pseudobitemporal hemianopias) are almost always caused by a congenital anomaly causing rotation or tilting of the optic discs (Figure 40.9) (see Chapter 15). Bilateral cecocentral scotomas can also masquerade as bitemporal field defects.

Rule 3

A homonymous visual field defect is present in the same hemifield or visual quadrant of each eye. The only exception to this rule is the monocular temporal crescent syndrome, in which only unpaired visual fibers residing in the contralateral anterior medial occipital lobe are affected.

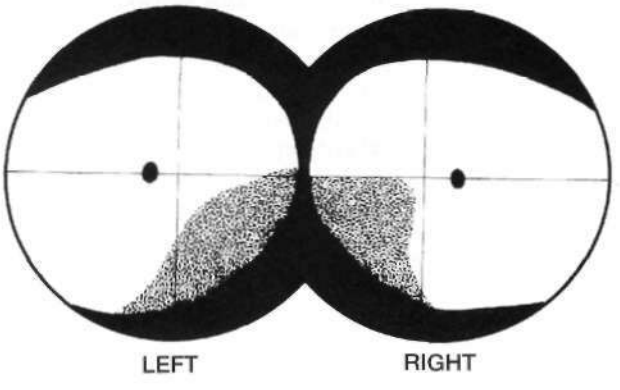

FIGURE 40.8 Binasal hemianopic visual field defects.

Rule 4

Incongruous hemianopias are seen in more anterior retrochiasmal lesions (e.g., those affecting the optic tract or temporal lobe; Figure 40.10). Optic tract hemianopias often are associated with a contralateral relative afferent pupillary defect.

Rule 5

Congruous homonymous hemianopias have patterns that are identical in each affected visual field; they usually result from occipital lobe infarcts (Figure 40.11).

Rule 8

Even a complete unilateral homonymous hemianopia does not decrease the visual acuity because the remaining macular cortex in the opposite hemisphere is still functioning. If input to both macular cortices is abnormal, however, then central acuity often is diminished, but the acuities should be equal in both eyes. If the visual acuities are unequal, there must be another explanation for the visual asymmetry.

NONORGANIC (FUNCTIONAL OR PSYCHOGENIC) VISUAL DISTURBANCES

Functional visual problems may represent up to 5% of an ophthalmologist's practice (Tomsak 1995). A variety of synonyms exist for these disorders, including *hysterical*

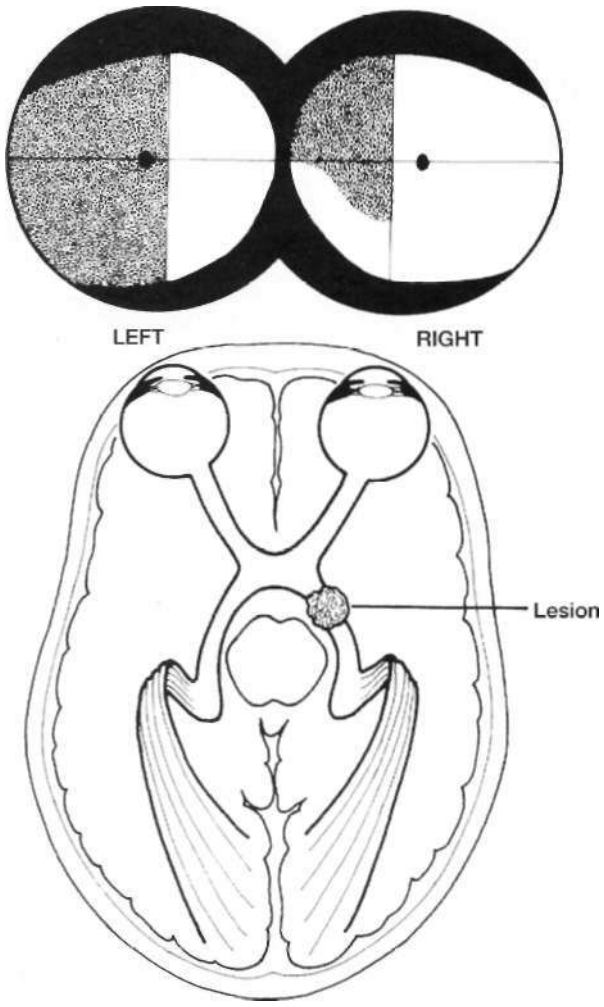

FIGURE 40.10 Incongruous left homonymous hemianopia from right optic tract lesion.

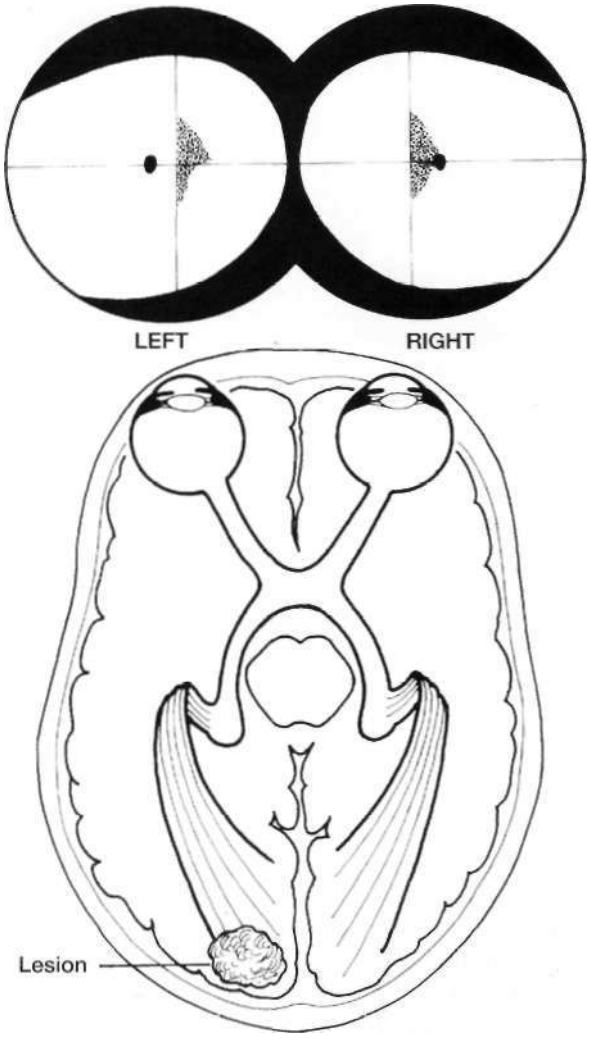

FIGURE 40.11 Congruous paracentral right homonymous hemianopia.

visual loss, psychogenic amblyopia, and *ocular conversion reaction* (Table 40.4).

Diagnostic Techniques

A careful social and family history is needed for evaluating patients with psychogenic visual disturbances, especially regarding abuse, peer pressure, and visually impaired friends and family members. Different tests are necessary for different functional visual disturbances. For example, if a person claims total blindness in one or both eyes, important tests might include examination of the pupils, optokinetic nystagmus, and the use of a large mirror held close to the face to induce eye movement via a pursuit refit[1] x. If the patient claims some vision, then it is often useful to test for disparity in distance and near acuity and for stereopsis.

Visual fields are extremely important and usually have one of four patterns: tubular contraction, spiral, star-shaped, and isopter inversion (Figure 40.12). A confrontation field done at different distances can be useful in evaluating a patient with tunnel vision. Normally the area of visual field increases with increasing distance from the object. In other words, the normal visual field funnels. Thus

Table 40,4; Some forms of functional visual disturbance

Visual acuity loss (one or both eyes)
Visual field loss (unilateral or bilateral)
Color perception abnormalities
Convergence insufficiency or accommodation insufficiency
Convergence spasm
Loss of depth perception
Diplopia
Night blindness
Photophobia
Pharmacological pupils
Voluntary nystagmus

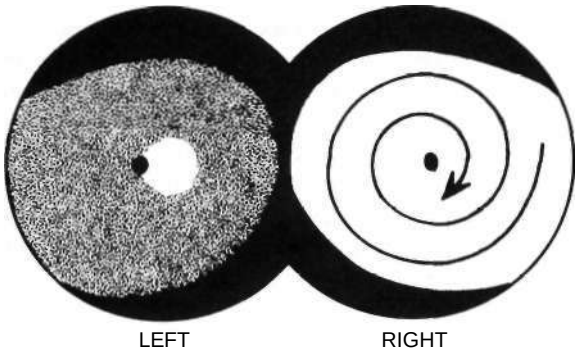

FIGURE 40.12 Two common visual field abnormalities with psychogenic vision loss. Left: Concentric (tubular) contraction. Right: Spiral pattern (seen only with kinetic visual field testing).

the visual field of a patient with an organic cause for tunnel vision should enlarge as the distance from the examiner or object increases. If the field does not expand at longer distances, the visual disturbance is not organic (see Figure 40.4). Isopter inversion means that the visual field plotted with a larger test object is smaller than the visual field plotted with a smaller test object; this also does not have an organic cause.

The use of visual evoked potentials (VEPs) to diagnose functional visual loss can be frustrating. If the VEP is normal, useful information is gained, but factitious abnormalities in the VEP are easily induced by normal subjects who fix eccentrically on the target or who converge and accommodate to blur their vision. Therefore an abnormal VEP is not always diagnostic of an organic visual disturbance.

Approximately one half of patients with functional visual disorders improve with time and reassurance (Tomsak 1995). Factors that indicate a good prognosis include youth and the presence of anxiety, whereas older age and depression are associated with a poor prognosis.

Pediatric Afferent Neuro-Ophthalmology

Examination techniques for children often differ from those for adulrs, and the reader is referred to more comprehensive discussions of the pediatric neuro-ophthalmological examination (Tomsak 1995; Brodsky, Baker, and Hamcd 1996). Many of the same diseases that affect vision in adults also affect children, but some are specific to youths or present during early growth and development (Table 40.5). Optic nerve hypoplasia, Leber's congenital amaurosis, and albinism are discussed in more detail.

Tabic 40.5: Neurological causes of vision loss in children

Albinism
Leber's congenital amaurosis
Gliomas of the optic nerves or chiasm
Craniopharyngiomas
Optic nerve hypoplasia
Other optic nerve dysplasias
Hereditary optic atrophies

Optic Nerve Hypoplasia

Optic nerve hypoplasia is a congenital and nonprogressive condition that may reflect a primary defect in differentiation of the retinal ganglion cell axons. The optic disc and scleral canal are of subnormal diameter; a peripapillary ring of pigmentation often is present, called the *double-ring sign* (see Chapter 15). The hypoplasia may be segmental, as in children born of insulin-dependent diabetic mothers.

Optic nerve hypoplasia may Iv unilateral 01 bilateral. Visual acuities may be variable in affected eyes and can be anywhere from 20/20 to light perception. Associated ocular conditions include microphthalmos, aniridia, and albinism. Astigmatism is common. Visual field defects usually are nasal or inferior altitudinal.

Patients with bilateral optic nerve hypoplasia often have strabismus, nystagmus, endocrine disturbances, and developmental delay. The common endocrine disturbances are hypothyroidism, growth hormone deficiency, diabetes insipidus, and neonatal hypoglycemia. Bilateral optic nerve hypoplasia in association with absence of the septum pelliicidum and hypopituitarism is called *septo-optic dysplasia* (de Morsier's syndrome). Optic nerve hypoplasia usually is sporadic but may be associated with fetal alcohol syndrome, marernal diabetes, or maternal anticonvulsant ingestion during pregnancy.

Leber's Congenital Amaurosis

Leber's congenital amaurosis is most broadly defined as a syndrome of bilaterally poor vision beginning in early childhood that is associated with a depressed or absent electroretinogram result. It is estimated to be the cause of 10-18% of childhood blindness. This disease is not related to Leber's hereditary optic neuropathy (see Chapters 14 and 15). Visual acuity in Leber's congenital amaurosis usually is less than 20/200 (6/60 metric). The retinal pigment epithelium has a salt-and-peppcr appearance, and rerinal vascular attenuation is sometimes marked. Optic disc swelling may be present. Pathological changes in the retina are variable and may affect all layers or just the ganglion cells. Nystagmus occurs in approximately 75% of cases, and oculomotor apraxia and other eye movement problems may be present. Approximately 30% of patients with Leber's congenital amaurosis have neurological abnormalities, which include hyperkinetic behavior, poor coordination, spastic paraparesis, psychomotor retardation, and hydrocephalus. Patients may exhibit the oculodigital phenomenon, or eye gouging, as an attempt to

produce phosphenes from mechanical stimulation of the retina. Leber's congenital amaurosis usually occurs sporadically but may be inherited in an autosomal recessive manner in approximately one third of cases.

Albinism

Albinism is a genetically determined abnormality in melanin synthesis that is associated with congenital nystagmus, foveal hypoplasia, and impaired visual acuity. Albinoidism affects tissues derived from the neural crest (iris, skin, hair) and does not have associated visual abnormalities. True albinism may affect the skin and the eyes (oculocutaneous albinism) or may affect the eyes only (ocular albinism) and be less obvious to the examiner. The ocular fundus can be totally devoid of pigment or simply have a blond appearance. The degree of visual impairment seems related to the degree of ocular pigmentation; tyrosinase-negative albinos have more marked reductions in visual acuity and more obvious nystagmus. Normal foveal development appears to be influenced by melanin in the retinal pigment epithelium in the macular area.

In albinos, about 20% of axons from temporal retinal ganglion ceils cross at the optic chiasm; this has been confirmed by VEP studies that demonstrate significant hemispheric asymmetry to monocular stimulation. Albinos lack normal stcrcopsis. Albinism also occurs in the Hermansky-Pudlak syndrome (albinism with hemorrhagic diathesis) and in the Chediak-Higashi syndrome (a complex neurodegenerative disorder associated with pyogenic episodes) (sec Chapter 66).

Chapter 41
Neuro-Otology

B. Todd Troost and Lisa C. Arguello

Neuro-otology is a subspecialty that encompasses disorders of the peripheral and central auditory and vestibular systems. Neuro-otology is similar to neuro-ophthalmology in that it is defined by those who practice it. Most neuro-otologists have come from the field of otolaryngology, and their emphasis has been on the organ that is presumably abnormal: the ear. This resembles the early history of neuro-ophthalmology, when the emphasis was primarily on the eye; only later were central visual ocular motor connections and symptoms considered, and the field began to involve neurologists. Similarly, neuro-orology concentrated on the primary functions of the ear, vestibular and auditory, without much reference to information processing in the central nervous system or to neurological conditions that could produce dizziness, vertigo, or alterations in hearing. As outlined in Chapter 18, many neurological and systemic conditions can produce dizziness and disequilibrarion. Therefore neurologists have become increasingly involved in evaluating patients complaining of dizziness. Just as retinal disorders remain primarily the province of the ophthalmologist, so hearing disorders, which are primarily peripheral, remain largely the province of the otolaryngologist.

Because auditory complaints often accompany vestibular symptoms, it is incumbent on neurologists who treat dizzy patients to become familiar with some aspects of auditory as well as vestibular testing.

INVESTIGATIONS

Vestibular Testing

The primary vestibular rests are the electronystagmogram (KNG), rotational tests, and posturography.

Standard ENG is well described elsewhere (Baloh 1998; Bojrab and Stockwell 1994), Eye movements are recorded by means of the corneal-retinal potential by surface electrodes and are printed on strip chart recording paper or analyzed by computer. Currently, many laboratories use infrared video goggles for nystagmus testing, which can produce a pictorial record of the presence of vertical nystagmus, as distinct from eyelid artifact. Standard testing usually includes calibration, gaze testing, bithermal or simulraneous caloric testing, positional testing, and pursuit and optokinetic nystagmus. In most clinical laboratories, eye movements are recorded using only bitemporal electrodes that monitor the movements of both eyes. In more sophisticated laboratories, the movements of each eye are recorded separately. Individual recordings are necessary to determine asymmetries between the eyes, such as occur in internuclear ophthalmoplegia. During calibration, the patient is asked to look between two targets, ±10 degrees from the center of fixation. Frequent overshoots indicate ocular dysmctria, a sign of cerebellar system disorder (Chapter 16).

Most laboratories perform bithermal caloric testing (Figure 41.1A), in which each ear is irrigated separately with warm and cool stimulation produced by water or by air jets. The resulting nystagmus is analyzed manually or by computer to determine the slow phase of the induced nystagmus. Peak slow-phase velocity (SPV) resulting from the warm and cool stimulation of one ear is compared with that from the other ear. The most important finding during ENG is a significant difference in the responses. A difference of more than 20% between ears is a clear indication of hypofunction in one peripheral vestibular apparatus {provided there are no technical artifacts), and the ear with the weaker response is said to have a reduced vestibular response or unilateral weakness (canal paresis). The quality of such testing varies widely among laboratories. If possible, the neurologist should always review the primary tracings or at least have available the calculated SPVs from each ear. The absolute value of SPVs is not as important as the comparison between responses of each ear.

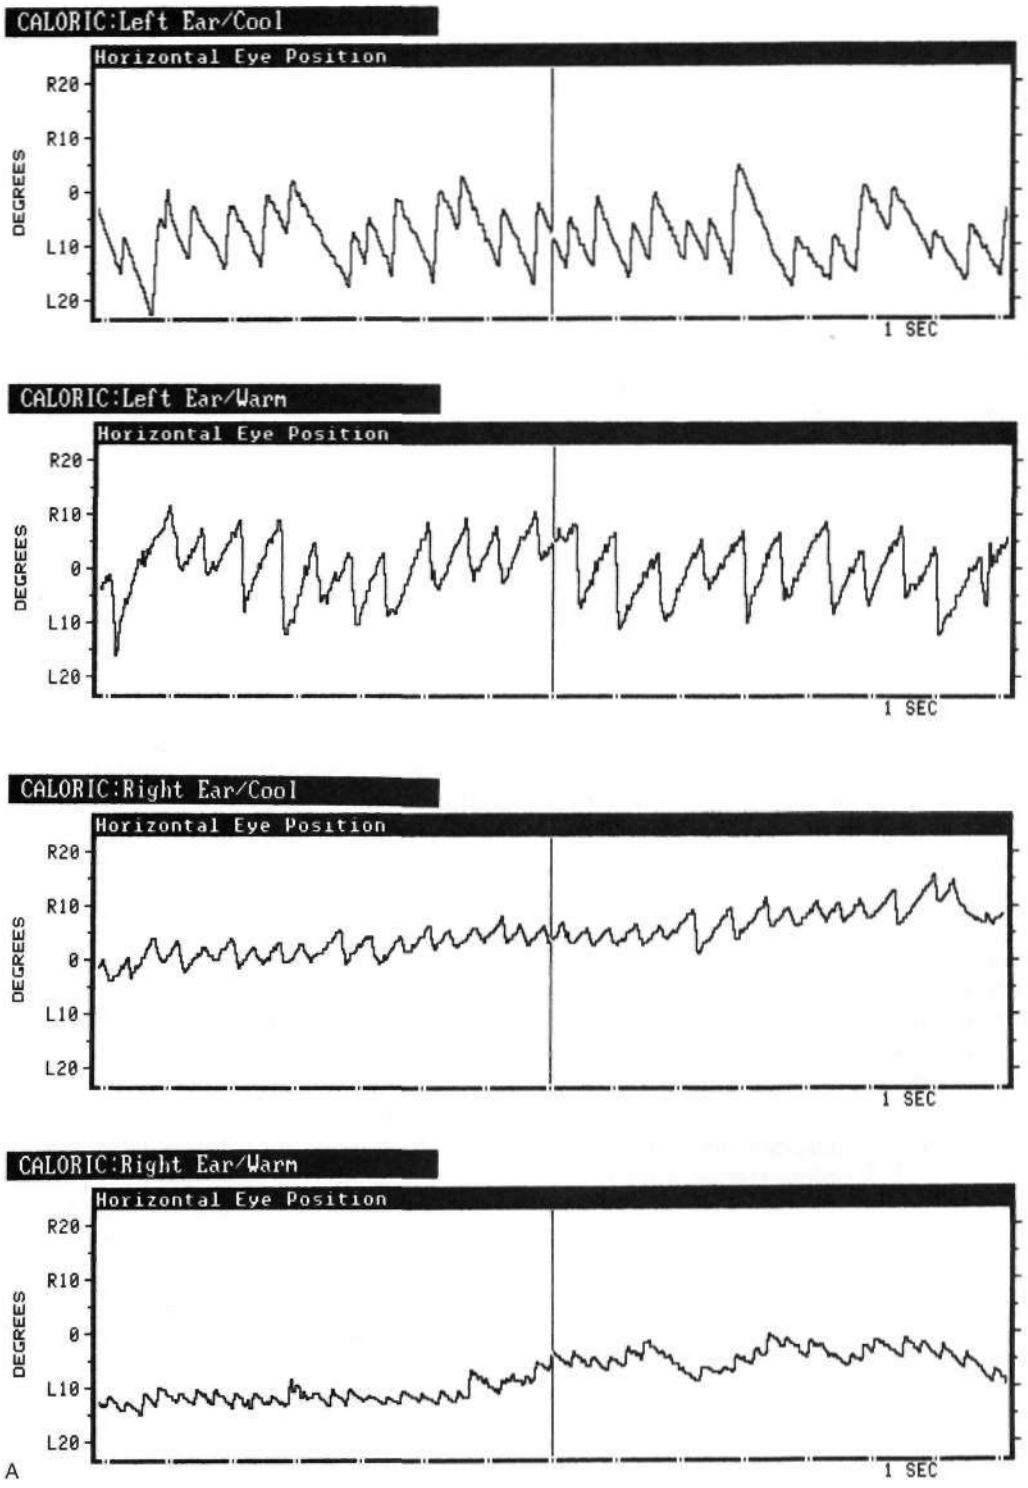

FIGURE 41.1 Computer printout of electron ystagmog ram. (A) Bithermal caloric irrigation. First panel: Responses obtained stimulating the left car with cool air (24'C). Right-beating nystagmus is provoked with a peak slow-phase velocity of 47 degrees per second. Second panel: Left-beating nystagmus provoked by stimulating the left ear with warm air (50°C). Peak slow-phase velocity is measured at 45 degrees per second- Third panel: Left-beating nystagmus induced by stimulating the right ear with cool air (15 degrees per second). Fourth panel: Right-beating nystagmus produced by stimulating the right ear with warm air (12 degrees per second). Results of caloric stimulation indicate a unilateral weakness (canal paresis) of 54% on the right side, suggesting a lesion involving the labyrinth or vestibular nerve on the right side.

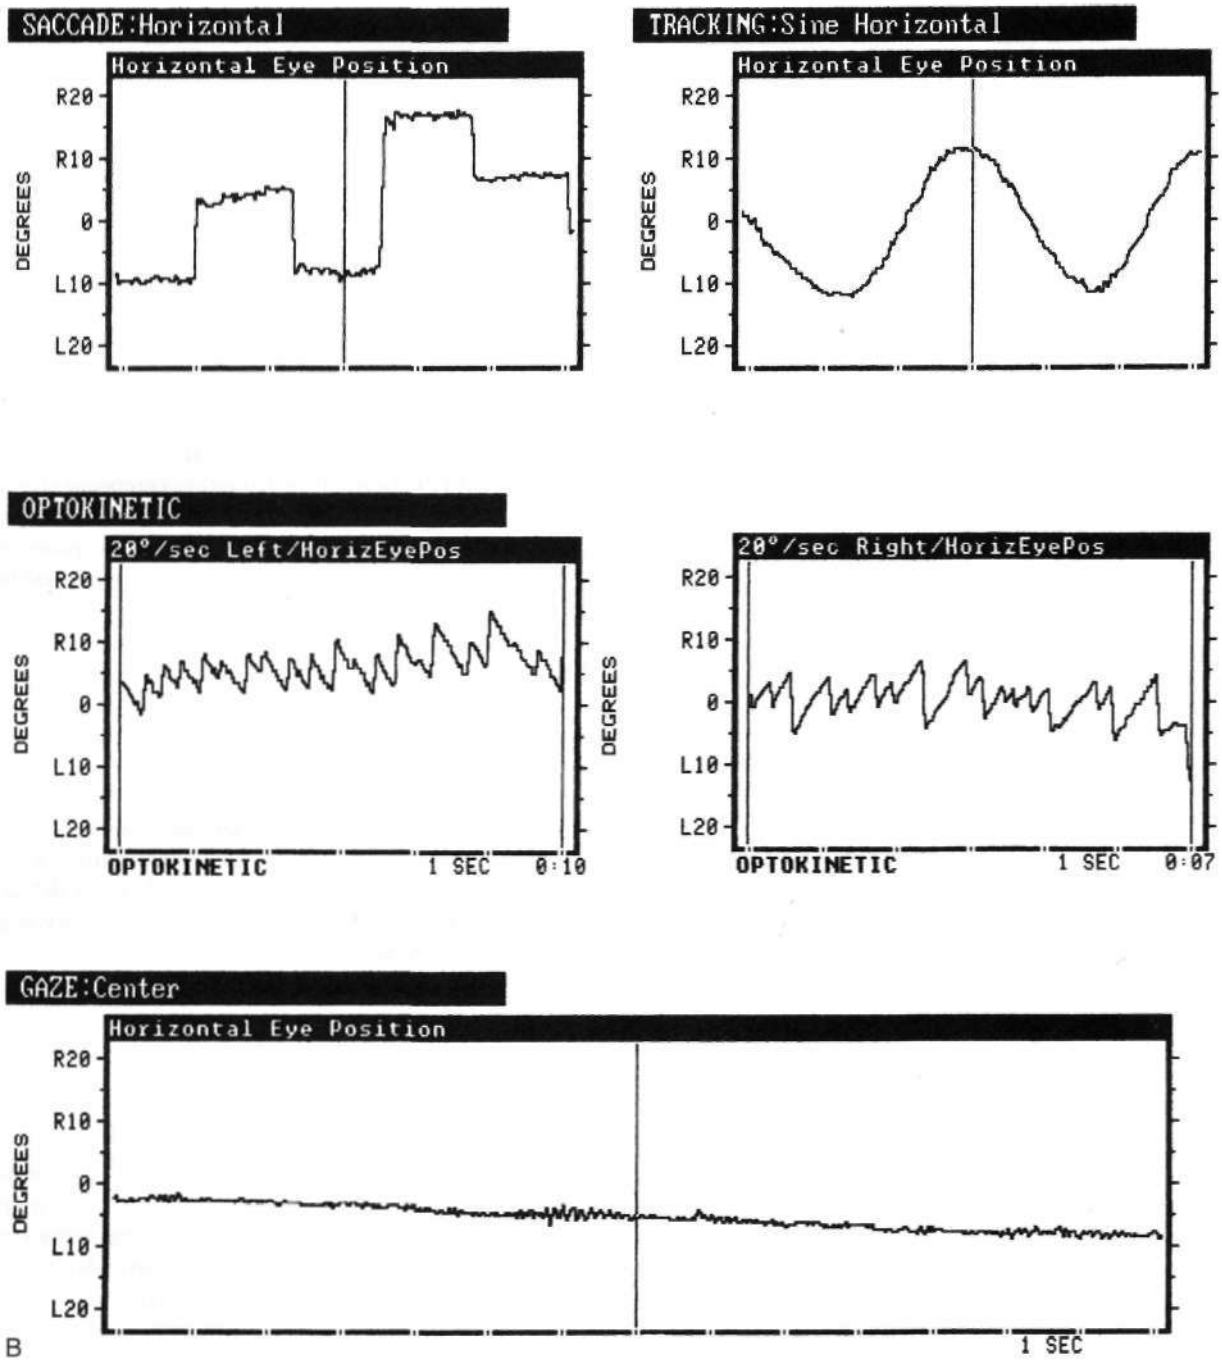

FIGURE 41.1, cont'd. (B) Ocular motor assessment. First panel, left; Saccadic eye movements showing no significant overshoot or dysmetria; normal. First panel, right: Horizontal ocular tracking, normal, without interspersed saccades. Second panel: Optokinetic responses demonstrating symmetry. Third panel: Central gaze showing no significant spontaneous nystagmus.

Another value sometimes given is directional preponderance. One sums the values of the SPV of right-beating nystagmus (cold water in the left ear and warm water in the right ear) and compares the sum with that of the SPV values of left-beating nystagmus (cold water in the right ear and warm water in the left ear). The significance of directional preponderance remains unclear and often is not calculated. Primary position nystagmus can add to or subtract from the nystagmus produced by caloric stimulation, altering the results.

The ability to suppress a caloric-induced nystagmus by visual fixation is evaluated during caloric testing. Most normal subjects can suppress the nystagmus to at least one half of its original amplitude during visual fixation. The

inability to suppress caloric-induced nystagmus usually is interpreted as indicating a central lesion, particularly cerebellar dysfunction. However, many normal people, particularly those who experience intense vestibular symptoms during testing, cannot suppress the induced nystagmus to less than 50% of the baseline value.

The ocular motor assessment consists of saccadic eye movement, gaze testing, tracking (visual pursuit), and optokinetic tests (Figure 41.IB). With the current availability of a commercial apparatus for recording and analyzing fast eye movements, ocular motor evaluation is feasible. Most saccade tests measure the speed and accuracy of saccadic eye movements at various amplitudes. The results are printed out as a velocity-amplitude relationship and compared with those of age-matched controls. Ideally, each eye should be measured individually and recorded in each horizontal direction. Vertical eye movements usually are not studied because the standard recording apparatus does not eliminate eyelid artifact and often does not give accurate vertical eye movement information.

During rotational testing in vestibular function laboratories, the patient is rotated in a chair controlled by a computer. The chair rotates slowly at different constant velocities, usually expressed in terms of frequency or cycles per second (hertz). Typical rotation speeds include 0.01 Hz, 0.02 Hz, 0.04 Hz, 0.08 Hz, and 0.16 Hz, all slow speeds. Patients are rotated in the dark with their eyes open while performing mental tasks designed to distract them from mental imagery, which can suppress eye movement. During a chair rotation to the right, the eyes move to the left and then reccnter with a fast phase. Thus the slow component (phase) is in the direction opposite the spin, and the fast component of the resultant nystagmus is in the direction of the rotation. A computer eliminates the fast components, and a slow phase is reconstructed and compared with the speed of the chair rotation. In this way, a gain (slow eye movement speed divided by chair rotation speed) at different frequencies is obtained. Measuring symmetry compares the responses of rotating in one direction with those rotating in the opposite direction.

Another measurement made during rotational testing is of the time relationship between slow eye movements and the slow movement of the chair. This difference is called the phase lag, and various phase lags are also plotted against the frequency of rotation of the chair. Therefore both gain and phase plots are produced during rotational testing. Unlike caloric testing, rotational testing (which stimulates both ears simultaneously) generally provides little clear-cut information about the site of the lesion; however, it is beneficial in quantitating bilateral weakness in a reproducible fashion. The symmetrical response of a person with a unilateral peripheral vestibular abnormality indicates vestibular compensation. Patients who become asymptomatic after peripheral vestibular abnormality can still show a phase lag, particularly at the lower rotation frequencies. An abnormal phase lag is a nonspecific marker and usually indicates some degree of vestibular peripheral abnormality. Rotational test abnormalities are quite reproducible, more so than caloric tests, and it is often difficult to determine which side is abnormal and whether any resultant abnormality is peripheral or central with rotation tests alone. Such determinations must be made using other information, such as the results of an ENG or a clinical examination.

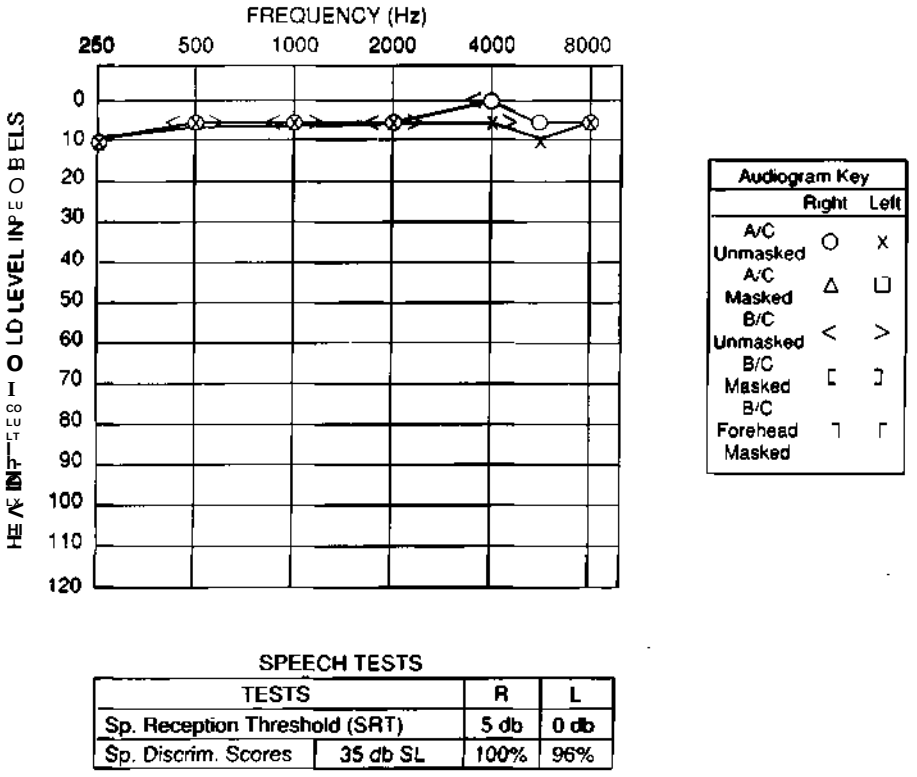
Posturography is an attempt to quantify the Romberg test (Furman 1995). Changes in body sway during Romberg testing, with the feet directly together, with eyes open and with eyes closed, are measured by means of a computer. Most of the earlier attempts to quantify the Romberg test used a static posture platform, but correlating an abnormality with different states (e.g., peripheral vestibulopathy, peripheral neuropathy, cerebellar dysfunction, and neuromuscular disorders) on the platform was largely unsuccessful. Now, a dynamic posture platform is used. The patient is surrounded by a movable visual field, and the posture platform itself may be moved. The theory is that moving the visual surround may eliminate visual cues that help maintain posture. Similarly, moving the posture platform in response to a movement of the feet also may eliminate proprioceptive cues, which assist in posture maintenance. Both visual and proprioceptive cues may be eliminated simultaneously. Theoretically, attempts to maintain posture depend solely on vestibular afferent information. The test results in all conditions are reported, and the interpretation is based on the systems that are defective. Dynamic posturography is a promising technology that is still being improved.

Audiological Testing

Audiological assessment is the basis for quantifying auditory impairment. Most neurologists rely on clinical hearing testing and may use tuning forks, as described in Chapter 19.

In defining an auditory abnormality, tuning forks are no substitute for a complete audiological battery. Audiological testing is most reliable in defining peripheral or cochlear auditory disturbances and often may provide useful information, based on subtests, to diagnose retrocochlear disease. Basic assessment and subtests may be helpful in identifying cerebellopontine angle tumor, most commonly a vestibular schwannoma. Central auditory testing for the rare central disorders of audition is more difficult and poorly understood. Detailed descriptions of audiological tests, both peripheral and central, arc provided in standard texts (Troost and Waller 1998).

The basic audiological evaluation establishes the degree and configuration of hearing loss, assesses ability to discriminate a speech signal, and provides some insight into the type of loss and possible cause. The test battery consists of pure-tone air and bone conduction thresholds,



SPEECH TESTS

TESTS		R	L
Sp. Reception Threshold (SRT)		5 db	0 db
Sp. Discrim. Scores	35 db SL	100%	96%

FIGURE 41.2 Normal audiometric results showing normal hearing sensitivity with excellent speech discrimination bilaterally. (A/C = air conduction; B/C = bone conduction.)

speech thresholds, speech discrimination testing, and immittance measures.

Pure-tone air conduction thresholds provide a measure of hearing sensitivity as a function of frequency and intensity (Figure 41.2). When a hearing loss is present, the pure-tone air conduction test indicates reduced hearing sensitivity.

Definitions

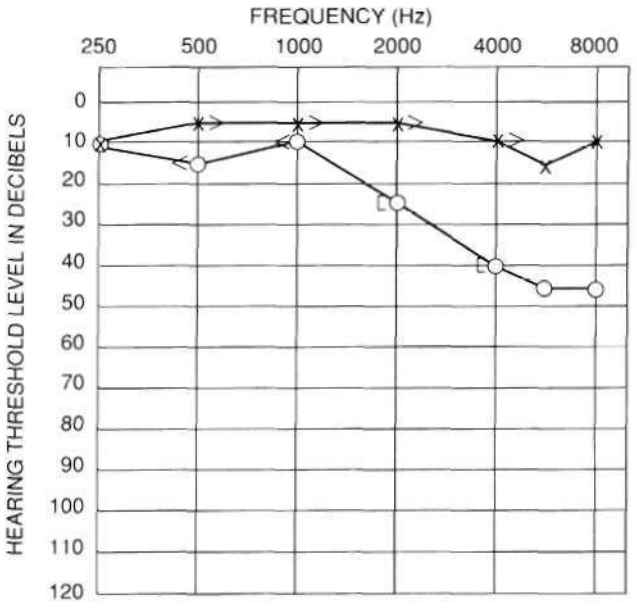
It is appropriate at this point to define some basic audiometric terms. Pure tones are defined by their frequency (pitch) and intensity (loudness). Normal hearing levels for pure tones are defined by international standards. Brief-duration pure tones at selected frequencies are presented through earphones (air conduction) or a bone conduction oscillator on the mastoid bone (bone conduction). The audiogram indicates the lowest intensity that a person can hear at a given frequency and displays the degree (in decibels) and configuration (sensitivity loss as a function of frequency) of a hearing loss. *Thresholds* can be defined as the lowest-in tensity signal that a person can detect approximately 50% of the time during a given number of presentations. The speech reception threshold (SRT) is the lowest intensity level at which the listener can identify or understand speech 50% of the time. The SRT may also be called the *spondee threshold* because spondees arc the test material. Spondee words are two-syllable words that are given equal syllable stress, such as *baseball, toothbrush, sidewalk, oatmeal, popcorn,* and *railroad.* Once the SRT is determined in this manner, the audiologist determines speech discrimination ability by presenting a list of 50 phonetically balanced words at volume levels approximately .35^*0 dB above SRT. The list is a standardized one, containing monosyllabic words of equal phonetic composition. Word recognition is scored as the percentage correct, with each correct word counting for 2% of the total. Pure-tone bone conduction thresholds are obtained when a stimulus is presented by bone conduction,

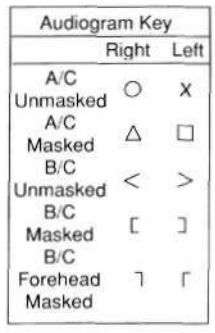
Bone conduction tests are intended to be a direct measure of inner ear sensitivity. Comparison of air and bone conduction thresholds establishes the type of hearing loss. Conductive loss results from disorders in the outer or middle ear. Sensorineural loss is associated with disorders of the cochlear and eighth cranial nerves. Mixed loss is a conductive and sensorineural loss coexisting in the same ear.

Speech Testing

Speech reception threshold testing measures the patient's ability to repeat familiar spondaic words. It provides a comparative measure for confirming pure-tone thresholds. Lack of agreement between speech thresholds and pure-tone threshold averages indicates a discrepancy and the need for additional testing or retesting to establish valid measures.

Word recognition tests measure a patient's ability to differentiate speech sounds. Discrimination ability may be





SPEECH TESTS

FIGURE 41.3 Abnormal audiogram. Findings indicate normal hearing sensitivity for the left ear, with a mild to moderate high-frequency hearing loss for the right ear. The asymmetrical hearing loss, in addition to the decreased discrimination score for the right ear, indicates possible retrocochlear pathology, such as a vestibular schwannoma. (A/C = air conduction; B/C = bone conduction.)

affected in varying amounts, depending on the type, cause, configuration, and degree of hearing loss. Discrimination scores contribute to estimates of the amount of handicap to be expected from the hearing loss and to the prognosis for rehabilitation.

Figure 41.3 depicts an audiogram from a patient with a cerebellopontine angle tumor demonstrating asymmetrical hearing loss. Patients with asymmetrical heating sensitivity should undergo neuroimaging to rule out a cerebellopontine angle tumor.

Middle Ear Testing

Immittance measures assess the status of the middle ear and confirm information obtained in other tests of the battery. The basic immittance battery consists of tympanometry, static immittance, and acoustic reflex thresholds. Data from the tympanogram permit determination of the static compliance of the middle ear system. A result of "type A tympanogram" means that mobility of the tympanic membrane and middle ear structures is within normal limits (see Chapter 19).

Acoustic Reflex Testing

Acoustic reflex measures a contraction of the stapedius muscle (innervated by the seventh cranial nerve) in response to a loud sound. The afferent limb of the reflex arch is through the auditory portion of the eighth cranial nerve, and the efferent portion of the reflex arch is through the seventh cranial nerve. The stapedius muscle normally would contract bilaterally regardless of which car was stimulated, assuming normal afferent input. After contraction of the stapedius muscle, the tympanic membrane is tightened or stiffened, thereby increasing the impedance or resistance of the eardrum to acoustic energy and resulting in a slight attenuation of sound transmitted through the middle ear system. In a normal subject, the acoustic reflex occurs in response to a pure tone between 70 and 100 dB above hearing level or when a white noise stimulus is presented at 65 dB above hearing level. Patients with conductive hearing loss do not have reflexes because the lesion prevents a change in compliance with stapedius muscle contraction. With cochlear lesions, the acoustic reflex may be present at sensation levels less than 60 dB above the auditory pure-tone threshold, which is a form of abnormal loudness growth or recruitment. Cochlear hearing losses must be moderate or severe before the acoustic reflex is lost. In contrast, patients with retrocochlear or eighth cranial nerve lesions often have abnormal acoustic reflexes with normal hearing. The reflex may be absent or exhibit an elevated threshold or abnormal decay. Reflex decay is present if the amplitude of the reflex decreases to half its original size within 10 seconds of stimulation at 1000 Hz, 10 dB above reflex threshold. This abnormality occurs in approximately 80% of patients with acoustic neuromas. Observation of the pattern of acoustic reflex testing, along with hearing evaluation, permits inferences to support the presence of a cochlear, conductive, or neural lesion of the seventh or eighth cranial nerves (Table 41.1).

Tahle 41.1: Pattern of acoustic reflex measurements with unilateral lesions

	Stimulus presented			
	C	ɹ	**C**	*I*
	Reflex measured			
Type of lesion	*/*	*C*	**C**	*1*
Cochlear (<85 dBHL)	-	+	+	+
Conductive (>30 dBHL)	-	-	+	-
VIII cranial nerve	+	-	+	-
VII cranial nerve	-	+	+	-

C = contralateral to lesion; dBHL = decibels hearing loss; I = ipsilateral to lesion; + = reflex present; — = reflex absent.
Source: Adapted from Baloh, R. W. 1984, *Dizziness, Hearing Loss, and Tinnitus: The Essentials of Neurolology,* Davis, Philadelphia, pp. 59-96.

Accurate administration of the basic test battery should establish the presence and the characteristics of hearing loss. Interpretation of the battery and observation of patient behavior may indicate a need for additional testing, such as neutoimaging, hearing aid evaluation, or medical evaluation.

Evoked Potentials

Bt a in stem auditory evoked potentials ate also known as brainstem auditory evoked responses or auditory brainstem responses (ABRs) (see Chapter 36A). These physiological measutes can be used to evaluate the auditory pathways from the ear to the upper brainstem. In addition, ABR threshold testing, although not a test of hearing sensitivity, may be used to determine behavioral threshold sensitivity in infants or uncooperative patients. The most consistent and reproducible potentials are a series of five submicrovolt waves that occur within 10 milliseconds of an auditory stimulus. These potentials are recorded by averaging 1000-2000 responses from click stimuli by use of a computer system and amplifying the response (figure 41.4). The anatomical correlates of the five reliable potentials have been only roughly approximated. Wave I of the brainstem auditory evoked potential is a manifestation of the action potentials of the eighth cranial nerve and is generated in the distal portion of the nerve adjacent to the cochlea. Wave II may be generated by the eighth cranial nerve or cochlear nuclei. Wave III is thought to be generated at the level of the superior olive, and waves IV and V are generated in the rostral pons or in the midbrain near the infetior colliculus. The complex anatomy of the central auditory pathway (Troost and Waller 1998), with multiple crossing of fibers from the level of the cochlear nuclei to the inferior colliculus, makes interpretation of central disturbances in the evoked responses difficult.

The brainstem auditory evoked potential is a sensitive, noninvasive diagnostic test for diagnosing cerebellopontine angle tumors. It is used to differentiate cochlear from eighth cranial nerve hearing defects and, on some occasions, demonstrates an auditory abnormality when behavioral audiometric testing is still normal. The majority of patients with acoustic tumors have abnormal responses.

The least specific finding is the absence of all waves. This occurs in some patients with vestibular schwannoma and in some with cerebellopontine angle meningiomas. Such patients often have marked hearing deficits with poor discrimination on behavioral testing, suggesting retrocochlear disease. The absence of all waves should not occur

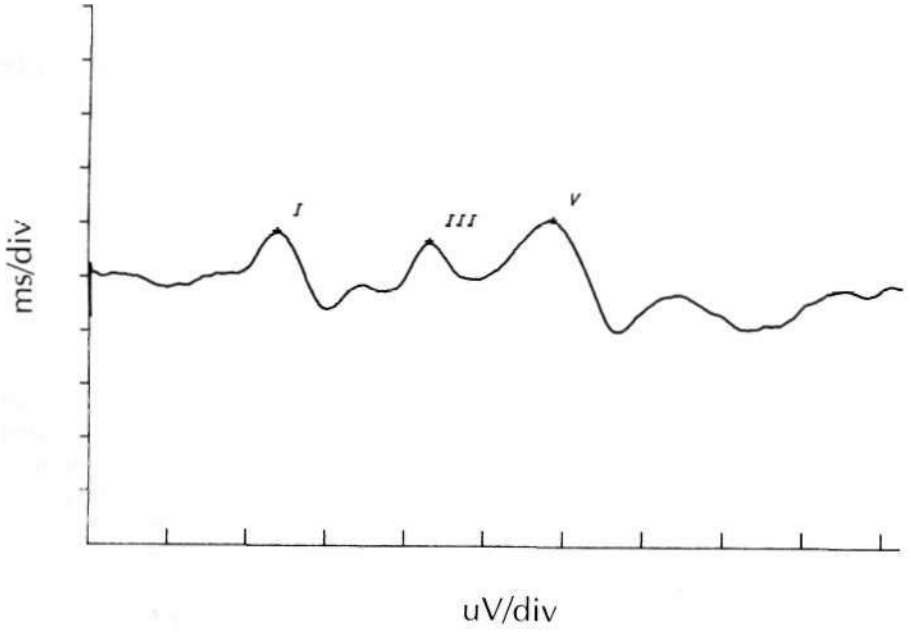

FIGURE 41.4 Brainstem auditory evoked potential in a normal adult. Responses were recorded between electrodes on the vertex and the ipsilateral mastoid. Waves I, HI, and V are labeled. (uV/div = microvolts per division; ms/div = milliseconds per division.)

unless a severe hearing loss exists. The most specific evoked potential abnormality is the presence of an increase in interwave intervals. Abnormal interwave latencies {I-III or I-V) are the most specific and sensitive abnormalities seen with cerebellopontine angle tumors. The abnormal prolongation or absence of wave V at increased click rates is also characteristic of retrocochlear disorders. Increased absolute latencies of all waves, when compared with responses from the other ear, may signify a conductive deficit.

Before ABR testing, the patient should undergo a full audiological evaluation. **The ABR** does not test hearing itself, and both conductive and sensorineural hearing losses can affect the wave latencies and amplitudes.

Other Tests

Electrocochleography is a method of recording the stimulus-related electrical potentials associated with the inner ear and auditory nerve, including the cochlear microphonic, summating potential, and compound action potential of the auditory nerve. This measure is beneficial in the differential diagnosis of certain types of sensory disorders, such as Meniere's disease. The amplitude of the summating potential and compound action potential is measured and is of primary interest in evaluating an ear for increased endolymphatic pressure.

High-resolution computed tomographic scanning provides excellent imaging of the temporal bone and assists in defining congenital abnormalities and infection. Magnetic resonance imaging has largely supplanted computed tomography for the diagnosis of cerebellopontine angle tumors. Contrast-enhanced magnetic resonance imaging and special imaging techniques have allowed diagnosis of unusual lesions, such as meningeal carcinomatosis, which may affect the cerebellopontine angle and eighth cranial nerve. It is also useful in evaluating sudden hearing loss because it may show bilateral metastatic deposits in the cerebellopontine angle or other conditions responsible for sudden bilateral hearing loss (Fitzgerald and Mark 1998),

Table 41.2: Medical therapy for vertigo

Class	*Dosage **
Antihistamines	
Meclizine	2550 mg 3 times/day
Cyclizinc	50 mg 12 times/day
Dimenhydriuate	50 mg 12 times/day
Promethazine	2550 mg/day
Anticholinergics	
Scopolamine tablets	0.45-0.50 mg 12 times/day
Scopolamine transdermal patch	1/day for 3 days
Donna tal[f]	1 three times/day
Sympathomimetics	
Ephedrine	25 mg/day
Antiemetics	
Tr imeth o benza m id e	250 mg 12 times/day PO 200-mg suppository
Promethazine	2550 mg/day
Prochlorperazine	510 mg 13 times/day PO 25-mg suppository
Tranquilizers	
Diazepam	510 mg 13 times/day
Oxazepam	1060 mg/day
Haloperidob	0.5-1.0 mg 12 times/day
Combination preparations and others (dosages as listed above)	
Scopolamine with ephedrine	
Scopolamine with promethazine	
Ephedrine with promethazine	
Diuretics	
Diet	

* Usual adult starting dosage; maintenance dosage can be increased by a factor of 2-3. The most common side effect is drowsiness.

[+]This is a combination preparation, containing a mixture of atropine alkaloids with approximately one fourth grain (15.0-16.2 mg) phenobarbital.

*Note the very low dosage when compared with usual antipsychotic treatment. Nevertheless, the patient should still be observed for dystonias.

MANAGEMENT OF PERIPHERAL VESTIBULOPATHY

Medical Treatment

Therapy is outlined for symptomatic treatment of dizziness presumed to be of peripheral origin (Table 41.2), When a definitive diagnosis, such as vestibular schwannoma, autoimmune disorder, perilymph fistula, or systemic vasculitis, has been made, therapy must be directed to the underlying disorder.

In treating a patient with dizziness, particularly one with a chronic problem who has seen numerous physicians, understanding and patience are needed to relieve anxiety and depression. One may need to reassure the patient of the absence of progression in the usual case and the natural history of most symptoms with peripheral vestibulopathy (i.e., improvement with time). Exercise therapy is especially helpful for patients with positional vertigo (Brandt, Steddin, and Daroff 1994; Furman and Cass 1999).

Although most of the drugs used for dizziness are loosely called *vestibular suppressants,* it is often unclear which agents will be effective in a given patient. The mechanism of action of these drugs is largely unknown. The primary vestibular afferent system could be suppressed directly or indirectly through the inhibitory portion of a vestibular efferent system. An important effect of some agents may be to act on other sensory systems, such as proprioceptive or visual inputs to the vestibular nuclei of the brainstem.

Hew controlled studies have investigated the response of patients with presumed peripheral vestibular dysfunction. The use of many drugs for treating such patients is based on studies of the prevention of motion sickness in normal subjects or of various regimens used by otologists to treat patients with Meniere's disease.

Antihistamines are among the most commonly used agents in treating dizziness. Few neurologists see a dizzy patient who has not already been treated with meclizine. Histamine antagonists are classified according to the responses to histamine that are prevented. Antagonists that act at receptors for histamine are classified as H] or H_2 receptor-blocking agents, or simply Hi or H_2 blockers.

Antihistamines in the Hi antagonist group are used for dizziness. Stimulation of the vestibular apparatus produces motion sickness, but the vestibular cerebellar integrative vomiting center and medullary chemorcccptivc trigger zone are involved in the process. Electrophysiological recordings in dogs show that diphenhydramine diminishes excitability of the vestibular nuclear complex to vestibular afferent activity induced by motion or electrical stimulation of the vestibular afferents. The H| blockers effective in motion sickness may act by central antagonism of acetylcholine, as does scopolamine. Promethazine, a phenothiazinc with strong acetylcholine-blocking action, is one of the most effective agents in preventing motion sickness.

Anticholinergics that block the muscarinic effect of acetylcholine often are used for motion sickness. Atropine acts centrally to stimulate the medulla and cerebrum, but the closely related alkaloid 1-hyoscine or scopolamine is more widely used. Transdermal delivery of scopolamine may prevent or mitigate the nausea and vomiting associated with motion sickness but not the dizziness. In general, transdermal scopolamine is not useful in patients with vestibulopathy. Common side effects arc blurred vision and dry mouth, in addition to occasional confusion. Some patients have significant difficulty when they try to discontinue scopolamine patches. A side effect of low-dose oral scopolamine or atropine is the transient bradycardia (4-8 beats reduction per minute) associated with the peak action of oral scopolamine at 90 minutes and diminishing thereafter.

Sympathomimetic agents may be used to treat motion sickness, particularly in combination with anticholinergics. The sole agent in this class that may have an application, in combination with other drugs, is ephedrine, but tolerance may develop after a few weeks of treatment.

Antiemetics should be used when prominent nausea is a symptom. Many of the antihistaminic and anticholinergic drugs listed here arc also used for their antiemetic actions. Prochlorperazine should be used with caution, particularly by the intramuscular route, because of the high frequency of dystonic reactions.

Tranquilizer is the general name given to drugs from different classes having central and probably peripheral effects. Such drugs include benzodiazepines, buty top hen ones, and phenothiazincs. Despite extensive publicity concerning the use and abuse of diazepam and the lack of direct evidence of an effect on the vestibular system, diazepam is still one of the most widely prescribed drugs for treating dizziness. It should not be the first choice, primarily because of the significant potential for habituation and depression and because it can actually cause dizziness. Nonetheless, it remains the first choice of many neuro-otologists and otologists. The mechanism of action of the benzodiazepines appears related to the metabolism or action of y-aminobutyric acid. Potential effects on the vestibular system are speculative. Other longer-acting benzodiazepines may be helpful in certain patients, but no study has substantiated their effectiveness. Haloperidol in small oral dosages appears to be effective in many patients with peripheral vestibular dysfunction, including those with positional vertigo, who seem to be less affected by other antidizziness medications.

Combination preparations, including agents listed in Table 41.2, often are useful, particularly the combination of ephedrine and promethazine. Some other agents and regimens used primarily to treat Meniere's disease are briefly reviewed in this section. Because in some cases an effect on blood supply to the peripheral end organ might be a factor, agents such as cyclandelate are used. Reports in the literature are contradictory, and the therapeutic value of cyclandelate has never been convincingly demonstrated for any condition.

An unusually high frequency of metabolic abnormalities, particularly hyperlipidemia, has been reported in series of patients with peripheral vestibular dysfunction, especially Meniere's disease. For this reason, dietary regimens have been prescribed as adjunct therapy. Among the most widely used medical therapy in Meniere's disease is the combination of salt restriction (1000- to 2000-mg sodium diets) and diuretic therapy. There is still uncertainty about the natural history of Meniere's disease, and it is unknown whether medical management affects the ultimate outcome for vestibular function or hearing. However, because the long-term results of surgery, such as endolymphatic shunts, are far from proven, there is still a clear role for medical management in this condition.

Exercise therapy can be beneficial in treating persistent positional vertigo (Brandt, Steddin, and Daroff 1994). Patients are first instructed about the type of exercise to be done. They are asked to move rapidly from a scared position to lying on one side. They remain in that position for 30 seconds and then return to the upright position and wait until any recrudescence of symptoms subsides, or for a minimum of 30 seconds. The patients are then instructed to move rapidly lateral to the opposite recumbent position and wait for 30 seconds and then return to the upright position, thus completing one repetition. Patients are asked to perform 20 repetitions two times a day. Most patients experience significant relief within a week, although it might take 3 months to become asymptomatic. Although

there are some recurrences, the majority of patients are permanently cured. This exercise, called *Brandt-Daroff,* has been largely replaced by more complicated maneuvers (Brandt, Steddin, and Daroff 1994) that can alleviate the problem in a single office visit. On the rare occasions when rhe exercise therapy is unsuccessful, such patients are candidates for section of the nerve from the posterior semicircular canal.

Surgical Treatment

Surgical treatment of chronic peripheral vestibular dysfunction is primarily destructive. In patients with severe Meniere's disease for whom medical therapy has been ineffective and who have severe recurrent disabling attacks, a labyrinthectomy may be performed. Unfortunately, Meniere's disease may become bilateral, eventually resulting in the need for labyrinthectomy or vestibular nerve section on the contralareral side. A medical labyrinthectomy may he performed by the use of aminoglycoside drugs, which are particularly destructive to the peripheral vestibular hair cells. Surgical or medical labyrinthectomy usually is a last resort for patients who have clearly defined, severe attacks of peripheral vestibulopathy, presumably from Meniere's disease.

Various shunting procedures have been used to treat MniieiT's disease and endolymphatic hydrops. Although some patients can benefit, long-term success with such shunting procedures to the mastoid region and to the subarachnoid space has been modest.

MANAGEMENT OF CENTRAL AND SYSTEMIC VESTIBULAR DISORDERS

Medical Treatment

The management of central vestibular disorders depends on the diagnosis. A simple separation into peripheral and central vestibular dysfuncrion is not always possible, as discussed in Chapter 18. Some patients have inadequare central compensation for a peripheral vesribular abnormality and thus remain symptomatic. In such patients, medical therapy for peripheral vestibular dysfunction may prove quite effective. When a specific diagnosis (e.g., postural hypotension secondary to diabetic peripheral neuropathy) is made, attention should be directed to treatment of the primary condition. Severe postural hypotension is notoriously difficult to manage. Although mineralocorticoids have been used, they should be prescribed cautiously to avoid congestive heart failure.

The patient who is diagnosed as having primary disease of the central nervous system, whether brainstem infarction or spinocerebellar degeneration, must be treated as would a patient without the accompanying symptoms of disequihbration. Medical therapy of vertebrobasilar insufficiency is directed at preventing new infarctions, primarily with antiplatelet agents and anticoagulation. Cerebellar dysfunction not caused by tumor may be treated symptomatically. On occasion, isoniazid might reduce ataxia. Vestibular suppressant medication can add a modicum of improvement, and agents helpful in the therapy of essential tremor, such as beta-blocking drugs or primidone, may result in symptomatic improvement.

Therapy for systemic conditions producing vertigo also depends on the diagnosis. Systemic drug therapy, as with benzodiazepines, may actually cause disequilibration. Withdrawal of all drugs, whether anticonvulsants or benzodiazepines, must be done cautiously to prevent withdrawal reactions,

Surgical Treatment

Surgical treatment is directed primarily toward removal of the tumors that can affect the peripheral or central vestibular apparatus. When disequilibration, ataxia, or dizziness is caused by a Chiari malformation (see Chapters 66 and 77), surgical decompression of the posterior fossa can produce major symptomatic relief.

Chapter 42
Neurourology

Clare J. Fowler and Ranan DasGupta

The investigation and management of disorders of urogenital function were formerly regarded as the domain of urologists. But as neurologists and rehabilitation specialists become aware of the range of possible effective nonsurgical treatments and increasingly investigate patients' complaints of disordered urogenital function, they are taking a more active interest in uroneurology, or bladder dysfunction viewed from a neutological perspective. This chapter describes what a neurologist needs to know to manage neurogenic urogenital problems. Urodynamic, neurophysiological, and radiological investigations and available medical treatments are described.

INVESTIGATIONS

Physical Examination of Patients with Urogenital Symptoms

The findings on clinical examination are crucial to determining whether a patient has a neurological cause for a urogenital complaint. The reflexes that control the storage and phases of bladder function are transspinal, connecting the pontine micturition center to the sacral spinal cord (Figure 42.1). The examination therefore should concenttatc on the lowet limbs because the spinal segments that innervate the bladder are caudal to those that innervate the legs, and spinal cord disease that affects the innervation of the bladder almost inevitably also produces lower limb signs. Exceptions might be lesions of the low sacral cord or ainus, bur only the most caudal lesions tail to produce some overactivity in the legs and extensor plantar responses. Cauda equina lesions at SI and S2 may impair the ankle reflexes, and those at S3 may affect the intrinsic foot muscles, causing foot deformities and fasciculation of the muscles. Saddle anesthesia is a feature of cauda equina or conus lesions, but the patient is more likely to spontaneously complain of the symptom than the physician is to discover sensory loss on examination. As explained in the following sections, sacral reflex responses recorded electrophysiologically are of limited value, and when elicited clinically they are even less useful.

Examination for evidence of peripheral neuropathy is important. Peripheral neuropathy, notably diabetic, is a common cause of male erectile dysfunction (MED), and as the neuropathy progresses, abnormalities of innervation of the detrusor muscle may develop also. Clear evidence of neuropathy affecting the feet is likely to emetge before bladder innervation is involved.

When the neurological examination of the legs is completed, the patient should be asked to stand and the lumbosacral spine inspected. Congenital malformations of the spine can produce symptoms presenting in adulthood, and dimpling in the sacral region, hypertrichosis, and a nevus or sinus may prove to be relevant.

Evidence of extrapyramidal disease, cerebellar ataxia, laryngeal involvement, and postural hypotension should raise suspicion of multiple system atrophy (MSA), a condition characterized by early and severe urinary incontinence and MED.

If a patient with urogenital complaints has a normal neurological examination, detailed investigation with imaging and neurophysiology is unlikely to teveal a relevant underlying neurological disorder.

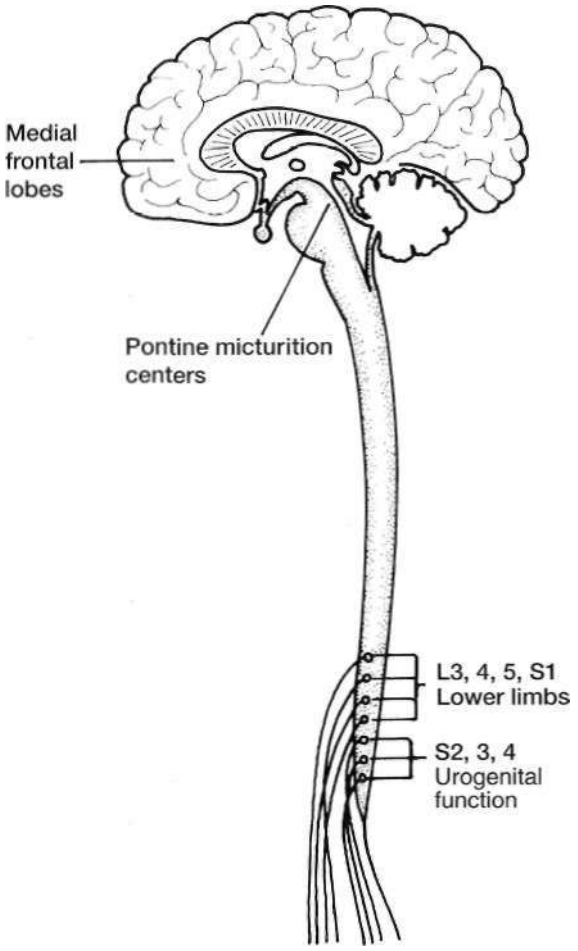

FIGURE **42.1** The peripheral innervation of the Madder and genitalia arises from the sacral spinal cord, and central control over the hladder is exercised by micturition centers in the pons and frontal lobes. It is obvious from this organization that any spinal cord lesion causing neurological symptoms and signs in the lower limb will interrupt the transspinal connections between the pons and sacral cord, also causing impaired bladder control. Likewise, it would he unusual fot spinal pathology to cause a disorder of bladder function without also producing a neurological deficit of the lower limbs unless the lesion affected only the conus.

Urological Investigations

Patients with urogenital complaints without known neurological disease should he investigated fitst by a urologist; otherwise, urological disorders such as prostatic hypertrophy, urethral strictures, interstitial cystitis, **and** bladder stones may go unrecognized. Flexible cystoscopy can be performed as a painless outpatient procedure and readily excludes intravesical disorders. By contrast, if the patient develops genitourinary symptoms as part of a progressive neurological disease, the neurologist should initially become involved in the management of those symptoms. However if the patient does not respond to fitst-line medical treatments or experiences hematuria or recurrent urinary tract infections, a urological opinion should he sought.

Urodynamic Studies

Urodynamic studies examine the function of **the** lower urinary tract. Included in this term are measurements of urine flow rate, residual volume, cystometry during filling and voiding, videocystomerry, urethral pressure profile measurements, and pelvic floor neurophysiology. The term *urodynamics* is used often incorrectly as a synonym for *cystometry.*

From the patient's point of view, tests of bladder function can be divided into the noninvasive tests and those involving a urethral catheter.

Noninvasive Bladder Investigations

The patient or a caregiver can keep a voiding diary of the approximate amount drunk, frequency of micturition, and episodes of incontinence, recorded over the course of several days. This is a useful measure of the severity of bladder complaints on which management decisions can he based.

Urinary flowmetry is a valuable noninvasive investigation, particularly when combined with an ultrasound measurement of the postmicturition residual volume. A commonly used design for a flow meter consists of a commode or urinal into which the patient passes urine as naturally as possible. In the base of the collecting system is a spinning disk; urine flow tends to slow the rotation of the disk, which a servomotor holds constant. Urine flow is derived from measurement of the power necessary ro maintain disk rotation, and the machine usually produces a graphic printout and an analysis of the time taken to reach maximal flow, the maximum and average flow rate, and the voided volume (Figure 42.2).

It is important that the patient prepares to perform the test with a comfortably full bladder, containing if possible a volume of at least 200 ml.. Privacy is essential; a spurious result might be obtained if the patient is not fully relaxed. **Published** nomograms give urine free flow rates against volume for men and women. An aging effect has been found in men over age *65* but not in women. A significant neurogenic bladder disorder is unlikely if the patient has good bladder capacity and normal urine flow rate and empties to completion, all of which may he noninvasivcly demonstrated.

Knowledge of a patient's postmicturition residual volume is critical in planning treatment of neurogenic hladder symptoms. Although this information is available from urethral catheterization after voiding, the same data can be obtained noninvasively by ultrasound. Small, simple ultra sound machines are available that require little operator training and make it easy to determine whether the

postmicturition residual volume is negligible or greater than 100 mL (Figure 42.3).

Larger, more elaborate ultrasound machines are found in radiology departments equipped for urological work, and in some instances ultrasound scanning of the upper urinary tracts has replaced intravenous urography as a means of examining the kidneys and ureters for dilatation, stones, and tumors. Interpretation of those scans takes special expertise.

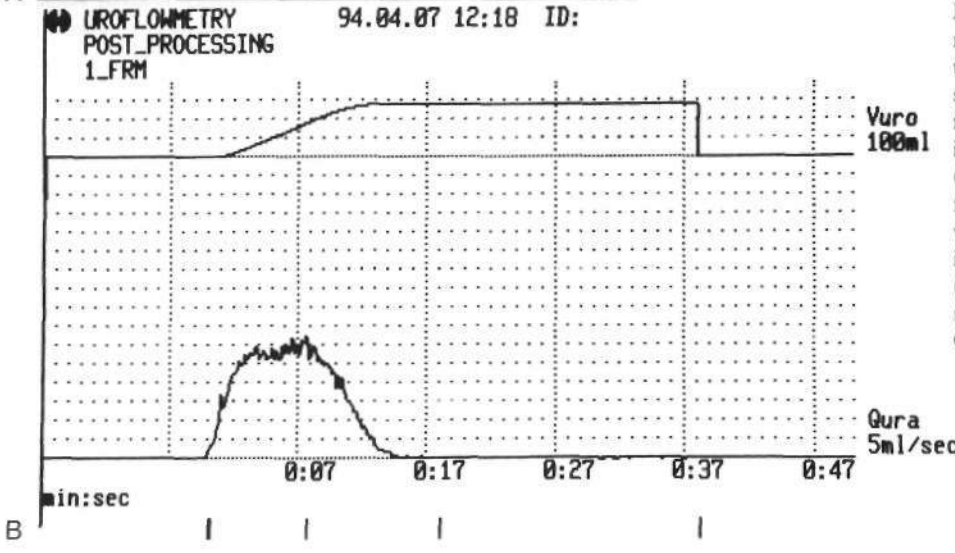
FIGURE 42.3 Postmicturition residual volume can be measured using a small, portable ultrasound machine.

Investigations Necessitating Catheterization

Cystometry, the registration of bladder pressure, can be performed during filling and voiding. The essential measurement is the intravesical pressure, but because this also reflects increases in intra-abdominal pressure, rectal pressure must be simultaneously recorded and the value subtracted from the measured intravesical pressure to calculate the true changes of detrusor pressure alone. The efficiency of the subtraction usually is checked at the beginning of cystometry by asking the subject to cough (Figure 42.4). This produces an increase in abdominal pressure and hence intravesical pressure but no increase in detrusor pressure.

Two catheters are used for these measurements. A dual-lumen (6-Fr) catheter is inserted through the urethra for filling the bladder and measuring intravesical pressure. Another fine-gauge catheter (4 Fr) is then inserted into the

A



B

FIGURE 42.2 (A) Urinary flow meter. The side of the uroflow transducer has been cut away to show the disk at the base of the funnel that rotates as urine passes into the collecting vessel. (B) Typical (normal) printout from the uroflowmeter. A total of 290 mL was voided (*upper trace*), with a maximum flow rate of 30 mL per second (*lower trace*). (Reprinted with permission from Dantec Medical A/S, Copenhagen.)

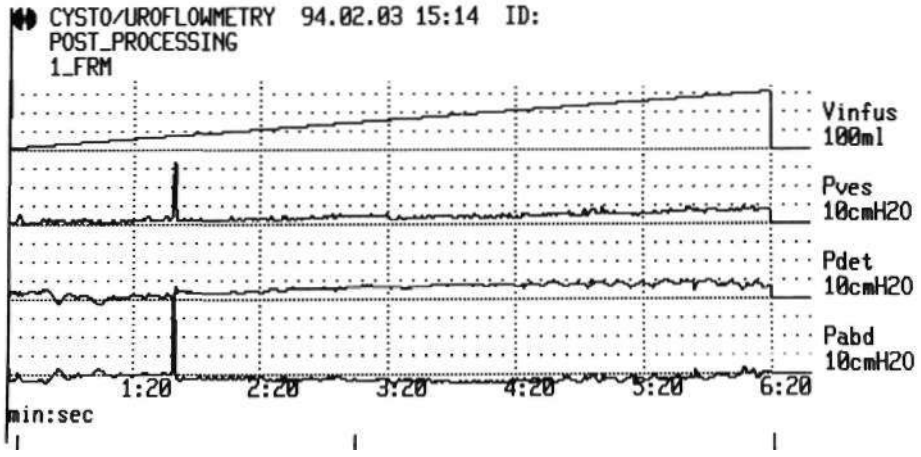


FIGURE 42.4 Cytometry during bladder filling. The bladder was lilled *(top truce)* at 50 mL per minute {Vinfus) to a total of 300 mL. Detrusor pressure fl'det'l is derived by subtracting pressure in the rectum (Pabd) from the measured intravesical pressure (Pves). At the beginning of the trace these two values can be seen to be subtracting effectively because on coughing there is an abrupt increase in intravesical pressure but no increase in detrusor pressure. Pdet did not exceed 10 cm of water, which is normal.

rectum to record intra-abdominal pressure. Once the lines arc in place and satisfactory subtraction of the two pressures demonstrated, bladder filling may commence. The rate of filling is recorded by the machine, which pumps sterile water or saline solution through the filling catheter into the bladder. The optimum rate of bladder filling has been much discussed, and there is little doubt that it affects the result, but for speed and convenience most laboratories use filling rates of 50 mL per minute. This is unphysiologically rapid but does mean that full bladder capacity usually can be reached within 7 or B minutes. First sensation of bladder filling may be reported at about 100 mL and full capacity reached between 400 and 600 mL. In healthy subjects the bladder expands to contain this amount of fluid without an increase of pressure of more than 15 cm of water (Figure 42.4). A bladder that behaves in this way is said to be stable. The main abnormality sought through cystometry in patients with incontinence is detrusor overactivity. According to the most recent definition of the International Continence Society, detrusor overactivity is a urodynamic observation characterized by involuntary detrusor contractions during the filling phase that may be spontaneous or provoked. The disorder is called *neurogenic detrusor overactivity* when a neurological condition is recognized as being causative, and the term replaces the formerly used *detrusor byper-reflvxia, Idiopathic detrusor overactivity* is the term used when there is no defined cause, and this replaces *detrusor instability* (Abrams ct al. 2002). It should be emphasized that the urodynamic findings of neurogenic detrusor overactivity is indistinguishable from idiopathic detrusor overactivity.

When bladder filling has been completed, the filling catheter is removed, and the patienr voids into the flow meter with the intravesical and rectal pressure lines still in place. Urine flow rate depends both on detrusor pressure **and** outlet resistance. Much valuable information can be obtained about the latter by measuring detrusor pressure and urine flow. As a rough guide, the pressure for men should he less than 50 cm water and for women less than 30 cm water, with flow rates greater than 15 mL per second and 20 mL per second, respectively. With increasingly sophisticated developments in the equipment used for urodynamic studies, real-time computer analysis of rhe flow rates and pressures has become available. Much debate surrounds the question of the best mathematical formula to use in analyzing the degree of outflow obstruction; this is of particular importance in investigating suspected prostatic hypertrophy.

When cystometry is carried out using a contrast filling medium and the procedure is radlograpfiically screened, the technique is known as vidcocystomctry, which gives much additional information about the lower urinary tract. The advantages are that the bladder outline can be inspected during filling, and any reflux into the ureters is seen. A neurogenic bladder often produces characterisric changes with thickening of the bladder wall and bladder diverticula. Urologists and urogynecologists have found videocystometry useful in detecting sphincter or bladder neck incompetence in genuine stress incontinence, and the opportunity to inspect the outflow tract during voiding is of great value in patients with suspected obstruction. However, the procedure exposes the patient to irradiation and is inevitably more expensive than simple cystometry. In assessing patients with spinal cord injury, when examination of the upper tracts is critical, videourodynamic studies have an important role, but simple cystometry alone usually is adequate to demonstrate detrusor overactivity in nontraumatic neurogenic bladder disorders. A general criticism of cystometric studies is that, valuable as they are in demonstrating the underlying pathophysiology of a patient's urinary tract, the findings contribute little knowledge of the underlying cause of the disorder. *Urodynamic diagnosis* therefore is a meaningless term.

The urethral pressure profile is measured using a catheter-mounted transducer that is drawn slowly through the urethra by **a** motorized armature. The test can be performed in men or women and is called static if no

additional procedure such as coughing or straining is performed. If intravesical pressure is measured simultaneously and the patient is asked to cough repeatedly while the catheter is withdrawn, the transmission of the cough impulse in the urethra and bladder can be measured and expressed as the transmission pressure ratio, k was hoped that measurements of the urethral pressure profile and parameters derived from it would he useful in assessing genuine stress incontinence, but the overlap of measurements in controls and in women with genuine stress incontinence is such that the test is without diagnostic value in that context. However, it may be of value in assessing women with obstructed voiding, some of whom have abnormally high urethral pressures.

Neurophysiological Investigations

Various neurophysiological investigations of the pelvic floor have been developed by which the innervation of muscles that are difficult to test clinically can be assessed. These tests have been used by urologists, andrologists, urogynecologists, and colorectal surgeons. The role of clinical neurophysiological testing in assessing incontinence has recently been reviewed by an expert panel {Fowler 2002).

Electromyography

Electromyography (EMG) was first introduced as part of urodynamic studies to assess the extent of relaxation of the urethral sphincter during voiding. Interruption of the neural pathways between the pons and the sacral cord results in loss of coordination of sphincter and detrusor muscle activity, a condition known as detrusor-sphincter dyssynergia. In this disorder, instead of the sphincter relaxing to initiate and facilitate urine flow, it contracts at the same time the detrusor contracts. This may have important consequences, including incomplete bladder emptying and the potentially lethal condition of upper urinary tract dilatation, leading to renal failure. For this reason it was considered important that dyssynergic detrusor-sphincter activity be recognized. However, sphincter EMG is now rarely tecorded, for a number of reasons. First, it is often technically difficult to obtain a good-quality EMG signal from a site as inaccessible as the urethral sphincter, particularly in the hostile recording environment in which urodynamic studies are performed. The best signal is obtained using a needle recording electrode, but the discomfort from the needle itself is likely to impair normal relaxation of the pelvic floor. Surface recording electrodes have been used but rarely pick up signals well from distant muscles. Furthermore, there is doubt about the value of the information the procedure provides. Detrusor-sphincter dyssynergia is a disorder that arises as a consequence of spinal cord disease; if the patient comes to the urodynamic laboratory in a wheelchair or has even a milder degree of paraparesis, dyssynergic bladder activity can reasonably be presumed. The urologist's main concern is to establish whether it is causing upper ttact dilatation, and for this videocystometry is needed to detect ureteric reflux. Video screening allows the outlet tract to be seen, and sphincter EMG recording becomes redundant.

Although there is doubt about the value of kinesiological FMG studies recorded during urodynamics, the value of EMG studies of the pelvic floor performed as a separate neurophysiological investigation to assess innervation is more certain. EMG has been used to demonstrate changes of denervation and reinnervation in the urethral or anal sphincter or pelvic floor in several neurogenic disorders. The motor units of the pelvic floor and sphincters fire tonically, so they can be captured conveniently using a trigger and delay line and subjected to individual motor unit analysis. Well-established values exist for the normal duration and amplitude of motor units recorded from the sphincters and other pelvic floor muscles using a concentric-needle electrode, Reinnervation can be detected by abnormal prolongation of duration or increase in amplitude of motor units. Alternatively, single-fiber EMG studies can look for changes of reinnervation producing an increase in fiber density. Changes of denervation and reinnervation have been demonstrated in patients with idiopathic fecal incontinence, showing that there is a significant neurogenic component to this disorder. Denervation of the pelvic floor has been demonstrated in women with genuine stress incontinence. EMG of the pelvic floor is of particular value in demonstrating the existence and extent of denervation and reinnervation in patients suspected of having a cauda equina lesion.

Sphincter Electromyography in the Diagnosis of MSA

MSA may have protean manifestations, but urinary incontinence is often an early and troublesome complaint. In a study of 62 patients with established MSA, 56% had been seen by a urologist or gynecologist before the correct neurological diagnosis was made (Beck, Betts, and Fowler 1994). The early development of incontinence and its severity is caused by a combination of factors. It has been suggested that loss of pontine neurons causes the detrusor overactivity that occurs in the early stages of the disease. Loss of the parasympathetic innervation of the detrusor leads to poor contractility and incomplete emptying, and incontinence is compounded by sphincter weakness caused by loss of the anterior horn cells, which innervate the sphincters. These anterior horn cells lie in the sacral spinal cord in a group of cells known as Onufs nucleus. Neuropathologies! studies have shown that these anterior horn cells are selectively lost in MSA. Sphincter EMG can show changes of reinnervation in the muscles innervated by these neurons, characteristically manifest by prolongation of duration of motor units. These changes can be detected

easily, but it is important to include measurement of the late components of the potentials. Either sphincter may be studied, but the more superficial anal sphincter is most conveniently studied.

Although there has been recent debate about the value of sphincter EMG in the differential diagnosis of parkinsonism, a body of opinion maintains that a highly abnormal result in a patient with mild parkinsonism is of value in establishing a diagnosis of probable MSA (Vodusek 2001). In more advanced stages, however, EMC docs not appear to differentiate between MSA and other parkinsonian disorders. In early stages of the disease the EMG may be important not only for the neurologist but also for the utologist because inappropriate surgery can then be avoided. The response to medical management of incontinence in MSA, especially in the early stages of the disease, often is very good.

Sphincter Electromyography in Investigating Urinary Retention in Young Women

Urinary retention in young women has long been an enigma, and in standard urological texts the differential diagnosis of this condition used to be stated as either multiple sclerosis (MS) or a psychogenic disorder. Much the same is said about obstructed voiding in young women. However, upper motor neuron signs are not found in these young women, and their bladder disturbance is an isolated complaint, unaccompanied by other definite neutological features. Magnetic resonance imaging in particular, but also other laboratory investigations, can readily rule out MS ot a cauda equina lesion, and often there is no apparent neutological ot utological explanation. It has been proposed that this abnormal spontaneous activity results in an impaitment of relaxation of the urethral sphincter, which may cause urinary retention in some women and obsttucted voiding in others. Thus the EMG abnormality can be found in several bladder disorders because clinical presentation is determined by the behavior of the detrusor, not the urethral sphincter muscle. An association between the occurrence of this EMG abnormality in the urethral sphincter and polycystic ovaries was described in the original description of the syndrome {Fowler et al. 1.988).

Attempts to ttcat this primary sphincter disorder with hormonal manipulation, injections of botulinum toxin, application of trinitrate cteam, alpha blockers, and oral anticonvulsants have been largely unsuccessful. However, women with this syndrome have been found to respond particulatly well to sacral nerve stimulation using an implanted stimulator (Swinn et al. 2002) (see Sacral Nerve Stimulators later in this chapter). Although it is not difficult to understand how sacral nerve stimulation (which probably acts by stimulating pelvic afferents) mijdir suppress detrusor overactivity, the mechanism wheteby it reverses urinary retention is far from clear and is being researched.

Other Neurophysiologies Investigations of the Pelvic Floor

Other neurophysiological means of assessment rest largely on measurements of conduction velocity or latency and therefore correlate less well with function.

The bulbocavernous reflex was the first measurement of nerve conduction to be performed in the sacral region. Stimulation of the dorsal nerve of the penis or clitoris results in a reflex contraction of much of the pelvic floor musculature. The bulbocavernous reflex may be obtained by recording from the bulbocavernous muscle, although synchronous conttaction also can be recorded from the sphinctets. The latency of this reflex gives an estimate of conduction through the affcient and efferent fibers at the S2-S4 level, and a demonstrable delay may be of localizing neurological value. The limitation of this test is that, like all other reflex studies, it measures only conduction in the fastest fibers, the largest myelinated fibers. Many disorders of urogenital function and MED in particular are the result of unmyelinated fiber disease, and conduction in those fibers is not tested by this means. Furthermore, normal latency sacral reflexes may be obtained in patients with partial cauda equina lesions. Howcvct, a pathologically prolonged response in a patient suspected of having a ncutogenic disorder is valuable.

The pudenda] evoked potential may be as easily recotded as the tibial evoked potential and, remarkably, has a similar morphology and latency (Figute 42.5), despite the much shortet conduction distance involved. This similarity is thought to reflect the slower conducting affetent pathways of the potential. When it was first described it was hoped that by recording the pudendal tcsponse much could be learned about the affetent innervation of the urogenital ttact. However, in practice this has not proved to be the case. Although thete have been many reports of abnormal pudendal somatosensory evoked potentials in patients with established neurological disease and urogenital disorders, such as bladder or sexual dysfunction in MS, the diagnostic value of this test is minimal. This is because the spinal cord disease that gives tise to the urogenital disorder and delays conduction of the potential is almost always also clinically evident (Delodovici and Fowler 1995).

Electrical and magnetic stimulation have been used to measure motor conduction velocity from cortex to muscles in the pelvic floor. Magnetic stimulation also has been used to study spinal conduction between the cortex and sacral spinal cord. Stimulation of the motor cortex to produce a contraction of the pelvic floor entails a higher intensity of stimulation than that needed to produce a contraction in the lower limb, which in turn entails a higher intensity than that needed to cause uppet limb muscle contraction. This is thought to reflect the interhemispheric location of the cottical representation of the perineum. However, it is possible to obtain responses from the sphincters and pelvic floor. Prolonged conduction times in patients with

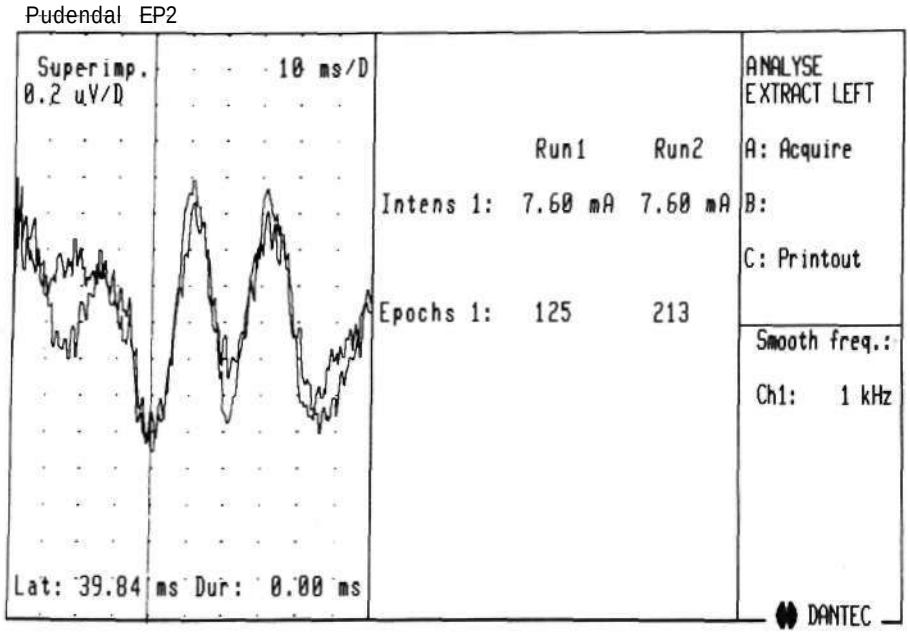

FIGURE 42.5 The pudendal somatosensory evoked potential. In this figure the cursor has been set to measure the latency of the first positive deflection, the PI or P40 shown here at 39.8 ms. Two evoked potentials have been superimposed to demonstrate the consistency of the response.

neurogenic bladder disorders have been reported, but no study showing abnormal conduction times in patients with bladder symptoms who do not have clinical evidence of spinal cord disease has been reported.

Stimulation of the spinal roots has been performed wirh magnetic stimulation and electrical stimulation. Magnetic stimulation of the sacral roots is a painless, simple means of testing sacral root conduction. It is important when making recordings in response to central nervous system stimulation to use a needle electrode to record from the sphincter muscles, to avoid volume conducted responses from the gluteal muscles. It is now thought that it is not possible to stimulate the efferent innervation of the detrusor directly by magnetic stimulation, and any rise in detrusor pressure is caused by an afferently mediated reflex contraction (Bcmehnans, Mundy, and Craggs 1999). Repetitive magnetic stimulation of the roots has been shown to transiently block detrusor hyper-reflex ic contractions in patients with spinal cord injuries.

Use of a per rectal stimulator for measuring terminal pudendal motor latency leads to the identification of abnormally slow conduction in the pudendal nerve in women with idiopathic neurogenic anorectal incontinence. Pudendal nerve stimulation proved to be valuable in establishing the pathogenesis of several pelvic floor disorders, but because motor latency is a poor reflection of axonal loss, terminal pudendal motor latency should not be used alone to assess denervation.

To assess the functionally important innervarion of the urogenital tract, some means of testing the unmyelinated and small myelinated fibers of the region is needed. Different approaches have been taken ro this problem, and some success has been achieved by measuring the sympathetic skin responses from the genital region. These potential changes can be obtained using the same technique used for recording from the foot and hand in response to electrical stimulation of the median nerve or for magnetic stimulation of the brain. In some patients with MED caused by diabetic neuropathy, the responses from the perineum cannot be recorded. However, one of the limitations of this method is that a small response cannor be considered abnormal, and only an absent response is thought to be significant. Similarities between continuously recorded sympathetic skin responses and the activity that has been called corpus cavernosal KMG are marked, and the possibility remains that this latter signal is a form of electrodermal response.

Because many neuropathies are length dependent, it has been argued that relevant abnormalities of small fiber function causing urogenital dysfunction can be detected in the feet of patients with generalized peripheral neuropathy. Testing thermal thresholds in the lower limbs therefore is of particular value in these circumstances.

Neuroimaging

The ease and clarity with which the cauda equina and conus region can be visualized by magnetic resonance imaging have made it the investigation of choice in patients suspected of having a structural lesion causing a neurogenic bladder disorder. In conditions of congenital cord malformation, rhe bony, dural, and intradural abnormalities are clearly shown on magnetic resonance imaging. Plain roentgenographic films of the region generally are nor helpful because they may show normal results with a lesion of the cauda equina, and spina bifida occulta is a common incidental finding.

Table 42.1: Medication for treatment of detrusor overactivity

Route	*Agent*	*Side effects*
Oral	Anticholinergics (e.g., oxybutynin, tolterodine, darifenacin)	Dry mouth, blurred vision, drowsiness
Oral	Tricyclic antidepressants (e.g., imipramine)	Tolerance
Oral	Desmopressin (or Desmospray intranasally)	Hyponatremia
Intravesical instillation	Vanilloids {capsaicin, rcsiniferatoxin)	Pungency
Sublingual spray	Cannabis-based medicinal extract	Dry mouth, disorientation
Intradctrusor injection	Botulinum toxin	No long-term data

MANAGEMENT OF BLADDER DISORDERS

Detrusor Overactivity

Dettusot overactivity is the major cause of incontinence in patients with neurogenic bladder disorders and is charactetized by the development of spontaneous incteases in bladder pressure that the patient is unable to suppress. These usually occur at volumes less than normal capacity so that the patient also complains of frequency. Urgency is felt as the detrusor muscle begins to contract, and if the pressure continues to increase, the patient senses impending micturition.

Anticholinergic medications are the mainstay of treatment for detrusor overactivity. Table 42.1 lists commonly used drugs.

Anticholinergics are the most widely used drugs for urgency and urge incontinence, acting specifically on muscarinic receptors. The first-line medications in this group are oxybutynin and tolterodine. The starting dosage for oxybutynin is 2.5 mg twice daily (up to a maximum of 20 mg daily in divided doses), and that for tolterodine is 2 mg twice daily; a newer once-daily formulation is now available for both medications. The main side effect is dry mouth; blurred vision, drowsiness, and constipation are less common. Darifenacin is a newer anticholinergic with greater specificity for the M3 receptor (the predominant type in the bladder). Propiverine and trospium chloride are other anticholinergic agents used in detrusor overactivity.

Positive anecdotal reports on the effect of cannabis in controlling bladder symptoms in patients with MS and identification of the cannabinyid receptor in animal and human studies have led to studies of caiinabis-based medicinal extracts in this group. An open-label study in patients with advanced MS (in whom indwelling catheterization was being considered) has shown promising results, with improvements in frequency, nocturia, and incontinence (Brady et al. 2001). The mechanism of action remains to be elucidated.

Botulinum-A toxin is a neuromuscular blocking agent that inhibits the release of acetylcholine from nerve terminals. It has been used to treat disorders of overactive muscle (including various dystonias) and has recently been introduced in the treatment of bladder overactivity by injection into the detrusor smooth muscle (Schurch et al. 2000). The effect is thought to last 6-12 months, and long-term results are eagerly awaited.

Desmopressin spray, first introduced to treat diabetes insipidus, is widely prescribed for children with nocturnal enuresis. Patients with MS and nighttime frequency also have used it. For a disabled patient and caregiver, the difficulties of the patient having to use the toilet several times a night can be significant. One or two nasal puffs of desmopressin from a mctered-dose spray administered on retiring reduces urine output for 6-8 hours and may significantly lessen nighttime urinary frequency. An oral preparation of desmopressin is now available. Daytime use seems to be free of ill effects, but the medication can be used only once in 24 hours and should not be given to oldet adults, in whom its use may precipitate congestive heart failure. Increased nighttime frequency does not seem to occur in those who have used it during the day. The serum sodium may decrease, usually to not less than 132 mmol/liter. If significant hyponatremia does occur, it usually happens within the first week or so, and the chief symptoms are general malaise, headache, and visible edema of the face and ankles. There is a rapid restitution of the sodium level once the medication is stopped.

Animal studies have shown that the lower urinary tract is richly innervated by capsaicin-sensitive afferent neurons, now known to be small sensory nerves expressing the vanilloid (VR1) receptor. In healthy animals, these afferenrs are quiescent, although they may be activated by inflammation by bacteria or chemicals, giving rise to the symptoms of cystitis. Under physiological circumstances in animals with an intact spinal cord, the detrusor reflexes are transspinal, with the afferent limb from the bladder to the spinal cord conveyed by small myelinated *AS* fibers (Figure 42,6), In chronic spinal animal models, after a period of spinal shock, a new afferent limb from the detrusor emerges as being of dominant functional importance, the afferent fibers of which are unmyelinated C fibers. In the case of the neurogenic bladder, the afferents that drive the volume-determined reflex detrusor contractions probably are sensitive to capsaicin. Capsaicin has a biphasic effect; it is initially an irritant, but if applied in sufficiently high concentration its secondary effect is as a selective neurotoxin acting on unmyelinated afferent C fibers.

Intravesical capsaicin has been used to decrease detrusor overactivity in patients with intractable incontinence caused

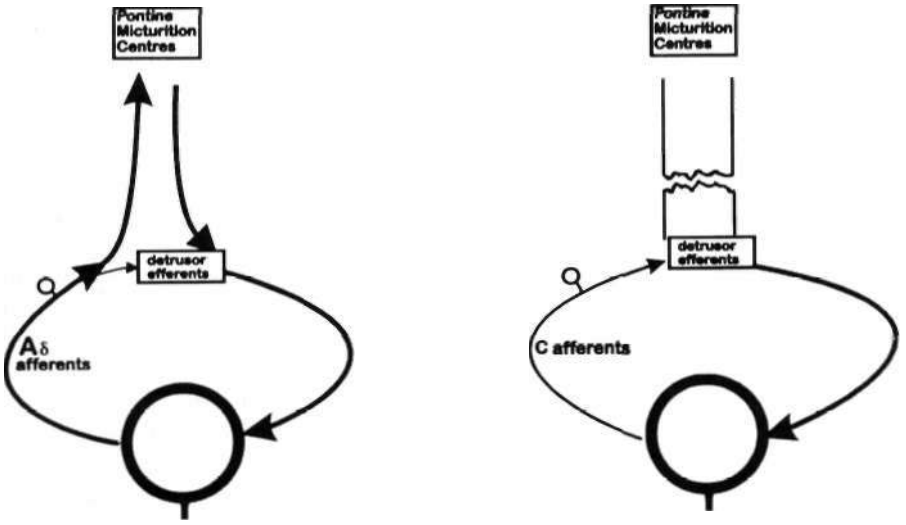

FIGURE 42.6 The route of afferent impulses from the bladder to the pontine micturition center in a patient with an intact spinal cord. (A) In health the peripheral bladder afferents are mainly A5 fibers. (B) After transection of the spinal cord a new reflex emerges at a sacral level, the afferents of which are unmyelinated capsaicin-scnsitive C fibers.

hy spinal cord disease. A 1- or 2-mmol solution of capsaicin in 30% alcohol and 70% saline was instilled into the bladder using a balloon catheter and left for 30 minutes. Some patients experienced a decrease in episodes of incontinence, and the benefit lasted up to 6 months, at which time the instillation must be repeated (Fowler et al. 1994). However, the pungency of capsaicin and its nonpharmaceutical status meant that resiniferatoxin, a much less irritating, selective neurotoxin vanilloid, was the preferred alternative. Although there have been reports of its effectiveness in treating hypersensitive bladdct disorders and detrusor overactivity of spinal origin, large-scale clinical trials were abandoned when it was found that the molecule's adsorption to plastic was affecting the efficacy of the studies. More recently, a study controlling for **this** factor demonstrated a reduction in episodes of incontinence in patients with idiopathic detrusor instability, suggesting that C-fiber overactivity has a role in the genesis of that condition (Silva et al. 2002). Unfortunately, there are currently major difficulties in obtaining supplies of pharmaceutical-grade resiniferatoxin.

Incomplete Bladder Emptying or Urinary Retention

The widespread use of intermittent catheterization has had a great effect on the management of the neurogenic bladder. Incomplete emptying can exacerbate detrusor overactivity, and an overactive bladder constantly stimulated by a residual volume responds by contracting and producing symptoms of urgency and frequency. Incomplete emptying is particularly likely to occur in patients with spinal cord disease caused by a combination of detrusor sphinctet dyssynergia occurring during attempts to void and poorly sustained detrusor contractions during the voiding phase. A generally accepted figure for significant residual volume is 100 mL. It seems that higher volumes may be usefully removed using intermittent self-catheterization.

Sterile intermittent catheterization was first introduced in the 1960s, but it was found that a clean rather than sterile technique was adequate. Used in children with spina bifida and even older adults with disotdets of bladder emptying, it has proved highly effective in many patients with MS and various other neurogenic bladder disorders.

Patients often are unaware of the extent to which they incompletely empty their bladder, and the amount of residual volume often is a surprise for both the patient and the doctor. For this reason, this parameter is the single most important measurement to be made when planning bladder management (Fowler 1996; Figure 42.7). The volume may be measured ultrasound or in-out catheterization.

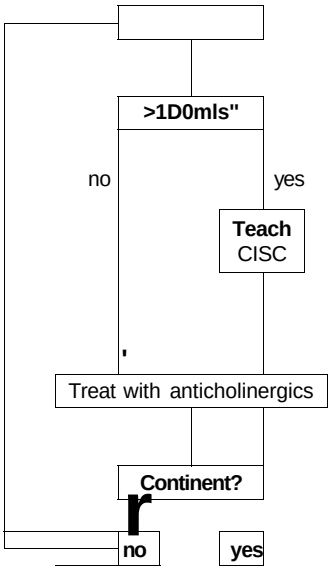

FIGURE 42.7 Algorithm showing the recommended management of neurological incontinence. (CISC = clean intermittent self-catheterization; PVR = posrvoid residual).

The advantage of the latter procedure is that it familiarizes the patient with catheterization and so makes teaching the technique of self-catheterization easier. Intermittent catheterization is best performed by the patients themselves, who should be taught by someone experienced in the method. In the United Kingdom, nurse continence advisors are particularly expert at this. A main requirement for success with this technique is patient motivation; a degree of physical disability may be overcome if the patient is sufficiently motivated. As a general rule, if patients are able to write and feed themselves they are likely to be able to perform the procedure. Sometimes tremor, impaired visual acuity, spasticity, and rigidity may make it impossible for the patient to sclf-cathcterize; in such circumstances catheterization may be performed by a partner or care assistant. Because the principle of this technique is to reduce the postmicturition residual volume, most patients are advised initially to perform the technique at least twice a day. No fixed limit exists on how often it should be performed, and it may be done throughout the day, but it should be performed regularly; the worst possible state of affairs is for the patient to do it very occasionally because this may introduce bacteria but does not have a constant beneficial effect on bladder emptying. Although bacteriuria is noted in 50% of patients doing clean intermittent self-catheterization, the incidence of symptomatic urinary tract infections is low. Transient hematuria when the patient first learns the method is common.

In spinal cord disease, a combination of intermittent self-catheterization and an oral anticholinergic deals effectively with both aspects of bladder malfunction (the intermittent catheterization for the incomplete emptying and the anticholinergic for overactivity). In a patient with a borderline significant residual volume, starting an anticholinergic may increase it (Figure 42.8). This should be suspected if the medication has a beneficial effect for several days that then disappears. Also, a patient who has marked hesitancy and difficulty in initiating micturition should wait to start an anticholinergic until intermittent catheterization is well established; otherwise, complete retention may result. This combined approach works well in patients with spinal cord disease such as MS if the patient is not too severely disabled. It is also highly effective in the earlier stages of MSA because incomplete bladder emptying is particularly likely to present a problem in rhat disorder. Intermittent self-catheterization is the main means of symptomatic relief in women with urinary retention, although a number of them find the technique unacceptable because of discomfort on withdrawing the catheter, presumably caused by the hypertrophicd muscle contracting down on the catheter.

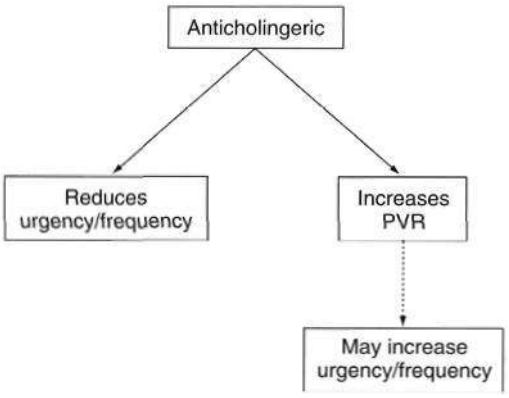

FIGURE 42.8 Although an anticholinergic is effective in lessening detrusor overactivity, it may also impair bladder emptying. The resulting increase in postmicturition residual volume (PVR) may lead to worsening symptoms of urgency and frequency.

Permanent Indwelling Catheters

Although a combination of anticholinergic medication and intermittent catheterization is the optimal management for patients with detrusor overactivity and incomplete bladder emptying, there comes a rime when the patient is no longer able to perform self-catheterization or when urge incontinence and frequency are unmanageable. In patients with spinal cord disease this may be reached when the patient is no longer ambulatory, and at this stage an indwelling catheter becomes necessary (Figure 42.9).

The most immediate simple solution is an indwelling Foley catheter, a device held in place by an inflatable balloon in the bladder proximal to the catheter opening, but the long-term ill effects of these devices are well known. One of the major problems may be urine leakage around the catheter, which occurs when strong detrusor contractions produce a rapid urine flow that cannot drain quickly enough. A common reaction is to insert a larger-caliber catheter, with the effect that the bladder closure mechanism becomes progressively stretched and destroyed. The detrusor contractions may be of sufficient intensity to extrude the 10- or 20-mL balloon from the bladder, further rupturing the bladder neck. The result may then be a totally incompetent bladder neck and urethra. Bladder stones and recurrent, resistant infections are also more likely in a bladder with an indwelling catheter.

A preferred alternative to an indwelling urethral catheter is a suprapubic catheter. This can be inserted under local anesthetic. However, the procedure should be undertaken only by a trained urologist because there is a danger that bowel overlying the bladder may he punctured, especially in patients with small, contracted bladders. Once in situ, the catheter is left on constant drainage. Because no attempt is made to close the urethra, continence depends on the suprapubic drain remaining unimpeded. If the catheter becomes blocked or kinked, the patient leaks urethrally. Although it is by no means a perfect system, a suprapubic catheter is a better long-term alternative to an indwelling urethral catheter and often is the method of choice in

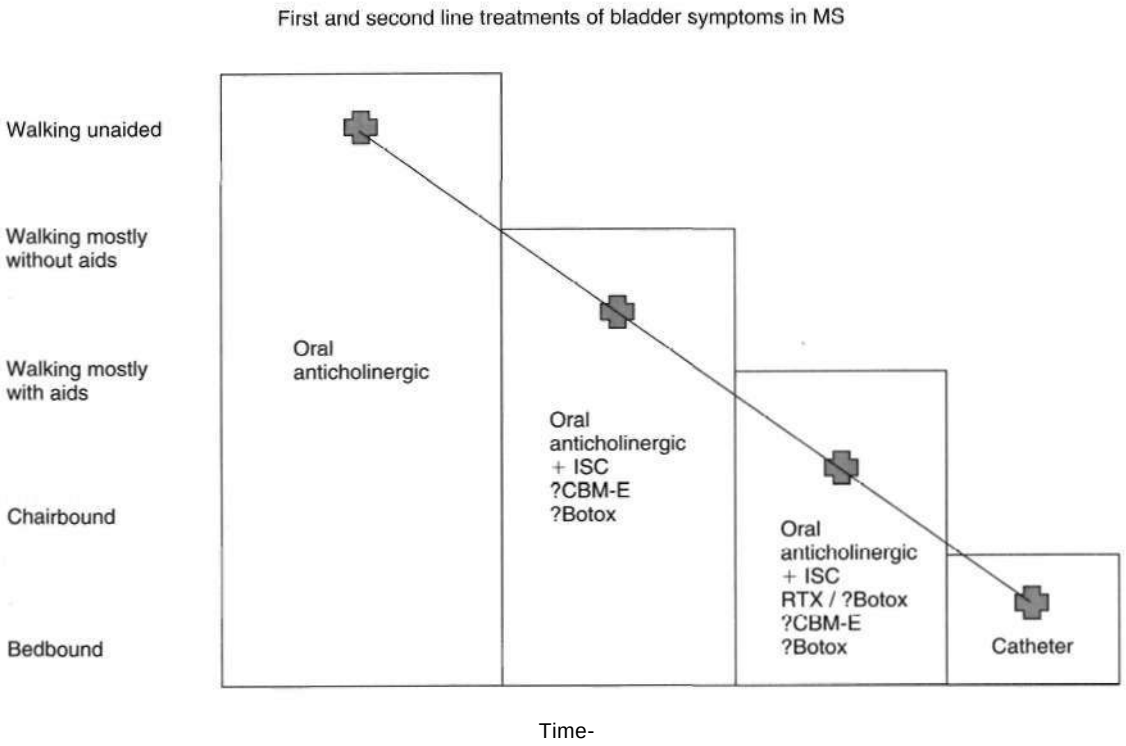

FIGURE 42.9 The bladder symptoms in multiple sclerosis become increasingly difficult to manage with progression of spinal cord disease. This diagram summarizes the various measures that may be effective at each stage. {Botox = borulinum toxin; CBM-E = cannabis-hased medicinal extract; ISC = intermittent self-catheterization; RTX = resiniferatoxin.)

managing incontinence in patients for whom other means are no longer effective.

External Device

If urge incontinence is the main problem and the bladder empties completely, some men are able to wear an external device attached around the penis. The simplest and least obtrusive is a self-sealing latex condom sheath, which can be pur on each night or kept in place for up to 3 days. More elaborate body-worn appliances are also available, but an expett must fit them. An effective external appliance for women has not been devised.

Sacral Nerve Stimulators

An extradural sacral nerve stimulator can be highly effective in lessening detrusor overactivity that is resistant to anticholinergic medication. It seems highly likely that its mechanism of action is by stimulation in the ptesacral region of the pelvic afferents, which arc known to have an inhibitory effect on the detrusor. However, it is more difficult to explain how it may have an effect in young women with urinary retention,

Implanting a stimulatot is a two-stage procedure; rhe first stage is an outpatient procedure in which the stimulating lead is inserted through an S3 foramen under local anesthesia and connected to an external stimulator for 3 days. If the patient's symptoms improve significantly during this time, as judged by measutement of residual volumes and diary-recorded voided volumes, the patient is eligible for a permanent stimulator. Formerly this was implanted under general anesthesia in a subcutaneous pocket and the stimulating lead tunneled subcutaneously back to the sacrum and the electrode implanted through the foramen, but there is now a trend to implant the definitive stimulating lead as a minimally invasive procedure with the patient awake and able to report sensations induced by the lead in different positions because a strong sensation in the central perineal region seems to be ctitical for obtaining a good clinical outcome. The stimulator is continuously active, giving a 15-Hz pulse to the sacral nerves on one side. The permanent stimulators arc expensive, and the patient may need to undergo a number of revisions, but in well-selected cases this form of treatment can gteatly improve bladder symptoms.

Nerve Root Stimulators

In patients who have suffeted a complete spinal cord transection but in whom the caudal section of the cord and its roots are intact, the implantation of a nerve root stimulatot should be considered. This device was pioneered

by **Professor** Giles Brindiey and his collaborators, and approximately 2000 have been implanted worldwide. The principle on which they work is that the stimulating electrodes are placed around the lower sacral roots {S2-S4) and activated by an external switching device. The stimulating electrodes are implanted during a neurosurgical procedure and usually are applied intrathccally to the anterior roots; the posterior roots are cut at the same time. After the implant, the stimulation parameters are adjusted so that the patient obtains the maximum benefit from the stimulator in terms of making the bladder contract for voiding, assisting defecation, or even producing a penile erection. Although the procedure is highly effective in selected cases, the additional neural deficit caused by the need for section of the dorsal roots and consequent loss of reflex erections has reduced its popularity. These stimulators are suitable only for patients with complete spinal cord lesions rather than partial cord lesions or progressive neurological disease.

Surgery

Various urological procedures can be carried out to treat incontinence, as summarized in Table 42.2. A surgical procedure to rectify a disorder causing incontinence in an otherwise fit and healthy patient often is highly successful, and even after spinal cord injury a surgical option may be the best solution for long-term bladder management. However, this does not apply to patients with progressive neurological disease causing incontinence. For example, at a time when the bladder is becoming unmanageable by a combination of intermittent catheterization and an anticholinergic, the patient with MS may just be managing to remain independent. This is not the moment to suggest major urological surgery. Few patients with progressive neurological disease affecting bladder control opt for surgery.

MANAGEMENT OF NEUROGENIC SEXUAL DYSFUNCTION

A discussion of the patient's difficulty is the first step in advising management for sexual dysfunction. An explanation of the neurological basis of sexual dysfunction, sometimes to both partners, may relieve anxieties that the problem was thought to be psychological in origin. The topic can be introduced without embarrassment during explanation of the neurological basis of any coexistent bladder symptoms. The main qualification for undertaking this type of discussion is that the doctor should feel comfortable with it and able to convey this comfort to the patient. Patients prefer to discuss intimate problems with someone they know already, and this is usually the neurologist they see regularly.

Table 42.2: Urological operations that may be performed to treat various causes of incontinence

Disorder	*Surgical procedure*
Genuine stress incontinence	Bladder neck suspension, transvaginal tape
Detrusor overactivity	Augmentation cystoplasty
Sphincter failure	Arrificlil sphincter
Intractable incontinence	Urinary diversion with stoma collection bag

Sexual Dysfunction in Women

Little is known about sexual dysfunction in women with neurological disease. Although patients rarely complained in the past, problems undoubtedly occur, and they may become more evident in the current climate of frank discussions about male sexual dysfunction. Women with spinal cord disease such as MS encounter difficulties with intercourse because of poor bladder control and lower limb spasticity, in addition to loss of sensation (Hulter and Lundberg 1995), Loss of perineal sensation is a major problem for women with cauda equina lesions and may be a persisting cause of dissatisfaction, even when adequate means of managing bladder and bowel have been established. The erotic apathy that may occur with temporal lobe epilepsy can be a serious cause of disharmony in couples,

Male Erectile Dysfunction

The treatment of MED has been transformed in recent years by the introduction of orally active erectogenic agents. The first such agent was sildenafil (Viagra). This is a phosphodiesterase inhibitor that increases nitric oxide release in the corpora cavernosa and thus induces penile erection. Clinical studies have demonstrated that the optimal dosage should be taken up to 1 hour before anticipated sexual activity. It is not an aphrodisiac, but it improves penile erection with appropriate stimulation. The medication appears to have few side effects, and those that exist relate to its vasodilator action. In some patients it produces headache, flushing, and dyspepsia. The medication has undergone extensive testing in many groups of patients with MED and has been shown to be well tolerated. Contraindications to this medication include myocardial infarction in the previous fi months, concomitant use of nitrates, and other strong cardiac risk factors. It has been shown to be effective in men with a variety of medical conditions and in particular is of benefit in diabetic-induced MED and in spinal cord-injured patients; it has been shown to be very effective in MS.

Sildenafil has been shown to be highly effective in treating erectile dysfunction in a double-blind, placebo-controlled

trial in 217 men with MS using self-administered questionnaires. In response to the question "Did the medication you took over the last 4 weeks improve your erections?" 89% of those receiving sildenafil said "y^{es}!" compared with 24% of those receiving placebo. Furthermore, the study demonstrated an improvement in quality of life after treatment (Fowler et al. 2002).

Other phosphodiesterase inhibitors such as tadalafil and vardenafil arc expected to be available soon; they differ from sildenafil in terms of speed of onset and in duration of effect. Long-term results arc awaited.

Sublingual apomorphine hydrochloride is a D1/D2 dopamine receptor agonist that acts centrally to induce penile erection. At a dosage of 2 mg, increasing to 3 mg, it has a reported faster onset than sildenafil, with nausea in 7%. Whether it works in patients with MS remains to be seen.

Although oral agents arc now established as first-line treatment for most patients, some patients will need an alternative. This may be an injection of prostaglandin El (alprostadil) directly into the penis, which acts by relaxing the smooth muscle of the cavemosal vessels. The administration of alprostadil as an intraurethral pellet, called medicated urethral system for erection (MUSE), was introduced to obviate self-injection.

For men who do not respond to vasoactive agents or who want to use alternative means of treatment, vacuum pump devices may be suggested. These induce tumescence in a rigid cylinder that is placed over the penis and from which the air is pumped by hand. A band is then placed around the base of the penis, and the cylinder is removed.

Rarely in some men, usually those with vascular disease rather than progressive neurological illness, a penile prosthesis is implanted. The implants are available either as a simple semirigid or malleable rod or a complex inflatable device.

With the advent of an effective nonsurgical therapy for erectile failure, the emphasis for investigation and treatment of MED has changed. Previously, investigations aimed at determining whether the cause of erectile failure was organic or psychosomatic. Various neurophysiological investigations were used in an attempt to identify a neurological basis, and nocturnal penile tumescence studies were considered to be the major deciding factor. However, it is now well established that nocturnal erections are preserved in men with spinal cord injury or partial spinal cord dysfunction, as occurs in MS. Furthermore, there is no single neurophysiological test that can distinguish between neurogenic and psychogenic erectile dysfunction. Assessment of the response to an intracorporeal injection of a vasoactive agent provides some information about the likely pathogenesis because men with neurogenic or psychogenic erectile difficulties respond well, whereas those with vascular disease do not. The role of the International Index of Erectile Function questionnaire in assessing MED has become well established.

Ejaculatory Failure

Ejaculatory failure commonly accompanies erectile failure of neurogenic origin in men wirh spinal cord disease, whereas in diabetics, ejaculation seems to be better preserved than erectile function. Much less can be done for ejaculatory difficulties, although it is worth trying oral yohimbine. This substance is obtained from the yohimbine tree, which grows in West Africa. It is an «$_2$-adrcnergic blocker that is said to facilitate male sexual arousal. A controlled trial of the effect of yohimbine in treating organic MED showed a small effect when compared with placebo. The recommended dosage is either a starting dose of 10 mg (increasing to 20 mg) taken approximately 2 hours before intercourse is attempted or 5 mg three times a **day** taken regularly. Its side effects include a feeling of general exciration, anxiety, nausea, and trembling hands.

Infertility caused by ejaculatory failure can be managed by means quite different from those that would be suggested for ejaculatory difficulties. Patients should be referred to a center that specializes in this problem; such centers usually arc found in association with a spinal cotd unit.

MANAGEMENT OF FECAL **INCONTINENCE**

Coordinated lower bowel function depends less on the integrity of the spinal cord than does bladder function. Consequently, fecal incontinence is much less common than urinary incontinence in neurological disease. Indeed, the first step in managing fecal incontinence is to establish the cause (see Chapter 32). It is usually evident from the history if the complaint is caused by a diatrheal state or urgency of defecation, and if so the patient should be referred to a gastroenterologist for investigation. If no cause can be found and the problem persists, symptomatic treatment with a constipating agent that reduces lower bowel motility, such as loperamide, may be helpful.

Many patients with partial spinal cord disease complain of constipation, and some of them also have occasional fecal incontinence. Constipation can be caused by either slow colonic transit or difficulties with defecation. The incontinence may result from loss of voluntary control of the pelvic floor. If this occurs, the patient should use suppositories and attempt to empty the bowel at a predictable and convenient time, thereby lessening the risk of unexpected defecation. A survey of patients with spinal cord injury found that problems with bowel function were a major physical and psychological problem and were rated only slightly less serious than the loss of mobility (Glickman and Kainm 1996).

Pelvic floor incompetence can occur in the context of a Cauda equina lesion or as a result of more selective neurological injury to the pudendal nerves. Referral to a colorectal surgeon is necessary for consideration of a sphincter repair or postanal repair. Alternatively, a

"ncosphincter" can be created using healthy nonsphincter striated muscle, such as the gracilis, transposed around the anal canal.

Chapter 43
Neuroepidemiology

Mitchell T. Wallin and John F. Kurtzke

A useful definition of epidemiology is "the science of the natural history of diseases." This concept is based on the original roots of the word: *logos,* from *legein,* "to study"; *epi,* "[what is] on"; *demos,* "the people." In epidemiology, the unit of study is a person affected with a disorder of interest. Therefore diagnosis is the essential prerequisite. This is why Hie neurologist must be an essential pari of any inquiry into the epidemiology of neurological diseases.

After diagnosis, the most important question is the frequency of a disorder. Much of this type of information has been based on case series, that is, the scries of cases encountered by individual practitioners, clinics, or hospitals. However, whether taken as numerator alone (case series) or compared with all admissions (relative frequency), the difficulty with such data is that one has little assurance that what has been included is representative of the total population. Such case material needs to be referenced to its proper denominator, its true source: the finite population at risk.

POPULATION-BASED RATES

Ratios of cases to population, together with the period to which they refer, make up the population-based rares. Those commonly measured are the incidence rate, mortality rate, and the so-called prevalence rate. They arc ordinarily expressed in unit-population values. For example, 10 cases among a communiry of 20,000 represent a rate of 50 per 100,000 population or 0.5 per 1000.

The *incidence* or *attack rate* is the number of new cases over a defined study period divided by the population at risk. This is usually given as an annual incidence rate in cases per 100,000 population per year. The date of onset of clinical symptoms typically dictates the time of accession, although occasionally the date of first diagnosis is used.

The *(point) prevalence rate* is more properly called a *ratio,* but it refers to the number of those affected, both old and new cases, at one point in time within the community per unit of population. The *lifetime prevalence rate* refers to the proportion of persons manifesting a disorder of interest during the period of their life up to the survey date. It is typically reported per 1000 of the population at risk. If there is no change in case-fatality ratios over time and no change in annual incidence rates (and no migration), then the average annual incidence rare times the average duration of illness in years equals the point prevalence rate.

When numerator and denominator for a rate each refers to an entire community, their quotient is a crude rate, for all ages. When both terms of the ratio are delimited by age or sex, these are age-specific or sex-specific rates. Such rates for consecutive age groups, from birth to the oldest group of each sex, provide the best description of a disease within a community.

In comparing morbidity or mortality rates between two communities for an age-related disorder (such as stroke or epilepsy), there may be differences in crude rates solely because of differences in the age distributions of the denominator populations. This can be avoided by comparing only the individual age-specific rates between the two, but this rapidly becomes unwieldy. Methods exist for adjusting the crude rates for all ages to permit such comparisons. One such method involves taking community

age-specific rates and multiplying them by the proportion of a "standard" population within the same age group. The sum of all such products provides an age-adjusted (to a standard) rate, or a rate for all ages adjusted to a standard population. One common standard in the United States is its population for a given census year,

The *mortality* or *death rate* is the number of deaths in a population in a period with a particular disease as the underlying cause, such as an annual death rate per 100,000 population. The standardized mortality ratio (SMR) is the observed number of deaths in the study group of interest, divided by the expected number of deaths based on the standard population rates applied to the study group.

The great advantage of death rates is their current availability over time and geographical area for many disorders. Geographical distributions arc especially informative because most population studies available are, of necessity, spot surveys that may tell us little about areas that were not investigated. Most often, too, the numbers are larger by orders of magnitude than those that prevalence studies can provide. The principal disadvantage, and it is a major one, is the question of diagnostic accuracy. There are also problems with coding practices and demographic errors (age and residence in particular),

The code used for mortality rates is a three- or four-digir number representing a specific diagnosis in the *International Statistical Classification of Diseases, Injuries and Causes of Death* (/CD), which is revised about every 10 years. The changes in the tenth revision *[ICD-10)* were major. *ICD-10* was published in 1992 with the innovation of an alphanumeric coding scheme of one letter followed by three numbers (e.g., 163.1, cerebral infarction due to thrombosis of precerebral arteries). One drawback of the *ICD* system of classification is that several diseases are frequently subserved under the same primary code. To provide a more refined classification for individual diseases, several disciplines have published specialty-related expansions of the primary *ICD* structure. *ICD-10-NA* is the expansion of the codes relating to neurological diseases, so that virtually every known neurological disease or condition has a unique alphanumerical identifier (World Health Organization 1997; van Drimmelen-Krabbe et al. 1998). In the United States, hospitals currently use the *ICD-9* clinical modification, which may be replaced hy an update based on **the** *ICD-10.*

Space precludes attention to community survey methods, risk factors, treatment comparisons, and statistical methods—all intrinsic aspects of epidemiology. As for neuroepidemiology *per se,* the material presented here provides some highlights for a few major diseases chosen to represent the field.

CEREBROVASCULAR DISEASE

Stroke is the third leading cause of death and the most common reason for disability in Western countries (Poungvarin 1998) (see Chapter 57). Cerebrovascular disease has been variably classified, particularly in mortality data. The general usage in morbidity studies has been to subdivide stroke into (1) subarachnoid hemorrhage {SAH}, (2) intracerebral hemorrhage, and (3) cerebral infarction. Cerebral infarction is the most common type of stroke in developed countries, making up more than 70% of cases. Intracranial hemorrhages make up about 10-15% of strokes, SAH make up less than 5%, and the remainder are of undetermined etiology.

Mortality Rates

Between 1950 and 1996, U.S. stroke death rates declined by 70% overall (Centers for Disease Control and Prevention 1999). There are similar decreasing rates for other countries, including Japan, Australia, New Zealand, Canada, and all of Western Europe. Reported rates over the last four to five decades actually increased for Czechoslovakia, Yugoslavia, Bulgaria, Poland, and Hungary. The changes in stroke death rates by racial/ethnic groups in the United States between 1990 and 1998 are recorded in Table 43.1. The age-adjusted stroke death rate was higher for black non-Hispanics compared with other groups. The stroke death rates for American Indians

Table 43.1: Age-adjusted death rates (1940 U.S. standard population) per 100,000 for stroke by race and Hispanic origin 1990, 1998, and percent change form 1990 to 1998: United States

Year	*Total*	*Non-bispanic white*	*Non-hispanic black*	*Hispanic*	*American Indian or Alaska native*	*Asian or Pacific Islander*
1990*	27.5	25.1	47,8	20.7	19.1	24.7
1998	25.1	23.3	42.5	19.0	19.6	22.7
Percent change 1990 to 1998	-9.0	7.2	-11.1	-8.2	2.6	-8.1

* Age-adjusted death rates for 1990 were calculated based on population estimates for July 1, 1990. Rates published elsewhere for 1990 are based on the enumerated population on April 1, 1990, for the year in which the decennial census was taken. Rates for noncensus years are based on July 1 (mid year) populations. In order to measure changes over time, rates based on the July 1 populations are used. *Source:* Keppel, K. G., Pearcy, J. N., & Wagener, D. K. 2002, "Trends in racial and ethnic-specific rates for the health status indicators: United States, 1990-98". *CDC-Statistical Notes,* vol. 23, pp. 1-15.

or Alaska natives increased by 3%, and the rates for the other four groups declined by 7-11%.

U.S. racial and ethnic disparities in mortality by stroke type have been reported for the period 1995-1998 (Ayala et al. 2001). National Vital Statistics Death certificate data were used to calculate age-standardized rates for ischemic stroke, intracerebral hemorrhage, and subarachnoid hemorrhage among Hispanics, Blacks, American Indians/Alaska Natives, Asians/Pacific Islanders, and whites. For ischemic stroke, the ratio of the age standardized death rate among blacks (96 per 100,000) compared with whites was 1.30. All other groups had lower rates of ischemic stroke compared with those of whites. Death rates for intracerebral hemorrhage were highest for blacks (23 per 100,000) and Asian/Pacific Islanders (20 per 100,000), with corresponding risk ratios compared with whites of 1,70 and 1.52. Subarachnoid hemorrhage death rates were higher for all other minority groups as compared with whites.

Morbidity Rates

Like mortality rates, stroke incidence has declined rapidly over the past fifty years. In Rochester, Minnesota, stroke incidence fell by 54% from 1945-1954 and 1975-1979. Over the past two decades, however, stroke incidence rates have stabilized or slightly decreased in Western countries (Thorvaldsen et al. 1999). Average annual age-adjusted incidence rates by sex show a modest, but possibly increasing, male excess. In recent years the annual stroke incidence rate in Europe and North America has been between 100 and 300 per 100,000 population.

Rates in the United States for blacks remain higher than do those for whites. The Greater Cincinnati and Northern Kentucky Stroke Study was the first large metropolitan-based study of stroke trends among blacks (Brodenck et al. 1998). The incidence for first-ever stroke among blacks in the region was 288 per 100,000 (age- and sex-adjusted 1990 U.S. population). The incidence rate for first-ever and recurrent stroke was 411 per 100,000. The first stroke incidence rate was approximately 1.6 greater than the overall age- and sex-ad] Listed incidence rate of stroke among the white population of Rochester, Minnesota, in 1985-1989. Figure 43.1 illustrates those age-specific incidence rates in these two populations. Based on extrapolation techniques using the two study populations, there were at least 731,000 first-ever or recurrent strokes in the United States in 1996.

In Rochester, Minnesota, the age-adjusted average annual incidence rate declined from 200 per 100,000 population during 1945-1954 to 107 per 100,000 for 1975-1979. The decrease was for both sexes, for essentially all ages, and for both cerebral hemorrhage and thrombosis; it was not found for SAH, however. Brown et al. (1996) reported an extension of the Rochester data through 1989, A 13% *increase* in total stroke incidence rates was noted during the years 1985-1989 versus 1975-1979. The most prominent increases were in those 85 years or older.

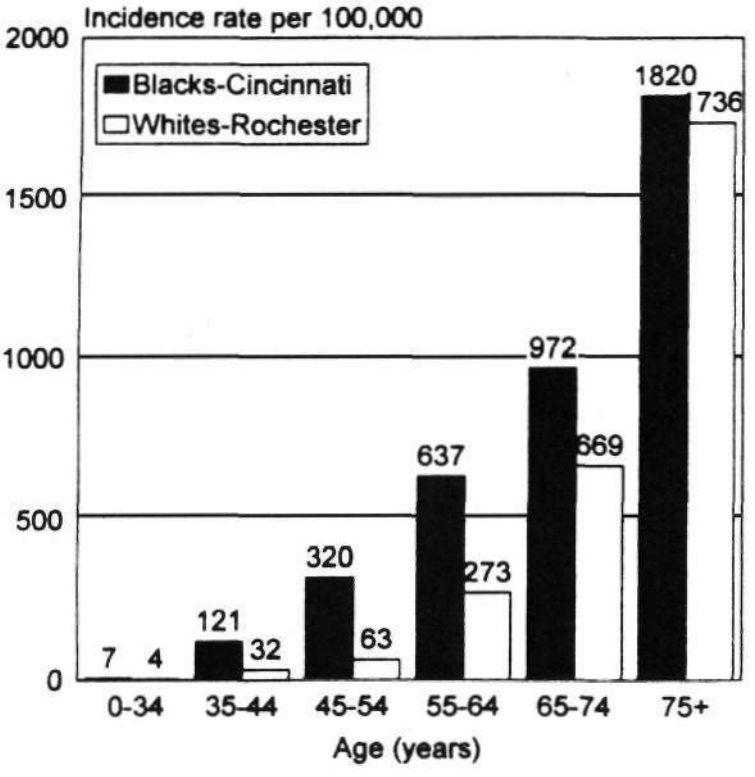

FIGURE 43.1 Age-specific incidence rates of first-ever stroke among blacks in Greater Cincinnati during the first 6 months of 1993 and among whites in Rochester, Minnesota, during 1585-1989. (Reprinted with permission from Brodcrick, J., Brott, T., & Kothari, R. 1998, "The Greater Cincinnati and Northern Kentucky Stroke Study: Preliminary first-ever and total incidence rates of stroke among blacks," *Stroke^* vol. 29, 415-421.)

Since 1975-1979, the incidence rate among women aged 85 years or older has increased 90%, with a corresponding increase of 11% for men.

The World Health Organization's Multinational Monitoring of Trends and Determinants in Cardiovascular Disease project is an ongoing study to compare incidence and mortality of stroke across multinational populations adjusted to a "world standard population" (Stegmayr et al. 1997). The highest incidence rates out of 18 countries were in men in Kuopio, Finland, and Novosibirsk, Russia (adjusted incidence rates >300 per 100,000). In women, the highest rates were in Novosibirsk. The highest rates for both sexes were more than three times higher than those in Friiili, Italy. In half the populations, the- stroke incidence rate was twice as high in men as in women. Significantly, a regression analysis showed that conventional cardiovascular risk factors (i.e., smoking and hypertension) explained only 21% of the variation of stroke incidence among the population in men and 42% among women.

Prevalence rates in the early 1980s were around 600 per 100,000 in the West and 900 per 100,000 in Asia. In the United Stares, age-, race, and sex-adjusted stroke prevalence rates increased from 1.41% in 1971-1975 to 1.87% in 1988-1994 (Muntner et al. 2002). This corresponded to an increase of 930,000 noninstitutionalized stroke survivors with increases observed in all age, race, and gender groups. With decreasing mortality trends and relatively stable stroke incidence rates during the 1980s, these data point to a decreasing stroke case fatality rate as a driver of this prevalence trend.

PRIMARY NEOPLASMS

Three large centralized databases have been created in the United States that provide descriptive epidemiologic data on primary brain tumors. These include the Central Brain Tumor Registry of the United States (CBTRUS); the Surveillance, Epidemiology and End Results (SEER) database; and the National Cancer Database (NCDB). According to the CBTRUS and SEER databases, an estimated 350,000 persons were living with a primary brain tumor diagnosis in the United States in the year 2000 (Davis et al. 2001). This translates to a prevalence rate of 131 per 100,000 persons. The lifetime risk of developing a CNS malignancy is estimated to be 0.66% for men and 0.54% for women (Ries et al. 2000). Little is known of the causes of most primary brain tumors, but their epidemiologic features may provide clues for more definitive studies.

In clinical experience, 85% of primary central nervous system (CNS) tumors are intracranial and 15% are intraspinal. For the brain, the major groupings are the gliomas (40-50%, of which about half are glioblastoma multiforme) and the meningiomas (15-20%). Pituitary adenomas plus neurilcmmomas, especially acoustic, add another 15-20%. The most common spinal cord tumors are neurofibroma and meningioma, followed by ependymoma and angioma.

Mortality Rates and Survival

In the United States between 1995 and 1999, malignant CNS tumor deaths by age showed a steep rise from very low rates in early adult life to a peak of around 20 per 100,000 by age 75, followed by a steep decline with further increasing age (Davis et al. 2001). There was a notable excess of whites over nonwhites in this group, with rates two to three times higher in the whites. There was also in all race groups an excess of male deaths.

Reported 5-year survival ratios have been about 60% for clinically diagnosed meningioma and 20% for gliomas as a group. Median survival for glioblastoma has been about 1 year after diagnosis. Taken together, median survival for benign brain tumors may be estimated at 6 years. The relative 5-year survival rate for children younger than age 15 years with brain and other nervous system tumors is now 61%, compared with 35% twenty years ago (Parker et al. 1997).

Survival for patients with metastatic brain tumors is poor. Even after whole brain radiation, median survival is about four months with 40-60% of patients dying of systemic disease (Lagcrwaard et al, 1999), Long-term survival for 740 patients with brain metastases was reviewed by Hall and colleagues (Hall et al. 2000). For all tumor types, the actuarial survival rate was 8.1% at 2 years, 4.8% at 3 years, and 2.4% at 5 years. At two years from diagnosis, ovarian carcinoma had the highest survival rate (23.9%) and small cell lung cancer the lowest (1.7%). Favorable prognostic variables for survival included a single metastatic lesion, surgical resection, and whole brain radiation.

Morbidity Rates

Average annual incidence rates for primary brain tumors in the more complete surveys have ranged mostly between 10 per 100,000 and 15 per 100,000 population, including pituitary tumor rates at 1-2 per 100,000. Primary tumors of the spinal cord arc recorded at about 1 per 100,000, and in one survey peripheral nerve tumors had a rate of 1.5 per 100,000.

From the late 1960s to the late 1980s, the incidence of primary brain neoplasms has at least doubled in the United States. The Connecticut Tumor Registry showed a dramatic increase in incidence for age groups 65-84 years, with relatively stable rates for younger cohorts. For the 65- to 69-ycar-old age group, the incidence rate increased from 18.42 per 100,000 in 1965-1969 to 28.29 per 100,000 in 1985-1988. Similar increases were seen in older age groups. There was a trend of increasing incidence for the

1890 and 1900 birth cohorts, implying a cohort effect. Whether these cohort trends are due to environmental effects or improved diagnostic capabilities is not clear.

Using the SEER database, incidence trends were computed by age group for malignant brain tumors for the years 1975-1997 (Figure 43.2). Incidence rates remained stable for those <20 years to 69 years of age during the period. There was a gradual increase in malignant tumor rates, however, for individuals older than 70 years between 1975 and 1990. During the 1990s, the rates for the oldest groups have essentially remained unchanged.

In meningioma, the age-specific rates continue to rise with age to the oldest group, and there is a female preponderance. The suspected excess in blacks was borne out in a survey in the Los Angeles County Cancer Surveillance program. Age-adjusted average annual incidence rates for meningiomas were 1.8 per f00,000 males and 2.7 per 100,000 females. Respective non-Hispanic white rates were 1.8 per 100,000 and 2.5 per 100,000; for blacks, they were 2,5 per 100,000 and 3.6 per 100,000. In Rochester, Minnesota, annual incidence rates for all cases were 4.9 per 100,000 males and 5.8 per 100,000 females for 1935-1977, but only 1.2 per 100,000 and 2.6 per 100,000 for cases diagnosed antemortem. The true rare for meningiomas, then, would seem to be around 5 per 100,000 population.

An overall estimate for malignant intracranial tumors is about 5 per 100,000 population, most of which is attributed to glioblastoma multiforme. For benign brain tumors, a reasonable figure would be 10 per 100,000; 5 per 100,000 for meningioma; and 1-2 per 100,000 each for benign gliomas, pituitary tumor, and all others.

Although some CNS tumors have a clear genetic character, fewer than 5% can be attributed to inheritance. Astrocytic gliomas may show loss of genetic information from chromosomes 9p, lOq, lip, 13q, 17p, *or* 22 (Kyritsis et al. 1993). Mutations of the *pS3* tumor-suppressor gene on the short arm of chromosome 17 are found mostly in malignant astrocytic forms and arc linked to malignant tumor transformation and progression. Many factors are implicated in human brain tumors, the vast majority of which are unsubstantiated by scientific evidence. High-dose radiation leads to an increased incidence of primary brain tumors, but the association of higher brain tumor risk with low doses of radiation is more controversial.

CONVULSIVE DISORDERS

Epilepsy is defined as recurrent seizures (i.e., two or more distinct seizure episodes) that are not the immediate result of an acute cerebral insult. The four broad categories of

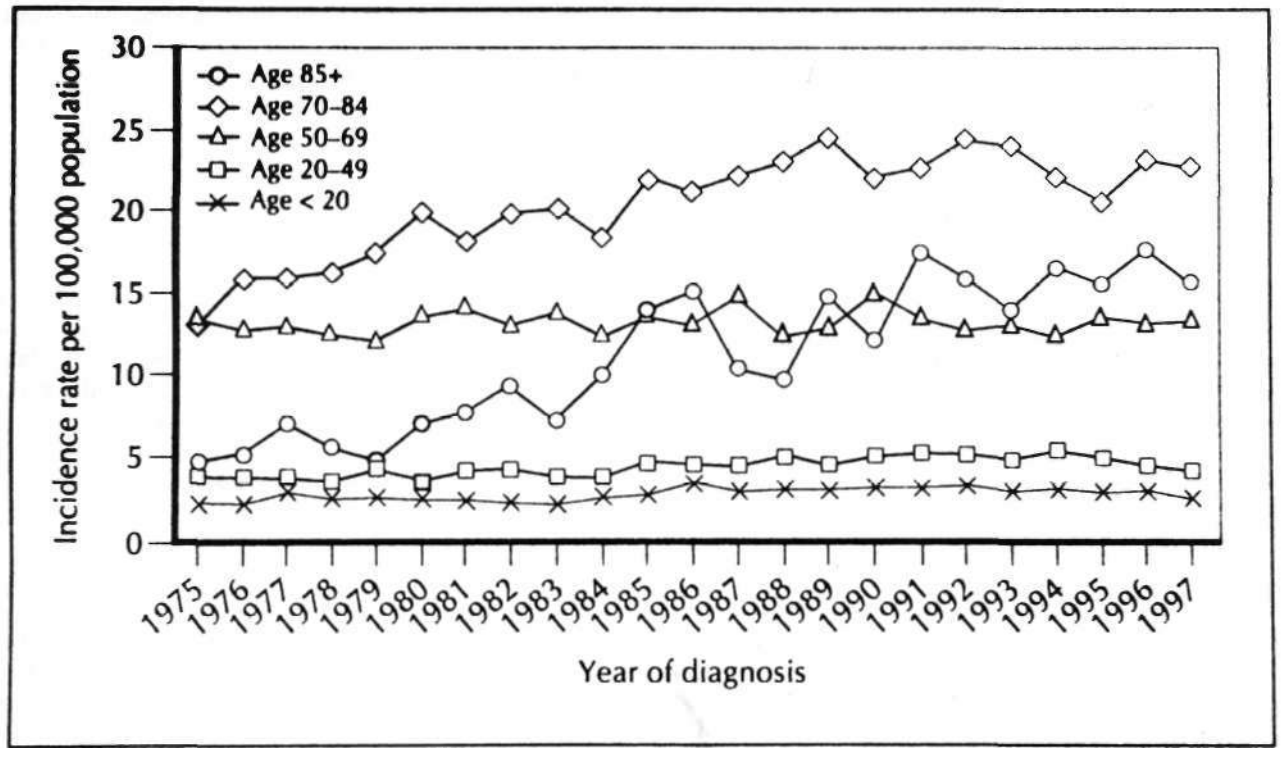

FIGURE 43.2 Trends in central nervous system malignancy incidence rates by age (years) at diagnosis: Surveillance, Epidemiology, and End Results 1975-1997. Incidence rates are age standardized to the United States 2000 standard population. Central nervous system malignancies were classified as ICD-0-2 topography codes C70.0 and C75.1-75.3 and behavior code 3. (Reprinted with permission from Gurney, J. & Kadan-Lottick, N. 2001, "Brain and other central nervous system tumors: Rates, trends, and epidemiology," *Curr Opin Oncol,* vol. 13, pp. 160-166.}

seizure disorders used in many epidemiologic studies are epilepsy, isolated seizures, febrile convulsions, and acute symptomatic seizures. Depending on the amount of clinical and electroencephalographic (EEG) information available, patients with epilepsy can then be further subclassificd by seizure type. The major types of seizures are generalized tonic-clonic (grand mal), absence (petit mal), incomplete convulsive (myoclonic), simple partial (focal), and complex partial (temporal lobe or psychomotor). Status epilepticus is defined as any seizure lasting for 30 minutes or longer or intermittent seizures lasting for longer than 30 minutes from which the patient did not regain consciousness. There are other seizure disorders that do not fulfill the standard definitions of epilepsy that require separate classification in epidemiological studies.

Mortality Rates

Several population studies have reported excess mortality rates with epilepsy compared with that expected. Nilsson etal. (1997) used the Stockholm County inpatient register to study 9601 patients hospitalized during 1980-1989 with a diagnosis of epilepsy. Fach patient was studied until death or December 31, 1992. The calculated standardized mortality ratio was 3.6, meaning that people with epilepsy were *3.6* times more likely to die during the follow-up period than were the general population. Causes of death included those related to epilepsy (e.g., brain tumor, stroke, and dementia}, complications of seizures (e.g., pneumonia and falls), and other causes. Surprisingly, motor vehicle accidents did not contribute to the decreased survival in the Stockholm epilepsy population. Rafnsson et al. (2001) showed that all-cause mortality was increased among men (SMR 2.25) but not women {SMR 0.79) in an Icelandic population-based incidence cohort of patients with unprovoked seizures. The increased male mortality was partly attributable to excess deaths from accidents ant) suicides. This pattern of a higher male mortality in an epilepsy cohort has been confirmed in other studies as well. Using a time trend analysis, O'Donoghue and Sander (1997) reported on the epilepsy mortality in a U.K. population from 1896-1965. The overall standard mortality ratio was 2.3, with little variation during the entire period. In general, these studies indicate that epilepsy is associated with a higher risk for death. Furthermore, the introduction of modem treatments for epilepsy has not appeared to affect reported mortality, but only a minority of affected subjects have epilepsy listed as a cause of death.

Age-specific mortality rates for Rochester, Minnesota, are shown in Figure 43.3. Mortality rates were similar to age-specific prevalence rates but were 1000-fold less. This finding suggests that each year 0.1% of the patients with epilepsy die of causes directly related to their epilepsy.

Status epilepticus (SE) affects 105,000 to 152,000 persons annually in the United States (DeLorenzo, Hauser, and Towne 1996). SE is a neurological emergency, and despite improvements in treatment, mortality is still high. Population-based studies have reported 30-day mortality rates of about 20%. Short-term mortality after SE is associated with the presence of an underlying acute etiology. Logroscino et al. (2002) are the first to report on the long-term mortality after an initial episode of SE. The study was a population-based retrospective cohort performed in Rochester, Minnesota, between 1965 and 1984. Forty percent of subjects who survived the initial 30 days after SE died within the next 10 years. Long term mortality was worse for patients with myoclonic status epilepticus, those presenting with SF. lasting more than 24 hours, and for those with symptomatic SE. Long term mortality rates for patients with idiopathic/cryptogenic SE was not increased. The results indicate that SE alone does not modify long-term mortality.

Morbidity Kates

Figure 43.3 shows morbidity measures for epilepsy in Rochester, Minnesota, by age group. Age-specific incidence of epilepsy was high during the first year of life, declined during childhood and adolescence, and then increased again after age 55. The cumulative incidence of epilepsy was 1.2% through age 24 and steadily increased to 4.4% through age 85 years. Age-specific prevalence increased with advancing age; nearly 1.5% of the population over 75 years had active epilepsy.

Point prevalence and average annual incidence rates for epilepsy are available from a number of community surveys. In general, the prevalence of convulsive disorders is about 3–9 per 1000 population. In Bogota, Colombia, there was a strikingly high rate, 19,5 per 1000, which included inactive seizure disorders. Prevalence rates have tended to increase in recent years in several surveys. Males and blacks do have higher rates than females and whites.

Between 1979 and 1987, prevalence for active epilepsy was 5.1 per 1000 in Vecchiano, Italy; 6.3 per 1000 in Kuopio Central Hospital District (CUD), Finland; 6.8 per 1000 in Rochester; and 8.0 per 1000 in northern Ecuador, Follow-up of a U.K. birth cohort showed a rate of 4.3 per 1000 at age 10 years,

Worldwide, neurocysticercosis is considered the most common reason for epilepsy, being twice as common in developing as in developed countries (International League Against Epilepsy 1994). Neurocysticercosis affects thousands of people in Latin America, Asia, and Africa. The disease has also been reported more frequently in industrialized countries with a high immigration rate of people from endemic countries. A collaborative network of U.S. emergency departments reported on the epidemiology of neurocysticercosis in seizure patients (Ong et al. 2002).

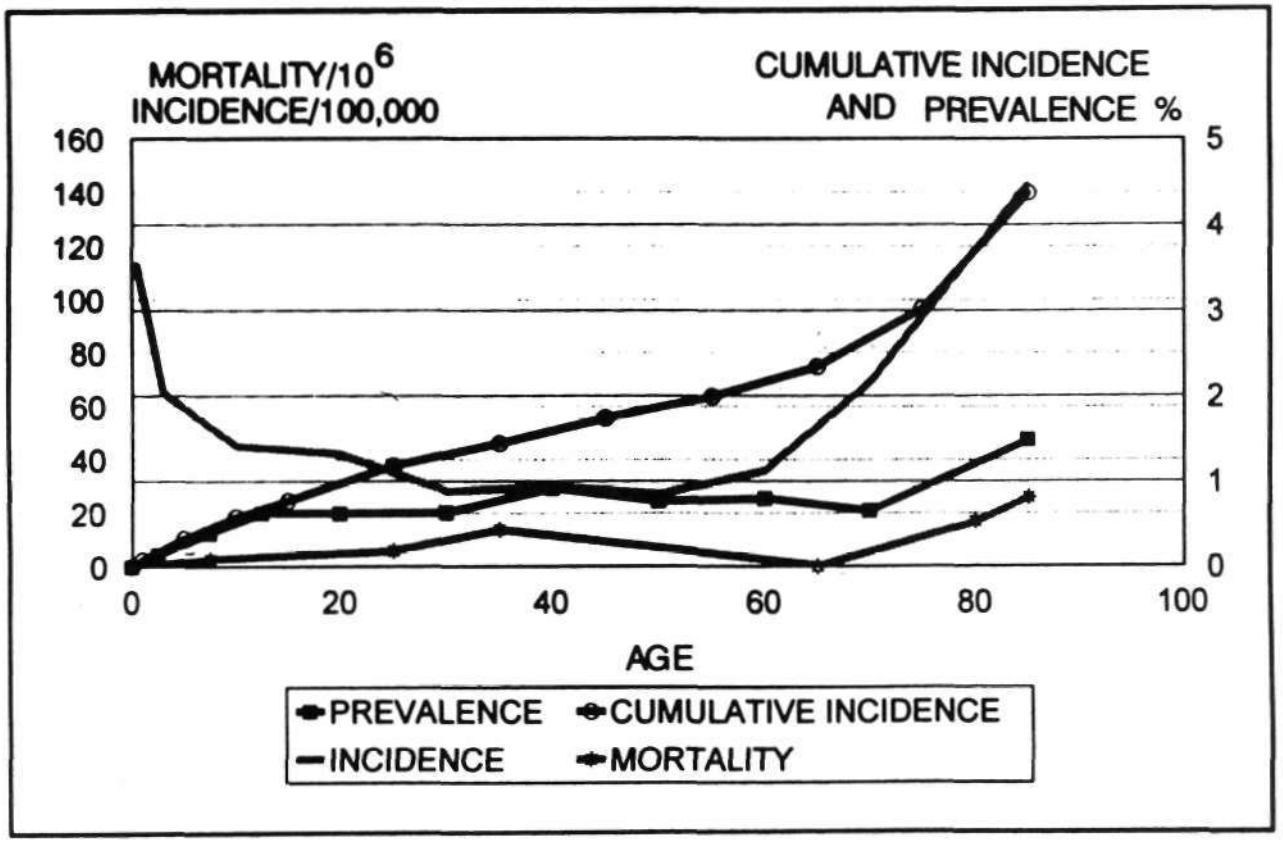

FIGURE 43.3 Measures of epilepsy (Rochester, Minnesota, 1935-1984): age-specific incidence per 100,000 person-years; cumulative incidence (percent); age-specific prevalence (percent); and age-specific mortality per 100,000 person-years. (Used with permission from Hauscr, W. A., Annegcrs, J. F., & Rocca, W. A. 1996, "Descriptive epidemiology of epilepsy: Contribution of population-based studies from Rochester, Minnesota," *Mayo Clin* fYoe, vol. 71, pp. 576-586.)

Data were collected on patients with seizures at 11 university-affiliated urban emergency departments from 1996-1998. Of the 1801 patients enrolled, 2.1% had seizures attributable to neurocysticercosis. The disease was widely distributed throughout the United States **with** highest concentration in Hispanics in the southwestern region.

Average annual incidence rates for epilepsy as of 1980 were approximarely 20-70 per 100,000 population per year. There was a slight male excess, which averaged about 1.2 to 1.0, and almost a 2 to 1 black-white ratio. Later surveys showed annual rates of 24 per 100,000 for Kuopio, Finland; 34 per 100,000 for Vastetbotten, Sweden; and 48 per 100,000 for Rochester, Minnesota. Ecuador provided an annual incidence rate of 190 per 100,000 in 1985-1986. A high frequency of epilepsy appears to exist in Central and South America, as suggested by death and prevalence rates. Elsewhere in the West, an expected range for annual incidence is approximately 30-60 per 100,000, with a reasonable general estimate of 50 per 100,000. With the concomitant prevalence rates, an average duration of active seizure disorders could then be calculated as about 13 years.

Age-specific incidence rates for epilepsy from several surveys showed a sharp decrease from maximal rates in infancy to adolescence and thereafter a slow decline for new cases throughout life. In others, rates were essentially constant after infancy or showed an irregular rise with age. In Rochester, Minnesota, however, the configuration was U-shaped, with a marked increase in incidence rates at age 75 and older (Figure 43.4). This configuration reflects generalized tonic-clonic disorders, together with absence and myoclonic seizures for the left arm of the U, and partial epilepsies for the right arm. Myoclonic seizures were the major type diagnosed during the first year of life; they were also the most common in the 1- to 4-year-old age group, but rarely occurred after 5 years of age. Absence (petit mal) seizures peaked in the 1- to 4-year-old age group and did not begin in patients older than 20. Complex partial (psychomotor) and generalized tonic clonic (grand mal) seizures both had fairly consistent incidence rates of 5-15 per 100,000 in ages 5-69 after low maxima at ages 1^1; for age 70 and older, the rates of each were sharply higher. The grand mal rates had similar configuration for both primary and secondary seizures. Simple partial (focal) seizures increased only slightly with age.

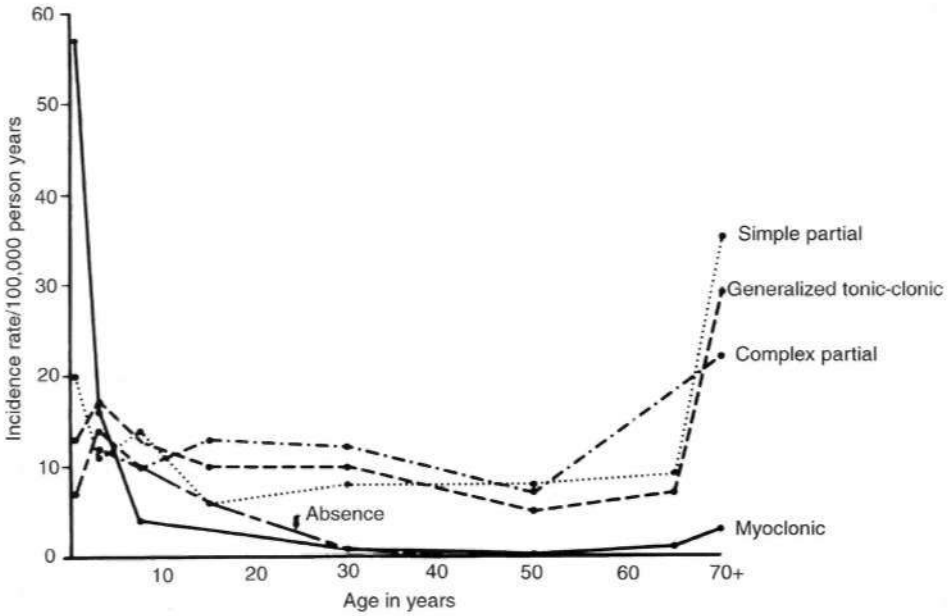

FIGURE 43.4 Epilepsy. Average annual age-specific incidence rates per 100,000 population by clinical type of seizure (absence, myoclonic, generalized, simple per complex partial). (Reprinted with permission from Kurtzke, J. F. & Kurland, L. T. 1983, "The epidemiology of neurologic disease," in *Clinical Neurology*, vol. 4, eds A. B. Baker & L. H. Baker, Harper & Row, Philadelphia.)

Febrile Seizures

The risk of a child developing febrile seizures has been about 2%, varying between 1% and 4%, in the United States and Europe. Surveys from Japan and the Mariana Islands showed rates of 7% and 11%, respectively. The Guaymi Indians of Panama had a rate of 14%. As with epilepsy in general, there was a male preponderance of 1.2 to 1 for febrile convulsions. In most studies, recurrent febrile seizures occur in about one third of the cases, and overall the risk of later epilepsy is about 2^1% for simple and 11 % for complex febrile seizures.

MULTIPLE SCLEROSIS

Mortality Rates and Survival

Over the last four decades, mortality for multiple sclerosis (MS) declined steadily in North America and Western Europe and remained stable or increased in eastern and northern Europe. As to cause of death, many patients with MS die of complications related to their disease. Koch-Henriksen and colleagues (1998) attributed more than half of all deaths in a large population cohort to MS or complications from the disease. As more patients with MS survive to older ages, however, a greater proportion of them can be expected to die of causes unrelated to MS, and thus will not be coded as dying of MS. This last point is supported by analysis of contributory causes of the death of patients with MS in Denmark and in the United States.

The estimated 25-year survival of the MS population in Rochester, Minnesota, was 76.2%, compared with 87.7% for the general U.S. white population of a similar age and gender (Wynn et al. 1990). Survival for men was less than for women. This survival figure was slightly greater than earlier estimates. The Danish National MS Registry data provided a median survival of 30 years from onset of the disease (Bronnum-Hansen, Koch-Henriksen, and Hyllested 1994). Median survival for World War II veterans from MS disease onset was 43 years (white females), 30 years (black males), and 34 years (white males) (Wallin, Page, and Kurtzke 2000).

Morbidity Rates

Prevalence rates **for** Europe and the Mediterranean basin as of 1980 arc plotted against geographical latitude in Figure 43.5. The surveys appeared to separate into two zones or clusters, one to the north with rates of 30 per 100,000 and higher, considered high frequency, and the other to the south with rates less than 30 per 100,000 but greater than 4 per 100,000 population, classified as medium frequency.

The northernmost parts of Scandinavia and the Mediterranean basin were medium-prevalence regions in 1980. More recent surveys of Italy and its islands, however, have documented prevalence rates well into the sixties, and therefore this country is now clearly within the high-frequency band (Kurtzke 1993). This appears to be a recent change because some of the earlier Italian surveys with lower rates were well done.

Boiko (1994) of Moscow University summarized a large literature on the distribution of MS in the former Soviet Union that was previously unavailable in the West. Much of northwestern Russia past Kiev and Moscow appears to be of high prevalence (greater than or equal to 30 per 100,000), surrounded to the north, east, and south

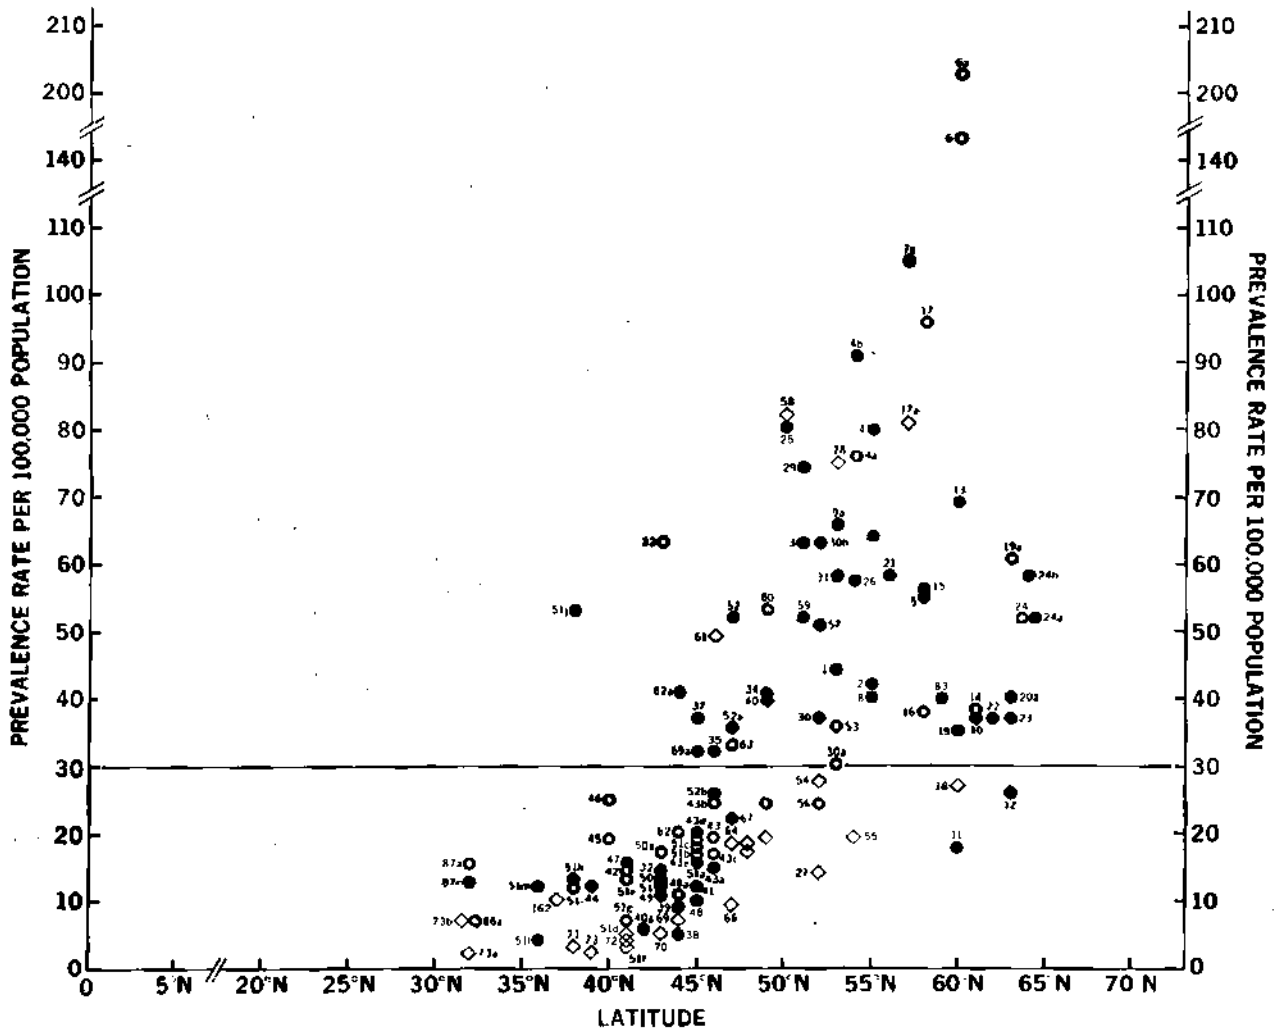

FIGURE 43.5 Multiple sclerosis (MS). Prevalence rates per 100,000 population for probable MS in Europe and the Mediterranean area as of 1980, correlated with geographical latitude. Numbers identify studies in Kutrzke {1980}. *Solid circles* represent class A (best) surveys; *open circles,* class B; *open diamonds,* class C; and *closed diamonds,* class E (MS: amyotrophic lateral sclerosis case ratios). Class C (poor) studies arc listed only if no better-quality survey was available for the specific site. (Reprinted with permission from Kurtzke, J. F. 1980, "Geographic distribution of multiple sclerosis: An update with special reference to Europe and the Mediterranean basin," *Acta Neurol Scand,* vol. 62, pp. 65-80. Copyright 1980, Munksgaard International Publishers Ltd., Copenhagen, Denmark.)

by medium-prevalence areas (5-29 per 100,000). Overall, the Ukraine and the Caucasus seemed on average to be in the medium-prevalence range. Uzbekistan, Samarkand, Turkistan, and Turkmenistan appeared to be low. In the Far East, medium prevalence once again appeared, and rates were indeed in the high range in the central and western parts of the Amur region, which abuts the Pacific Ocean above China and includes Vladivostok.

The general worldwide distribution of MS may be described within three zones of frequency or risk. The high-risk zone, with prevalence rates of .30 per 100,000 and above population, included northern and central Europe into the former Soviet Union, the northern United States, Canada, New Zealand, and southeastern Australia. These regions were bounded by areas of medium frequency, with prevalence rates between 5 and 29 per 100,000, consisting of the southern United States, possibly northern-most Norway, and probably Russia from the Ural mountains into Siberia, as well as the Ukraine. Except for Italy, now with high rates, the entire northern Mediterranean basin from Spain to Israel was of medium prevalence. In this zone, too, still fall most of Australia and perhaps Hawaii and the midportion of South America, plus whites in South Africa. Low-frequency areas, with prevalence rates below 5 per 100,000, comprised all other known areas of Asia, Africa, Alaska, Greenland, and the Caribbean region, including Mexico and probably northern South America. Recent data suggest medium rates in the North African littoral and high rates in Spain, Portugal, Israel, and Cyprus (Kurtzke 1997).

MS clearly is a place-related disorder. All the high- and medium-risk areas are found in Europe or the European colonies: Canada, the United States, Australia, New Zealand, South Africa, and probahly central and southern South America. MS likely originated in northwestern Europe and was brought to the other lands by European settlers. In Europe itself, although the disease clearly has shown geographical clustering in some countries, there is evidence even within these clusters of diffusion over time.

In the United States, white females are at greater risk than arc white males; blacks, Native Americans, and Asians all were at notably lower risk than whites. These race and sex differences persist regardless of geography.

The annual incidence rate in high-MS areas at present is about 3—5 per 100,000 population, whereas in low-risk areas it is about 1 per 1,000,000. Medium-risk areas have an incidence near 1 per 100,000. In Denmark in 1939-1945, age-specific incidence rates rose rapidly, from essentially zero in childhood to a peak at about age 27 of more than 9 per 100,000 for females and almost 7 per 100,000 for males. Beyond age 40, there was little difference between the sexes, both of whose rates declined equally to zero by age 60. Most recent evidence suggests women of all races in the United States have higher rates than males (Wallin, Page, and Kurtzke 2000a).

Family Studies

Family studies in MS have provided a means of assessing environmental factors against a set genetic background. Studies have shown that the risk for multiple family members with MS is 3—4% for primary relatives and 20-30% for monozygotic twins. This is in contrast to the general population prevalence of approximately 0.1%. The increased family frequency might be related to shared environment as opposed to shared genetic factors because close relatives would be expected to share similar environmental influences. However, further evidence that MS is under some genetic control includes the following:

1. Twin studies, most of which show an excess of concordant monozygous twins. The difference in concordance rates between monozygotic and dizygotic twins is primarily attributable to genetic factors. The maximum concordance rate for MS in monozygotic twins is about 30%. This indicates that although genes play a role in MS, the maximal effect of genes is at most 30%.
2. The association of HLA alleles and MS, and the higher frequency of HLA sharing in affected sibling pairs.
3. Population groups relatively resistant to MS in high-frequency areas (Asians and Amerindians in North America, Lapps in Scandinavia, and Gypsies in Hungary).

Genetic screening has been used more recently to identify candidate markers for MS. This approach tests families with multiple cases of MS for linkage to polymorphic markers spread through the genome. There have been five published genomic screens for linkage in MS, the Lit est Coraddii et a I. (2001). Although some chromosome markers have been suggestive of linkage, there have been no major predisposing genes found.

Migration in Multiple Sclerosis

If the risk of MS is altered by a change of environments, MS must In- an acquired, i-xos^nmis, I/IH inmniemal disease or set of diseases. In a number of studies of MS in migrants, there was a tendency for immigrants to retain much of, but not all, the risk of their birthplace if they came from high- or medium-risk areas. Evidence also surfaced that migrants from low-risk areas to high-risk areas increased their risk of MS. A large case-control series among U.S. veterans clearly demonstrated a change in risk of MS by changing residence between birth and entry into military service. Those moving south decreased their risk; those moving north increased it. This series also indicated that the time when such moves are critical is well after birth but also well before clinical onset.

As part of our studies on MS in the Faroe Islands (see Epidemics of Multiple Sclerosis, later in the chapter), we identified a group of 15 patients who had been living, for at least 3 years before onset, off the islands in high-MS-risk Denmark. These long overseas residences were limited to the 10 years or so before clinical onset. All the patients stayed off the Faroes for at least 2 years between ages 11 and 43. We concluded that residence in a high-MS-risk area by a susceptible but virgin (as to MS) population for a period of 2 years from age 11 could result in clinical MS, which would begin after a further incubation period of 6 or 7 years (Kurtzke 1993).

Kurtzke and colleagues (1998) identified North African immigrants among 7500 MS patients in a nationwide survey in France in 1986. A total of 260 had immigrated from North Africa, mostly between 1960 and 1965. Two thirds were from Algeria, where virtually its entire European population had emigrated in 1962 at the end of the Algerian war for independence. The migrants were younger at prevalence day (1986) and at onset of MS than the French-born individuals with MS. The 225 with onset more than one year after migration presumably acquired their MS in France. They provided an age-adjusted (U.S. 1960) MS prevalence rate 1.5 times that for all of France. If the latter is taken at 50 per 100,000 population, their estimated adjusted rate is 77. The other 27 migrants with presumed acquisition in North Africa had an estimated adjusted prevalence of 16.6 per 100,000, the same as expected in their native land.

There are other studies of migrants from high- to iow-nsk areas that suggest a critical age for risk retention, Those migrating at age 15 or older retained the MS risk of their birthplace, but those migrating before age 15 acquired

the lower risk of their new residence. This also indicates that young children are much less susceptihle to MS, despite their then living in high-risk areas (Northern Europe).

Two reviews highlighted some of the inherent problems with migration studies (Kurtzke 1997; Martyn and Gale 1997). Defining the population at risk, choosing appropriate denominators, and ensuring complete case ascertainment are critical. Ages at migration and follow-up are also important. Updates of migration studies that reported relatively little change in risk for MS of the initial migrants showed that the risk for MS in offspring of these immigrants has increased to the levels of the population of the host country.

Epidemics of Multiple Sclerosis

The Faroe Islands are a semi-independent unit of the Kingdom of Denmark in the North Atlantic Ocean between Iceland and Norway. As of 1998, we had found 54 native resident Faroese with onset of MS in this century. There were none before 1943, but between 1943 and 1949, 17 patients had symptom onset in this populace of less than 30,000. If, as noted, Faroese migrants required two years exposure from age 11 on to acquire MS, the same should be true for the resident Faroese, two years before 1943 being 1941. We therefore divided the entire resident series of 54 according to when they had attained age 11, by 1941 or later. The 17 with onset between 1943-1949 were then joined by four more of that age, whose onset was 1950-1961. These 21 patients constituted a type 1 point source epidemic of MS. Annual incidence rates rose steeply from 0 to over 10 per 100,000 in 1945, and then fell almost as steeply with a short tail. The other 33 patients were divided by when they too reached age 11, and in this way provided three more (type 2) epidemics of 10, 10, and 13 patients each (data as of 1991 are shown in Figure 43.6) (Kurtzke and Heltberg 2001).

We concluded that the disease was introduced into the Islands by British troops who occupied the islands for 5 years, starting in April 1940. What was likely introduced was an infection that was transmitted during the war to the Faroese population at risk, of whom the epidemic I cases of clinical MS were a part. We called this infection the *primary MS affection* (PMSA), which we defined as a single, specific, widespread, systemic but unknown infectious disease (that may be totally asymptomatic). PMSA produces clinical neurological MS (CNMS) in only a small proportion of the affected population after an incubation period averaging 6 years in virgin populations and perhaps 12 years in endemic areas. Using this hypothesis, transmissibility is limited to part or all of this systemic phase, which ends by the usual age of onset of MS symptoms.

The PMSA cases from the first cohort of Faroese transmitted the disease to the next Faroese population cohort, those who reached age 1 I in the period when the first cohort was transmissible. Included in the second Faroese cohort were the epidemic 11 cases of CNMS, and this cohort similarly transmitted PMSA to the third population cohort with its own (epidemic III) cases, and from there to the fourth cohort with epidemic IV.

Two years of exposure between age 11 and 47 are therefore required to acquire PMSA in virgin but susceptible populations. Thus PMSA appears to be a specific, but unknown, age-limited infection that can be acquired only during these hormonally active years, and one that only rarely leads to clinical MS.

HUMAN IMMUNODEFICIENCY VIRUS AND NEUROLOGICAL DISEASE

Human Immunodeficiency Virus Epidemic

Human immunodeficiency virus (HIV) infection has become a global epidemic since it was first identified in 1981 as the cause of acquired immunodeficiency syndrome (AIDS). The virus is a member of the retrovirus family and selectively infects T-helper cells (T4, $CD4^+$), causing a defect in cell-mediated immunity. It is spread through blood and bodily fluids. After acute infection, most people enter an asymptomatic period of 8-10 years before the virus manifests clinically through immune dysregulation (Harrison and McArthur 1995) (see Chapter 59).

Despite recent advances in treatment and prevention, the scope of the HIV epidemic remains daunting. An estimated 36 million persons worldwide are infected with HIV; an additional 21.8 million have died (UNAIDS 2000). The vast majority of cases occur in sub-Saharan Africa where in some regions HIV prevalence exceeds 25%. More than 14,000 new HIV infections occur daily with *53* million in the year 2000 alone.

During the first 6 months of 1996, the first reported decline in AIDS mortality occurred in the United States (CDC 1997). Compared with estimates for January-June 1995 (24,900), there was a 13% drop in AIDS deaths in January-June 1996 (22,000). This decline occurred in all racial and ethnic groups and in all regions of the United States. Sclik and colleagues (2002) argue from U.S. death certificate data that the fall in AIDS deaths after 1995 was probably due to the increasing use of highly active antiretroviral therapy (HAART). They note that the proportions of deaths of individuals with HIV that were caused by other conditions increased between 1995 and 1999.

Neurological Aspects of Human Immunodeficiency Virus Infection

HIV disease can produce a variety of effects on both the central and peripheral nervous systems (Price 1996).

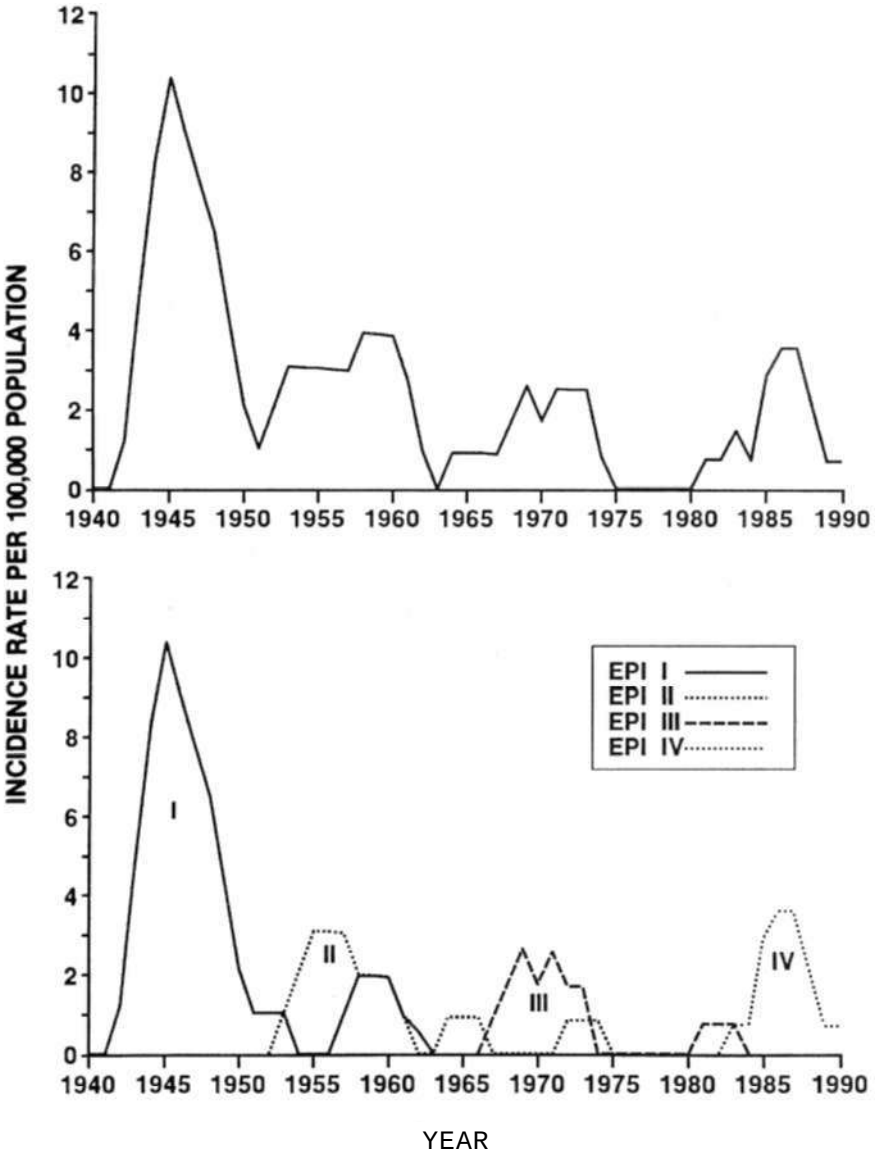

FIGURE 43.6 Multiple sclerosis in the Faroes as of 1991; annual incidence rates per 100,000 population calculated as 3-ycar centered moving averaged for four epidemics (hPI) defined by time when patients were age 11, by 1941 or later. Top: total series. Bottom: rates by epidemic. (Reprinted with permission from Kurtzke, J. F., Hyllcstcd, K., Heltberg, K., et al. 1993, "Multiple sclerosis in die Faroe Islands. 5. The occurrence of the fourth epidemic as validation of transmission," *Acta Neurol Scand*, vol. 8ii, pp. 161-173. Copyright 1993, Munksgaard International Publishers Ltd., Copenhagen, Denmark.)

A useful way of classifying these complications is to use the temporal profile of HIV infection on the immune system (Table 43.2 illustrates a simplified classification scheme). Early complications include acute aseptic meningitis, acute and chronic demyelinating polyneuropathy, and multiple mononeuropathy. These early complications are autoimmune in nature and occur at CD4 cell counts greater than 200 cells/mm . Late complications typically appear when there is a severe depression in cellular immunity with CD4 counts less than 200 cells/mm^3. Most of these disorders are opportunistic infections (cryptococcal meningitis) or a reactivation of a prior infection (toxoplasmosis and progressive multifocal lcukoenccphalopathy [PML]). HIV dementia, distal sensory polyneuropathy, and vacuolar myelopathy arc directly related to late stages of HIV infection itself. Other complications of the nervous system involve metabolic and toxic effects of treatment, including zidovudine myopathy and nucleoside neuropathy.

Tahic 43.2: Neurological complications of human immunodeficiency virus

Early complications (CD4 >200 cells/mm)*
Acute aseptic meningitis
Demyelinating polyneuropathy (acute and chronic)
Mononeuritis

Late complications ($CD4^+$<200 cells/mm^1}
Cryptococcal meningitis
Cytomegalovirus encephalitis or polyradiculopathy
Cerebral toxoplasmosis
Progressive multifocal I eu koe nee p halo pa thy
Primary central nervous system lymphoma
Human immunodeficiency virus dementia
Sensory neuropathy
Vacuolar myelopathy

Six AIDS-indicator neurological illnesses are defined by the CDC: HIV dementia, CNS cryptococcal infection, CMV infection, primary CNS lymphoma, CNS toxoplasmosis, and PML. The CDC records data on these illnesses primarily if they are the initial AIDS diagnosis. Morbidity of these illnesses in the course of HIV infection must, therefore, be studied in other populations. One such population is the Multicenter AIDS Cohort Study, which is a longitudinal study of the natural history of HIV-1 infection in homosexual and bisexual men in five U.S. cities: Baltimore, Washington, Chicago, Pittsburgh, and Los Angeles. For the years 1985-1992, there was an upward trend for all incidence rates, with the exception of HIV dementia (Bacellat ct al. 1994). After adjusting for CD4 cell counts in the cohort, however, most incidence trends remained stable. An extension of this cohort study through 1998 showed a significant decrease in incidence rates for HIV dementia, cryptococcal meningitis, and CNS lymphoma (Sacktor et al. 2001). Incidence fates dtopped most dramatically in 1996 after the introduction of HAART therapy. There was a trend for decreased incidence rates fot toxoplasmosis, and PML rates remained stable.

Brodtetal. (1997) reported on the changing incidence of AIDS-defining illnesses in the Frankfurt AIDS Cohort Study, consisting of approximately 1000 homosexual men. Major AIDS-defining illnesses decreased between 1992 and 1996 (Figure 43.7). Included in the decline were toxoplasmic encephalitis, CMV disease, PML, and AIDS encephalopathy, all of which reached incidence rates less than 5 per 100 patient-years. Treatment with combination antiretroviral therapy and with protease inhibitors increased during the study period. Undoubtedly, these new combination therapies have had a role in the declining incidence rates in this cohort.

OVERVIEW OF NEUROLOGICAL DISORDERS

What follows are the best estimates of the numerical impact of neurological diseases. The data refer primarily to whites of the Occident. For the 66 disorders listed in Tables 43.3 and 43.4, the average annual incidence rates add up to over 2500 per 100,000 population, or 2.5%. This includes eight disorders for which only one tenth of the incident cases were thought to require neurological attention: the two vertebrogenic pain syndromes, nonmigrainous headache, nonbrain head injury, alcoholism, psychosis, nonsevere mental retardation, and deafness. Total blindness numbers were taken as an estimate for the proportion of all the visually impaired patients that the neurologist should encounter. Even if all headaches, trauma, vertebrogenic pain, vision loss, deafness, and psychosis are excluded from consideration, there arc still more than 1100 new cases of neurological disease beginning each year in every 100,000 of the population, or more than one case for every 100 people.

There arc arguments, however, as to what such numbers really denote in terms of the number of neurologists required. In the United States, patient care needs alone for 240 million people were estimated to require 14,000 neurologists, according to the American Neurological Association-American Academy of Neurology Joint Commission on Neurology (Bradley 2000). Other, similar estimates were 11,200 (Graduate Medical Education National Advisory Committee [GMENAC] Delphi Panel), 6200 (GMENAC Advisory Panel), and 12,600 (Committee on National Needs for Neurologists [CN3], American Academy of Neurology), The last source estimated total needs for clinical neurologists, including faculty, at 16,500 neurologists, twice the figure of the GMENAC Advisory Panel, The primnry discrepancy for patient care needs is not so much the frequency of neurological disorders but rather the differences in proportions of patients that each group thought should be seen by neurologists. Also in question is whether attention is needed acutely or throughout the course of the illness (i.e., are neurologists to be consultants or practitioners?). Furthermore, the figure for total needs for the GMENAC Advisory Panel was based on a marked undercount of current faculty neurologists.

Predictions of the numbers of neurologists in the United States have ranged widely. Using a survey conducted by the American Academy of Neurology in 1996, Holloway and colleagues (1999) calculated the density of U.S. neurologists to be 3.4 per 100,000 population (9164 neurologists/ 265,179,411 population). A survey of all residency training

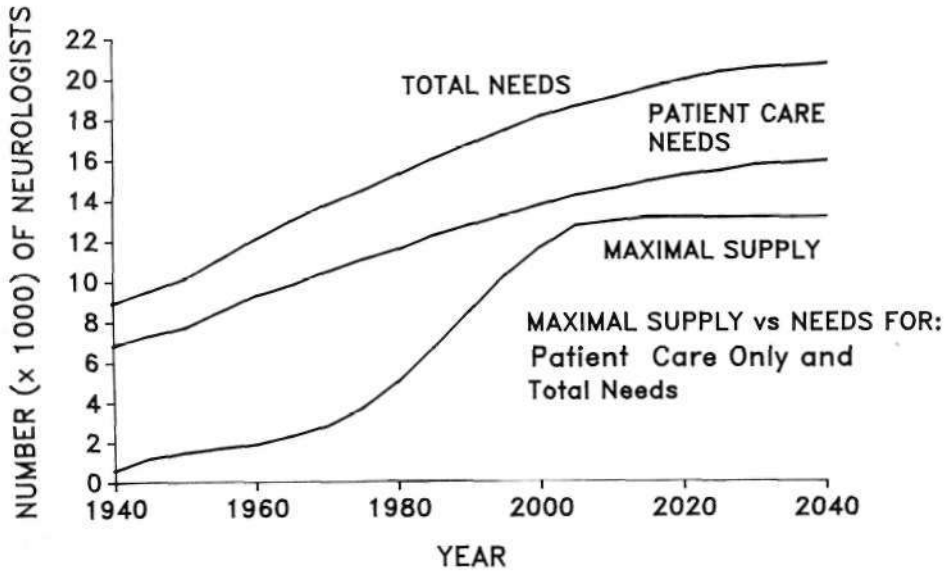

FIGURE 43.8 Neurologists in the United States, 1940-2040. Estimated maximal supply versus needs (patient care needs alone and total needs). (Reprinted with permission from Kurrzke, J. F., Murphy, F, M., & Smith, M. A. 1991, "On the production of neurologists in the United States: An update," *Neurology,* vol. 41, pp. 1-9.)

programs in 1985-1986 and recalculations by actuarial methods estimated the number of general neurologists to be 7500 for 1990, plus 1100 child neurologists, for a total of 8600. The figure for the year 2000 was 11,800 total. The number of neurologists was then predicted to plateau near the year 2020 at approximately 13,700, including 1700 child neurologists, of whom 9800 (1100 child) would be board certified. These total figures are approximately 30% (in 2010) to *35%* (in 2050) below the estimated need (Figure 43.8). Neurology is not, nor do we believe it will be, an overstocked specialty in the United States—if neurologists arc permitted to practice neurology as it has developed here.

Neurological practice, of course, varies widely among countries and even within the United States. The concept of the neurologist as a physician directly responsible for both acute and chronic care of patients with neurological diseases has only evolved over the last 25 years in the United States. But such responsibilities, as well as provisions for continuity of care, are explicit statements in the current special requirements for residency training programs in neurology and child neurology.

Regardless of the type of practice a given country deems appropriate for neurologists, the patients with neurological disease will exist. The data in Tables 43.3, 43.4, 43.5, and 43.6 therefore could well serve as a basis at least for a

Chapter 44
Clinical Neurogenetics

Thomas D. Bird and Stephen J. Tapscott

To appteciate the variety and complexity of genetic influences in neurological diseases, one must first understand the basic principles of human inheritance patterns. This chapter is an introduction to the various modes of inheritance, including single gene (Mendelian), chromosomal, multifactorial, and mitochondrial. More tecent insights regarding imprinting, anticipation, and uniparental disomy ate also briefly discussed. Furthermore, thete are likely to be many patients with a neurological disorder that is the result of a combination between a genetic predisposition and an environmentally acquired insult. All these phenomena are of clinical importance and form an introduction for a more detailed analysis of the relevant molecular biology.

MENDELIAN DISORDERS

Mendelian disorders are caused by mutations in single genes. They can be autosomal dominant, autosomal recessive, or X-linked.

Autosomal Dominant Disotdcrs

The 46 chromosomes contained in the nucleus of each human cell represent 22 pairs of autosomes, one of each pair being inherited from the mother and the other from the father (Figure 44.1). The twenty-third pair contains the sex chromosomes—the Y inherited from the father and the X from the mothet. In autosomal dominant disotdcrs, a mutation occurring in a single gene on any of the 22 autosomes can ptoduce clinical symptoms or signs. The carrier of a single mutation on one chromosome is called a *heterozygote.* Each child of an affected person has a 50% risk of inheriting the mutation and potentially developing the disease. Males and females arc affected in equal proportions; the disease appears over multiple genctations, and heterozygote mothers or fathers pass the gene on with equal risk to sons or daughters (Figure 44.2 and Table 44.1).

Examples of autosomal dominant neurological disorders include neurofibromatosis, tuberous sclerosis, Huntington's disease, several forms of hereditary ataxias and hereditary neuropathies, myotonic dystrophy, juvenile myoclonic epilepsy, benign neonatal convulsions, and some forms of familial Alzheimer's disease.

Expression of a gene refers to any clinical manifestation of the mutation. This could include a seizure, mental retardation, skin lesions, an abnormal electroencephalogram (EEC), a movement disorder, dementia, or slow nerve conduction velocities, *Phenotype* refers to the observed biochemical, physiological, or clinical manifestations in an individual. *Genotype* refers to the genetic constitution of an individual, specifically the alleles ai one chromosomal locus.

Penetrance of a gene refers to the proportion of gene carriers who show any clinical expression. For example, if out of 100 known earners of a mutation there are 80 with some clinical manifestation and 20 without, the gene is said to show 80% penetrance. Penetrance is age- and

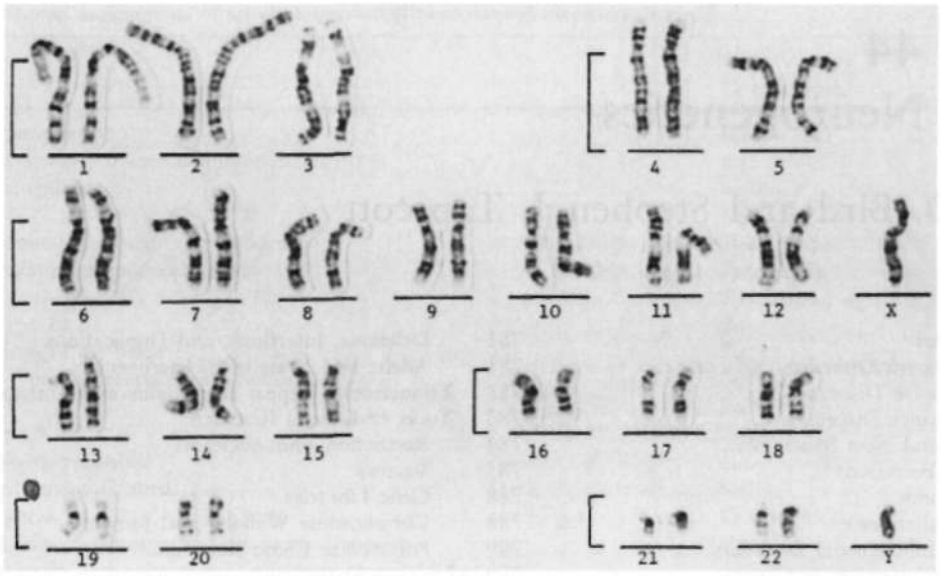

FIGURE 44.1 A normal male karyotype. The chromosomes are in the early metaphase stage of mitosis. The 22 pairs of autosomes and one pair of sex chromosomes are distinguished by their size and arm ratio and by each chromosome's unique pattern of transverse bands. The chromosomes here are stained by the Giemsa banding technique. Note that this male karyotype has one X and one Y chromosome. A normal female karyotype would have 2 Xs and no Y. (Photomicrograph courtesy I. Teshima.)

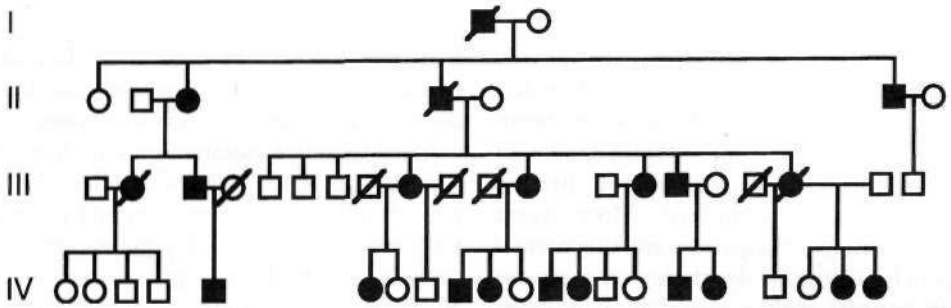

FIGURE 44.2 Pedigree demonstrating autosomal dominant inheritance in a family with Charcot-Marie-Tooth (CMT) neuropathy. Squares indicate males, and solid symbols represent persons affected with the disease. A slash through a symbol indicates a death. Note that multiple generations are involved, males and females are affected, and there is transmission from father to son (male to-male).

Table 44.1: Patterns of inheritance

Autosomal dominant	*Autosomal recessive*	*X-linked inheritance*	*Primary mitochondrial*
50% risk to each child	25% risk of homozygosity	Carrier females have: 50% risk to sons 50% risk to daughters	Transmission via females only
Males and females affected in equal proportions	Males and females affected in equal proportions	Affected males have: 0% risk to sons All daughters are carriers	All children at risk
Male-to-male transmission	Single affected generation	Males affected: Only (recessive) Worse (dominant)	Highly variable expression and severity
Multiple affected generations	Consanguinity sometimes present	Multiple affected generations	Cytoplasmic inheritance
Highly variable expression		Female transmission Affected females are mosaic	

test-dependent. That is, a gene such as Huntington's disease may show only 10% penetrance at age 20, but 90% penetrance at age 60. Also, the recorded penetrance of a gene may increase with more detailed and careful testing and examination. For example, the apparent penetrance of the tuberous sclerosis gene will increase with careful skin examination and magnetic resonance imaging (MR1) of individuals at risk. Likewise, asymptomatic carriers of a putative epilepsy gene may have only an abnormal EEG and no seizures.

Gene *carrier* was used to refer only to asymptomatic persons having a mutant allele (gene) for a recessive disorder. Nowadays, it may refer to any person having an abnormal gene, symptomatic or asymptomatic, recessive or dominant.

For some dominant mutations, the heterozygous carrier may show mild manifestations of the disease, whereas the *homozygous* carrier of a mutant gene at the same locus on a chromosome pair demonstrates much more severe clinical manifestations. An example of this is familial hypercholesterolemia, in which a heterozygous carrier may have myocardial infarction at age 48, whereas a homozygote (having inherited the mutation from each parent) may have a coronary occlusion at age 12. This phenomenon tends to blur the distinction between dominant and recessive diseases. On the other hand, for some dominant mutations such as Huntington's disease, the homozygous state is no worse than the heterozygous state. Huntington's disease therefore acts like a "true" dominant disorder.

Genetic heterogeneity refers to the phenomenon in which similar clinical phenotypes are the result of entirely different genetic mutations. For example, the Charcot-Marie-Tooth (CMT) hereditary neuropathy syndrome type 1 can be the result of different mutations in at least three different chtomosomal loci (chromosomes 1, 16, and 17) (Dejonghe et al. 1997). Likewise, there are more than 20 different dominant mutations causing hereditary ataxias. Clinical examination does not usually reveal which gene is involved.

Different forms of a gene at one locus are called *alleles.* If different mutations in the same gene each cause a clinical disorder, this is called *allelic genetic heterogeneity.* If mutations in different genes at different chromosomal loci each cause a similar disorder, it is called *nonallelic genetic heterogeneity.*

Autosomal Recessive Disorders

With autosomal recessive inheritance, the heterozygous carriers of a single mutation are usually clinically normal; rarely, they may show some clinical signs (manifesting heterozygotes). However, individuals who have inherited a mutation in the same gene from both parents (homozygotes) will show clinical manifestations of the disease. If both parents are carriers of a mutation in the same gene, then each of their children has a 25% risk for being homozygous for that gene and having the disease. Autosomal recessive disorders are usually seen in only one generation, typically among siblings (Figure 44,3; see Table 44.1), Both males and females can be affected. In small families, autosomal recessive disorders may appear as isolated or sporadic cases. Autosomal recessive disorders may sometimes appear in multiple generations of highly inbred families with consanguineous marriages. Examples of autosomal recessive neurological disorders include phenylketonuria, Tay-Sachs disease, Lafora-body myoclonic epilepsy, infantile spinal muscular atrophy, Wilson's disease, and Friedreich's ataxia.

X-Linked Inheritance Disorders

In X-linked disorders, a mutation occurs in a gene On the X chromosome. Heterozygous female carriers are usually clinically normal but occasionally have mild manifestations of the disease (manifesting carriers). In X-linked recessive

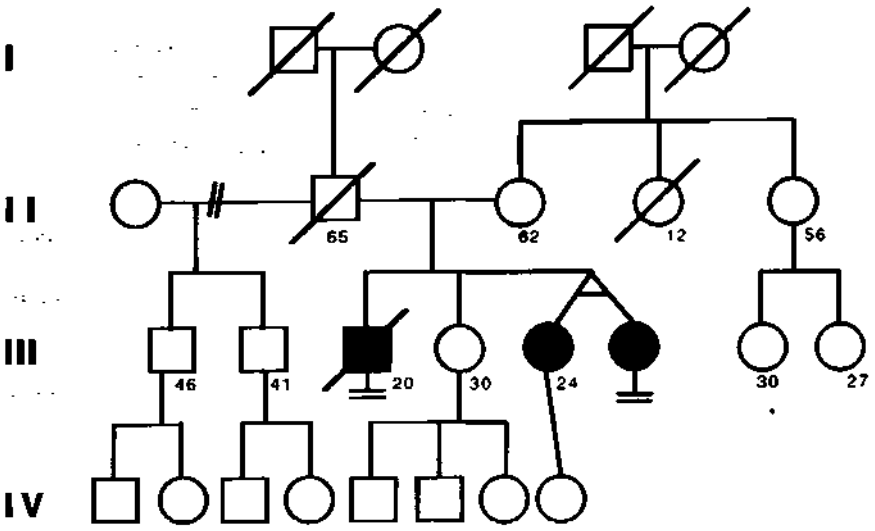

FIGURE 44.3 Pedigree demonstrating autosomal recessive inheritance in a family with Friedreich's ataxia. Three of four siblings in ^t'licnnioii *1* are aftotted (homozygous). The two affected sisters are 24-year-old identical twins. Their affected brother died at age 20. Parents are unaffected (heterozygous). Two parallel horizontal lines indicate no children.

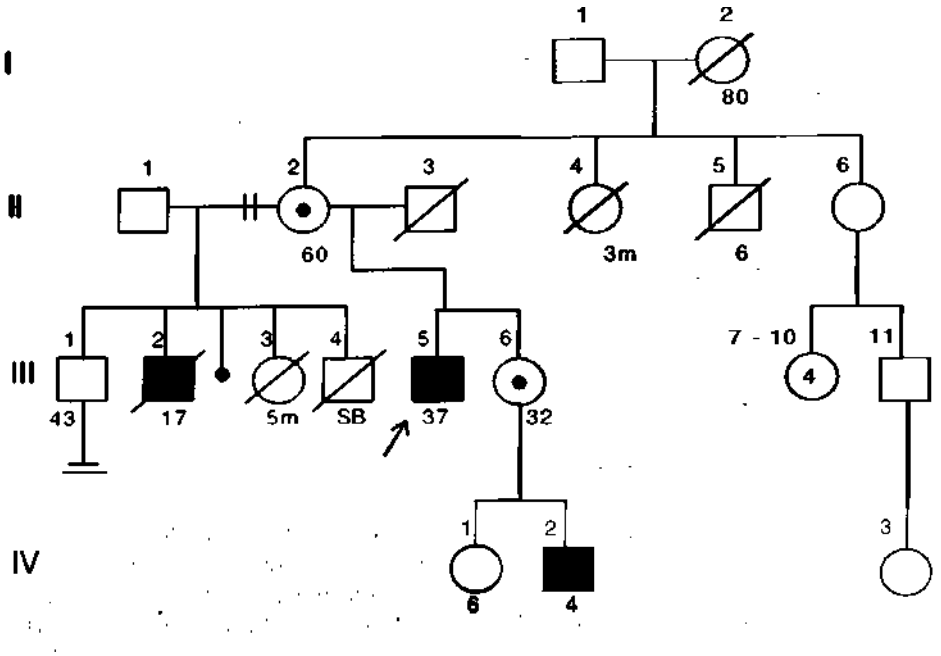

FIGURE 44.4 Pedigree with X-linked recessive inheritance in a family with Pelizaeus-Merzbacher leukodystrophy. Note that only males arc affected in two generations, and they are related by clinically normal carrier females (depicted by circle with a dot). There is no male-to-male transmission of the disease.

disorders, each son of a carrier female is at 50% risk for the disease. Each daughter of a carrier female is at 50% risk for also being a carrier. Affected males are said to be *hemizygous.* If an affected male has children, his daughters are at 100% risk for being carriers (they automatically inherit his abnormal X chromosome), and his sons do not risk inheriting the mutation (because they automatically inherit only the Y chromosome from their father). Thus X-linked recessive disease shows almost exclusively affected males in multiple generations with transmission through normal carrier females, and it never shows male-to-male transmission (Figure 44.4; see Tabic 44.1), Examples of X-linkcd recessive neurological disorders include Menkes' kinky hair syndrome, Pelizaeus-Merzbacher disease, the fragile-X mental retardation syndrome, Kennedy's spinal-bulbar muscular atrophy, Duchenne's and Becker's muscular dystrophies, and adrcnoleukodystrophy.

Heterozygous female carriers of X-linked disorders may occasionally have clinical manifestations because of the phenomenon of *random X-inactivation* (also called *lyonization).* In any given cell, only one X is active. Therefore women are *mosaic* for the X chromosome. In a few carrier females, a large proportion of their cells contain active X chromosomes bearing the mutation. Thus they may occasionally express signs of the disorder.

X-linked dominant inheritance also occasionally occurs. In this situation, heterozygous females commonly express the disease, but the condition is generally more severe in hemizygous males.

The Y chromosome contains only a few genes, such as the testis-determining factor, and no neurological disorder is related to a Y chromosome gene.

Sporadic Cases and New Mutations

A single case of an apparently genetic disease may occur in a family. Such isolated cases are often called *sporadic.* There are several different possible explanations for this phenomenon, and they may have different implications for genetic counseling. For example, the disease may not be genetic at all but actually have an environmental cause. This would represent a nongenetic *phenocopy* and, of course, would not be inherited. An example would be lead poisoning mimicking acute intermittent porphyria. Also, autosomal recessive disorders may often appear as isolated cases in small sibships, because the risks to children of carrier parents are only 25% with each pregnancy. There are recessive disorders that can look phenotypically very much like other diseases that are dominant {e.g., some hereditary neuropathies, ataxias, and movement disorders). Risks to rhe children of persons with autosomal recessive diseases are very small unless the individual happens to mate with a carrier of the same disease gene (and most such carriers are very rare in the general population).

Sporadic instances of dominant diseases may represent actual *new mutations.* The exact causes of new mutations for human diseases are generally unknown, but irradiation, toxins, and viral exposures presumably play a role. Some new mutations seem to result from the sudden expansion of unstable regions of DNA (described later). In any case, each offspring of a person with a new dominant mutation is at 50% risk for inheriting the abnormal gene, even when there are no other previously affected persons in the family.

Furthermore, a sporadic instance of a disease may represent *false paternity.* That is, the affected individual may not he aware of the fact that his or her true biological

father (and not the apparent father) carried a particular disease gene. Nevertheless, if the disorder is dominant, the children of the affected person are at 50% risk.

Finally, some carriers of dominant disease genes have only very mild clinical expression or none at all *{lack of penetrance).* Affected children of such individuals assume that neither of their parents had the disease, and the child appears to be a new isolated case. Detailed evaluation of their parents may uncover mild physical signs and explain the apparent sporadic case. Such situations are especially common with dominant disorders with highly variable expression such as CMT disease, neurofibromatosis, tuberous sclerosis, and myotonic dystrophy,

Chromosomal Aberrations

Detailed chemical banding of chromosomes has greatly improved the identification of microscopic alterations especially with prometaphase high-resolution banding (Figure 44.5). Molecular cytogenetic techniques can demonstrate DNA sequences directly on chromosome preparations so that the exact regional location of a DNA sequence on its corresponding chromosome can be determined. This is accomplished by use of biotin antibodies bound to a fluorochrome, the so-called fluorescent *in situ* hybridization (FISH) technique.

Gross aberrations of chromosomes may result in structural defects that are microscopically observable during karyotyping. Examples of such aberrations include trisomies, deletions, duplications, insertions, inversions, isochromosomes, ring chromosomes, and translocations. Because these aberrations are relatively large, they may impair many genes and result in severe clinical manifestations, such as spontaneous abortion, stillbirth, neonatal death, severe mental retardation, or multiple congenital anomalies. Neurological problems are common. Trisomy 21, or Down syndrome, is a common cause of mental retardation in which the prevalence of seizures is on the order of 5% and that is associated with Alzheimer's disease after age 40. Seizures may occur in 25-50% of patients who are trisomic for chromosomes 13, 18, or 22. A partial deletion of the short arm of chromosome 4 (Wolf-Hirschhorn syndrome, or chromosome 4p—) has a high frequency of convulsions (approximately 70%), In contrast, another short-arm deletion syndrome (cri du chat syndrome, or chromosome 5p—) is seldom associated with seizures.

Most chromosomal aberrations are sporadic and have very small recurrence risks in subsequent pregnancies (typically on the order of 1% or less). Occasionally, a chromosomal syndrome is in he rued through normal carriers of a balanced *chromosomal translocation* (e.g., Down syndrome as the result of a chromosome 14/21 Robertsonian translocation). Children of balanced-translocation carriers have a 4-15% risk of being chromosomally unbalanced and having the clinical syndrome (Figure 44.6).

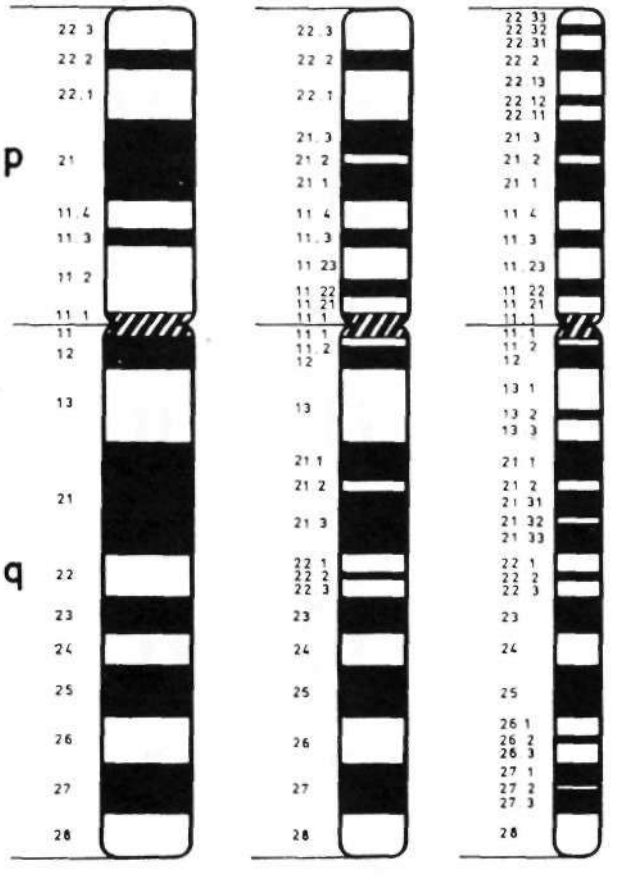

FIGURE 44.5 Schematic diagram of the X chromosome at three different stages of banding resolution showing the standard bunding partem and the system numbering chromosome hands and sub-bands. A "p" refers to the short arm and a "q" refers to the long arm of individual chromosomes. Note, for example, that band Xp21, which includes the D lichen nc/Becker muscular dystrophy gene, can be further resolved into bands Xp21.1, Xp21.2, and Xp21.3. (Reprinted with permission from Harnden, D. G. & Klinger, H. P. [eds]. 1985, *ISCN 1985: An International System for Hitman Cytogenetic Nomenclature,* Kargcr, Basel.)

Aberrations of the sex chromosomes include the following: Turner's syndrome (XO) in females associated with short stature, infertility, and visuospatial problems but not mental retardation; Klinefelter's syndrome (XXY) in males associated with infertility, hypogonadism, tall stature, and psychosocial adjustment problems; XYY syndrome in males associated with tall stature and behavioral problems; and XXX syndrome in females with mental retardation.

Some patients with very mild manifestations of a chromosomal disorder may be the result of *somatic mosaicism.* In such individuals, the chromosomal defect occurs postfertilization in the early stages of embryo development. In the full-grown individual, only a **small** proportion of cells carries the chromosomal defect. For example, a few individuals have rhe facial manifestations of Down syndrome but have normal intelligence. Careful karyotyping may show normal results in most cells,

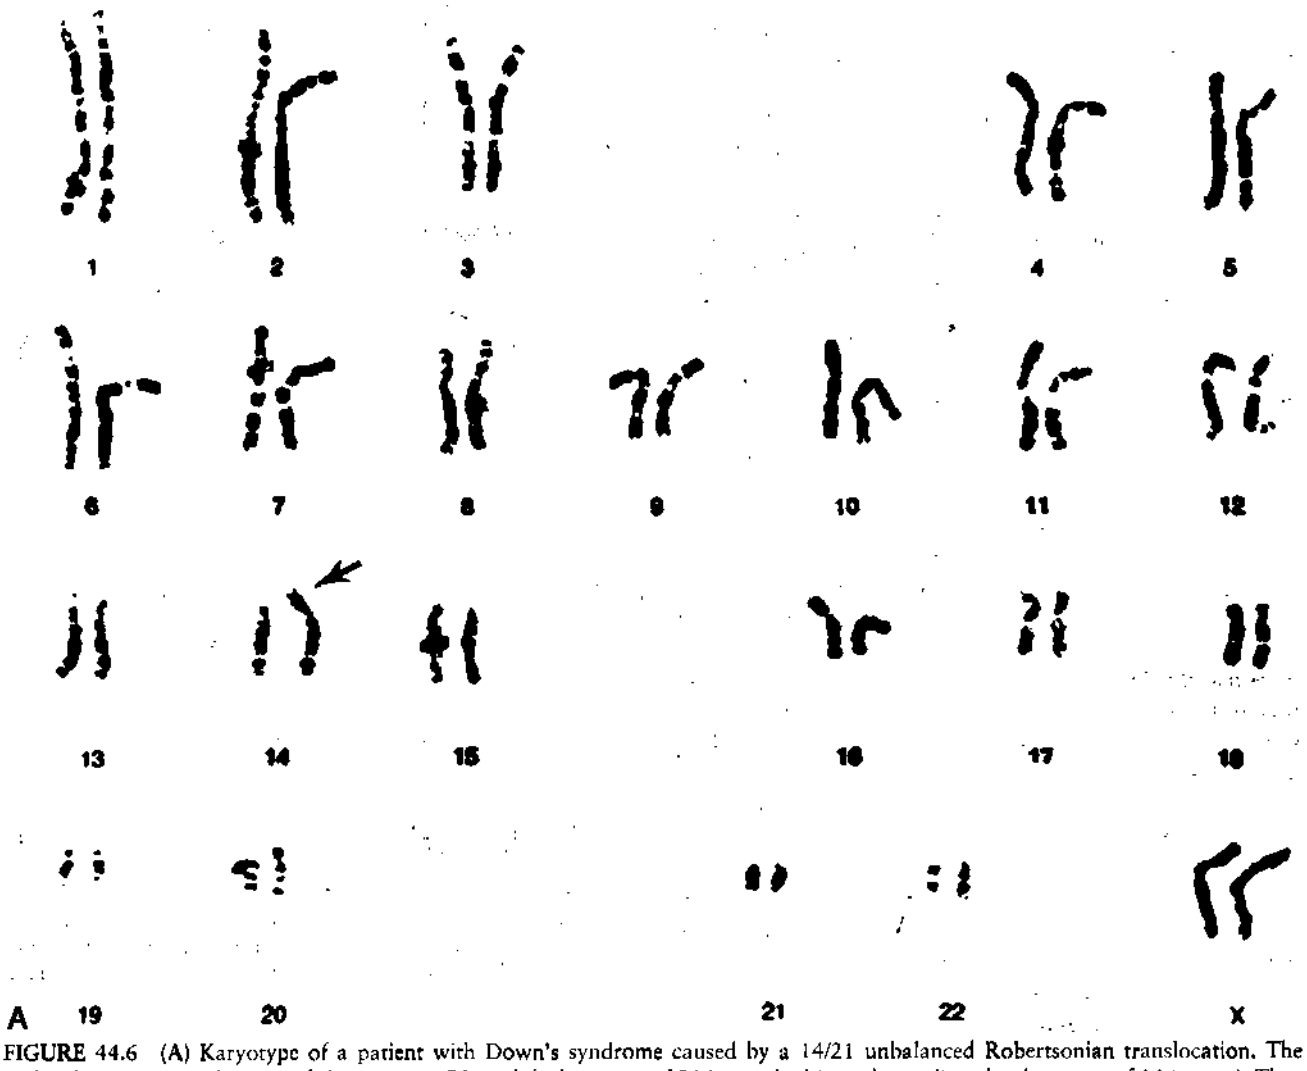

FIGURE 44.6 (A) Karyotype of a patient with Down's syndrome caused by a 14/21 unbalanced Robertsonian translocation. The patient has two normal copies of chromosome 21, and the long arm of 21 is attached (translocated) to the short arm of 14 (*arrow*). Thus there are three copies (trisomy) of 21, although the total number of chromosomes appears to be normal (46). *Continued*

although a small proportion has trisomy 21. These individuals have mosaic Down syndrome.

Some small chromosomal deletions may be submicroscopic (not visible on the usual karyotype) but produce defects in several adjacent genes. This may result in a so-called *contiguous gene deletion syndrome.* One well-documented example is a boy who had Duchennc's muscular dystrophy, retinitis pigmentosa, chronic granulomatous disease, and McLeod's syndrome. This was the result of a deletion affecting four adjacent genes on the X chromosome; the boy's X-chromosomal DNA played a major role in the discovery of the gene for Duchenne's muscular dystrophy.

Individuals with an inherited mutation at a single locus on one chromosome may acquire an additional somatic mutation at the same locus on the other chromosome of that pair, resulting in the *two-htt phenomenon.* For example, an individual who has inherited a mutation in the retinoblastoma gene on chromosome 13 may develop multiple eye tumors, because an additional acquired somatic mutation occurs at the same locus in the other member of the chromosome 13 pair in a retinal cell. This results in homozygosity for the mutation and the subsequent growth of the tumor, because the normal gene suppresses tumor growth. A similar phenomenon occurs in many astrocytomas involving the tumor suppressor gene *(pS3)* on chromosome 17p.

imprinting refers to germ line-specific modification of chromosomes and their genetic material. This results in differential expression of genetic information when inherited from the mother, as compared with inheritance from the father. The phenomenon is probably at least partially

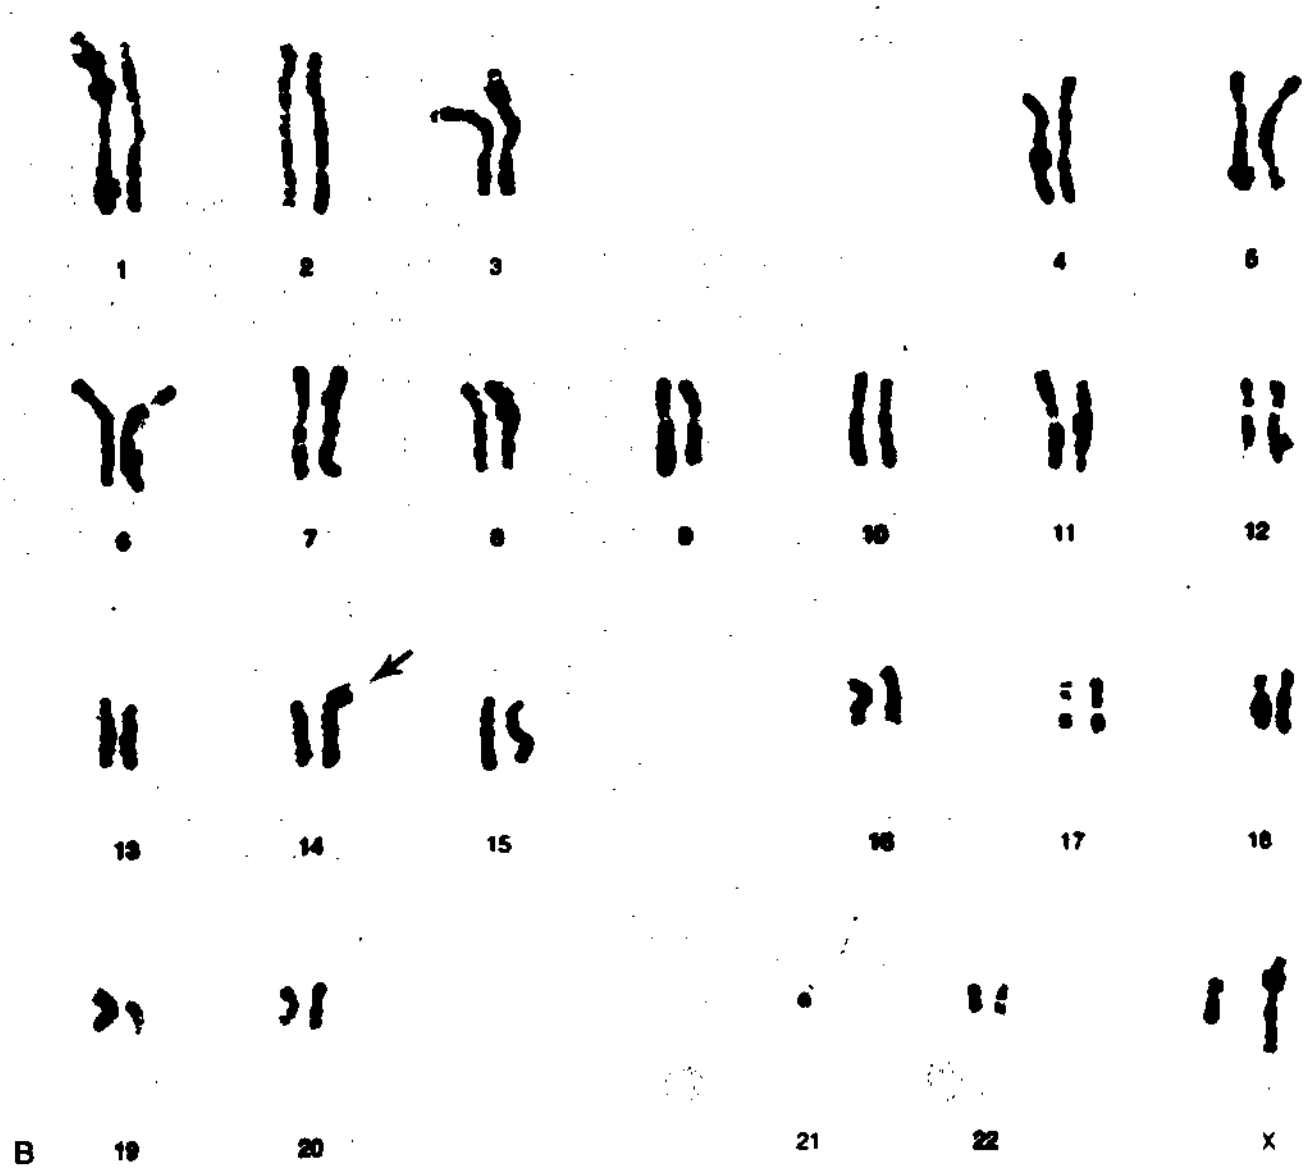

FIGURE 44.6, cont'd (B) A carrier of 14/21 translocation has the chromosome 14 with the attached 21 (*arrow*) but only one other copy of chromosome 21. Thus there is the normal total number (2) of chromosome 21, although the person appears to have only 45 chromosomes. (Courtesy K. Leppig.)

reined m differential metfiylation of DNA, which is known to inactivate some genes. An example of imprinting occuts in the unusual inheritance pattern yf the fragile-X mental retardation syndrome. In this disorder, some males with normal intelligence transmit the gene to their daughters, who may also be mentally normal but who subsequently have mentally retarded sons. The involved region of the X chromosome is altered as it passes through oogenesis in the mother. It has also been speculated that imprinting may play a role in juvenile Huntington's disease, which occurs almost exclusively in the offspring of affected fathers, and in neonatal myotonic dystrophy, which occurs almost exclusively in the offspring of affected mothers.

Angelman's syndrome and the Prader-Willi syndrome both result from a small deletion in the same site ot chromosome 15. However, it an individual inherits the deletion from a maternal chromosome 15, the result is Angelman's syndrome, whereas if the mutation is on a paternal chromosome 15, the result is Prader-Willi syndrome. This appears to be another example of imprinting. Of further interest here is that although mental retardation is common to both disorders, seizures are much more common in Angelman's syndrome, and a

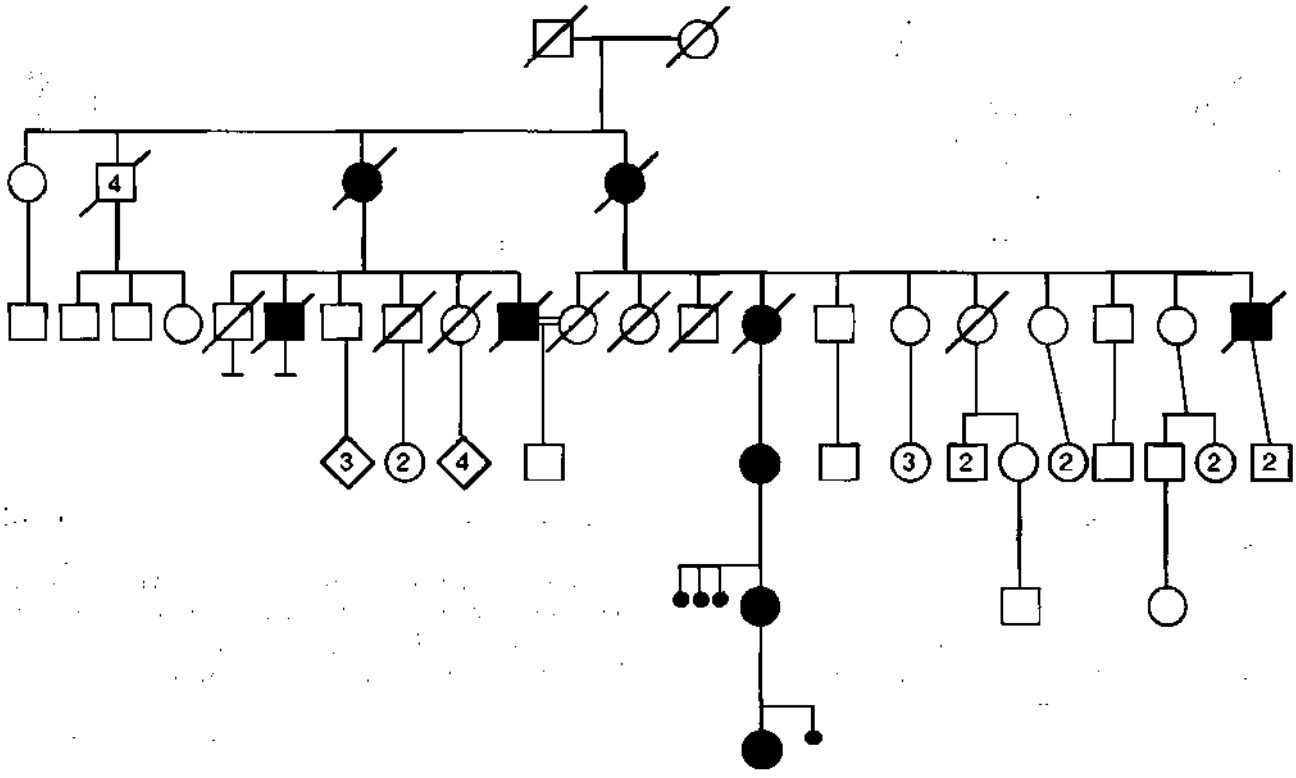
y-aminobutyric acid receptor gene maps to rhe involved region of chromosome 15.

Uniparental Disomy

As noted previously, normally within each pair of chromosomes one is inherited from the mother and the other from the father. Occasionally, however, an individual may inherit both members of a chromosomal pair from a single parent. This is called *uniparental disomy.* This occurrence has resulted in some interesting genetic phenomena. An individual who was homozygous for the autosomal recessive cystic fibrosis (CF) gene was found to have only a carrier mother (the father was demonstrated not to be a carrier of rhe CF mutation), It was further determined that the affected child had inherited both chromosome 7s (the site of the CF gene) from the heterozygous mother. This same phenomenon has also occurred in a child with autosomal recessive spinal muscular atrophy.

Mitochondrial Inheritance

In the past few years, it has become apparent that several interesting disorders are the result of mutations in mitochondrial DNA (DiMauro 1993). Mitochondrial DNA codes for 13 proteins that are involved in oxidative phosphorylation and for ribosomal and transfer RNAs. Mitochondrial DNA is inherited in the cytoplasm of a mother's egg but is not inherited from the sperm of the father. Therefore primary mitochondrial disorders are transmitted only by mothers and never by fathers *(cytoplasmic inheritance)* (Figure 44,7), Male and female children can both be affected, and the disease may appear in all children of an affected mother. The ovum contains many mitochondria, only some of which have the mutation in the mitochondrial DNA in such a primary mitoehondriopathy. Each child of an affected mother may vary in the number of mitochondria that he or she has inherited that contain the DNA mutation. Furthermore, the proportion of mutant mitochondria may vary considerably from cell to cell in any given affected individual *(heteroplasmy).* Therefore mitochondrial disorders often show extreme variability in clinical expression both within and between families. Point mutations in mitochondrial DNA tend to be inherited through females, whereas deletions of mitochondrial DNA rend ro be noninherited, sporadic events in isolated individuals. Primary mitochondrial disorders include the myoclonus epilepsy with ragged-red fibers (MFRRF) syndrome; the mitochondrial encephalomyopathy, lactic acidosis, and stroke (MELAS) syndrome; Leber's hereditary optic neuropathy (LHON); and the



EIGURE 44.7 Pedigree demonstrating mitochondrial inheritance in a family with a variant of myoclonus epilepsy with ragged-red fibers (MERRF). Note that multiple generations are involved, male and females arc both affected, but the disease is only transmitted by females. The small dots attached by vertical lines represent spontaneous abortions.

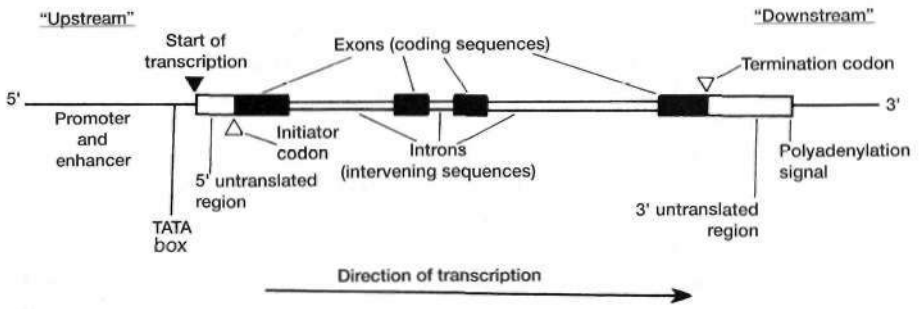


FIGURE 44.8 Hypothetical structure of a typical gene. The exons contain the three base-pair codons that are eventually translated into the amino acids of a polypeptide. The intervening sequences of introns are spliced out of the genetic code during transcription. A gene may have one or many exons. A gene may range in size from a few thousand base pairs to several million base pairs,

Kearns-Sayre syndrome (myopathy, retinopathy, cardiomyopathy).

Most of the macromolectiles of mitochondria are encoded by nuclear genes, mutations of which are inherited in a typical mendelian fashion. Mutations of the nuclear mitochondrial genes are responsible for the secondary mitochondriopathies. These disorders are actively being elucidated.

Polygenic and Multifactorial Disorders

Some syndromes are presumed to be the result of the additive effect of a small number of multiple genes. Such polygenic conditions are mostly speculative but could include some forms of mental retardation, hypertension, epilepsy, dementia, or diabetes mellitus.

Multifactorial inheritance refers to disorders that result from the combination of an inherited predisposition acting in concert with an acquired environmental insult. Some latent carriers of a single gene mutation may be unmasked by exposure to an environmental agent. Symptomatic acute intermittent porphyria following phenobarbital administration is an example. The area of pharmacogenetics will be of great importance to neurology as the genetic control of anticonvulsant and other drug metabolism becomes fully delineated. Genetically programmed rapid or slow metabolizers of anticonvulsants present major challenges to the clinical management of seizure disorders. Multiple sclerosis is suspected to be another model of multifactorial inheritance in which there is a presumed genetic immunological predisposition to some unknown environmental trigger.

Table 44.2: The human genome

3 billion base pairs (bp)
30,000–40,000 functional genes
3000–5000 known genetic disorders
1000 bp = 1 kilobase (kb)
1 million bp = 1 megabase (Mb)
1% recombination = 1 cM (centimorgan)
1 cM = 1 Mb

ORGANIZATION AND EXPRESSION OF GENES

Most genetic information inherited by each individual is coded in the nuclear chromosomal DNA, although mitochondrial DNA and maternally transmitted RNA molecules can contribute important inherited information. DNA is composed of the four bases—adenine, guanine, cytosine, and thymine—as deoxyribonucleotides. Human chromosomes contain a total of approximately 3 billion base pairs (bp) (Table 44.2). It has been estimated that the human genome codes for approximately 35,000 different genes. A gene is a region of the DNA that contains the information necessary for the appropriate expression of a specific RNA species (Figure 44,8). Regions of DNA are converted to RNA by a process called transcription. Specialized regions of the DNA, termed enhancers and promoters, regulate the initiation of RNA transcription, A complex set of proteins that composes the RNA polymerase holoenzyme is recruited to the promoter and proceeds along the DNA in a *5′* to 3' direction, producing a copy of the DNA sequence in ribonucleotides composed ol the same bases as DNA except that uracil substitutes for thymine (Figure 44.9). Most RNA is processed in the nucleus: it receives a cap on the *5′* end and a polyadenylation tail gets spliced to the 3' end. In addition, most genes have introns, regions of the RNA that arc removed in the nucleus, splicing together the regions present in the mature RNA, the exons, that get exported to the cytoplasm. Each gene can have multiple exons, and several different RNA species can be generated from a single gene by alternative exon usage or splicing, a process that is regulated both by the sequence of the RNA and by factors that interact with the RNA ui a tissue-specific manner.

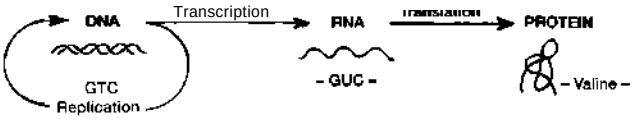

FIGURE 44.9 Schematic diagram demonstrating transcription of DNA into RNA followed by translation of the RNA to a polypeptide protein. The GTC codon in DNA is transcribed to GUC in RNA, then translated to valine in the protein. Transcription occurs in the nucleus and translation occurs in the cytoplasmic ribosomes.

The mature RNA is transported out of the nucleus to the cytoplasm as messenger RNA (mRNA). In the cytoplasm the nbosome attaches to the capped 5' end of the mRNA and translates the mRNA into a protein using a three base-pair code, the genetic code. Each three bases represents a unit of information termed a codon, either specifying an amino acid or a signal for the ribosome to terminate translation. Because there are 64 possible combinations of four bases taken three at a time and only 20 amino acids used for protein synthesis, each amino acid is represented by more than one codon. Most of the degeneracy in the codons occurs in the position of the third base. For example, valine is specified by GUN, where N represents any of the four bases; alanine is specified by GCN and glycine by GAN. As discussed later, base changes in the DNA that occur in the third position of these codons will not change the amino acid specified and will be silent mutations.

How does the ribosome know which of the three possible reading frames to translate into a protein? There are some rules that increase the probability that the ribosome will initiate transcription in a particular reading frame. First, the ribosome scans along the RNA but does not initiate protein translation until it reaches the codon for methionine, the codon ATG. RNA sequences surrounding the ATG determine the probability that protein translation will be initiated and sometimes the ribosome will pass several potential initiation codons until it reaches an ATG in the context of a favorable surrounding sequence, the Kozak consensus sequence. Once translation is initiated, sequential codons are used to determine the protein sequence until the ribosome encounters a stop codon that causes it to cease translation and dissociate from the mRNA. The codons between a methionine and a stop codon are referred to as an open reading frame **(ORE),** because it has the potential to be translated into a protein by a ribosome.

The amino acids are brought to the codon by a small, specialized RNA molecule, the transfer RNA (tRNA). Each tRNA has a region that is the complementary triplet sequence to the codon, called the anticodon. The 3' end of the tRNA is covalently linked to a specific amino acid. Therefore when the tRNA anticodon pairs with the mRNA codon, ii brings the spccilicd ammo acid into position to In- added to the nascent polypeptide chain. (For a more detailed discussion of the molecular biology of gene expression see Alberts et al. 2002.)

The estimated 30,000 to 40,000 human genes actually are responsible for a much larger number of final protein products (probably four to five times more). This multiplication effect is accomplished in several different ways. One is the variable splicing of genes described previously. A single gene may result in several different types of RNA depending on the addition or subtraction of various exons. Another mechanism is the posr-rranslarional modification of proteins, including glycosylation and/or phosphorylation, that produces a huge variety of protein variation. Proteomics, the study of this protein variability and its role in normal biology and mechanisms of disease, is a burgeoning new field of molecular research.

POLYMORPHISMS, MUTATIONS, AND EVOLUTION

During the replication of any cell, the DNA has to be faithfully copied. A complex set of proteins copies the DNA, proofreads, and corrects the copied product. The average mutation rate, the rate of incorporating the wrong nucleotide in the final DNA product, is approximately one per one billion replicated bases. Given the size of the human genome, mutations are an anticipated event with nearly all replication cycles. The population diversity generated by these low mutation rates is thought to be critical for evolution and species adaptation. Therefore the imperfection of DNA replication that sometimes gives rise to disease also supports the survival of the species.

The accumulated mutations that have occurred since the common ancestor of *Homo sapiens* are reflected as sequence differences between individuals. On average, DNA from two unrelated individuals will have one difference every 500 hundred bp, for an average total of 6,000,000 differences per genome. These single base-pair differences are called single nucleotide polymorphisms (SNPs). Although most SNPs represent silent mutations, some have profound consequences on human characteristics, such as the polymorphism in codon six of the beta-chain of hemoglobin that substitutes valine for glutamate and causes sickle cell anemia when present as a homozygous polymorphism.

The SNPs can be used as markers of a chromosomal region. Because each of a parent's paired chromosomes will have different SNPs, the SNPs donated to each child can be identified, and cross-over events can be used to map the location of a gene for a particular trait. Identifying the SNPs that segregate with a trait will identify the region of the chromosome that contains the gene conferring the trait. Historically, restriction endonucleases were used to identify a subset of SNPs. Restriction endonucleases recognize and cut DNA at small palindromic sequences, cleaving the DNA **into** smaller fragments. If an SNP occurs at an cndonuclease restriction site, then the size of the fragment will be changed. These restriction fragment length polymorphisms (RFLPs) can be used as genomic markers to **follow the** segregation of chromosomal regions within families (see discussion of linkage analysis later).

Because only SNPs that changed the sequence of a known restriction site could be used for **RFLP** analysis, only a small portion of all SNPs were informative. Recent advances in hybridization techniques, such as DNA microchip arrays, can screen for nearly any identified SNP. High-density SNP maps of the human genome are being constructed that have the promise of rapidly mapping

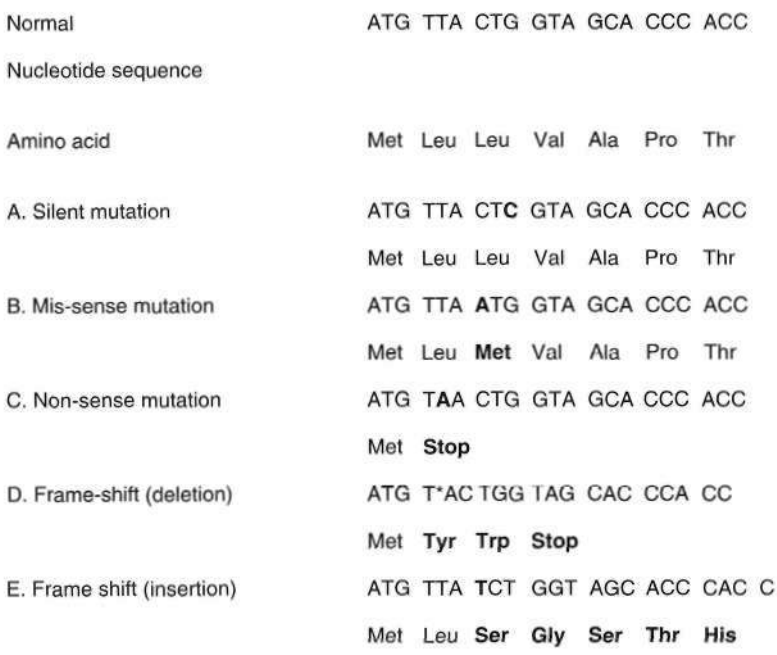

FIGURE 44.10 Types of mutations. Single base-pair changes in a coding region can cause different types of mutations. (A) Conversion of a guanine to a cytosine in the third codon is *a* silent mutation because it does not change the amino acid in the protein. (B) Conversion of the cytosine to an adenosine in the third codon is a mis-sense mutation because it results in the substitution of a methionine for a leucine in the protein. (C) Conversion of the thymine to an adenosine in the second codon is a non-sense mutation because it creates a stop codon and terminates translation of the protein. (D) and (F.) Single or double base-pair insertions or deletions are frame-shift mutations, because they change the reading frame of the mRNA, resulting in multiple mis-sense or non-sense codon changes. In (D) the second T has been deleted from the second codon leading to *a* premature stop codon. In (E) a T has been inserted at the beginning of the third codon leading to a new amino acid sequence. (Bold type face indicates a change from the reference sequence.)

an individual human genome at high resolution. The possibility of high-density genetic mapping in a large population may allow the association of particular sets of SNPs with phenotypic characteristics in the absence of generating family pedigrees.

In addition to SNPs, repeat polymorphisms have been used to map genetic traits. The genome is interspersed with simple dinucleotide, trinucleotide, and tetranucleotide repeats. During DNA replication these repetitive elements can gain or lose repeat units. The high rare of repeat instability makes these elements highly polymorphic in the population. Although most of the repeat instability is thought to be without phenotypic consequence and is mainly used to establish linkage with a disease, the expansion of some trinucleotide repeats can cause diseases, as discussed later.

Strains of mice and other laboratory animals have been inbred to minimize the number of genetic differences between individuals, whereas the human population is outbred and maintains a high degree of genetic diversity. This diversity represents the imperfect system of DNA replication and repair that regularly introduces imitations into the population. The mutations, or polymorphisms, that have accumulated during the evolution of the human species contributes to the rich diversity of the human phenotype but also to the prevalence of genetic diseases.

GENETIC MECHANISMS OF HUMAN DISEASE

Single Base-Pair Mutations

Mutations that alter a single base pair can be completely silent mutations or cause profound disease. If the mutation is in the coding region of a gene there are four possible outcomes. A silent mutation changes the base pair but does not change the amino acid specified by the codon (Figure 44.10A). In a mis-sense mutation, the codon is changed to specify a different amino acid {Figure 44.10B), possibly affecting the function of the protein. A non-sense mutation converts an amino acid codon into a stop codon, causing a premature termination of the protein polypeptide (Figure 44.1 OC). This type of mutation sometimes occurs in neurofibromatosis *(NF1)* {Figure 44.11) Finally, a frame-shift mutation either introduces or deletes base pairs, resulting in a shift in the reading frame of the ribosome (Figure 44.10D and E) and is one of the common mutations in Tay-Sachs disease (Figure 44.12).

Mutations that occur in noncoding regions are often silent but have the potential to occur in the regulatory regions of promotors or enhancers or in regions critical for appropriate RNA splicing. Mutations that occur in the genes coding for tRNA can have broad effects on protein synthesis. Neurological diseases sometimes caused by mutations in introns that result in abnormal splicing include ataxia telangiectasia, neurofibromatosis 1, and frontotemporal dementia *(FTD P-17).*

FIGURE 44.11 The substitution of a T for a C in the neurofibromatosis gene (*NF1*) results in a non-sense mutation in the coding sequence, which causes a premature termination of translation (stop codon).

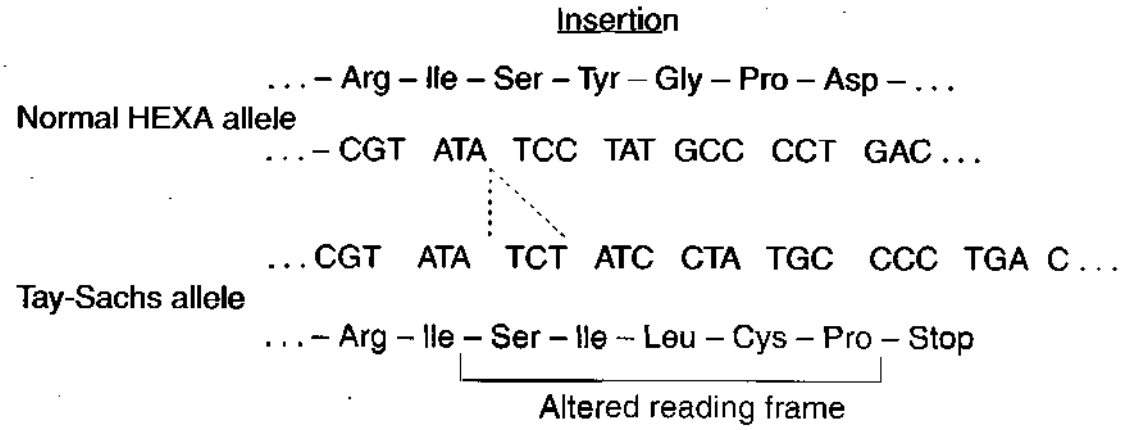

FIGURE 44.12 A four base-pair insertion in the hexosaminidase-A gene leads to a frame-shift mutation. This is the major cause of Tay-Sachs disease in Ashkenazi Jews.

Deletions, Insertions, and Duplications

Deletions and insertions of DNA can either disrupt the coding sequence of a gene or remove the gene entirely. Deletions in the dystrophin gene can cause the severe Duchcnnc's muscular dystrophy or the more mild Becker's muscular dystrophy. The dystrophin gene spans more than 2 million bp and has more than 40 exons, making it one of the largest known genes (Figure 44.13), Deletions of the gene that disrupt the reading frame result in a truncated protein that is not stable and cause the Duchenne phenotype. Internal deletions of the gene that maintain the reading frame, removing internal sections of the protein but leaving the aminotcrminal and carboxytcrminal regions intact, are often associated with the more mild Becker phenotype.

Insertions of small regions of DNA can either add new codons to a gene or change the reading frame of the portion of the gene that follows the insertion. A four base-pair insertion in the hexosaminidase-A gene causes a reading frame shift that inactivates the protein (see Figure 44,12), Carriers of a single allele are asymptomatic and homozygous individuals have Tay-Sachs disease.

Deletions and duplications of very large regions of the genome are associated with specific syndromes. In some cases it is thought that the disease is caused by the loss or addition of a copy of a specific gene. For example, a point mutation in the peripheral myelin protein-22 *(PMP-22)* gene causes a demyelinating peripheral neuropathy (CMT-lA/hereditory motor-sensory neuropathy |HMSN]-I). The most common cause of CMT-1A, however, is a duplication of a 1,5 megabasc (1.5 million bp) region of chromosome 17p that encompasses the *PMP-22* gene, Because a balanced translocation that results in a trisomy of chromosome 17p has a similar neuropathy, it is likely that the presence of an additional copy of the *PMP-22* gene causes the demyelinating neuropathy. The possibility that some aspects of myelination might be sensitive to gene dosage of *PMP-22* is supported by the observation that the deletion of the 1.5 megabase region encompassing the *PMP-22* gene results in hereditary neuropathy with liability to pressure palsies (HNPP).

Allelic and Nonallelic Heterogeneity

Figure 44.14 illustrates that several different mutations can all result in similar disease phcnotypes, in this case inherited demyelinating neuropathies. As noted previously, a duplication of 1.5 million bp of chromosome 17p that includes the *PMP-22* gene results in an autosomal dominant demyelinating neuropathy (CMT-1A). One point mutation in *PMP-22* causes a phenotypically similar dominant neuropathy, whereas a different point mutation in *PMP-22* gives rise to a recessively inherited demyelinating neuropathy. Deletion of the entire 1.5 million bp region containing the *PMP-22* gene causes the phenotypically distinct demyelinating disease HNPP. Inherited demyelinating syndromes of the CMT type are also caused by mutations of other genes. A point mutation in the P-zero (P0) myelin protein gene on chromosome 1 causes demyelinating peripheral neuropathy (CMT-1B). Finally, a mutation in ;i gap junction protein connexin32 gene on the X chromosome results in an X-linked inherited demyelinating neuropathy (CMT-X). The mutations involving *PMP-22* are examples of the allelic genetic heterogeneity of CMT-1A, whereas the group of mutations of chromosomes 1, 17, and X that cause clinically similar demyelinating inherited peripheral neuropathies are examples of the nonallelic genetic heterogeneity of the CMT syndrome.

TRINUCLEOTIDE REPEAT EXPANSIONS AND ANTICIPATION

The phenomenon of generic anticipation has been debated for many decades. The term was primarily used to describe

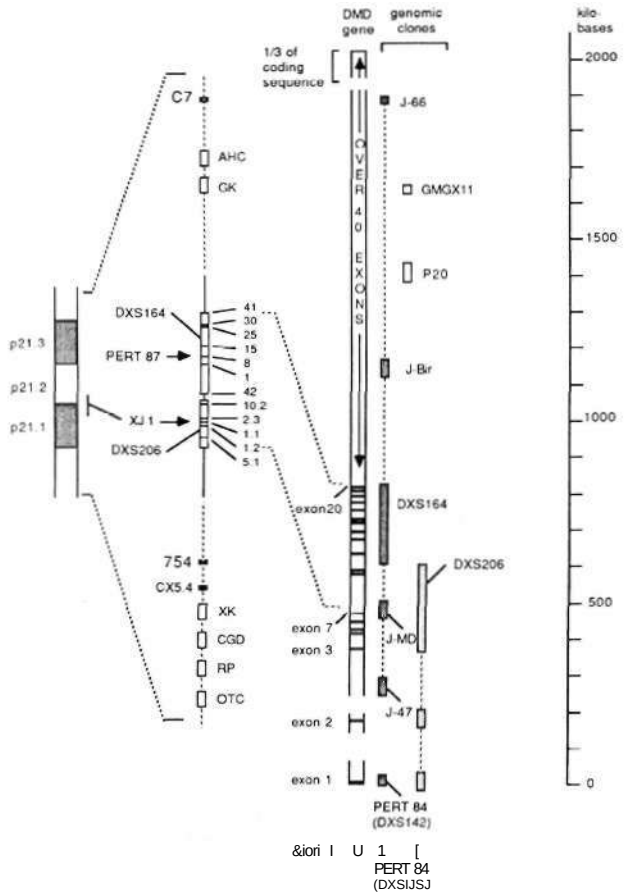

FIGURE 44.13 Schematic of the Duchenne's muscular dystrophy gene. On the left is the tegion of the X chromosome that contains the gene, showing the relation of the chromosomal region to the DXS164 and DXS206 regions, detected by the pERT and XJ1 probes, respectively. The genes for congenital adrenal hypoplasia *[AHCj*, glycerol kinase *(CK)*, the McLeod phenotype *(XK)*, chronic granulomatous disease (CGD), retinitis pigmentosa (RP), and ornithine transcarhamylase *{OTC)* are shown in their relative positions. C7 and 754 are anonymous flanking probes often used in restriction fragment length polymorphism (RFLP) analysis. On the tight is the genomic map showing the relation between the DXS164 and DXS206 regions and exons of the gene. At the time this figure was produced, exons 1 and 2 were not yet linked to one another or to DXS206 and are shown connected to DXS206 by a dashed line. Several "jump" clones *{}-&(>*, J-Bir, J-MD, J-47) found by isolation of deletion junctions with pERT K7 probes arc shown connected to the DXS164 locus. Probe pERT84 and the untelated probes GMGX11 and P20 are shown in their approximate positions. The size of the gene is about 2 Mb.

the observed increasing clinical severity of the autosomal dominant myotonic dystrophy gene over subsequent generations (Harper 2001). Typically, a father might have early-onset cataracts, his daughter mild muscle weakness and myotonia, and the daughter's child severe weakness and myotonia associated with mental retardation. This repeatedly observed clinical observation of increasing disease severity across generations has now been given a biologic foundation. Myotonic dystrophy is caused by the expansion of a trinucleotide repeat in the dystrophia myotonia protein kinase *{DMPK)* gene on chromosome 19. The general population has between 5 and 44 repeats of the CTG trinucleotide. Expansions of more than 100 repeats cause myotonic dystrophy, and very large expansions of thousands of repeats are associated with more severe forms of the disease. The size of the expansion can change from parent to offspring, and increases across generations account for the clinical phenomenon of anticipation (Figure 44.15). Recent studies have shown that the direction of the DNA replication fork may be a critical factor in repeat instability.

Several neurogenetic diseases have now been shown to be caused by unstable triplet repeats, including Kennedy's X-linked spinal-bulbar muscular atrophy, the fragilc-X mental retardation syndrome, Huntington's disease, several forms of hereditary ataxia (SCA-1, -2, -3, -6, -7, -8, -12, and Friedreich's ataxia), and a rare form of dentatorubral-pallidoluysian atrophy (DRPLA) (Zoghbi and Orr 2000). As seen in Figure 44.16, many of these diseases arc caused by the expansion of a CAG repeat in the coding region of the gene. In each case the reading frame of the CAG repeat codes for a stretch of glutamines, producing a longer polyglutamine tract in the protein product. For some of these diseases it has been shown that this polyglutamine tract results in abnormal nuclear inclusions that might contribute to the cause of the disease.

Three of these repeat diseases, however, are caused by repeat expansions in noncoding regions of the gene. In fragile-X syndrome, there is an expanded CGG repeat in the 5' untranslated region of the *FRX-1* gene. Methylation of this sequence is associated with suppressed expression of the *FRX-1* gene. Because *FRX-1* is on the X-chromosome, males have only one copy of the gene and inactivation results in the fragile-X syndrome of mental retardation. In Friedreich's ataxia, an expanded repeat is present in an intron of the frataxin gene and is thought to decrease gene expression, Friedreich's ataxia is a recessive disease and both alleles have an expansion or mutation in affected individuals. In the most common form of myotonic dystrophy the repeat expansion occurs in the 3' untranslated region of the *DMPK* gene on chromosome 19. Therefore the repeat is present in the mRNA after the stop codon and does not alter the ORF for the protein. It has been demonstrated that the repeat can decrease *DMPK* expression by interfering with RNA processing and nuclear transport. The expanded CUG repeat in the RNA appears to cause the disease. Indeed, a similar myotonic dystrophy (DM2) is caused by the expansion of a CCTG repeat in the intron of the *ZNF9* gene on chromosome 3, resulting in a CCUG repeat in the RNA.

Trinucleotide repeat expansions have formed the basis of rapid diagnostic tests for their associated diseases. Polymerase chain reaction (PCR) (see later) and Southern hybridization to genomic DNA obtained from blood samples can be used to determine the repeat size in individuals. The presence of an expansion indicates that the individual inherited the mutation that can cause the disease.

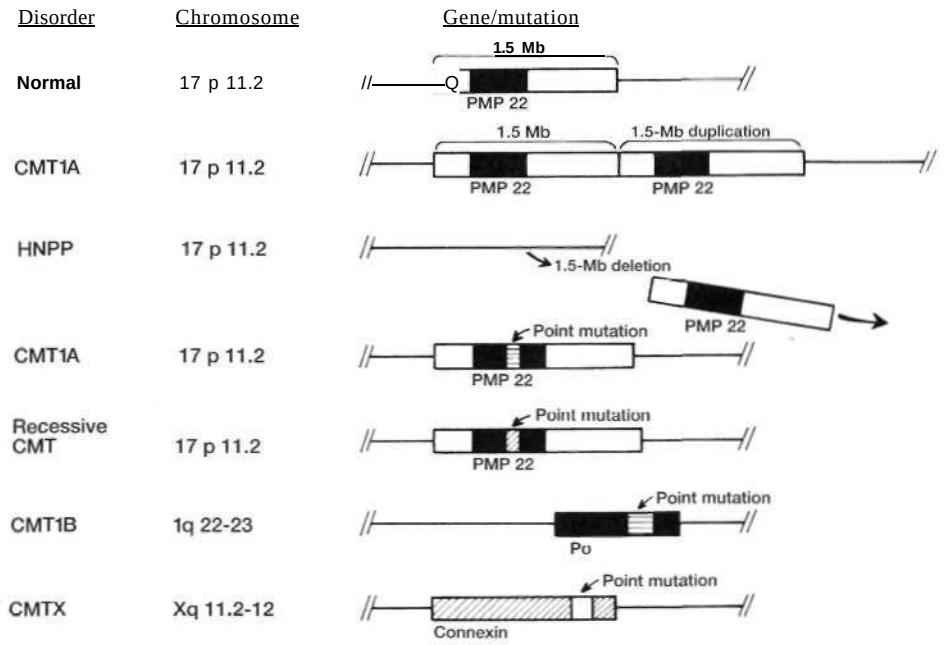

FIGURE 44.14 Several different mutations resulting in various forms of hereditary neuropathy (Charcot-Marie-Tooth [CMT]/ hereditary motor-sensory neuropathy [HMSN]) and thus examples of genetic heterogeneity. The normal sequence of DNA at chromosome 17p11.2 has a 1.5-Mb region that includes a peripheral myelin gene (*PMP-22*). A 1.5-Mb tandem duplication results in CMT-1A, and a 1.5-Mb deletion of the same region results in hereditary neuropathy with liability to pressure palsies (HNPP). Two different point mutations in the *PMP-22* gene can cause either a dominant form of CMT-1A or a recessive form of CMT. Furthermore, a point mutation in the P0 myelin protein gene at chromosome 1q22-23 results in CMT-1B, a clinical syndrome very similar to CMT-1A. Finally, a point mutation in the connexin32 gene at Xq11.2-12 results in an X-linked inherited form of neuropathy.

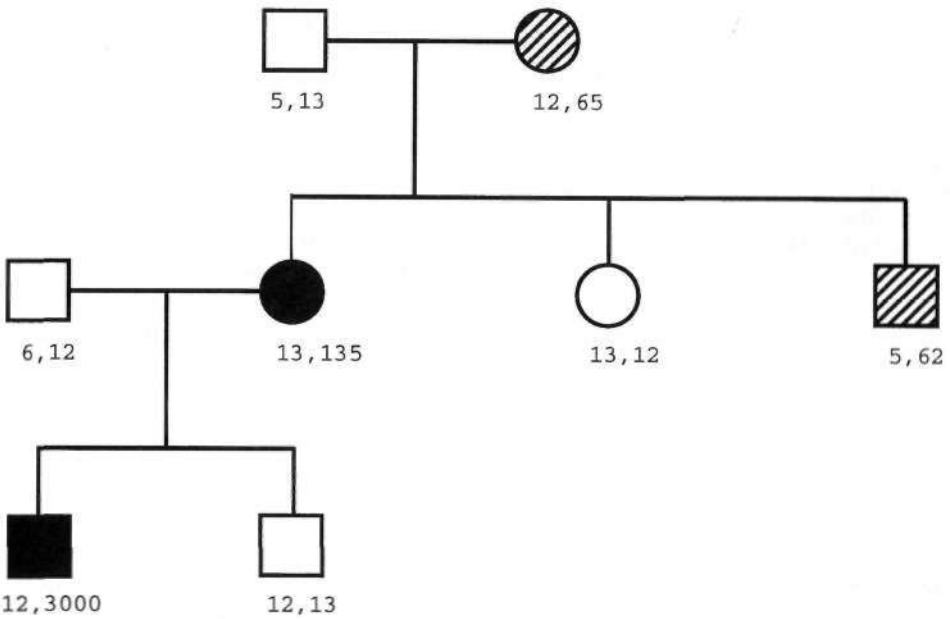

FIGURE 44.15 Clinical anticipation is partly explained by generation instability of the CTG trinucleotide repeats at the myotonic dystrophy locus. In this hypothetical family, the first-generation male has two normal-sized repeats at the myotonic dystrophy locus (the numbers under the symbol indicate the repeat size for each allele), whereas the first-generation female has one normal allele and one allele above the normal range but below the range that causes the clinical syndrome, referred to as a premutation range expansion. With transmission to the second generation, the premutation allele is unstable and is expanded to 135 repeats in a daughter that develops the clinical syndrome of myotonic dystrophy and contracted to 62 repeats in a son who remains asymptomatic. In the third generation, there is a large expansion of the repeat from 135 in the mother to 3000 in the son who is affected with a severe congenital form of myotonic dystrophy. Hatched symbols indicate abnormal size repeat but no clinical disease; filled symbols indicate clinical disease.

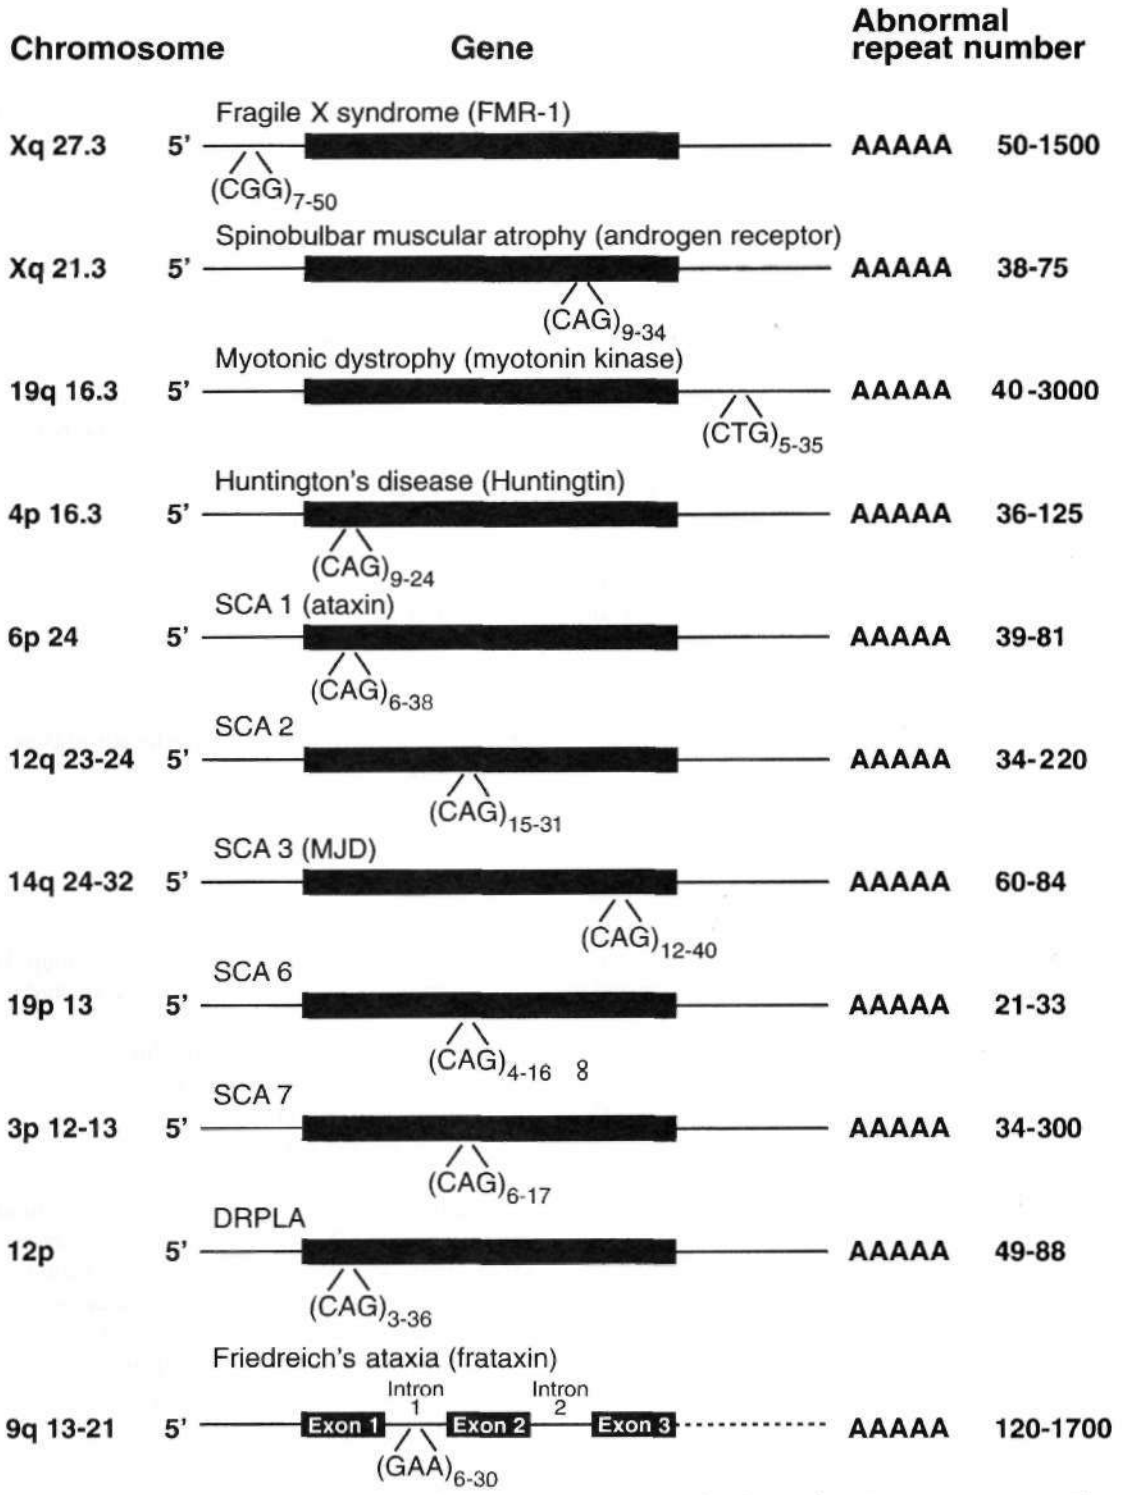

FIGURE 44.16 Eleven neurological diseases that have been shown to be associated with trinucleotide repeat expansions. The region of DNA containing each gene's protein-coding segments is indicated by the solid horizontal bar. The repeats (CGG, CAG, or GAA) may lie inside or outside these coding segments. The range of normal number of repeats found in the general population is indicated next to each repeat region. The abnormal number of repeats that may be found in affected individuals is indicated in the last column. MJD = Machado-Joseph disease.

Interpretation of the results, however, can be complex (Bird 1999). For example, having the expansion is not the same as having the symptoms of the disease. Nor does it accurately predict the age of onset or severity of disease for any individual. In many cases there is significant somatic heterogeneity of repeat length, meaning that the expansion size might be different in blood cells compared with other tissues, such as brain or muscle. Therefore although expansion length roughly correlates with disease onscr and severity when analyzing a large population, the correlation is not sufficient to accurately predict the course of the disease in any single individual. Furthermore, an individual can have an expansion that is in an intermediate range between the normal and the affected populations (e.g., 29 to 35 repeats in the *HD* gene). This ambiguity is a **difficult** issue for both patients and physicians because their association with the disease phenotype is not clear. Finally, in some of these syndromes a few patients have been described who have the clinical characteristics of the disease but do not have an expanded repeat at the disease locus. In summary, the ability to directly test for repeat size has dramatically improved our ability to identify people at risk for these inherited syndromes, but we still have much to learn about the application of this knowledge to patient care.

TOOLS **OF GENETIC** RESEARCH

Restriction Endonucleases

Certain bacterial enzymes have the ability to cleave foreign DNA into fragments, their site of action being restricted to specific sites within the molecule. This function appears to be an evolutionary development that protects the organism's own DNA from incorporating foreign DNA. Each restriction cndonuclease can recognize a specific DNA sequence *(restriction site)* several bases in length and cut a strand of foreign DNA at a particular position within that sequence. The sequences on the paired strands at which a restriction enzyme cuts arc palindromic; that is, the sequences on the two strands read the same but in opposite directions. For example, the restriction enzyme Hindlll cuts a duplex strand of DNA as follows:

1. 5'A | AGCTT3'
2. 3' TTCGA | A 5'

If the same enzyme is used to cut both the DNA of the vector and the DNA to be incorporated into it, the cut ends of the foreign and host DNA may join by complementary base pairing, thereby incorporating the foreign DNA into that of the vector. After base pairing, the ends of the strands are sealed together by the enzyme DNA ligasc (which tequires ATP),

The fragments of the DNA produced by restriction enzymes along a particular DNA segment can he used to construct a restriction map, showing the cutting sites for the various enzymes in relation to one another,

The technique used to detect specific sequences of **DNA** is Southern blotting, named after its originator. The DNA of interest is digested into short fragments by one or more restriction enzymes, and gel electrophoresis is used to separate the fragments by size. The DNA is then denatured to the single-strand form and transferred by blotting with paper towels to a more stable medium, nitrocellulose filter membrane. The pattern of DNA fragments on the gel is faithfully transferred to the filter membrane. The resulting blot can be baked to make it more permanent and can then be hybridized to a specific probe. Using autoradiography, the fragment(s) of interest can be visualized on the blot (Figure 44.17).

Because the size of each DNA fragment is determined by position of the sequence recognized by the restriction enzyme used to cleave the DNA, polymorphisms that alter a restriction site will result in a change in the size of a DNA fragment (Figure 44.17B), These RFLPs have been used in linkage analysis (see later).

By analogy to Southern blots, the transfer of RNA molecules is called Northern blotting, and the transfer of proteins is Western blotting. (Northern and Western do not derive from names of scientists,)

Vectors

Vectors arc prokaryotic organisms, or DNA molecules, into which foreign DNA can be grafted for cloning. Four types are commonly used: plasmids, phages, cosmids, and yeast artificial chromosomes (YACs).

Plasmids are small, circular duplex DNA molecules within bacteria and yeast that replicate independently of the host chromosome. The genes they carry may be of great importance for the survival of the host cell, such as genes for antibiotic resistance. The plasmids used for DNA cloning have been constructed with three essentia] features: (1) an origin of DNA replication allowing the recombinant DNA molecule to replicate in the host; (2) a marker such as a gene for antibiotic resistance that can be used to select for bacterial cells containing the plasmid; and (3) a region into which small fragments (<6-10 kb) of cloned DNA can be inserted, with the help of cleavage sites for one or more restriction enzymes.

Phage (bacteriophage) is a virus that infects bacteria. Its duplex DNA molecule may either become incorporated into the bacterial chromosome or replicate independently and produce large numbers of phage particles, which lyse the host cell and infect other bacteria in the culture. The presence of phage-infected bacteria is shown by plaques (clear areas) in the culture dish. Specialized versions of the best-known phage, phage lambda, have been developed that can carry intermediate-sized fragments (5-20 kb) of cloned insert DNA. There are also single-strand phage

cloning vectors, which have special advantages fur DNA sequencing and other experimental uses.

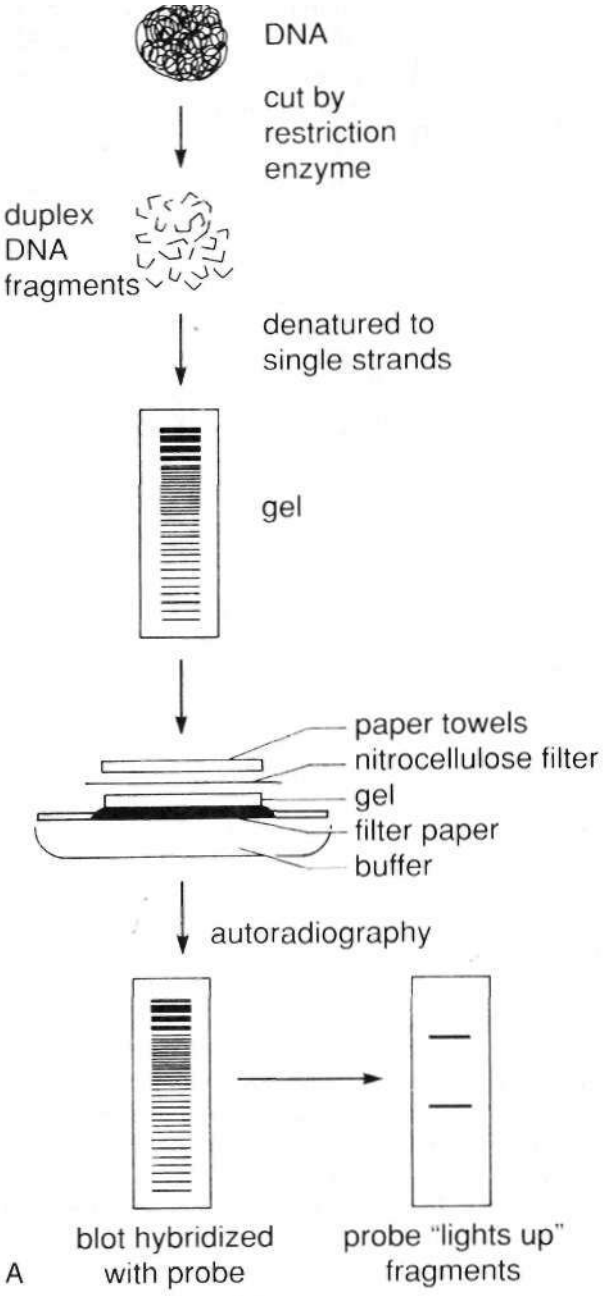
A cosmid is a construct that combines plasmid and phage features. It is composed of plasmid DNA that contains the cos site of phage lambda, which carries the sequences required to package the cloned insert DNA. Like other vectors, it also contains a replication origin and selectable markers. Cosmids have an advantage over plasmid and phage vectors because relatively long (35- to 45-kb) foreign DNA sequences can be inserted into them,

Until recently, it was not possible to clone DNA fragments of 100 kb to more than 1000 kb. With tin-advent of rare cutting-restriction endonucleases that cut at rare sites, these large ftagments can now be cloned using special yeast and bacterial vectors. The new constructs are called YACs or bacterial artificial chromosomes (BAOs).

Gene Libraries

A set of DNA fragments from a specific source that has been cloned in appropriate vectors is called a gene lihraty, indicating that it contains genetic information from its DNA source. A human gene library may be prepared from total genomic DNA or from the DNA of a single chromosome or chromosome segment. Although the experimental procedures may be complex, the principle is relatively simple. The DNA of interest and that of the vectot are cleaved by the same enzyme and allowed to reeombine. In principle, all or most of the DNA of interest will be inserted into the vector DNA. The vectors, some of which now contain the foreign DNA sequences of interest, ate inserted into bacterial hosts, allowed to multiply *in vitro* undet selective conditions, and stored for long-term availability. To access the clones that have incorporated the DNA sequences of interest, it is necessary to use a method ot selection. This process often requires the use of radioactive DNA or RNA probes that are specific for the sequence of interest and will hybtidize with them.

For many experimental purposes, *complementary DMA (cDNA) libraries* are used. Complementary DNA is prepared from mature mRNA obtained from a tissue in which the gene of interest is expressed. This is not a trivial procedure, because most tissues contain many types of mRNA transcripts, among which the specific one tran-scribed from the gene of interest may be rare. Because an mRNA transcript is a continuous RNA strand containing only the exons of the gene and lacking the introns, it is considerably shorter than the corresponding genomic DNA molecule (e.g., 14 kb of mRNA instead of about 2000 kb of DNA for the *DMD* gene). The single mRNA strand to be copied is prepared by addition of an oligo (dt) primer that hybridizes to the poly-A tract and allows reverse transcrip-tase to begin synthesis of a complementary DNA strand. The DNA strand ends in a short hairpin loop. The RNA transcript is then degraded, leaving the single DNA strand,



FICUKE 44.17 (A) The technique of Southern blotting. DNA is cut into small fragments by restriction endonucleases, separated on a gel, then transferred by blotting onto nitrocellulose membrane (see text). *Continued*

which is converted into a duplex molecule by the action of DNA polymerase 1 using the hairpin as the primer. The hairpin is degraded by the enzyme SI nuclease, leaving a duplex DNA molecule copy of the original mRNA molecule that can be inserted into an appropriate vector molecule, amplified, and stored. A LDNA library prepared from a given tissue usually contains a variety of clones representing all the different genes that are being expressed in that tissue at that developmental stage.

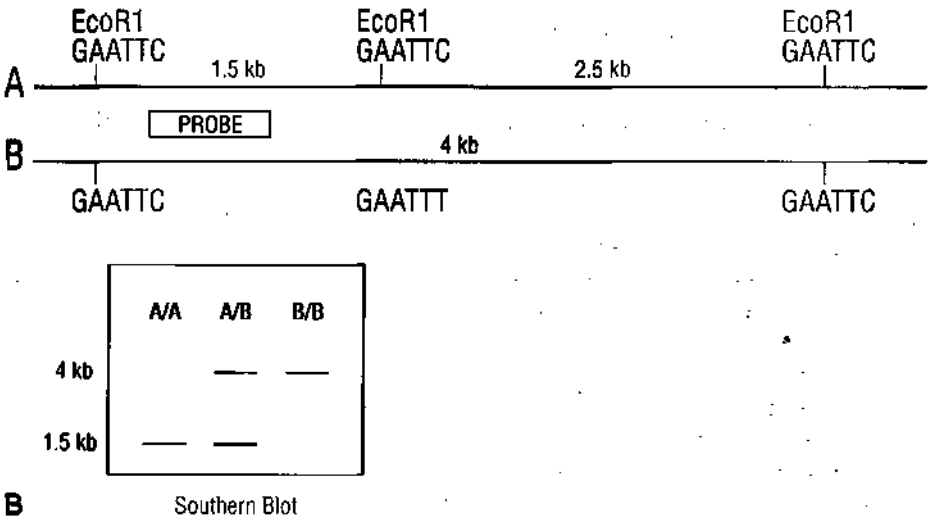


FIGURE 44.17, cont'd. (B) Restriction fragment length polymorphisms (RFLPs) can result from single nucleotide polymorphisms (SNPs) that change the recognition sequence for a restriction enzyme. The restriction enzyme EcoRl recognizes the recognition site GAATTC. Allele A has three F.coRI restriction sites in the region of the probe. When the enzyme cuts at these sites, two pieces of DNA are produced (1.5 kband 2.5 kb). Allele B has an SNP that eliminates one of the sites because GAATTC has been changed to GAA I J I. Now, with allele B the restriction enzyme only cuts in two places producing a single 4-kb length of DNA. Southern blot hybridization can be used to determine whether an individual has inherited two A alleles (A/A), two B alleles (B/B), or is heterozygous (A/B).

Chromosome Walking and Jumping

Chromosome walking is an approach used to clone relatively long stretches of the genome. The walk begins with a clone that has already been isolated. Terminal fragments of the clone are used as probes to identify adjacent overlapping clones from a genomic library. This process can be repeated to cover lengths of 100 kb or more, but the size of a single step is limited by the size of the insert of foreign DNA that can be incorporated into vectors, about 20 kb for lambda vectors and 45 kb for cosmids. The direction of the walk along the chromosome can be determined by making successive restriction maps and identifying matching regions.

Much longer distances can be covered by chromosome jumping. In this method, very long (100-200 kb) restriction fragments of genomic DNA are circularized *in vitro*, resulting in the formation of artificial junctions between sequences normally separated by long distances. These junctions are then cloned using conventional technology and radioactive probes. The clones isolated thus contain the starting sequence (the probe binding site} and a new genomic sequence 100-200 kb away. Because the sequence between the sites is not cloned by this method, one has effectively jumped from the probe site to a position 100-200 kb farther along the chromosome.

Polymerase Chain Reaction

PCR represents a powerful technique for the analysis of DNA. Basically, it is a tool for greatly amplifying tiny pieces of DNA. This includes, for example, minute samples of hair, blood, skin, sperm, or saliva. It is especially useful in the diagnosis of human genetic mutations through the analysis of small blood samples, including identification of the trinucleotide repeat expansions described previously, The theory and technology underlying PCR are beyond the scope of this chapter, PCR and its application to neurological disease are well described by Darnell (1993). PCR uses a heat-stable DNA polymerase to extend synthetic DNA primers that flank and bind to DNA sequences of interest. Samples are then heated to near 100°C to denature the DNA into single strands and cooled to reanneal newly synthesized DNA with the synthetic primers. As this cycle is repeated, newly synthesized DNA is available to anneal with primers and be extended. In this way the reaction amplifies itself (a chain reaction) with a doubling of products at each cycle. Thirty cycles can be performed in a few hours in a single tube in an automated thermal cycling machine. Thus a relatively small input yields an enormous amplification of product—ideally more than 200 copies of a single starting molecule. However, one of the problems with PCR is its great sensitivity, sometimes resulting in false results from amplification of minute amounts of contaminating DNA (Darnell 1993).

LINKAGE ANALYSIS

Genetic linkage analysis has been extensively used to map genes for human diseases to specific chromosomes. The concept is straightforward (Ott 1990), All genetic mutations occur at a single point or locus somewhere on the

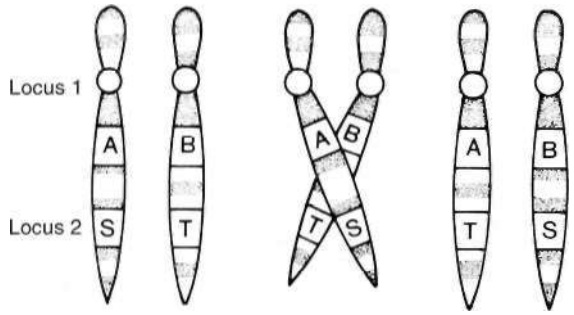

FIGURE 44.18 A crossover between the long arms of a homologous chromosome pair resulting in a recombination between the hypothetical linked genes. The gene loci at A and S arc close to each other on the saint chromosome (linked). The alleles at locus 1 are A and B. The alleles ar locus 2 are S and T. Thus this person is heterozygous at both the 1 (AB) and 2 (ST) loci. Locus 1 could represent the site of a disease gene, and locus 2 could be the site of a polymorphic DNA marker. Initially, gametes resulting from these chromosomes would be AS or BT. Following the crossover and recombination, the gametes would he AT or BS. The A allele at locus 1 would now be inherited with the S allele at locus 2.

22 human autosomes or the X chromosome. If two genes occur close to each other on the same chromosome, they are said to be linked. Note that linkage is simply a physical relationship between two loci on a chromosome and implies no pathogenetic or metabolic association between the two genes.

Crossing over of homologous chromosomes during meiosis may result in a recombination between the two loci of linked genes (Figure 44.18). The frequency with which these recombinations occut increases with increasing distance between the two genes. Therefore the frequency ol recombination events between two loci is a relative measure of the distance between them, A 1% frequency of recombination between two loci indicates 1 ccntimorgan (cM) of genetic distance between them. One centimorgan represents about 1 million DNA base pairs (1000 kb). (Note that a cM represents recombination events and is an estimate of genetic distance on a chromosome but not a true physical distance,) The total human genome contains approximately 3300 cM and at least 30,000 genes. It should be noted that recombination frequencies (crossovers) are not necessarily the same for chromosomes in males and females (generally more frequent in females for unknown reasons), not always the same for different chromosomes, and not the same for different portions of the same chromosome (recombination hot spots). The recombination frequency is expressed by the Greek letter theta (?) and has a maximum of 0.5 (one half, or 50%).

If a dominant monogenic clinical disorder is traced through a family pedigree to the inheritance of another unrelated genetic marker (such as the ABO blood group), one can determine the probability that the two genetic traits (the disorder and the marker) are linked or not linked. If all persons affected with the genetic disorder always have the same form (polymorphism) of the genetic marker and all unaffected persons have the other form of the marker, the two genetic traits are said to be segregating together. If enough individuals can be tested, the two traits can be shown to be linked or unlinked.

In order for linkage analysis of a family to be useful, the family must be informative for both the disease and the genetic marker. That is, it must be possible to distinguish between persons affected and unaffected with the disease, and there must be variability of the polymorphic states of the marker within the family. For example, the first two generations of the family in Figure 44.19 are not informative, because all the offspring in the second generation are type AB for the marker whether they have the disorder or not. However, in the third generation all the affected individuals have the AB form of the marker, and all the unaffected individuals are type AA. The pedigree contains useful genetic linkage information because there have been several informative matings in the second generation. On inspection of the pedigree, it becomes apparent that the disease seems to be segregating with the B form of the genetic marker. Linkage analysis of this family would then give us an estimate of the probability that the disorder is indeed linked to the genetic marker under study.

A statistical measure of linkage is the LOD score, which is an estimate of the probability or likelihood that two genetic traits are linked. The LOD score is the log of the odds favoring linkage versus independent assortment. A LOD score of +3.0 represents theoretical odds of 1000 to 1 (10) that two traits are linked and is generally accepted as proof of linkage, especially if the analysis has been restricted to a single family. (A LOD score of +3 actually represents a practical probability of about 95% that two genes are linked.) A true linkage relationship in a large, genetically homogeneous population of families should produce a LOD score of +4 or +5 with a highly polymorphic marker. A LOD score of —2.0 represents odds of 100 to 1 (10^2) that two traits are not linked. LOD scores falling between +3.0 and -2,0 are more or less suggestive of linkage, respectively, but not accepted as proof. LOD scores are calculated for a given recombination fraction. Two traits may be considered loosely linked with a recombination fraction of 10-20%, closely linked with a recombination fraction of about 5%, or tightly linked with a recombination fracrion of 1% or less. (These are helpful but not strict definitions.) As noted previously, the recombination fraction is related to distance along the chromosome. During linkage analysis LOD scores are computed for many possible recombination fractions. Therefore the recombination fraction with the highest positive LOD score is the best estimate of the distance between two potentially linked genes.

The usefulness of genetic linkage analysis is demonstrated in Table 44.3. The LOD scores for three different CMT families are shown for various genetic markers on chromosomes 1 and 17. Family 1520 has clearly positive LOD scores (greater than +3.0) for two markers

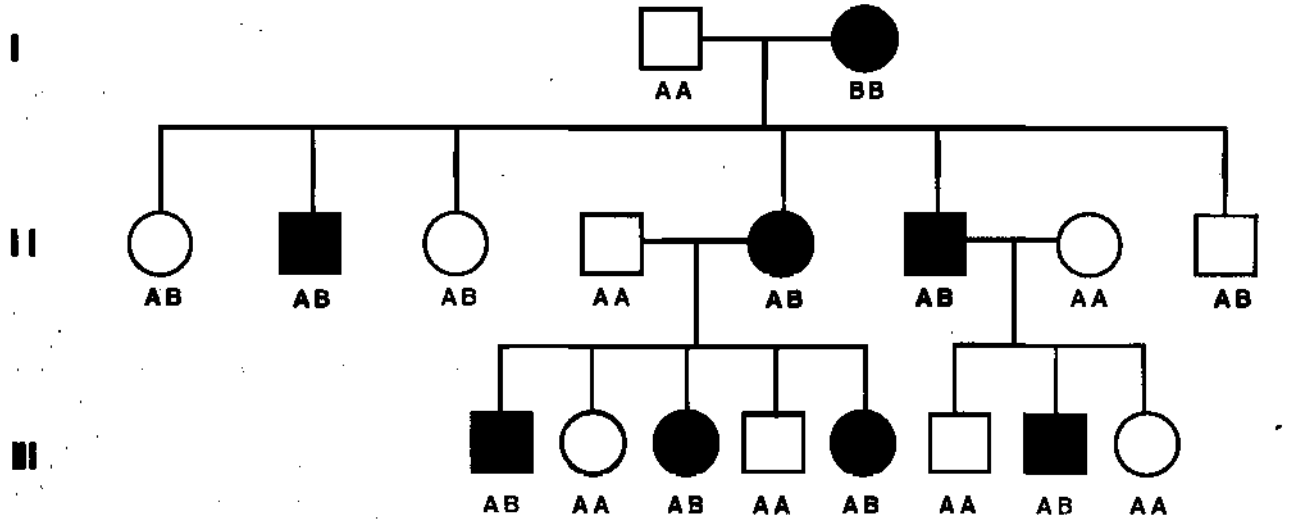

FIGURE 44.19 Autosomal dominant inheritance (uninformative mating versus informative mating.) Pedigree demonstrating the basic principle of linkage analysis. Persons affected with the disease are indicated with solid symbols. Results of genetic testing for inherited DNA markers (A and B) are indicated under each symbol. Generation 2 is uninformative, because there is no obvious association between the disease and the genetic markers. However, generation 3 makes the family analysis informative. It now can be seen that all affected individuals have inherited the B allele of the DNA marker, and none of the unaffected persons lias in lie ri red the B allele. This suggests that the disease gene resides in a chromosomal region close to the genes for the A and B genetic markers—that is, the analysis suggests linkage. If the chromosomal location of the A and B markers is known, then it is likely that the disease gene also lies on this chromosome.

on chromosome 17 and negative LOD scores for two markers on chromosome 1. The gene for hereditary neuropathy in this family must lie on the short arm of chromosome 17, and such families are designated CMT-1A. The IND family has a very significant negative LOD score with a marker on chromosome 17 (—4.10) and positive LOD scores with the chromosome 1 markers. The gene for hereditary neuropathy in the IND family must lie on the long arm of chromosome 1, and such families are designated as CMT-1B. Finally, family 1550 has significantly negative LOD scores, with all markers on both chromosomes 1 and 17. The gene for hereditary neuropathy in this family must lie elsewhere in the human genome, and such a family is tentatively designated as CMT-1C. Thus genetic linkage analysis has demonstrated genetic heterogeneity and indicated that there arc at least three distinct genetic forms of autosomal dominant GMT with separate genes on chromosomes lq, 17p, and some other location,

LOD scores from different families comparing a genetic marker and a disease may be added if one is certain that the families have the same genetic disorder (a mutation at the same locus). (The LOD scores are added because they represent logs or exponents, as noted previously.) For example, the first four families with CMT to undergo linkage analysis had a cumulative added LOD score of greater than 4-6.0 for linkage with the Duffy blood group locus on chromosome 1. This was accepted as proof of linkage of this form of autosomal dominant CMT to a marker on chromosome 1. Subsequently, numerous

Table 44.3: Comparison of linkage analysis for three Charcot-Marie-Tooth (CMT) disease families

	Family		
Marker	*#1520*	*IND*	*#1550*

Duffy (Fy)	3.1 I	1.96	-6.67
Fey I	-8.85	5.17'	-0.97
R. Chromosome 17p markers (LOD scores at O.0S recombination)			
EW 301	3.10*	NI	-4.62
pTH 17.19	3.15*	NI	-2.3.5
8B10	NI	-4.10	NI

*l.OD score >3.0, indicating strong evidence for linkage.
NI = not informative.

families with autosomal dominant hereditary neuropathy have had negative LOD scores for the Duffy locus. This raises an important issue in genetic linkage analysis that is a common and complex problem. There are two possible explanations for these different LOD scores for families with apparently the same disease. The first is that they all do have exactly the same generic disease (mutations at the same locus). The LOD scores should all be added, and the net total score shows no linkage with Duffy. However, a second explanation is that different families with a similar clinical syndrome may represent genetic heterogeneity (mutations at different loci). Positive and negative LOD scores from the various families when added will cancel out and show no linkage, whereas linkage may be present in one or a few families and be missed during the pooling of multifamily data. Often, the issue of possible genetic heterogeneity must await the evaluation of further families and the generation of additional linkage data. Further investigation has, for example, indeed shown that a common locus for CMT resides on chromosome 17, and a less common locus for CMT is on chromosome 1.

Genetic heterogeneity can be difficult to predict from clinical or pathological information. For example, it was once thought that the so-called peripheral and central forms of neurofibromatosis might actually represent different expressions of the same genetic disease (mutation) or at least be alleles (different mutations at the same locus). However, linkage analysis has shown that the two conditions are entirely different mutations on chromosomes 17 and 22, respectively. A similar situation has occurred with hereditary polycystic kidney disease and tuberous sclerosis. That is, the same clinical syndrome (phenotype) shows genetic heterogeneity by linkage analysis. On the other hand, two forms of familial polyposis of the colon that seemed different phenotypically have proved to be mutations at the same locus. Likewise, families with early- and late-onset Huntington's disease represent mutations at the same locus on chromosome 4.

Obviously, it is safest to limit linkage analysis to single large families, eliminating the problem of genetic heterogeneity. Unfortunately, most single families are not large enough to generate statistically significant linkage data. Data from multiple families arc often pooled but must be viewed with healthy skepticism until the data are unequivocally significant or it is clearly established by other means that the families arc genetically homogeneous. For example, initial studies showing linkage of schizophrenia to chromosome 5 markers and manic depressive illness to chromosomes 11 and X have not been replicated, and the assignments remain uncertain.

Statistical tests are available that give an indication of genetic heterogeneity by comparing LOD scores from various families with similar clinical disorders. The results may range from a high probability to a very low probability of linkage.

Also, separate families with disorders produced by alleles (different mutations at the same locus) can appropriately have pooling of their linkage analysis data. For example, Becker's and Duchenne's muscular dystrophies are now known to be allelic mutations in the same gene and show the same linkage relationships to other X-chromosome markers.

It should also be obvious that correct clinical diagnosis of each and every family member is crucial in linkage analysis. Incorrecrly identified family members will produce serious errors in the analysis and can falsely bias the data toward linkage or nonlinkage. For example, with hereditary neuropathy with slow nerve conduction, clinically equivocal cases must have careful nerve conduction velocity (NCV) studies. In myotonic dystrophy, electromyography (EMG) and slit-lamp examination of the lens may be necessary in family members at risk who appear clinically unaffected by physical examination. Imprecise clinical diagnosis is partly responsible for the conflicting linkage results in studies of schizophrenia. Also, diseases with delayed onset (such as Huntington's and Alzheimer's diseases) must have age-of-onset correction factors included in the analysis.

One may also take advantage of two or more genetic markers known to reside close to each other on the same chromosome, in a statistical technique known as multipoint genetic linkage analysis. This increases the power of demonstrating linkage and may allow more refined subrcgional location of a given disorder.

If the gene controlling the expression of a marker is known to have its locus on a specific chromosome, then any genetic trait that is shown to be linked to that marker must also have its locus on the same chromosome. Thus the power of linkage analysis is the actual identification of genetic loci on specific chromosomes or even finely mapped regions of a chromosome. This can lead to advances in diagnosis and even to the discovery of the nature of mutations and the protein abnormalities underlying genetic diseases.

If there arc no previous clues to the chromosomal location of a genetic disease, then a large number of random genetic-markers covering all human chromosomes must be systematically studied to discover a linkage relationship. It is estimated that about 200 to 300 evenly spaced markers would reasonably cover the entire human genome. More than enough markers are now available. The markers must be polymorphic—that is, have several possible identifiable forms in the general population so that various combinations can be found in any given family. Theoretically, with enough genetic markers and sufficient time and effort, all monogenic disorders can be located on specific chromosomes. This task can be very tedious and time consuming. A remarkable advance has been the advent of new DNA polymorphisms that make available the hundreds and even thousands of inherited markers necessary to cover the human genome in a complete manner. The first such markers were RFLPs, which arc now complemented by a variable number of tandem repeats (VNTR) and

microsatcllitc CA repeats, which make most families informative and improve the success rate of linkage studies. The first example of an autosomal dominant linkage relationship using these new techniques was the linkage of the Huntington's disease gene in 1983 to the D4S10 (G8) RFLP marker on the distal end of the short arm of chromosome 4. The pace of chromosomal assignment of neutological diseases has subsequently greatly accelerated. There are now more than 200 disorders of the nervous system with specific chromosomal assignments (Tables 44.4 and 44.5).

POSITIONAL CLONING

Once disease genes have been given regional assignments on chromosomes by linkage analysis, the search is begun to identify the gene itself by *positional cloning* (previously [erined *reverie genetics).* I his strategy relies only on the chromosomal location of the gene. Once the gene is discovered, one can attempt to determine the protein for which it codes. This strategy is the opposite of beginning with a known protein, determining its amino acid sequence, and using that information to locate and isolate a gene. All the tools and methods described previously are brought to bear in the process of isolating a gene, including restriction endonucleases, genetic libraries, vectors including YACs, and chromosome walking and jumping. The strategy has been spectacularly successful with the identification of numerous genes for neurological disorders including Duchenne's and Becker's muscular dystrophies, myotonic dystrophy, Huntington's disease, and neurofibromatosis. Several examples of such genes and their known protein functions are shown in Table 44.6.

How is it known when a gene is found? Another way to express this question is, "How is it known if a change in a DNA sequence represents a benign polymorphism or causes a clinically significant alteration in the functions of a protein?" One method is to return to linkage analysis and demonstrate that the newly discovered change, or mutation, always segregates with the disease in the family. That is, people with the disease always have the mutation, and people without the disease never have the mutation. Obviously, penetrance and expression must be taken into consideration. Furthermore, unrelated, normal individuals in the general population never show the mutation. It is also useful to demonstrate de novo occurrence of the mutation. That is, isolated individuals with the disease carry the mutation, hut the mutation is not found in any of their siblings or either of their parents (and paternity is proved).

What follows gene identification? When a new gene is isolated, relatively little may be known about its function. The DNA and predicted amino acid sequences can be compared with those of known genes and proteins in humans and other species. Also, the amino acid sequence can be analyzed for the presence of predicted secondary-structures and specific functional motifs, such as known membrane-spanning regions. Antibodies can be raised to the gene product; then the distribution, cellular, and subcellular location of the protein can be determined.

To study the effect of overexpression or underexpression of a gene, the foreign gene can be introduced into a mouse germ-cell line to produce transgenic animals. Eggs are removed from a female mouse and fertilized with sperm in a test tube, and a recombinant plasmid carrying a new gene is microinjected into the zygote. The new gene can be placed under the control of a promotor, and high expression levels can be reached. One can then study overexpression of that particular gene in the resulting transgenic animals. Attempts have been made, for example, to overexpress the amyloid precursor protein gene in transgenic mice as a model of Alzheimer's disease.

Knockout mutants can also be created. Embryonic stem cells are used, and a portion of the mouse gene is exchanged for an altered DNA sequence—for example, one containing a pre mature-stop codon. This technology can produce heterozygotes (having one mutant and one normal allele) or homozygotes (having no functional gene product at that locus, so-called null mutants). Homozygous knockout mice may also provide an important source of cell lines that lack the gene product. Knockout mice for the P0 myelin gene have been produced, for example, to aid in understanding hereditary neuropathies.

The two major long-term goals of neurogenetic research are (1) to further our understanding of the biological and physiological functions of the human organism and (2) to create new diagnostic, therapeutic, and preventative measures for human genetic diseases.

GENETIC COUNSELING

Genetic counseling is a perfect example of the mixture of art and science inherent in the practice of medicine. It requires the communication of complex data to patients by physicians in an objective and nonjudgmental but diplomatic and compassionate fashion. The first step in genetic counseling is to establish an accurate diagnosis. This is obviously critical and must be done as carefully as possible. As in all of medicine, the accurate diagnosis of genetic diseases depends on history, physical examination, and laboratory tests. In addition, obtaining a full family pedigree is important. Information about medical disorders in other family members will provide important clues to the diagnosis in the ptoband. Also, inspection of the family pedigree will often indicate the correct inheritance pattern, be it dominant, recessive, X-linked, or mitochondrial (see Figures 44.2, 44.3, 44.4, and 44.7).

Following accurate diagnosis, the next major step in genetic counseling is educating the patient. This includes an estimate of risk to the proband and other family members

Table 44.4: Chromosomal assignments of selected autosomal neurological disorders

Disorder	*Chromosome*	*Inheritance pattern*

Bilateral acoustic neurofibromatosis (NF2)	22qll-13.1	AD

AD = autosomal dominant; AR = autosoma! recessive; MR = mental retardation; SCA = spinocerebellar ataxia.

for inheriting the pertinent gene. Risks always need to be put into context and perspective. For example, with each pregnancy all normal couples take a *2-A%* risk of having a child with birth defects. It is often unpredictable how any given person will react to a risk probability for inheriting a disease. Some people will find a 50% risk of no great concern, whereas others may find a 1% risk to be very disturbing. Obviously, the perceived severity or burden of the disease is of major importance. Physicians, patients, and other family members may not agree as to what constitutes a "severe" disease. In addition to risk estimates, the counselor must give a description of expected symptoms and signs, natural history of the disease, variability of expression, and long-term prognosis. Potential treatment options must also be discussed. Physicians are accustomed to considerable variability in symptoms and prognosis of various diseases, but these ambiguities can be difficult concepts for many patients.

The presymptomatic diagnosis of neurogenetic disorders is becoming more common. Huntington's disease has been a model in this regard. By DNA testing for the trinucleotide repeat expansion on chromosome 4, carriers of the HD

Table 44.S: Regional assignments of selected X-linked neurological disorders

Kallman anosmia-hypogonadism	Xp22.3	Pelizaeus-Merzbacher disease	**Xq22**
Aicardi's syndrome (MR, seizures, agenesis corpus callosum)	Xp22	Coffin-Lowry (MR, seizures, dysmorphic)	**Xq22**

MELAS — mitochondrial, encephalopathy, lactic acidosis, and strokelike episodes; MERRF myoclonic epilepsy, ragged red fibers.

gene can now be fairly reliably detected, as described previously (the exception being the equivocal range of 33 to 35 repeats). This means we have the ability to discover who has inherited the gene for a severe, progressive, incurable, fatal degenerative brain disease. At the same time, we are unable to predict age of onset or severity of the disease with much accuracy. These issues raise serious problems for both the physician and the patient, including the patient's motivation for having the test, the patient's emotional reaction to the result, and potential long-term implications for employment and insurance. Detailed discussions of these medical and ethical issues are available (Bird 1999; Guidelines 1994; Hersch et al. 1994).

Finally, genetic counseling should include opportunities fot follow-up and long-term contact with the patient. The patient must be given an opportunity to ask questions. Additional testing of the patient and other family members may be necessary. Detailed genetic counseling often involves a long-term process involving months or years, and it becomes a basic thread in the fabric of good medical care.

Chapter 45
Neuroimmunology

Tanuja Chitnis and Samia J. Khoury

The past decade has provided a rich interaction between the fields of neurology and immunology. This has given rise to new therapies for multiple sclerosis (MS) and has improved existing treatments of many other neuroimmunological diseases. A solid grasp of immunology is required to use the emerging therapies in the field of neuroimmunology. Here we provide a brief overview **of the major** components of the immune system and highlight important advances in the field of neuroimmunology.

The immune system function is to protect the organism against infectious agents and prevent reinfection by maintaining immunologic memory, to perform tumor surveillance, and to help healing and prevent damage from dying cells.

The immune system normally does not react to **self-**antigens, a state known as tolerance, except in the setting of autoimmune disease. Conversely, an active immune system is important in tumor surveillance. A critical factor in tumor survival is its ability to mask itself from immune surveillance. The normal functions of the immune system and the disorders resulting from its dysfunction arc listed in Table 45.1.

ADAPTIVE AND **INNATE IMMUNITY**

The immune system has two functional divisions: the innate immune system and the adaptive immune system. The innate immune system acts nonspecifically as the body's first line of defense against pathogens. However, this type of response, if perpetuated, would result in unwanted nonspecific damage to the host. Therefore a secondary, antigen-specific response develops and leads the attack. This is mediated by T cells and B cells, which are equipped with antigen specific receptors. The effector cells release mediators and trigger other components of the immune system to eliminate the target. Subpopulations of T and B cells develop and maintain immunological memory, which facilitates a more rapid response in the case of recurrenr infection.

The innate immune system consists of the following components:

1. Skin—The exterior surface of the body, primarily the skin, is the body's primary defense against foreign pathogens. In addition many inflammatory cells and antigen-presenting cells (APCs) line the epidermis **and** serve as the first line of defense.
2. Phagocytes—Phagocytes are cells capable of phagocytosing foreign pathogens. They include polymorphonuclear cells, monocytes, and macrophages. These cells are present in the blood, as well as in organs. They recognize cell surface receptors on a variety of microorganisms that allow them to attach nonspecifically and phagocytose pathogens, which are then killed via intracellular lysosomes.

Tabic 45.1: Normal functions and disorders of the immune system

Normal functions

Immunity against microorganisms and pathogens
Wound healing
Tumor surveillance
Disorders resulting from immune system dysfunction
Autoimmunity
Immune-mediated disorders
Bystander damage
Graft rejection

3. Natural killer (NK) cells—NK cells recognize cell surface molecules on virally infected or tumor cells. They subsequently bind to the infected cells and kill them via cell-media ted cytotoxicity.
4. Acute-phase proteins—C-reactive protein is a model acute-phase protein whose concentration increases in response to infection. C-re active protein binds to cell surface molecules on a variery of bacteria and fungi and acts as an opsonin, essentially increasing recognition of pathogens by phagocytic cells.
5. Complement system—The complement system is a cascade of scrum proteins whose overall function is to enhance and mediate inflammation. The complement system has the intrinsic ability to lyse the cell membranes of many cells including bacteria. It functions in concert with components of both the innate and adaptive immune systems and can also act as an opsonin, facilitating phagocytosis. The complement cascade can be directly activated by certain microorganisms through the alternative pathway, or it can be activated by particular antibody subtypes through the classical parhway.

The adaptive immune response consists of the following components:

1. Antibodies—Antibodies, otherwise known as immunoglobulins (Igs) are able to specifically recognize a variety of free antigens. Igs are produced by B cells and arc present on their cell surface. In addition, Igs arc secrered in large amounts in the serum. Antibodies recognize specific microbial and other antigens through their antigen-binding sires and bind phagocytes via their Fc receptors, thereby facilitating antigen removal. Some subclasses of Ig are capable of activating complement via their Fc portion, thereby lysing their targets.
2. B cells—The primary function of B cells is to produce antibody. Antigen binding to B cells stimulates proliferation and maturation of that particular B cell, with subsequent enhancement of antigen-specific antibody production. Most B cells express class II major histocompatibility complex (MHC) antigens and have the ability to function as APCs.

i. T cells—T cells or thymus-derived cells have the ability to recognize specific antigens via their T-cell receptors (TCRs). T cells may be classified into two main groups, T-helper (Th) cells expressing CD4 antigen on their cell surface and T cytotoxic (Tc) cells expressing CDS on rheir surface. CD4 T cells recognize antigen presented in association with MHC class II on the surface of APCs. CD4 T cells provide help to promote B-cell maturation and antibody production and produce factors called cytokines to enhance the innate or nonspecific immune response. CDS T cells recognize antigen in association with MHC class I antigen on the surface of most cells and play an important role in the elimination of virus-infected cells. Cytotoxic T cells are capable of damaging rarger cells via the release of degrading enzymes and cytokines. Responses in which the T cell plays a major role are termed cell-mediated immunity (CMI), T celi-macrophage interactions often lead to delayed reactions, termed delayed-type hypersensirivity (DTH).

4. Antigen-presenting cells (APCs)—APCs are required to present antigen to T cells. They are found primarily in the skin, lymph nodes, spleen, and thymus. Unlike B cells that can recognize free antigen, T cells are only capable of recognizing antigen in the context of self MHC molecules. APCs process antigen intracellularly and present antigen peptide in the groove of their MHC class II molecules. The primary APCs are macrophages, monocytes, dendritic cells, and Langerhans' cells.

PRINCIPAL COMPONENTS OF THE IMMUNE SYSTEM

Cells of the immune system arise from the pluripotent stem cells in the bone marrow and diverge into the lymphoid or myeloid lineages. The myeloid lineage primarily contains cells with phagocytic functions such as neutrophils, basophils, eosinophils, and macrophages. The lymphoid lineage consists of T cells, B cells, and NK cells.

Monocytes and Macrophages

Bone marrow-derived myeloid progenitor cells give rise to monocytes (mononuclear phagocytes of the reticuloendothelial system) that serve important immune functions. They constitute about 4% of the peripheral blood leukocytes and are morphologically identified by an abundant cytoplasm and a kidney-shaped nucleus. Their cyroplasm conrains many enzymes, which are important for killing microorganisms and processing antigens. Monocytes

differentiate into tissue-specific macrophages, including Kupffer cells of the liver, and brain microglia.

Natural Killer Cells

NK cells make up about 2.5% of peripheral blood lymphocytes and are synonymous with large granular lymphocytes because of their large intracytoplasmic azurophilic granules and high cytoplasm-to-nucleus ratio. Unlike cytotoxic CD8+ T cells, NK cells lack immunological memory and have the ability to kill a wide variety of tumor and virus-infected cells without MHC restriction (see the discussion of the function of MHC genes) or activation. NK cells lack the cell surface markers present on B cells and T cells. The biological function of the NK cell is uncertain. In view of its *in vitro* function of lysing tumor cells, it may play a role in tumor immunity (Trichincri 1989). NK1+ T cells are a subset of cells sharing characteristics of both NK cells and T cells. They express the «/f> TCR and the NK1.l receptor. These cells are significant because of their ability to secrete large amounts of interleukin-4 (IL-4) in response to TCR stimulation and may play a role in maturation of Th2 cells (see later).

T Lymphocytes

T cells originate from the thymus. Differentiation of T cells occurs in the thymus, and every T cell that leaves the thymus is conferred with a unique specificity for recognizing antigens. T cells that recognize self-antigens are generally either deleted or rendered tolerant within the thymus, a process called central tolerance.

T cells may be divided into two groups on the basis of expression of either the CD4+ or CD8+ marker, Functionally, CD4+ T cells are involved in DTH responses and also provide help for B-cell differentiation (and hence are termed helper T cells). In contrast, CD8+ T cells are involved in class I restricted lysis of antigen-specific targets (and hence are termed cytotoxic T cells). T cells with suppressor activity can express either CD4 or CD8.

T-Cell Receptors

The TCR consists of two glycosylated polypeptide chains, alpha (a) and beta (/3), of 45,000 and 40,000 dalton molecular weight, respectively. This heterodimer of an alpha and beta chain is linked by disulfide bonds. Amino acid sequences show that each chain consists of variable (V), joining (J), and constant (C) regions closely resembling Igs (Figure 45.1). There are about 10^2 TCR-variable genes, grouped by homology into a small number of families, compared with 10^3 or greater for Igs (see later). The principles governing generation of diversity in the TCR are very similar to those for Ig genes. T cells can only recognize short peptides that are associated with MHC molecules. In contrast, the Ig receptor can recognize peptides, whole proteins, nucleic acids, lipids, and small chemicals.

T cells also express a variety of nonpolymorphic antigens on their surfaces. The most abundantly expressed is CD45, comprising 10% of lymphocyte membrane proteins. CD45 exists as a number of isoforms that differ in the molecular weight of their extracellular domains as a result of RNA splicing. These isoforms can be distinguished serologically. The low molecular weight (CD45RO) isoforms define activated, or memory, T-cell populations.

B Lymphocytes

B cells are the precursors of antibody-secreting cells. The cells develop in the bone marrow and during their ontogeny acquire Ig receptors that commit them to recognizing specific antigens for the rest of their lives. B cells normally express IgM on their cell surfaces but switch to other isotypes as a consequence of T cell help, while maintaining antigen specificity (see later). Following antigenic challenge, T lymphocytes assist (help) B cells directly (cognate interaction) or indirectly by secreting helper factors (noncognate interaction), to differentiate and form mature anti body-sec ret ing plasma cells.

Immunoglobulins

Igs are glycoproteins that are the secretory product of plasma cells. Their biochemical structure and genomic organization is shown in Figure 45.1. All Ig molecules share a number of common features. Each molecule consists of two identical polypeptide light chains (kappa or lambda) linked to two identical heavy chains. The light and heavy chains arc stabilized by intrachain and interchain disulfide bonds. According to the biochemical nature of the heavy chain, Igs are divided into five main classes: IgM, IgD, IgG, IgA, and IgE. These may be further divided into subclasses depending on differences in the heavy chain.

Each heavy and light chain consists of variable and constant regions. The amino terminus is characterized by sequence variability in both the light and the heavy chain, and each variable heavy- and light-chain unit acts as the antigen-binding site (the Fab portion). The carboxy terminal of the heavy chain (also known as the Fc portion) is involved in binding to host tissue and in fixing complement. This part of the molecule is important for antibody-dependent, cell-mediated cytotoxicity by cells of the reticuloendothelial system and for complement-mediated cell lysis. Classes of Igs differ in their ability to fix complement. In humans, IgM, IgG1, and IgG3 antibodies are capable of activating the complement cascade.

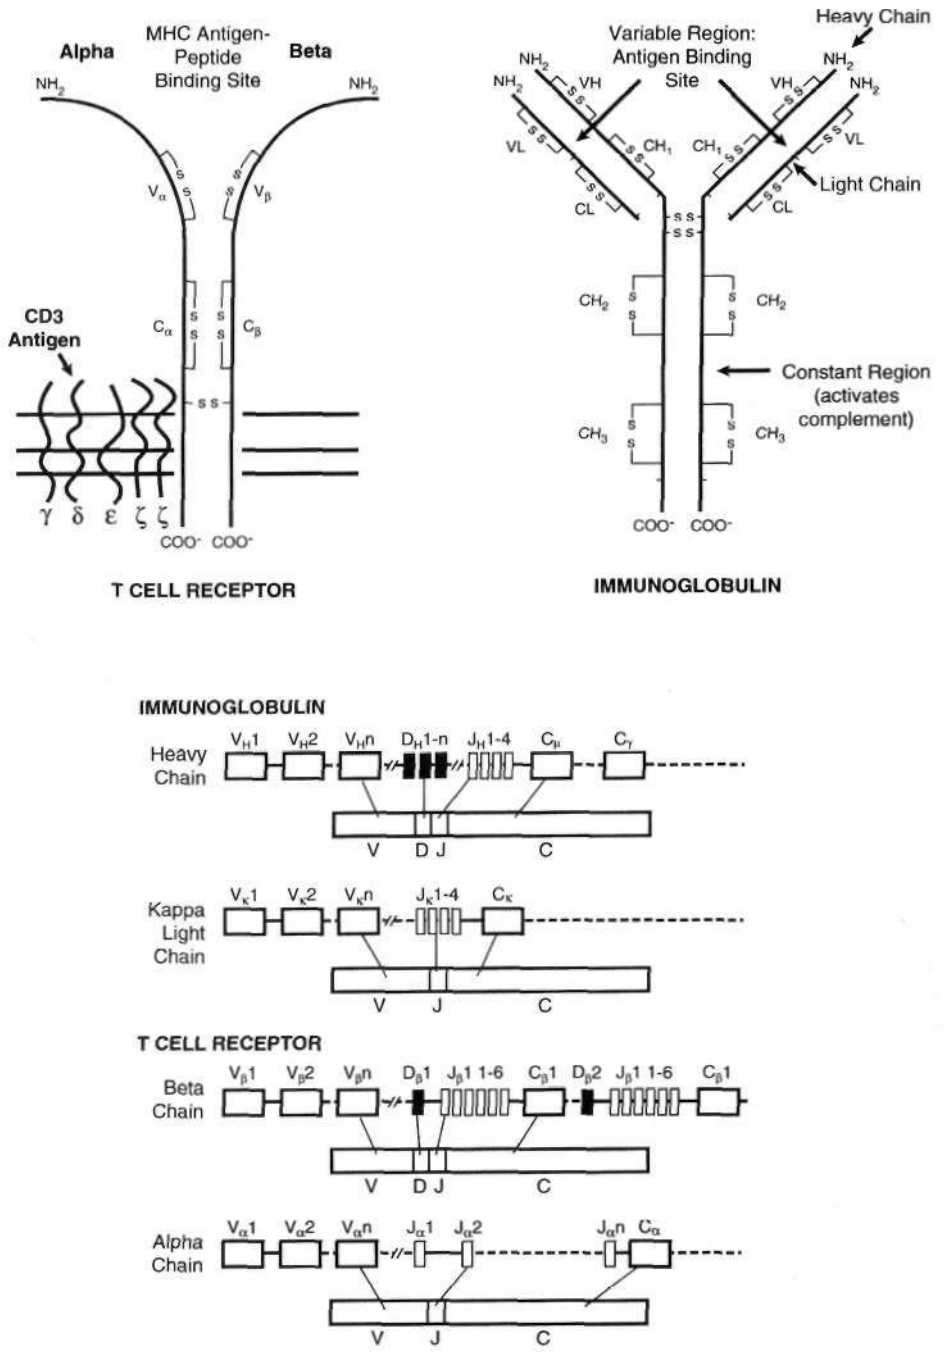

FIGURE 45.1 Molecular and **gl'llCtic** <)[•!•;)IIi/Htioil **()t tilt' Tl_v[l** receptor (TCR) and immunoglobulin (Ig) molecule. (A, B) Structural organization of the TCR and lg molecule. The TCR is a heterodimer consisting of two chains, a and b; the Ig molecule consists of two heavy and light chains. Both molecules are stabilized by interchain and intrachain disulfide bonds. Variable-region domains are located at the amino terminal, and constant-region domains are located on the carboxy terminal. The antigen binding site on the Ig molecule is located between the variable-region domains of the heavy and light chains. The variable region of the TCR recognizes foreign peptides in the context of self-major histocompatibility complex (MHC) molecules. The TCR is also associated with the CD3 antigen (consisting of g, d, e, and z-z chains) to form the TCR complex. (C) Organization of the gene families of Ig and TCR. The common feature of the four gene pools is that they contain a numbet of variable (V) gene segments that are separated from the constant (C) region genes by the joining (J) genes. In the case of the TCR b chain and the Ig heavy-chain gene, additional diversity (D) genes are present. During ontogeny, one of the V gene segments is juxtaposed to the J segment through a process of chromosomal rearrangement to form the V(D)J gene. This, along with the constant region genes, is transcribed to fotm messenger RNA and then protein.

GENETICS OF THE IMMUNE SYSTEM

Antigen Receptor Gene **Rearrangements**

During B- and T-ccll development, multiple gene rearrangements occur to form their respective antigen receptors, the Ig and the TCR. Diversity of the antigen receptors is due to diversity in theit principal components, the variable (V) gene segment and the joining (J) gene segments. One of the many V gene segments is juxtaposed by chromosomal rearrangements with one of the J segments (and when present, with the diversity [D] segment) to form the complete variable region gene, Recombinational inaccuracies at the joining sites of the V, D, and J regions further increase the diversity of the antigen receptors.

Constant (C) gene segments are present in all receptors. The V, D, J, and C gene segments along with the intervening noncoding gene segments between the J and C regions are initially transcribed into mature RNA. Through a process of RNA splicing, the noncoding gene segments are excised and the V(D)JC messenget RNA (mRNA) is

translated into protein. In addition, after binding antigen B cells undergo somatic mutations that increase the diversity and the affinity of antigen binding. This phenomenon does not occut in T cells. During isotypc switching in B cells, futthcr rearrangements lead to recombinarion of the same variable region gene with new constant region genes (see Figure 45.1).

Major Histocompatibility and Human Leukocyte Antigens

MHC gene products or the human leukocyte antigens (HI.As) serve to distinguish self from nonself. In addition, they serve the important function of presenting antigen to the appropriate cells. The MHC class I gene product contains an MHC-cncoded alpha chain, and a smaller non-MHC encoded /^-microglobulin chain. The MHC class II gene product consists of two polypeptide chains, alpha and beta, which are noncovalently linked. Both class I and class II proteins are stabilized by intrachain disulfide bonds. Class I antigens are expressed on all nucleated cells, whereas class II antigens are constitutively expressed only on dendritic cells, macrophages, and B cells and are also expressed on a variety of activated cells, including T cells, endothelial cells, and astrocytes.

In humans, class I molecules are HLA-A, B, and C, whereas the class II molecules are HLA-DP, DQ, and DR. Several alleles are recognized for each locus; thus the HLA-A locus has at least 20 alleles, and HLA-B has at least 40. The number of alleles for the D region appears to be as extensive as that for HLA-A, HLA-B, and HLA-C. In view of the extensive polymorphisms present, the chances of two unrelated individuals sharing identical HLA antigens are extremely low. The reason for the extensive diversity and the evolutionary pressure that lead to this are not fully-understood (Nepom 1991).

Class I antigens regulate the specificity of cytotoxic T cells, which are responsible for killing cells bearing viral anrigens or foreign transplantation antigens (Figure 45.2). The target cells share class I MHC genes with the cytotoxic cell. Thus the cytotoxic cell that is specific for a particular virus is capable of recognizing the antigenic determinants of the virus only in association with a particular MHC class I gene product. The function of class II MHC gene products appears to be to regulate the specificity of T-helper cells,

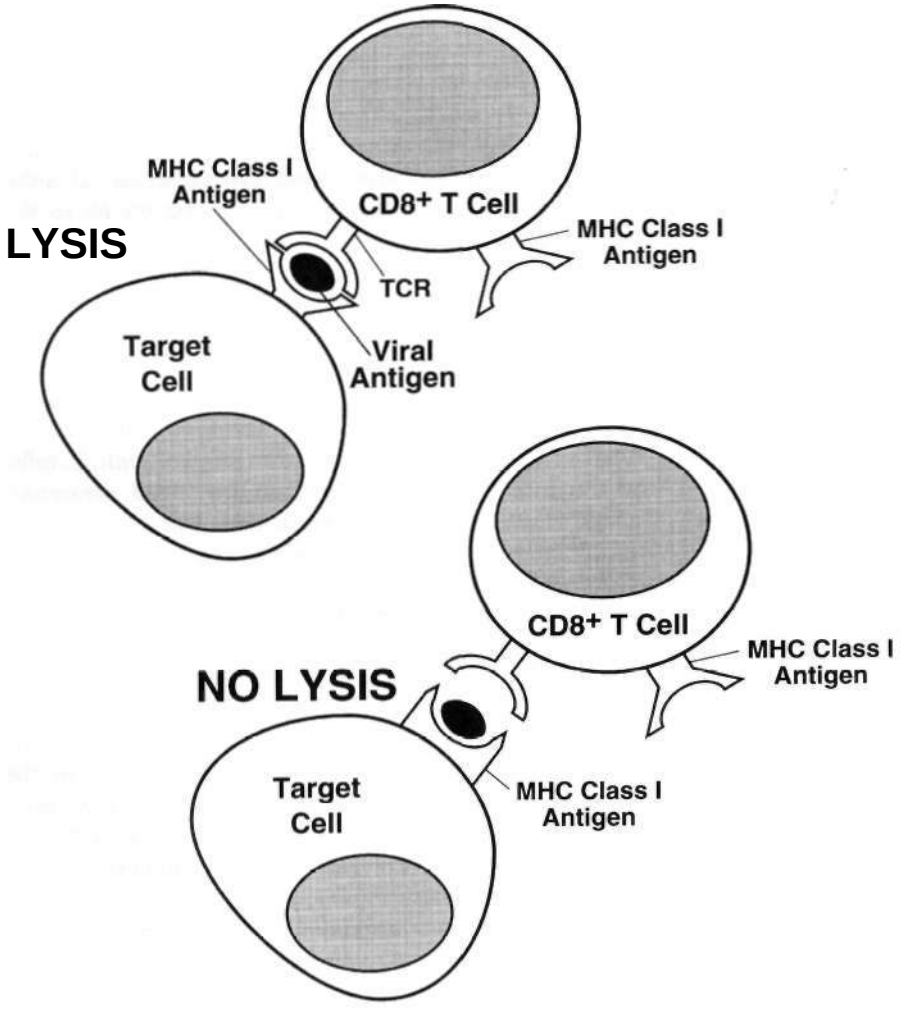

FIGURE 45.2 The phenomenon of major histocompatibility complex (MHC) restriction. For antigen-specific eytolysis of virus-infected targets to occur, T cells should be sensitized to the virus and share the same class I HLA with the target cell. In the lower part of the figure, the MHC class I antigen expressed on the CD8+ T cell is different from the MHC class 1 antigen expressed on the target cell; therefore lysis does not occur. TCR = T-cell receptor.

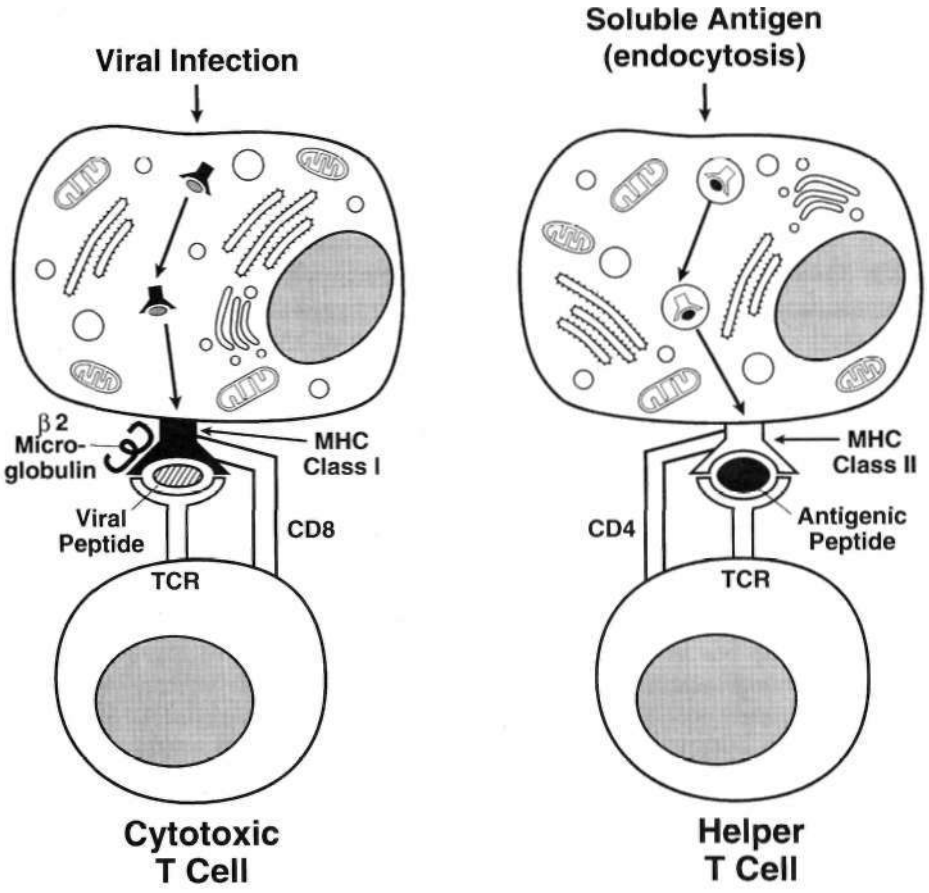

FIGURE 45.3 Antigenic recognition of cytotoxic and helper T cells. The cytotoxic T cell recognizes viral peptides associated with human leukocyte antigen-A (HLA-A), HLA-B, or HI.A-C molecules. The coreceptor for the helper T cell is the CD4 molecule. MHC = major histocompatibility complex; TCR = T-cell receptor.

which, in turn, regulate DTH and antibody response to foreign antigens. Similarly, an immunized T-cell population will recognize a foreign antigen only if it is presented on the surface of an APC that shares the same class II MHC antigen specificity as the immunized T-cell population. Thus the functional specificity of the T-cell population is restricted by the MHC molecules that they recognize. CD8+ T cells (cytotoxic) and CD4+ T cells (helper) are referred to as MHC class I and class II restricted T cells, respectively (Figure 45.3).

The analysis of the three-dimensional structure of the class I and class II molecules has confirmed the notion that these molecules are carriers of immunogenic peptides that are processed by APCs and presented on the cell surface (Figure 45.4), Both MHC class I and class II molecules share similarities in crystal structure that allow them to accept and retain immunogenic peptides in grooves, or pockets, and present them to T cells (Brown et al. 1993).

ORGANIZATION OF THE IMMUNE RESPONSE

Initiation of **the** Immune Response

Antigen Presentation

One of the crucial initial steps in the immune response is the presentation of encountered antigens to the immune system. Antigens are carried from their site of arrival in the periphery by way of lymphatics or blood vessels to the lymph nodes and spleen. There, antigens are then taken up by cells of the monocyte-macrophage lineage and by B cells, processed intracellularly, and presented not as whole molecules but as highly immunogenic peptides.

Accessory Molecules for T-Cell Activation

The interaction of MHC-peptide complex with T cells, although necessary, is insufficient for T-cell activation. Other classes of molecules are involved in T-cell antigen recognition, activation, intracellular signaling, adhesion, and trafficking of T cells to their target organs. The distinction between the functions of these classes of molecules is not absolute, and many may be involved in interactions between other cells of the immune system.

CD3, Molecules whose primary role is signaling include the CD3 molecule. The CD3 molecule is part of the TCR complex. Although the TCR interacts with the MHC-peptide complex on APCs, the signals for the subsequent enactment of T-cell activation and proliferation are delivered by the CD3 antigen. The cytoplasmic tail of the CD3 proteins contains one copy of a sequence motif important for signaling functions, called the immunoreceptor tyrosine-bascd activation motif (ITAM).

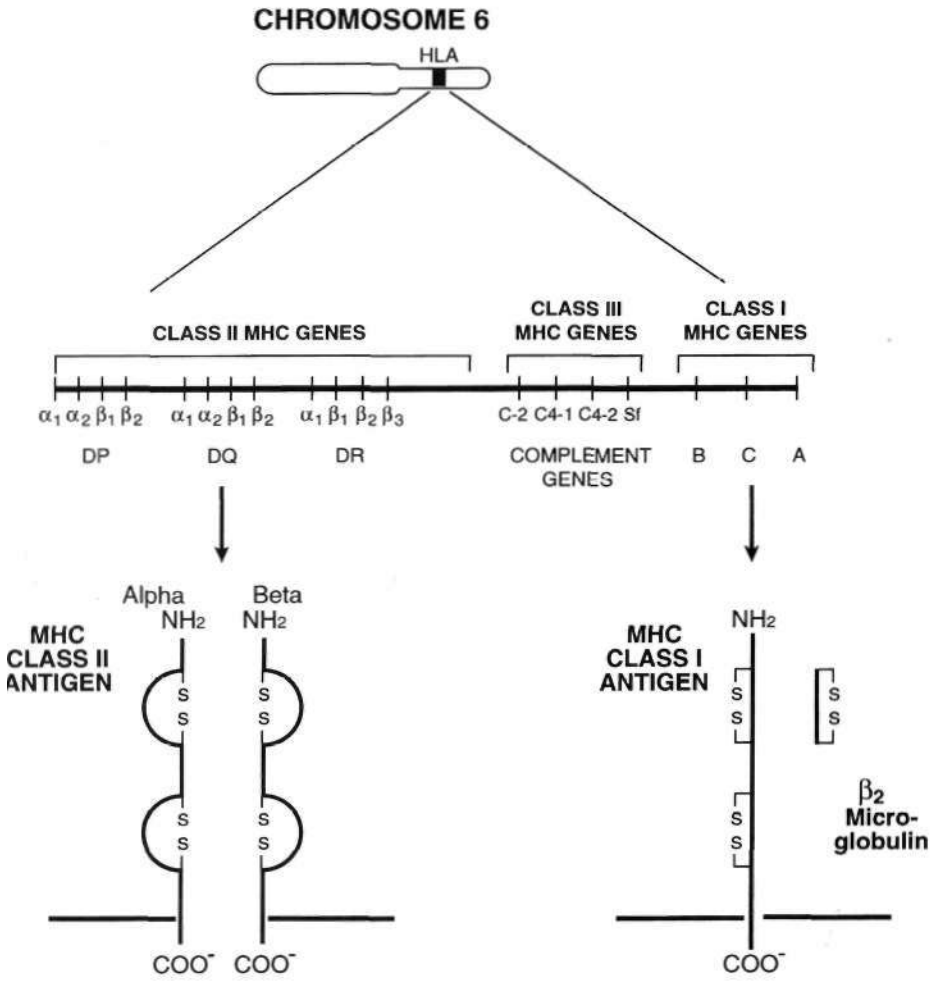

FIGURE 45.4 Schematic diagram tit [In- human leukocyte antigen (HLA) complex in humans, located on chromosome 6. The HLA class 1 gene (HLA-A, -B, and -C) codes for a single heavy-chain molecule. The /^-microglobulin is coded by genes on a different chromosome. The HLA class II genes (DR, DP, and DQ) form the a-b heterodimer. The HLA class 111 genes include those encoding for members of the complement family of proteins. MHC = major histocompatibility complex.

Phosphorylation of the ITAM initiates intracellular signaling events. In experimental situations, anti-CD3 antibodies can nonspecifically activate these intracellular signals, producing activated T cells in the absence of antigen.

CD4 and CD8. CD4 or CDS antigens are expressed on mature T cells and serve an accessory role in signaling and antigen recognition. CD4 binds to a nonpolymorphic site on the MHC class II beta chain, and CDS binds to the alpha-3 domain of the MHC class I molecule. Signals for cell division that are delivered to the nucleus are mediated by second messengers. When the receptor binds its ligand, it causes the activation of protein kinases. These kinases add phosphate groups to other proteins that ultimately signal the cell to divide. CD4, CD8, and CD3 on T cells and CD19 on B cells are examples of receptors that are linked to kinases. CD4 is the cell surface receptor for human immunodeficiency virus (HIV-1), and the fact that certain non-T cells, such as microglia and macrophages, can express low levels of CD4 may explain the propensity of the virus for the central nervous system (CNS).

Costimulatory Molecules. Other molecules required for costimulation in T-cell activation are B7-CD28; CD40-CD154; the integrin families that include vascular cell adhesion molecule 1 (VCAM-1), intercellular adhesion molecule (ICAM-1), and leukocyte function antigen 3 (LFA-3); CD45; and CD2. The integrin family also mediates T-ccll adhesion, facilitates interaction with the APCs, mediates adhesion to nonhematopoietic cells such as endothelial cells, and guides cell traffic. Other molecules primarily involved in cell migration into tissues, are CD-44, L-selectin, and matrix metalloproteinases (MMPs) (Figure 45.5). L-Selectin facilitates the rolling of leukocytes along the surface of endothelial cells and functions as a homing receptor to target peripheral lymphoid organs. The MMPs are a family of proteinases, secreted by inflammatory cells, that digest specific components of the extracellular matrix. MMPs facilitate lymphocyte entry through basement membranes and are the principal pathway through which T-cclls enter the CNS. In addition, MMPs may cleave the membrane-bound form of tumor necrosis factor-alpha (TNF-a), facilitating the secretion of this cytokine. Chemokines

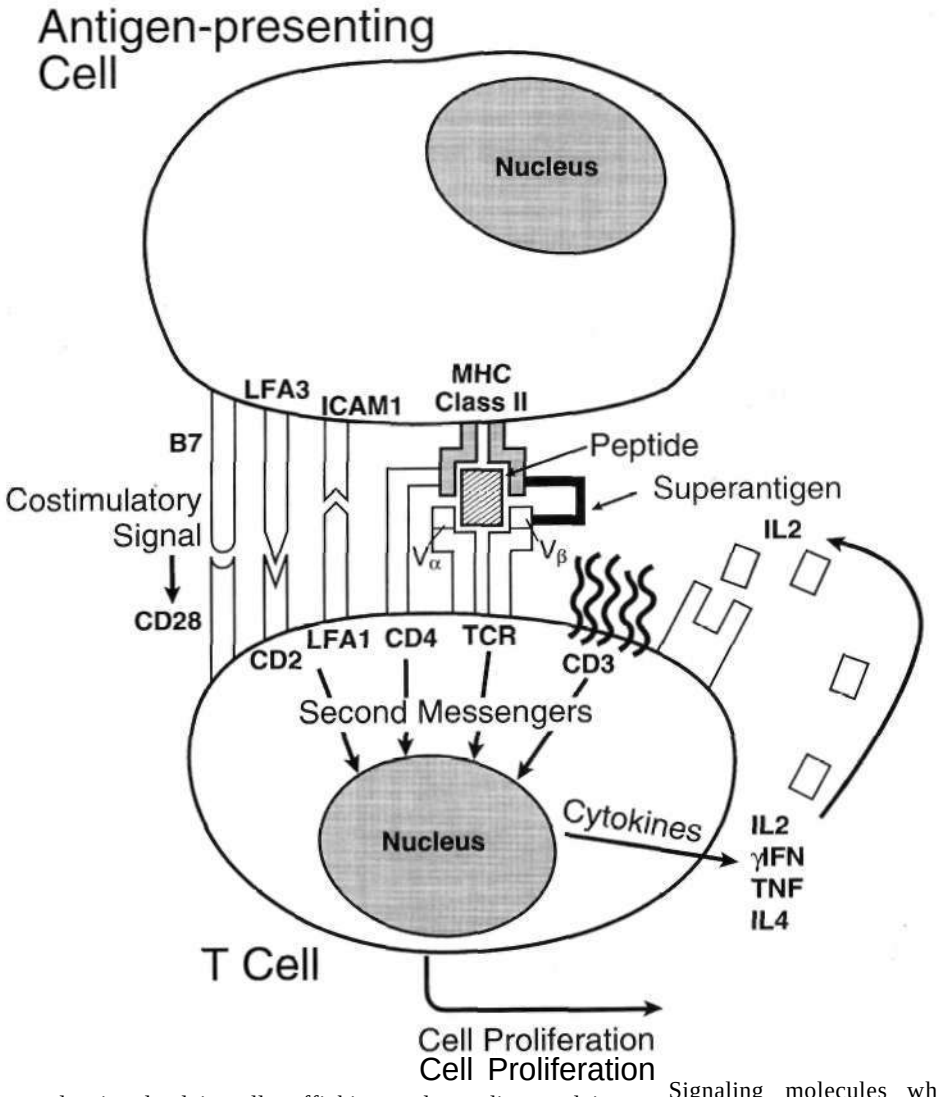

FIGURE 45.5 Antigen-driven activation of helper T cells. Proliferation of T cells requires the delivery of a number of concordant signals. Along with stimulation through the T-cell receptor-CD3 complex, the presence of appropriate costimulatory signals via CD28 antigen, adhesion molecules, leukocyte function antigen 1 (LFA1) and CD2, and the coreceptor molecule CD4 are essentia) for T-cell activation and proliferation. The membrane events ⊱t anriiteu recognition lead to acti vation of second messengers. The second messengers signal the nucleus and cell to divide and secrete cytokines. lntcrleukin-2 (IL-2) acts as an autocrine growth stimulator, thereby amplifying the response. lFN-y = interferon gamma; MHC = major histocompatibility complex; TCR = T-cell receptor; TNF = tumor necrosis factor.

Cell Proliferation

are also involved in cell trafficking and are discussed in a separate section.

The B7-CD28 interaction is one of the most extensively studied costimulatory systems. The B7 molecules arc expressed on antigen presenring cells, and their expression is induced in activated cells. There are two forms of B7, B7-1 (CD80) and B7-2 (CD86), that share some homology but have different expression kinetics. The B7 molecules interact with their ligand CD28, which is constitutively expressed on most T cells. Rinding of the CD28 molecule mediates intracytoplasmic signals that increase expression of the growth factor IL-2 and enhance expression of the anti-apoptotic molecule Bcl-x_L. An alternate ligand for B7 is CTLA-4, which is homologous to CD28 in structure, but in contrast to CD28 functions to inhibit T-cell activation. CTLA-4 is upregulated after T-cell activation and serves to downregulate the immune response.

Accessory Molecules for B-Cell Activation

Like T cells, B cells require accessory molecules that supplement signals mediated through cell-surface Igs. Signaling molecules whose functions arc likely to be analogous to CD3 are linked to Ig. Unlike T cells that may only respond to peptide antigens, B cells can respond to proteins, peptides, polysaccharides, nucleic acids, lipids, and small chemicals. B cells responding to peptide antigens are dependent on T-cell help for proliferation and differentiation, and the antigens are termed thymus-dependent (T-depcndent). Nonprotein antigens do not require T-ccll help to induce antibody production and are therefore T-inde pen dent.

The interaction between B cells and T-hclper (CD4+) cells requires expression of MHC class II by B cells and is antigen dependent. In addition, a number of other molecules mediate adhesion between T and B cells and induce signaling for B-cell activation. These include B7 expressed on B cells interacting with CD28 on T cells and CD40 on B cells interacting with CD 154 . Interaction of 1 - helper and B cells occurs in the peripheral lymphoid organs, initially in the primary follicles and later in the germinal centers of the follicle. Activation of B cells induces activation of transcription factors (c-Fos, JunB, Wl-'&B, and c-Myc), which in turn promote proliferation and Ig

secretion. Cytokines elicited from the T-helper cell induce isorype switching in B cells, producing stronger and long-lived memory responses, in contrast to weak IgM responses to T-independent antigens.

Further generation of high-affinity antibody producing B cells and memory B cells occurs in the germinal center of lymphoid follicles, through a process called affinity maturation. As the amount of available antigen lessens, B cells that do not express high-affinity receptors for antigen are eliminated by apoptosis. Some B cells lose the ability to produce Ig but survive for long periods and become memory B cells.

Regulation of the Immune Response

Cytokines

Cytokines play a major role in the regulation of the immune response. Cytokines are broadly divided into the following categories, which are not mutually exclusive: (1) growth factors: II-1, II.-2, IL-3, and IL-4 and colony-stimulating factors; (2) activation factors, such as interferons (alpha, beta, and gamma, which are also antiviral); (3) regulatory or cytotoxic factors, including IL-10, IL-12, transforming growth factor-beta (TGF-$), lymphotoxins, and tumor nectosis factor-alpha (TNF-a); and (4) chemokines that are chcmotactic inflammatory factors, such as IL-8, MIP-1K, and MIP-l/J.

Cytokines are necessary for T-celi activation and for the amplification and modulation of the immune response. A limited representation of the cytokines that participate in the immune response is shown in Table 45.2. Secretion of IL-1 by macrophages results in stimulation of T cells. This leads to synthesis of IL-2 and IL-2 receptors and finally to the clonal expansion of T cells. Only activated T cells express the IL-2 receptor; therefore the cytokine induced expansion favors antigen-activated cells only. T-cell activation causes secretion of interferon-gam ma (IFN-j/), which induces expression of MHC class I and class II molecules on many cell types including APCs. This in turn increases the T-cell response to the antigen. Secretion of IL-2 also results in activation of NK cells that mediate lysis of tumor cell targets. In addition, IL-3 is released, resulting in stimulation of hematopoietic stem cells. The signal for differentiation of B cells to form antibody-secreting cells involves clonal expansion and differentiation of virgin memory B cells, IL-4 and B-cell differentiation factors secreted by T cells induce differentiation and expansion of committed B cells to become plasma cells.

IFN-w and IFN-/J are both type I interferons. IFN-a is produced by macrophages, whereas IFN-^l is produced by fibroblasts. Both inhibit viral replication by causing cells to synthesize enzymes that interfere with viral replication. They also can inhibit the proliferation of lymphocytes by unknown mechanisms.

Although the emphasis has been on factors that cause expansion and differentiation of lymphocytes, there are cytokines that can downregulate immune responses. Thus IFN-a and IFN-^, in addition to possessing antiviral properties, can modulate antibody response by virtue of their antiproliferative properties. Similarly, TGF-/3 (a cytokine produced by T cells and macrophages) can also decrease cell proliferation. IL-10, a growth factor for B cells, inhibits the production of *lYN-y* and thus may have anti-inflammatory effects.

CD4+ T-helper cells differentiate into Th I or Th2 phenotypes, which secrete characteristic cytokines, and stimulate specific functions. Thl cells secrete IFN-j/, IL-2, and TNF-a. These cytokines exert proinflammatory functions and, in Thl-mediated diseases such as MS, promote tissue injury. IL-2, TNF-a, and IFN-y mediate activation of macrophages and induce 1)111, l'h 1 cell differentiation is driven by IL-12, a cytokine produced by monocytes and macrophages. In contrast, the Th2 cytokines IL-4, IL-5, IL-*6*, IL-10, and IL-13 promote antibody production by B cells, enhance eosinophil functions, and generally suppress CMI. Th3 cells secrete TGF-/S, which inhibits proliferation of T cells and inhibits activation of macrophages. Cytokines of the Thl type may inhibit production of Th2 cytokines and vice versa.

Chemokines

Chemokines are a recently discovered and extensively studied group of molecules that aid in leukocyte mobility and directed movement. Chemokines may be grouped into two subfamilies based on the configuration and binding of the two terminal cysteine residues. If the two residues participating in disulfide bonding are adjacent, they are termed the C-C family (e.g., MCP, MlP-la, RANTES). Those separated by one amino acid, are C-X-C family members (e.g., IL-8), where X indicates a nonconserved amino acid. An important recent discovery is that two chemokine receptors, CCR-5 and CXCR-4, can act as coreceptors for strains of HIV. Chemokines are produced by a variety of immune and nonimmune cells. Monocytes, T cells, basophils, and eosinophils express chemokiiu' receptors, and these receptor ligatid interactions are critical to the recruitment of leukocytes into specific tissues,

Termination of an Immune Response

The primary goal of the immune response is to protect the organism from infectious agents and to generare memory T- and B-cell responses that provide accelerated and high-avidity secondary responses on re-encounteting antigens. It is desirable to terminate these responses once an antigen has been cleared. In parallel, the immune system must constantly function to prevent autoimmune activation

Table 45.2: An abridged list of cytokines involved in interactions between the immune and nervous systems

Cytokine	*Cell source*	*Cells principally affected*	*Major functions*
IL-I	Most cells; macrophages, microglia	Most cells; T colls, microglia, astrocytes, macrophages	Costimulates T- and B-cell activation Induces **11.-6,** promotes IL-2 and IL-2R transcription Endogenous pyrogen, induces sleep
II.-2	T cells	T cells, NK colls, B cells	Growth stimulation
IL-3	T cells	Bone marrow precursors for all cell lineages	Growth stimulation
IL-4	T cells	B cells, T cells, macrophages	MHC II uprcgulation Isotypc switching (IgGl, IgE)
IL-6	Macrophages, endothelial cells, fibroblasts, T cells	Hepatocytes, B cells, T cells	Inflammation, costimulates T-cell activation Ml *K.* I uprcgulation, increases vascular permeability Acute phase response (Schwartzman reaction)
1L-10	Macrophages, T cells	Macrophages, T cells	Inhibition of lFN-y, TNF-o, **IL-6** production Downregulation of MHC expression (macrophages)
II.-12	Macrophages, dendritic cells	T cells, NK cells	Costimulates B-cell growth, $CD4^+$ Thl cell differentiation, IFN-y synthesis, cytolytic function
Interferon-^, interferon-^	Many cells; leukocytes, macrophages	Many cells, macrophages	Inhibits proliferation, viral replication Downregulates MHC I Inhibits cytokine production
Interferon-/	T cells, NK cells	Astrocytes, macrophages, endothelia, NK cells	MHC I and II expression Induces TNF-or production, isotype switching (IgG_{2n}) Synergizes with TNE-a for many functions
TNF-t(	Macrophages, microglia (T cells)	Most cells, including oligodendrocytes	Cytotoxic (e.g., for oligodendrocytes), lethal at high doses Upregulates MHC, promotes leukocyte extravasation Induces IL-1, IL-6, cachexia; endogenous pyrogen
Lymphotoxin (TNF-/J)	T colls	Most cells (shares receptor with TNF-a)	Cytotoxic (at short range Or through contact) Promotes extravasation
TGF-jS	Most cells; macrophages, T cells	Most colls	Pleiotropic, antiproliferative, anticytokine Promotes vascularization, healing

IFN = interferon; Ig = immunoglobulin; IL = interleukin; MHC major histocompatibility complex; NK = natural killer; TGF = tumor growth factor; TNE = tumor necrosis factor.

and maintain self-tolerance. A number of systems operate to prevent uncontrolled responses. Here we discuss the termination of individual components of the immune response. Following is a discussion of the mechanisms that maintain self-tolerance, many of which are also involved in immune-response termination.

B-cell Inhibition

In most instances, an antigen is cleared either by cells of the reticuloendothelial system or through the formation of antigen-antibody complexes. These complexes can themselves result in the inhibition of B-cell differentiation and

proliferation through binding of the Fc receptor to the CD32 (FcyRU/S) receptor on the surface of the B cell.

Immunoglobulin

The variable region of the lg and the TCR molecule represent novel proteins that can act as antigens. Antigenic variable regions are called idiotopes, and responses against such antigens are called anti-idiotypic. Niels Jerne's network hypothesis postulates that anti-idiotypic responses serve to regulate the immune response; however, the extent to which this operates is unclear.

T Cells

Termination of the T-ccll immune response is mediated by several mechanisms including anergy, deletion, and suppressor cell activity. Anergy or functional unresponsiveness occurs when there is insufficient T-cell activation. Repeated stimulation of T cells may lead to activation induced cell death through apoptosis. Cytokine-mediatcd regulation can also serve to terminate the immune response notably by secretion of Th2 and Th3 cytokines. Suppressor cells generally inhibit the immune response through secretion of cytokines, through cytotoxic mechanisms, or by modulation of the function of APCs. A combination of these mechanisms cooperate to maintain self-tolerance, particularly peripheral tolerance, and are discussed later.

SELF-TOLERANCE

An organism's ability to maintain a state of unresponsiveness to its own antigens is termed self-tolerance. Self-tolerance is maintained through three principal mechanisms: deletion, anergy, and suppression. Self-tolerance may he broadly categorized as either central or peripheral tolerance. Similar mechanisms may also be used to induce tolerance to a foreign antigen or to terminate an immune response.

Central Tolerance

Bone marrow stem cells migrate to the thymus, thereby becoming thymocytes, or T cells. In this location, T-cell VDJ germline genetic elements recombine to create *a* and *fi* chains, which in turn form the TCR. Thymocytes then undergo a process of education that involves positive and negative selection. Positive selection of thymocytes occurs in the thymus cortex when the cells are in the double negative stage, CD4— CDS—. The cortex contains dendritic and epithelial cells that present MHC antigens to the developing thymocytes. T cells with receptor having no affinity to MHC will fail to receive signals needed for maturation and will die *in situ.* Those with low affinity toward MHC survive *Mid* become single-positive thymocytes depending on their affinity toward MHC] I (CD8+) or MHC II (CD4+). In the thymus medulla, thymocytes that display a high affinity toward self-antigen are deleted by apoptosis, a process called negative selection. Most T-ceil education occurs in the thymus; however, extra-thymic sites may exist.

Peripheral Tolerance

Self-reactive lymphocytes may escape central tolerance; therefore peripheral mechanisms exist to maintain self-tolerance. This is termed peripheral tolerance. Peripheral tolerance is maintained through clonal anergy or clonal deletion. It is not clear to what extent each of these mechanisms functions in maintaining human self-tolerance; however, extensive research has been done to elucidate the mechanisms through which anergy and deletion work. In addition, self-tolerance may be maintained despite the presence of antigen-responsive lymphocytes. It is postulated that this is due to the presence of suppressor T cells or other factors, which may interfere with a successful lymphocyte response.

Anergy Due to Failure of T-cell Activation

In normal circumstances, an APC presents antigen as a peptide + MHC complex (signal one). In the absence of signal one, the T cell dies because of neglect. If signal one is presented in the absence of cosrimulaiory signals (signal two), the T cell becomes anergic. An example of this situation occurs when an antigen is presented by non-professional APCs that lack the appropriate costimulatory molecules (figure 4.S.6}. However, when a T cell gets activated, it upregulates the expression of an alternate costimulatory molecule, CTLA—4 . CTLA4 engagement by CD SO and CD86 on the surface of APCs sends a negative signal to the T cell, inhibiting cell growth and proliferation. Animals deficient for CTLA—4 expression on their T lymphocytes have an uncontrolled lymphoproliferative phenotype with auto re activity (Waterhouse et al. 1995).

Apoptosis

Apoptosis is the process in which a cell undergoes programmed cell death. As opposed to necrosis when interruption of the supply of nutrients triggers cell death, apoptosis may be triggered by various signals including withdrawal of growth factors, cytokines, exposure to corticosteroids, and repeated exposure to antigens. Mediators of apoptosis include the *Bel* family of genes, which are mostly antiapoptotic, and the *Fas* family of genes, which are proapoptotic. Activated T cells also express Fas ligand (CD95L or FasL) and Fas (CD95); ligation of Fas and FasL induces apoptosis of the T cells.

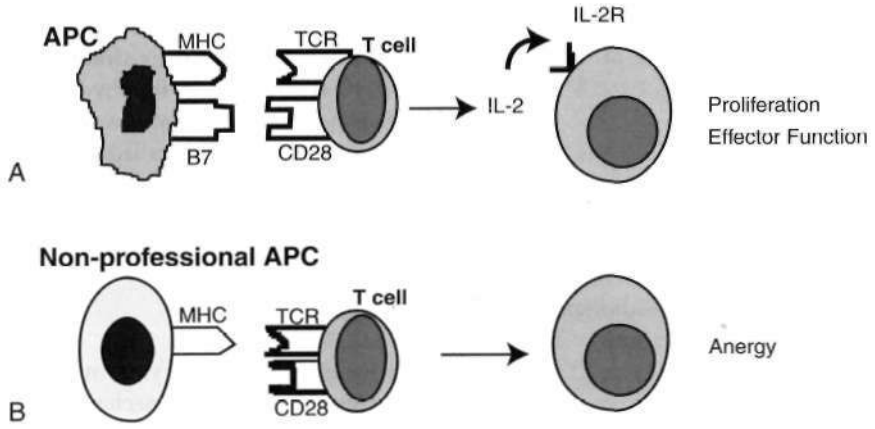

FIGURE 45.6 A two-signal model of Tcell activation. Activation of the Tcell receptor (TCR) by an antigen-major histocompatibility complex (MHC) provides signal 1, which is sufficient to induce the T cell to enter the cell cycle and begin blast transformation, which is characterized by an increase in cell size. Signal 2, the costimulatory signal, can be provided to the T cell through interaction of CD28 with molecules of the R7 family found on the surface of bone-marrow-derived antigen-presenting cells (APCs). In this instance (A), TCR signals are complemented, enabling the T cell to proliferate, produce cytokines, and develop mature effector functions. In the absence of a second signal, T-cell activation is abortive, and the cell becomes anergic {B). Signal 2 might not be delivered if the APC does not express a costimulatory ligand on its surface, perhaps because a nonprofessional APC, such as an epithelial cell, is presenting antigen (B). IL = interleukin.

Repeated stimulation with an antigen may also induce apoptosis via the Fas/FasL pathway, a process termed *activation-induced cell death* (AICD). Therefore an autoreactive T lymphocyte may encounter large doses of self-antigen in the periphery and consequently may be deleted by AICD. Mice lacking Fas or FasL develop a lupus-like syndrome (Zhou et al, 1996), and mutations in the Fas gene were associated with an autoimmune disease with lymphoproliferation in humans (Drappa et al. 1996).

IL-2 is the prototypical growth factor, inducing clonal expansion of antigen-stimulated lymphocytes. However, paradoxically, disruption of the IL-2 gene leads to accumulation of activated lymphocytes and autoimmune syndromes (Sadlack ct al. 1993). This is because IL-2 induces the transcription and surface expression of Fas ligand (FasL). Interactions of Fas with FasL lead to cell death (Figure 45.7). Therefore IL-2 plays a dual role in T-cell regulation, reflecting a possible role for cytokine concentration and timing of exposure. Othet cytokines that mediate apoptosis and cell death are TNF-o; and IFN-y. Complete absence of either of these cytokines results in deficient T-cell apoptosis, inability to terminate the immune response, and uncontrolled autoimmune disease.

Suppressor T cells

Suppressor T cells function to downregulate CD4 and CDS T cell responses. T-suppressor cells can be of the CD4+ or CD8-F subtypes. Suppressor cells have been found in several animal models of disease, and some are antigen specific. *In vitro* they can be generated under similar conditions used to generate anergic cells, and it has been postulated that they ate the same entity (Lombardi et al. 1994). Suppressor T cells may mediate supptession through the production of modulating cytokines (Th2 or TGF-/3}, via cell-cell contact and expression of negative regulatory molecules (CTLA-4), or through other mechanisms that are currently being explored. In humans, there is little evidence for antigen-specific suppressor cell responses. MS patients have been found to have fewet CD4+ CD25+ cells than normal controls, suggesting that suppressor cells may play a role in modulating this disease.

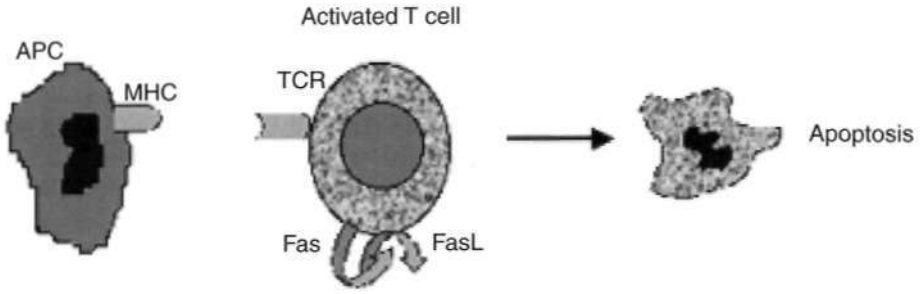

FIGURE 45.7 Activation of the T cell leads to coexpression of the death receptor Fas (f ~,*D95)* and its ligand (FasL), resulting in death of the cell and of the neighboring cells. APC = antigen-presenting cell; MHC = major histocompatibility complex; TCR = T-cell receptor.

THE IMMUNE SYSTEM AND THE CENTRAL NERVOUS SYSTEM

Immunological reactions in the CNS differ from those in the rest of the body because of its unique architecture, cellular composition, and molecular expression. The CNS has been tetmed an *immunologically privileged site* because of the relative improved survival of allografts within this region. Indeed, the same factors that play a role in immunological tolerance in the CNS play a tolc in immune-mediated diseases involving the CNS, infections of the CNS, tumor survival, and therapies.

Important factors relevant to immunological tesponscs in the CNS are as follows: (1) absence of lymphatic drainage, limiting the immunological circulation; (2) the blood-brain barrier (BBB), which limits the passage of immune cells and factors; (3) the low level of expression of MHC factors, particularly MHCII in the resident cells of the CNS; (4) the lack of potent APCs, such as dendritic or Langerhans' cells; and (5) the presence of immunosuppressive factots such as TGF-/3 (Wilbanks and Streilein 1992).

Because of the lack of a lymphatic system, antigens drain along perivascular spaces. Monocyte-derived CNS resident cells play an important role in immune surveillance in these areas. Using bone marrow chimeras, it has been demonstrated that perivascular microglia are derived from bone marrow macrophages (Hickey and Kimura 1988). Other subclasses of microglia include parenchymal microglia and monocytes of the meninges.

The BBB is composed of tight junctions between endothelial cells and a layer of astrocytic foot processes that prevent entry of inflammatory cells and other factors into the CNS. Entry of inflammatory cells across the BBB is facilitated by up regulation of adhesion molecules, [CAM-1 and VCAM-1 on endothelial cells. T cells must be activated before crossing the BBB. Entty is facilitated by expression of receptots for adhesion molecules, including alpha-4-integrin,

The CNS houses cells that arc capable of antigen-presentation under certain conditions *in vitro,* but to what extent this occurs *in vivo* remains under debate. In the CNS, endogenous expression of MHC class I and class II on APCs, such as microglia, is low and in oligodendrocytes and astrocytes it is almost undetectable. Neurons express MHC class I only when damaged and in the presence of IFN-y (Neumann et al. 1995). Expression of MHC antigens on both microglia and astrocytes are enhanced by the presence of cytokines, TNF-a, and IFN-y (Zajiceck 1992). Under inflammatory conditions, microglial cells are likely to be the principal APCs in the nervous system {Perry 1994).

Immune privilege in the CNS is influenced by the previously discussed factors. A series of studies have demonstrated that immune privilege also exists in the anterior chamber of the eye, which shares many of the characteristics of the CNS. Anterior chamber immune privilege is due in part to expression of TGF-jS in the aqueous of the eye. In the CNS, TGF-0 is produced by astrocytes and microglia and may play a role in down-regulating immune responses locally. Increased expression of Fas ligand in the CNS compared with the peripheral nervous system (PNS) may increase apoptosis of T cells, thereby downregulating the immune response (Moalem eral. 1999).

Some CNS tumors express large amounts of TGF-^S, which may play a role in protecting them from immune surveillance. CNS tumors may also express Fas or Fas ligand, again protecting them from immune surveillance.

Cells of the CNS not only respond to inflammatory stimuli but are also capable of secreting cytokines. Neural cells also secrete cytokines, often directly under the influence of lymphocytes. Microglia produce TNF-a and IL-1. Astrocytes secrete cytokines and are also influenced by IL-1 and interferons to divide and express proteins such as costimulatory molecules on their surfaces. These observations lead to the conclusion that the brain is not an immunologically sequestered organ but that it interacts, produces immunologically active factors, and is closely involved with the systemic immune response.

PUTATIVE MECHANISMS OF HUMAN AUTOIMMUNE DISEASE

Why does autoimmune disease occur? It largely results as a culmination of interactions between genetic predisposition, environmental factors, and failure of self-tolerance maintenance mechanisms. Some diseases such as MS arc termed *immune mediated,* because no definitive autoantigen has been demonstrated. Other diseases are clear cases of molecular mimicry such as Gd1b mediated axonal neuropathy, in which the self-antigen attacked by the immune system is similar to that of an environmental antigen (in this case the Penner 0:19 serotype of *Campylobacter jejuni).* Thus autoimmune diseases may be mediated by heterogeneous mechanisms, and in some cases more than one mechanism may be operating.

Autoimmune diseases may be classified as T- or B-cell mediated. Some, such as myasthenia gravis (MG), are mediated through a combination of both. In many B-cell mediated diseases, an autoantigen has been identified, to which the B cell produces autoantibodies. Examples ate MG, in which sera from patients contain antibodies to the alpha subunit of the TCR, and Lambert-Eaton syndrome in which symptoms ate caused by antibodies targeting calcium channels. In contrast to T-ce 11-media ted diseases, identification of autoantigens in antibody-mediated diseases may be easier, because B cells react to whole proteins, whereas the determinants recognized by T cells tend to be APC-proccsscd small peptides of 10-20 amino acids. Thus for T-cell-mediated diseases such as MS, inflammatory demyclinating polyneuropathy, and polymyositis (PM) there is little evidence demonstrating a causal relationship

between an autoantigen and autoimmune disease. In addition, T-cell reactivity to autoantigens does not necessarily guarantee disease, because auto re activity to some self-antigens is seen in healthy individuals. Thus the only conclusive evidence that can indicate causality between an antigen and T-cell-mediated autoimmune disease would be the reversal of the disease process by removal of the putative autoreactive T-cell repertoire. Although this has been feasible in some animal models, establishing the efficacy of such a strategy is difficult in most human T-cell-mediated diseases.

Genetic Factors

Genetics plays a role in susceptibility to autoimmune diseases. In particular, an association between certain MHC haplotypes and disease has been noted. MS is linked to the HI.A-DR2 allele, and the relative risk of having this allele in the Northern European population is 3.8. MG has been linked to HLA-DR3. However, the presence of the allele docs not guarantee disease. In general, the relative risk of developing disease among individuals who carry the antigen may be calculated by the following formula:

Number of patients carrying the HLA antigen	number of controls lacking the antigen
Number of patients lacking the HLA antigen	number of controls carrying the antigen

Association of a particular HLA haplotype with autoimmune disease may be due to the ability of a patticular MHC molecule to bind and present autoantigen to the T cell. Conversely, if an MHC molecule does not bind a particular self-antigen in the thymus, the developing T cell will not recognize that antigen as self and will escape negative selection. Therefore certain MHC haplotypes have an association with disease, whereas others protect against disease. Disease linkage tends to be with class II genes of the MHC rather than class I, suggesting a key role for T-cell autoimmunity.

Association of a particular HLA-haplotype with disease may be due to its linkage to another locus or disease susceptibility gene. Linkage disequilibrium refers to the increased chance of inheriting two alleles together because they are genetically linked as opposed to inheriting them together as separate random events.

One of the most obvious genetic factors associated with autoimmune disease is sex. Recently, much attention has been focused on the role of sex hormones in regulating the immune system. Many autoimmune diseases arc more frequent in females; systemic lupus erythematosus (SLE) is 10 times more common in women, and MS twice as common in females. Evidence from animal models has shown that females are more resistant to infections and reject foreign skin grafts sooner than their male counterparts. This is especially true during periods of high estrogen availability. Estrogen levels decrease after ovulation or during pregnancy, with a progesterone surge. The lowering of estrogen ensures immunological toletancc toward the sperm and subsequently toward the fetus. Therefore estrogen's effects on the immune system may predispose women toward autoimmune diseases. This is reflected in experimental disease models of autoimmunity. Only female (NZB X NZW)F1 mice develop the SLE-like disease, and this is abrogated by androgen treatment. Similarly, in experimental autoimmune encephalomyelitis (EAE) the experimental model fot MS, female SJL mice are more susceptible to disease induction and are protected with testosterone (Dalai et al. 1997).

Failure of self-tolerance mechanisms may lead to autoimmune disease, and this has been seen in experimental models. In particular, Fas and FasL knockout mice develop a severe systemic autoimmune disease resembling SLE. Fas or FasL abnormalities have not been identified in SLE but have been described in a rare lymphoproliferative syndrome (Drappa et al. 1996). Ir is not known to what extent failure of self-tolerance may contribute to autoimmunity.

Environmental Factors

Environmental factors may play a role in the pathogenesis of autoimmune diseases. Molecular mimicry is one of the mechanisms implicated. In this situation, an environmental antigen resembling a self-antigen elicits an immune response ro both itself and the sclf-antigcn. The environmental antigen involved in molecular mimicry may be a supcrantigen. Superantigens have the property of stimulating all T cells that express a given TCR variable gene family, regardless of their exact specificity, because of direct TCR-superantigen intctaction (Dellabona et al. 1990). They are usually of bacterial or viral origin and bind as intact molecules to MHC.

In many cases of molecular mimicry, the environmental antigen is a pathogen, and autoimmune disease follows the pathogen-caused disease. The classic example of this is strcptococcal-induced endocarditis. Neurological diseases caused by this mechanism include streptococcal-induced chorea, Gdlb axonal neuropathy, and the anti-Hu paraneoplastic syndrome. Molecular mimicry has been implicated in many neurological diseases. However, thus far, a definitive pathogen has yet to be identified in MS and chronic inflammatory demyelinating polyneuropathy. Difficulty in identifying the disease-causing pathogen may be partially due to the chtonicity of these diseases, and the original autoantigen may have already disappeared.

It is possible that once an inflammatory reaction proceeds, the tissue injury may expose other self-antigens that wete previously unrecognized by the immune system.

For unknown reasons, peripheral tolerance mechanisms may fail, and an autoimmune reaction ensues. If an autoimmune reaction spreads from one antigen to another by this mechanism, this is termed *determinant spreading* or *epitope spreading.* Epitope spreading may play a role in perpetuating immune-mediated reactions and therefore in causing chronic diseases.

DISEASES IN NEUROIMMUNOLOGY

Immune-mediated disorders occur at all levels of the nervous system. Disotdcrs of the CNS and PNS, including the peripheral nerve, neuromuscular junction, and muscle have been described. Some of these disorders are clearly autoimmune, in that a cleat autoantigen has been identified, whetcas others are immune mediated. In this section, we identify neurological immune-mediated diseases and highlight immunological features pertinent to pathogenesis and treatment. A full description of each disease may be found in the appropriate sections ot tins book.

Multiple Sclerosis

MS is a heterogeneous disease and is characterized by neurological deficits disseminated in time and space. It is a major cause of disability in the adult population in North America. Women are predominantly affected in a ratio of 2:1. The disease is chatactcrized by a varying array of neurological deficits. There are four main disease types, classified on the basis of the clinical disease course: relapsing-remitting (RR), secondaty ptogtessivc (SP), primary progressive (PP), and progressive relapsing (PR). RR disease affects *65%* of patients and is characterized by onset of neurological deficits that remit over a period of weeks to months. Aftet 15 years, most RR patients go on to have an SP form of disease, in which neurological deficits become fixed and accumulate. PP patients accumulate permanent neurological deficits from the onset of disease, whetcas patients with PR disease have a combination of progressive and stepwise deficits. Disease onset generally occurs in the early 20s for RR disease and in the mid-30s for PP disease.

MS is a complex polygenic disease. Monozygotic twins have a concordance rate of 27%, whereas dizygotic twins of the same sex display a 2.3% concotdance rate. The incidence for first-degtee relatives of MS patients is 2-5%, whereas the incidence for the general population is 0.2%, Genetic linkage studies have been performed and several regions of interest have been found, but the most robust association remains with the HLA region. There is an increased incidence of MS in patients with the HLA-DR2 (DR1501) haplotype (Chataway et al, 1998; Name-, et al. 1998; Sawcet and Goodfcllow 1998). MS temains most prevalent among people of Northern European descent. There is a lower prevalence in other populations, such as Arabic and Mediterranean people, but among those with disease there is a higher incidence of other disease-associated haplotypes such as DR4 and DR6.

Therefore genetic factors play an important role in pathogenesis; however, migration and othet studies have demonstrated that environment also plays a critical role. Epidemiological studies have shown that residence in certain geographical areas and immigration to these areas before the age of 15 increases the incidence of MS. In addition, there is a diminishing north to south gradient in MS prevalence in the Northern Hemisphere, with an opposite trend in the Southern Hemisphere.

Pathologically, MS is characterized by inflammatory infiltrates in the CNS white matter with resultant demyelination. and axonal transections (Trapp et al. 1998) producing sclerotic plaques. Inflammation is generally perivenular, and lesions typically occur in the periventricular subcortical white matter, corpus callosum, optic nerve, brainstem, cerebellum, and spinal cord. Recently, the pathology of MS lesions has been classified into four distinct subtypes with the following predominant features: (1) cellulat infilttation, (2) antibody deposition, (3) oligodendrocyte apoptosis, and (4) oligodendrocyte death without apoptosis (Lucchinetti et al. 2000). The observations to date show a single subtype of lesion in each patient raising the possibility of distinct MS disease pathogenetic types.

It is clear that the immune system plays a central role in mediating CNS damage in MS. Oligoclonal bands are commonly observed in the CNS of MS patients; however, the target of these antibodies has yet to be elucidated. CMI primarily involving T-helper cells is believed to play an important role in initiating the disease, and immunological studies have substantiated the presence of activated T cells in MS. Most of the therapies for MS also target T cells. No clear autoantigen has been described in MS, and it thetefore remains an immune-mediated disease rather than autoimmune disease. Reactivity to various myelin antigens, including myelin basic ptotein (MBP), ptoteolipid ptotein (PLP), and myelin oligodendrocyte protein (MOG) has been investigated. MBP-reactive T cells are present in notmal individuals; however, MS patients have a higher frequency of activated MBP-reactive T cells in the peripheral blood and the cerebrospinal fluid (CSF) (Zhang et al. 1994).

MS is thought to be a T-helper 1 {Thl) mediated disease. Thl cells secrete predominantly the Thl cytokine IFN-y. Increased levels of Thl cytokines have been observed in MS lesions, and a clinical trial of IFN-y worsened MS. In addition, there is increased production of EL-I2 (the ma]or inducer of Thl cytokines) by APCs in the peripheral blood of MS patients, especially those with active disease. EAE, the animal model of MS, has been helpful in dissecting the pathogenic mechanisms of the disease. Vatious EAE models have demonstrated that mice with a Thl cytokine profile are more susceptible to EAE than wild-type mice, whereas animals with a Th2 (IL-4, IL-10) cytokine ptofile are resistant to disease development. However, this is far from

being a universal finding because EAE can be induced by transfer of Th2 cells.

The immunopathogenesis of MS is thought to involve activation of myelin-specific T cells via molecular mimicry or by a superantigen presumably in the periphery. The cells then cross the BBB and get reactivated in the CNS when they ate presented with their cognate antigen. Adhesion molecules and their ligands are expressed on T cells and endothelial cells to facilitate passage through the BBB. VCAM-1 and its ligand VLA-4 are upregulatcd in T cells during chronic disease thus perpetuating inflammation, wheteas ICAM-1 and its ligand LEA-1 were upregulated in both acute and chronic lesions (Canncllа and Raine 1995). Several studies have demonstrated increases of soluble ICAM-1 in CSF and L-selectin in serum during exacerbations of disease. The invasion of activated T cells into the btain and possible reactivation within the CNS initiates a cascade of cytokines. IL-2, IFN-^, and TNF-a activate macrophages, which in turn elicit nitric oxide and TNF-a. In experimental models, myelin damage is mediated by nitric oxide lipid peroxidation, direct TNF-a damage, and complement-induced pore formation. As mentioned previously, Th2 cytokines can induce B-cell activation and antibody production that further damage myelin. F.ach of these steps in the pathogenesis may be targeted for therapeutic intervention.

A number of immune-mediated autoimmune disorders of the nervous system are available for study in laboratory animals. Besides allowing for the analysis of the immunoregulatory network, they have been critical in designing immunotherapies. Although these model systems show many similarities to the human disease, it is likely that the human and experimental diseases have different immunological substrates; therefore extrapolation to human disease should be undertaken with caution (Owens and Sriram 1995).

Two major animal models exist that mimic the clinical manifestations of MS. These arc EAE and Theiler's murine encephalomyelitis virus-induced disease (TMFV-IDD). The issue of whether cither of these diseases is identical to MS in their pathogenesis remains unresolved.

EAE is a T-cell-mediated autoimmune dcmyelinating disease of the CNS. The disease can be induced in a number of experimental laboratory animals including primates by subcutaneous injection of whole-brain homogenate or of a purified preparation of MBP, PLP, or MOG. By altering the immunization protocols and animal strains, a relapsing remitting or a chronic form of the disease may be induced.

TMEV-IDD is induced by injecting TMEV picornavirus into the cerebral hemisphere. The virus infects neurons and glial cells. In some strains of mice, the host is unable to clear the virus, resulting in encephalitis and death; in other cases, the virus is cleared completely, and the host is resistant to demyelination. In TMEV-IDD susceptible strains of mice, the virus is partially cleared, saving the host from death but inciting an immune response that results in demyelination. Thus the damage induced by the virus is due to a failute of the host to mount a fully protective response, which predisposes the pathogen to persistence, resulting in immunopathology. TMEV-IDD is a T-ccll-mediated disease; although the exact immunological mechanisms inducing demyelination remain unclear, damage may be a result of epitope spreading (Miller et al. 1997). Studies in both EAE and TMEV have contributed vastly to our understanding of MS, and these models offer a system for testing new therapeutics.

Details of available therapies in MS are discussed in Chapter 60. Here, we discuss the immunological mechanisms of currently used medications, as well as experimental therapeutic strategies,

During the past 10 years IFN-0 therapy for MS has become one of the most important advances in the treatment of this disease. It is available in three different forms—subcutaneous IFN-/J-lb (Betaseron), subcutaneous IFN-jS-la (Rebif), or intramuscular IFN-0-la (Avonex). Interferons have many properties including suppressing proliferation of viruses and T cells. The mechanisms of IFN-/3 action in MS has been attributed to several different mechanisms. Intcrferon-associated increased production of IL-10 by macrophages downregulates the number of Thl cells. IFN-/J has also been shown to decrease production of IL-12 by dendritic cells, potential CNS APCs. In addition, IFN-*fi* modulates adhesion molecule expression, primarily by facilitating the conversion of cell-associated VCAM-1 into soluble VCAM-1. These drugs also downregulate costimulatory molecule expression, thus decreasing T-ccll activation and migration to the CNS (Yong 2002).

Glatiramcr acetate (GA) also known as copolymcr-1 or Copaxone is anothet class of drug recently used in the treatment of MS. In contrast to lFN-,8, GA is a synthetic molecule that was originally designed to resemble MBP. It is composed of random repetitive sequences of the amino acids glutamic acid, lysine, alanine, and tyrosine (G-L-A-T). Its mechanism of action is unclear; however, it is thought to bind with high affinity to the MHC groove, leading to the generation of GA-spccific T cells. Several studies have suggested that GA-specific T cells are Th2 biased, and animal models have demonstrated that these cells can migrate to the CNS and ameliorate EAE disease (Aharoni 1997). Studies in patients treated with GA have also demonstrated this Th2 bias {Dnda et al. 2000) and also have shown an upregulation of these cells during the first 3 months of treatment, with a subsequent downregulation or anergy during the next 3 months. The significance of this finding is unclear. It is thought that GA mediates its effects via migration of GA-specific Th2 cells into the CNS, where they downregulate the immune response locally. It has also been demonstrated that GA-specific T cells protect from optic nerve crush injuries, possibly by production of brain-derived neurotrophic factor (BDNF) (Kipnis et al. 2000).

Altered peptide ligands (API.) resembling MBP have been used in phase I trials for MS, with little success.

Two concurrent trials were initiated using the same compound CGP77116. One showed an increased number of lesions on magnetic resonance imaging (MRI) in some patients after the initiation of treatment (Bielckova 2000). In the other trial, 9% of patients developed allergic-type reactions associated with a Th2 deviation (Kappos 2000), Both trials were stopped because of safety concerns.

Other therapies that are currently under investigation in phase I and II trials include anti-VLA4 antibody that blocks the entry of activated cells to the CNS, anti-GDI 54 antibody that blocks CD40-CD154 T cell costimulatory signal, and CTLA4Ig. The latter blocks B7-CD28 costimulatory signals on T cells and may induce T cell anergy *in vivo.*

Many therapeutic strategies that have been used in the past nonspecifically target components of the immune response. Nonspecific strategies include cyclophosphamide, mitoxantrone, and cladribine, which deplete the bone marrow including T cells. Recent work has demonstrated that cyclophosphamide rather than causing T-cell depletion may work by inducing a cytokine switch with a decrease in IL-12 and an increase in IL-4, IL-5, and TGF-/J (Comabclla etal. 1998).

The role of the immune response in the induction of axonal damage in MS is unclear; however, both bystander damage or specific mechanisms that target neurons may be the causative factors. Therefore early modulation of the immune response is critical,

Efforts have been made toward replacement of damaged oligodendrocytes with transplant grafts. In addition, because axonal damage has occurred, transplantation of neurons or their progenitors is a promising avenue of research,

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is defined as a monophasic demyelinating disease associated with vaccination or a systemic viral infection, which may affect both adults and children. It was originally described in association with rabies and smallpox vaccines, both of which were prepared with neural tissues, suggesting a parallel with EAE, the animal model of MS. These vaccines have since been modified, using non-neural human diploid cell lines. ADEM has not been associated with any vaccines that are currently administered in the United States. The parainfectious variant of ADEM has been associated with measles infection, rubella, mumps, and several other viruses.

The lesions in ADEM resemble those of MS. The CNS white matter contains perivascular inflammatory infiltrates, as well as demycliuation. The most likely mechanism by which this disease occurs is molecular mimicry. Experimental evidence has shown that T cells isolated from patients with ADEM are 10 times more likely to react with MBP than controls, likening this disease to EAE in animal models (Pohl-Koppc et al. 1998). Because of the monophasic nature of the illness, it appears that the immunological response occurs acutely, but further reaction is abrogated.

MRI demonstrates multifocal white matter lesions involving the cerebrum, brainstem, cerebellum, and spinal cord, which may or may not enhance with gadolinium, Lesions generally resolve over time. CSF is characterized by normal pressure, moderately elevated cell count (5-100/ uL), moderately elevated protein (40-100mg/dL), and normal glucose. The presence of red blood cells may indicate a diagnosis of hemorrhagic leukoencephalitis. Oligoclonal bands may very rarely be present, and these cases should be followed for the development of MS.

Acute episodes of ADEM should be treated with intravenous steroids. The usual dose is 1 g of mcthylprednisolone (Solu-Medrol) for 5 days in adults. Refractory cases have been treated with plasmapheresis or cyclophosphamide. Cases that are suspicious for MS should be followed with MRI.

Immune-Mediated Neuropathies

The immune-mediated neuropathies are a large and heterogeneous group of diseases. We shall focus on acute inflammatory demyelinating polyneuropathy {AIDP) and chronic inflammatory demyelinating polyneuropathy (GIDP), which may be defined by the time to peak disability; in the former, 4 weeks, and in the latter, 2 months. Although AIDP and GIDP share many characteristics, the question of whether one is a continuum of the other, is still under debate. AIDP or Guillain-Barrc (GBS) syndrome usually presents with symmetrical ascending weakness and may be associated with autonomic dysfunction and respiratory depression. Sensory systems may be involved and may present with paresthesias or numbness. Demycliuation and axonal damage may be involved to varying degrees. If the patient's symptoms continue to progress beyond 4 weeks, the illness is termed CIDP.

AIDP is the most common acute paralytic disease in the Western world, with a mean annual incidence of 1.8 per 100,000 persons. There is an increasing incidence with age. Mortality was generally due to respiratory failure and has now been significantly reduced with the introduction of positive pressure ventilation. Epidemics have been found, most notably, in northern China where a high incidence has been associated with C. *jejuni* infections (McKhann ct al. 1993).

AIDP or GBS is characterized pathologically by a perineuria! lymphocytic, monocytic, and macrophage infiltrate. Several autoantibodies to myelin glycolipids have been identified, including GM1, Gdla, and Gdlb, Antibody-mediated demyelination as a result of complement fixation has been identified in pathology specimens. In some cases, axonal damage is present and is believed to

be a result of bystander damage. GBS is primarily an antibody-mediated disease as evidenced by the fact that many patients improve after treatment with plasmapheresis and that serum from GBS patients causes demyelination after transfer into experimental animals and peripheral nerve cultures.

The occurrence of AIDP has been linked to many infectious diseases, including C. *jejuni*, herpes virus, *Mycoplasma pneumonia*, and many other bacterial and viral infections, as well as vaccinations. The incidence of infection has been reported to be 90% in the 30 days before occurrence of GBS, C. *jejuni* is one of the most commonly identifiable agents, and molecular mimicry and host susceptibility are believed to play a role in disease pathogenesis. Autoantibodies not present in controls have been identified in the sera of GBS patients associated with C. *jejuni*, including GM1, Gdla, Gdlb, and Gqlb (Sheikh et al. 1998).

In contrast to AIDP, in CIDP no specific autoantibodies have yet been discovered. The histopathologic;! 1 picture is similar to AIDP; however, most studies identify fewer inflammatory infiltrates. Nerve biopsy reveals mixed demyelination and axonal changes. Onion bulbs may be present indicating attempts at remyclination. There is little laboratory evidence that this disease is antibody mediated; however, paradoxically, patients do improve with plasmapheresis. There is indirect evidence that GIDP is T-cell mediated; however, this area is still under investigation.

Treatment of AIDP involves supportive care and cardiac and respiratory monitoring. Plasmapheresis or intravenous immunoglobulin (IVIG) have been used tor acute treatment of AIDP and have been shown to be equally effective in shortening the recovery time. High-dose steroids have not been found to be effective in AIDP.

In contrast to AIDP, CIDP responds well to high-dose oral steroids. Both plasmapheresis and IVIG have been used with success. Plasmapheresis is a short-term immunotherapy, which nonspecifically removes antibodies from the circulation. IVIG is an immunomodulating agent commonly used in the treatment of allergic and autoimmune diseases. Immunosuppressants such as cyclosporine A, cyclophosphamide, and azathioprine have had positive outcomes in refractory cases; however, these require further testing in controlled studies.

Autoimmune Myasthenia Gravis

MG is a disorder of the neuromuscular junction. It is an autoimmune disorder, and 80-90% of cases have detectable autoantibodies to the alpha subunit of the acetylcholine receptor (AChR). MG is characterized by fluctuating weakness and fatigability, primarily in muscles innervated by the cranial nerves, but may occur in skeletal and respiratory muscles. MG has a biphasic age distribution. Most cases occur in women ages 20^40 years, and the remainder in older patients with an equal sex distribution. Thymomas occur in 10-15% of cases; most are in the older age group. Seventy-five percent of patients will have some thymic abnormality, 85% being thymic hyperplasia. MG is often associated with other autoimmune diseases, thyroid disorders, rheumatoid arthritis (RA), pernicious anemia, and SLE. A similar syndrome termed Lambert-Eaton is associated with antibodies against the presynaptic, voltage-gated calcium channel.

Autoimmune MG is caused by the presence of anti-AChR antibodies and is a B-ce!l-medmted disease, bighty to 90% of patients have detectable autoantibodies. These are polyclonal and may be of any IgG subtype. Transfer of serum from myasthenic patients to experimental animals results in neuromuscular blockade. The mechanism by which antibody mediates neurological symptoms is controversial. Possible mechanisms include neuromuscular blockade or damage to the AChR from complement mediated damage after attachment of the IgG antibody. There is, however, poor correlation between scrum antibody titers and disease course and severity.

Although the B cell is the effector cell producing antibodies, experimental evidence has shown that autoreactive T cells are necessary for the disease to occur (Yi and Lefvert 1994), Removal of the thymus results in improvement of disease in 80-90% of myasthenic patients. The role of thymic abnormalities remains unclear, and patients wirh thymomas have antibodies to additional skeletal muscle ptotcins such as the ryanodine receptor and titin. Patients may also display symptoms of neuromyotonia.

A large body of research is targeted at understanding the reasons for the failure of T-cell and subsequent failure of B-cell tolerance in MG. Both normal and myasthenic thymus glands contain myoid cells and epithelial cells that express the AChR, T cells expressing the V beta 5.1+ TCRs are over-re pre sen ted both in the core of germinal centers and in perifollicular areas of hyperplastic thymuses, suggesting a role in the autoimmune response (Truffault et al. 1997). Failure of central or thymic tolerance may play an important role in disease pathogenesis.

Genetic factors play a role in the pathogenesis of autoimmune MG, but monozygotic twins demonstrate less than 50% concordance rate. There is a moderate association of MG with the HLA antigens B8 and DRw3 in young women. The stronger association with HLA-DQw2 remains controversial, There is an unusually high incidence of other autoimmune diseases such as SLE, RA, and thyroid diseases in first-degree relatives of myasthenic patients suggesting the presence of shared autoimmune genes.

Therapies in MG are targeted toward alleviating symptoms with acetylcholinesterase inhibitors and using strategies to abrogate the disease target the immune system. Thymectomy is recommended for patients 15-65 years old, with 80-90% remission rate (Durelli et al. 1991). The thymus plays an important role in T-cell education in the developing human; therefore prepubertal thymectomy is discouraged. A variety of anticholinesterase inhibitors

provide temporary symptomatic relief in most patients. Pyridostigmine bromide (Mestinon) and neostigmine bromide (Prostigmin) are the most commonly used agents and must be taken daily.

MG is an antibody-mediated disease, and therefore responds to therapies that nonspecifically target antibodies. Both plasmapheresis and treatment with 1VIG are used for acute MG exacerbations or in preparation **for** surgery (Gajdos et al. 1997). Because the autoantigen is known in MG, investigational therapies may target specific molecules such as the B-cell surface Ig or the TCR and deliver immunotoxins.

Immunosuppressives such as cyclosporine and azathioprine are used to augment treatment when symptoms are not adequately controlled by the previously mentioned methods, but the decision to use such agents must balance the need and the side effects. Gorticosteroids are used at various stages of treatment and have multiple effects on the immune system, including reducing AChR antibody levels.

Inflammatory Muscle Diseases

PM, dermatomyositis (DM), and inclusion body myositis (IBM) are all immune-mediated diseases of the muscle and the surrounding connective tissue. Each has its own unique clinical and immunohistological features. Both PM and DM are more common in females, whereas IBM is more common in males. DM is associated with an increased risk of cancer, and therefore a full cancer screening should be part of patient management.

PM is thought to result from a multitude of causes, including systemic autoimmune, connective tissue disorders, and viral and bacterial infections. PM is characterized histopathologically by an endomysial inflammatory infilttate containing predominantly GD8+ T cells. There is relative sparing of blood vessels. In one subtype of PM, T cells with *y$* receptors have been identified surrounding non-necrotic muscle fibers (Hohlfeld et al. 1991).

In contrast, DM is characterized by peri fascicular atrophy. There is hypoperfusion and subsequent degeneration of the muscle fibers in the periphery of the fascicle secondary to microvascular damage. Damage to capillaries resulting in microinfarcts is mediated by complement. Immunofluorescence studies have revealed immune-complex deposition within the endothelium, indicating that this is an antibody-mediated disease; therefore the disease differs from PM (Kissel et al. 1986).

Various autoantibodies directed against nuclear and cytoplasmic cell components are found in up to 30% of inflammatory myopathies. Most are nonspecific for connective tissue disease. Viruses including Goxsackie B are implicated in the pathogenesis of disease, and both PM and DM patients may have anti-Jo-1 antibodies to the viral enzyme histidyl-tRNA synthetase (Mathews and Bernstein 1983).

As with PM, IBM is mediated by CD8+ T cells. However, in contrast to PM, the muscle biopsy in IBM may also demonstrate the presence of characteristic autophagic •'rimmed" vacuoles. Amyloid deposits may be demonstrated in the muscle, similar to those seen in Alzheimer's disease, suggesting similarities in pathogenesis of these two diseases (Askanas et al. 1992).

The mainstay of treatment of PM and DM is steroids. Dosages may vary from 60-100 mg/day of prednisone, and duration is determined by clinical outcome. Alternative treatment options for the inflammatory myositis diseases include IVIG, methotrexate, azathioprine, cyclophosphamide, cyclosporine, and in extreme cases total body irradiation (Mastaglia 1998). Mortality rates vary between 15-35% and are generally due to cardiac or respiratory failure. Because there is a higher incidence ot malignancy with PM and DM, screening for breast, lung, hematological, ovary, stomach, and colon carcinoma should be performed on each patient with the diagnosis. IBM may be more resistant to steroid therapy and is often diagnosed after an assumed PM fails to respond to treatment.

THE IMMUNE RESPONSE TO INFECTIOUS DISEASES

The immune response within the CNS must carefully balance the need to eliminate the pathogen and the risk of inducing bystander damage to the delicate and vital nervous tissues. It is believed that it is for this reason the immune response in the CNS deviates from that in the rest of the body, and it remains an immune-privileged site. The result is that many pathogens are not completely eliminated and may persist to cause further symptoms. Examples of this are CNS syphilis, Lyme neuroborreliosis, herpes zoster, HIV, and *Mycobacterium tuberculosis.* Lyme *Borrelia* incites IFN-y production, with correspondingly low levels of IL-4 in the CSV, thus predisposing the CNS tissue to bystander damage.

The portal of entry and site of replication of the pathogen plays a critical role in the elimination of the infection. In the case of viral meningitis, the portal of entry is the mucosal membrane, usually the nasopharynx. This incites a strong local immune response to the proliferating organism. By the time the virus disseminates to the leptomeninges, a sufficient immune response has been mounted in the periphery to eliminate the pathogen. However, in the case of viral encephalitis, the CNS invasion is so sudden that the peripheral immune system has insufficient time to react, and the weak CNS immune response is often inadequate, resulting in a poor outcome.

TUMOR IMMUNOLOGY

The immunological response to tumors has elicited much interest in the past 10 years. This field provides

opportunities for understanding the cause and immunological features of tumors and venues for treatment.

The body uses a mechanism called tumor immunosurveillance to prevent the formation of tumors or inhibit further growth. The main effector cells are CTLs, NK cells, and TNF-a producing macrophages. Tumor-reactive antibodies have also been identified in patients but are thought to play a lesser role. It has been recognized that tumors express tumor specific antigens that may be recognized by the previously mentioned cells. However, tumor cells may escape the body's natural surveillance mechanisms resulting in cancer. Tumor cells escape surveillance mechanisms by masking or modulating antigens on their surface, downregulation of class I and II, thereby inhibiting antigen presentation, and through the expression of immunosuppressant factors.

Tumors in the CNS have similar abilities to evade the immune system, and it has been shown that some gliomas produce high levels of TGF-/3, an immunosuppressant. In addition, there may be downregulation of class II MHC; however, this is controversial. It has recently been established that gliomas may express high levels of FasL, allowing for local apoptosis of Fas-bearing cells including lymphocytes.

Therapies are being designed to exploit the body's natural tumor immunosurveillance mechanisms. One avenue of research is vaccination with killed tumor cells or tumor antigens. Another technique employs genetic engineering to transfect tumors with plasmids bearing genes for costimulatory molecules to enhance the tumor APC ability. Injection of cytokines such as IL-2 and TNF-a, which enhance lymphocyte and NK function, has been attempted with variable results. Alternately introduction of stimulated lymphokine-activated cells (LAK) holds promise.

PARANEOPLASTIC SYNDROMES

Neurological paraneoplastic disorders are defined as neurological syndromes arising in association with a cancer. These are mediated by antibodies produced by the immune system in reaction to a tumor antigen, which cross react with neural tissue. Because many autoantibodies have been identified, the pathogenesis of paraneoplastic syndromes is autoimmune. It is likely that aberrant, primitive, ot hamartoma to us antigens are expressed by the tumor cells. The anti-Hu antibody arises in association with small cell cancer of the lung and cross-reacts with neurons to produce a syndrome of encephalomyelitis and/or sensory neuropathy. Similarly, anti-Yo antibody produces cerebellar degeneration because of cross-reactivity with Purkinjc cell cytoplasm and is associated with breast and ovarian cancer. Opsoclonus-myoclonus syndrome is due to and-Ri antibody and has been associated with cancer of the ovary and breast.

There is evidence of a more active cellular infiltrate in tumors associated with paraneoplastic syndrome than those not associated with a paraneoplastic syndrome. Therefore one can postulate that the immune system is more active in these situations. Cancers associated with paraneoplastic syndromes are generally associated with a bettet outcome.

THE IMMUNOLOGY OF CNS TRANSPLANT

Recently, there have been many advances in the field of CNS transplant, with the use of fetal dopaminergic striatal cells, and now various types of genetically engineered cells. A major factor in the survival of these grafts is their immunogenicity. As stated previously, the CNS is an immune privileged site. Therefore transplant grafts in the CNS tend to have longer survival times than peripheral grafts; however, this is not absolute, and cellular infiltrates associated with rejection have been identified. The immunology of CNS transplant grafts is currently under investigation and will be a critical factor in graft survival.

CONCLUSION

The field of immunology has progressed significantly in the past 20 years. This knowledge is currently being applied to immune-mediated diseases in neurology. In this rich environment, we can expect many advances in the field of neuroimmunology including new therapies and better strategies for inducing remissions.

Chapter 46
Neurovirology

John R. Corboy and Kenneth L. Tyler

BACKGROUND

Neurovirology is the study of viral infections of the nervous system. Viruses are small, replicating microorganisms that are unable to multiply outside a host organism—that is, they are obligate intracellular parasites. They are classified into families based on the (1) nature of their genome; (2) site and method of replication; and (3) structural features including size, shape, symmetry, and the presence or absence of an envelope. Viruses can infect humans, other animals, and even other microorganisms such as bacteria. Some viruses may infect more than one host species, whereas others are restricted to one or just a few hosts. Similarly, viral infections may be restricted to single organs or focal areas within an organ of a host or may be widespread. Viral infections may be acute, chronic, or recurrent, and their manifestations may be altered by a variety of host factors, including age, nutritional status, and immimocompetence.

In this chapter, we begin with a description of the basic features of the major clinical syndromes associated with viral infections of the human nervous system. Next is a sequential overview of the individual steps in the pathogenesis of viral central nervous system (CNS) infection, beginning with the entry of viruses into the host and ending with a discussion of the mechanisms by which viruses injure rarget cells within the CNS and other organs. The chapter concludes with a brief review of the diagnosis and treatment of CNS viral infections. More detailed information on specific viral CNS infections can be found in Chapter 59B.

CLINICAL SYNDROMES

Meningitis

Viral meningitis is an infection of the subarachnoid space caused by a virus (Rotbart 2000) (Table 46.1). Most cases of viral meningitis are acute, benign, self-limited illnesses. Less commonly, viruses may produce recurrent or chronic meningitis. Although viral meningitis often occurs as an isolated syndrome, it also may involve the brain (meningoencephalitis), spinal cord (men in goencep halomyelitis), or nerve roots (meningoradiculitis). Viruses are the most common cause of *aseptic meningitis*, a generic term for cases of meningitis in which bacteria cannot be isolated from the cerebrospinal fluid (CSF). Using modern diagnostic techniques, it can be shown that up to 85% to *95%* of cases of acute aseptic meningitis are caused by enteroviruses (especially Echo 3-7, [l]J, 11.21, and 30 and Coxsackie A9 and Bl-5) (Rotbart 2000). The remainder are caused by arboviruses {California encephalitis virus, St. Louis encephalitis virus, Western equine encephalitis virus [WEEV], Eastern equine encephalitis virus |EEEV], West Nile virus [WNVj), herpesviruses, human immunodeficiency virus (HIV), and mumps. It is important to recognize that the same viruses that produce meningitis

Table 46.1: Synopsis of clinical syndromes caused by families of neurotropic viruses and their diagnosis and treatment

Taxonomy	*Disease*	*I .atxirat'iry*	*Treatment*
RNA viruses			
Picornaviridac		CSF PCR; brain, CSF culture	Supportive ?Pleconaril
Coxsackie	Men, my el		
Echo	Men, my el		
Polio	Men, my el		
Togaviridac		HI, CF, NA, IFA	Supporrivc
EEEV	Enc	Brain Ag or cukure, CSF IgM	
WEEV	1.ML	Brain Ag	
VEEV	Enc	CSF IgM	
Rubella	Enc		
Flaviviridae		HI, CF, NA	Supportive
SLEV	Enc, men	CSF IgM, IFA	
JEV	KIK\ men	CSF Ag, IFA	
Murray Valley	Enc	Oil lure	
West Nile virus	Enc, men, myel, PN, ON	Serum/CSF IgM, serum IgG, CSF PCR	Supportive
Reoviridac			**Supportive**
Colorado tick fever	Enc, men	RBC Ag, HI, CF, NA, IFA	
Rhabdoviridac			Supportive
Habit's	Enc, myel	Ag (skin, conjunctiva, brain), PCR brain, IFA, CF, HI, CIE, culture	Postexposute prophylaxis
Borna	?Enc/affective dsorder		
Paramyxoviridac			Supportive
Measles	Enc-SSPE	i.:si- i.n.\i	?Ribavirin
Mumps	Men* enc_s myd	CSF culture, serum IgM, IgG	
Nipah	Enc, myel	ELISA, NA, cell culture	rRibavirin
Fiendra	Enc	EI.ISA, NA, cell culture	rRibavirin
Orthomyxoviridae			Supportive
Influenza	Postin enc	Culture from other site	
Bunyaviridae			Supportive
La Crosse	Enc, men	i si .uhure. CSF [B.M, HI, CF, NA, IFA, CIE	**? Ribavirin**
Arcnaviridae			Supportive
LCMV	Men, enc	CSF, blood, urine culture, serology	
Kctroviridac			
HIV-1	Enc, men, myel, PN, myos	Blood ELISA, clinical	Combination antivirals
HTLV-I	Myel, enc	Blood ELISA, CSF IgG	]nterferon-«
I)\A viruses			
Herpesviridae			
HSV-1	Enc, men, postin	CSF PCR, brain culture	Acyclovir Famciclovir Valacyclovir
HSV-2	Men, enc	CSF PCR, brain culture	Same as HSV-1
V/.V	Gan, myel, enc, postin	(SI- Iv R, brain or lesion culture	Same as HSV-1
EBV	Enc, men, myel, postin, NT	CSF PCR, serology	Supportive
CMV	Enc, PR, myel	CSF PCR, brain or CSF culture	Ganciclovir Foscarnet Cidofovir
HHV-6	Enc, febrile seizures, ?MuLtip]e sclerosis	CSF PCR, blood culture	Ganciclovir
HHV-8	?NT, ?enc	PCR blood, serology	Supportive
Papovaviridac			Supportive
JCV	Enc	CSF PCR, brain 1SH	?Cidofovir
Aden ol\ rid ae			Supporrive

Ag = antigen; CF = complement fixation; CrE = countcrimmunoelectrophoresis; CMV = cytomegalovirus; CSF = cerebrospinal fluid; EBV = Epstein-Bart virus; EEEV = Eastern equine encephalitis virus; ELISA = enzyme-linked immunosorbent assay; Enc = encephalitis; Gan = ganglionitis; HHV-6, -8 = human herpesvirus type 6, 8; HI = hemagglutination inhibition; HIV-1 = human immunodeficiency virus type 1; HSV-1, -2 = herpes simplex virus type 1, 2; HTLV-I = human T-lymphotropic virus type i; IFA = immum)fluorescent antibody; IgG = immunoglobulin G; IgM = immunoglobulin M; ISH = *in situ* hybridization; JCV = J C vitus; JEV = Japanese encephalitis virus; LCMV = lymphocytic choriomeningitis virus; Men = meningitis; Myel = myelitis; Myos = myositis; NA = neutralizing antibody; NT = neoplastic transformation; ON = optic neuritis; PCR = polymerase chain reaction; PN = polyneuropathy; Postin = postinfectious; PR = polyradiculitis; RBC = red blood cell; SLEV = St. Louis encephalitis virus; SSPE = subacute sclerosing panencephalitis; VZV = varicella zoster virus; WEEV = western equine encephalitis virus.

also can produce encephalitis, although specific viruses differ in the frequency with which they cause the two syndromes. For example, herpes simplex virus type 1 (HSV-1) more commonly produces encephalitis than meningitis, although the converse is true for herpes simplex virus type 2 (HSV-2). Similarly, most arboviruses are more likely to produce encephalitis than meningitis, whereas most enteroviruses produce far more cases of meningitis than encephalitis.

The cardinal clinical features of viral meningitis include fever, headache, and nuchal rigidity (meningismus). Common associated symptoms include nausea, vomiting, abdominal pain, chills, and generalized malaise. These symptoms are similar to but less severe than those found with bacterial meningitis. The presence of significant alteration in mental status, focal neurological signs or symptoms, or seizures suggests that infection has involved the brain parenchyma producing encephalitis rather than remaining restricted to the subarachnoid space. Symptoms of viral meningitis develop over hours to days and rarely persist for more than a week to 10 days.

The most important diagnostic test in a case of suspected viral meningitis is examination of the CSF. Typical CSF findings include a mild to moderate lymphocytic pleocytosis, slightly elevated protein concentration, and a normal glucose concentration. Stain results for microorganisms including bacteria (Gram's stain), mycobacteria (Ziehl-Neelsen stain), and cryptococci (India ink stain) are negative, as are test results for bacterial, cryptococcal, and fungal antigens and for the presence of endotoxin. Among the common causes of acute viral meningitis, most can be specifically identified using polymerase chain reaction (PCR) of CSF.

In general, acute viral meningitis is a self-limited illness requiring only symptomatic therapy with analgesics and bed rest. Acute viral meningitis caused by HSV-1 or HSV-2 may be treated with intravenous or oral acyclovir, oral famciclovir, or oral valacyclovir, although data supporting their efficacy are largely anecdotal. Acute HIV-1 meningoencephalitis may respond to combined antirctroviral therapy with zidovudine, other reverse transcription inhibitors, and protease inhibitors. Enterovirus meningitis may respond to pleconaril.

A small number of patients have recurrent episodes of aseptic meningitis (Tedder et al. 1994}, First described by Mollarct in 1944, these episodes may recur over years and generally arc self-limired and resolve without residual sequelae. Studies using CSF PCR suggest that most cases of benign recurrent lymphocytic meningitis are caused by HSV-2.

As noted, most cases of viral meningitis resolve within 7-10 days. Some patients report mild persistent symptoms including headache or fatigue. Resolution of CSF abnormalities may lag behind clinical improvement, and a mild pleocytosis may persist for several weeks. Immunocompromised patients may develop chronic viral meningitis. The most common and extensively described example-is chronic enteroviral meningitis, often resulting from Echovirus 11, in patients with agammaglobulinemia.

Encephalitis

Viral encephalitis is a viral infection of the brain parenchyma (Whitley and Gnann 2002). Most human viral cncephalitides are acute infections. Infection may-involve the entire brain (diffuse encephalitis) or be confined predominantly to specific areas (focal encephalitis). In the United States, HSV-1 is the most common cause of acute focal sporadic encephalitis in adults, with several thousand cases occurring throughout the year. Epidemics of encephalitis in the United Stares may be caused by flaviviruses (St. Louis encephalitis virus, WNV), togaviruses (EEEV, Western encephalitis virus, and Venezuelan encephalitis virus), and bunyaviruses (California encephalitis virus and LaCrosse virus) (Nash ct al. 2001). These viruses are often designated *arboviruses*, reflecting that they are borne by arthropod vectors such as mosquitoes and ticks. Other encephalitis-producing arboviruses are common in other parts of the world, such as Japanese encephalitis virus in China and the Far East and tick-borne encephalitis in Northern and Central Europe and Scandinavia. Arbovirus cncephalitides typically have well-defined seasonal and geographical predilections reflecting the life cycle and distribution of their arthropod vectors. In the United States, infections occur predominantly during the summer months and decline precipitously in frequency after the first winter freezes reduce the number of insect vectors. Certain arboviruses have relatively limited geographical ranges (e.g., EEEV, California encephalitis virus), whereas others produce cases of encephalitis throughout the United States (e.g., St. Louis encephalitis virus). WEEV has an intermediate pattern, with human cases limited to the western two thirds of the United States. WNV produced the original human outbreak in New York City in 1999, in which 7 of the 59 patients with encephalitis or meningitis died (Nash et al. 2001), and since that time human infection has spread to many states. In 2002 there were 4156 human cases of WNV in *39* states in the United States with 284 deaths. Greatest incidences were in Illinois, Louisiana, Ohio, Mississippi, and Indiana, with human cases as far west as California (http://www.cdc.gov/ncidod/dvbid/wcstnile/index.htm).

The symptoms of acute viral encephalitis include fever, headache, and focal neurological symptoms and signs. Common neurological signs and symptoms include decreased level of consciousness, altered mentation, focal weakness, speech disturbances, and seizures. Diffuse encephalitides, such as that caused by St. Louis encephalitis virus, result in widespread neurological dysfunction. The CSF pattern in viral encephalitis is similar to that found in viral meningitis, with moderate pleocytosis, elevated

protein, and normal glucose concentrations. In severe cases of encephalitis, almost nil patients have abnormalities on neuroimaging studies. Computerized axial tomography shows areas of hypodensity, and magnetic resonance imaging (MRI) reveals areas of increased signal on T2-weighted images, resulting from tissue destruction and associated cerebral edema. Electroencephalography (EEG) may show diffuse slowing, seizures, or epileptiform discharges in multiple locations. As with viral meningitis, specific diagnosis depends on isolation of the virus, serological studies, or amplification of viral nucleic acid from CSF by PCR (Davis 2000; Redington and Tyler 2002). Specific treatment is available for encephalitis caused by HSV, varicella zoster virus (VZV), cytomegalovirus (CMV), and HIV (see therapy, later in this chapter). Treatment of encephalitis caused by viruses other than HSV is generally supportive; however, interferon-a and ribavirin are being tested in several viral enccphalitidcs. Morbidity and mortality vary with the specific virus. For example, Epstein-Barr virus (EBV) encephalitis is associated generally with a good prognosis and complete recovery, whereas EEEV is associated with substantial morbidity and mortality.

HSV-1 encephalitis in adults is the prototype of a focal viral encephalitis. Infection and associated tissue injury predominantly involve the inferior temporal and frontal brain regions and may be unilateral or bilateral. Patients often develop bizarre behavior, hallucinations, focal or generalized seizures, aphasia, and hemiparesis. Neuroimaging study results are almost invariably abnormal, although computed tomographic scans are considerably less sensitive than MRI and may be normal early after onset of infection, MRI reveals areas of increased T2 signal in the frontotcmporal regions, often with significant associated mass effect. The EEG may be the first laboratory test to show the focal nature of the lesion. EEG abnormalities can include seizures, sharp waves, and periodic latcralizcd epileptiform discharges, often localized to the frontotemporal regions. CSF is abnormal, with a lymphocytic pleocytosis of up to several hundred cells per microliter, an elevated protein, and normal glucose concentrations. Amplification of HSV DNA from CSF by PCR is extremely sensitive and specific and allows for rapid definitive diagnosis of HSV encephalitis. The PCR result may remain positive for 2-3 weeks in HSV-1 encephalitis, even in treated patients. PCR has largely supplanted other diagnostic techniques, although demonstration of HSV-specific intrathecal antibody synthesis (see diagnostic techniques, later in this chapter) or identification of **HSV** by immunocytochemistry or culrure of brain biopsy specimens remain useful in certain specific circumstances. Prompt treatment of HSV encephalitis with intravenous acyclovir (30 mg/kg/day for at least 14 days) reduces mortality from 70% in untreated patients to as little as 15% (Raschilas et al. 2002; Whitley 1997). Despite apparently optimal antiviral therapy, a significant number of treated patients are left with moderate to severe disability. Corticosteroids may be used as adjunctive therapy in patients with increased intracranial pressure and significant brain edema, although their efficacy has never been evaluated in controlled clinical trials. Poor prognostic features include delay in initiation of therapy, diminished level of consciousness, age older than 30 years, occurrence of hospital-acquired infection, and high CNS viral load.

In most viral cncephalitides, it appears that the neuron is the target cell for the viral infection. Oligodendrocytes, however, are the target of the JC virus, in which infection results in the clinical syndrome of progressive multifocal leukoencephalopathy (PML). PML is manifested usually by a subacute course of confusion, weakness, and visual disturbance. Infection occurs almost exclusively in patients with the acquired immunodeficiency syndrome (AIDS) or other forms of impaired cell-mediated immunity, MRI reveals multifocal confluent white matter lesions, often in the parietal-occipital region, and without associated mass effect. Some patients have enhancement at the margins of their lesions on gadolinium-enhanced Tl-weighted scans. The CSF is usually normal, although occasionally a mild lymphocytic pleocytosis occurs. PCR amplification of JC viral DNA from CSF is specific for PML, but of only modest sensitivity (70-80%). If the PCR result is negative, definitive diagnosis requires brain biopsy with demonstration of either JC virus antigen by immunocytochemistry or DNA by *in situ* hybridization (ISH). Typical ncuropathological features include noninflammatory demyelination associated with the presence of bizarrely shaped and enlarged multinucleated astrocytes and oligodendrocytes bearing intranuclear viral inclusions. Neurons are typically spared. Currently, no specific therapy exists for **PML,** although clinical trials of cidofovir and topoisomerase inhibitors arc currently in progress. To date, results with cidofovir have not been promising. Prognosis remains grim, with most patients dying within a few months of diagnosis. There are rare reports of stabilization of disease or even remission in patients who have recovered from their immunocompromised state. For example, initiation of antirerroviral therapy in previously untreated or inadequately treated patients with AIDS with PML may result in clinical improvement that parallels reconstitution of their immunological status.

Most viral encephalitides manifest as acute, monophasic infections. Encephalitis resulting from the emerging Nipah virus (paramyxovirus family), however, can sometimes relapse or present acutely with encephalitis up to 21 months after the original, encephalitic or asymptomatic infection. A small number of viral cncephalitides are chronic in their presentation. HIV-1 often infects the nervous system shortly after peripheral inoculation and may result in an acute, and sometimes severe, meningoencephalitis (Berger and Levy 1997; Gendelman et al. 1998). More common, however, is a more chronic infection that manifests clinically when the $CD4^+$ lymphocyte count usually is less

than 200 cells per pL. This results in a slowly progressive dementia referred to as the *AIDS-dementia complex* or the *HlV-1 -associated dementia.* Symptoms include a slowing of behavioral responses and motor function, personality changes, and withdrawal from social activities. CSF shows only a modest pleocytosis and elevation of protein, and the MRI may reveal numerous punctate or confluent lesions in the subcortical white and gray matter on T2-weighted imago. Pathological abnormalities include multinucleated giant cells, microglial nodules, myelin pallor, and neuronal loss in multiple areas. Aggressive treatment with zidovudine (formerly azidothymidine [AZT|) alone or in combination with other reverse transcriptase inhibitors and viral protease inhibitors probably has reduced the incidence and prevalence of AIDS-dementia complex over the last 10 years and may stabilize or improve neuropsychological function in those patients not previously treated with these medications (Bcrger and Levy 1997; Gcndelman et al. 1998). Some of these medicines have greater CSF penetration than others, but studies of the utility of specific treatment regimens, which take this into account, have not been attempted (Redington and Tyler 2002). Another therapeutic approach involves the use of drugs designed to inhibit HIV-induccd neuronal damage rather than directly inhibiting **viral** replication. For example, nimodipine, a voltage-dependent calcium-channel antagonist, is currently undergoing clinical trials in AIDS-dementia complex.

Rarely, measles and rubella can produce chronic CNS infection (subacute sclerosing panencephalitis and progressive rubella panencephalitis, respectively). Fewer than 20 cases of progressive rubella panencephalitis have been reported, and the incidence of subacute sclerosing panencephalitis has declined dramatically following widespread use of measles vaccine. Symptoms of subacute sclerosing panencephalitis begin with a progressive decline in cognitive function and behavioral abnormalities followed by the appearance of myoclonic jerks and corticospinal tract dysfunction. Over one half of the affected patients were initially infected with measles virus before the age of 2 years, although signs and symptoms of subacute sclerosing panencephalitis do not typically develop until between 5 and 15 years of age. CSF shows massive elevation in IgG, oligoclonal bands, and extremely high titers of measles-specific antibodies. EEC is diffusely slow early in the disease, and later reveals a pattern of high-voltage and generalized 4- to 6-Hz polyphasic sharp and slow-wave complexes followed by periods of low-voltage attenuated activity (burst suppression). Neuroimaging studies show generalized ventricular enlargement and evidence of periventricular and subcortical white matter disease. There is no effective therapy for subacute sclerosing panencephalitis, although anecdotal reports have suggested possible therapeutic benefits from isoprinosine, intraventricular interferon-or, and ribavirin. Death usually occurs within several years of onset. Progressive rubella panencephalitis develops 6-12 years after congenital or perinatal rubella infection. It is manifested by cognitive difficulties followed by progressive ataxia, dysarthria, nystagmus, weakness, and seizures. There is no effective therapy.

Myelitis

Viral myelitis is viral infection of the spinal cord. Paralytic infection caused by wild-type poliovirus has now been almost entirely eliminated from the Western hemisphere, but poliomyelitis still serves as the prototypical viral myelitis. Before mass immunization in the developed countries in the 1950s and 1960s, poliomyelitis was the most common form ol viral myelitis in the world. After the introduction of mass immunization, the incidence of paralytic polio in the United States dropped from 13.7 cases per 100,000 to 0.003 cases per 100,000. Although paralysis caused by wild-type virus no longer occurs in the United States, approximately 10-20 cases a year of paralytic polio occur in vaccinated individuals or their close contacts and have been associated with reversion to virulence of vaccine strains (vaccine-associated poliomyelitis). Neurological illness may also follow inadvertent vaccination of children or adults with unrecognized immunodeficiency. Polio has been targeted by the World Health Organization for eradication through an aggressive vaccine campaign analogous to that used for smallpox.

During polio epidemics, more than 90% of infections are asymptomatic. Approximately 4—8% of infected individuals have a minor viral illness consisting of mild fever, sore throat, gastrointestinal upset, headache, and malaise. Just 1-2% develop neurological involvement, which begins with acute viral meningitis. This is followed 2-5 days later by multifocal, asymmetrical paralysis, primarily of the extremities, reflecting the infection of the anterior horn cells of the spinal cord. Involvement usually is more severe in the legs than the arms, more proximally than distally. Paralysis may spread over 3-5 days. On examination the muscles are flaccid and weak, and reflexes are typically diminished. Approximately 10-20% of such paralytic patients may have significant bulbar involvement, with chewing, swallowing, and breathing difficulties. Encephalitis is uncommon, but may occur. A progressive postpolio syndrome, which develops decades after original paralytic infection, does not appear to be associated with reactivation of poliovirus infection.

A similar pattern of illness may occur with both nonpolio enteroviruses (notably enteroviruses 70 and 71), and viruses other than enteroviruses. A syndrome similar to that of poliomyelitis has been described in patients with WNV (MMWR, 2002a) (http://www.cdc.gov/ncidod/dvbid/westnile/index.htm).

Myelitis caused by HSV and EBV may present as an acute transverse myelitis. A similar picture may follow VZV infection (shingles), although this is more commonly associated with a local myelitis producing muscle weakness

limited to muscles belonging to myotomes in proximity to involved cutaneous dermatomes. Chronic myelitis may oecur as a result of retroviral infection (Berger and Levy 1997; Gendelman et al. 1998). In the late stages of HIV-1 infection, often in association with AIDS-dcmentia complex, patients with AIDS may develop a slowly progressive myelopathy with symptoms and signs of weakness, small- and large-fiber sensory loss, increased tone, impotence, and bowel and bladder dysfunction. The most common area affected pathologically is the thoracic spinal cord, which may show atrophy on T2-wcighted MRI. At autopsy, pathological examination of the spinal cord reveals vacuolar changes in 20-50% of HIV-infected individuals. The pathogenesis of HIV-associated vacuolar myelopathy is unknown. Antirerroviral drugs do not prevent disease progression, suggesting that myelopathy may be caused by indirect effects of HIV rather than as a result of direct virus-mediated in jury. Promising results in pilot treatment trials using [.-methionine support this hypothesis and suggest that myelopathy may be caused by interference with transmethylation mechanisms analogous to, but not identical with, those seen in B_t2 deficiency.

Infection with human T-lymphotropic virus type I (HTLV-I) is endemic in Japan and the Caribbean. In some patients it is associated with an acute T-ccll leukemia, whereas others develop a slowly progressive myelopathy referred to *as tropica! spastic paraparesis (TSP)* or *HTLV-I-associated myelopathy (HAM).* The syndrome affects males more often than females, and typically has onset before age 30. Symptoms consist primarily of upper motor neuron weakness and bladder disturbance, with variable sensory loss. Rarely, there may be encephalitis. By 10 years after symptom onset, 60-70% of individuals are unable to walk. MRI lesions are variable and can include cord swelling and enhancement in the acute stages followed by atrophy in later stages. The CSF shows mild pleocytosis, increased protein, immunoglobulin G (IgG) and IgG synthesis, and the presence of oligoclonal bands. The pathology shows myelin loss with axonal degeneration, especially in the lateral corticospinal and spinocerebellar tracts. There is chronic inflammation, with leptomeningeal and perivascular cuffing with lymphocytes, plasma cells, and histiocytes. Injury may be mediated by HTI.V-I-specific cytotoxic T cells rather than caused by direct viral injury to cells. As a result, the most effective therapies seem to involve use of immunomodulating agents, including interferon-a and corticosteroids. In general, this is a chronic, slowly progressive illness that extends over many years.

Ganglionitis

Viral ganglionitis is a viral infection of dorsal root or cranial nerve ganglia, infection with VZV is the prototype for this type of infection. Primary infection with VZV produces varicella (chickenpox). Following the acute infection, virus becomes latent in sensory ganglia. Decline in cell-mediated immunity may precipitate viral reactivation and probably accounts for the increased incidence of shingles with increasing age and in immunocompromised patients. Reactivation produces shingles, with pain, itching, and paresthesias, followed by erythematous papular skin lesions in a dermatomal pattern. The lesions develop into vesicles that then crust over. Most often, a single dermatome is involved, although disseminated shingles may occur, especially in immunocompromised patients. The areas most commonly involved are thoracic and lumbar dermatomes, the ophthalmic division of the trigeminal ganglion (zoster ophthalmicus), and the geniculate ganglion (Ramsay Hunt syndrome). Rarely, patients may present with dermatomal pain in the absence of skin lesions, so-called *zoster sine herpete.* Resolution of shingles may be complicated by the development of chronic pain in the involved dermatome (postherpetic neuralgia). The duration and severity of shingles may be reduced by antiviral drugs including acyclovir, famciclovir, and valacyclovir. Some studies suggest that prompt initiation of antiviral therapy, especially in older patients, may reduce the subsequent incidence of postherpetic neuralgia. Therapy for postherpetic neuralgia includes analgesics, corticosteroids, and other medications with efficacy in the treatment of chronic pain syndromes including anticonvulsants (e.g., carbamazepine and gabapentin) and tricyclic antidepressants (e.g., amitriptyline and imipraminc). In addition to these peripheral nerve complications, reactivation of VZV can sometimes be associated with myelitis or encephalitis/arteritis in both immunocompetent and immunocompromised patients (Gilden et al. 2000).

Polyradiculitis

Polyradiculitis may he caused by viral infection of the nerve roots and is distinguished from polyneuropathy by the predominant involvement of the nerve roots rather than the peripheral nerves. The most common example is CMV polyradiculitis in patients with AIDS (Berger and Levy 1997; Gendelman et al. 1998). A rare manifestation in patients with AIDS is an acutc-subacute multifocal polyradiculopathy affecting primarily the lumbosacral roots. Patients appear ill, with fever, pain, weakness, and variable sensory and bladder dysfunction. The symptoms and signs are progressive, often in spite of aggressive antiviral therapy with ganciclovir and foscarnet, although some individuals have shown significant improvement or resolution of symptoms,

Polyneuropathy

Viral polyneuropathy is viral infection of multiple peripheral nerves and is distinguished from polyradiculitis by the

relative sparing of the nerve roots, although the two syndromes can coexist. A significant number of patients with AIDS develop a primarily sensory, axonal polyneuropathy late in the disease (Berger and Levy 1997; Gendelman et al. 1998). This is characterized by both large- and **small-fiber** dysfunction and may be extremely painful. The cause is presumed to be HIV-1 itself, because no other opportunistic infection or other cause (e.g., vitamin deficiency, endocrine abnormality) has been identified as the cause in these patients. Rare cases are caused by vasculitis, requiring a nerve biopsy for diagnosis. An axonal polyneuropathy also has been seen in 10% of patients with WNV encephalitis or meningitis (Nashetal. 2001).

Myositis

Although symptoms of muscle pain (myalgia) commonly accompany a variety of viral infections, true viral myositis is rare. Most cases follow infection with influenza, HIV-1, or enteroviruses. Symptoms of myositis include muscle pain and weakness associated with evidence of muscle fiber injury. Common indicators of muscle fiber injury include elevations in muscle enzymes (creatine kinase, aldolase), a myopathic pattern on electromyographic studies, and evidence of muscle fiber necrosis and inflammation on muscle biopsy. A small number of patients with AIDS develop myopathy, which may be secondary ro treatment with zidovudine or to HIV-1 itself (Berger and Levy 1997; Gendelman er al. 1998). Typical features of a proximal, greater than distal muscle weakness with wasting characterize the latter, which may be painful. Muscle enzyme levels are elevated and the electromyographic result is consistent with muscle damage. This may improve with antiviral therapy.

Neoplastic Transformation

Primary CNS lymphomas are lymphomas that arise in and are restricted to the CNS, usually just the brain. Although primary CNS lymphomas account for just 3% of all brain neoplasms, their incidence is rising in both immunocompromised and immunocompetent patients. In patients with AIDS, nearly 100% of primary CNS lymphomas contain EBV DNA, and more than one half contain human herpes virus 8 (HHV-8, also known as *Kaposfs sarcoma-associated herpes virus)* DNA. In non-AIDS patients with this lymphoma, the percentages are lower, but DNA from both viruses is found. What pathogenic role these viruses play in primary CNS lymphomas is unclear, but both have been associated with other tumors, including other lymphomas. The retrovirus HTLV-I has been associated with both acute T-cell leukemia and the progressive myelopathy HAM. Interestingly, it is extremely rare for one patient to develop both these disorders. This may be caused, in part, by the fact that both are relatively rare. Another possibility is there are variations in either viral or patient characteristics, or both, which predispose individuals to develop one or the other disorder, but these features are unknown at this time.

ROLE OF THE IMMUNE SYSTEM

Age-related attenuation in virus-specific cell-mediated immune responses may play a role in facilitating reactivation of certain latent viruses. Several CNS viral infections result from the reactivation of latent virus infections acquired earlier in life. Common examples include shingles resulting from the reactivation of VZV or herpes labia lis and herpes genitalis resulting from reactivation of HSV. Some forms of reactivation occur almost exclusively in immunocompromised individuals, as exemplified by PML resulting from reactivation of JC virus.

In immunosupprcssed patients, the nature of potential viral infections of the nervous system may change dramatically. Some primary viral CNS infections are seen almost exclusively in the immunosuppresscd (e.g., CMV-induced polyradiculitis, myelitis, and ventriculitis). Immunosuppression also may exacerbate the severity of viral infections. Reactivation of zoster usually leads to the development of shingles limited to a single dermatome, but in an immunocompromised individual it may result in disseminated zoster. Although relatively unusual in patients with AIDS, HSV-1 encephalitis often lacks the typical frontotemporal distribution noted in immunocompetent patients (see previous discussion). Finally, persistent infections resulting from failure of the host's immune system to clear virus may facilitate the development of viruses resistant to antiviral therapy. This is illustrated by the increased frequency of acyclovir-resistant HSV and ganciclovir-resistant CMV isolates in individuals with AIDS.

Activation of the immune system may sometimes contribute to CNS injury. There are several immune-mediated postviral or parainfectious syndromes involving the peripheral nervous system and CNS. The hallmark of many of these syndromes is the presence of demyelination. The pathogenic mechanisms producing demyelination or other types of postviral nervous system injury are not completely understood. In some cases immune-mediated damage may involve the process of molecular mimicry. In this situation, the immune system recognizes an epitope on an infecting virus. This epitope, or one closely related to it, is shared with a protein in the nervous system, often myelin-associated. Because the CNS is relatively sequestered behind the blood-brain barrier, the immune system may not recognize antigens within the nervous system as part of self. In responding to the foreign antigen, the immune system therefore may react inappropriately against this shared epitope.

The Guillain-Barre syndrome, in which multiple peripheral nerves undergo acute demyelination, may be preceded by a viral infection. Common viral antecedents include infection with 1I1V-1, CMV, EBV, and hepatitis viruses. The mechanisms by which antecedent infections precipitate peripheral nerve demyelination are not completely understood. However, cases of Guillam-Rarrc syndrome associated with bacterial infection by *Campylobacter jejuni* may involve molecular mimicry, and an analogous situation may occur following certain viral infections.

Acute disseminated encephalomyelitis is a monophasic illness of the CNS in which demyelination follows infection with a number of viruses, including measles, varicella, rubella, influenza A, mumps, EBV, or preceding vaccination. Generally, the neurological illness follows the systemic illness by days to weeks and may occur in from 1 in 1000 to 1 in 20,000 or more cases, depending on the virus. A postinfectious illness has been described also after HSV-1 encephalitis in adults. This resembles acute disseminated encephalomyelitis and is associated with postinfectious demyelination, rather than reactivation or persistence of HSV infection. MRI scans reveal disseminated white matter disease, and viral DNA is not present in the CSF.

Other examples of postviral syndromes include Reye's syndrome, postpolio syndrome, and chronic fatigue syndrome. The pathogenesis of these syndromes is still poorly understood.

Viruses and Multiple Sclerosis

The cause and pathogenesis of multiple sclerosis (MS) remain incompletely understood, but there is general agreement that both genetical and environmental components play a role. Several lines of evidence have suggested the possibility that one or more viruses might be the environmental factor in MS. JC virus in humans and other viruses in rodents are known to produce demyelination, either by direct infection of oligodendrocytes or by indirect effects of immune overactivity or dysregulation. Viral infection or vaccination often precedes acute disseminated encephalomyelitis, which results in widespread demyelination that is similar pathologically to the acute lesion of MS. Finally, acute viral infections with influenza and other viruses may precede acute exacerbations of MS. A long list of viruses has been investigated as possible etiological agents in MS, Candidate viruses have included paramyxoviruses, corona viruses, retroviruses, and herpesviruses including HHV-6. An etiological role for these viruses in MS has been suggested based on finding elevated titers of specific viral antibodies in the CSF or serum or detection of viral DNA or antigen in the blood, CSF, or brain. In some cases, viruses have reportedly been isolated from CNS tissues of patients with MS. Routinely, further study has shown that the findings cannot be replicated or are nonspecific. The important immunological abnormalities of CSF oligoclonal bands and elevated IgG have not yet been linked to a specific viral infection. Thus although the possibility that MS is related to viral infection is tantalizing, definitive proof of such an association is still lacking,

PATHOGENESIS OF CENTRAL NERVOUS SYSTEM VIRAL INFECTIONS

Stages in Viral Pathogenesis

Viral pathogenesis is the method by which a virus produces disease in the host (Tyler and Nathanson 2001).

Entry

Vituses that infect the CNS must first enter the host, then spread from their initial site of entry to the CNS. Viruses that enter the host typically do so through the respiratory tract, gastrointestinal tract, genitoutinary tract, skin, or ocular conjunctiva. Individual neurotropic viruses use each of these pathways to infect the CNS. Fot example, infections caused by many herpesviruses and HIV may begin at the mucous membranes of the mouth or genital tract. Coxsackie, polio, cchovirus, and enteroviruses enter the host through the gastrointestinal tract following otal inoculation. Viruses transmitted by the bite of arthtopod vectors such as ticks ot mosquitoes (arboviruses) including the togavituses, flaviviruses, and bunyaviruses responsible for most epidemic outbreaks of encephalitis arc transmitted across the skin barrier to the underlying subcutaneous tissues by bite of the vector. More dramatic examples of transdermal inoculation occur when the bite of a tabid animal transmits tabies or a monkey bite transmits herpesvirus simiae into the subcutaneous tissue and muscle.

Viruses are rarely inoculated directly into the bloodstream by arthropod or animal bites but may be iatrogenically introduced ditectly into the blood following transfusion or injection (Tyler and Nathanson 2001). Ttansfusion of blood or blood products has been implicated in the pathogenesis of infection by a variety of potentially neurotropic viruses including HIV, HTl.V-I, HTLV-II, hepatitis viruses, CMV, EBV, parvoviruses (B19), and most recently WNV (MMWR, 2002b).

The respiratory tract provides a portal of entry for such potentially neurotropic viruses as the paramyxoviruses (measles, mumps), certain toga viruses (rubella), and herpesviruses (VZV). In most, but not all, of these cases entry through the respiratory tract usually occurs without initiating respiratory symptoms. Exceptions occur, as when primary varicella (chickenpox) infection is associated with varicella pneumonitis.

A final and rare portal of entry for neurotropic viruses is through the conjunctiva of the eye. Although many viruses can induce conjunctivitis, and conjunctival infection can occur as a secondary manifestation of systemic viral

infections (e.g., measles), the only neurotropic virus to enter the host via this route is enterovirus 70.

Systemic Invasion

The exact cellular pathways used hy neurotropic viruses to initiate systemic invasion following initial entry into the host are understood incompletely (Tyler and Nathanson 2001). Experimental studies following the fate of reoviruses after oral or respiratory inoculation into rodents have provided important insights into this process. Following oral inoculation into neonatal mice, reoviruses adhere to the surface of specialized epithelial cells, referred to as M (microfold) cells, that overlie submucosal collections of small intestinal lymphoid tissue (Peyer's patches). Virus can be followed as it is transported across M cells to the underlying lymphoid tissue, from which it can disseminate to the nervous system by hematogenous or neural spread (vide infra). A similar sequence of events occurs following intratracheal inoculation of reovirus into rats, M cells play a similar role in the transport of poliovirus and HIV following inirial enteric infection.

Polarized Infection

Another important evenr in facilitating systemic invasion by neurotropic viruses may be the capacity of cerrain viruses to be released preferentially from either the apical or basolateral surface of infected cells (polarized infection). In the case of epithelial cells located at mucosal surfaces, apical release of virus favors local spread of infection, whereas basolateral release allows viral access ro submucosal tissues. A number of neurotropic viruses including HIV, poliovirus, and pseudorabies virus are capahle of polarized infection. In the case of both HIV and pseudorabies virus, it appears that viral envelope glycoproteins are inserted preferentially into one side of the cellular membrane and that this site determines the subsequent direction of viral release in polarized epithelial cells. Information that determines the direction of membrane sorting of the envelope glycoproteins is contained in their amino acid sequence (sorting signal).

Spread

Once a neurotropic virus has entered the host, it must then spread to reach the CNS {Tyler and Nathanson 2001). The two predominant pathways for viral spread to the CNS are through the bloodstream and through nerves. As noted, under special circumstances viruses may be inoculared directly into the bloodstream, generating a *passive viremia,* This is distinct from the *active viremia* that is generated following viral replication. Passive viremia is typically brief (<24 hours) and of low titer. Experimental studies with bunyaviruses in mice suggest that less than 0.1% of virus present in a subcutaneous inoculum enters the bloodstream as a passive viremia. In the case of passive viremia, the likelihood that a virus will successfully reach the CNS depends predominantly on the magnitude of the inoculum and the adequacy of host defenses. Factors that impair the capacity of the reticuloendothelial system to clear circulating virus may facilitate CNS invasion.

Viremia

Active viremia may occur in two phases (Tyler and Nathanson 2001). In the initial phase (primary viremia) virus enters the bloodstream after replicating in cells near the site of initial entry. The types of cells depend on both the nature of the infecting virus and the site of entry and may include epithelial cells, lymphoid cells, dendritic cells such as macrophages and Langerhans' cells, adipose, or muscle cells. Primary viremias are typically of brief duration and low titer. They serve to disseminate virus to a variety of organs and tissues where subsequent replication allows for the generation of a more sustained and higher titer viremia (secondary viremia). Typical sites of secondary viral replication in the host include spleen, liver, bone marrow, and endorhelial cells. In contradistinction to passive viremia, the secondary phase of active viremia typically lasts far longer (several days to a week) and are typically several orders of magnitude higher in titer.

Viremia is a dynamic process, the net result of which reflects the continuing introduction of virus into the bloodstream and its subsequent clearance by a variety of host defense mechanisms (Tyler and Nathanson 2001). The duration of time a virus particle spends in the host circulation has been called its *transit time.* Early studies suggest that for most viruses, transit times are between 1 and 60 minutes. The appearance of circulating neutralizing virus specific antibody coincides with, and in most circumstances appears to be responsible for, the abrupt termination of most active viremias. In the presence of antibody, viral transit times arc dramatically reduced. Conversely, inhibirion of host reticuloendothelial phagocytosis can markedly increase viral transit rime.

Viruses that enter the bloodstream may travel free in the plasma, in association with cells, or in both states (Tyler and Nathanson 2001). Most picornaviruses, as exemplified by poliovirus, and most togaviruses travel free in the plasma. Many neurotropic viruses are cell-associated or circulate in both cell-free and cell-associated states. This group includes HIV, the herpesviruses (HSV, VZV, CMV, EBV), measles, mumps, and rubella. Cell-associated virus is associated most commonly with circulating lymphocytes and monocytes and may show striking cell-type specificity, For example, cell-associated HIV is found almost exclusively in $CD4^+$ circulating T lymphocytes and monocytes. Monocyte infection also occurs with CMV, measles, and certain flaviviruses and rogaviruses including dengue and rubella. HTLV-I and HHV-6 and HHV-7 can either acutely

or persistently infect T lymphocytes. Conversely, EBV preferentially replicates in circulating B lymphocytes. The arbovirus, Colorado tick fever virus, provides an unusual example of virus associated with erythrocytes. Colorado tick fever virus initially infects erythroid precursor cells in the bone marrow (as these cells mature they are released into the circulation, carrying virus with them). Although some viruses have been found in association with circulating neutrophils or platelets, the importance of this association remains to be established.

In many cases only a small percentage of potentially susceptible circulating cells actually harbor infectious virus; however, this can vary dramatically with the particular virus and state of disease in the host. The frequency of cell infection has been studied extensively in HIV-positive humans. There is a general correlation between the severity of disease and the proportion of infected cells. For example, only 0.2-10.0% of $CD4^1$ T lymphocytes of asymptomatic HIV-positive individuals are HIV infected. This percentage can increase to as high as 60% in individuals with advanced AIDS, The percentage of cells that harbor HIV genome, as detected by ISH or *in situ* PCR appears to be significantly higher than the percentage of cells from which infectious virus can be isolated.

As noted, active plasma vircmia is typically terminated by the appearance of virus-specific antibody (Tyler and Nathanson 2001). Phagocytic cells in reticuloendothelial organs such as the liver or spleen clear virus-antibody complexes from the circulation. In many cases the binding of the Fc portion of the antiviral antibody molecule to specific receptors on the surface of macrophages and other phagocytic cells facilitates this process. Under certain circumstances viral-antibody complexes may retain infectivity and Fc receptor-mediated binding may actually provide a route of entry that allows viral infection of target cells. This process is referred to as *antibody-mediated enhancement* and has been shown to play an important role in the pathogenesis of Dengue virus infection. At times the host may fail to mount an antibody response to a circulating virus. Examples of such host tolerance can occur following congenital infection with lymphocytic choriomeningitis virus or when immunosuppression prevents the host from producing antibody.

Central Nervous System Invasion and the Blood-Brain Barrier

The mechanism by which circulating viruses exit the bloodstream to invade target tissues is still poorly understood (Tyler and Nathanson 2001). This problem is particularly complex in the CNS where the existence of the blood-brain barrier adds an additional anatomical dimension not present in other organs. The anatomical substrate for the blood-brain barrier includes high-resistance tight junctions {zona occludens) between brain capillary endothelial cells. The capillary endothelial cells are separated from brain parenchyma by a dense basement membrane. The basement membrane is covered on its parenchymal-facing surface by a complex network of processes derived from CNS astrocytes. The blood-brain barrier should be considered a selectively permeable barrier. Many small molecules (<30 kD} can cross freely, as can lipophilic compounds. A variety of transport systems also allow for facilitated transport of substances including D-glucose, essential neutral amino acids, and certain circulating peptides including insulin.

Any process that disrupts the integrity of the blood-brain barrier can facilitate viral invasion of the CNS. Experiment.! I ly, this is illustrated by the enhanced CNS invasion of certain neurotropic viruses that follows pretreatment of animals with vasoactive amines or carbon monoxide.

It has long been suggested that bloodborne viruses may invade the CNS at specific anatomical sites (loci minoris resistante) in which the capillary endothelial cells are not joined by tight junctions (fenestrated capillary endothelium), the basement membrane is sparse, and astrocyte foot processes are scant or absent (Tyler and Nathanson 2001). These areas include the choroid plexus, circumvcntricular organs (area postrema, median eminence, subfornical and subcommissural organs), and the posterior pituitary. Under experimental condirions several bloodborne neurotropic viruses including mumps, rat parvovirus, and both Western and Eastern encephalitis viruses can be shown to initiate CNS infection through the choroid plexus. This route of infection is likely to occur in many types of viral infection in which hydrocephalus is a prominent feature. The infection and subsequent sloughing of ependymal cells obstruct the flow of CSF and contributes to subsequent induction of obstructive hydrocephalus. Infection of the stroma of the choroid plexus is followed by infection of choroid plexus epithelial cells and subsequent entry of virus into the ventricular CSF. Virus then spreads from the ventricular CSF to infect the ependymal cells lining the ventricles and the subependymal tissues.

Some viruses can directly infect cerebral capillary endothelial cells and can spread from these cells into the surrounding brain tissue (Tyler and Nathanson 2001). Among the neurotropic viruses that have been visualized inside cerebral endothelial cells by electron microscopy or shown to be capable of growing in endothelial cells are picornaviruses, such as poliovirus and Theiler's virus, togaviruses, bunyaviruses, reoviruses, CMV, and several retroviruses including HIV.

Another potential mechanism of viral CNS infection has been evocatively referred to as the *Trojan horse* model (Tyler and Nathanson 2001), In this model viruses infect and are transported within circulating cells, which subsequently enter the CNS via diapedesis, bringing virus with them. This model was described originally for lentivirus infection but is likely to be of more generalized importance. Indirect support for this model as

a mechanism of CNS invasion following HIV infection comes from the fact that most HIV strains isolated from CNS tissue are macrophage tropic, and most HIV-infected cells within the CNS are of microglial-macrophage lineage.

In addition to monocytes and macrophages, several additional types of cells including neutrophils and lymphocytes are capable of crossing the blood-brain barrier by diapedesis. The molecular mechanisms involved in this process are beginning to be unraveled and include the interaction between specific cellular receptors and molecules on endothelial cell surfaces including leukocyte function antigens, intercellular adhesion molecules (ICAMs), vascular cell adhesion molecules (VCAMs), and intcgrins. Chemokines, such as macrophage inhibitory protein-la and monocyte chemoattractaiit protein secreted by macrophages may serve as chemotactic factors enhancing lymphocyte or monocyte migration into CNS tissue. Macrophages may also secrete nitric oxide and other free radicals that can react to form neurotoxic molecules or enzymes (e.g., gelatinase B) that degrade matrix proteins and thereby facilitate cellular penetration of the subendothclial basement membrane.

Specific receptors have been identified for many of the inducible adhesion molecules including ICAM-1, which binds to lymphocyte function-associated antigen (LFA-1) on lymphocytes and macrophage-1 antigen on monocytes, and VCAM-1, which binds to very late activation antigen-4 (VLA-4). In some models of CNS infection or inflammatory disease (e.g., experimental allergic encephalomyelitis) antibodies directed against ICAM-1, VCAM-1, or their respective receptors (LFA-1, VLA-4) can be shown to inhibit binding of lymphocytes to brain capillary endothelium and the subsequent diapedesis of lymphocytes into brain parenchyma. Infection with viruses including measles and HIV can alter the expression of LFA-1, CD11/CD18 integrins, ICAM-1, VCAMs, and other similar molecules, thereby facilitating egress and extravascular dissemination of lymphocytes and related cells from the circulation into brain tissue.

Neural Spread

Another major pathway of spread for neurotropic viruses from the site of entry to the CNS is through nerves (neural spread) (Tyler and Nathanson 2001). Viruses capable of spreading through nerves include HSV, rabies, poliovirus, reovirus, pseudorabies, coronaviruses, and Borna disease virus. Experimental studies have established certain basic features of neural spread that seem to be common to a large number of neurotropic viruses. Although replication in non-neural rissue (e.g., muscle cells for rabies) typically precedes viral entry into nerves, ir is not essential. This was elegantly demonstrated in studies by Bodian and colleagues with polioviruses in monkeys. In these animals, immersion of the distal stump of the sciatic nerve in a solution of poliovirus was sufficient to induce paralytic poliomyelitis. Although some viruses, such as HSV, are capable of infecting perineural cells including Schwann cells, the physiologically important route of neural spread is through axoplasmic transport within neurons. The axoplasmic transport of viruses has been demonstrated repeatedly by ultrastructural visualization of virions or viral nucleocapsids within the axons of neurons. The process has been studied also using cultured neurons in which the neural cell body and its processes are isolated from each other in a specially designed multichamber tissue culture system. The effects of initiating infection at the cell soma or via the distal end of axons can then be investigated.

Examples exist in which neurally spreading viruses travel within axons of motor, sensory, or autonomic neurons, suggesting that all types of neural cells can participate in this process. Depending on the initial site of infection and the particular virus, neural spread may involve either the anterograde or retrograde systems of transport. Studies of the kinetics of viral spread and the effects of pharmacological inhibitors indicate that neural spread occurs predominantly and perhaps exclusively via the microtubule-associated system of fast axonal transport. Some viruses, including reoviruses, can be shown to bind directly to microtubules, although it appears likely that transport is mediated by virus contained within microtubule-associated vesicles rather than by the direct interaction of virions with the mierotubular transport system,

All neurally spreading viruses also appear to be capable of transncuronal spread. Conceivably, this spread may occur at either synaptic or nonsynaptic sites. However, studies in which viruses such as HSV, coronavirus, or pseudorabies virus have been used as neuroanatomical tracers suggest that transncuronal transport occurs within particular pathways and that viruses do not promiscuously jump from one nerve fiber to an anatomically unrelated fiber system that lies in contiguity or proximity. This suggests that trans-synaptic transport may be more functionally important than nonsynaptic transport. Neurons, like epithelial cells, are polarized cells. The typical neuron has a cell body with short dendritic processes and a long axon. Selective entry and subsequent release of viral particles from distinct parts of the cell may facilitate trans-synaptic spread of virus. There is evidence, on at least some types of neurons, that the cell receptors for certain viruses, including HSV and rabies, may be concentrated near synaptic terminals. Similarly, in certain experimental models of infection, rabies virions accumulate in muscle cells near the neuromuscular junction.

Viruses that are capable of spreading to the CNS through nerves escape the inhibitory effects of the blood-brain barrier. Many nerve cells, including the motor neurons of the spinal cord, the sensory neurons within dorsal root ganglia, and olfactory neurons have processes that extend outside the blood-brain barrier, A virus, such as rabies, that enters motor neuron axons in the periphery (e.g., at the neuromuscular junction) is transported retrograde directly

into the CNS. Experimentally, it can be shown that certain neurotropic viruses including reovirus, poliovirus, pseudorabies virus, and swine hemagglutinating encephalomyelitis virus, which can enter the host through the intestine, infect neurons in the myenteric plexus and are then transported to the CNS via the vagal nerve to reach the dorsal motor nucleus of the vagus in the medulla.

It is important to recognize that hematogenous and neural spread need not be mutually exclusive processes. Some viruses use different pathways of spread at different stages in their life cycle. For example, VZV spreads via the bloodstream to the skin to produce the characteristic rash of chickenpox. Virus then spreads centripetally through the axons of sensory nerves to reach their cell bodies in dorsal root ganglia. Reactivation of varicella from dorsal root ganglions results in centrifugal spread of virus from the cell bodies of sensory neurons to specific skin dermatomes to produce zoster. In some cases, different strains of the same virus use different pathways to spread to the CNS. For example, after inttamuscular inoculation into mice reovirus serotype 1 Lang (TIL) spreads predominantly via the bloodstream to reach the spinal cord, whereas reovirus serotype 3 Dearing (T3D) spreads via nerves.

The penetration of a neurotropic virus into the CNS depends on its pathway of spread (Tyler and Nathanson 2001). As noted, neutally spreading viruses such as rabies, HSV, and VZV can enter the peripheral axons of either motor neurons or the peripheral processes of bipolar sensory neurons. Once inside these cells, virions or virion nucleocapsids are transported into the CNS via axoplasmic transport. The rods of olfactory receptor cells, a special class of sensory neurons, also lie outside the CNS within the epithelium of the nasal mucosa. Many neurotropic viruses including HSV, coronaviruses, poliovirus, vesicular stomatitis virus, and certain togaviruses can be shown to infect olfactory neurons under experimental conditions. From these neurons, virus can then spread sequentially to the olfactory bulb and enterorhinal cortex. Although experimental studies have demonstrated repeatedly that olfactory spread is a feasible pathway for viral invasion of the CNS, it has been difficult to definitely demonstrate that this pathway is of importance for the pathogenesis of naturally occurring human CNS infection. However, there are isolated cases of herpes simplex encephalitis and rabies infection following massive aerosol exposure in which the neuropathological features are consistent with this method of CNS infection.

Neurotropism

Once a virus has invaded the CNS, the clinical features of illness depend on the regions of the CNS that are infected and subsequently injured by the virus. The capacity of a virus to infect specific populations of cells is referred to as *tropism,* and when infection involves cells within the CNS, as *neurotropism.* When a virus specifically infects neurons within the CNS it is occasionally referred to as *neuronotropic.*

Tropism is the end result of a complex and multifactorial interaction between an infecting virus and a host (Tyler and Nathanson 2001). Factors that can influence tropism include (1) epidemiological factors including the age, sex, immune status, and genetical composition of the host; (2) the site of entry and pathway of spread of a virus within the host; (3) the interaction between the virion cell attachment protein and target cell receptors on host cells; and (4) viral proteins that enhance transcription of viral proteins in a cell- or tissue-specific manner.

Viral Receptors

One of the most dramatic and productive areas of viral research has been the identification of host cell receptors fot a large number of viruses (Tyler and Nathanson 2001). Examples of receptors for neurotropic viruses are shown in Table 46.2.

In some cases the assignment of a specific host cell receptor remains controversial. It has also become clear that many viruses are capable of using more than one cellular receptor and in some cases more than one pathway to enter cells {e.g., direct membrane penetration and receptor-mediated endocytosis). Different strains of the same virus may also use different host cell receptors. For many viruses, as exemplified by the herpesviruses, the interaction with host cell receptors is a complex process that involves the interaction of multiple virion surface proteins with the target cell (Tyler and Nathanson 2001). Similarly, for viruses such as HIV, additional cell surface proteins serve as coreceptor molecules that can dramatically influence the success with which the virion binds to its primary receptor (Berger and Levy 1997; Gcndelman et al. 1998). The first of the HIV coreceptor molecules identified was fusin (CXCR-4), a G-p rote in-like transmembrane protein, which functions as a coreceptor for T-lymphocyte tropic viral strains. Subsequently, a variety of molecules were found to serve as coreceptors for macrophage-tropic HIV strains including the /3-chcmokine receptors for macrophage inhibitory protein-la, macrophage inhibitory protein-lb, and RANTES (CCR3, CCR5). HIV also illustrates the fact that a single virus can use different receptors to infect distinct classes of cells. For example, although CD4 and the coreceptor molecules CXCR4, CCR3, and CCR5 arc key determinants of microglial infection, galactosylceramide or related glycolipids appear to be the critical receptor for HIV on colonic and cervical epithelial cells and certain types of cultured neuroblastoma cells.

Viral Effects on Target Celts

The interaction between a virus and a target cell can have a variety of outcomes (Tyler and Nathanson 2001). Some

Table 46.2: l-'.x:jniples DI neurotropic viruses and their host cell receptors

Family	*Example*	*Receptor*
Arenaviridae	LCMV	ot-Dystroglycan
Coronaviridae	MHV	Carcinoembryonic antigen family
Hcrpcsviridae	EBV	CD21 (CR2 receptor)
	HSV	Heparan sulfate
		HVEM
		PVR-1
	Pseudorabies	Heparan sulfate
		PVR-1
	CMV	Heparan sulfate
		^-Microglobulin
Myxoviridae	Influenza	Sialic acid residues
	Measles	CD46
		Moesin
Parvoviridae	Parvovirus B19	Erythrocyte P antigen
Picomaviridae	Coxsackievirus	Decay accelerating factor (CD55)
		Vitronectin receptor
		Inregrin a_v^j
	Kchovirus	Jntegrin VLA-2 (a_2/j,)
	Polio virus	IgGsuperfamily (PVR)
Reoviridae	Reovirus T3D	Sialic acid residues
		JAM
Retroviridae	HIV	CD4
		Chcmokinc receptors (CXCR5, CCR4)
		Galactosylceramide
Rhabdoviridac	Rabies	Acetylcholine receptor
		NCAM
		NGF-R
		Gangliosides
		Phospholipids [phosphatidyl serine)
Togaviridae	Sindbis	Lam in in receptor

CMV = cytomegalovirus; EBV = Epstein-Barr virus; HIV = human immunodeficiency virus; HSV = herpes simplex virus; JAM = Junctional adhesion molecule, MHV = mouse hepatitis virus; NCAM = neural cell adhesion molecule, NGF-R = nerve growth factor receptor, PVR = poliovirus receptor related protein; VLA-2 = very late activation antigen-2.

viruses are capable of becoming latent in neurons. In this situation, infected neurons contain viral genomes, either integrated into their DNA or episomally. Latently infected cells may display little or no obvious alteration in morphology or function. Viral latency in neuronal cells has been extensively studied for HSV, although the molecular mechanisms underlying the establishment, maintenance, and reactivation from latency are still only incompletely understood. Much research has involved attempts to identify viral genes, transcripts, or proteins expressed during latency (e.g., latency-associated transcripts) and the interplay between these factors and host cell proteins including trophic factors (e.g., nerve growth factor) and signal transduction proteins.

In some cases, infection of neuronal cells can result in perturbation of differentiated cellular functions without striking alterations in cellular morphology. For example, viral infection results in diminished production of growth hormone by infected, but morphologically normal, pituitary cells. The resulting growth hormone deficiency accounts for a dramatic Hunting syndrome in infected mice. Another example is inhibition of production of various ncurotransmittcr-rclated proteins, including tyrosine hydroxylase, choline acetyltransferase, and acetylcholinesterase, in virus-infected cells.

Virus infection can also lead to cell death. There are two major forms of cell death: necrosis and apoptosis, Apoptotic cell death is characterized by shrinkage and cytoplasmic membrane blebbing (zeiosis) associated with compacting, margination, and fragmenrarion of nuclear chromatin. In many cases the chromatin fragmentation occurs predominantly where nucleosomes are bound to DNA. This internucleosomal cleavage resulrs in the generation of DNA fragments that arc mulriplcs of 180—200 nucleotide base pairs in length. This oligonucleosomal ladder of DNA fragments can be visualized by isolating DNA from apoptotic cells and clcctrophorcsing it on agarose gels followed by rhe use of DNA sraining dyes (e.g., ethidium bromide). Their characteristic ultrastructural or morphological changes and demonstration of DNA fragmentation typically identify apoptotic cells in tissues. One method of demonstrating this fragmentation in cells involves terminal deoxytidyl nick end-labeling, which makes use of the fact that apoptotic DNA fragmentation produces large numbers of DNA ends containing 3'OH groups. A biotinylated or otherwise labeled nucleotide is added to these free ends using terminal deoxynucleotidyl transferase. The labeled nucleoride is then identified immunocy toe hemic ally or by immunofluorescence. It is important to recognize that terminal deoxytidyl nick end-labeling staining alone is not pathognomonic for apoptosis and that accurate identification of apoptotic cells requires demonstration of both the characteristic morphological changes and associated evidence of DNA fragmentation.

In contradistinction to apoptotic cell death, necrotic cell death is characterized by early failure of cytoplasmic membrane integrity. The resulting release of intracellular proteins, including a variety of enzymes, typically induces a prominent inflammatory response. DNA fragmentation occurs in necrotic cells, but the fragments are of a wide variety of sizes, and fragmentation does not occur predominantly at internucleosomal points.

Many neuronotropic viruses have been shown to induce apoptosis in cultured cells including neurons. Examples of neurotropic viruses capable of inducing apoptosis in cell culture include bunyaviruses (LaCrosse), herpesviruses (VZV), picornaviruses (poliovirus, Thcilcr's virus), reoviruses (T.3D), retroviruses (HIV-1, HTLV-I), rhabdoviruses (rabies virus), and togaviruses (Sindbis), Several of these viruses, including LaCrosse, Theiler's virus, reovirus,

HIV-1, and Sindbis, have been shown also to produce apoptosis in vivo. In many cases an excellent correlation exists between the distribution of viral infectivity as demonstrated by immunocytochemistry to localize viral antigens or ISH to localize viral nucleic acid, apoptotic cells, and neuropathological injury,

The viral and cellular mechanisms responsible for induction of apoptosis are still incompletely understood. For some viruses experimental studies have identified specific viral genes or proteins that may be important in induction of apoptosis including the <r1 protein of reoviruses, gpl20 of HIV, and E2 glycoprotein of Sindbis. The mechanism by which these viruses trigger apoptosis is gradually becoming better understood. In some cases viral infection may result in activation of proteases involved in apoptotic cascades, as exemplified by calpain activation during reovirus infection of cultured cells. In other cases apoptosis may be triggered by virus-induced alterations in intracellular calcium concentration, a mechanism suggested for HIV gpI20-induced neuronal cell death. Infection of cells with viruses including reovirus, Sindbis, and HTLV-I may perturb signal transduction pathways that lead to the activation of transcription factors that in turn induce gene activation resulting in apoptosis. This pathway has been elegantly elucidated for HTLV-I. HTLV-I *tax* protein interacts with and activates the cellular kinase MEKK1. Activated MEKK1 phosphorylates and thereby activates the I/cB kinase. kB kinase phosphorylates LrB. kB is complexed with NF»rB in the cytoplasm. **The** cytoplasmic NF^B-kB complex is inactive. However, once kB is phosphorylated by kB kinase it is rapidly ubiquitinated and degraded. NF/fB is then free to translocate to the nucleus, where it functions as a transcriptional activator. The results of NFKB-dependent transactivation may be either proapoptotic or antiapoptotic depending on the nature of the inducing stimulus and the cell type. In many viral systems the end effect of NFVB activation seems to be proapoptotic as inhibition of its activation inhibits virus-induced apoptosis.

DIAGNOSTIC TECHNIQUES

The diagnosis of CNS viral infections has evolved in parallel with the increasing sophistication in research techniques. In the seventeenth and eighteenth centuries, the classification of CNS diseases was based predominantly on their cardinal symptoms. Most cases of what would today be recognized as viral encephalitis or meningitis were simply considered brain fevers. In a similar vein, rabies virus infection was typically included under the descriptive term "hydrophobia," and many cases of viral myelitis were lumped together under designations such as "debility of the lower extremities."

In the nineteenth century, improved methods for the fixation and staining of tissues and enhancement in the quality of microscopical optics ushered in a golden era for pathology in general, and neuropathology in particular. Neurological diseases, including those caused by viruses, were now characterized and classified according to the regions of the CNS involved and the nature of the pathological injury. Improved nosology of neurological disease reflected the new emphasis on neuropathology, as exemplified in Charcot's classic descriptions of poliomyelitis, the name reflecting the predominant involvement of the gray matter of the spinal cord and the associated inflammation.

The nineteenth century also saw the first attempts to systematically examine how specific pathogens produced disease. In the area of ncurovirology this was strikingly demonstrated in Pasteur's studies of rabies virus. Pasteur carefully elucidated rabies' mode of infection, route of spread, and localization within nervous tissue. Pasteur's work can be said to have inaugurated the scientific study of both microbial pathogenesis in general and the pathogenesis of viral CNS infections in particular.

Early studies of the pathogenesis of CNS viral infection were limited by their almost exclusive dependence on visualizing pathological alterations in tissue as a marker for viral infection. In some cases this was facilitated by the presence of specific markers of viral infection such as the cytoplasmic Negri and Lyssa body inclusions in rabies and the Cowdry type A intranuclear inclusions seen in herpesvirus infections. The availability of electron microscopy allowed viral particles to be identified in both biopsy and autopsy tissues derived from patients with CNS viral infections. However, electron microscopy was too cumbersome to permit routine quantification of the number of viral parricles or the sequential tracking of the development and spread of virus infection.

The advent in the 1950s of tissue culture systems to cultivate viruses allowed for easier and more precise quantification of the amount of virus present in particular tissues. Another significant advance was the ability ro localize viral antigens in tissue using immunocytochemica! methods. This began following Coons's description in the late 1940s of techniques to couple antibodies with fluorescent molecules and the use of these antibodies to localize antigens in tissues. This technique was not applied to the study of CNS viral infection in any comprehensive manner until the 1960s when R. T. Johnson used fluorescein-conjugated antiviral antibodies to study the spread of HSV and Sindbis virus to the CNS.

In the modern era, immu no flu orescent techniques have been supplemented by immunocytochemical techniques in which antibodies arc linked, either directly or indirectly via avidin-biotin or similar coupling reactions, to enzymes such as horseradish peroxidase, alkaline phosphatase, or glucose oxidase. Antigen-antibody binding is then detected by use of a criminogenic substrate. The availability of monoclonal antibodies directed against specific epitopes on individual viral proteins has further extended the range of immunocytochemical studies.

Techniques to identify the presence of viral nucleic acid, including genomic RNA or DNA, and messenger RNAs has added another valuable ser of tools ro studying the localization and pathogenesis of CNS viral infections. Initially, these studies involved the localization of labeled probes complementary to viral mRNA or gene sequences, a technique known as ISH. PCR has also added an invaluable diagnostic tool (see later in this section).

A variety of clinical features should raise the possibility of CNS viral infection. These include fever, meningismus, altered or depressed consciousness, and focal neurological signs. Sometimes the specific clinical scenario combined with results from CSF analysis, neuroimaging srudies, and EEG may allow a presumptive diagnosis of a viral CNS infection. For example, in an immunocompetent adult patient in the United States who presents during the winter with acute onset of fever, depressed consciousness, and seizures, HSV-I encephalitis is an important diagnostic consideration. A number of reviews of the role of laboratory investigation in the diagnosis and management of HSV encephalitis have now appeared. If the CSF profile, neuroimaging studies, and EEG are consistent with this diagnosis, then empirical antiviral therapy with acyclovir should be instituted promptly. However, a significant number of patients with clinical and laboratory features indistinguishable from HSV-1 encephalitis have other treatable viral and nonviral diseases. Because all currently available antiviral drugs are efficacious only against particular viruses, it becomes critical to develop fast, sensitive, and specific techniques for viral diagnosis.

Before the application of molecular biological techniques to vira! diagnosis, identification of viral infections depended on culture, serology, and antigen detection (see Table 46.1). Viruses can be cultured from body fluids including CSF (many viruses), blood or blood cells (herpesviruses, retroviruses), urine (CMV), feces (poliovirus, echovirus), nasopharyngeal washings (enteroviruses, mumps, adenovirus, influenza viruses), or tissues such as skin lesions (HSV-1 and -2, VZV) or brain (many viruses). Systems used for isolation of virus include a variety of cultured cell lines, chick embryo chorioallantoic membranes, and direct inoculation into neonatal mice. The sensitivity of these methods varies widely and depends on the particular virus and the specimen being tested. In general, viral isolation is slow, inefficient, and expensive.

Several immunological tests are available to identify acute viral infection of the nervous system. Most commonly used tests arc designed to quantify levels of virus-specific antibodies. For many viral infections, demonstration of a fourfold or greater increase in virus-specific antibody titers between acute and convalescent sera is diagnostic of acute infection. Demonstration of virus-specific antibody in a single scrum specimen is generally not adequate to diagnose an acute viral infection, because it may merely indicate past exposure. The presence of virus-specific IgM in serum or CSF is usually indicative of recent infection, because IgM antibody rarely persists for more than a few months. Detection of intrathecal virus-specific antibody production is a useful diagnostic test for many CNS viral infections. However, increases in virus-specific antibody in the CSF may result from breakdown of the blood-brain barrier or from polyclonal immune activation as occurs in certain diseases including systemic lupus erythematosus and MS. Correcting for leakage of protein across the blood-brain barrier using the CSF to serum albumin ratio may enhance the specificity of intrathecal antibody tests. Showing that intrathecal antibody responses arc limited to a particular virus, rather than part of a more general phenomenon, also enhances the specificity of antibody testing. When antibody production resulrs from activation of a few discrete B-cell clones within the CNS compartment, oligoclonal bands may be detected in CSF. Oligoclonal bands are not specific for viral infection and occur in a wide variety of immunological neurological diseases. Virus-specific antibody responses are rarely detectable until 2 or 3 weeks after onset of illness, and hence an increase in such a titer between acute and convalescent sera is required for diagnosis. As a result, serological tests arc rarely useful in acute diagnosis and management of viral infections.

Diagnosis of specific viral infections can be made also by identification of viral antigens in tissues or body fluids including CSF. The most commonly employed techniques use radiolabeled or enzyme-linked antibodies in immunosorbent assays. Viral antigens in tissues or cells can be identified using enzyme-linked or fluorescent-labeled virus-specific antibodies. In general, detection of viral antigens provides rapid, sensitive, and specific diagnosis, but the techniques are suitable for only a limited number of viral infections. The major limitation of the technique is the requirement that virus-infected tissue be available for study. In the case of viral CNS infections, this often requires brain biopsy, because antigen is only rarely detectable in CSF.

The application of molecular biological techniques to the diagnosis of viral CNS infections has revolutionized diagnosis. The most useful techniques are designed to identify viral nucleic acid in body fluids or tissue specimens. For analysis of intact tissues, ISH with radiolabeled or enzyme-labeled (especially horseradish peroxidase and digoxigenin) viral nucleic acid probes allows for reasonably rapid viral identification. This technique also has been adapted for use with small populations of cells, as might be available from body fluids such as saliva or urine. The major advantages of this technique are its great specificity and its capacity to detect even a few copies of the viral nucleic acid. ISH is useful also in identifying individual infected cells in tissue specimens.

After extracting cellular and genomic DNA or RNA from a tissue, two basic techniques, immunoblotring and PCR, can be used to determine whether viral nucleic acid is present in the sample. The older techniques, Southern hybridization for DNA and Northern hybridization for RNA, involve the same hybridization techniques described

previously for ISH, except the target nucleic acid has been extracted from the infected tissue, digested with restriction end on ue leases, run on a gel, and transferred and fixed to a membrane. The advantages of these techniques are the same as for ISH, and they are technically simpler. Their only disadvantage is the inability to identify which cells in a population are infected, but this has little effect on the clinical management of the patient.

The major revolution in diagnostic virology has been the rapid development of PCR {DcBiasi and Tyler 1999). By using known nucleotide sequences 20 bases or longer as primers, PCR allows for amplification of tiny quantities of whole genes or just fragments of genes of interest. In its simplest form, this is performed as liquid PCR, with a single set of primers, using exttacted DNA or RNA samples. Aliquots of the amplified nucleic acid arc run on a gel containing ethidium bromide and visualized under ultra-violet light. This is a highly specific and sensitive technique, which is able to identify a small number of copies of viral nucleic acid among thousands ot cells. Technical and methodological advances have allowed for even greater sensitivity and specificity, so that single copies of genes can often be identified in samples of nucleic acid derived from large numbers of cells. These advances include the addition of a hybridization step after running the sample on a gel; the use of nested PCR, in which a PCR reaction is first done with an outer set of primers, and then a small aliquot of this fitst teaction is subjected to a second round of PCR using an inner set of primers that are contained within the first amplified gene prod net; and *in situ* PCR, in which PCR is done on intact tissues and followed by ISH. In clinical laboratory practice nearly all PCR tests involve liquid PCR of target nucleic acid extracted from body fluids or tissues. For viral meningoencephalitis, PCR of CSF or other body fluids is the study of choice. Reptoduciblc protocols exist for HSV-1 and -2, CMV, EBV, VZV, HHV-6, HIV-1, and enteroviruses.

Sensitivity of PCR varies according to the tissue or body fluid from which the nucleic acid is derived and the viral genes assayed. For example, from patients with AIDS with biopsy-proven PML, JC virus can be amplified from 100% of brain samples, 89% of peripheral blood lymphocytes, and 79% of CSF samples. By contrast, sensitivity of HSV PCR from CSF of patients with biopsy-proven HSV-1 encephalitis is extremely high and exceeds 95%. There have been reports of false-negative HSV PCRs obtained during the first 72 hours of infection (Weil et al. 2002). The incidence of positive PCRs also declines with time following infection and associated therapy. Only "~20% of CSF PCRs remain positive after day 14 of illness.

In asymptomatic immunocompetent individuals the CSF does not contain amplifiablc viral nucleic acid. The finding in the appropriate clinical setting of viral nucleic acid in CSF by PCR is virtually diagnostic of viral CNS infection. Extensive experience suggests that false-positive CSF PCR results arc extremely rare when the test is performed by a reliable laboratory according to generally accepted techniques designed to minimize the risk of inadvertent contamination. The value of a negative CSF PCR test result in excluding a specific viral infection varies with the specific virus and the clinical setting.

PCR has been used also to amplify viral nucleic acid directly from brain tissue. The sensitivity and specificity of brain tissue PCR have not yet been established. Initial studies suggest that PCR may amplify viral nucleic acid from the brain tissue of asymptomatic individuals without known or neuropathologically evident neurological disease. The frequency of positive brain tissue PCR results depends on the specific virus, the PCR techniques, and the region of the brain being examined. The high incidence of positive brain tissue PCR results in apparently normal individuals means that extreme caution should be exercised in interpreting positive brain tissue PCR results as evidence for acute viral infection. Positive brain tissue PCR results have been used also to suggest a viral cause for a diverse group of neurological disorders including Rasmussen's syndrome, MS, epilepsy, and Alzheimer's disease. These associations should be considered suspect until more information about brain tissue PCR becomes available.

THERAPY

Therapy for viral infections of the nervous system can be categorized as preventive, supportive, or antiviral (Rcding-ton and Tyler 2002). The simplest preventive therapies are designed to eliminate or greatly reduce the likelihood of inoculation with potential infectious agents. This can include public health measures such as mosquito or tick eradication programs and improvement of sewage systems and aggressive eradication of insects and mammals infected with tabics or arboviruses; blood transfusion screening programs to avoid transmission of HIV-1, hepatitis B and C, HTLV-I, and other infections via blood products; and education programs, such as the promotion of safe sex programs to limit the risk of transmission of sexually transmitted diseases, or efforts to increase the number of homes with screened windows and doors in areas with arbovirus epidemics. Changes in personal behavior, such as elimination of unsafe sexual practices (to avoid contact with, e.g., HIV-1) or changing of work schedules (to avoid exposure at high-risk times to arboviruses) also may be extremely important. Postexposure practices such as removal of ticks or proper wound care (e.g., in rabies permitting bleeding and washing with inactivating soap and water) also may reduce the risk of viral transmission in some cases.

The other significant approach to prevention is immu-noprophylaxis with vaccines. Traditionally, vaccines have been divided into *live attenuated vaccines,* producing infection with and immune response to nonvirulcnt strains of virus, and immunization with *inactivated, non-replicating virus vaccines.* Recombinant DNA technology

has produced vaccines that stimulate immune responses directed against single viral antigens or subunits of antigens. The antiviral vaccines routinely administered in the United States during early childhood, including those to mumps, measles, varicella, polio, and rubella viruses, all are live, attenuated vaccines, which may retain a certain amount of pathogenicity or may revert to a more neurovirulcnt form. This may pose a relatively higher risk of the use of these vaccines in immunocompromised patients, who may not cleat the infection properly. In the United States, the relative risk of paralytic complications of oral polio vaccine is increased markedly in the immunocompromised patient population. The vaccine to Japanese encephalitis virus, used extensively in Japan, China, and other areas of the Far East, is inactivated. The inactivated rabies vaccine is used both for preexposure prophylaxis in individuals at relatively high risk of bites from rabid animals and in combination with human rabies immune glohulin for postexposure prophylaxis.

Supportive and Symptomatic Therapy

After onset of viral infections of rhe nervous system, supportive care can be very helpful. For the common viral meningitides and encephalitides, this may include bed rest, analgesics, anticonvulsants, and antipyretics. Aggressive management of pneumonia and other bacterial infections, hypotension, dysautonomia, and elevated intracranial pressure may be crucial in more severe infections such as rabies or EEEV. Judicious use of high-dose glucocorticoids in the first several (.lays ot HSV-1 encephalitis therapy, when there is a great deal of cerebral edema and the risk of herniation is high, may be useful, although this has not been properly studied. After resolution of the acute neurological illness, rehabilitative services may be a necessary and important part of the patient's return to his or her usual activities.

For postinfectious neurological illnesses, modulation or alteration of the immune system may have positive results. In Guillain-Barrc syndrome, both plasmapheresis and administration of intravenous immunoglobulin have been shown to significantly reduce morbidity. In acute disseminated encephalomyelitis and related postinfectious demyelinating disorders, high doses of intravenous glucocorticoids typically arc used, although their efficacy has never been established.

The era of antiviral drug use in nervous system infections was ushered in with the landmark studies of Whitley and colleagues, who looked first at adenosine arabiuoside and subsequently acyclovir in the treatment of HSV-1 encephalitis. Their studies showed a clear, significant effect of acyclovir in reducing mortality, especially if given early in the course of the illness, and morbidity. Subsequently, acyclovir has been shown effective against VZV, also a member of the alpha-herpesvirus subfamily.

All of the antiviral therapies developed to date interrupt one or more crucial steps in the life cycle of the replicating virus. Acyclovir inhibits the HSV-encoded DNA polymerase. The active metabolite is acyclovir triphosphate. The initial phosphorylation of acyclovir occurs much more efficiently in virus-infected cells, because it requires a virus-encoded enzyme (thymidine kinase). This selective phosphorylation, and the fact that acyclovir triphosphate is a much more potent inhibitor of HSV DNA polymerase than human DNA polymerase, accounts for acyclovir's specificity of action. Acyclovir is not effective as an antiviral agent against viruses that lack a DNA polymerase (e.g., RNA viruses) or against DNA viruses without a virus-encoded thymidine kinase (e.g., CMV). The newer antiviral drugs famciclovir and valacyclovir have similar mechanisms of action and specificity as acyclovir. The primary advantage of these agents is their enhanced bioavailability after oral administration and their longer half-life that permits less frequent dosing intervals.

Ganciclovir has a similar mechanism of action to acyclovir. Its major advantage is its efficacy against CMV infection. CMV lacks a virus-encoded thymidine kinase, but ganciclovir, unlike acyclovir, is phosphorylated in CMV-infected cells by another virally encoded kinase. Cidofovir is a newer antiviral nucleoside analogue that like ganciclovir does not depend for its activity on the presence of a virus-encoded thymidine kinase. It is efficacious against CMV and has been used with success in treating CMV retinopathy and CNS infections. The drug has a prolonged iiitiML-ellular half-lite that permits once-daily dosing. Complications of intravenous therapy include nephrotoxicity and bone marrow suppression.

Another antiviral drug, foscarnet, is also effective against CMV. Foscarnet is an inorganic pyrophosphate analogue that differs in its mechanism of action from the nucleoside analogues (e.g., acyclovir, ganciclovir). Unlike the nucleoside analogues, foscarnet is not metabolized inside infected cells, but like the nucleosides it also acts to inhibit viral DNA polymerase. The utility of foscarnet is limited by its toxicity, nonetheless it remains useful in the treatment of infections caused by CMV and acyclovir-resistant strains of HSV.

A number of antiviral drugs have been developed to combat HIV-1 infection (Bcrgcr and Eevy 1997; Gendelman et al. 1998). The first generation of antirctrovirai drugs were inhibitors of reverse transcriptase, the viral enzyme necessary for production of the DNA form of the virus. Zidovudine, and subsequently dideoxyinosinc and didcoxycytidine, have been shown to delay the progression of AIDS-demcntia complex. Newer antiretroviral drugs include a number of protease inhibitors. These drugs work by inhibiting an enzyme required for the processing of viral proteins. Therapeutic regimens using complex combinations of several different protease inhibitors have

had a dramatic effect on the progression of HIV infection, and in the incidence of many HIV-related opportunistic infections. It remains to be seen whether these effects will be sustained. Studies of the efficacy of protease inhibitors on the neurological complications of HIV infection arc limited, but one study has shown that multidrug therapy including protease inhibitors can reduce HIV-1 viral load in the CSF.

Although azidothymidine appears to have efficacy *in vitro* against HTLV-I, it has not been clinically successful in the treatment of HAM. This may reflect the fact that neuronal injury in HAM may result from immunological attack by virus-specific cytotoxic T cells, rather than as a result of direct viral infection. Consistent with this model of pathogenesis is the suggestion that treatment with immunomodulatory agents including corticosteroids and interferon-a may be beneficial in HAM.

Chapter 47
Neuroendocrinology

Paul E. Cooper

Homeostasis—the maintenance of the constancy of the internal milieu—requires, in all but the simplest of organisms, communication among cells and organs that are widely separated. This communication is achieved through the coordinated interaction of the nervous, endocrine, and immune systems. It is the study of this coordinated interaction that is the field of neuroendocrinology,

NONENDOCRINE HYPOTHALAMUS

Neuropeptides, Neurotransmitters, and Neurohormones

The term *neurotransmitter* is applied traditionally to a substance released by one neuron to act on an adjacent neuron in a stimulatory or inhibitory fashion. The effect is usually rapid, brief, and confined to a small area of the neuron surface. In contrast, a *hormone* is a substance that is released into the bloodstream and travels to a distant site to act over seconds, minutes, or hours to produce its effect over a large area of the cell. *Neuropeptides* can act in cither fashion. For example, the neuropeptide vasopressin, produced by the neurons of the supraoptic and paraventricular nuclei, is released into the bloodstream and has a hormonal action on the collecting ducts in the kidney. In the central nervous system, vasopressin acts as a neurotransmitter. Similarly, the neuropeptide substance P acts as a neurotransmitter in primary sensory neurons that convey pain signals and as a neurohormone in the hypothalamus.

The influence of neuropeptides on the brain can be divided into two broad categories: organizational and activational. Organizational effects occur during neuronal differentiation, growth, and development and bring about permanent, structural changes in the organization oi the brain that affect its function. An example is the structural and organizational changes brought about in the brain by prenatal exposure to testosterone. Activational effects are those that change pre-established patterns of neuronal activity, such as an increased rate of neuronal firing caused by exposure of a neuron to substance P. Numerous neuropeptides are found in the brain, and research has shown these compounds to have a variety of effects on neuronal function (Table 47.1).

Neuropeptides and the Immune System

Stress, acting through the hypothalamic-pituitary-adrenal axis, modulates the function of the immune system. Certain peptides and their receptors, once thought to be unique to either the immune or neuroendocrine system, are actually found in both.

Cytokines (interleukin [IL]-I, -2, -4, and -6, and tumor necrosis factor [TNF]) arc synthesized by glial cells in the central nervous system in response to cell

Table 47.1: Neuropeptides found in the brain and their effects on brain function*

Neuropeptide	*Central nervous system function*
Hypothalamic peptides modulating pituitary function	
Corticotropin (ACTH)-relea sing hormone	Regulation of ACTH secretion
	Integration of behavioral and biochemical responses to stress
Vasopressin	Learning and memory facilitation
	Memory processes
Oxytocin	Induction of maternal and M-viial behaviors
Growth hormone-releasing hormone	Regulation of growth-hormone secretion
Growth hormone release inhibiting hormone (somatostatin)	Regulation of growth-hormone secretion
Ghrelin	Regulation of growth-hormone secretion
	Regulation of feeding
Thyrotropin-releasing hormone	Regulation of thyroid-stimulating hormone secretion
	May he involved in depression
	Enhances neuromuscular function
Gonadotropin-reIcasing hormone (luteinizing hormone-releasing hormone)	Regulates gonadotropin secretion
	Sexual receptivity
Prolactin-releasing peptide	Stimulates prolactin secretion
Neurotensin	Endogenous neuroleptic
	Regulates mesolimbie, mesocortical, and nigrostriatal dopamine neurons
	Thermoregulation
	Analgesia
Neuropeptide V	Satiety and drinking
	Sexual behavior
	Locomotion
	Memory
Pituitary peptides	
Prolactin	
Growth hormone	
Thyroid-stimulating hormone	
Follicle-stimulating hormone	
Luteinizing hormone	
Proopiomelanocortin	
ACTH	
ACTH-like intermediate lobe peptides	
^-Endorphin	Analgesic mechanisms
	Feeding
	Thermoregulation
	Learning and memory
/i-Lipotropic hormone	
Melanocyte-stimulating hormone *(a* and *y)*	
Oxytocin	
Vasopressin	
Neurophysins	
Brain-gastrointestinal tract peptides	
Vasoactive intestinal polypeptide	Cerebral blood flow
Somatostatin	
Insulin	Feeding behavior
	Hunger
Glucagon	
Pancreatic polypeptide	
Gastrin	
Cholecystokinin	Feeding behavior
	Satiety
	Modulates dopamine neuron activity
Tachykinins (e.g., substance P)	Substance P colocalizcs with serotonin and is involved in nociception

Continued

Tabic 47.1, cont'd. Neuropeptides found in die brain and their effects on brain function*

Neuropeptide	*Central nervous system function*
Secretin	
Thyrotropin-releasing hormone	
Bombesin	Thermoregulation
	Appetite
Orcxins (hypocretin)	Gastric and GI motility and secretion
	Pancreatic hormone release
	Regulation of energy homeostasis
Growth factors	
Insulin-like growth factors I and II	
Nerve growth factors	Axonal plasticity
Opioid family	
Endorphins	
Enkephalins (Met-, Leu-)	Analgesic mechanisms
	Feeding
	Temperature control
	Learning and memory
	Cardiovascular control
Dynorphins	
Kytorphin	
Neuropeptides modulating immune function	
ACTH	
Endorphins	
Interferons

Similarly, immunocompetent cells contain hormones and neuropeptides that may affect neuroendocrine and brain cells (Table 47.3). Despite speculation about the ability of the psyche to influence immunological function and therefore disease outcome, there is no conclusive evidence to date to suggest that this is clinically significant (Reichlin 1993).

Temperature Regulation

The hypothalamus plays a key role in ensuring that body temperature is maintained within narrow limits by balancing the heat gained from metabolic activity and the environment with the heat lost to the environment. A theoretical schema of the mechanisms of hypothalamic temperature regulation is depicted in Figure 47.1. Although numerous neurotransmitters and peptides alter body temperature, their physiological roles remain unclear.

Hypothalamic injury can cause disordered temperature regulation. One potentially serious consequence is the hyperthermia that may occur when the preoptic anterior hypothalamic area is damaged or irritated by ischemia, subarachnoid hemorrhage, trauma, or surgery. In some patients, the marked impairment of heat loss mechanisms and the resulting hyperthermia may be fatal. In those individuals who survive, temperature control returns to normal over a period of days to weeks; chronic hyperthermia of hypothalamic origin is uncommon. It may occur when there is ongoing inability to dissipate heat adequately or when there is difficulty sensing temperature elevations. Chronic hypothalamic hyperthermia does not

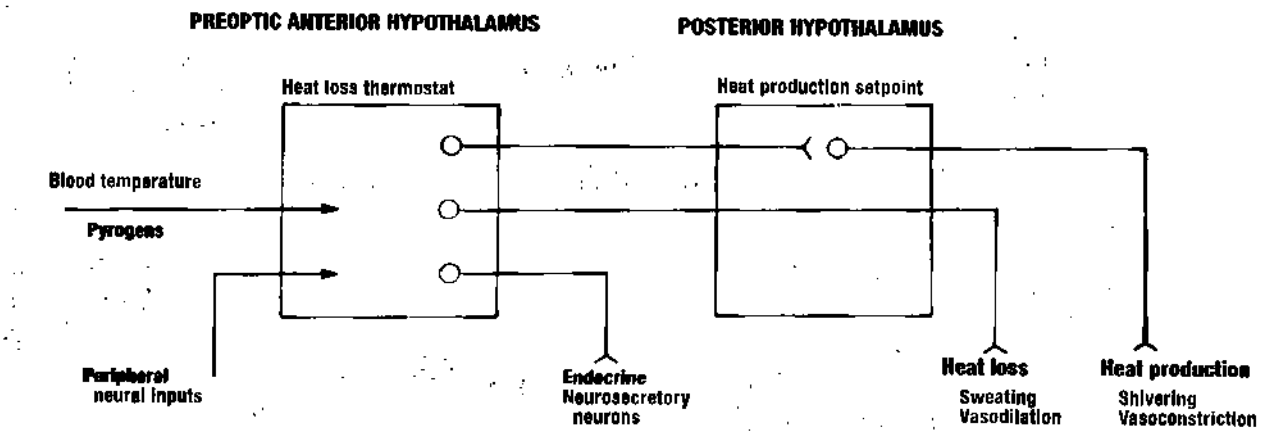

FIGURE 47.1 Schematic representation of hypothalamic temperature-regulation mechanisms. The preoptic anterior hypothalamus functions as a thermostat and contains mechanisms for regulation of heat loss. The posterior hypothalamus integrates heat-production mechanisms. Lesions of the preoptic anterior hypothalamus result in hyperthermia; lesions of the posterior hypothalamus cause hypothermia or poikilothermia. (Reprinted with permission from Cooper, P. E. & Martin, J. B. 1983, "Neuroendocrine disease," in *The Clinical Netimsciences,* ed R. N. Rosciiherg, Churchill Livingstone, New York)

respond to salicylates and other antipyretics because it is not prostaglandin-mediated. Both acute and chronic hypothermia can be caused by hypothalamic injury, the most common causes being head trauma, infarction, and demyelination. Also in the differential diagnosis one should consider severe hypothyroidism, Wernicke's disease, and drug effect. Some patients with no apparent hypothalamic structural abnormalities may have episodes of recurrent hypothermia. The cause of this syndrome is unclear although the response of some patients to anticonvulsant agents, and of others to clonidine or cyproheptadine, suggests a possible neurotransmitter abnormality. Agenesis of the corpus callosum, in association with episodic hyperhidrosis and hypothermia (Shapiro's syndrome), is caused in some individuals by an abnormally low hypothalamic set point. These symptoms may respond to clonidine (an α_2-adrenergic agonist). A similar condition associated with hyperthermia (so-called reverse Shapiro's syndrome) has been found to respond with normalization of temperature to low-dose L-dopa and hypothermia with higher doses (Hirayama et al. 1994). Large lesions in the posterior hypothalamus may impair both heat production by altering the set point and heat loss by damaging the outflow from the preoptic anterior hypothalamic area. This results in poikilothermia, a condition in which body temperature varies with the environmental temperature.

Fever

The body's inflammatory cells (primarily monocytes) release cytokines in response to infection and inflammation. These cytokines act on the hypothalamus to cause fever. IL-1 circulates from areas of inflammation to the hypothalamus, where it acts to induce phospholipases that release arachidonic acids from plasma membranes. This results in an increase in prostaglandin E, which in turn increases the body temperature set point. The body then uses its normal physiological mechanisms of vasoconstriction, vasodilation, sweating, and shivering to maintain this new set point. TNF, another cytokine, acts directly on the hypothalamus to raise the set point and stimulates the production of IL-1. Bacterial endotoxin is a potent stimulator of macrophages, the major source of production and release of TNF. IL-6 and ^-interferon are two other cytokines that act directly on the hypothalamus to raise the set point. It is probably through interfering with prostaglandins that drugs such as acetylsalicylic acid and acetaminophen are useful in treating fever.

A complex interaction occurs among the cytokines. IL-1 stimulates its own production, as do elevated levels of y-interferon. IL-4 suppresses the production of IL-1, TNF, and IL-6. IL-1 production is inhibited also by glucocorticoids and prostaglandin E.

In otherwise healthy individuals, extreme elevations of body temperature (as high as 41.1^{U}C [106°F]) sometimes can be toletated without serious effects. However, hyperthermia associated with prolonged exertion, heatstroke, malignant hyperthermia, neuroleptic malignant syndrome, hyperthyroidism, phcochromocytoma crisis, and some drugs may have serious and even fatal consequences (Simon 1993). Exertional hyperthermia occurs with prolonged physical activity, particularly in hot, humid weather. It may decrease athletic performance and cause muscle cramps or heat exhaustion. When severe, it may result in heatstroke, a syndrome characterized by hyperthermia, hypotension, tachycardia, hyperventilation, and decreased consciousness. Malignant hyperthermia, a syndrome associated most often with the use of various general anesthetic agents, is caused by a disorder of muscle that involves an excessive release of calcium from sarcoplasmic reticulum that stimulates severe muscle contraction (see Chapters 70 and 85). The neuroleptic malignant syndrome is characterized by diffuse muscular rigidity,

akinesia, and fever accompanied by a decreased consciousness level and evidence of autonomic dysfunction: labile blood pressure, tachyarrhythmias, excessive sweating, and incontinence. The neuroleptic malignant syndrome is associated with taking major tranquilizers, with rapid withdrawing from dopaminergic agents, and less commonly with administration of tricyclic antidepressants. It appears to result from an alteration of temperature control mechanisms in the hypothalamus. As part of treatment, withdrawal of the patient from all neuroleptics is mandatory. In addition to general supportive measures, the use of bromocriptine (5 mg orally or nasogastrically four times daily) or dantrolene (2-3 mg/kg daily intravenously to a maximum of 10 mg/kg per day) may hasten recovery.

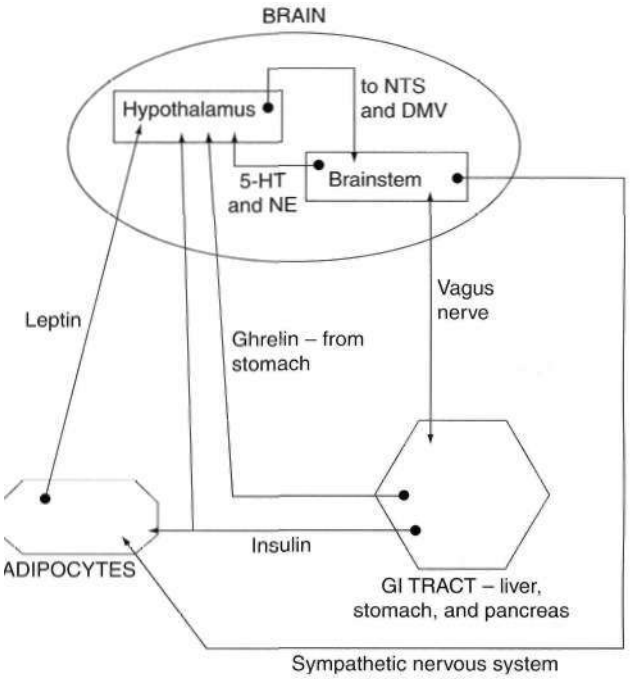
Appetite

Given free access to food and water, most animals maintain their body weight within narrow limits. If there is a change in the intake of energy (a change in the size or number of individual meals that is not balanced by an equal and opposite change in energy LLSC), then the animal experiences a change in weight. One possible model of nutrient balance is depicted in Figure 47.2. There are four components to energy balance: (1) the afferent system, (2) the central nervous system processing unit, (3) the efferent system, and (4) the absorption of food from the gut and its metabolism in the liver. Disorders at any point in these systems may lead to weight loss or weight gain.

In response to a meal or to starving, hormonal and neural signals are generated in the periphery. Some are short-term, and others are long-term. Some relate to satiety, others relate to feeding behavior, and still others relate to "thinness and fatness." Ghrelin, a stimulator of growth hormone (GH) release, is released from the stomach in the fasting state. Ghrelin activates neuropeptide Y and agouti-relatcd protein in the hypothalamus that leads to increased feeding and deposition of energy into body fat. Peripheral insulin seems to mediate a satiety signal in the ventromedial! hypothalamus. Leptin is the other component of the afferent system (see later),

Destruction of the ventromedian hypothalamus, both in animals and in humans, leads to obesity. Lesions in the paraventricular nucleus have a similar effect. Overeating (hyperphagia) is only one of the mechanisms producing hypothalamic obesity. Hypothalamic lesions also can cause weight loss. Lesions in the dorsomedial nucleus lead to **a** reduction in body weight and fat stores, as do lesions in the lateral hypothalamus. Studies in the decerebrate rat suggest that oral motor and meal-size responses are dependent on centers in the caudal brainstem on which the hypothalamus has only a modulatory effect (Grill and Kaplan 2002).

Meal size and food intake are influenced by many different stimuli. Sensory cues such as the sight, aroma, and taste of food arc major factors in dietary obesity. A decrease in blood glucose or a decrease in the oxidation of fatty acids in the liver stimulates the act of eating. Stomach distention gives rise to neural and hormonal signals that reduce food intake. Gastrointestinal (GI) peptides such as cholecystokinin, **bombesin, and** glucagon inhibit feeding by their actions on the autonomic nervous system, particularly the vagal nucleus. Increased fatty acid oxidation leads to higher levels of 3-h yd roxy bury rate that act on the hypothalamus to reduce food intake. Interference with any of these sensing systems in the central nervous system can lead to obesity. Neuropeptide Y infused into the ventral



E1GURE 47.2 Sympathetic Nervous System. In the regulation of energy balance, the brain is the central processing unit. It receives afferent neuronal signals from the vagus nerve, via the brainstem and hormonal signals—ghrelin (from the stomach), insulin (from the pancreas), and leptin (from adipocytes). The brainstem also has input to the hypothalamus via norepinephrine (from the locus ccrulcus) and serotonin (5-OH-tryptamine) (from the raphe nuclei). These afferent signals are interpreted both in the brainstem (in the nucleus of the tractus solitarius) and in the hypothalamus (in the ventral medial nucleus). The ventral medial nucleus of the hypothalamus communicates with the lateral hypothalamic area (I.HA) and the paraventricular nucleus (PVN) by means of pro-opiomelanoeortin-cocaine/ampheta mine-regulated transcript (POMC-CART) an anorexigenic peptide (the release of which is stimulated by insulin and leptin) and by neuropeptide Y/agouti-related protein (NPY/AGRP) an orexigenic peptide (the release of which is stimulated by ghrelin and inhibited by leptin and insulin). Output from the LHA and PVN is either via the sympathetic nervous system—which leads to energy expenditure through physical activity, activation of ^-adrenergic receptors and uncoupling proteins in the adipocyte to cause energy release through lipolysis. Output via the vagus nerve leads to increased insulin secretion, which causes adipogenesis and energy storage. For a more complete explanation of this control of energy balance the interested reader is directed to I.ustig 2001.

medial nucleus of the hypothalamus induces obesity, perhaps by inhibiting sympathetic drive and stimulating insulin release. Although this may explain obesity with hypothalamic lesions, obesity related to eating highly palatable food is probably not related to central changes in neuropeptide Y,

In animals, the *ob, db,* and *fa* genes play a role in the ability of adipose tissue to regulate feeding through a circulating factor. The product of the *ob* gene, leptin, is a peptide that when administered peripherally to the genetically obese *(ob/ob)* mouse—an animal that is deficient in leptin—reduces its intake of food, with a resulting decrease in body weight The role ot leptin in appetite regulation is complex. Leptin does not reverse the obesity seen in *db/db* mice and in obese humans. In these situations, serum leptin concentrations are higher than in subjects of normal weight, suggesting an insensitivity to endogenous leptin production.

When melanocyte-stimulating hormone (alpha-MSH) binds to its receptor in the hypothalamus it causes satiety. Up to 5% of obese children have been found to have an abnormality of the alpha-MSH receptor—MC_4R as a cause of their obesity (Lustig 2001).

The orexins (hypocretins) are neuropeptides that play a role in energy balance and arousal. Narcolepsy is caused by failure of orexin-mediated signaling. They are found in the hypothalamus where they regulate sleep-wake cycles and in the GI tract where they excite secretomotor neurons and modulate gastric and intestinal motility and secretion.

Anorexia nervosa and bulimia nervosa are clinical eating disorders seen primarily in young women and girls. Anorexia nervosa is characterized by reduced caloric intake and increased physical activity associated with weight loss, a distorted body image, and a fear of gaining weight. Bulimia nervosa is characterised by episodic gorging, followed by self-induced vomiting, laxative and diuretic abuse, dieting, and exercise to reduce weight. For many years, these syndromes were considered to be purely psychiatric. However, the finding of reduced serotonin levels in the cerebrospinal fluid (CSF) of patients with bulimia nervosa, the low CSF levels of norepinephrine in patients with anorexia nervosa, and the enhanced secretion of cholecystokinin in patients with anorexia nervosa suggest that neurotransmitter or neuropeptide abnormalities could be responsible for at least part of the clinical picture in these patients. Furthermore, patients with anorexia nervosa seem to have an increased total daily energy expenditure because of their increased physical activity. Whether these are causes or effects of the condition remains to be determined.

Emotion and Libido

Fxperimental and clinical data support the hypothesis that interaction of the frontal and temporal lobes and the limbic system is necessary for normal emotional function. Lesion and stimulation experiments in the cat have shown that rage reactions can be provoked from the hypothalamus. In the human, electrical stimulation of the septal region produces feelings of pleasure or sexual gratification, whereas lesions of the caudal hypothalamus or manipulation of this area during surgery may cause attacks of rage. The amygdala, with its rich input from polyscnsory areas and limbic-associated areas and its output to the hypothalamus, and other subcortical areas are important structures through which the external environment can influence and cause emotional responses.

Libido, like other feelings, requires the participation of both hypothalamic and extrahypothalamic sites. In most instances of hypothalamic disease, loss of libido is caused by impaired release of gonadotropin-releasing hormone (GnRH) and a subsequent decrease in testicular testosterone in men. In women, libido is related more to adrenal androgens. These levels may be low in women with cotticottopin (ACTH) deficiency and secondary adrenal insufficiency. Hypersexuality associated with hypothalamic disease is rare and may occur with or without a subjective increase in libido.

There is a gradually expanding understanding of the human hypothalamus in relation to normal development, sexual differentiation, aging, and some degenerative neurological disorders (Swaab et al. 1993). The sexually dimorphic nucleus, or intermediate nucleus, of the preoptic area is twice the volume in male subjects as it is in female subjects. The size does not differ between homosexual and heterosexual men. Although the shape of the suprachiasmatic nucleus differs in male and female subjects, the vasopressin cell number and volume are similar in men and women. Homosexual men seem to have a larger suprachiasmatic nucleus, containing twice as many cells as heterosexual men (Swaab et al. 1993). The significance of this observation is, at present, uncettain.

Biological Rhythms

Most endocrine rhythms are circadian—that is, a complete cycle takes approximately 24 hours. Although longer and shorter cycles do occur, the circadian rhythms have been studied most extensively. In many animals, light plays an important role in regulating circadian rhythms. Nerve fibers project from the optic chiasm to the suprachiasmatic and arcuate nuclei of the hypothalamus. The hypothalamus is responsible for the hormonal rhythms, such as Cortisol and GH secretion and the behavioral rhythms such as sleep-wake cycles and estrous activity. Although patients with hypothalamic disease often have disturbances in their biological rhythms, these are usually of less clinical importance than the other problems caused by such lesions.

Hyporhalamic-Pituitary Unit Functional Anatomy

In humans, discernible hypothalamic-pituitary tissue begins to develop during week 5 of embryonic life. Rathke's pouch, a diverticulum of the buccal cavity, forms and expands dorsally to contact and invest the diverticulum, which develops from the floor of the third ventricle. By week 11, the buccal tissue has lost its connection with the foregut and has flattened to form the primitive anterior pituitary, whereas the neural tissue from the floor of the third ventricle is forming the posterior pituitary. Residual Rathke's pouch tissue is postulated to give rise to the craniopharyngiomas, which can occur in this region. Rarely, ectopic functional pituitary tissue in the oropharynx can cause signs and symptoms of hyperpituitarism.

The hypothalamus, despite its small size, is the region of brain with the highest concentrations of neurotransmitters and neuropeptides. Beginning with the pioneering work of Ernst and Berta Scharrer and Geoffrey Harris in the 1940s, the hypothalamus lias been assigned a central role in the regulation of anterior pituitary function. In addition to the identified hypophysiotropic hormones (Table 47.4), other peptides with putative regulatory functions are found in high concentration in the hypothalamus, including neurotensin, substance P, cholccystokinin, neuropeptide Y, vasoactive intestinal polypeptide, and the opioid peptides. The hypothalamus is also rich in acetylcholine, norepinephrine, dopamine, serotonin, histamine, and y-aminobutyric acid. In many neurons, these neurotransmitters colocalize with peptides, although this colocalization and presumptive corelease have uncertain physiological significance. A common presentation of patients with nonfunctioning pituitary or parapituitary tumors is symptoms produced by compression of neural structures adjacent to the pituitary gland. Understanding these symptoms requires knowledge of the anatomy of the region (Figure 47.3).

Tumor erosion of the floor of the sella turcica may lead to CSF rhinorrhea. Conversely, sinusitis or sphenoid sinus mucocele can invade the sella and cause anterior pituitary dysfunction. Expansion of pituitary tumors into the cavernous sinus can produce a variety of upper cranial nerve palsies. This is especially common with the sudden expansion of pituitary tumors that occurs in pituitary apoplexy. Carotid aneurysms or ectatic carotid arteries in the cavernous sinus may expand medially and mimic pituitary adenomas by enlarging the sella and causing anterior pituitary hypofunction.

The dura overlying the sella is sensitive to pain and, when stretched by expanding pituitary tumors, gives rise to headache referred to rhe vertex and retro-orbitally. In certain individuals, especially if intracranial pressure is elevated, the dura may herniate in the reverse direction into the sella, where with time continued pulsation of the CSF leads to remodeling and expansion of the sella. This produces the radiological finding of the empty sella syndrome, another cause of which is lymphocytic hypophysitis. The pituitary gland becomes a thin ribbon of tissue along the walls of the expanded sella, and the sella consists mostly of CSF. Rarely is there evidence of pituitary function impairment in such patients.

Expansion of pituitary tumors out of the sella tends to lead to compression of the anterior and inferior crossing fibers of the optic chiasm (see Chapters 14 and 40). These fibers subserve vision in the superior temporal quadrants. Therefore pituitary adenomas typically cause bitemporal superior quadrantanopias. Lesions such as craniopharyngiomas that impinge on the posterior and superior optic chiasm tend to present with bitemporal inferior quadrantanopias. Despite these rules, the variability of the positioning of the optic chiasm and the tendency for tumors to be asymmetrical in their growth result in a wide variety of field defects being caused by parasellar lesions.

Blood Supply

The pituitary's major source of blood is via the superior and inferior hypophyseal arteries (Figure 47.4). The posterior pituitary gland is supplied principally by the inferior hypophyseal arteries and is drained by the inferior hypophyseal veins. The superior hypophyseal artery forms a primary capillary plexus in the median eminence of the hypothalamus. From here, the blood flows into the long hypophyseal portal veins, which carry it to the anterior

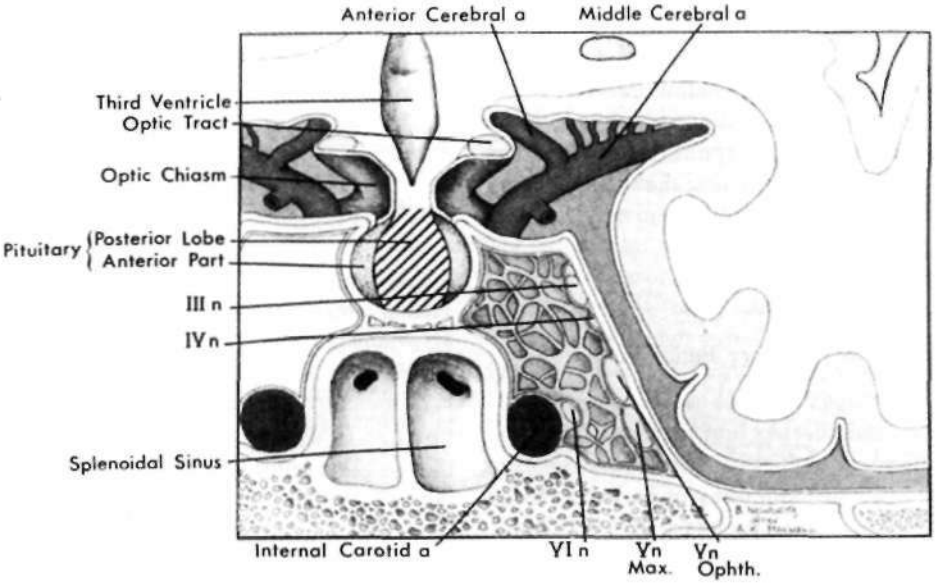

FIGURE 47.3 Diagrammatic representation of the anatomical relations of the pituitary fossa and cavernous sinus. The lateral wall of the sella turcica is formed by the cavernous sinus. The sinus contains the carotid artery, two branches of the fifth cranial nerve (ophthalmic and maxillary), third nerve (oculomotor), fourth nerve (trochlear), and sixth nerve (abducens). The optic chiasm and optic tract are located superior and lateral, respectively, to the pituitary. (Reprinted with permission from Martin, J. B., Reichlin, S., &c Brown, G. M. 1977, *Clinical Neuroendocrinotogy,* Davis, Philadelphia. Drawing by B. Newberg.)

pituitary. Although some of the blood from the anterior pituitary drains into the cavernous sinus, some drains into the posterior pituitary, and some returns to the median eminence via the long portal veins, which are capable of bidirectional blood flow. This vascular anatomy provides a potential mechanism for the important feedback loops that ate necessary for regulation of hypothalamic-pimitary function.

ANTERIOR PITUITARY

Hypothalamic Control of Anterior Pituitary Secretion

The hypothalamus produces hypophysiotrophic substances that control the secretion of anterior pituitary hormones. Five neuropeptides and one neurotransmitter (dopamine) are known to be important physiological regulators of

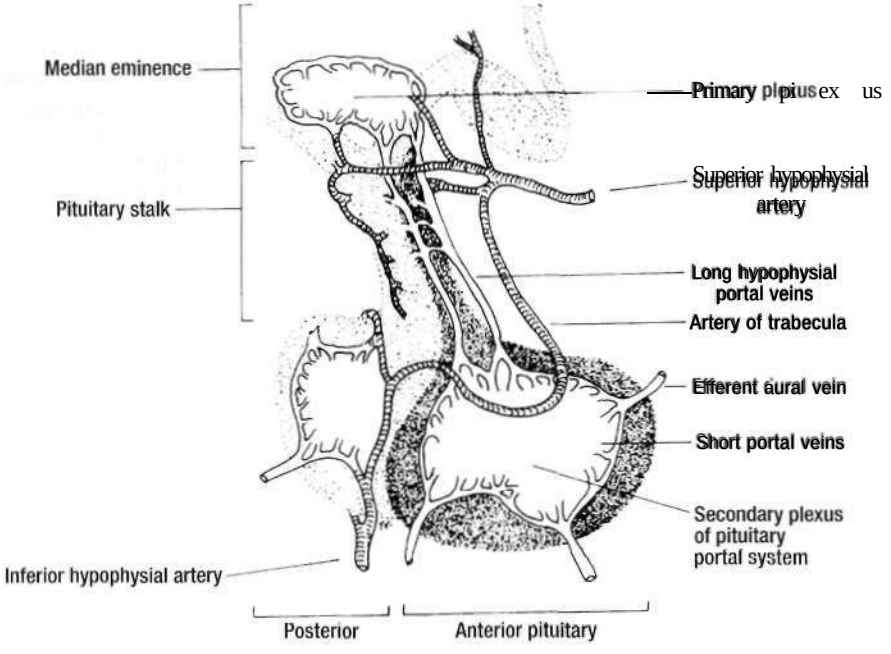

FIGURE 47.4 The blood supply of the median eminence and pituitary gland. {Reprinted with permission from Marrin, J. B. &C Cooper, P. E. 1983, "Neuroendocrine disease,"[1] in *The Clinical h!enrosciences,* ed R. N. Rosenberg, Churchill Livingstone, New York)

pituitary function {see Table 47.4). In addition, several neurotransmitters affect pituitary hormone release, although their physiological role remains uncertain. The pri-cursor moliviili' for (riiKI i, in addition to containing the sequence for GnRH, contains a peptide that is a potent inhibitor of prolactin release, suggesting that hypothalamic control of pituitary secretion may be even more compli-cated than previously thought.

Abnormalities of Anterior Pituitary Function

Hypofunction

The causes of pituitary insufficiency are summarized in Table 47.5. In general, the symptoms of hypopituitarism (Table 47,6) are those of the secondary failure of end-organ function. Because the symptoms usually develop slowly and some autonomous end-organ function remains, the symptoms are often less severe than those that occur with primary end-organ disease. The term *Simtnonds' disease* is applied to panhypopituitarism. When this develops postpartum following an episode of pituitary infarction, it is called *Sheeban's syndrome.*

Intrauterine growth is independent of GH. Therefore although GH-dcficient children are of normal size at birth, they fail to grow. Somatic growth in the human is mediated by at least two factors: insulin-like growth factor I (IGF-I) and insulin-like growth factor II (IGF-II). IGF-I production in the liver is GH-dependent, whereas IGF-II is relatively insensitive to GH. True GH deficiency is rare. It may present in an isolated fashion or as part of general pituitary failure. Apparent GH deficiency may result from an isolated deficiency of GH-releasing hormone or a lack of GH receptors in the liver leading to failure of IGF-I production (Laron dwarf). GH is a contra-insulin hormone, and, in children especially, its deficiency may be associated with episodes of fasting hypoglycemia. A detailed discus-sion of growth is beyond the scope of this chapter. The interested reader is referred to the review by Rosenfield (19%).

Tabic 47.S: Causes of pituitary insufficiency

- Pituitary aplasia
  - Complete
  - Mono hormonal

  - Radiotherapy
  - Compression by cysts or tumors
- Pituitary apoplexy
- Pituitary infarction
- Hypophysitis
  - Infection
  - Granulomatous disease
  - Autoimmune disease
- Hypothalamic failure

Pituitary insufficiency in the child may present as delayed or absent puberty. Onset of puberty depends, to some extent, on achievement of a critical body mass. Thus, anything that delays growth, such as GH deficiency or hypothyroidism, delays puberty. If breasts or sexual hair have not started to develop in girls by age 14, or if testicular enlargement and sexual hair have not occurred in boys by age 15, then puberty should be considered delayed. Luteinizing hormone (LH) or follicle-stimulating hormone (FSH) deficiency may occur as part of generalized pituitary failure or as a result of high prolactin levels or of GnRH deficiency.

One cause of hypopituitarism is *pituitary apoplexy,* a term that should be reserved for infarction of, or

hemorrhage into, the pituitary gland or a pituitary adenoma that is of sufficient severity to produce signs of compression of parasellar structures or evidence of meningeal irritation. The sudden expansion of the pituitary gland may lead to chiasmal compression or cranial nerve palsies. Rupture of the necrotic gland into the CSF may lead to a picture that is indistinguishable clinically from subarachnoid hemorrhage caused by rupture of a berry aneurysm or arteriovenous malformation. Hypotension, aggravated by pre-existing ACTH deficiency, may further complicate the picture. The diagnosis can usually be made readily by computed tomographic (CT) scanning or magnetic resonance imaging (MRI). Treatment includes general supportive measures, corticosteroid replacement, and, if necessary, surgical decompression.

Hyperfunction

Precocious Puberty. Development nf secondary sexual characteristics before age *$* in girls and age *9* in boys is considered abnormal. Approximately one fifth of girls and one half of boys develop precocious puberty because of neurological lesions. A variety of tumors have been associated with the development of precocious puberty including hamartoma; teratoma; ependymoma; optic nerve glioma; glioma; and neurofibroma, either alone or as part of von Recklinghausen's syndrome. Tumors are most commonly located in the posterior hypothalamus, pineal gland, or median eminence, or they put pressure on the floor of the third ventricle. The cause of precocious puberty under these circumstances has not been clearly delineated. However, some of these tumors may be an ectopic source of GnRH or of human chorionic gonadotropin, a placental peptide with LH- and FSH-like activity.

In the investigation of precocious puberty, LH and FSH levels should be measured as well as human chorionic gonadotropin. A CT scan or MRI of the head is mandatory. If LH and FSH levels are in the adult range and the head scan result is negative, it is most likely that the precocious puberty is idiopathic. High human chorionic gonadotropin levels suggest ectopic production. If LH and FSH levels are low, then adrenal, ovarian or testicular, or exogenous causes must be sought.

Chronic administration of long-acting analogues of GnRH is followed by an initial stimulation of LH and FSH secretion and then complete inhibition. This effect on LH and FSH release can be used to prevent progression of hypothalamic precocious puberty.

Hyperprolactinemia. Probably the most common abnormality of pituitary function encountered by the neuroendocrinologist is hyperprolactinemia. The causes of hyperprolactinemia are summarized in Table 47.7. Prolactin levels in excess of 200 ng/mL (normal, *<25* ng/mL) are almost always caused by excessive production of the hormone by a pituitary adenoma. In premenopausal

women, the development of amenorrhea secondary to direct inhibition of LH and FSH by prolactin leads to early investigation and diagnosis of tumors at the microadenoma (<10 mm in diameter) stage. In men, the insidious onset of impotence and reduced libido usually means that these tumors arc found iate, often only after they have produced signs and symptoms of optic nerve compression. Galactorrhea is a common accompaniment of elevated prolactin in women and a rare finding in men.

Serum prolactin levels increase after generalized tonic-clonic seizures and complex partial seizures but show no change after virtually all cases of psychogenic, absence, or simple partial seizures or complex partial seizures of frontal lobe origin. Following a seizure, prolactin levels peak at 15-20 minutes, then decrease to baseline levels within 60 minutes. The increase should be at least two times baseline. Caution should be exercised in interpreting early-morning prolactin levels, because there is a normal 50-100% increase in prolactin just before waking. Furthermore, prolactin elevations are far from specific for epilepsy, and there may be some tendency for the elevation to attenuate in patients with frequent seizures.

Because prolactin secretion is under strong inhibitory control by the hypothalamus, anything that interferes with the free flow of blood down the pituitary portal veins can reduce tin[1] exposure ol the pituitary m the dopamine

released by the hypothalamus. This results in raised peripheral blood prolactin levels. In patients with this condition, prolactin levels usually range from 50-150 ng/mL (normal, <25 ng/mL). Such elevations can be seen, for example, in patients with granulomatous disease involving the pituitary stalk; however, the most common situation in which this occurs is in patients in whom the pituitary stalk is kinked by a pituitary adenoma. In such circumstances, this may lead to the erroneous assumption that the pituitary adenoma is secreting prolactin, and long-term therapy with bromocriptine might be undertaken. I have seen such patients whose prolactin levels became normal but whose tumors continued to grow. The mistake with these patients is to assume that a macroadenoma would result in a moderately elevated prolactin level, when in reality microprolactinomas usually produce prolactin levels in excess of 200 ng/ml. and macroadenomas would be expected to have much higher levels, often in excess of 1000 ng/mL.

Patients treated with neuroleptic medications also may have elevated prolactin levels, and occasionally the elevation is enough to cause galactorrhea or amenorrhea. In such patients, it may be uncertain whether symptoms are secondary to drug-induced hyperprolactinemia or a microadenoma. My practice is to perform an MRI scan of the pituitary to look for a tumor and to perform dynamic pituitary testing with thyrotropin-releasing hormone and metoclopramide. In most individuals, drug-induced hyperprolactinemia responds normally to stimulation with these agents. The treatment of drug-induced hyperprolactinemia is difficult. In many instances, the drug cannot be stopped, and often there is a concern about using drugs such as bromocriptine because of their potential to block the beneficial effects of the patient's neuroleptics and because of their ability to cause hallucinations or frank psychosis. Such patients may benefit from the use of atypical antipsychotics with reduced or absent action at dopamine receptors {at normal therapeutic doses}.

Gigantism and Acromegaly. Excessive amounts of circulating GH before closure of the epiphyses leads to gigantism. If the epiphyses have closed, then only tissue still capable of responding to GH grows, leading to the clinical syndrome of acromegaly. The clinical features of acromegaly arc summarized in Table 47.8, Of particular note to the neurologist and neurosurgeon is the frequent complaint of headache and symptoms related to the carpal tunnel syndrome. It is not uncommon to find patients with acromegaly who have had carpal tunnel releases performed 3-5 years before diagnosis of their disease.

Most cases of gigantism and acromegaly are caused by excess GH production by a pituitary adenoma. However, rare cases of ectopic GH production have been described, and excessive GH-releasing hormone production by pancreatic rumors can cause acromegaly. Excess production ol GH-releasing hormone by the hypothalamus could theoretically cause an identical clinical syndrome.

Table 47.8: Common clinical signs and symptoms of acromegaly

Headache, felt at the vertex and behind the eyes
Impaired glucose tolerance and diabetes mellitus
t iil.ry.riiifiit of hands and feet
Enlargement of the jaw, with increased spacing between the teeth and malocclusion
Hypertension
Menstrual irregularities or soft tissue growrh
Thick skin
Doughlike feel to palm (e.g., during handshake)
Carpal tumid syndrome
Arthralgia and osteoarthritis
Proximal muscle weakness
Hypcrhidrosis

Cushing's Disease and Nelson's Syndrome. The term *Cushing's syndrome* refers to the clinical picture caused by exposure to excessive corticostetoids, either endogenous or exogenous. If this picture is caused by excessive production of ACTH from the pituitary, it is referred to as *Cushing's disease.* Its common clinical features are listed in Table 47.9. The syndrome of hyperpigmentation and local compression of parapituitary structures that occurs in approximately 10% of patients with Cushing's disease who have been treated with bilateral adrenalectomy is called *Nelson's syndrome.*

For years now, the dexamethasone suppression test has been pivotal in the diagnosis of Cushing's disease. Normal patients, given 0.5 mg of dexamethasone every *6* hours for eight doses, during the second 24 hours of administration, show a suppression of Cortisol production, as reflected by reduced urinary levels of 17-ketogenic stetoids or urinary free Cortisol, Patients with Cushing's disease usually show a similar suppression only when the dose of dexamethasone is increased to 2 mg every 6 hours for eight doses. Also, in Cushing's disease, ACTH levels are in the normal range or moderately elevated. Failure to suppress on high-dose dexamethasone and unmeasurable ACTH levels is seen with primary adrenal problems such as adenoma or carcinoma. Ectopic ACTH production is usually unsuppressible, and the ACTH levels are much higher than those

Table 47.9: Common clinical features of Cushing's disease

Truncal obesity: Arms and legs tend to be thin; excess fat deposition in preauricular and supraclavicular fat pads
Hypertension
Impaired glucose tolerance and diabetes mellitus
Menstrual irregularities or amenorrhea
Excessive hair growth
Acne
Proximal myopathy
Abdominal striae (purplish)
Osteoporosis
Thin skin with excessive bruising

seen in typical pituitary Cushing's disease, although there are many exceptions to these rules. First, the dexamcthasone test itself can be perturbed by a variety of influences and give false results. Second, there are well-documented cases of ectopic ACTH production and primary adrenal problems that produce dcxamethasone suppression test results compatible with a diagnosis of pituitary ACTH production. Intermittent excess ACTH production can give rise to false-normal results in patients who actually have Cushing's disease.

Even when all test results point to a pituitary source for the excessive ACTH production, care must still be taken in diagnosing someone with Cushing's disease. Patients may or may not have an abnormality of the sella on CT or MRI. Intermediate lobe cysts or clefts may mimic the appearance of adenoma on CT or MRI. In such cases, simultaneous sampling from the petrosal sinuses bilaterally and the inferior vena cava can help localize the excessive ACTH production.

The pituitary glands of some patients with biochemical Cushing's disease do not show adenoma formation but show evidence of hyperplasia of the cells that secrete ACTH, Although this picture can be caused by the ectopic production of corticotropin-releasing hormone, the hypothalamic peptide that stimulates the release of ACTH, or an excessive release of corticotropin-releasing hormone from the hypothalamus, this happens in less than 0.3% of patients with Cushing's disease who have pituitary surgery.

Excessive Secretion of Thyroid-Stimulating Hormone. Elevated levels of thyroid-stimulating hormone (TSH) are seen most commonly with primary hypothyroidism. The resulting pituitary hypertrophy can infrequently be of sufficient magnitude to cause visual field defects. Hyperthyroidism caused by excessive TSH secretion is a rare (accounting for <1% of all pituitary tumors) but well-recognized entity, and these tumors arc readily visible on CT scans.

Pituitary resistance to thyroid hormone may produce also a clinical picture of hyperthyroidism with high-normal or mildly elevated TSH levels. Unlike the case of TSH-secreting tumors, which arc relatively autonomous, the TSH levels in patients with pituitary resistance usually respond well to stimulation with thyrotropin-rclcasing hormone or to suppression with dexamethasone or dopamine.

Gonadotropin-Sec re ting Tumors. Many pituitary tumors, formerly classified as nonfunctioning, arc actually gonadotropin- or gonadotropin subunit-producing tumors. The usual presentation is a macroadenoma in an elderly man; however, they occur in individuals of all ages and both sexes, with a male preponderance.

Many of these tumors secrete only ESH, and only rarely do they secrete LH alone. Some may secrete both LH and FSH, and others secrete biologically inactive gonadotropin subunits: a-subunit, LH-^J subunit, or *¥$H-0* subunit. Most clinical radioimmunoassays used to measure LH and FSH require the *a-* and ^J-subunits to be associated before they register in the assay. This means that subunit secretion is not detected. FSH levels usually are elevated in patients with FSH-sccreting tumors, and testosterone or estradiol levels are almost always low. In patients with LH-secreting tumors, LH levels are usually elevated and estradiol or testosterone levels may be high. Despite high sex steroid levels, these patients are often clinically hypogonadal. Patients with tumors that secrete both LH and FSH usually have normal or high sex stctoid levels, but again, they are clinically hypogonadal. Because subunits are biologically inactive, subunit-sccrcting tumors do not interfere directly with hormonal function, although through pressure effects on the pituitary, they can cause hypopituitarism.

Long-standing primary hypogonadism may cause pituitary enlargement secondary to gonadotroph hyperplasia. Rarely, this may lead to gonadotroph tumor development. Most of the time, the pituitaty enlargement is asymptomatic and regresses in response to sex steroid replacement.

Pituitary Tumors and Pituitary Hyperplasia

Pituitary tumors account for approximately 15% of all intracranial tumors. Although most are benign, they can be locally invasive. Only rarely is true malignancy evidenced by metastases. The old classification of pituitary adenomas into chromophobe, acidophil, and basophil has been supplanted by a more functional classification based on immunological and electron microscopic examinations (Table 47.10). Hyperplasia of various cellular elements of the pituitary is relatively rare and is usually seen in cases of ectopic hypothalamic-releasing hormone production.

G proteins are a family of proteins, comprising *a-*, *fi-*, and y-subunits, that bind to guanine nucleotides. Their role in pituitary tumor genesis has been reviewed by Spada et al. (1993). There are several classes of G proteins. Gs proteins are activators of adenylyl cyclase. Gi proteins are

Table 47,10: Classification of pituitary adenomas

Tumor	*Percent*
Growth hormone cell adenoma	14.0
Prolactin cell adenoma	27.2
Growth hormone-prolactin cell adenoma	8.4
Corticotroph cell adenoma	8.1
Thyrotroph tell adenoma	1.0
Gonadotroph cell adenoma	6.4
Clinically nonfunctioning adenoma	31.2
Plurihormonal adenoma	3.7

Source: Modified with permission from Thapar, K., Kovacs, K., Muller, P. J. 1995, "Clinical-pathological correlations of pituitary tumours," *Clin Endocrinol Metab*, vol. 9, pp. 243-270.

substrates for pertussis toxin and may inhibit adenylyl cyclase. Gq proteins are mediators of phospholipase C activation. The functions of GI2 and GI.-5 proteins arc, at the moment, unknown. The a-subunit of the Gs protein contains the guanosine triphosphate (GTP) binding site. After the Gs protein binds to GTP, there is release of the beta/gamma-dimer and the active w-GTP complex. The intrinsic GTPase activity of the a-subunit hydrolyzes ff-GTP to a-guanosine diphosphate to end the activity.

A variety of mutations involving single amino acid substitutions in the portion of the *Gs* gene that codes the Gs or-subunit have been identified in nearly 40% of GH-secreting tumors. These mutations inhibit the breakdown of the ff-subunit and thereby mimic the effect of specific growth factors, which lead to increased adenylate cyclase activity and elevated intracellular cyclic adenosine monophosphate levels. Somatostatin inhibits both GH and cyclic adenosine monophosphate production, and this may be the mechanism by which it shrinks GH-secreting pituitary tumors.

The *ras* proteins, a family of at least three protooucogenes, arc structurally similar to G proteins. Like the G proteins, *ras* proteins affect cell differentiation and proliferation. *Ras* mutations arc found commonly in thyroid tumors but are uncommon in other endocrine neoplasms. A *rat* mutation has been found in a particularly invasive prolactinoma.

Transforming growth factor-or is found on normal human adenohypophyseal cells and on tumors. It is capable of altering the production of GH and causing cell proliferation. GH-secreting tumors also express epidermal growth factor, as do some other human pituitary adenomas. Aggressive G! l-secrcting tumors have excessive numbers ot transforming growth factor-** and epidermal growth factor receptors (Ezzat 1997).

Although the observations on G proteins seem to support the hypothesis that pituitary adenomas are of primary pituitary origin, it is still possible that alterations in G-protein function could be triggered initially by abnormal hypothalamic or peripheral stimulation. In support of this latter hypothesis, transgenic mice that overexpress GH-releasing hormone (GHRH) develop pituitary tumors; however, humans with continuous overstimulation of the pituitary by ectopic GHRH production do nor seem to develop pituitary adenomas. Estradiol has mitogenic action of pituitary prolactin-secreting cells. Although prolactin-secreting tumors are the most common human pituitary tumors, their cause is uncertain. Estradiol exposure may lead to prolactinoma formation through the action of transforming growth factor beta (TGF-^J).

Other Tumors

Gliomas, meningiomas, chordomas, teratomas, and dermoid and epidermoid tumors can all occur in the region of the sella turcica and may mimic the local compressive effects of primary pituitary tumors. The pituitary gland is the site of metastatic deposits in 4% of cancer patients. Usually these metastases are asymptomatic; when symptoms do occur, however, they are most often related to disturbance of posterior pituitary function,

Craniopharyngiomas are only one third as common as pituitary tumors. They are thought to arise from residual resrs of Rathke's pouch tissue. Most commonly found in a suprasellar location, they also occur anywhere along the pituitary-hypothalamic axis, including within the sella. Craniopharyngiomas can appear at any age; however, approximately one third of the cases arise before age IS. Because these tumors produce no hormones, patients present with signs of local compression, especially of the visual system, or with hypothalamic dysfunction such as growth failure or diabetes insipidus (DI). In children, almost one half show evidence of growth failure. Three fourths of these patients, adults and children, have visual symptoms.

Hypophysitis

Hypophysitis from infection or granulomatous disease such as sarcoidosis can result in hypopituitarism. Lymphocytic hypophysitis, a sterile inflammation of the pituitary of probable autoimmune origin, is seen almost exclusively in women, particularly in pregnancy. Usually it causes hypopituitarism, although it can cause hvpiTpml.icnnemia and may be a cause of the empty sella syndrome.

POSTERIOR PITUITARY

Physiology

Vasopressin

Vasopressin or antidiuretic hormone (ADH), an essential hormone in fluid and electrolyte homeostasis, is synthesized in the magnocellular neurons of the supraoptic and paraventricular nuclei as a large precursor molecule, which is cleaved enzymatically to yield vasopressin and neurophysin. The function of this latter peptide is unknown.

Four vasopressin-containing pathways have been recognized in the brain: (1) liypothalamoneurohypophysial, (2) paraventricular nucleus to the zona incerta of the median eminence, (3) paraventricular nucleus to the limbic system (amygdala), and (4) paraventricular nucleus to the brainstem and spinal cord. The best characterized of these is the hypophyscal-portal pathway. Virtually all of the neurons from the supraoptic nuclei contribute to this pathway, whereas only a portion of paraventricular nuclei terminate in the posterior pituitary. Some of the vasopressin-containing fibers from the paraventricular nuclei appear to be more

involved in ACTH regulation than in fluid balance. Vasopressin-containing fibers also project widely outside the hypothalamus, where there is evidence to suggest they may participate in memory.

Oxytocin

Oxytocin, like vasopressin, is synthesized in magnocellular neurons of the supraoptic and paraventricular nuclei as a large precursor molecule, which is cleaved into oxytocin and a specific ncurophysin. Many of the physiological stimuli of vasopressin also result in oxytocin release, and, although in suprapbysiological doses oxytocin does have ADH-like properties, its physiological role in these circumstances remains obscure. The only specific stimulus that causes the release of oxytocin but not vasopressin is suckling. Oxytocin's role in normal lactation and parturition in the human remains to be defined clearly.

Thirst and Drinking

Certain cells of the anterior hypothalamus are sensitive to changes in the osmolality of the blood bathing them and respond by signaling the cells of the supraoptic and paraventricular nuclei to alter their secretion of vasopressin. These cells arc most sensitive to osmotic substances that do not freely diffuse into cells, such as sodium, sucrose, and mannitol. Substances such as urea produce less osmotic stimulation because they diffuse freely. Glucose, in addition to diffusing freely, actually inhibits ADH release. These cells respond not only to increased osmolality and hence dehydration but also to hypotension with marked increases in ADH secretion.

Water homeostasis cannot be maintained by antidiuresis alone but also requires thirst and the drinking behavior induced by it. A drinking center is thought to be located near the feeding center in the lateral hypothalamus. Angiotensin may play an important role in stimulating drinking in humans and animals.

Sodium Homeostasis and Atrial Natriuretic Peptide

Sodium homeostasis is extremely important for normal functioning of the organism. Most of the regulation of body sodium takes place in the kidney. Sodium reabsorption is under the control of the renin-angiotcnsin-aldosterone system. Under normal physiological circumstances, aldosterone, the principal mincralocorticoid produced by the adrenal gland, is affected in only a minor way by ACTH.

The human heart has been shown to synthesize and secrete atrial natriuretic peptide, which has diuretic, natriuretic (increased urinary sodium excretion), and vasorelaxant properties. In addition to atrial natriuretic peptide, the brain contains brain natriuretic peptide and C-type natriuretic peptide. Because of the pattern of their distribution in the brain, these substances may have important roles in the central control of the cardiovascular system. The natriuretic peptides seem to act as natural antagonists to the central actions of angiotensin II.

Diabetes Insipidus

DI is a clinical syndrome characterized by sevete thirst, polydipsia, and polyuria. Central DI must be distinguished from nephrogenic DI (an inability of the kidney to respond to ADH) and from compulsive water drinking. Distinguishing these entities is normally done using a water deprivation test. A urine osmolality of greater than 750 mmol/L following water deprivation excludes the diagnosis of DI. Centra] DI is characterized by an increase in osmolality to greater than 750 mmol/L following desamino-D-arginine-vasopressin (DDAVP). In nephrogenic DI, there is little change in osmolality after DDAVP. The polyuria induced by chronic compulsive water drinking may produce a renal tubular concentrating defect because of medullary washout—that is, the loss of sodium and other solutes from around the loops of Hcnlc. This can make it difficult to differentiate partial DI of central or renal cause from polydipsia. Treatment with DDAVP and gradual fluid restriction can be used to reverse the medullary washout and hence increase the sensitivity of the test.

The water deprivation test must be strictly supervised by a physician familiar with the technique. Severe and potentially fatal dehydration can occur rapidly in patients with complete DI. Similarly, patients with compulsive water drinking given DDAVP can drink themselves into hyponatremic coma.

Etiology

Approximately one third of patients with central DI have no demonstrable disease of the hypothalamic-postenor pituitary unit. The remaining patients have damage to the supraoptic-hypophyseal-portal pathway from trauma, surgery, tumors, inflammatory lesions (which may be granulomatous or infectious), or vascular lesions. In patients with polyuria, the urine should be examined to ensure that there is not a solute diuresis, as with hyperglycemia, or that a type of nephrogenic DI has not been induced by hypokalemia, hypercalcemia, or lithium carbonate therapy. The investigation of DI is well summarized by Baylis (1995).

Management

Patients with DI excrete mainly water, and therefore water alone is the mainstay of their management. Patients who are alert and have intact thirst mechanisms should be given free access to water. Only if urine output exceeds 7 L per day is treatment necessary. In most circumstances, DDAVP given as a nasal solution is the treatment of choice.

To avoid water intoxication, it is preferable to under-replace these patients and allow them to modulate their water balance by drinking.

The unconscious patient can present a problem in management. When calculating such a patient's fluid needs, one should be aware that the urine in DI is electrolyte poor. Thus the electrolyte requirements of such a patient are little different from those of other patients. The bulk of the urinary replacement should be given as 5% dextrose in water. The administration of 5% dextrose in 0.2 NaCl or solutions with even higher salt concentrations present a high solute load to the kidney and tend to exacerbate the polyuria.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Etiology and Pathophysiology

The syndrome of inappropriate ADH secretion (SIADH) is characterized by low serum sodium, high urine sodium, and urine relatively or absolutely hyperosmolar to serum. Before making the diagnosis, the physician must exclude all of the following: (1) dehydration, (2) edema-forming states such as congestive cardiac failure, (3) primary renal disease, (4) adrenal or thyroid insufficiency, and (5) use of medication that causes salt-loss in urine (e.g., diuretics).

The initial clue to the diagnosis of SIADH is the low scrum sodium. Measured scrum osmolality must also be low to exclude the artifactual hyponatremia that occurs with hypcrlipidemia and hypcrproteinemia, in which the sodium concentration in the plasma water is actually normal. The urine osmolality in SIADH is not always above the serum osmolality, but the urine is less than maximally dilute, which excludes the dilutional hyponatremia of water intoxication. Causes of SIADH are listed in Table 47.1 1.

Table 47.11: Causes of the syndrome of inappropriate antidiuretic hormone secretion

- Disorders of the nervous system
  - Tumor
  - Trauma
  - Surgery
  - Metabolic encephalopathy
  - Infections (meningitis, encephalitis)
  - Vascular (e.g., stroke)
  - Subdural hematoma
  - Hydrocephalus
  - Guillain-Barrc syndrome
  - Acute intermittent porphyria
- Drugs
  - Carbamazepine
  - Chlor promazine
  - Chlorpropamide
  - Cis-platinum
  - Clofibrate
  - Cyclophosphamide
  - Oxytocin
  - Thiazide diuretics
  - Vasopressin
  - Vinblastine
  - Vincrisrine
  - Tricyclic antidepressants
  - Selective serotonin reuptake inhibitors (SSRIs)
- Disorders of the chest
  - Pneumonia
  - Tuberculosis
  - Cystic fibrosis
  - Pneumothorax
  - Empyema
  - Asthma
- Endocrine causes
  - Hypoad renal ism
  - Hypothyroidism
- Ectopic production of antidiuretic hormone
- Carcinoma: lung, gastrointestinal tracr, and genitourinary tract (especially kidney)
  - Mesothelioma
  - Lymphoma and leukemia
  - Thymoma
  - Sarcoma
- Idiopathic

Clinical Features

The clinical features of SIADH are nonspecific and are related to the hypo-osmolality of the body fluids. The more rapidly this develops, the more symptomatic is the patient. Serum sodium less than 115 mmol/L is almost always associated with confusion or obtundation, and seizures can occur. With milder hyponatremia, the symptoms may be nonspecific, including fatigue, general malaise, loss of appetite, and some clouding of consciousness.

Treatment

For asymptomatic or mildly symptomatic SIADH-induced hyponatremia, the mainstay of treatment is restriction of fluid. Intake should be reduced to insensible losses (approximately 800 mL per day). Obtundation by itself does not necessitate more aggressive treatment of hyponatremia. However, in patients with severe hyponatremia complicated by seizures, a more rapid partial correction can be undertaken. Diuresis is induced with furosemide (1 mg/kg intravenously), and urinary losses are replaced with 3% sodium chloride at a rate of 0.1 mL per kg per minute, to which appropriate amounts of potassium are added (to counter urinary losses). There is considerable controversy over the rate at which serum sodium can be raised safely. Ayus and Arieff (1993) suggest that active correction be by no more than 20-25 mmol/L during the first 48 hours, to a level no higher than 130 mmol/L. They suggest that the rate

of treatment is not important. Patients must he monitored carefully to avoid acute elevation to hypcrnatremic or even normonatremic levels, and to avoid a change of more than 25 mmol/L in 48 hours, which seems to be dangerous and can cause central pontine myelinolysis. Prolonged fluid restriction is often poorly tolerated by patients, who may quickly become noncompliant. In cases in which the underlying cause of the SIADH cannot be eliminated or corrected, the drug demeclocycline, a tetracycline, in a dose of 300-600 mg twice a day, induces a temporary nephrogenic DI and alleviates the necessity for fluid restriction.

Cerebral Salt Wasting

Some patients with hyponatremia do not have SIADH secretion with resultant retention of renal free water. Instead they have an inappropriate natriuresis. Hyponatremia, accompanied by renal sodium loss and volume depletion, occurs in patients with primary cerebral tumors, carcinomatous meningitis, subarachnoid hemorrhage, and head trauma and following intracranial surgery and pituitary surgery. Unlike patients with SIADl 1. these patients respond to vigorous sodium and water replacement, and their condition is actually worsened by fluid restriction. This inappropriate natriuresis that accompanies intracranial disease (so-called cerebral salt wasting) may be caused either by a natriuretic hormone such as atrial natriuretic peptide or by an alteration of the neural input to the kidney.

It is critical to distinguish between these patients and those with SIADH, because the treatment for SIADH worsens the hyponatremia of cerebral salt wasting. Differentiation is best done by a careful assessment of volume status, using the clinical and laboratory examination to detect signs of volume depletion. If there is uncertainty about the diagnosis, the patient should have fluids restricted. Then, if the natriuresis persists in the face of volume restriction, the syndrome of cerebral salt wasting should be suspected and appropriate therapy instituted.

APPROACH TO THE PATIENT WITH HYPOTHALAMIC-PITUITARY DYSFUNCTION

History and Physical Examination

Patients with suspected hypothalamic or pituitary disorders should be questioned specifically about dysfunction of the nonendocrine aspects of the hypothalamus, including appetite, body temperature, sleep-wake cycles, emotion, libido, and autonomic nervous system function. Such symptoms may point to a hypothalamic rather than a pituitary location. A careful functional inquiry should also cover clinical aspects of the hyperfunction and hypofunction of each of the anterior and posterior pituitary hormones,

Because of the proximity of the optic nerves to the hypothalamic-pituitary unit, a careful examination of the visual fields is essential (see Chapters 14 and 40).

Assessment by Imaging Studies

MR] has replaced CT scanning as the investigation of choice in the diagnosis of pituitary and parapituitary lesions. Stadnik ct al. {1 994) indicate that the use of MRI with gadolinium contrast is associated with a detection rate of 82-94%. When using two-dimensional techniques, it is important to obtain thin (1-2 mm) coronal slices of the sella to achieve the best results. Cerebral angiography is rarely required, because large cerebral aneurysms mimicking pituitary adenomas are readily picked up by MRI. Angiography is reserved primarily to demonstrate the blood supply of suspected meningiomas.

Endocrinological Investigation

Not every patient with hypothalamic-pituitary disease requires a full battery of pituitary tests. In general, one attempts to determine the extent of pituitary functional damage, if any, and—in patients in whom blood levels of hormones are elevated or if there is a clinical suspicion of excessive hormonal secretion—to determine if the hormones in question respond normally to physiological suppressors and stimulators.

No single endocrine rest can provide all the answers about pituitary function. Conclusions are based on a synthesis of evidence gained from clinical examination, endocrine tests, and MRI. Endocrine testing is used to determine the residual pituitary function following surgery or radiotherapy. The return of biochemical markers of abnormal pituitary sectetion or their failure to resolve is used to gauge the success of surgery and to aid in differentiating scar tissue from tumor recurrence on postoperative MRI scans. Table 47.12 summarizes pituitary tests and their use.

Treatment of Pituitary Tumors

Medical

Prolactinoma. Hyperprolactinemia of whatever cause often can be suppressed by the dopamine agonist bromocriptine, but such suppression is not diagnostic of a prolactinoma. Bromocriptine (2.5-7.5 mg per day in divided doses) usually normalizes serum prolactin. Maximum shrinkage of tumors occurs within 6 months

Table 47.12: Common tests of pituitary function

Test	*Comments*
Insulin hypoglycemia (regular insulin 0.1 U/kg body weight IV, fasting)	Adequate hypoglycemia is associated with a rise in growth hormone, ACTH, and prolactin. It is probably the most physiological stressor of the hypothalamic-pituitary-adrenal axis. The test should not be used in patients with epilepsy or unstable angina.
Gonadorropin-releasing hormone (2 ug/kg IV to a maximum of 100 ng)	Stimulates LH and FSH release directly at the pituitary. May be used to test LH and FSH reserve. Cannot reliably distinguish between pituitary and long-standing hypothalamic problem.
Thyrotropin-releasing hormone (7 pg/kg IV to a maximum of 400 ug)	Stimulates thyroid-stimulating hormone and prolactin pituitary. Failure of prolactin to respond to thyrotropin-stimulating hormone is very suggestive of autonomous secretion by an adenoma but exceptions do occur.
Meryrapone test (750 mg q4h for 6 doses; collect 24-hr urines the day before, day of, and day after the test)	Meryraponc blocks the production of Cortisol in the adrenal gland. This results in increased ACTH secretion. It is an alternative to insulin hypoglycemia as a test of the hypothalamic-pituitary-adrenal axis
L-Dopa (500 mg po)	L-Dopa can be used to stimulate growth hormone release (probably by increasing growth hormone-releasing hormone). It is a less potent stimulus than insulin-induced hypoglycemia but can be used as an alternative.

ACTH = corticotropin; FSH = follicle-stimulating hormone; LH liMi'iin/iii!', hormone.

and often within 6-8 weeks. Experience indicates that bromocriptine is safe to use to restore fertility. Once pregnancy occurs, the bromocriptine can be stopped with little risk of expansion of the prolactinoma during the remainder of the pregnancy and the immediate postpartum period. Bromocriptine appears to cause growth of fibrous tissue in prolactinomas. In a few patients, this may allow bromocriptine to be withdrawn without prolactin levels rebounding. This fibrous tissue may make such tumors more difficult to remove surgically and result in lower rates of surgical success. Cabergolinc, a newer dopamine agonist appears to be equally effective but better tolerated and can be taken once or twice a week instead of daily.

Cushing's Disease. The results of long-term medical therapy of Cushing's disease have been disappointing. Cyproheptadine temporarily lowers ACTH levels in some patients; however, it is rarely effective for long and is commonly associated with somnolence and increased appetite. Drugs such as mctyrapone and ketoconazole, which block corticosteroid synthesis, can be used to lower Cortisol levels and improve patients' clinical status before surgery. Ketoconazole can be used to control Cortisol levels over the long-term, but patients must be monitored closely for side effects. Recently, mifepristone (RU 486), in high dose, has been shown to provide good control of Cushing's disease that was refractory to other medications.

Acromegaly. Until the development of a long-acting somatostatin analogue (octreotide), the outcome of medical therapy for acromegaly, like that for Cushing's disease, was disappointing. Bromocriptine, in doses of 20-60 mg per day, could reduce GH levels and cause tumor shrinkage, hut it seldom normalized GH levels. Octreotide can normalize GH levels when given by subcutaneous injection every 8 hours. This route of administration is the main drawback to its clinical use, but eventually it may be possible to give it as an intranasal preparation similar to DDAVP. The analogue can be combined with bromocriptine if necessary to achieve maximal suppression and tumor shrinkage.

Thyroid-Stimulating Hormone-Secreting and Gonadotropin-Secreting Tumors. Most patients with these types of tumors are treated surgically, sometimes followed by radiotherapy. TSH-secreting tumors respond to octreotide with *a* decrease in hormone production; however, there is little if any tumor shrinkage. Early reports suggest that octreotide can reduce levels of or-subunit secretion in gonadotropin-secreting tumors, as can bromocriptine. Although some tumor shrinkage may occur with bromocriptine, it is unclear whether long-term octreotide use will have the same effect,

Surgical

In a medically fit patient with an accessible lesion, surgery is the treatment of choice for all nonsecretory pituitary and parapituitary lesions. For secretory tumors, surgery offers the possibility of rapid and complete cute. It is the preferred treatment when serious compression of parapituitary structures occurs. Surgical cure rates have been reported to be more than 80% in cases of microadenoma, although these rates may well be lower when strict endocrine criteria

for cure are applied and when patients are followed for 15 years. In the hands of an experienced neurosurgeon, pituitary surgery has low morbidity and mortality.

Radiotherapy

Conventional radiotherapy is used primarily as an adjunct to surgery and medical therapy, most commonly in the treatment of acromegaly, although octreotide may reduce its use. It is also used frequently in surgical failures in cases of Cushing's disease. It is rarely used in treating microprolactinoma in North America, although it is used in larger tumors. Recurrence of nonsecrcting adenomas after partial removal is effectively prevented by radiotherapy. The major problems with conventional radiotherapy are the long delay in the onset of its effect (often I $ months), its tendency to incomplete efficacy in secretory tumors, and the high frequency of eventual development of panhypopituitarism.

Proton beam therapy permits a dose of radiation to be given at the pituitary gland that is 20-25 times greater than with conventional radiotherapy techniques. At the same time, radiation doses to other brain areas are limited. Unfortunately, because this technique requires the use of a cyclotron to produce protons, it is available in only a few centers. The reported results compare favorably with those of transsphenoidal surgery. Similar results can probably be obtained using the gamma knife. Because of the sensitivity of the optic nerves and chiasm to high doses of radiation, visual field defects and suprasellar extension of tumor arc relative contraindications to the use of these techniques.

Treatment of Hypopituitarism

Vasopressin, ACTH, and TSH are the pituitary hormones critical to an individual's health and well-being. The management of vasopressin deficiency has been discussed already. ACTH deficiency is managed by glucocorticoid replacement; mineralocorticoid supplementation is seldom necessary. Most patients require 5 mg of prednisone (or 25 mg of cortisone acetate) each morning, and some require an additional 2.5 mg of prednisone in the evening. With the development of mild intercurrent illness the dose of prednisone should be doubled. Corticosteroid replacement in the glucocorticoid-dcficicnt patient with serious illness or undergoing surgery consists of hydrocortisone sodium succinate, 10 mg per hour intravenously, around the clock. As the patient recovers, the dose is slowly tapered to maintenance levels.

TSH deficiency is managed by j.-thyroxine replacement. Suppression of elevated TSH cannot be relied on to determine the adequacy of replacement in patients with pituitary-hypothalamic disease. Resolution of the clinical signs and symptoms of hypothyroidism is the important goal. In patients adequately replaced (i.e., with triiodothyronine [T}] levels in the upper one half of the therapeutic range), thyroxine (T_4) levels arc often at or above the upper limit of normal.

Gonadotropin deficiency is usually managed by administration of testosterone or estrogen. This, however, does not restore fertility. In patients for whom fertility is sought, a reproductive endocrinologist consultation and administration of various substitution therapies for LH and FSH may allow induction of fertility.

GH deficiency in children is treated by the administration of synthetic GH. CH-dcficient adults currently do not receive GH replacement. There is gathering evidence **that** muscle strength, wound healing, and lean body mass are all improved by treating these individuals with synthetic CH. Unfortunately, these studies have been short term, and the dose of GH required for long-term replacement is unknown. Because of the potentially deleterious effects of excessive levels of GH, studies are under way to determine appropriate replacement doses. There is no therapy available for prolactin deficiency.

NEUROSECRETION SYNDROMES

Apudomas

The term *APUD* is applied to cells that are capable of Amine Precursor Uptake and Decarboxylation. These cells are distributed throughout the body and arc capable of synthesizing biogenic amines or polypeptide hormones. APUD cells are found in the pituitary gland, adrenal gland, peripheral autonomic ganglia, lung, GI tract, pancreas, gonads, and thymus. Tumors arising from APUD cells are referred to as *apudomas.* As a class of tumors they generally produce symptoms through the secretion of biogenic amines (norepinephrine, epinephrine, dopamine, serotonin) or hormones. Of the apudomas, insulinomas, gastrinomas, vasoactive intestinal polypeptide-secreting tumors, medullary carcinomas of the thyroid, pheochromocytomas, and carcinoid tumors can all present as clinical emergencies. Of these, only pheochromocytomas and carcinoid tumors are discussed here.

Pbeocbramacytoma

Pheochromocytomas are rare tumors that arise most commonly (85-90% of the time) from the catecholaminc-producing cells of the adrenal medulla; they can also arise from extra-adrenal chromaffin tissue in the cervical and thoracic regions and in the abdomen. The majority of these tumors occur spontaneously; however, they can be part of other syndromes such as multiple endocrine neoplasia type II and **lib,** von Hippel-Lindau disease, neurofibromatosis, ataxia-telangiectasia, tuberous sclerosis, and Sturgc-Wcbcr syndrome.

Pheochromocytomas predominantly secrete norepinephrine, epinephrine, and some dopamine. These compounds

are responsible for the most common symptoms **of** pheochromocytoma: throbbing headache, sweating, palpitations, pallor, nausea, vomiting, and tremor. Pheochromocytomas arc also capable *o* secreting other neuropeptides that can be responsible for different clinical symptoms {Fonseca and Bouloux 1993). Pheochromocytoma should be suspected in patients with progressive or malignant hypertension; hypertension of early onset without family history; hypertension resistant to conventional therapy; paradoxical worsening of hypertension in response to treatment with beta blockers; and a history of pressor response provoked by anesthesia, labor or delivery, or angiography. I screen for pheochromocytoma by collecting two 24-hour urine specimens and having them analyzed **for** vanillylmandelic acid, norepinephrine, epinephrine, and metanephrines. These collections should be done at a time the patient is symptomatic because periodic hormone secretion does occur and levels may at times be normal. The completeness of the 24-hour collection should be confirmed by an analysis of urinary creatinine.

Tumor localization can usually be achieved by CT scanning of the adrenals. If a wider search is necessary, MRI scanning may be more helpful. ^{m}I-MIBG (meta-iodobenzyl guanidine), an iodinatcd guanethidine derivative, is taken up by chromaffin tissue and can be helpful in the localization of nonadrcnal tumors and metastases. Some centers have been using " 'indium-labeled pentetreotide, an analogue of somatostatin, to localue somatostatin receptors on these tumors. Soma tost a tin-receptor scanning and positron emission tomographic scanning with hydroxyephedrine remain experimental.

Patients with pheochromocytoma should be managed in centers with previous experience of the treatment of this type of tumor. Suitable preoperarive preparation is necessary to prevent hypertensive or hypotensive crisis during surgery. For benign tumors, complete surgical removal is the treatment of choice. Malignant tumors may be palliated with a variety ol treatments.

Carcinoid Tumors

Carcinoid tumors arise from entetochromaffin cells in the GI tract, pancreas, or lungs and only rarely from the thymus or gonads. When carcinoid tumors release biogenic amines directly inro the systemic circulation, bypassing the liver, the carcinoid syndrome results. This is characterized by episodes of flushing, often with accompanying diarrhea or asthma. Later in the syndrome there is fibrosis of the endomyocardium. Carcinoid tumors may be a source of ectopic ACTH, corticotropin-releasing hormone, or GHRH secretion.

The diagnosis is made by finding elevated urinary 5-hydroxyindolacetic acid levels. As in pheochromocytoma, carcinoids also secrere peprides (e.g., kallikrein, substance P, neurotensin} and other amines (e.g., histamine, dopamine), and some of these substances may be responsible for the flushing that occurs in the syndrome,

Surgery is the treatment of choice; however, by the time the tumors become symptomatic they are often incurable because of the metastases. Serotonin antagonists may be used to treat some of the symptoms, and octreotide may successfully manage carcinoid crisis.

Chapter 48
Management of Neurological Disease

Walter G. Bradley, Robert B. Daroff, Gerald M. Fenichel, and Joseph Jankovic

Wc discussed how an experienced neurologist uses the history of the patient's illness, the neurological examination, and investigations to diagnose neurological disease in Chapters 1 and 35. In this chaptet, wc present some general principles guiding the management of neurological disease. Chapters 49-54 cover individual areas of neurological management, such as pain management, neuropharmacology, intensive cate, neurosurgery, and neurological rehabilitation. Details about the management of individual neurological diseases are presented in Chapters 55-85. In addition many aspects of management are common to all neurological disorders and are discussed in this chapter.

PRINCIPLES OF NEUROLOGICAL MANAGEMENT

As in all medical disciplines, many neurological diseases are "incurable." However, this does not mean that there is nothing that can be done to help the patient. The help that can be provided short of curing the disease ranges from treating the symptoms to providing support for the patient and family and end of life cate (Table 48.1). Medical personnel are so committed to the scientific undctstanding of diseases and their treatment that there is a natural tendency to feel guilty when confronted with a patient with an incurable disease. The number of neurological diseases that are curable or can be arrested is constantly expanding as a result of research. However, a physician who is fixated on the need to cure disease may simply concentrate on making the diagnosis, and give no thought to its management. Such a physician will tell the patient that it is an incurable disease, so there is no point in coining back for further appointments ("diagnose and *adias").* This attitude is not only an abrogation of the physician's responsibility to care for the patient, hut it also leaves the patient without the many modalities of assistance that can be ptovided even to patients with incutable disease. The neurologist who is interested in treating the patient will review with the patient and the family all the issues listed in Table 48.1. It is often necessary to spend more time with the patient with an incurable disease than with one for whom effective treatment is available. In addition to providing all the practical help available, the compassionate neurologist should shatc the gtief and provide consolation; both ate essential aspects of patient management.

GOALS OF TREATMENT

In defining the goals of treatment it is important to separate neurological impairment, disability, and handicap. *Neurological impairment* (the presence of abnormal neurological signs) allows a diagnosis to be made, Impairment may cause *disability,* which in turn produces a *handicap.* The patient does not care about the abnormal neurological signs, but wants correction of the disability and relief from the handicap. For instance, a stroke causes a hemiplegia, which is the impairment. The hemiplegia causes difficulty in walking, which is the disability. The difficulty in walking may make it impossible for the patient to leave the house, which is the handicap. It may not be possible to correct the undct lying stroke or the hemiparesis, but symptomatic treatment, such as providing physical therapy, a walker, and a wheelchair, can help alleviate the handicap. The improvement in functional state of a stroke patient resulting from neurological rehabilitation is gratifying when compared with the state of untreated patients.

Amyotrophic lateral sclerosis (ALS) is perhaps the disease that epitomizes the role of symptomatic cate (Miller et al. 1999, 2002). Patients with ALS often report

Table 48.1: Help a physician can provide to patients with any disease

End of life care

being told by their doctor that they have ALS; that they are likely to die within 3 years; and that because nothing can be done for them they should go home, put their affairs in order, and prepare to die. A doctor who dispenses such advice is not only uncaring, but also leaves the patient without hope and the symptomatic treatment that can help the patient circumvent the disabilities and handicaps that attend the disease. The psychological support of a caring neurologist who is familiar with the disease can be of great help to the patient and the family. There is an increasing number of lay organizations and support groups that provide information and services. Patients will often have found these by searching the internet, but the physician should keep available the addresses and phone numbers of the key organizations to give to patients.

Symptomatic treatment depends on the nature of the disease. It can consist of arresting an attack in a disease such as multiple sclerosis; circumventing the effects of the disease, such as with antispasticity medications; or end of life care for a patient approaching death. The latter is sometimes called palliative care, but in fact every treatment short of cure, even in the early stages of a disease, is palliative.

Arresting an Attack

Many neurological diseases cause episodic attacks. These include strokes, migraine, multiple sclerosis, epilepsy, and periodic paralysis, and in some of these diseases treatment may halt the attacks. Although it does not cure the underlying disease, aborting the attacks is of great help to the patient. Triptan-class drugs generally arrest a migraine, and valproate, a beta blocker, or a calcium channel blocker will reduce the frequency of the attacks (see Chapter 75). Status epilepticus can usually be arrested by intravenous phenytoin, diazepam, or barbiturate, and the frequency of epileptic attacks can he reduced by anticonvulsant drugs (see Chapter 73). Intravenous and intra-arrerial thrombolytics may terminate an otherwise disastrous "brain attack" (stroke) (see Chapter 57A).

Slowing Disease Progression

There are many examples of treatments that slow the progress of neurological disease. A malignant cerebral glioma is almost universally fatal, but high-dose corticosteroids, neurosurgical debulking, and radiotherapy may slow tumor growth and lengthen survival (see Chapters 5SSE and 581*). The /3-interferons and glatiramer may reduce relapses and slow the progress of multiple sclerosis (see Chapter *60).* Liver transplantation in familial amyloid polyneuropathy may slow or arrest disease progression (see Chapter 82). Riluzole may slow the progress of ALS (see Chapter 80).

Relieving Symptoms

Symptomatic treatment is available for many neurological diseases. Relief of pain, although not curative, is the most important duty of the physician and can be accomplished in many ways (see Chapter 50). Baclofen and tizanidine can reduce spasticity, particularly in spinal cord disease, without affecting the disorder causing it. Injections of hotulinum toxin provide marked relief for several months in patients with dystonia, spasticity, and other disorders manifested by abnormal muscle contractions. High-dose corticosteroid therapy reduces the edema surrounding a brain tumor, temporarily relieving headache and neurological deficits without necessarily affecting tumor growth. In Parkinson's disease, dopaminergic drugs partly or completely relieve symptoms for a period without affecting the progressive degeneration of substantia nigra neurons (see Chapter 77), The physician-patient relationship and the placebo response arc both important tools used by the experienced neurologist in helping to relieve a patient's symptoms.

Circumventing Functional Disability

Neurological diseases like Alzheimer's disease, Parkinson's disease, and ALS have a course that is usually continuously progressive. Others, like stroke and spinal cord injury, have an acute onset and the damage occurs before the neurologist first sees the patient. Although some recovery is expected, substantial functional deficits often persist. In both situations, there are many ways to circumvent the functional disability and the resultant handicap.

Neurological rehabilitation is the discipline that concentrates on restoration of function (see Chapter 54). Physical and occupational therapy help the patient to strengthen weak muscles, to retrain the nervous system to compensate

for lost function, to increase mobility, and to reduce spasticity. Some believe that cognitive or behavioral therapy may similarly re-educate undamaged cortical areas to compensate for the effects of brain injury and stroke. Orthopedic procedures can be beneficial for rehabilitation; transfer of the tibialis posterior tendon to the dorsum of the foot can correct a footdrop in appropriate cases. Surgical release of Achilles tendon and iliotibial contractures in boys with Duchenne's muscular dystrophy can delay the loss of ability to walk by 2 years or more.

Aids and appliances, such as ankle-foot orthoses to prevent footdrop, canes, walkers, and wheelchairs, can increase mobility and limit handicap. Changes to the home and work environment, such as a ramp or stair lift, widening of doors to allow wheelchair access, rails for the bath and toilet, or replacement of the bath with a shower and shower chair, can be of great help to the patient. Only the ingenuity of clinicians and biomechanical engineers, the availability of technology, and the cost limit the scope of such appliances. Cochlear implants are already in clinical use for those born deaf. Computer-controlled motorized body and lower-limb braces may allow paraplegic patients to walk,

The range of options available to help a patient with a severe, chronic neurological disease can be illustrated by reference to ALS (Miller et al. 1999, 2002). In the early stages, the patient may simply need enlarged handles on pens, tools, and utensils to compensate for a weak hand grip or a cane to help with walking. Later, the patient may need a wheelchair and home adaptation. Speech therapy, a communication board, or a computer with specialized software can help when speech is severely impaired. Weight loss and choking from dysphagia may necessitate a percutaneous gastrostomy. An incentive spirometer and an artificial cough machine can protect respiratory function (see Respiratory Failure, later in this chapter). If the patient decides not to use a ventilator, end of life and hospice care are needed.

Management of disabilities in patients with progressive neurological diseases may tax the neurologist's knowledge and ingenuity, but the beneficial effect of symptomatic therapy on patients and families makes the effort worthwhile and demonstrates that no neurological disease is **untreatable.**

PRINCIPLES OF SYMPTOM MANAGEMENT

Treatment of Common Neurological Symptoms

A number of symptoms, such as pain, weakness, dysphagia, and respiratory failure, are common to many different neurological diseases. General principles governing the management of these symptoms are outlined below and more fully discussed in Chapters 49, 50, 51, and 54. Specific treatment for individual diseases is discussed in the relevant chapters in Volume II of this book.

Pain

The first step in pain management is to diagnose the source of the pain and assess the prognosis of the disease {see Chapter 50), Consider, for example, a patient with incapacitating pain in one leg from carcinoma infiltrating the lumbosacral plexus on one side. This patient's life expectancy is measured in months, and progressive plexus damage will produce leg paralysis. Destructive surgery (see below) and narcotics are justified in this situation. Tachyphylaxis for narcotics can occur, and the oral dose of narcotics required to control pain may rise rapidly in patients who live for several months. This does not appear to occur with morphine administered by an intrathecal or epidural spinal catheter using a subcutaneous infusion pump. Surgical interruption of pain pathways is considered the final choice to relieve pain from carcinomatous infiltration of the lumbosacral plexus. These procedures include surgical or chemical posterior rhizotomy, contralateral anterolateral spinothalamic tractotomy in the midthoracic region, or stereotactic contralateral thalamotomy,

Narcotics should not be used for patients with nonmalignant chronic pain syndromes, such as painful polyneuropathies or low back pain, because of the risk of producing drug dependency. Biofeedback, hypnosis, and acupuncture may help some patients control the pain. Antidepressant drugs benefit many chronic pain syndromes by blocking the neurochemical transmitter mechanisms of central nervous pain pathways, as well as treating depression. This is a point that needs to be explained to the **patient.** Sometimes a single drug may he effective, but frequently a combination of a selective serotonin reuptake inhibitor (SSRI), such as sertraline, and a tricyclic, such as amitriptylinc, is better,

Sensory Loss, Paresthesias, and Burning Pain

Occasionally, sensory loss produces an intolerable positive sensation termed *anesthesia dolorosa,* which may respond to a combination of a tricyclic with either carbamazepine or an SSRI. Paresthesias generally result from damage to the large diameter myelinated axons in the peripheral nerves or posterior columns of the spinal cord. Two thirds of patients with painful paresthesias and electric shock-like pains can obtain relief with carbamazepine, and a smaller proportion with phenytoin. Burning sensations from small fiber peripheral neuropathies arc often helped by a tricyclic or SSRI, or a combination of the two. Gabapentin in high doses (up to 4,8 g/day) can benefit burning and to a lesser extent other pains.

Weakness

The management of weakness, considered more fully in Chapter 54, is a major component of neurological rehabilitation. The choice of treatment depends on the

extent, severity, and prognosis of the patient's weakness. For example, weakness of dorsiflexion of the ankle due to Charcor-Marie-Toorh disease may be treated with a triple arthrodesis of the foot. Such a procedure, however, would not be appropriate to overcome the footdrop caused by a more rapidly progressive condition, such as ALS. For such patients, an ankle-foot orthosis would be best. Most neuromuscular conditions are benefited by exercise, although fatigue limits the amount that can be tolerated. Myasthenia gravis, however, is worsened by exercise. Weakness due to upper motor neuron disease can be helped by physical and occupational therapy to promote the use of alternative neuronal pathways. Medications such as baclofen and tizanidine reduce spasticity and may improve function in upper motor neuron disorders.

Ataxia

Ataxia can result from cerebellar dysfunction or sensory deafferentation. If the disease causing the ataxia cannot be reversed, occasionally treatment with trihexyphenidyl or a benzodiazepine can decrease the degree of ataxia. A weighted cuff placed on an ataxic limb may lessen incoordination; the added inertia reduces the excursion of the limb during movement. Gait ataxia is best managed by the use of walking aids, such as a cane, walker, or wheelchair. The gait of elderly patients, whose loss of postural reflexes causes retropulsion and falls, is improved if the center of gravity is displaced forward by increasing the height of the heels on the shoes and lowering the walker so that the patient must stoop forward.

Slowness of Movement or Abnormal Involuntary Movements

Along with rest tremor and rigidity, slowness of movement (bradykinesia) is one of the clinical hallmarks of Parkinson's disease and other parkinsonian disorders. Bradykinesia usually responds to dopaminergic therapy. Conversely, excessive involuntary movements, such as chorea and stereotypies, typically improve with drugs that deplete dopamine. Postural tremors (e.g., essential tremor) often improve with beta blockers and primidone. Botulinum toxin injections are considered the treatment of choice for most focal dystonias. Stereotactic surgery, particularly high frequency deep brain stimulation, is an emerging therapeutic strategy in patients with severe movement disorders that continue to be troublesome or disabling despite optimal medical therapy (Jankovic 2001).

Aphasia and Dysarthria

The treatment of language disorders is, in principle, very similar to that of limb weakness. Speech therapy can improve aphasia by retraining the nonspeech areas of the brain to compensate for the effects of damaged speech centers. If the lesion is limited, some aspects of language function may be preserved and so provide an immediate mechanism for communication. For instance, an aphasic patient may be able to communicate through writing. With speech therapy, dysarthric patients can learn to slow their delivery and emphasize words, thus improving the clarity of speech. Treatment with baclofen may improve the spastic dysarthria of upper motor neuron disorders.

Respiratory Failure

Respiratory failure can develop in several neurological diseases (Table 48.2} (sec also Chapter 51). Patients with chronic neuromuscular diseases often complain of respiratory distress when they are close to pulmonary failure. Patients with a weak diaphragm experience dyspnea when lying supine because the abdominal contents prolapse into the chest, thereby lowering the patient's vital capacity and tidal volume. A neurologist or pulmonary specialisr who is relatively inexperienced in neurological problems affecting respiration may underestimate the warning signs of potentially fatal respiratory failure. This is particularly true in myasthenia gravis and Guillain-Barrc syndrome. Blood gas measuremenrs do not change until late in the development of respiratory failure in chronic neuromuscular diseases. By the time hypoxia and hypercapnia develop in the blood, the patient may be bordering on acute respiratory collapse. Reduced vital capacity, patient distress, and a good knowledge of the disease are better ways of judging impending respiratory failure. A patient with Duchenne's muscular dystrophy and a vital capacity of 600 mL may survive for several years without dyspnea. A patient with myasthenia gravis who has a vital capacity of 1200 mL but is anxious, sweating, and complaining of dyspnea is at serious risk of developing total respiratory paralysis. With borderline respiratory function, sleep or sedation may produce carbon dioxide retention and narcosis, respiratory suppression, and death.

Ethical Considerations in the Treatment of Respiratory Failure. Respiratory failure, once invariably fatal, is now commonly treated by noninvasive positive pressure

Tahle 48.2: Types of neurological disease associated with respiratory failure

Acute neurological disease
Brainstem damage
High cervical cord injury
Subacute or chronic neurological disease
Bulbar palsy with airway compromise
Motor neuron degenerations, such as amyotrophic lateral sclerosis
Neuropathies, such as Guillain-Barre syndrome
Neuromuscular junction diseases, such as myasthenia gravis
Muscle diseases, such as muscular dystrophy

ventilation in the early stages, and by intubation and positive pressure ventilation in the terminal stages. The treatment of chronic progressive respiratory failure in neuromuscular diseases like ALS and muscular dystrophy is very challenging (Jones, Darras, and DeVivo 2003}. However, cultural differences in expectations in different countries must be recognized. For example, in Japan it is the established practice to provide the patient with ALS with a tracheostomy and positive pressure ventilation when signs of respiratory failure appear. In Western countries, most consider that life on a ventilator is far from ideal, and quality-of-lifc issues must he discussed by the neurologist with the patient and family before intubation (Bernat 2002; Miller etal. 1999,2002).

Ideally, decisions about life support measures should be made long before the patient is in acute respiratory distress, because it is more difficult to make these decisions when death is imminent. Patients and families require considerable counseling by the neurologist and pulmonary specialist. Parients may benefit from speaking to others who have experienced the situation. Many patients cannot make a definitive decision about life-support measures and so defer the decision until the emergency occurs.

In these matters, the decision of a competent patient, or of the health care surrogate (in the case of an incompetent patient, or one with whom communication is impossible) holds primacy. For instance, a 40-year-old patient with ALS may request respiratory support to see a child graduate or marry, even though there is no likelihood of recovery. The physician may be able to accommodate this request. However, a request to continue ventilator support for a 90-year-old patient with terminal cancer and a severe brainstem stroke is not considered rational, and the physician will try to convey the hopelessness of the situation, and the patient's unnecessary suffering, to the next of kin. Those who decide against ventilator support should provide a living will or terminal care document to their physician and next of kin and legally grant to a designated person (the health care surrogate} the power of attorney to make medical management decisions for them if they become incompetent. Even if patients have prepared a living will, they will be taken by emergency services to a hospital emergency department and be intubated unless proper arrangements arc in place for end of life care at home, usually through hospice services (Miller et al. 2002).

For those who decide to request ventilator support, health insurance and economic matters must be considered. Although the availability of insurance to cover the cost of ventilator care is paramount in the United States, in Japan the government pays for the costs of 24-hour home ventilatory care for all ALS patients.

Patients with a tracheostomy may still be able to talk using a valved tracheosromy tube or a partially inflated cuff, but many lose bulbar functions and need to use communication devices, such as computers, typewriters, or letter boards. Many of the conditions listed in Table 48.2 also cause limb paralysis, which further impairs the patient's quality of life. Quality of life usually becomes an issue when ventilator dependency becomes permanent. In many patients the prognosis becomes clear within a relatively shorr time, as with stroke and coma. Because the patient is unconscious, the next of kin must decide, with the advice of the doctor, whether to continue ventilator support. If the family requests that respiratory support be discontinued, it is standard medical practice in most parts of the world to do so (Bernat 2002). The legal and ethical issues arc more complex with an awake and competent patient who requests that the ventilator be switched off. Although the legal systems in many parts of the world accept that such requests fall under the right of the patient to refuse medical treatment, involvement of a hospital ethics committee is strongly recommended (Bernat 2002).

Managing Terminal Respiratory Failure. If the patient opts for life-support measures, an elective tracheostomy and intermittent positive pressure ventilation should be offered at the first signs of terminal respiratory failure. Patients who have respiratory insufficiency, whether or not they decide to opt for tracheostomy, can often be helped for a prolonged period by noninvasive positive pressure ventilation through a nose mask or nasal "pillows." Patients who decide against respiratory support should be counseled *not to go to the hospital in a crisis* because they will inevitably be intubated. They should be referred to home hospice services, and when terminal respiratory distress appears, home treatment with oxygen, morphine, and sedation will be provided, despite the risk that this may hasten death. Neurologists should learn to manage chronic respiratory failure due to neurological disease. Although neurologists must work collaboratively with the intensive care specialist and hospice doctors, rhey should assume an active role in management decisions.

Memory Impairment and Dementia

Alzheimer's disease is the most common cause of progressive impairment of memory and dementia, and only symptomatic care is possible, which includes anticholinesterase inhibitors. Some causes of progressive demenria are curable (see Chapter 72), and their recognition is important. Even if no specific curative treatment is available, the experienced neurologists can provide essential advice to the family of a patient with a condition like Alzheimer's disease on how to anticipate problems and minimize them. This includes helping the patient to make shopping lists and checklists of things to do before leaving the kitchen or the house and before going to bed. For a period, these measures can prevent the patient from leaving the house unlocked or a pot boiling on the stove. Inevitably, the patient will have difficulty managing a checkbook, and a family member should take over money management before financial disaster occurs. The patient will eventually need either a

live-in companion or to move in with a family member or into a nursing home. Much of the neurologist's efforts are directed toward helping the patient and family to circumvent problems and adjust to expected changes. Family members need access to books and publications by foundations and support groups, such as the Alzheimer's Disease Association.

Treatment of Secondary Effects of Neurological Disease

Predictable reactions occur in a patient who is given the diagnosis of a chronic neurological disease. These reactions progress at variable rates through the stages of anger, denial, "why me?", depression, and eventually acceptance, often with oscillation among these phases. The neurologist must provide support through this process of adjustment, sometimes with the assistance of a mental health professional.

The impact of the disease on the family must also be considered. The family members caring for a patient with Alzheimer's disease often say that it is like looking after a young child but with much more stress. The family of a boy with Duchenne's muscular dystrophy experiences both mental and physical stress because the child will eventually lose the ability to walk and must be lifted in and out of chairs, bed, and bath (Jones, Darras, and DeVivo 2003). Mechanical lifting devices can help, but they are slow and clumsy. Often, a home needs alterations to allow one-level living and wheelchair access. Someone needs to get up several times a night to turn the patient in bed. Lack of sleep and increasing daytime care strain the family dynamics. Other children may be neglected and emotionally deprived; marital disharmony is common. The physician may need to refer the family for counseling or put them in touch with a family support group. The school aurhorities need information and encouragement for the child to continue in mainstream schooling. As the young man with Duchenne's muscular dystrophy reaches maturity, he may consider college or employment, and the neurologist can provide information to assist the relevant authorities.

The neurologist caring for a patient with a progressive neurological disease plays an important role for both the patient and the family. Help from many other professionals is often required, but the neurologist must anchor the management team.

EXPLAINING THE PROGNOSIS

Establishing the diagnosis is necessary to define the prognosis for the patient and the family. The physician should ascertain what the patient and family want to know, and provide answers at a rate they can accept. Some patients fear that they will die or become a "vegetable" within a few months and are greatly relieved to learn that they have several years of useful life ahead. Patients may wish to make financial arrangements or accelerate unfulfilled plans if the prognosis is poor. Patients may not always wish to be told the prognosis, but relatives generally want to know. The neurologist should always present the prognosis with some caveats, because the diagnosis may be wrong or the disease may not follow the expected course. Patients should always be given some hope; even ALS can arrest or remit (Tucker er al. 1991)! A useful way to cushion bad advice is to say that the patient needs to *hope for the best but plan for the worst.*

PALLIATION AND CARE OF THE TERMINALLY ILL PATIENT

Palliative care starts from the earliest stage that the patient is seen by the physician. Pain, depression, and anxiety are the three major symptoms that require palliation. The treatment of pain is considered in Chapter 50. Psychological reactions are treated with a range of pharmacological agents, including benzodiazepines for anxiety, neuroleptics for psychotic symptoms, and an ever-increasing list of medications for depression. However, the psychological support for the patient and family provided by the doctor is usually more important than pharmacological therapy. The experienced neurologist provides help to the patient and family by drawing on lessons learned from treating many similar patients. Even though the disease and its effects cannot be arrested, the neurologist can ease the burden. When possible, the neurologisr should discuss each new phase of the disease with the patient and family *before* it occurs. No patient likes to hear of impending deterioration, but if the neurologist clarifies the importance of anticipation, the patient is reassured that the doctor is ready ro deal with change, when and if it occurs.

GENETIC COUNSELING

Approximately 1 in 10 neurological conditions is inherited. The rapid advances in molecular genetics require that the neurologist keep abreast of the many diseases that can be diagnosed by genetic testing (see Chapter 44). A parent with a neurological disease commonly fears that the disease will pass to the children. Hence if a disease has no hereditary component the couple should be reassured. If the disease has a hereditary tendency, the risk to offspring must be discussed. For instance, the chance of multiple sclerosis occurring in the offspring of a patient with multiple sclerosis is higher than that in the general population, but it is still only about 3%.

However, in Huntington's disease the risk that each offspring will inherit the disease is 50%; at-risk individuals may choose not to have children because of this. Such couples can be advised about alternatives, including

adoption; artificial insemination hy donor, when the husband is at risk; and surrogate gamete in vitro fertilization when the wife is at risk. An individual carrying a mutant gene who wishes to have a child can use the technique of embryo genotesting. After in vitro fertilization with the parents' ova and sperm, the embryo is allowed to grow to the four or eight cell stage. A single cell is then removed for DNA testing; embryos bearing two normal huntingtin genes are accepted for implantation. Cost and availability of services limit the use of this procedure.

The neurologist should provide the patient and spouse with the available information about the mode of inheritance of the disease and, where relevant, the possibilities for prenatal and preclinical diagnosis. A couple's attitude to therapeutic termination of pregnancy should be part of the discussion. When a disease has an autosomal recessive mode of inheritance and the gene frequency in the population is low, the children of an affected parent are at very little risk unless the patient marries a close relative. If the gene frequency in the general population is known, the risk of having an affected child can be quantified.

Each pregnancy of a parent with a fully penetrant autosomal dominant disorder has a 50% risk of resulting in an offspring bearing the mutant gene. If the proband is apparently a sporadic case, a risk approaching 50% must still be given because many apparently sporadic cases are in fact due to dominantly inherited mutations in which the proband was the product of undisclosed parentage, new mutations, and unrecognized mild disease in other family members.

In response to genetic counseling, some patients may make what the neurologist considers to be an irrational decision about having children. Some patients consider 50% quite good odds even when considering the risk of having a child with Huntington's chorea. On the other hand, some patients may decide against having children because of odds of 1 in 100. In both circumstances, physicians should offer advice, and can even say what decision they would make in the same circumstances, but must emphasize that the ultimate decision rests with the couple.

The result of genetic testing can reveal that an asymptomatic individual will almost certainly develop the disorder. Asymptomatic individuals who carry the mutation for the disease can be identified by the use of testing for the mutant gene. Huntington's disease and myotonic dystrophy ate two such examples. Because Huntington's disease currently is nor treatable and Huntington's patients have a high suicide rate, the neurologist should be aware of the risks that accompany disclosure. The services of a qualified genetic counselor is very helpful for managing these problems. Before testing is begun, the genetic counselor will review thoroughly the hypothetical possibilities and the potential responses with the patient and spouse. Though most people think they want to know their generic status, after considering the implications, many conclude that a positive gene test would be too difficult to tolerate and hence forego screening.

CONCLUSION

In this chapter, we have presented a general outline of the principles involved in managing patients with neurological disease. When taken together with Chapters 49-54, dealing with specific aspects of neurological management, and with Chapters 55-85, dealing with the individual diseases, there can be no doubt that the neurologist is more than just a diagnostician. Although the diagnosis is essential, the neurologist's proper focus is on the treatment and management of the patient and the disease.

Chapter 49
Principles of Neuropharmacology and Therapeutics

Michael J. McLean

Molecular genetic techniques are gradually revealing how changes in ligand (or neurotransmitter) gated receptors and voltage-gated ion channels in different parts of the neuraxis produce neurological disease. These genetic advances have helped focus the development of new drug therapies. This chapter reviews some of the basic knowledge concerning neurotransmitter systems, their receptors, and their implicated diseases. This chapter attempts to synthesize a small picture of a vast, complex, interactive, molecular world.

NEUROTRANSMITTERS, NEUROMODULATORS, AND RECEPTORS

The ability to purify, sequence, and clone functional receptors and neurotransmitter transporters proves the existence of discrete, selective macromolecules that regulate neurotransmission **in different** parts of the nervous system. Neurotransmitters include amino acids (e.g., y-aminobutyric acid [GABA] and glutamate) and biogenic amines (e.g., serotonin and norepinephrine [NE]), Polypeptides processed from larger precursor peptides serve dual roles as neurotransmitters and neuromodulators. A combination of biochemical techniques and cloning of receptors with variable subunit composition have revealed the structural and functional features of various receptor types (Figure 49.1).

Ligand-gatcd receptors are broadly of two types: *inotropic* and *metabotropic.* Some neurotransmitters bind to both inotropic and metabotropic receptors. For example, glutamate activates three different excitatory inotropic receptors and nine different metabotropic receptors (mGluRs). The mGluRs can be divided into three groups: One is excitatory by virtue of G protein coupling to phospholipid hydrolysis and intracellular calcium release. The other two are negatively coupled to adenylate cyclase. The result of their activation is to decrease activity dependent on cyclic adenosine monophosphate (cAMP) and reduce neurotransmitter release (autoreceptor function). In the short run, the control of neuronal activity is within normal limits by modulating excitatory and inhibitory events simultaneously. Many steps can go awry in the interlocking cascades resulting in pathological processes. These steps serve as points of molecular diagnosis and targets for pharmacological intervention. In the end, genetic regulation determines the subunit **composition, turnover** rate, and number of receptors in the membrane under extant conditions.

Guanosine triphosphare (GTP)-binding proteins (G proteins) couple several receptors to intracellular signaling systems. This links neuronal excitability to energy metabolism and second messenger systems. Normally, neuronal

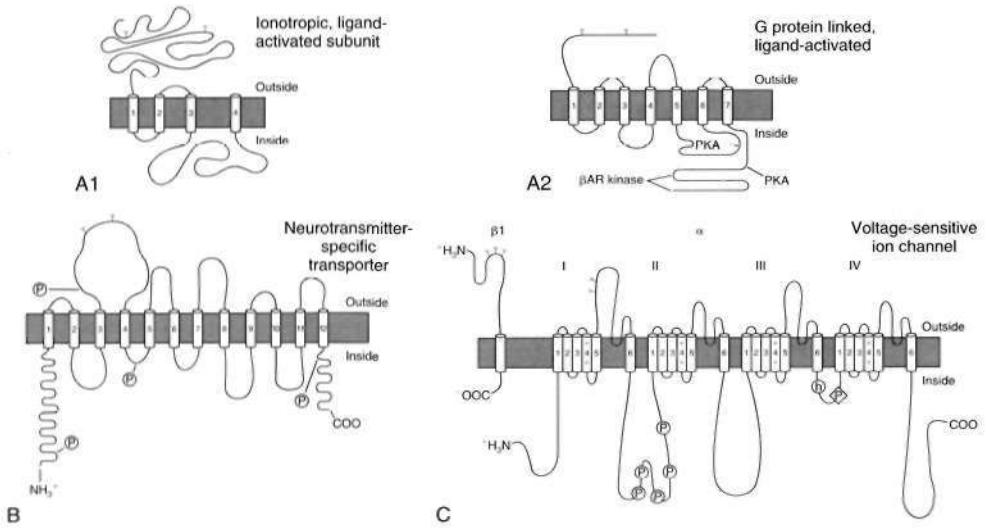

FIGURE 49.1 Molecular structure of Iigand-activated receptors, neurotransmitter transpottets, and voltage-sensitive ion channels. (Al) Ionotropic, tigand-activated receptor structure. A single subunit consisting of an amino and carboxy peptide sequence, font transmembrane segments, and connecting loops is shown. Assembly of approximately five suhunits is thought to be necessary ro construct ligand-gatcd ion-conducting channels. (A2) Some receptors of known neurotransmitters arc coupled to intracellular second-messenger systems indirectly by interaction with C! proteins. G protein-linked receptors arc thought ro have extracellular amino sequences, each followed by seven covalently linked transmembrane domains and an intracellular carboxy terminal of variable length. Kadi transmembrane domain is covalcntly linked by a loop of amino acid residues. The intracellular loop connecting the fifth and sixth ttansmembrane domains is thought to modulate interaction with G proteins, along with the tarhnw icrTiim.il sequence. function of the *(I* adrenergic receptor depicted here K modulated In phosphorylation at different sites by /(-adrenergic receptor kinase (/iAR kinase) or protein kinase A (PKA). (B) The termination of the action of amine neutotransmitters depends on specific transporters, which reduce synaptic concentrations of a neurotransmitter by re-uptake. Transporter proteins have 12 membrane-spanning regions, and both the amino and carboxy regions arc thought to be intracellular. A long extracellular loop connecting rhe third and fourth transmembrane domains is thought to contain the recognition sequence for a specific neurotransmitter, thereby conferring specificity on the transporter system. (C) Voltage-sensitive ion channels arc sequences of 1800-2100 amino acids. They are essentially multiple suhunits that are covalcntly linked. The example shown is the structure of rhe voltage-sensitive sodium channel. The fourth transmembrane domain in each of the four suhunits is positively charged and is likely to be the voltage-sensitive gare. When folded on itself, the four su bun its line a central cavity such that rhe fourth transmembrane domain in each of the suhunits is in a position to open or close the channel depending on its conformational state. Voltage changes and binding of various alkaloids may alter the opening and closure of the channel. The intracellular loop berween the third and fourth subunits contains a sequence that is thought to be responsible for spontaneous inactivation of the sodium channel. The intra cellular loop con nee ring the first and second subunits has multiple sites for modulation by phosphory la ting systems. The amino and carboxy terminals are both thought to be intracellular. Accessory subunits *(ft* is shown) can modulate the kinetics and, possibly, the drug-binding characteristics of the channel. Accessory subunits have been described for hoth the sodium and calcium channels that have been cloned to date. These figures show putative structures based on sequences of purified receptors, Transporters, and ion channels, h = sequence required for spontaneous inactivation of the channel; P = phosphorylation site; Y = glycosylation site; — = anionic loi for retrodotoxin binding; + = cationic sites on voltage-sensing transmembrane segment, (Al Redrawn with permission from Macdonald, R. L. & Olsen, R. W. 1*994*, "GA6A_A receptor channels," *Annu Rev Ncurosci,* **vol.** 17, pp. 569-602; A2 redrawn with permission from Liggett, S. A. 1992, "Cellular and molecular biology of voltage-gated sodium channels," *Pharmacol Rev,* vol. 72, pp. S15-S48.)

activity does not exceed the capacity of its neuronal support. Conditions in **which energy metabolism** is inadequate to support the degree of activity (e.g., sustained depolarization resulting from leakage of excitatory amino acids and potassium) may result in reversible or irreversible dysfunction (excitotoxicity and neuronal death). The genetic regulation of transmitter release and receptors under normal and pathological circumstances is the subject of intense investigation,

Ligand-Gated Receptors

Inotropic receptors consist of channel-forming polypeptide subunits (Figure 49.1A1). Neurotransmitters of drugs that modulate these receptors facilitate or inhibit opening or closing of a central channel that allows passage of specific ions. The binding of agonists to inotropic receptors causes conformational changes of channel components. These changes alter ionic conductance and modify intracellular processes rhar require specific ions. The synthesis and identification of selective agonists and antagonists has facilitated understanding many receptors.

G Proteins

The binding of ligands to mctabotropic receptors activates GTP-binding proteins (G proteins) that modulate intracellular second-messenger systems. Any of several G proteins

may couple different receptor subtypes to specific signaling systems. When G proteins couple mctabotropic receptors directly to ion channels, their function appears to be inotropic. The established sequences for nearly 100 G protein-co u pled receptors seem to share several characteristics. They are all monomeric proteins with seven transmembrane domains, each consisting of 20 to 30 hydrophobic amino acids (Figure 49.1A2). The amino terminus, pockets formed by the transmembrane domain, and three extracellular polypeptide loops confer ligand-binding characteristics and membrane interactions. Intracellular polypeptide loops, especially the third loop, and the carboxyl terminus interact with G proteins and through them with other second-messenger sysrems.

G protein coupled receptors can be grouped based on conserved nucleotide sequences. A superfamily of traditional neurotransmitter receptors includes G protein binding receptors for adenosine, acetylcholine (ACh) (muscarinic type), NE, dopamine, serotonin, eannabinoids, and tachykinins. A second family of G protein binding receptors, with little homology in amino acid sequences to the first superfamily, localizes to the brain, endocrine systems, kidneys, and gastrointestinal tract, it includes receptors for peptides (e.g., secretin, calcitonin, parathormone, and vasoactive intestinal peptide) and neurohormones (e.g., glucagon, corticotropin, and growth hormone releasing factor).

G proteins are trimers consisting of alpha (of) (39-52 kD), beta *(0)* (35-36 kD), and gamma *(y)* (-500 kD) subunits. G proteins possess inherent GTPase activity. The result of binding a neurotransmitter or exogenous ligand to a specific receptor is the binding of the «-subunit of the G protein to the transmembrane receptor. In this configuration, GTP displaces guanosine diphosphate (GDP) from the a-subunit; then the *fi*- and y-subunits dissociate from the «-subunit, and the GTP binding K-subunit is liberated from the receptor. The activated or-subunit then regulates ion channels directly or activates the first enzyme in various enzyme cascades that modulate intracellular second messengers. These enzymes include adenylyl cyclase, phospholipase C, phospholipase A2, and phosphodiesterases. The activation of these enzymes is coupled to hydrolysis of GTP to GDP on the a-subunit and reassociation of the *fi*- and y-subunits with the a-subunit.

Mutations of G proteins alter function and cause disease. A series of mutations in G proteins are associated with pseudohypoparathyroidism, and a mutation in the gene for GTPase activation protein (GAP) is associated with neurofibromatosis type 1. Affected individuals show the abnormal GAP protein in neurons, Schwann cells, and oligodendrocytes. The ras family of small G proteins is implicated in the pathogenesis of human colorectal adenocarcinoma. This emphasizes the regulatory role of the ras family in growth and differentiation. Proto-oncogenes is the name used for genes encoding ras proteins. Some psychoactive drugs (antidepressants, lithium, opiates, cocaine, and alcohol) alter levels of G protein subunits. These changes may participate in both the therapeutic and addictive effects of psychoactive drugs.

y-Aminobutyric Acid

GABA is ubiquitous in the nervous system and regarded widely as the principal inhibitory neurotransmitter of the brain. Although this is true in the peripheral nervous system and central nervous system (GNS) of mature individuals, GABA may be excitatory during embryogenesis. During development, chloride ions flow outward instead of inward on channel opening, resulting from a less negative reversal potential for chloride ions. With maturation, the receptor composition may stay the same, but chloride permeability of the membrane declines abruptly and inward flow of chloride ions occurs through open channels in the center of GABA receptors.

Chemistry and Distribution

Glutamic acid dehydrogenase (GAD) synthesizes GABA from glutamare in the terminals of GABAergic neurons in the CNS. GABA transaminase (GABA-T), the principal degradarory enzyme, is present in mitochondria of GABA-synthesizing neurons and neurons bearing GABA reeeptors. The distribution of GABA-T is throughout the body, allowing rapid metabolism of exogenous GABA outside the nervous system. GABA-T reversibly deaminatcs GABA to succinic semialdehyde at the same time that *a*-ketoglutarate is aminated to form glutamate. This process occurs in synaptosomes and glia, and it may be important postsynaptically. Succinic semialdehyde dehydrogenase, aloni; with GAD and GABA-T, tonus the GABA *shunt,* which links amino acid and carbohydrate metabolism. The percentage of GABA in the total neuronal pool that contributes to neurotransmitter function is unknown.

GABA released from vesicles on depolarization of nerve terminals diffuses from the point of release and binds to postsynaptic receptors to produce fast inhibition. GABA also binds to presynaptic autoreceprors that modulate release of the transmitter. Enhancement of GABAergic inhibition is a major strategy for treatment and discovery of new drugs for disorders of neuronal hyperexcitability. The termination of GABA action is primarily by reuptake into neurons and glia by specific transporter molecules (Figure 49.IB) that are targets of pharmacotherapeutic agents and genetic alteration in disease.

GABA Receptors

$GABA_A$, GAB AH, and $GABA_C$ are rhe three classes of receptors known to bind GABA. $GABA_C$ receprors are in the retina. Binding of GABA opens chloride-selective channels in the center of the inotropic $GABA_A$ and GABAc receptors, resulting in a rapid influx of negatively

charged chloride ions through the postsynaptic membrane. The net increase of intraneuronai negativity results in so-called fast inhibitory postsynaptic potentials (IPSPs), except in the developing brain when the resting potential is negative to the chloride reversal potential. $GABA_{(1}$ receptors are metabotropic receptors that share extensive homology with metabotropic ghitamate receptors. The mediation of a long-lasting hyperpolarization or slow IPSP is by postsynaptic GABAn receptors linked directly by a G protein to a potassium channel. GABAD receptors are also present on the presynaptic membrane, where they serve as a ti to recep tors to inhibit or reduce the release of neurotransmitter GABA.

The *$GABA_A$ receptor* is a channel-forming aggregate of several different subunits, that is, a hetero-oligomer or hi'tiTonuT, Fifteen subtypes of five different subunits have been cloned from the mammalian brain. Mathematically, more than I SO,000 unique pentamers could be assembled from this number of subunits and provide an astounding range of receptor heterogeneity, with respect to both structure and pharmacology (Figure 49.2). Relatively few GABAA, however receptor complexes have been demonstrated in vivo, however.

$CABA_B$ receptors are distributed widely throughout the cerebral cortex, brainstem, and spinal cord. Binding of GABA or baclofen and its analogues to GABA^ receptors inhibit neurons directly by G protein-mediated opening of a potassium channel that produces a slowly peaking hyperpolarization, and indirectly by G protein-mediated enzymatic pathways that block calcium currents involved in neurotransmitter release (GABAn auto receptors) and membrane potential oscillations.

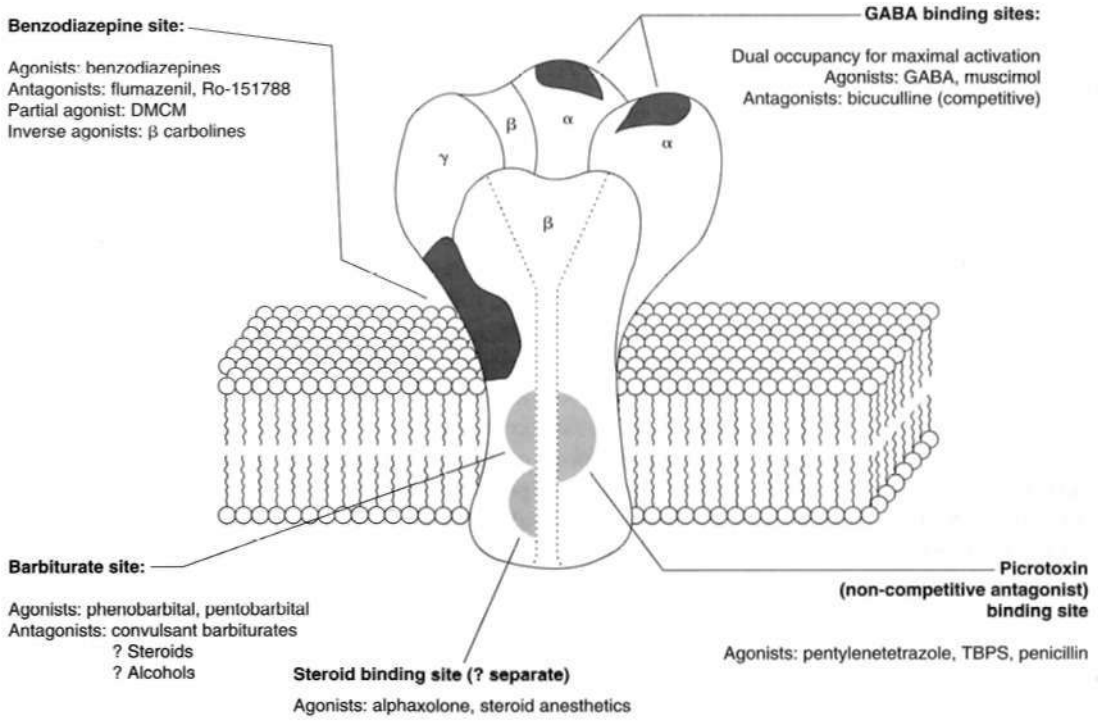

FIGURE 49.2 Pharmacology of the y-amino butyric acid subtype A ($GABA_A$) receptor. The $GABA_A$ receptor is thought to be an assembly of five subunits, probably of two to three distinct types per receptor. Affinity for GABA is modulated by a variable combination of or-, *fS*-, *y*-, and <S-subunits. The y-subunits are essential for benzodiazepine binding, but the binding site is probably a pocket between *y*- and /i-subunits near the membrane surface. In fully developed cells, binding of one or two GABA molecules leads to conformational changes, which opens a central pore and allows entry of chloride ion down its concentration gradient. The entry of anions into the intracellular milieu leads to hyperpolarization and decreased excitability. Multiple allosteric modulatory sites have been defined pharmacologically, including those for benzodiazepines, barbiturates, steroids (including anesthetics), and alcohols. Agonist binding to various modulatory sites generally increases the chloride conductance and enhances hyperpolarization. Antagonists and convulsant barbiturates decrease chloride conductance and hyperpolarization. These actions may promote seizures or anxiety. The pharmacology of the benzodiazepinc-binding site has been characterized best. Agonists and antagonists have been identified. The partial agonist methyl f>,7-dimethoxy-4-erhyl-beta-carboune-3-carboxylate (DMGM) enhances chloride conductance when it is present alone, but it diminishes the augmenting effect of benzodiazepines. The binding of ^-carbolines to the benzodiazepine site results in decreased chloride conductance due to a different conformational change. Barbiturates are thought to bind at a separate allosteric modulatory site. Allosteric modulators, such as phenobarbital and pentobarbital, augment the chloride conductance gated by GABA binding. Convulsive barbiturates also bind to this site. Steroids and alcohols may bind to the same site. Alternatively, steroids may bind to a separate allosteric site in or near the channel. Agonists at this site include alphaxalone and steroid anesthetics, A separate allosteric site in the channel is thought to bind the convulsant picrotoxin noncompetitive^. Binding of pierotoxin and other convulsants, such as pentylcnctctrazolc, penicillin, and r-burylbicycliiphosphoriirliionarc (TBPS), results in reduction of the chloride conductance activated by GABA. Endogenous substances, such as taurine and a putative naturally occurring benzodiazepine antagonist, arc also thought to alter the chloride conductance. The phosphorylation of intracellular loops of the different subunits is also thought to modulate receptor sensitivity anil availability.

Clinical Role of GABA Receptors

AJlosteric modulators of GABAA receptors are often used in the treatment of the epilepsies particularly generalized tonic-clonic and generalized absence status cpilepticus. In the course of experimental status epilepticus, $GABA_A$ receptors become less sensitive to benzodiazepines, thereby producing GABA-resistanr status epilepticus. This reveals how dynamic regulation of receptors can be. Barbiturates and benzodiazepines are believed to act at different sites ro increase GABA-activated inhibitory chloride current. Among the newer antiepileptic drugs, felbatol and topiramate augment chloride current allosterically at lion benzodiazepine sires. Vigabatnn, by Nocking GAISA-T and tiagabine, by blocking GABA reuptake by its transporter, elevate interstitial GABA concentrations. Tiagabine is an analogue of the GABA reuptake blocker, nipecotic acid. Benzodiazepines are often used alone or in combination to treat situational anxiety, panic attacks, other affective disorders, spasticity, and insomnia {Table 49.1}.

Baclofen is a prototypical spasmolytic agent (see Tabic 49.1). Activation of $GABA_R$ receptors facilitates kindling in animal models of epilepsy, modulates hippocampal long-term potentiation, underlies slow-wave sleep (stages III—IV), causes muscle relaxation, and has antinociceptive effects. Seizures may result from indirectly disinhibiting crucial limbic circuits or by activation of oscillatory membrane potentials due to marked hyperpolarization. $GABA_B$ receptor activation also facilitates generalized absence seizures in animal models, and GABAu antagonists are anticonvulsant in animal models. Some GABAu antagonists block the T-ca!cium current thought to underlie bursting behavior in the thalamus. The so-called date rape drug, y-hydroxybutyrate (GHB, also a drug of abuse), is a $GABA_B$ receptor agonist. GABAB antagonists may serve as an antidote. The sequence of a cloned $GABA_B$ receptor has extensive similarity to the metabotropic glutamate receptor and is negatively coupled to adenylate cyclase.

Genetic anomalies affecting GABA receptors have been associated with clinical disorders. Mutation of the *yl* subunit of GABAA receptors has been linked to the syndrome of childhood absence epilepsy with febrile seizures (GEFS+; Table 49.2). A specific human GABA,, receptor gene *(hR1b)* with inwardly rectifying potassium channels (Kir3 type) maps near a susceptibility locus for idiopathic generalized epilepsy on chromosome 6p21.3. This provides a candidate gene for some forms of inherited epilepsy.

Glycine

Glycine receptors are members of the ligand-gated ion channel superfamily group 1 that also includes $GABA_A$, serotonin $5\text{-}HT_3$, and nicotinic cholinergic receptors. Glycine receptors are cblonde-conducting inotropes bur blockade by strychnine makes their ionophores different from those of $GABA_A$ receptors. Glycine is also a co-agonist at excitatory N-methyl-D-aspartatc (NMDA)-type glutamate receptors. The involvement of glycine in cellular metabolism has complicated assessment of its role as a neurotransmitter. Glycine is a classic inhibitory neurotransmitter of the spinal cord and brainstem. It is the neurotransmitter of Renshaw cells; these interneurons modulate excitation of spinal motoneurons by recurrent inhibition. !t also is important as the neurotransmitter of reciprocally inhibited interneurons involved in stretch reflexes, allowing antagonist muscles to relax while agonists contract. This is important for motor coordination. Widespread distribution of glycinergic synapses indicates a more complex role. Glycine-iinmunoreacrivc somata and fibers have been described in the cochlear nucleus, the superior olivary complex, cranial nerve nuclei, the area postrema, deep cerebellar nuclei, the cerebellar cortex, and the retina. Interestingly, where immunorcactive cell bodies are absent, stained fibers appear. Examples are the periaqueductal gray, mesencephalic reticular formation,

Tabic 49.1: Role of GABA in Disease States

Disoriirr	*Fa tkophysiology*	*Treatment*
1. Epilepsy	Seizures oil withdrawal of BDZs	Restote BDZs, GABA augmenting AEDs
	Seizures with pyridoxine deficiency (cofactor for CAD and GABA-T) due to decreased GABA	Administer pyridoxine
		Antiabsence AEDs
	GABA metabolite, j'-hydroxybutyrate causes absence-like seizures GABAu activation facilitates absence seizures	GABAu antagonists, antiabsence AEDs
		Vigabatrin enhances midbrain GABA
	Midbrain "gate" for secondary generalization of seizures	Barbiturates; AEDs with other mechanisms
	GABAA receptors become BDZ resistant during experimental status epilepticus	GABA-enhancing drugs; AEDs with other mechanisms
	GA1SA,\ antagonists (e.g., bicucullme, picrotoxin) produce seizures in experimental models	No known preventative or restorative Rx
	Fewer GABAergic neurons in human focal epilepsies	Estrogen antagonists; GABA augmenting AEDs
	Proconvulsant effect of estrogen due to GABA antagonism	
2. Anxiety states	Excessive excitation presumed to underlie panic, situational anxiety, and other mood disorders	m>A

AED = antiepileptic drug; BDZ = benzodiazepine; GABA = K-aminobutyric acid; GAD = glutamic acid dehydrogenase; Rx = treatment.

the pretectal region, intralaminar nuclei of the thalamus, and the anterior and posterior hypothalamus (including preoptic areas). This suggests that those areas receive projections from unknown sources. Physiological effects of glycine in some of these regions are strychnine sensitive. In rats, cortical glycinergic fibers are sparsely distributed. Glycinergic inhibitory potentials were discovered in cerebellar intcmcurons, olfactory bulb neurons, and hippocampal CA3 neurons with electrophysiological techniques. In these regions, glycine modulates motor rhythms, reflexes, and sensory processing. Glycine provides recurrent and surround inhibition that enhances the fidelity of pathway activation by preventing lateral dispersal of inpurs to crucial circuits.

The function of non-NMDA related glycine receptors changes during development. They are excitatory in early stages because the chloride equilibrium potential is set at a less negative potential than the resting potential. At a specific stage, expression of a chloride transporter lowers the intracellular chloride concentration making the chloride equilibrium porential more negative than the resting potential. Thereafter, glycine receptor activation becomes inhibitory under most conditions.

Throughout the neuraxis, glycine acts as a co-agonist at NMDA receptors. Its role is excitatory. Evidence indicates that some NMDA receptors lack voltage-dependent magnesium block (see later) and are activated by glycine not glutamate. Because patches of glycine receptors are near postsynaptic glutamate receptors, glycine is positioned to modulate both inhibition and excitation simultaneously. Extremes of either activity are ptevented. As more is learned of how alterations in glycinergic neurotransmission contribute to disease, pharmacological therapeutics related to glycine will increase.

Chemistry and Distribution

Glycine, the structutally simplest amino acid, is a nonessential amino acid. It comprises up to *5%* of dietary protein and is distributed to all tissues of the body. It is readily transported across the blood-brain barrier and is probably transported into neurons. Glycine is synthesized, even in brain, from glucose and pyruvate and/or serine. The immediate precursor is serine, with which it is reversibly interconvertible. The rate-limiting enzyme in the synthesis of glycine is serine hydroxymethyl transferase, which requires tetrahydrofolate, pyridoxal phosphate, and manganese ions as cofactors. Ubiquity of this reaction prevents it from localizing glycinergic neurons. Glycine is an important one-carbon donor in the synthesis of peptides, proteins (including creatine), nucleotides, nucleic acids and glutathione. For metabolism, glycine binds to pyridoxal phosphate and is cleaved to form 5,10-methylene-tetrahydrofolate and ammonia. These products integrate glycine metabolism into multiple aspects of amino acid and protein processing,

The origin and partitioning of the neurotransmitter pool of glycine are unclear. Glycine is released from presynaptic vesicles. In some locations, it is coreleased with GABA, suggesting that the vesicular inhibitory amino acid transporter in presynaptic terminals of GABAergic and glycinergic neurons is not selective. This and the demonstration of selective transporter molecules on glia suggest a neuromodulator role of glycine.

Glycine Receptors

Glycine receptors are pentamers. The second transmembrane domains (TM2) of the alpha subunits are alpha-helices that form the pore. Four different alpha subunits (al-4), two with splice-variants, and one modulatory *fi* subunit have been identified. Adult glycine receptors are thought to include three *a* (predominantly c*l) and two *fi* subunits. In developing animals, «2 subunits predominate. Functional and pharmacological properties of various receptors differ. The diversity of constructs allows for regional, and perhaps pathological, variation in receptor expression.

Glycine binds near the membrane on the extracellular N-terminus of a subunits consisting of four transmembrane domains and connecting loops (see Figure 49.1 Al). Outward movement of the TM2 domain opens the channel. Dcscnsitization is slow compared with other receptors, but mutations in the intracellular loop between TM1 and TM2 enhance desensitization. The endogenous substances, taurine and ^-alanine, bind with lower affinity. Strychnine binds to two regions of the extracellular N terminus and blocks channel activation. Binding of low concentrations of zinc, released from vesicles with the transmitter, to the N-terminus enhances glycine-activated current. High concentrations (>10 micromolar) of zinc decrease the current. Phosphorylation and glycosylation of the large intracellular loop between TM3 and TM4 modulate channel function. Conflicting effects of phosphorylations mediated by protein kinases A and C and calcium-dependent calmodulin kinase 2 have been demonstrated under different experimental conditions and in a variety of cell types. The contradictory findings have not been completely explained. The receptors are anchored in rhe membrane by gephyrin. Turnover involves ubiquitination (attachment of ubiquirin), internalization, and degradation.

The pharmacology of glycine receptors is not as well worked out as that of GABA receptors. Alcohols and volatile .inesthetics increase glycine-activated currents. 1 lie pain neurotransmitter, substance P (SP), potentiates glycine activation. The GABA receptor antagonist picrotoxin blocks glycine receptors as well. It binds to *a* subunits at an undetermined site that does not affect strychnine binding. Both mean open time and frequency of channels openings are decreased. This suggests that that picrotoxin alters coupling between agonist binding and channel activation, rather than by producing a competitive block. Some l.-type calcium channel blockers (verapamil and some dihydropyridines) block glycine receptors while others (nitrendipine and nicardipine) increase glycine-activated current. Some opioids and dextromethorphan inhibit glycine-mediated inhibition, a potentially proconvulsant effect. The neuroprotective agent riluzole enhances glycine receptor desensitization. Effects of neurosteroids depend on the subunit composition of the glycine receptors.

This mixed bag of effects may contribute to variable efficacy and adverse effects of the clinically used drugs but docs not steer the development of compounds that selectively and predictably target glycine receptors. However, several tropeincs that were first shown to block 5-HT3 receptors, including tropisetron and bemesetron,

have been found to enhance glycine receptor activity at low concentrations. Glycine and tropeines together inhibit strychnine binding. The tropeincs arc highly potent and do not displace zinc, propofol, or ethanol. Therefore they seem to recognize a novel binding site and may prove useful for clinical drug development. The anticonvulsant, chlormethiazole, potentiates glycine.

Clinical Role of Glycine Receptors

Mutations affecting genes encoding glycine receptor subunits produce disorders of motor function in mice, cattle, horses, and man. These mutations reduce glycinergic inhibition in several ways. Three autosomal recessive disorders in mice are manifested by tremor, muscle rigidity, myoclonic jerks, and exaggerated startle responses. Hyperekplexia is a congenital startle syndrome of humans with similar findings. Several mutations can produce the human phenotype (Table 49.2}. Clonazepam, a GABA receptor agonist, is considered the drug of choice for treating the abnormal movements. Clonazepam is thought to augment GABA-ergic inhibition and compensates for deficits in glycinergic inhibition. High doses with attendant adverse effects are required for benefit. This could also reflect recruitment of additional mechanisms of action of clonazepam, namely glycine receptor activation, at high concentrations. Specific glycine receptor agonists or allosteric modulators undoubtedly would be useful.

Mutations of genes that encode mitochondrial glycine cleavage enzymes cause nonketotic hyperglycinemia (glycine encephalopathy; see Table 49.2).

Glutamate and Aspartate

Chemistry and Distribution

Glutamate and aspartate are nonessential dicarboxylic amino acids. They excite mammalian cerebral cortical neurons. Glutamate is the most common amino acid in the nervous system and is the principal excitatory neurotransmitter in the brain. Other glutamate functions are to modulate ammonia metabolism, to form proteins, and to serve as a precursor to Krebs cycle intermediates and GABA. Exclusively aspartate-driven pathways have not been isolated or identified. Glutamate and aspartate are chemically interconvertible, and both are agonists with different affinities at glutamate receptors (GluRs). Excitatory amino acid analogues and release of endogenous stores of glutamate in pathological settings cause neuronal damage. This process is called *excitotoxicity.*

Glutamate and aspartate are synthesized within central neurons and glia from carbohydrates involved in the tricarboxylic acid cycle. The mitochondrial enzyme, aspartate transaminase, interconverts glutamate and aspartate and is involved in the production of transmitter-related pools of both amino acids. Glia contain glutamine synthetase, which converts glutamate to glutamine. Glutamine is subsequently transferred to neurons, where it is deaminatcd to glutamate by glutaminase. This glial inactivation and the specific uptake systems for glutamate reduce interstitial glutamate levels to terminate the neurotransmitter action and prevent excitotoxic damage.

Glutamate concentrations are highest in the temporal lobe, basal ganglia, cerebellum, and neocortex. Gluramatergic pathways descend from the brainstem to the spinal cord, where segmental glutamarergic interneurons are also present. Some primary afferent pathways are glutamatergic.

Glutamate Receptors

The two main classes of glutamate receptors (GluRs) are ionotropic and metabotropic. The basis for identification of three ionotropic GluR subclasses B is their affinity for the synthetic analogs: NMDA, «-amino-3-hydroxy-5-merhyl-isoxazole-4-propionic acid (AMPA), and kainic acid (KA; kainate). All three compounds produce seizures and brain injury when administered systemically or into the cerebral ventricles of animals. The NMDA and AMPA receptor subtypes have received attention, because they are implicated in the pathogenesis of seizures, stroke, and neurodegenerative diseases and because highly selective antagonists are available. A family of metabotropic receptors has functions related to phosphorylation of ionotropic receptors and release of intracellular calcium.

Ionotropic glutamate receptors contain ligand-gated ion channels and are important in rapid excitatory neurotransmission in the CNS. Ionotropic receptor subunits are single polypeptide sequences that fold into a tertiary structure. The subunits aggregate to form receptor-channel complexes. Based on the size of ion channels needed to conduct both monovalent and divalent cations, it is assumed that glutamate channels in the brain are pentamers composed of at least two different types of subunits.

NMDA Receptors. Subunits of cloned NMDA receptors form ion channels with many pharmacological properties of native NMDA receptors. Using *in situ* hybridization techniques, the differential distribution of NMDA receptor subunits varies among several regions of the adult brain and at different stages of development. For example, mRNA for NMDA-R1 subunits exists in virtually all neurons, whereas the expression of isoforms of NMDA-R2 is variable throughout the nervous system. These findings suggest that brain NMDA receptors are heteromcric and that functional diversity is a result of combination of NMDA-Ri subunits with various types of NMDA-R2 subunits. Therefore drugs can be designed to target specific brain regions, possibly even in unique pathological conditions. The intracellular carboxy-tenninal region of rhe NMDA-R2 subunit is large, more than 400 amino acid residues compared with the usual 50 to 100 residues

found in AMPA/kainate receptors. Protein kinase C can phosphorylate this region as a means of regulating synaptic efficacy and plasticity, as in the case of long-term potentiation.

AMPA Receptors. GluR subunits 1 to 4 can assemble into recombinant receptors with high (nanomolar) or low (micromolar) affinity for KA. Mixing and matching receptor subunits alters channel kinetics and confers unique properties. For example, channels containing GluR-1 and GluR-3 subunits are permeable to calcium, whereas inclusion of GluR-2 subunits results in low permeability to calcium. Highly calcium-permeable AMPA receptors are more abundant during development in some regions of the brain. Different subunits localize to different human chromosomes: GluR-1 to chromosome 5, GluR-2 to chromosome 4, GluR-3 to the X chromosome, and GluR-4 to chromosome 11. Excitotoxicity is a pathogenetic mechanism in neurodegenerative disorders. Chromosome 4 contains genes encoding GluR-2 and huntingtin, a gene product involved in Huntington's disease. Mutations or editing of various subunits may be important in the pathogenesis of acute disorders of the nervous system, including epilepsy and stroke, and inherited disorders of the nervous system.

Kainate Receptors, Recombinant receptors with a high affinity for kainate can be formed from subunits GluR-5, -6, and -7 and sequences from another family, KA-1 and -2. Chromosome 21 contains the gene coding for GluR-5 subunits in humans. Some cases of familial amyotrophic lateral sclerosis (ALS) also localize to chromosome 21, This is a coincidence, because GluR-5 are expressed only in some neurons in the dorsal horn where they may function in pain transmission, and the chromosome 21-linked cases of familial ALS are due to mutations of the *SOD'l* gene.

Metabotropic Receptors

The metabotropic glutamatc receptor (mGluR) family consists of nine receptors with uniquely conserved regions in the transmembrane domains. These receptors have little homology with the neurotransmitter superfamily or the hormone receptors. The glutamatergic mGluRs are much larger than other G protein linked receptors. Modulation of receptor activity occurs by glycosylations at the extracellular N-terminus and by phosphorylation at multiple threonine and serine residues of the intracellular C-terminus. In addition, phosphorylation of the loop between transmembrane domains 3 and 4 may modulate interaction with G proteins. Association of the metabotropic receptors with different G proteins and effector systems can then produce a variety of responses by modulating ionotropic receptors and intracellular biochemical processes. Both ionotropic and metabotropic receptors are in the same region of the postsynaptic membrane and are probably coactivated.

Retinal glutamate pre fere nri ally activates (+) -2-amino-4-phosphonobutyric acid (1-AP4), a metabotropic receptor in bipolar cells, resulting in G protein dependent activation of phosphodiesterase. This opens a sodium channel by decreasing the concentration of cyclic nucleotides. L-AP4 receptors may also be present presynaptically in the brain. Several metabotropic receptors are activated by (+) -trans-l-aminocyclopentane-l,3-dicarboxylic acid (ACPD). The G proteins, in turn, activate phospholipase C that releases two intracellular second messengers, diacylglyccrol (DAG) and inositol triphosphate (IP3), from membrane lipids. Activation of protein kinase C by DAG phosphorylates GluRs. For example, phosphorylation of the NMDA receptor relieves voltage-dependent magnesium block and augments calcium influx through activated channels, IP3 releases calcium from intracellular stores such as the endoplasmic reticulum. This step may lead to production of nitric oxide, which has mixed presynpatic and postsynaptic actions. It may decrease NMDA receptor activity by binding to the redox site. Excessive activation of these so-called Group I mctabotropes (mGluR| and mGluRj) contributes to excitotoxicity. Different metabotropic receptors (Groups II and III) alter cAMP levels and may be neuroprotective.

The regulation of glutamate receptors includes interlocking mechanisms that facilitate excitability, such as long-term potentiation and synchrony, without cell injury. Increased intracellular calcium contributes to long-term potentiation, an experimental model of synaptic plasticity. In the hippocampus, the production of long-term potentiation is by brief high-frequency tetanic stimulation of Schacffer collaterals. Stimulation enhances excitatory postsynaptic potentials (EPSPs) in CA1 neurons. An early, or induction, phase lasts about 30 seconds and requires activation of NMDA receptors. A prolonged maintenance phase may last hours, and it depends on phosphorylation of receptors. The result is increased synaptic efficacy, which may be important in learning and memory. Long-term potentiation is facilitated by specific agonists of metabotropic GluRs and is prevented by highly selective antagonists and blockade of protein kinase C (e.g., by staurosporine). Injection of staurosporine also reduces hippocampal injury produced by brain ischemia in rodents. This suggests that antagonists of multiple steps in the calcium-releasing enzyme cascade activated by metabotropic GluRs may be neuroprotective.

Postsynaptic metabotropic receptor activation in hippocampal pyramidal neurons also closes voltage-dependent potassium (M-typej and calcium-dependent potassium channels. These effects prolong repetitive firing of action potentials. Activation of presynaptic metabotropic receptors reduces the release of glutamatc, probably by blockade of ion channels that admit the calcium needed for excitation-release coupling. The result is a filtering effect that reduces the efficacy of low-intensity stimulation and amplifies (postsynaptically) inputs strong enough to bypass

the reduction of neurotransmitter release. This bias on the signal-to-noise ratio is a proposed mechanism of controlling attentiveness.

Activation of presynaptic mctabotropic glutamate receptors also reduces IPSPs, presumably by reducing GABA release. This reduction of inhibition combined with the postsynaptic excitatory effects of metabotropic receptor activation may be proconvulsant. Injection of ACPD into the hippocampus results in the development of limbic seizures and damage that simulates the injury produced by kindling cpileptogenesis,

The cause of contralateral turning behavior induced by ACPD injection into the striatum may be enhanced dopamine release, because haloperidol and dopamine depletion blocks the effect. This suggests .1 role for metabotropic GluRs in motor system dysfunction and a possible therapeutic role for metabotropic receptor antagonists. Activation of metabotropic receptors in the brainstem excites barorcf lex-like responses, suggesting a further role in cardiovascular tcgulation.

Pharmacology of Glutamate Receptors

Ionotropic glutamate receptors have several known agonists and antagonists (Figure 49.3). Activation of NMDA receptors requires binding of agonists at two sites. The principal site is the NMDA or glutamate-binding site. The most important endogenous agonist is glutamate, although other endogenous agonists (e.g., aspartate and quinolinate) may bind at the same site. Phosphonate derivatives (e.g., AP-5 and AP-7; CPP and CPP-ene) are among the many synthesized high-affinity competitive antagonists for glutamate binding to this site. The second essential site binds glycine. Neurotransmitter glycine mediates IPSPs in the spinal cord, but glycine is present in sufficient quantities in interstitial fluid to serve a permissive or co-agonist function at NMDA receptors. The channel within the NMDA receptor cannot open when glycine is removed completely under experimental conditions. This makes the glycine site a strategic target for designer antagonists, such as 7-chlorokynurenic acid.

One of the most important controls on the ionic conductance through the NMDA receptor channel is voltage-sensitive block by magnesium. Hippocampal pyramidal neurons, for example, require 10 mV to remove the magnesium block. This effectively raises the threshold for opening NMDA receptor channels. It also means that modulation of firing rates by AMPA-receptor-mediated neurotransmission can occur at smaller depolarizations without activation of the NMDA channels. The fact that phencyclidine, initially developed as an anesthetic but now an illegal hallucinogen ("angel dust"}, is an NMDA channel blocker suggests that NMDA channel blockade is psychotogenic. However, phencyclidine has other actions, and some clinically used NMDA channel blockers produce no significant adverse behavioral effects. Another dissociative anesthetic in clinical use, ketamine, is also an NMDA channel blocker with psychotogenic effects. Drugs that block the channel, including the prototype MK-801 and the cough suppressant dextromethorphan have potential therapeutic value for diverse neurological conditions.

A separate site that modulates the gating of the channel binds polyamines, such as spermine and spermidine, which neurons synthesize. Different concentration-dependent effects have been observed. Another site, called the REDOX site, binds nitric oxide, a volatile gaseous by-product of cell metabolism,

Endogenous zinc reduces NMDA-acrivated current. Zinc is present in high concentrations in the hippocampus and released with some neurotransmitters in the nervous system. Hydrogen ions also modulate the ionic conductance. The conductance is maximal at slightly alkaline pH and reduces with increasing acidity. This may prove to be an important safeguard. During hypoxic-ischemic injury, progressive acidification resulting from glycolytic metabolism may turn off the NMDA receptor channels and limit the transmembrane influx of calcium that underlies excitotoxic cell death.

AMPA receptors are less understood. These ion channels are opened with slight depolarization and do not demonstrate voltage-dependent magnesium block. AMPA channels admit sodium (entering) and potassium ions (exiting), but calcium-conducting AMPA receptors (without GluR-2 subunits) are presenr in the cerebellum and in other locations at certain times in development {see previous discussion). Highly selective quinoxazolidmedione antagonists, such as CNQX and DNQX, have been synthesized. Activation of AMPA receptor channels may depolarize the neuron sufficiently to remove voltage-dependent magnesium block and activate NMDA channels. AMPA and NMDA channels are coactivated and are present on the same parts of neurons; these two receptor channels, each with diverse modulators, can he envisioned as acting in concert.

Kainate channels are the least understood of glutamate receptors. Experiments with selective antagonists should help to understand their properties better. The anticonvulsant drug, topiramate, reduces kainate-gated but not NMDA-gated activity. The molecular mechanism of this effect appears to be indirect by altering phosphorylation of kainate channels.

Metabotropic receptors are best activated by L-glutamate. No known agents in clinical use block metabotropic receptors significantly. Several ATP-dependent protein kinases normally are activated by the metabotropic GluR. Because a series of enzymes is involved in this cascade, it stands to reason that selective antagonists at each enzyme step could be developed as therapeutic agents to control glutamatergic hyperactivity. It is also conceivable that mixtures of antagonists of inotropic and metabotropic GluRs might ultimately be used to limit or prevent neuronal damage induced by prolonged srarus epileptieus or stroke.

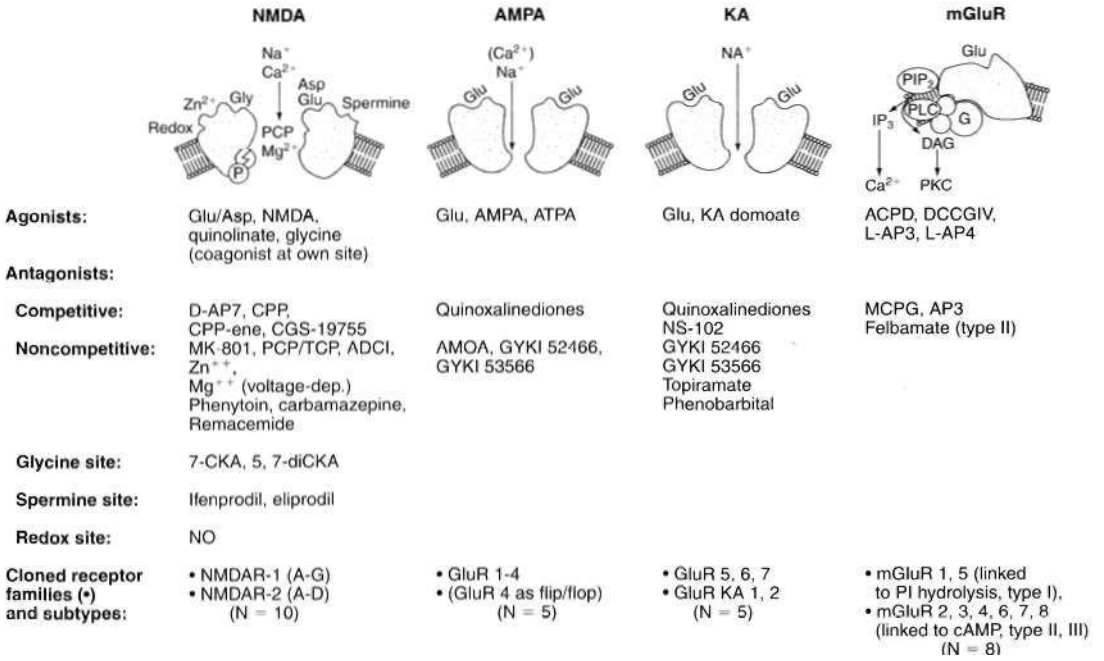

FIGURE 49.3 Pharmacology of gluramare receptors (GluRs). The GluR family includes three ionotropic receptors that recognize the exogenous ligands N-methyl-o-aspartatc (NMDA), u'-amino-3-hydroxy-.')-methylisoxazole-4-propionic acid (AMPA), and kainatc. A family of metabotropic receptors is also activated by glutamatc. These receptors are linked to phosphoinositidc hydrolysis and cyclic adenosine monophosphate (cAMP) production. Release of synaptic glutamate is thought to activate all the receptor subtypes within diffusion range. This results in mixed postsynaptic effects, depending on the profile of receptor types. Aspartate and quinolinic acid are naturally occurring agonists that activate a mixed cationic conductance (sodium and calcium enter, and potassium exits) through the NMDA type of ionotropic receptors. Glycine is a coagonist, but it is insufficient to activate the ionic conductance alone. The binding of zinc (Zn^{2+}) to a separate site tends to decrease the ionic conductance through the channel. A polyamine site binds agonists, which increase the conductance at low concentrations and inhibit the conductance at high concentrations. The channel itself has a voltage-sensitive binding site for magnesium (Mg^{+}). Until sufficient depolarization leads to dissociation of magnesium from its binding site, the conductance is blocked or low. Noncompetitive agonists, such as MK-801 and PCP, bind in the channel. Activation of the mctabotropic GluR (mGluR) may ultimately activate nitric oxide synthetase and result in the production of nitric oxide, which feeds back negatively by binding to the redox site on the NMDA receptor and results in a decreased entry of calcium and sodium. Two gene families, NMDAR-1 and NMDAR-2, have been cloned. These two families contain multiple receptor isoforms. AMPA and kainate receptor subtypes are also ionotropic but are less well characterized because of the limited availability, until recently, of antagonists. Competitive and noncompetitive antagonists have been discovered, however, and they are listed above. The AMPA family consists of five gene products, CiluR 1-4. Alternate splicing results in flip and flop conformcrs of the GluR 4 isoform. Kainate receptors contain subunits of two gene families. GluR 5, 6, and 7 constitute one family, and GluR KA-1 and *-2* constitute the second family. Some AMPA channels are activated less potently by kainate. Metabotropic receptors are linked through G proteins to phospholipase C and phosphoinositidc metabolism. The mGluRs 1 and 5 result in increased diacylglycerol (DAG) and inositol triphosphate (IP3). IP.i serves as a second messenger to release calcium from intracellular stores, and DAG activates protein kinase C. These actions may result in phosphorylation of the NMDA channel, an action that removes the voltage-sensitive magnesium block. Phosphorylation of calcium calmodulin and activation of nitric oxide synthetase results in synthesis of the ephemeral second messenger nitric oxide, which can modify both presynaptic and postsynaptic function. Other metabotropic receptors, including mGluRs 2, 3, 4, 6, and 7, arc linked to cAMP production and regulation of metabolic processes.

Clinical Role of Glutamate Receptors

The normal role of the neurotransmitter glutamate is to generate fast EPSPs that contain two components. The production of one component is by activation of **AMPA** and/or kainate receptors through a hroad range of mcmlir.nic potentials. The production of the other is by activation of NMDA receptors with increased calcium entry after sufficient depolarization removes voltage-dependent magnesium block. The factors determining the duration of these EPSPs are the amount and pattern of neurotransmitter release, the rate of reuptake of glutamate, and activity-dependent modulation of the response by coactivation of metabotropic receptors. Long-term potentiation may be involved in learning and memory. The marked prolongation of the EPSPs during long-term potentiation probably results from phosphorylation of inotropic receptors postsynaptically following activation of mGluRs.

Glutamateric hyperexcitability may underlie neuronal damage in diverse neurological diseases. Olney observed that injection of excitatory amino acids produced seizures and brain damage in rodents and introduced the concept of neuronal excitotoxicity. In vitro techniques and animal models have studied the concept. The administration of anticholinergic medications helped abbreviate seizures in an animal model of status epilepticus produced by excitatory amino acids. This suggests that enhancement of excitotoxicity follows entrainment of other excitatory systems after

the amino acid trigger. The spectrum of neurological disorders mediated by exeitotoxic injury includes epilepsy, stroke, and neurodegenerative disorders {Table 49.3). The development and evaluation of neuroprotective drugs have become a prioriry of the ncuroscience community (basic and clinical) and of' the pharmaceutical industry.

The involvement of glutamate in pain illustrates the potential for transforming physiologically regulated glutamatergic excitability into neuronal injury. NMDA receptor activation is involved in normal pain perception and in chronic pain states. The persistence of pain may require remodeling of nociceptive circuits in a way similar to that involved in kindling cpileptogenesis. Kindling is an experimental method of producing seizures in animals that, like long-term potentiation, depends on patterned stimulation. This laboratory model provides insight into cpileptogenesis and the mechanisms of action of antiepilcptic drugs. Even though kindling is unproved in humans, clinical epilepsy entails synaptic remodeling and giutamatergic hypcrexcitability as found in the kindling model of epilepsy. The amygdala and hippocampus kindle more readily than the neocortex. Even a single after-discharge produces structural changes in the hippocampus. Neurons in the dentate hylus die, and the dendritic processes of dentate granule cells sprout and spread to distances of up to 1 cm. The result is that an input that normally excites a discrete band of hippocampal neurons now produces hypersynchrony that can spread from the kindled focus and trigger seizures,

Tabic 49.3: Role of glutamate and other excitatory amino adds in clinical disorders and experimental models of neurological disease

Disorder/model	*Path ophysiology*	*Treatment*
1. Kindling cpileptogenesis	New NMDA component of the EPSP Loss of dentate granule cells and sprouting result in hypersynchrony	AEDs (e.g., MK-801) slow but do not prevent kindling acquisition Many AEDs prevent fully kindled seizures.
2. Epilepsy	Histological changes resemble kindling	Some AEDs block glutamate receptor subtypes: CBZ, FBM, REM vs. NMDA; I'l II'.. 'I'l'M v-. KA
3. Stroke	Hypoxic/ischemic injury leads to glutamate release and exciroroxicity	NMDA and AMPA antagonists (experimental) Na blocking AEDs (PHT, MK-801)
4. Nen rod egen era five disorders, e.g., Parkinson's disease, ALS	Delayed (apoptotic or programmed) death of neurons in specific brain regions	No methods to prevent progression
V AIDS dementia	Quinolinic acid (endogenous NMDA agonist amino acid} elevated in CSE	Mcmantine (experimental)
(.. XfoiKii.il glycine cncephalopath)	Genetic deficit of glycine cleavage enzyme results in elevated levels of NMDA co-agonist glycine	Dextromethorphan; tacrine (weak open channel blocker); other NMDA antagonists (?: rcmacemide, fclbamate, memantine)
7. Psychosis	Psychotogenic effects of competitive (CPP-ene) and noncompetitive (PCP) NMDA antagonists	Detoxification
8. Pain	Role in hypersensitivity and wind-up pain under investigation Glutamate microinjection into midbrain produces pain behaviors (experimental)	• NMDA antagonists (experimental)
9. Headache	Monosodium glutamate (MSG) produces migrainous headache (Chinese restaurant syndrome)	Abstinence from MSG Glutamate antagonists (hypothetical)
111. Alcoholism	Ethanol blocks NMDA receptors	Abstinence from cthanol
11. Dietary intoxication	BOAA in chick peas causes neurolathyrism Role of I1MAA in cyad flowers in Guamaman park in son ism/ALS/ dementia complex Exeitotoxic mechanisms	Avoidance of plant toxins in diet
12. Memory	LTP (experimental model) involves ionotropic and metabotropic NMDA receptors Antagonists could cause cognitive deficits	Discontinue offending drugs

AED = antiepileptic drug; ALS = amyotrophic lateral sclerosis; AMPA = a-amino-3-hydroxy-5-methylisoxazole-4-propionic acid; CSF = cerebrospinal fluid; EPSP = excitatory postsynaptic potential; LTP = long-term potentiation.

A new NMDA receptor component of excitatory synaptic potentials also underlies kindling. Kindling is permanent. No established method exists for unkindling. Strategies for preventing excitotoxic injury underlying kindling are under investigation. Drugs that augment (rABAergic inhibition, such as benzodiazepines or vigabatrin, and NMDA-channel blockers such as MK-801 slow the development of kindling.

In some cases, investigational compounds that seemed ideal in animal testing have been ineffective or proconvulsant in clinical trials. One competitive NMDA-antagonist, D-CPP-ene, appeared very effective and had little toxicity in animals. However, half of the eight patients in the phase II clinical trial experienced increased seizure frequency or status epilepticus, and all withdrew because of side effects, many of them cognitive. To explain this discrepancy between efficacy in animal models and patients, Loscher and colleagues have suggested that epileptic tissue may respond differently to drugs than normal tissue induced to express electrical and behavioral seizures. Anecdotes about the noncompetitive channel blocker MK-801 included psychotomimetic effects. MK-801 failed in clinical trials for other reasons, purportedly because of poor oral bioavailability and tachyphylaxis despite repeatedly increased doses.

What is the impact of such findings on the development of glutamate antagonists for clinical use? Eelbatol is an example of a noncompetitive NMDA-glutamate antagonist that did not produce untoward behavioral effects in most patients, yet potently decreased seizures. It has a relatively low affinity for its binding site. On the other hand, MK-801 and CPP-ene are very potent compounds with high affinities for their binding sites. These examples show that potent drugs with high selectivity may have side effects that limit clinical utility,

Mutations in genes encoding glutamate receptor subunits alter learning and memory and contribute to motor neuron disease in experimental models (see Table 49.2}. Mutations associated with Huntington's disease alter subunit composition of NMDA receptors and polymorphism in the kainatc receptor gene may contribute to variable age of onset of Huntington's disease (sec Table *49.2).*

ACETYLCHOLINE

The nicotinic receptor was the first to be purified, sequenced, and cloned. Over the past two decades, the structures of several nicotinic and muscarinic receptors, and of choline transporters and the synthetic enzyme, choline acetyl transferase (CAT), have been deduced using biochemical and molecular techniques.

Chemistry and Distribution

ACh is a monoamine neurotransmitter that rotates around bonds in its alkyl spine. The *cis* conformation is the predominant species in solution, but the *trans* conformation is the one that binds to muscarinic receptors. Therefore ACh binding to its receptor requires adaptive torsional changes within rhe molecule, presumably induced by electrostatic interactions with the receptor. The formation of ACh from choline and acetyl coenzyme A (Co-A) is catalyzed by CAT, and its hydrolysis is catalyzed by acetylcholinesterase (AChE). Histochemical localization of CAT allows detection of neurons capable of synthesizing ACh. CAT is synthesized in neuronal somata and transported down ixons to the nerve terminals. It is present in synaptosomes in two states: soluble in cytoplasm and bound to the outer membrane of the transmitter storage vesicles. Neurotransmitter synthesis takes place in the terminals. Neurons do not synthesize choline *de novo.* A high-affinity transporter recycles choline released by enzymatic degradarion of ACh by AChE or released into the interstitial space by the breakdown of phosphatidylcholine. The rate-limiting step in ACh synthesis may be the transport of acetyl Co-A out of mitochondria.

Neurons have two uptake systems for choline: a low-affinity and a high-affinity system. The high-affinity transporter gene has been cloned. However, hemicholinium, a potent inhibitor of neuronal choline uptake, does not block sodium-dependent choline uptake by the high-affinity transporter. This finding could indicate that functional components of the cloned transporter system are missing or malfunctioning. Alternatively, another system may be involved in vivo.

ACh is present in the cytoplasm and in vesicles in nerve terminals. Neurophysiological and neurochemical studies suggest the existence of two functional pools of ACh, one that is readily available for release and one held in reserve. How these pools relate to the location of ACh is uncertain. Newly synthesized ACh is the first released. An ATPase pumps hydrogen ions into the vesicles causing internal acidification and a positive charge. A highly specific transporter in rhe vesicle wall then exchanges ACh for hydrogen ions (countertransport) to maintain electroneutrality and the osmotic balance within the vesicle. Vesamicol blocks noncompetitively the uptake of ACh into vesicles. The release of newly synthesized radioactively labeled ACh is blocked without affecting ACh synthesis, the influx of calcium into nerve terminals, or high-affinity choline uptake. This provides strong evidence that cholinergic terminals release vesicular ACh. The readily available pool may be composed of vesicles close to the subsynaptic membrane and therefore more readily released by exocytosis. Vesicles more distant from the terminal membrane then represent the reserve pool.

Slow release of ACh occurs continuously, presumably because of spontaneous fusion of vesicles to the presynaptic membrane. The constant trickle of ACh produces miniature endplatc potentials that are detectable at rest. Depolarization of the axon terminal by the arrival of action potentials augments transmitter release. The amount

released depends on the duration of depolarization and rate of firing, the depolarization-induced influx of calcium through specific prc-synaptic calcium channels, and the ratio of extracellular calcium to magnesium. Each vesicle contains several thousand molecules of ACh, which are usually bound to ATP or a proteoglycan within the vesicles. Exocytosis releases all of these components after fusion of the vesicle to the inner side of the synaptic membrane. Calcium-ACh translocation of cytoplasmic ACh may contribute to depolarization induced release.

The released ACh diffuses across the synaptic space, where it binds to pathway-specific ACh recepcots in the central and peripheral nervous system and at the neuromuscular junction and exerts its physiological effects. The effect of ACh is terminated by dissociation from the postsynaptic receptors, hydrolysis by AChE, and reuptake of the released choline into the terminals. The exocytosis of neurotransmitter, membrane recycling, and reuptake of choline must be tightly coupled to avoid significant changes in the surface area of the synapse. Cycling of the vesicular membrane may be the rate-limiting step for both release and reuptake.

Cholinesterases are widely distributed in the body. The liver produces nonspecific or butyryl cholinesterase that circulates in the plasma and is present in the CNS. A specific AChE is associated with cholinergic innervation and localizes ;it synapses. The structure and the transcriptional and posttranscriptional regulation of AChE production are established. A soluble globular form of AChE and a so-called asymmetric form exist. The latter has a collagenous tail for membrane-binding in synaptic areas. AChE inhibition can occur by several mechanisms: (1) binding of dtugs such as edrophonium to the active site of the enzyme to prevent access of substrate; (2) binding of reversible inhibitors such as gallamine and propidium to peripheral binding sites on the enzyme; and (3) the combination of carbamyl groups of drugs, such as physostigmine and neostigmine, with the active site serine group. Anticholinesterase compounds can cause clinical symptoms in humans; these include insecticides, drugs used to treat myasthenia gravis, and those developed for use as chemical warfare agents.

Figure 49.4 outlines the pharmacology of ACh receptors.

Acetylcholine Receptors

Nicotinic and muscarinic receptors are distributed widely in the nervous system. Nicotinic receptors are present at the mammalian muscle endplate and sympathetic ganglion neurons. Centrally, nicotinic responses occur in the cerebral cortex, hippocampus, thalamus, neostriatum, and interpeduncular nucleus. The optic tectum seems to rely primarily on nicotinic muscarinic activity, as does the negative feedback of the Renshaw cell on motor neurons of the spinal cord,

Muscarinic receptors with a high affinity for pirenzepine, a high-affinity antagonist of M1 receptors, are abundant in the hippocampus and cerebral cortex. The cerebellum and brainstem contain neurons bearing receptors with low affinity for pirenzepine. Outside the CNS, muscarinic receptors are present on tissues innervated by parasympathetic postganglionic neurons. Some sympathetic responses, especially sweating and piloercction, depend on postganglionic sympathetic fibers that secrete ACh onto tissues with muscarinic receptors.

Muscle Nicotinic Receptors

The nicotinic ACh receptor was isolated and purified first, because of its abundance in *Torpedo* clcctroplax. The receptors arc so plentiful that they form virtually a crystalline array and are readily studied with electron microscopy. The receptor is a pentamer formed of different types of subunits: two a-subunits and one each of the *f}-*, *y-*, and *8-* subunits (Karlin 1993). Several receptor types are present in embryonic muscle and extrajunctionally in denervated adult muscle. Differences in subunit combinations account for subtle differences in conductance through these receptor subtypes. The pentameric structure surrounds a central cavity or channel that opens to a diameter of about *6.5* A when agonists bind to each of the c-subunits. Occupation of both sites is necessary for receptor activation. Sites within the channel bind noncompetitive inhibitors such as local anesthetics. The sequence of the different subunits includes a long extracellular amino end of approximately 200 amino acid residues followed by four membrane-spanning regions connected by intracellular and extracellular peptide loops. A short car boxy-terminal end follows. The subunits of *Torpedo* electroplax nicotinic ACh receptors have 495 to 5I2 amino acid residues each. Each of the membrane-spanning regions has 19 to 27 amino acid residues. The long cytoplasmic loop between the third and fourth membrane-spanning regions is about 150 residues long. This type of structure is typical of inotropic ncurotransmitter-gate receptors. Because of the hydrophobic! ty of the membrane-spa lining regions, it seems likely that the organization of the residues is in *a* helical or 0-pleated sheet formations. The different subunits have about 30-40% identity of their amino acid residues. The agonist-binding site is included in the extracellular amino terminal segment, and mutations in this portion of the a-subunits cause changes in the binding of ACh,

Lophotoxin, a diterpenoid plant toxin, competitively blocks the binding of ACh at residues 190 to 192 of the a-subunit. Serine residues in the *fi-* and y-subunits and in the second membrane-spanning region bind the noncompetitive inhibitors chlorpromazine and tetraphenylphosphonium. tr-Toxins from snake venom, including «-bungaiotoxin, bind to extensive regions of the *a-* subunit. Hcxamcthonium and decamethonium produce a voltage-dependent block of recombinant neuromuscular

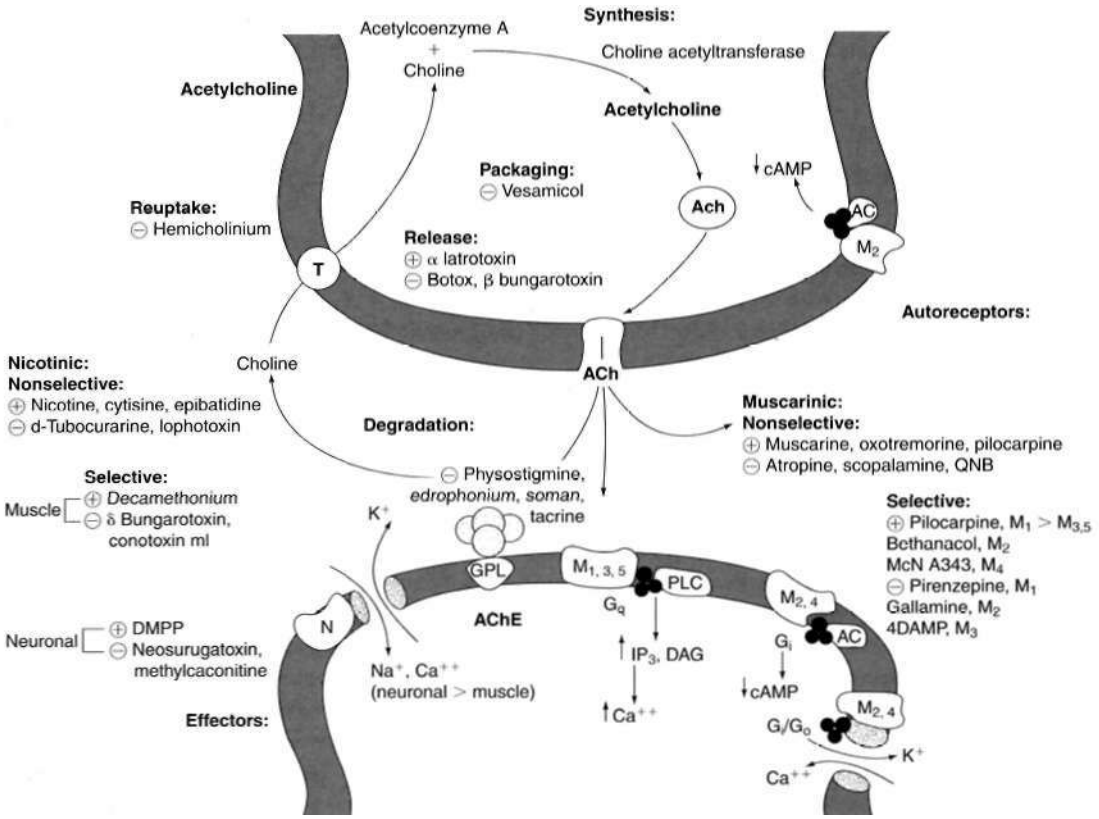

FIGURE 49.4 I'harniacologyofccntralacctylcholincfAt^hJreceptors.Therearenoclinicallyusediiihihirorsof AChsyntliesis.Thepackagingof ACh into presynaptic vesicles can be reduced experimentally hy vesamicol. Release of ACh is enhanced hy or-latrotoxin and inhibited by botulinum toxin (Botox) and /J-bungarotoxm. Release is also modulated hy presynaptic autoreceptors. The G protein-linked M> muscarinic receptor decreases cyclic adenosine monophosphate (cAMP) production presynaptically and indirectly decreases neurotransmitter release, presumably by decreasing activation by phosphorylation of calcium-dependent calmodulin. Released ACh diffuses across the synaptic cleft and activates both nicotinic and muscarinic receptors in the CNS. Nicotinic receptors are ionotropic, and activation results in admission of sodium and exit of potassium through the channel. Muscarinic receptors are metahotropic. Muscarinic M_h M_5, and M_5 receptors are linked by Gq to phospholipase C. Activation of these receptors results in increased intracellular calcium due to the production of inositol Triphosphate (IP.i) as the intracellular second messenger. Muscarinic M_z and M_4 are linked to adenylyl cyclase hy the inhibitory G protein Gj. The result is decreased intracellular cAMP, Some postsynaptic M; and M^ receptors arc linked by G proteins directly to ion channels, which allow entry of calcium and exit of potassium. The action of ACh at its postsynaptic receptors is terminated principally by degradation. Acetylcholinesterase (AChE) in the postsynaptic membrane results in the release of choline, which is rescqucstcrcd by a specific transporter (T) in the presynaptic membrane and is then resynthesized into ACh for subsequent release. Agonists (+) and antagonists (-) have been identified for many of these specific receptors and processes,

nicotinic-cholinergic receptors suggesting that they enter the channel. Other toxins bind at different sites. Neosurugatoxin selectively blocks ganglionic nicotinic receptors, and lophotoxin blocks ganglionic and neuromuscular nicotinic receptors. The marine cr-conotoxins, G1A and M1, potently block neuromuscular transmission but not ganglionic nicotinic activity. This differential binding suggesrs that the ganglionic nicotinic receptors differ in subunit composition from the neuromuscular receptor.

Neuronal Nicotinic Receptors

Neuronal nicotinic receptors are inotropic receptors. Ten or more receptor subunit genes have been cloned. Functional ACh-gated channels arc expressed in frog oocytes injected with mRNAs for *a*- and ,6-receptor subunits in combination or when cell lines are transfected with cDNAs for both *u*- and /I receptor subunits.

Central nicotinic neuronal receptors have been mapped using *in situ* hybridization methods. The «2-subunit is widely distributed. Different brain regions contain variable electrophysiological and pharmacological properties of receptors containing a2-subunits in combination with several other subunits.

Neuronal Muscarinic Receptors

Muscarinic receptors are metahotropic receptors. Five receptors belonging to the family of G protein-associated receptors have been isolated. Agonists bind in a deep

pocket formed by the seven transmembrane regions. Variations in the long third intracellular loop result not only in differences in the binding to G proteins, but also in the effects of antagonists, as shown by site-directed mutagenesis. This technique introduces mutations of one or a few amino acids that alter receptor function. Selectivity of antagonists for cloned receptors parallels pharmacologically defined receptor activity in naturally occurring, intact systems. For example, pirenzepine selectively blocks both cloned and naturally occurring Ml receptors and AFDX-116 preferentially blocks M2 receptors.

Muscarinic receptor types M1, M3, and M5 couple to members of the Gq family of G proteins. In turn, the G protein activated by ligand binding to the receptor activates phospholipase C. This results in phospholipid hydrolysis that liberates two intracellular second messengers, IP3 and diacylglyccrol (DAG). Each of these intracellular second messengers has unique effects, as described previously. The IP3 releases intracellular calcium stores and can be involved in cascades of cellular injury. DAG activates protein kinase C, which phosphorylates several receptors and alters their conductance states. Receptors of the M2 and M4 type couple to the a-subunit of the inhibitory Gi protein that inhibits adenylyl cyclase and reduces intracellular cAMP levels. Alternatively, these two receptors can couple to certain ion channels directly by either of the GTP-binding proteins, Gi or Go. Muscarinic receptor subtypes are differentially distributed in the brain. The hippocampus is virtually devoid of the M2-type receptor, but the other four types are expressed to varying degrees, with Ml having the densest expression. ACh induces a pirenzepine-insensitive hyperpolarization in the thalamus where the M2 receptor is significantly expressed. The hyperpolarization appears to result directly from increased potassium conductance secondary to receptor activation coupled to Gi. Thus physiologically and pharmacologically defined regional effects of ACh parallel expression of genes for various subtypes of muscarinic receptors.

A consideration of long-term regulation of receptor numbers is an important property of muscarinic receptors for designing drugs to treat neurological disorders. Prolonged exposure to ACh or other agonists causes downregulation of muscarinic receptors. The Alzheimer's disease treatment agent, tetrahydroaminoacridine, raises brain ACh levels by weakly inhibiting AChE. Reports of mixed efficacy could in part be due to downregulation of receptors, which opposes the effect of chronically increased ACh levels. Protein kinase activation can mimic the effects of prolonged exposure to agonists. Presumably, phosphorylation reduces affinity of the receptor for agonists, and dephosphorylation, by unknown phosphorylases, results in resensitization or availability of the receptors. Phosphorylation-dcpendent desensitization may be a common mode of regulation of G protein-coupled receptors. Control of this process could provide therapeutic agents designed to modulate receptor numbers in specific brain regions.

Acetylcholine Receptors in Disease States

The treatment of several clinical disorders uses cholinergic agents (Table 49.4). A number of important clinical disorders involve muscarinic cholinergic neurotransmission. Reduction of cholinergic neurons and capacity to synthesize ACh occurs with normal aging. However, premature degeneration of cholinergic neurons occurs in Alzheimer's disease. Excitotoxic injury to cholinergic neurons plays a role in Parkinson's and Huntington's diseases. Experimental models also implicate ACh in the pathophysiology of human epilepsy. Reduced ACh synthesis occurs in some inherited disorders of mitochondrial enzymes and thiamine-dependent pyruvate dehydrogenase (the enzyme that catalyzes the oxidation of pyruvate to acetyl Co-A). Affected patients have mental retardation, spasticity, ataxia, and dystonia. The symptom diversity emphasizes the multiple functions subserved by cholinergic neurotransmission. Medications that block muscarinic receptors are used to treat vertigo, motion sickness, and diarrhea. ACh triggers the pontogeniculooccipital (PGO) spikes at the onset of rapid eye movement (REM) sleep and anticholinergic medications have sleep-inducing properties. Smoking is an example of addiction resulting from habitual use of nicotine. Myasthenia gravis is an important clinical problem involving nicotinic receptors. Intoxications with pesticides, nerve agents, and bacterial toxins (e.g., botulinum toxin) affect cholinergic receptors centrally and peripherally. No discussion of cholinergic mechanisms would be complete without mentioning the mydriatic effect of belladonna *(Atropa belladonna),* once used as a cosmetic and later as a poison.

A mutation in the gene encoding the c4 nicotinic cholinergic receptor has been associated with autosomal dominant nocturnal frontal lobe epilepsy {see Table 49.2). Ongoing genetic research is examining the role of polymorphisms in AChR-associated genes in susceptibility to Alzheimer's disease

DOPAMINE

The role of dopamine in neurological disease initially received attention in 1957 with the demonstration that reserpine depletes the brain and heart of NE and dopamine. Dihydroxyphcnylalaninc (DOPA), a precursor of catecholamine synthesis, restores dopamine levels and reverses the sedative action of reserpine. During the 1960s, the formaldehyde fluorescence technique allowed the visualization of monoamines, including dopamine. Reports of low dopamine concentrations in the basal ganglia of patients with Parkinson's disease led to the discovery that increasing doses of L-dopa relieved the symptoms of parkinsonism. Optimizing dopaminergic neurotransmission remains central to the treatment of Parkinson's disease (see Chapter 78).

Table 49.4: Acetylcholine in disease states

Disorder	*Pathophysiology*	*Trail men t*
Nicotinic receptors		
1. Smoking	Habituation, associated behaviors	Slow taper and discontinuation
2. Myasthenia gravis	Antibodies against postsynaptic receptors at neuromuscular junction	AChE inhibitors + muscarinic antagonists
3. Myasthenic syndrome	Antibodies against presynaptic calcium channels reduce A eh release	Guanidine; amino pyridines sensitize netve terminals to Ca^{2+}; AChE' inhibitors
4. Botulism	Ingested toxin decreases Ach release	Guanidine or aminopyridiues; pyridostigmine; antitoxin
i. Snake bite (krait)	c-Bungarotoxin decreases Ach release; /f-Rungarotoxin blocks NAChR	Antivenin; good luck
6'. Pain	ACh released by acupuncture in adrenergic locus ceruleus and serotonergic dorsal raphe	Nicotine (old war movies); nicotinic agonists(dimethylphenylpiperazine)
Muscarinic receptors		
1. Aging	Decreased CAT and AChE accompany cognitive decline	No known preventative treatment
2. Alzheimer's disease	Excessive and premature loss of cholinergic neurons (n. basalts of Meynert)	Tacrine and doncpezil slow course
.5. Parkinson's disease	Excessive cholinergic activity in basal ganglia with loss of dopaminergic innervation	Muscarinic antagonists (trihexyphenidyl); tricyclic antidepressants
4. Huntington's disease	Decreased (. .AT in striatum	Muscarinic antagonist for some abnormal movements
5. Epilepsy	Seizures produced in animals by pilocarpine Seizures in man/anitnals by nerve agents (AChE inhibitors)	Anticonvulsants; benzodiazepines; memantine
6. AChE inhibitor intoxication	Nerve agents and pesticides produce-deadly seizures	Muscarinic anticholinergics; anticonvulsants
7. Pain	Spinal cord (posterior horn) and midbrain circuits involved in pain neu retransmission; Acupuncture releases ACh and opioids	Tricyclic antidepressants; acupuncture
8, Sleep	ACh triggers PGO spike at onset of REM Insomnia and narcolepsy increase REM	Antimuscarinic tricyclic aillidcpres^inK
9. Mitochondropathies	Decreased ACh synthesis (decreased acetyl Co-A synthesis due to low activity of thiamine-dependent pyruvate dehydrogenase and other enzymes)	No effective treatment
10. Vertigo/motion and space sickness	Vestibular ± vestibulocerebellar dysfunction	Antihistamines (meclizine}, tricyclic antidepressants, and phenorhiazines with anticholinergic action Antimuscarimcs (scopolamine + dcxedrine)

ACh = acetylcholine; AChE = acetylcholinesterase; CAT = choline acetyl transferase; REM = rapid eye movement.

Chemistry, Pharmacology, and Distribution

The catecholamines' (dopamine, NE, and epinephrine) synthesis from L-tyrosine is by a cascade of enzymes. Immiino-eytochemical and *in situ* hybridization techniques have allowed these enzymes to be purified to homogeneity, cloned, and localized in the CNS. Phenylalanine forms tyrosine, which is actively transported across the blood-brain barrier. The enzyme phenylalanine hydroxylase catalyzes the conversion. Deficiency of this enzyme is responsible for the classic form of phenylketonuria (see Chapter 71). Tyrosine hydroxylase catalyzes an alternate pathway in the synthesis of tyrosine from phenylalanine. Tyrosine hydroxylase is a cytoplasmic mixed-function oxidase that requires retra-hydrobiopterin and oxygen as cofactots.

Tyrosine hydroxylase catalyzes the conversion of L-tyrosine to L-dopa, and dopa decarboxylase, a pyridoxal phosphate-dependent enzyme (also known as aromatic acid decarboxylase), converts [,-dopa to dopamine. This lattet reaction is the target of oral precursor treatment with L-dopa in the treatment of Parkinson's disease. Dopa decarboxylase is present in the cytoplasm of catecholaminergic and serotonergic nerve terminals; this enzymatic step is intermediate in the synthesis of the other monoamines.

Dopamine is transported into storage vesicles for later release as a neurotransmitter. Amine transporters similar to drug resistance transporters of bacteria have been cloned; they characteristically have twelve transmembrane domains. The uptake of monoamines into storage vesicles is ATP-depcndent and linked to a proton pump. In the vesicles, the catechols form complexes with ATP and acidic proteins called chromogranins. Monoamine oxidase (MAO) deaminates free dopamine inside nerve terminals, Drugs that interfere with vesicular storage, such as

amphetamines or reserpinc, displace dopamine into the cytoplasm, where it is inactivated. Catechol-o-methyl transferase (COMT) breaks down dopamine that has diffused into the extracellular space.

The basal ganglia contain about 80% of total brain dopamine. Dopaminergic neurons in the ventral tegmental tract send fiber bundles to the nucleus acumbens (the mesolimbic tract) and to the cerebral cortex (the mcsocor-t:;,)l h.iiui\' . I I:HT-, also I'MLTIII from [IK- arcuate nucleus ro the median eminence. The mesolimbic projection ascends in the medial forebrain bundle. The further distribution of these fibers is to telencephalic structures including the olfactory bulb, olfactory nucleus and tubercle, lateral septal nucleus, stria terminalis, and parts of the hippocampus and amygdala. This branch also innervates the mesial frontal, anterior cingulatc, pyriform, and entorhinal cortices. The mesocortical projections terminate predominantly in the frontal (especially prefrontal) neocortex. Scattered groups of dopaminergic neurons are also present in the retina and spinal cord,

Dopamine Receptors

Dl and D2 arc the two families of dopamine receptors. Their different effects on adenylate cyclase originally separated these two families. DJ receptor activation augmented enzyme activity and D2 receptor activation decreases activity. Both families are linked to G proteins and have the predicted structure of seven transmembrane domains. The major difference between the two families of dopamine receptors is the sequence of the third intracyto-plasmic loop, which governs G protein binding.

The Dl family consists of two receptors, Dl and D5, which couple to the <y-siibunit of the stimulatory G protein, Gs. Gs activates adenylate cyclase directly and increases cAMP production from ATP. The mRNA for Dl is located primarily in the caudate, putamen, nucleus accumbens, and olfactory tubercle. The mRNA for D5 is primarily located in the hippocampus and hypothalamus.

The D2 family consists of four receptors (D2S, D2L, D3, and D4) linked to inhibitory G protein, or Gi. Activation of the receptors decreases the concentration of cAMP, The D2 receptor exists in two forms that arise from alternative splicing. They are expressed predominantly in the caudate, nucleus accumbens, putamen, and olfactory tubercle. The D3 receptors are highly expressed in the striatum and in the limbic areas. The D4 receptor is present in the frontal cortex, midbrain, amygdala, and medulla and to a lesser extent, basal ganglia, D3 and D4 receptors share a high affinity for atypical neuroleptics Such as clozapine. Atypical neuroleptics produce fewer extrapyramidal side effects than typical phenothiazine or butyrophenone neuroleptics that block D2 receptors. The relative antipsychotic efficacy of the atypical compound may be due to antagonism of the D3, D4, and D5 types of receptors in limbic structures and the cortex, whereas blockade of D2 receptors in the striatum may cause parkinsonian symptoms. This raises the hope that chronic-use of neuroleptics and antipsychotics need not result in tardive dyskinesia.

Pharmacology

Many aspects of dopaminergic neurotransmission are modifiable for clinical therapeutic advantage (Figure 49.5). Dopamine is released when nerve terminals are depolarized by the arrival of action potentials that open voltage-dependent calcium channels. The entry of calcium promotes the fusion of vesicles with the synaptic membrane and the release of soluble contents of the granules. Several classes of drugs alter the amount of catecholamines that are released, Reserpinc profoundly depletes dopamine and NE by initially augmenting their release, then irreversibly inhibiting their reuptake into storage vesicles. Both reserpine and guanethidine effectively reduce packaging. The depletion of catecholamines in animals is used as a model of parkinsonism,

Catecholamine transporters are not specific; they also transport tryptamine, tyramine, and amphetamines. Tyramine and amphetamines displace the catecholamines from their storage vesicles and cause depiction of the terminal and leakage of catecholamines from the nerve terminals. The initial result is an indirect increase of dopamine- and NE-mediated neurotransmission, but depletion may follow if drug exposure is chronic. The action of dopamine is terminated by reuptake or enzymatic degradation. An energy-dependent sodium exchanger mediates the uptake process. Blockers of Na-K-ATPase (e.g., cardiac glycosides), tricyclic antidepressants, cocaine, and amphetamines inhibit the sodium exchanger.

Enzymatic degradation is mediated by MAO and COMT. The two isoenzymes of MAO are types A and B. Type A is potently blocked experimentally by clorgyline and preferentially cataholizes 1ME and serotonin; type B is blocked by selegiline (deprcnyl). Type B is located prominently in serotonergic neurons and astrocytes and preferentially deaminates dopamine. Selegiline is metabolized to amphetamine and mcthamphetamine, which may increase alertness and mood elevation in addition to its effects on the movement disorder of Parkinson's disease. The COMT antagonist tolcapone (Ro 40-7592) received Eood and Drug Administration (FDA) approval for the treatment of Parkinson's disease,

Several selective agonists and antagonists, specific for subtypes of dopamine receptors, have been synthesized for investigation. Clinically used ergot derivatives include bromocriptine and pcrgolide. Bromocriptine is a more potent agonist at D2 than Dl and ff-adrencrgic receptors. It has weak antiparkinsonian action alone but has synergistic effects with endogenous dopamine. It is not usually

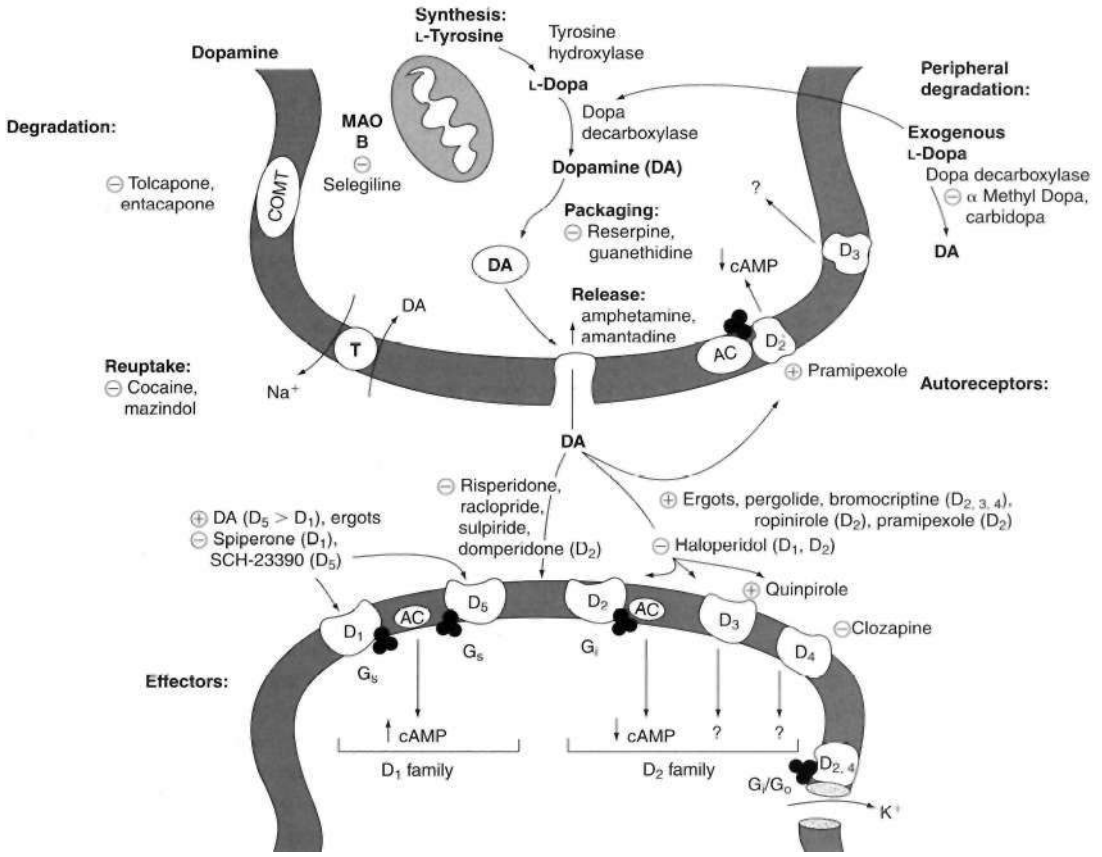

FIGURE 49.5 Pharmacology of dopamine neurotransmission. AC = adeny] cyclase; cAMP = cyclic adenosine monophosphate; COMT catechol O-mcrhyl transferase; MAO = monoamine oxidase; T = transporter (selective for a particular neurotransmitter).

considered an allosteric modulator but acts like one by enhancing the apparent affinity of the receptor or prolonging the binding of dopamine. In contrast, pergoiide is a D2 agonist at low doses and a mixed D2 and Dl antagonist at higher doses. Its presynaptic D2 effect is to decrease dopamine release postsynaptically. It has dopamine-like action and inhibits firing by binding to D2 receptors. Lisuride is a potent D2 agonist with lesser affinity for Dl and serotonin receptors. Side effects typical of antiparkinsonian medications (nightmares, hallucinations, and psychosis) limit its usefulness.

Non-ergot agonists are being developed to circumvent adverse psychiatric effects. The use of the agonist, a pi.) morphine, is limited by its peripheral dopaminergic effects, but it decreases "off-hours" in Parkinson's disease patients when it is administered subcutaneously. Intranasal and sublingual forms have been used safely. The FDA has approved highly potent and selective D2 agonists (ropinirole and pramipexole). Autoreceptors have much higher affinity for agonists than do postsynaptic receptors. Selective auto receptor (presynaptic D2 receptor) antagonists arc also under investigation. Hopefully, the combination of agents may allow normalization of dopaminergic activity without creating dystonia and dyskinesia.

The mechanism of action of amantadine is not established. It slightly improves the symptoms of Parkinson's disease and is best used as an adjunctive agent. Its efficacy decreases over a period of months, but discontinuation may cause worsening of symptoms suggesting partial desensitization. It probably has multiple weak actions that enhance dopamine release. This may be accomplished by displacing dopamine from vesicular storage and blocking reuptake. Other possible mechanisms of action are presynaptic D2 antagonism or allostcric enhancement of dopamine receptor activation. Non-dopaminergic mechanisms of actions of amantadine and memantine include antimuscarinic and NMDA channel-blocking actions. Memantine is also a weak sodium channel blocker with anticonvulsant efficacy in the maximal electroshock model. Selegiline selectively blocks MAO-B and augments dopamine concenttations in the brain.

Clinical Role of Dopamine

Both deficiency and excess of dopamine result in clinical disorders (Table 49.5*)*. Parkinson's disease is the prototypical deficiency state. Gynecomastia occuts when dopaminergic inhibition of prolactin release is removed

Table 49.5: Clinical role of dopamine

Disorder	*Pathophysiology*	*Treatment*
I. Parkinson's disease	Degeneration of dopaminergic neurons	Precursor: l.-dopa Prevent breakdown: MAO-B (selegiline) or COMT (tolcapone) block Receptor agonists: D2 selective (ropinirole, pramipexole); mixed (bromocriptine, pergolide, lisuride)
2. Psychosis	Excessive activity in dopaminergic pathways Increased expression of D2 receptors (human brain post mortem)	Receptor antagonists: D3,4 selective (clozapine); mixed (haloperidol; Thorazine)
3. Epilepsy	Facilitari'S kindling in experimental models Neuroleptics lower seizure threshold	None known Discontintic neuroleptics
Gynecomastia	Removal of dopamine inhibition of prolactin release	Bromocriptine
Spasticity	Dorsal horn circuitry	l.-dopa
Tardive dyskinesia (TD)	Prolonged use of neuroleptics (D2 antagonists) Clozapine/olanzapine {D3,4 antagonists) do not produce TD	Minimize duration of neuroleptic use when possible Use clozapine/olanzapine instead of D2 antagonists

COMT = Catechol-o-methyl transferase; MAO = monoamine oxidase.

pharmacologically (e.g., by antipsychotic medications) or by tumors affecting connections of the hypothalamus to the pituitary. The fatigability in patients with multiple sclerosis can be treated with dopaminomimetic drugs.

Mutations in dopamine receptor, tyrosine hydroxylase, and dopamine transporter genes have been implicated in increasing predisposition to movement disorders and schizophrenia (see Table 49.2). Also, mutations in transcription factors may predispose to movement disorders by decreasing the number of dopaminergic neurons produced during neurogenesis (see Table 49.2). The identification of candidate genes for various movement disorders is still in progress.

NOREPINEPHRINE AND EPINEPHRINE

NE and epinephrine were among the first CNS neurotransmitters characterized and visualized with fluorescence techniques. Disturbances of adrenergic neurotransmission occur in the Shy-Drager syndrome (multiple system atrophy) and probably in depression; yet our understanding of these two catecholamines is incomplete. They serve important roles in the regulation of blood volume and blood-pressure control. NE is also important in sleep-wake cycles and epileptogenesis.

Chemistry and Distribution

The adtencfgic neurons of the locus ceruleus, pons, and medulla project to virtually every area of the brain and spinal cord. These neurons contain tyrosine hydroxylase and dopa decarboxylase, to make dopamine. They also contain dopamine /(-hydroxylase (like tyrosine hydroxylase, a mixed-function oxidase), which catalyzes the conversion of dopamine to NE. This enzyme requires copper as a cofactor, and chelators such as diethyldithiocarbamate produce inhibition. Dopamine /J-hydroxylase is bound to the inner membrane of synaptic vesicles and released with NE in a tetrameric glycoprotein.

A small number of neurons in the medulla contain phenylethanolamine-N-methyl transferase (PNMT), an enzyme rh.it converts NE to epinephrine with S-adenosyl methionine as a methyl donor. These neurons project to the thalamus, brainstem, and spinal cord. The concentration of cpincphrinc-sccrcting terminals in the paraventricular nucleus suggests a role in the secretion of oxytocin and vasopressin. This, coupled with the dense innervation in the region of the dorsal motor nucleus of the vagus and nucleus solitarius, suggests a role in regulating cardiovascular and respiratory reflexes. A thitd projection synapses on the sympathetic intermedioventral nucleus of the spinal cord. Physiological experiments demonstrate a vasopressor area in the rostral medulla corresponding to the epinephrine-contaimng cell group. In addition, PNMT is overcxprcsscd in spontaneously hypertensive rats.

Circulating adrenocorticotropic hormone (ACTH) links the hypothalamie-pituitary axis to adrenal secretion of epinephrine. Corticosteroids, released from the adrenal cortex, regulate the synthesis of cpincphrine-synthesizing chromaffin cells in the adrenal medulla. This circuit integrates and controls salt and water metabolism, blood volume, and blood pressure. Central epinephrine pathways appear to contribute to these vitally important functions.

Norepinephrine and Epinephrine Receptors

NT, and epinephrine act at *a*- and /i-receptors in the brain and periphery. Four receptors are present in the brain: ccl-, *a2-*, *01-*, and 02-receptors, *jil*-Adrenergic receptors are predominantly in the heart and cerebral cortex, whereas

^2-receptors are principally found in the lung and cerebellum.

The known types of adrenergic receptors are members of the G protein superfamily. As such, they are believed to have seven transmembranc-spanning hydrophobic regions of 20 to 25 amino acids each, a long C terminal hydrophilic section that contains sites for phosphorylation, a shorter extracellular N terminal end that contains glycosylated residues, and a long third intracellular loop that interacts with G proteins. Sequence homology among /Jl- and *fll*-receptors is about 71%, The sequence diffctcnccs probably account for differences in agonist preference (/31-receptors equally prefer epinephrine and NE as agonists and practolol as an antagonist; ^2-receptors prefer epinephrine over NE, and terbutaline or salbutamol as an agonist). The catecholamine binding site is thought to be a pocket formed by the helical transmembrane regions. Agonist binding to both *fil*- and *02*- receptors activates the stimulatory protein Gs to increase cellular cAMP concentrations. Activation of jS-rcceptors results in coactivation of *fi*-adrenergic receptor kinase (BARK). This kinase phosphorylates the C terminus of the ^-receptor and ^-arrestin complexes with the receptor to decrease its affinity for Gs. Phosphorylation is a prominent mechanism of receptor desensitization. Other transcriptional, post-transcriptional, and post-translational regulations control the number of receptors.

Two families of a-adrenergic receptors are identified that are also G protein linked. The *otl*- and «2-receptor families have approximately 40% sequence homology with the *fil*-receptor. The o/1-group of receptors are linked by Gs to phospholipase C. Activation of phospholipasc C generates IP3 and DAG from membrane phospholipids. The [P3 triggers release of intracellular calcium, and DAG activates protein kinase C, which is then available for phosphorylation of membrane proteins. The of2-family is coupled to the inhibitory protein G; to decrease the cellular cAMP concentration.

Physiology and Pharmacology of Central Adrenergic Receptors

Several pharmacological agents allow clinical manipulation of adrenergic mechanisms at multiple levels {Figure 49.6). NE increases firing in hippocampal pyramidal neurons by blocking the slow after-hyperpolaming potential that follows a depolarizing burst. The principal current underlying this potential is a calcium-activated potassium current

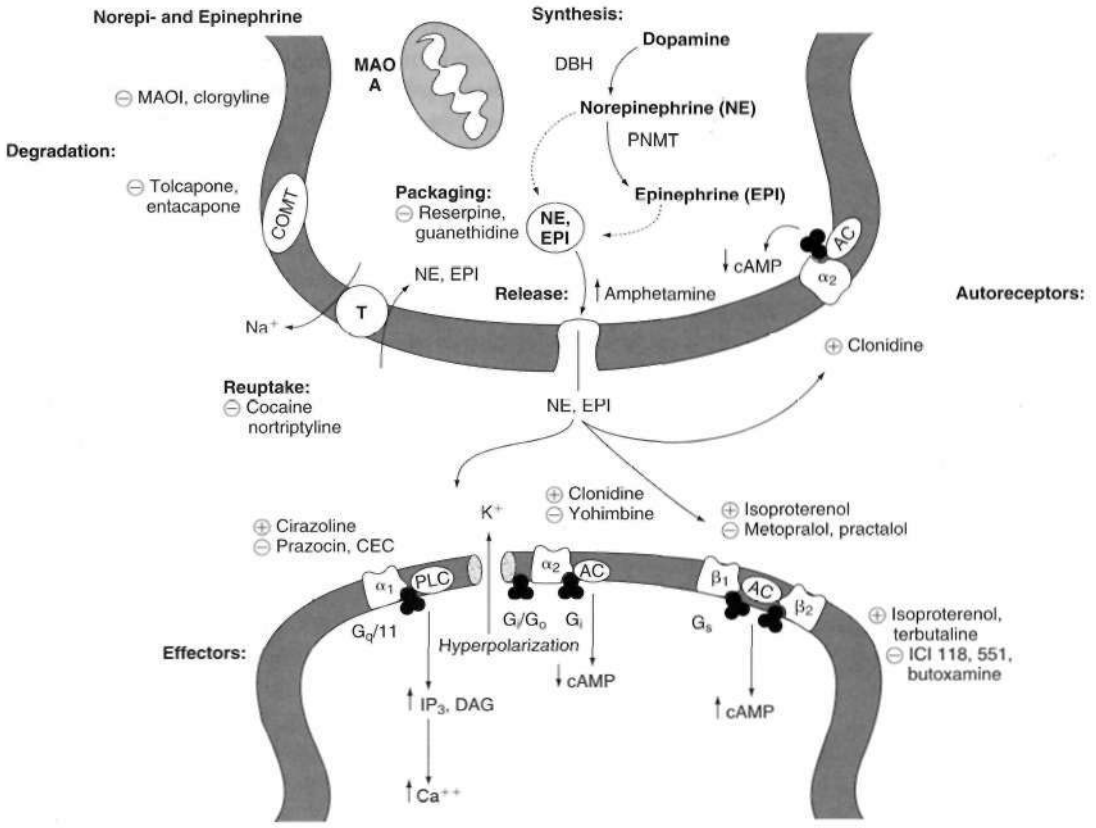

FIGURE 49.6 Pharmacology of catecholamine neurotransmission. AC = adenyl cyclase; cAMP = cyclic adenosine monophosphate; CEC = chlorocdiyk'lonidine; i)BH dopamine beta hydroxylase; ICI = manufacturer's abbreviation MAO = monoamine oxidase; MAOI = monoamine oxidase inhibitor; PLC = phospholipase C; PNMT = phcnylethaiiolaminc N-methyltransferase; T = transporter (selective for a particular neurotransmitter).

that is activated hy membrane depolarization. This effect of NE is blocked by *ji*\-selective antagonists but not by *fi2*-selective compounds or antagonists at ar-receptors, Isoproterenol is the most potent agonist in this regard, followed by epinephrine and NE; phenylephrine (al-agonist) and clonidine («2-agonist) are ineffective. NE also blocks afterhype rpolarization s in thalamic and preganglionic sympathetic neurons, although the receptor type has not been determined. In sympathetic neurons, NE abbreviates and decreases the amplitude of calcium spikes. Importantly, the action of NE is mimicked by cAMP analogues and forskolin, an activator of adenylate cyclase, and by blocking phosphodiesterase activity with methyl xanthines. The effect of NE is decreased by blocking adenylate cyclase. In addition, ^-receptor activation and cAMP analogues enhance calcium currents in dentate granule cells, similarly to the ^-adrenergic effect on the heart.

Excitatory effects of NE in various parts of the CNS and in sympathetic ganglion neurons result from al-receprors activation. This activity depends primarily on blockade of a resting potassium conductance. As a result, neurons depolarize, and firing rates increase. Inhibitory effects of NE result from or2-receptor activation, which increases potassium conductance. This hypcrpolarises the neuron and decreases its firing rates. NE acting at *oil* -receptors also blocks calcium current, an effect prevented by pertussis toxin, suggesting the involvement of a GTP-binding protein. Both of these inhibitory mechanisms may account for the auto receptor function of «2-receprors, which decrease neurotransmitter release.

Clinical Role of Adrenergic Receptors

Adrenergic innervation is involved in regulation of the cardiovascular system behavior and appetite. The Shy-Drager syndrome results from degeneration of adrenergic neurons. Depression involves adrenergic deficiency, whereas excessive adrenergic activity contributes to mania and intoxication with nonmedicinal drugs, such as cocaine. The inhibitory influence of *al*-agents (clonidine, tizanidine) is useful for treating spasticity and may have adjunctive utility for treating pain, epilepsy, and possibly sleep disorders. Table 49.6 summarizes these applications. Clinical dysautonomic disorders have been linked to mutations and/or polymorphisms in genes encoding dopamine-s-hydroxylase and the NE transporter (see Table 49.2).

SEROTONIN

In the mid-nineteenth century, a potent vasoconstrictive substance was identified in the serum of clotted blood and named vasotonin. It was almost 100 years later that 5-hydroxytryptaminc (serotonin) was isolated and synthesized. More than 95% of the body's serotonin is srorcd in platelets and the gastroinrestinal tract, and only 5% is in the brain. However, serotonin is distributed in brain regions that could affect behavior, especially the hypothalamus and the limbic system. It meets all criteria for being a neurotransmitter.

Chemistry and Distribution

The indole amino acid tryptophan is the precursor of serotonin. Tryptophan is derived from dietary protein and is transported with other neutral amino acids (including leucine, phenylalanine, and methionine) by the L-amino acid transport mechanism into the brain. Interestingly, gabapcntin, an antiepileptic drug, has an amino acid-like structure and is transported by this energy-dependent active transport mechanism. Tryptophan is metabolized to 5-hydroxytryptophan in serotonergic neurons through the action of tryptophan hydroxylase, a pteridine-recjuiring enzyme. Complementary DNAs that encode tryptophan hydroxylase have been cloned and sequenced. The enzyme contains 444 amino acids corresponding to a molecular weight of about 51 kD and is 50% homologous with tyrosine hydroxylase, the rate-limiting enzyme in catecholamine biosynthesis.

Next, 5-hydroxytryptophan is converted to serotonin through the action of L-aromatic amino acid decarboxylase. This enzyme is also present in catecholaminergic neurons, where it converts dopa to dopamine. The decarboxylase has also been sequenced. It contains 480 amino acids and has a molecular weight of 54 kD. *In situ* hybridization of its mRNA shows that the decarboxylase is present in serotonergic cells of the dorsal raphe and dopaminergic neurons in the midbrain. Raising the dietary intake of both tryptophan and 5-hydroxytryptophan increases brain serotonin levels, a strategy used in the treatment of postanoxic myoclonus with some success. Since the removal of commercial preparations of L-tryptophan from the market in 1992 because of a contaminant that caused the eosinophilia-myalgia syndrome, brewer's yeast has become an important source of L-tryptophan.

Hydroxylation of tryptophan by tryptophan hydroxylase is the rate-limiting step. Tyrosine hydroxylase is irreversibly inhibited by parachlorophenylalaninc (PCPA), which causes a long-lasting reduction of serotonin levels. PCPA is used often in experimental models designed to study the effects of brain serotonin depletion.

Fluorescence techniques localize nine groups of serotonergic neurons in the brainstem, primarily in the raphe nuclei. Serotonin-containing nerve terminals are widely distributed throughout the forebrain. Projections from the dorsal raphe, median raphe, and a pontomesencephalic cell group ascend through the dorsal paraventricular and ventral tegmental radiations to join the medial forebrain bundle, where they ascend with dopaminergic fibers. Axons of neurons in the caudal pons and

medulla project within the brainstem and down the spinal cord.

Neurons in the median raphe innervate limbic structures such as the hippocampus and septum, whereas neurons in the dorsal raphe are the principal innervation of the striatum and substantia nigra. Both neural groups send projections widely throughout the neocortex. Toxic amphetamine derivatives, such as 3,4-mcthylene dioxymethamphetamine (known in the illegal drug trade as "ecstasy") or p-chloroamphetamine, preferentially destroy dorsal raphe neurons more than median raphe neurons.

The synthesis of serotonin, like other monoamine neurotransmitters, is linked to neuronal activity. Invasion of the nerve terminal by action potentials firing at high frequency increases intraterminal calcium, the activation of calcium-dependent phosphorylating enzymes (e.g., calmodulin), and phosphorylation of tryptophan hydroxylase.

Serotonin is taken up into storage vesicles in nerve terminals by a specific transporter. In the vesicles, serotonin is bound to a specific binding protein without ATP. Rcscrpine and tetrabenazine inhibit the transporter and deplete the vesicles of serotonin. These agents also deplete catechol-containing vesicles. The transmitter-containing vesicles are released by exocytosis after depolarization of the terminals and entry of calcium.

Serotonergic terminals are associated with specialized postsynaptic regions in many parts of the brain, but they lack postsynaptic specializations in some areas where varicosities seem to run en passant. This is especially true of the dorsal raphe projections to the basal ganglia, where the release of serotonin is diffusely into the interspace, much as the release of neurotransmitters into the interspace of the heart. This type of telease allows a diffuse modulatory effect rather than the specific influence dictated by point-to-point synaptic contacts. Released serotonin diffuses to presynaptic (autoreceptors) and postsynaptic receptors, and a specific presynaptic reuptake system terminates its effects. The transporter is present on serotonergic neurons and glial cells. About 50% sequence homology exists between this and the transporters for catecholamines. Different systems express different functional recombinant transporters. Antidepressant drugs, such as the serotonin selective uptake blockers fluoxetine and sertraline, inhibit the cloned transporter.

The other mechanism for termination of serotonin action iscatabolism by MAO. Serotonergic neurons contain predominantly MAO-B, although MAO-A prefers serotonin as a substrate. The presence of MAO-B may prevent serotonergic neurons from accumulating catecholamines.

Serotonin Receptors

Seven subtypes of serotonin receptors have been identified in the brain. All seven were subsequently cloned, sequenced, and characterized. 5-HTl, 5-HT2, and 5-HT4 subtypes are coupled to G proteins and modulate one or more second messenger systems. The 5-HT3 subtype is a ligand-gated ion channel. Physiological roles of the other types is less well understood. Pharmacology of cloned receptors correlates well with that determined by receptor binding techniques (Figure 49.7}.

The 5-HTl family consists of four receptor subtypes, 1A to ID. In the hippocampus and raphe nuclei, 5-HT1A receptors open potassium channels and cause hyperpolarization by a G protein-coupled interaction. 5-HT1A receptors both increase and decrease cAMP formation by G protein-coupled effects on adenylyl cyclase. Buspirone, a novel anxiolytic compound, is a partial agonist at 5-HT1A receptors. The exertion of its effect may be by the hyperpolarizing action of serotonin on these receptors. Excitation by serotonin could result from blockade of a resting or leak potassium conductance, or from the calcium-dependent potassium conductance underlying the slow after-hyperpolarization.

5-HT1B and 5-HT1D receptors inhibit adenylate cyclase and decrease cAMP. The densest expression of these receptor subtypes is in the substantia nigra. 5-HT1C receptors and 5-HT2 receptors stimulate the production of IP3 through a phospholipasc C-linked pathway. 5-HT2 receptors also close potassium channels through a G protein-coupled mechanism that results in a slow depolarization.

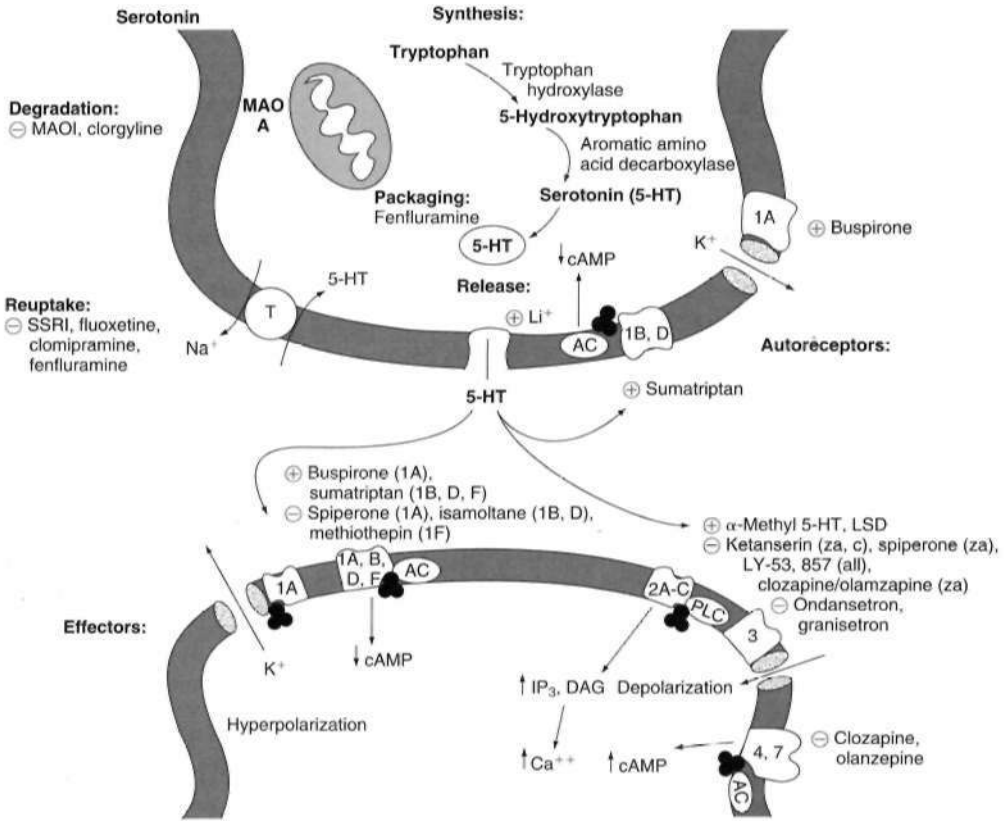

FIGURE 49.7 Pharmacology of serotonin neurotransmission. AC = adenyl cyclase; cAMP = cyclic adenosine monophosphate; DAG = diacylgrycerol; LSD = lysergic acid diethylamide; LY = Lilly Pharmaceuticals; MAO = monoamine oxidase; MAOI = monoamine oxidase inhibitor; SSRI = selective serotonin reuptake inhibitors; T = transporter (selective for a particular neurotransmitter).

5-HT1B and **5-HT1D** receptors probably subserve the autoreceptor function of presynaptic serotonergic receptors; both are highly expressed in the basal ganglia. These subtypes may be involved in the pathophysiology of some movement disorders.

5-HT1C receptors, which are enriched in choroid plexus epithelial cells, may regulate the composition and volume of cerebrospinal fluid **(CSF).** Effects on mood and behavior may be mediated through 5-HT1C receptors in limbic structures. Expression of 5HT1C receptors in the basal ganglia suggests a possible role in motor behavior as well. A fifth subtype (5-HT1P) is found in the gastrointestinal tract and produces a slow depolarization of some myenteric plexus neurons.

5-HT2 receptors are highly expressed in various regions, including the cortex, limbic system, and basal ganglia. In the cortex, they are thought to he postsynaptic receptors on intrinsic neurons, because disruption of projection paths docs not influence the receptor density, as determined hy radioligand techniques.

The 5-HT3 receptor docs not belong to the G protein superfamily but is a ligand-gated ion channel. The depolarization caused by activation of this channel produces a fast excitatory potential. The 5-HT3 receptor subtype is most abundant in peripheral ganglia and nerves and in the substantia gelatinosa of the dorsal horn of the spinal cord. This suggests a role in the modulation of pain neurotransmission (see Chapter 52). 5-HT3 receptor antagonists, such as ondansetron and granisetron, are antiemetic. This effect corresponds to a high density of 5-HT3 receptors in the area postrema, the site of the chemoreccptor trigger zone.

The 5-HT4 receptor is coupled to adenylate cyclase and is associated with inhibition of potassium current in collicular neurons and the hippocampus. Receptor activation presumably increases cAVll', which then activates protein kinase A. The resultant phosphorylation inhibits the channel. The absence of selective antagonists makes it difficult to study the function of 5-HT4 receptors. Additional cloned serotonin receptors include 5-HT5A **and** -B, 5-HT6, and 5-HT7. These receptors are called "orphans" because their function remains unclear.

Long-term regulation of the serotonin receptors varies with receptor type and circumstances. As expected, 5-HT1 receptors downregulate when chronically exposed to mianserin, a receptor antagonist. Contrary to expectation, destruction of serotonergic neurons does not change 5-HT2 receptor density. However, 5-HT2 receptors downregulate and desensitize as expected after administration of hallucinogenic agonists, chronic administration of inhibitors of serotonin uptake, or chronic exposure to 5-HT2 receptor antagonists.

Clinical Role of Serotonin Receptors

Serotonin is an essential modulator of inhibition in the CNS and is involved in a wide variety of important functions and clinical disorders (Table 49.7). It has a prominent role in behavior disorders. It normally functions to promote sleep and is a precursor for the synthesis of melatonin, a regulator of circadian rhythms. Deficiency of serotonin underlies depression and its related sleep disorder. Psychotogenic drugs, such as lysergic acid diethylamide (LSD), bind to 5-HT2 receptors. This serves as a prototype for the pathophysiology of psychosis. Reduction of 51 IT-1 and -2 receptors and neuronal loss in the dorsal raphe in Alzheimer's disease may underlie behavioral changes in that degenerative disorder. The 5HT-1A partial agonist, Buspirone, is useful in the treatment of alcoholism. The role of serotonin in epilepsy is multi faceted. Depletion facilitates kindling epileptogcnesis and prevents the anticonvulsant effect of carbamazepine in the genetically epilepsy prone rats. Blockade of 5HT-2 receptors prevents the anti-convulsant effect of serotonin and tryptophan in experi-mental models. These findings suggest that serotonin may be an endogenous anticonvulsant. Some antidepressants lower seizure threshold, whereas others may be anti-convulsant, perhaps because of multiple mechanisms of action. Serotonin depletion decreases efficacy of opiate-induced analgesia and intrathecal administration of serotonin can produce analgesia by activating 5HT-1 receptors. The activation of 5HT-1D receptors by suma-triptan and its analogues are a standard for migraine therapy. The 5HT-3 agonist, ondansetron, and its analogs are antiemetic. Serotonin 5HT-1C receptors are plentiful in the choroid plexus and antagonists, including ondanse-tron, may help to decrease hydrocephaly. Anoxic injury to

the dorsal raphe results in myoclonus (Lance-Adams syndrome). Treatment with the serotonin precursor tryptophan may be beneficial for some, although some commercial preparations caused allergic reactions.

Mutations and polymorphisms of serotonin receptor genes are implicated in susceptibility to alcoholism, psychoses, and other behavioral disorders (see Table 49.2). Mice without 5-HT2C receptors are hyperalert and have audiogenic seizures. The serotonin transporter gene is under consideration as a candidate gene for bipolar disorder and polymorphism of this gene may predict susceptibility to depression.

PEPTIDES

The role of peptide hormones, such as oxytocin and vasopressin, in pituitary and visceral function indicated the importance of peptides initially. The principal role of peptides as neurotransmitters was discovered first in coelencerates, then in vertebrates. The role of some neuropeptides as cotransmitters and modulators of excitability in vertebrates is of interest in the present discussion for several reasons. First, neuropeptides co-localize with conventional neurotransmitters (Tabic 49.8). Depending on the pattern of firing, peptides may be released in temporal sequence after the conventional transmitters. In turn, the peptides modulate release and postsynaptic efficacy of the principal transmitter. Second, overexpression and underexpression of various peptides have been implicated in a broad array of clinical disorders (Table 49.9). Elucidation of how dysfunction of peptidergic neurotransmission and neuromodulation occurs is a stimulus for the development of novel treatment agents that are antagonists or agonists at peptide receptors. Third, identification of mutations in genes for peptides or peptide receptors is providing insight into pathogenesis of clinical disorders, susceptibility to diseases and adverse effects of drugs, and novel avenues for the development of therapeutic agents (Table 49.10).

Neuropeptides are sequences of 10 to 50 amino acids that are enzymatically cleaved from larger precursor peptides 90 to 500 amino acids in length. Alternate splicing of RNA transcripts results in multiple mRNAs and increases the variety of products of peptide and peptide receptor genes. Synthesis of peptide transmitters and modulators differs from the synthesis of conventional transmitters that takes place locally in nerve endings. After intranuclear transcription, translation of peptide mRNAs takes place in the neuronal somata on ribosomes on the endoplasmic reticulum. Further processing in the Golgi apparatus leads to production of large dense core

Table 49.10: Mutations of peptide receptor genes in relation to disorders in humans and experimental animals

Peptide/receptor	*Mu tation/a Iteration*	*Disorder*	*Comments*
Calcitonin gene-related peptide (CGRP)	*CALCA* gene polymorphisms	One associated with bipolar and unipolar depression, bur nor schizophrenia or Parkinson's disease	Supports role in affective disorder
Cholecysrokinin (CCK)	Four polymorphic sires in CCK gene	One associated with susceptibility to hallucinosis in Parkinson's patients raking i.-dopa	Subtle change suggesting susceptibility to adverse drug effects
Corticotropin releasing hormone (CRH)	1. Human ptomoter gene polymorphism 2. Increased CRF mRNA post kindling in rats 3. CRH overexpression in transgenic mice 4. CRH receptor type 1 knockout 5. CRH receptor type 2 knockout	1. Rheumatoid arthritis susceptibility marker 2. Promotion of experimental epileptogenesis I. Increased anxiety-related activity, impaired learning 4. Reduced anxiety-related activity, impaired spatial memory 5. Increased anxiety-related activity	1. Supports regulatory role in inflammation and immune events 2. CRH induces seizures and promotes epileptogenesis 3-5. Supports role of CRHR1 in anxiogenesis and memory/ learning impairment, and anxiolytic role of CRHR2. Impaired learning supports role of CRH in dementia
Galanin (GAL)	1. Inactivating mutation of GALR1 receptor gene in mice 2a,b. GAL overexpression in Transgenic mice	1. Spontaneous seizures, low levels of insulin-like growth factor 2a. Impaired learning and memory, reduced number of choline acetyl transferase imrmmoreactivc neurons, reduced susceptibility to seizures 2b. Reduces anxiety in mice in response to stress induced by noradrenergic challenge	1. Endogenous anticonvulsant effecr and neuroendocrine regulatory role 2a. Possible relation to Alzheimer's disease is **under** intense study 2b. Suggests potential for developing novel anxiolytic compounds
Neuropeptide Y (NPY)	la. NPY overexpression in transgenic mice 1b. NPY knockout mice 2. Reduced expression of mRNA for NPY in post mortem frontal cortex 3. Reduced mRNA for NPYl and Y2 receptors in postmortem prefrontal cortex	la. Reduced incidence of seizures in response to i.c.v. kainic acid and slowing of kindling epileprogenesis lb. Increased lethality of kainate-induccd seizures 2. Association with bipolar disorder 3. Association of decreased Yl with aging and Y2 with suicide as cause of dca[h	la,b. Importance as endogenous anticonvulsant suggests potential for developing novel anticonvulsant drugs 2. Supports role in affective disorders 3. Different receptor subtypes have different behavioral effects
Opioids	1. ii and *S* opioid receptor polymorphisms 2. Polymorphism in prodynorphin gene in temporal lobe surgery specimens	1. Weak association with addiction to opiates and alcohol 2. L-homozygotes had higher risk of secondarily tonie-clonic seizures and status epilepticus	I. Suggest basis tor genetic susceptibility to addiction 2. Suggests anticpilcprogenic and anticonvulsant role of dynorphin
Somatostatin (SST)	1. Human SSTR5 receptor gene polymorphism 2. SST knockout mice	1. Region includes genes associated with adult polycystic kidney disease **(PKD1)** and tuberous sclerosis (TSC2) 2. Increased severity of kainate-induccd seizures	1. Possible factor in neuropilakomatoses and developmental errors 2. Endogenous anticonvulsant

i.c.v = infracerebro ventricular,

vesicles {LDCVs) that move by axonal transport to nerve terminals before secretion. Release at synaptic terminals depends on firing frequency and duration of depolarization. Low-frequency firing results in sufficient Ca^{2+}* entry to effect release of conventional neurotransmitters from small synaptic vesicles. High-frequency sustained firing engages release of peptides from LDCVs. After release, peptides bind to specific presynaptic and postsynaptic receptors to modulate neurotransmitter release and postsynaptic efficacy. The effects of peptides are slower in

onset but more sustained. For example, NE and neuropeptide Y (NPY) may be present in sympathetic nerve endings on blood vessels. Release of NE is rapid, but rapid desensitization occurs. The slower release of NPY leads to more sustained vasoconstriction. Most neuropeptide receptors are G protein-coupled receptors with seven transmembrane domains (sec Figure 49.1A2). Peptide binding sites are present on loops near the outer membrane surface and on the extracellular N-terminal sequence. Receptor activation is mediated by intracellular signal transduction processes that depend on the type of G protein involved. Termination of synaptic events depends on diffusion and proteolysis of peptides, because there are no pep tide-selective transporters for reuptake and recycling. Diffusion results in stimulation of receptors on distant cells. One last important characteristic is that expression of peptides and their receptors is extremely plastic. It can be altered within a few hours of stimulation in a number of ways.

Calcitonin Gene-Related Peptide

Calcitonin gene-related peptide *a* (CGRPa) consists of 37 amino acids. CGRPa is produced by alternate splicing of transcripts of the calcitonin gene. The G protein-linked component of CGRPa is associated with a modulatory subunit RAMP 1 that enhances affinity for CGRP. After removal of the first seven amino acids, CGRP8-37 is an antagonist. A homologue, CGRP/S, is encoded by a different gene that does not contain an exon for calcitonin. CGRP (a > *0)* binds to two receptors, CGRP1 and CGRP2, that are coupled to G_s and stimulate cAMP production. CGRPa is manufactured by nociceptive dorsal root ganglion neurons that synapse in lamina I of the dorsal horn in particular and by ventral horn motor neurons as well. The rise in dorsal horn receptors after rhizotomy is a sign of denervation hypersensitivity, indicating the role of CGRP as a proalgesic neurotransmitter of primary afferent nociceptors. Levels of CGRP increased in some patients with reflex sympathetic dystrophy. Seizures in experimental models induce elevations of CGRP (in frontal lobes>striatum>hippocampus>amygdala). Severe hypoxic-ischemic injury to newborn rats also induced increases of CGRP in cerebral cortex, basal ganglia, and hippocampus. The blood of patients with vasospasm has elevated levels of CGRP. Nonpcptidc antagonists have been synthesized with the aim of developing novel therapies for neuropathic pain, migraine, and possibly seizures.

Cholecystokinin

Cholecystokinin (CCK) consists of 37 amino acids. It is produced from the polypeptide preprocholecystokinin, which contains 115 amino acids. Fragments of 4 to 56 residues are found in the brain. Most abundant and potent is a suifurated octapeptide (CCK-8S). Two receptors for CCK-8S (CCK_A and CCK_B) have been cloned from the brain of humans and animals. They arc coupled to Gq/11 and activate phospholipase C to produce diacyl glycerol and inositol triphosphate. These induce release of calcium from intracellular stores. Peripheral administration of CCK activates c-fos expression in brain indirectly via vagal afferents. This exemplifies how systemic elevations of CCK from the gut can trigger centrally mediated effects.

CCK is implicated in the mechanism of anxiety. Intravenous CCK triggers panic in patients with panic disorder. Effects of agonists and antagonists depend on the experimental paradigm, but CCK_{fi} agonists induce anxiety-like behaviors in animal models.

Results of several experimental paradigms in animals indicate enhanced learning and memory after CCK administration, However, in postmortem brain specimens of Alzheimer's disease patients and in those of matched controls, CCK peptides concentrations do not differ, or CCK is relatively reduced (not as severely as somatostatin). In an animal model, CCK-8S may have protected cholinergic neurons from degeneration after lesions of the basal forebrain. This finding is of uncertain clinical significance. Administration of the CCK-like peptide ceruletide to schizophrenic patients had no cognitive or antipsychotic effects but caused mild sedation. Ceruletide may improve some electrophysiological indicators of cognitive function or attention in young, but not elderly, healthy subjects. The CCK tetrapeptide fragment may affect memory adversely. A computer search yielded no published data from placebo-controlled clinical trials that support the idea that CCK enhances human learning or memory.

A small percentage of dorsal root ganglion neurons express mRNA for CCK. Axotomy markedly increases CCK expression in these neurons. This may play a role in neuropathic pain. Experimental findings suggest that CCK antagonizes pain-relieving effects of morphine. Thus giving CCK receptor (especially CCKu) antagonists with narcotics is an option for treatment of refractory pain.

Kindled seizures and status epilepticus raise CCK levels in cerebral cortex and parts of the hippocampus in experimental models. The suifurated fragment CCK-8S had anticonvulsant effects against picrotoxin- and electroshock-induced seizures. Rats with genetically determined audiogenic seizures had low brain CCK levels and CCK-8S prevented seizures. This suggests another molecular mechanism of action, perhaps by preventing increases of intracellular calcium by NMDA or other glutamate receptors. In the same rats, transfer of an exogenous CCK gene with viral vectors also prevented seizures. Ceruletide, a CCK-8S-like peptide, slowed kindling acquisition. Such findings suggest possible

anticonvulsant and anticpilcptogenic actions of CCK or synthetic analogues.

Corticotropin-Releasmg Hormone

Corticotropin-releasing hormone (CRH) or corricotropin-relcasing factor (CRF) is a 41 amino acid polypeptide. This peptide is involved in behavioral, endocrine, immune, and autonomic responses to stress. Two receptors that increase cAMP by interactions with G_s mediate these functions. The primary localization of CRF1 is to the cerebral and cerebellar cortices. Antagonists to CRF1 receptors are under development for the treatment of anxiety and depression. They have also reduced stroke-induced damage and inflammatory pain. CRF2 receptors exist in three splice variants that are differentially distributed. So far, no selective antagonists exist. The paraventricular and ventromedial hypothalamus and the septum contain *CRVloi* receptors. Involvement of these receptors could account for eating disorders. CRF2^ receptors are located in brain arterioles and in the choroid plexus. These could be involved in migraine and vasospasm. The localization ot *(.'.RYly* rt-ceptors is the amygdala where u could he involved in the several functions subserved by this critical area. Among these are the structures that links sensory inputs to emotion. In addition, CRF2 receptors inhibit angjogenesis and CRF2 deficient animals are hypertensive.

CRH is localized with, and enhances, the excitatory effect of glutamate under conditions of sustained firing. This contributes to hyperexcilability as seen in epilepsy. For example, CRH is involved in neurotoxicity and proconvul-sant effects of kainic acid and creates severe seizures in the developing brain. From the physiological standpoint, the release of CRH occurs under conditions akin to post-tetanic potentiation (PTP). Both sodium and calcium influx through voltage-sensitive channels at nerve terminals are important for PTP. Both ionic currents are targets for antiepileptic drugs, but CRH enhanced excitability opposes drug efficacy. Thus the development of CRH antagonists may offer improvement in control of age-dependent seizures.

Galanin

Galanin (GAL) has 30 amino acid residues in humans and 29 in other species. It is derived from prcprogalanin, a gene product with a 7 to 9 residue signaling sequence, followed by the 29- or 30-residue galanin sequence, and then a terminal 60-residue galanin message-associated peptide of unknown significance. The elongated sequences were isolated from the adrenal gland, gut, and urinary tract, for example. Estrogens regulate galanin niRNA transcription and increased expression occurs in the pituitary during pregnancy. Thyroid hormones, ACTH and GAL, are also inter-regulated. Galanin mRNA expression is increased up to 100-fold in sensory neurons and in neurons of the dorsal horn after axotomy.

Galanin is a potent inhibitor of hormone release including insulin, but it increases growth hormone release. In this role, it is a neuroendocrine regulator. Inhibition results from blockade of I.- and N-rype voltage-sensitive calcium channels, activation of ATP-sensitive hyperpolarizing potassium current, antagonism of ACh-stimulated phospholipase C activity, and reduction of cAMP. GALRl and GALR3 receptors mediate these actions. The expression of GALRl is in the hypothalamus, where it regulates the release of hormonal factors; in the spinal cord, where it dampens nociceptive barrages from the periphery; and, in the hippocampus, where it acts as an endogenous anticonvulsant. GALR2 receptors are in the hypothalamus, where they may stimulate growth hormone release, and in dorsal root ganglion neurons, where they may serve as autoreceptors to facilitate transmitter release. The excitatory effects of these receptors are mediated by activation of phospholipase C mediated by $G_{t|/|}$]. This leads to generation of diacylglyccrol and IP3, with the subsequent release of intracellular calcium.

Galanin colocalizes with ACh in some neurons and is released by sustained high-frequency firing. Galanin exerts a negative modulatory effect by reducing ACh release through presynaptic autoreceptors coupled to hyperpolarizing potassium current. Postynaptically, GAL opposes mus-carinic activation of phospholipase C. This relationship exemplifies how GAL might counter muscarinic over-stimulation. In the case of Alzheimer's disease, GAL could worsen cognitive deficits associated with loss of cholinergic neurons. As plaques increase, however, GAL immunoreac-tivity declines, either as a sign that lost neurons contained both ACh and GAL, or in compensation for changing activity levels. Effects on nociception further demonstrate the dual nature of GAL activity. Stimulation of GAL1 receptors in the dorsal horn is antinociceptive, whereas stimulation of GAL2 receptors on dorsal root ganglion neurons is pro nociceptive by facilitating release of pain-relared neurotransmitters such as glutamate and CGRP. Colocalization with NE provides an example in which GAL may contribute to depression. At low firing frequencies, adrenergic neurons of the locus ceruleus excite dopaminer-gic neurons of the ventral tegmental area. At high frequencies, corelease of GAL inhibits dopaminergic neu-rons. Direct injection of GAL into the ventral tegmental area induces symptoms in an animal model of depression. In this model, excessive GAL-mediated inhibition produced the disorder. On the other hand, anxiolytic effects result from instilling GAL into the lateral ventricle in animal models, suggesting that the effects of GAL-mediated inhibition depend on the area in which it occurs. Microinjection of GAL into the dentate hilus prevented the development of self-sustaining status epilcpticus in an animal model. This provides a rationale for developing GAL1 receptor agonists for the treatment of epilepsy.

Neuropeptide Y

NPY is a 36-residue polypeptide derived from preproneuropeptide Y. Its production requires the action of a signal peptidase, which removes a signaling sequence, and a prohormone convertase. The latter is an endopeptidase that removes the C-terminal flanking region during processing in the large dense-core vesicles. Six known receptors for NPY exist. Five (Yl, 2, 4, 5, 6) have been cloned and are coupled negatively to adenylate cyclase by G;. A proposed sixth receptor, Y3, explains differential binding of NPY and the pancreatic peptide YY. NPY, a potent vasoconstrictor, is abundant in brain and implicated in epilepsy, depression, anxiety, memory and cognition, and obesity. Increasing evidence exists that different receptor subtypes mediate each of the actions of NPY, in large part resulting from the development of knockout (lacking specific receptors) and transgenic (ove rex pressing a peptide or receptor) mouse models.

Concentrations of NPY and prepro-NPY levels rise after seizures induced by kainic acid, electroshock, or kindling. Inhibitory Y2 receptor expression increases in the hippocampus within six hours after seizure activity. NPY is coexpressed in a subset of GABA interneurons. Such findings in experimental animal models and in human specimens from epilepsy surgery suggest increased inhibitory neurotransmission involving NPY, and probably GABA, after seizures. Microinjection of NPY into the hippocampus prevents or ameliorates seizures after kainate administration and self-sustaining status epilepticus induced by perforant pathway stimulation *in vivo.* In NPY knockout mice, the lethality of kainate-induced seizures is greater than in wild type. In transgenic mice overexpressing NPY, seizures are more difficult to induce. Electrophysiological evidence comparing tissues from wild type and knockout mice suggests that Y5 receptors are necessary for the anticonvulsant effect. Other studies have suggested a role for Yl and Y2 receptors. A subset of neurons expresses both NPY and NE. Dopamine *fi*-h ydr ox yl as e-deficient mice are more sensitive to seizure-producing stimuli than NPY-deficient mice. This suggests that NE is a more potent endogenous anticonvulsant neurotransmitter than NPY.

Low levels of NPY in spinal fluid have been associated with major clinical depression and anxiety is often a comorbid feature of depression. Reduction of experimental anxiety by NPY in animal models depends on Yl receptors. Yl receptors are also important in sedation triggered by sleep-regulating areas of the posterior hypothalamus, as shown with knockout mice.

Some reports suggest that NPY effects memory retention and short-term memory in several experimental animal paradigms. Involvement in clinical dementias is unclear.

NPY colocalizes with NE in sympathetic neurons and inhibits release of NE, probably by a presynaptic autoreceptor mechanism. Nociceptive dorsal root ganglion neurons express Yl receptors and experimental inflammatory pain increases Yl receptors in ORG neurons and in cells of laminae I and II of the spinal cord. Modulation of NPY receptors may be a novel route for the development of anti-hyperalgesic drugs.

Opioid Peptides

Several classes of opioid peptides exist: methionine- and leucine-enkephalins derived from proenkephalin; dynorphins A and B and «-neoendorphin derived from prodynorphin; ^-endorphins derived from proopiomelanocortin; and, the most recently described, endomorphins 1 and 2 of uncertain gene origin. The distribution of three principal receptors, *5, K,* and ji, is different throughout the neuraxis. The peptides have different orders of preference for these receptors (enkephalins bind to *&>fi^K* receptors, dynorphins bind to *K>fi* and *S* receptors, and endorphins prefer *fj.* and *5* over *K* receptors). Endomorphins arc potent endogenous /* receptor agonists. The receptors are all negatively coupled to adenylate cyclase by G;, activate inwardly rectifying potassium current (hyperpolarizing) coupled to $G^{\wedge}_{0}$ and close N-calcium channels coupled to G_n. On balance, these mechanisms provide presynaptic inhibition of transmitter release by afferent neurons and inhibition of dorsal horn neurons mediated by postsynaptic receptors.

Opioid peptides have a documented role in pain and its control, seizures, drug abuse, psychiatric illnesses, locomotion, pregnancy, exercise, immune responsiveness, cardiovascular function, respiration, thermoregulation, and gastrointestinal activity. Administration of receptor agonists for the relief of pain and their adverse effects are well known. Comments on their role in pain and epilepsy serve to illustrate, the importance of the endogenous systems.

Opiatergic pathways descend from the midbrain to the superficial laminae of the dorsal horn, particularly to laminae I and II. *ji*- and ^-receptors are especially present in lamina II. Although the distribution of delta receptors is throughout the dorsal horn, their main concentration is in laminae I and II. These receptors, especially ^-receptors, are targets of pain modulation by exogenous opiates. Furthermore, their strategic dispositions indicate that multiple endogenous opioid peptides are projected to regions of the dorsal horn in which the first synapse along nociceptive pathways occurs. They decrease the responsiveness of dorsal horn neurons to incoming nociceptive volleys by affecting cAMP levels, blocking of calcium channels, and opening of potassium channels. Conceivably this system has phasic activation. In acute settings central propagation of afferent nociceptive volleys along spinothalamic pathways activates midbrain neurons (in the periaqueductal gray and pontine reticular formation). These neurons then project back to the active spinal levels and inhibit dorsal horn neurons. Synaptic delay

indicates that this system is reactive, not preemptive. It is more likely to prevenr persistent hyperexcirabiliry resulting from activation by afferent neurons; this is the situation in normal pain sensation. Sustained afferent volleys and depletion of the descending systems by sustained activity over time could contribute to chronic pain, a pain that is abnormal because it does not turn off.

Less well recognized is the fact that dorsal rhizotomy results in a loss of 50% or more of the total binding of opioid peptides in the dorsal horn. This indicates that primary afferent (dorsal root ganglion) neurons express receptors for opioid peptides, including endomorphins. Thus they express the means of controlling their own excitability. Disorders that reduce expression of these presynapric inhibitory receptors are more likely to contribute to chronic pain. Dorsal root ganglion neurons change the types of sodium channels they express in response to injury. These signs of plasticity indicate how primary afferents respond to pathological changes by genetic alterations.

Opiares have mixed effecrs on seizures. Proconvulsant effects of *n* opiates occur occasionally in clinical situations. High dosages of exogenous and possibly glucuronidared metabolites may explain some cases, whereas withdrawal explains others. u.- and <S-agonists enhanced hippocampal excitability and/or caused seizures in animal models. Morphine dependence enhances kindling acquisition and susceptibility to chemoconvulsant-induced seizures by interactions with GABA and NMDA systems. Seizures release opioid peptides. Naloxone reverses the protective effect of *fi*- and K-agents against chcmoconvulsant- and hypoxia-induced seizures. The same mechanisms of action that reduce nociception are operant in limbic structures involved in experimental seizure production.

Changes in opioid receptor systems occur after seizures and ischemia. Both conditions kill neurons. Kappa receprors increase in the hippocampus after chemically induced seizures and chronic alcohol administration. Opiate antagonists (e.g., naloxone) and ^-receptor agonists are neuroprotective after cerebral ischemia and in vitro conditions promoting hypcrexcitabiliry. Delta receptor agonists reduce loss of substantia nigra neurons after exposure to the toxin 6-hydroxy-dopamine and protect dopaminergic nerve rerminal from destruction by amphetamines, suggesting potent neuroprotective effects.

Substance P

SP is a member of the tachykinin family, discovered because of their ability to enhance smooth muscle contractility and salivation. The tachykinins are translated splice variants of inRNA transcribed from the prcprotachykinin gene. SP is an 11-residue polypeptide derived from three precursor peptides that result from the alternative mRNA splicing. SP is an agonist of NK-1 receptors that are involved in pain (e.g., fibromyalgia), migraine, affective disorders, and emesis. Autopsy specimens from depressed patients show decreased NK-1 receptors, a sign of downregulation resulting from excessive SP-relatcd activity. Experimenral antagonists of NK-1 receptors are antidepressant in animal models of depression. Three types of tachykinin receptors are differentially distributed in the CNS. Binding of agonists leads to rapid internalization and degradarion of receptors. Peptide and nonpeptide NK-1 receptor antagonists are useful tools for pharmacological research. Nonpeptide antagonists are under development and/or in clinical trials in all these areas.

SP is a pain neurotransmirter and excites dorsal horn neurons bearing synapses of nociceptive dorsal root ganglion neurons. SP-activated NK-1 receptors are concentrated in laminae I (65% of lamina I neurons bear NK-1 receptors) and H of the dorsal horn where primary nociceptors synapse. Dorsal rhizotomy leads to supersensitivity ro SP and increased expression of NK-1 receptors. Many dorsal root ganglion neurons express the peptide and the recepror. NK-2 and NK-3 receptors are found on dorsal horn neurons not afferenr fibers. NK-3 receptors increase in models of inflammation. Some evidence exists that SP modulates excitability of ventral horn neurons, and SP binding decreases dramatically with motor neuron loss in ALS models.

SP also enhances glutamate release in the hippocampus. This may explain its role in iniriation of status epilepticus triggered by dentate stimulation. Expression of preprotachykinin mRNA and SP arc increased after seizures, suggesting a role for SP in epileptogenesis. More than 50% of GABAergic neurons and more than 90% of NE-containing neurons of the locus ceruleus also contain SP. Some brainstem serotonin neurons also contain SP. These neurotransmitters play a role in disorders of mood and epilepsy.

Somaro statin

Somatostatin (SST) is a 14 amino acid peptide derived from rhe 92-residue product of the prcprosomatosratin gene. SST, a cyclic pepride, and its 28-residue cousin were first discovered in extracts of the hypothalamus. The name *somatostatin* was used because the extracts inhibited growrh hormone secretion. Hormonal functions of SST include growth regulation, inhibition of tumor growth, and modulation of endocrine and exocrine hormone release. Somarosratin has neurotransmitter and ncuromodularory functions in pain, epilepsy, sleep, cognition, and locomotion. Depolarizarion releases somatostatin from neurons. It colocalizes in some neurons with GABA. l'ive receptors (SSTl to 5) have been cloned that have differential distribution in the nervous system. Of these, SSTl and SST2 arc most studied for CNS effects. All five are negarively coupled to adenylate cyclase by Gi, although

there probably are splice variants coupled to phospholipid metabolism and excitation, e.g., SSTR2B. Electrophysiological evidence indicates G-dependent activation by SST-14 of hyperpolarizing potassium current (M type) and inhibition of voltage-dependent I.-type calcium current as mechanisms underlying inhibitory effects such as decreased glutamate release. SST-14 and -28 block potassium current and open i.-calcium channels. These excitatory effects probably involve increasing phospholipase C activity and intracellular calcium release. Correlation of these actions with receptor subtypes is incomplete. Somatostatin agonists reduce glutamate-activated but not GABA-activated currents by presynaptic inhibition employing SSTR1 receptors. SSTR2 receptors mediate reduction in depolarizing responses to applied glutamate. Some evidence exists of enhancement of responses of hippocampal neurons to ACh by SST.

Dorsal root ganglion neurons in laminae I and II of the dorsal horn contain SST receptors. SST in the superficial dorsal horn decreases with the induction of inflammatory arthritis in an animal model. Administration of SST into joint fluid reduces inflammatory pain of osteoarthritis and rheumatoid arthritis, probably by activating SSTR2 receptors on nociceptive afferents. Epidural or systemic administration of SST or a synthetic analogue, octreotide, relieves postoperative pain, opiate-resistant bone pain, and cancer pain. Thus interest is developing in producing SST analogues for use in the treatment of pain.

High-frequency neuronal activity releases SST. Seizures in experimental animal models enhance SST mRNA expression, whereas experimental status epileptic us decrease it through excitotoxic injury and loss of SST-containing neurons. SST-containing neurons also are fewer in temporal lobe specimens of patients with chronic medication-resistant epilepsy. Infusion of SST analogues blocked electrographic changes induced by excitatory amino acids. SST also has antiepileptogenic effects as injection of SST antibodies into the hippocampus facilitates kindling. Such observations have stimulated interest in development of SST analogues for the treatment of epilepsy.

Additional findings indicate a role of SST in other disorders. SST receptors change in some neurodegenerative diseases, such as Alzheimer's and Huntington's disease. Patients with mania, depression, and schizophrenia have altered CSF concentrations of SST. A few patients with panic attacks have benefited from SST administration. Clarification of the role of SST in these disorders is likely ro stimulate development of therapeutic analogues further.

Thyrotropin-Releasing Hormone

Thyrotropin-releasing hormone (TRH) is a tnpepride product of the preprothyrotropin releasing hormone gene. Two receptors have been cloned, TRHRl and TRHR2. The expression ot TRIIKI is extensive in limine structures. whereas the primary distribution of TRHR2 is in sensory areas. Intracellular calcium is rapidly mobilized by TRH binding to both receptors, which arc coupled to G_{tl}/n and activate phospholipase C. The calcium reduces inwardly rectifying potassium current allowing faster firing of action potentials. This action does not explain all of the actions of TRH. TR] 1 also reduces transcription of potassium channel genes and decreases the total cellular number of potassium channels. TRH probably reduces fast GABAergic IPSPs by a presynaptic mechanism. Furthermore, TRH increased the NMDA component of glutamate EPSPs. These effects should be excitatory. On the other hand, TRH inhibits voltage-gate calcium channels, activates calcium-dependent potassium channels, and has anticonvulsant effects that may depend on blockade of glutamate-stimulated uptake of calcium. These effects are inhibitory. Receptor specificity of these actions is not established, and it is difficult to conceive of a single unifying molecular mechanism for all of these actions. Recovery from traumatic brain and spinal cord injury in animal models was increased by TRH administration, indicating neuroprotective efficacy. In part, this may he due to elevations of kynurenine, a metabolite of tryptophan and a precursor of the NMDA antagonist kynurenic acid.

The basis of TRH use for depression is anecdotal observations. The proposed mechanism is inhibition of hyperactive glutamatergic neurons in frontal and subcortical limbic neurons. Such inhibition is the proposed mechanism of action of electroshock therapy, which also may increase TRH levels. TRH and the endogenous TRH-like tripeptide EEP produced antidepressant-like effects in an animal model of depression. EEP does not bind to TRH receptors and is processed from a different prohormone. Lithium modulates TRH and EEP levels in different brain regions and lithium withdrawal leads to marked elevations of both peptides. This suggests a role for TRH and TRH-like peptides in the antidepressant mechanisms of lithium. TRH also produces arousal in narcotized animals. The analeptic effect, without significant mood-stabilizing effects, has been documented in bipolar and schizophrenic patients.

Treatment of refractory epilepsy with TRH further illustrates the potential of using anticonvulsant neuropeptides as add-on therapy. Several small clinical trials demonstrated efficacy of TRH in the treatment of infantile spasms, Lennox-Gastaut syndrome, myoclonic seizures, and partial seizures with or without secondary generalization. No published placebo-controlled studies exist. Patients with infantile spasms, Lennox-Gastaut syndrome, and acquired immunodeficiency syndrome {AIDS) dementia have low CSF concentrations of kynurenic acid. TRH-induced elevation of kynurenic acid may be therapeutic in these illnesses. Interactions may occur with the pituitary - adrenocortical axis, especially ACTH, a known beneficial agent for infantile spasms. Evidence of anticonvulsant

effects of TRH in animal models supports the clinical data. TRH concentrations initially fall, perhaps resulting from ictal depletion, and then rise after kindled and clcctroshock-induccd seizures. EEP concentrations also rise. Prepro-rhyrotropin mRNA and receptor expression changes also increase after chemically and electrically induced seizures, perhaps representing compensatory or neuroprotective changes, lntrahippocampal TRH shortened after-discharge duration without major alterations of seizure stage in kindled animals. The chronic administration of a TRH analogue suppresses seizures and prolongs life in spontaneously epileptic rats.

Neuroprotective effects of TRH in vivo and in vitro suggest a possible role in preventing or ameliorating chronic pain by minimizing dorsal horn remodeling. A computer search failed to detect published studies of therapeutic trials of TRH for pain. Preclinical and small clinical studies of TRH for spinal cord injury have been promising, but no large clinical trials have been undertaken.

Vasoactive Intestinal Polypeptide

Vasoactive intestinal polypeptide (VIP) is a 28 amino acid polypeptide produced by a single VIP gene. Different genes encode the two receptors, VIP1 and VIP2. G_s positively couple both receptors to adenylate cyclase and raises cellular cAMP levels. VIPf receptors are concentrated in the hippocampus, olfactory bulb, and cortex. VIP2 receptors are highly expressed in the hippocampus, thalamus, and hypothalamus (especially the suprachiasmatic nucleus, which is involved in circadian rhythms}. Pineal content of VIP triples at night and, with NE, stimulates production and release of melatonin by stimulation of VIP1 receptors. Substituting aromatic amino acids at position 22 enhances the potency of agonists at VIP2 receptors and this leads to smooth muscle relaxing actions (bronchodilation, vasodilation). A third receptor activated primarily by pituitary adenylate cyclase-activating peptide (PACAP; a 38-residue peptide) also responds to VIP less potently. This receptor has five splice variants connected to cAMP and phospholipid metabolism. Its distribution overlaps that of the VIP receptors.

VIP plays important roles in neuronal development and survival. A VIP antagonist produced severe microcephaly in the mouse fetus. It protects against neuronal injury produced in vitro by glutamate, nitric oxide, nerve growth factor deficiency, HIV glycoprotein 120, and /j-amyloid in a mouse model of Alzheimer's disease. The mechanisms of these neuroprotective effects may include antagonism of nitric oxide toxicity by free radical scavenging, activation of cAMP response element-binding protein (CREB) that activates the antiapoptotic pro to-oncogene Bcl2, and inhibition of apoptosis-related caspases. It also has anti-inflammatory effects through inhibition of cytokine synthesis and regulation of inflammatory cells.

Highlighting the potential therapeutic importance of VIP in Alzheimer's disease is protection against /J-amyloid in vitro and in apolipoprotein E knockout mice. This has stimulated the development of lipophilic analogues of VIP that can cross the blood-brain barrier after oral administration. Low concentrations of VIP also protected against injury of cultured neurons by dopamine oxidation produces, suggesting a place for VIP agonist therapy in the treatment of Parkinson's disease. Unexplored is the potential for VIP-mediated neuroprotection to prevent remodeling of hippocampal circuits involved in kindling epileptogenesis and dorsal horn remodeling that produces allodynia.

VOLTAGE-GATED ION CHANNELS

The effects of neurotransmitters on membrane potentials contribute to patterns of action-potential firing and modulate neurotransmitter release by central neurons. G protein-mediated interactions with calcium or potassium channels mediate the actions of some neurotransmitters, such as ACh or serotonin. As the membrane potentials change under the influence of these neurotransmitter-gated ion channels, the likelihood of opening voltage-sensitive ion channels increases during EPSPs and decreases during IPSPs. EPSPs of sufficient amplitude to bring the membrane potential to threshold trigger action potentials. The upstroke of the action potential depends principally on the entry of sodium ions through voltage-activated sodium channels. In some instances, the influx of calcium through voltage-activated calcium channels contributes to the rising phase of the action potential. Conduction of sodium-dependent action potentials is along axons and causes depolarization of nerve terminals, triggering neurotransmitter release. Only calcium-dependent action potentials are identified in dendrites of central neurons. These action potentials probably serve to ensure the transmission of excitatory potentials on the distal dendrite to the soma and axon hillock where potentials sum to modulate axonal firing rates. Action-potential firing over the soma and down the axon couples the electrical output of the neuron to its biochemical machinery for the maintenance of the membrane potential and modulation of neurotransmitter release.

Largely, voltage-dependent calcium and potassium currents determine action-potential duration. Action-potential duration limits the maximal rate of firing. Calcium and potassium also generate after-potentials that modulate firing frequency and determine patterns of firing. Hyperpolarizing after-potentials slow firing, and depolarizing after-potentials increase firing.

Voltage changes in the nerve terminal modulate release of neurotransmitter. Action potential-induced depolarization of the terminals stimulates entry of calcium through voltage-dependent channels. The resultant slow depolarizing wave facilitates fusion of neurotransmitter-containing

vesicles with the releasing zone of the terminal and subsequent exocytosis of the neurotransmitter.

Activation of voltage-dependent chloride channels affords rapid entry of chloride ions, which increases the rate of action potential repolarization. The contribution of chloride ions to early repolarization is particularly evident in the action potentials of cardiac Purkinje fibers and skeletal muscle fibers.

Information encoded in the pattern and frequency of action potential firing is critical for the projection of activiry from one brain region to another along selectively activated pathways subserving specific functions. Myelination of central and some peripheral nerve fibers increases the fidelity and security of action potential firing and conduction over long distances. The brain operates in the millisecond timeframe. Brief (l-2msec) action potentials, high-velocity propagation along short myelinated fibers, and neurotransmission requiring less than a millisecond confer this property. Mutations associated with each of the voltage-sensitive ion channels have been associated with clinical disorders (Table 49.11). Discussion of these mutations is in Chapter 69.

Sodium Cliannels

Sodium Channel Structure

Voltage-gated sodium channels are glycosylated proteins with a molecular weight in the range of 230-270 kD. Channels from both sources consist of 1800 to 2000 amino acid a-subunits. The a-subunit seems to contain sequences conferring most of the known electrophysiological and pharmacological properties of these channels. Cloning techniques identified multiple isoforms of a-subunits. Functional diversity is less apparent and determined primarily by pharmacological and elecrrophysiological Techniques. In the rat brain, however, auxiliary $1- and j82-subunits exist with molecular weights ranging from 33,000-36,000 kD. These contain approximately 200 amino acid sequences that are not covalently bound to the £i-subunit. The /3-subunit of skeletal muscle is slightly larger but has properties similar to those of the brain ^-subunits. The j3-subunits probably modulate the rate of sodium channel inactivation (spontaneous closure) and possibly the voltage-dependence of activation of the channels.

Molecular pharmacology has identified sequences in the sodium channel that account for various functional features (see Figure 49.1C). Sequencing of the or-subunit suggests that both the amino and car boxy sequences are intracellular. The core sequence consisrs of four domains of six hydrophobic transmembrane sequences. Their connection is by intracellular and extracellular peptide loops. These domains are roughly analogous to subunits of neurotransmitter-gated receptors, but their linkage is covalent. They surround a central channel that allows passage of sodium and other ions of similar size on opening. The extracellular loop connecting the fifth and sixth transmembrane sequences of each domain is longer than the other extracellular loops. In the first domain, this loop is glycosylated. Intracellular loops connecting the sixth transmembrane segment of the first domain to the first transmembrane segment of the second domain is very long and contains many sites for modulation by phosphorylation. The intracellular loop connecting the third and fourth domains is relatively short. This loop seems to be responsible for the inactivation characteristics of the sodium channel. Phosphorylation of this loop by protein kinase C slows inactivation of the channel and links channel phosphorylation to activation of G proteins coupled to the cascade-activating protein kinase C. Binding of tctrodotoxin, isolated from the ovaries of the puffer fish of the genus *Tetradon*, depends on negatively charged residues in the extracellular loop linking the fifth and sixth transmembrane segments of each domain. The fourth transmembrane segments of each domain contain positively charged amino acid residues, which probably constitute the voltage sensor. Fither in response to electrical stimulation or ncurotransmitter-mediated changes in ionic conductance, voltage changes electrophorese these charged residues. The latter results in conformational changes in these segments and in relationship to other transmembrane segments in each domain of the sodium channel. The result is transitory opening of the sodium channel, with sodium entry until the kinetically slower inactivation process occurs.

Channel Function and Pharmacology

Flectrophysiological refinements from patch-clamp experiments and the molecular characterization of the channel have led to a well-focused picture of how sodium channels behave, singly and in concert. Sodium influx through voltage-sensitive channels generares the upstroke of action potentials recorded from axons and somata of central neurons. In the Hodgkin and Huxley model, channels may be in the resting, activated (conducting), or inactive configuration. With depolarization, available resting channels open quickly and nearly synchronously, and they admit sodium ions flowing inward along their concentration gradient. If this influx generates enough current, it triggers the action potential. The channels inactivate spontaneously as slower conformational changes close the inner mouths of the channels. Gradual repriming, or recovery from the inactive to the resting conformation, occurs after repolarization. The interval between spikes is largely determined by the number of available channels contributing to the next action potential. This confers rate-dependence. **The** transmembrane voltage confers voltage-dependence. At high frequencies (>150 Hz), the rate of cycling may not be fast enough for sufficient channels to rcprimc. The result is that sodium current \-^3 and maximal rate of rise of action

Tabic 49.11: Clinical disorders associated with mutations of voltage-sensitive ion channels (channeloparhics}

	Gene, *channel component affected*	*Disorder(s)*	*Comments*
Sodium channels			
	SCN1A, SCN4A, and *SCNSA* genes for different ot-subunits	Generalised epilepsy and febrile seizures plus Hyperkalemie and hypokalemic periodic paralysis Paramyotonia congenita Mi oronic conditions Long QT syndrome	Mutations involve different ff-subunits with a variety of substitutions and deletions
	SCN1B gene for 0-suminit	Generalized epilepsy and febrile seizures plus	
Calcium channels			
	Multiple CACN genes for or-subunits	Kpisodit ataxia type *1* (P/Q channels) Spinocerebellar ataxia type 6 (P/Q channels) Hypokalemic periodic paralysis (L channels) Familial hemiplegic migraine (P/Q channels) Malignant hyperthermia susceptibility (L channel) Incomplete X-linked congenital stationary night blindness (L channel)	Various mutations ol same or different types of a-subunits associated with different disorders
	CACNA2D1 gene for ^-suhunit	Malignant hyperthermia susceptibility Murine generalized spike-wave absence	
	CACNAB4 for 04-subunit	Idiopathic generalized epilepsy Murine generalized spike-wave absence	
	RYRl for ryanodine receptor	Malignant hyperthermia syndrome *+1*— central core disease Central core disease	
Potassium channels			
	KCN1A gene affecting Kv	Episodic ataxia -Im-partial epilepsy Isaac's syndrome (neuro myotonia)	Reduced Kv prolongs action porention dtiration and sodium current leading to hyperexcitability
	KCM2) gene affecting Kir2.1 of-subunit	Anderson's syndrome (defects of bone development, periodic paralysis and cardiac arrhythmia)	Mutation results in loss of stabilization of resting potential by G-protein activated inward rectifier
	KCNQ2 and *KCNQ3* genes	Familial benign neonatal convulsions	Reduce inhibitory M current
	Kcnal	Murine tonic-clonic seizures	Reduced Ca^{2}"*-sensitive potassium current causes loss of inhibitory after-hype rpolari/ations
Chloride channels			
	Cl.CNl	Myotonia congenita, autosomal dominant Myotonia congenita, autosomal recessive	F.ach disorder is associated with a variery of differenr substitutions and intron mutations

potentials (V_{ma}J decrease at fast rates. Although kinetic parameters vary, all voltage-sensitive ion channels must go through a similar operational cycle. Kinetic models of drug interaction with different aspects of sodium channel function have had an important impact on antiepileptic and antiarrhythmic drug development.

Several standard antiepileptic medications bind to sodium channels. 'This results in accumulation of sodium channels in the inactivated state, prolongation of refractoriness, and failure of some action potentials. At concentrations that correspond to therapeutic free-plasma levels, phenytoin, carbamazepine, and valproic acid limit sustained

high-frequency repetitive firing (SRF) of sodium-dependent action potentials involved in the spread of ictal activity. Some of the new antiepilcptic medications may also block sodium channels. Progressive reduction of V_{max} before action potential failure suggests an effect on sodium channels, although potassium and calcium currents could he involved. This effect on sodium channels parallels the ability of these compounds to protect against tonic hind-limb extension in the maximal elcctroshock model in animals. It may also contribute to clinical efficacy against partial seizures with or without secondary tonic-clonic generalization. Other compounds, including local anesthetics, verapamil, and tricyclic antidepressants, act at voltage-sensitive sodium channels hut are not useful clinically as anticpilcptics.

The effect of standard anticonvulsant drugs on sodium channels has several important characteristics. First, its effect is concentration-dependent, as expected from the clinical definition of therapeutic range. Second, the effect is voltage-dependent. At very negative transmembrane potentials, drugs bind to a small percentage of sodium channels with some reduction of sodium current or action potential rate of rise (tonic block). With depolarization, such as occurs at the ictal transition, drug binding becomes more likely and blockade accrues more quickly. Third, the effect on sodium channels is use-dependent, requiring multiple activations of sodium currents or firings of action potentials to become maximal. It is also frequency-dependent. Fast rates and less-negative membrane potentials enhance the blocks, which occur at the depolarizing shift signaling the ictal transition. Channels to which drug is bound are effectively unavailable to contribute the next action potential. Firing at slower rates is possible despite the continuing presence of the drug. Therefore anticonvulsant drugs with this action modulate rather than block sodium channel function.

How does this relate to clinical anticonvulsant effects? Ideally, concentration-dependence *in vitro* should predict the therapeutic range. Limitation of SRF by phenytoin, for example, occurs at concentrations equivalent to therapeutic free-plasma (i.e., not bound to plasma proteins) levels. Brain-tissue levels increase with time. Slow accumulation in brain may account for gradual improvement in efficacy on a constant dose of an anticonvulsant drug. Alternatively, an active metabolite may accumulate and add to the efficacy of the parent compound. For example, carbamazepine epoxide and the trans-2-en metabolite of valproic acid both limit high-frequency firing and accumulate in the brain and CSF. High-frequency action potentials fire along projection pathways from a chemically induced cortical focus. This firing pattern underlies the spread of abnormal activity from the seizure focus. Extrapolating from the cellular data, limitation of high-frequency action potential firing should prevent seizure spread. However, brief bursts of fast firing or firing sustained at slower rates are not blocked. This could explain refractoriness of some seizures to sodium channel-blocking medications.

Voltage-dependence may explain why ambulatory patients tolerate sodium channel blocking antiepilcptic medications chronically, with minimal dysfunction. Intcrictally, the patient may function almost as if the drug were **not** present. However, when abnormal focal activity commences with prolonged depolarization, drug action becomes more effective and limits high-frequency firing responsible for the spread of seizures. Frequency-dependence allows the use of drugs as anticonvulsants. Excessive sodium channels blockade may occur because of a high concentration of one drug or pharmacodynamic interaction between two sodium channel blockers. Sedation, reduced motor speed, and impaired cognition result. In the extreme, compounds that bind tightly and extensively to sodium channels, such as tetrodotoxin, are lethal. Therefore the same cellular action may be relevant to both therapeutic efficacy and toxicity.

Nociceptive fibers of peripheral nerve have tetrodotoxin-resistant sodium channels. Lidocaine blocks these more severely than the classic tetrodotoxin-sensitive, kinetically fast sodium channel of the CNS and mechanoceptive fibers. This exemplifies the functional diversity of sodium channels.

Point mutations in the gene on human chromosome 17q encoding the skeletal muscle sodium channel are the basis for some human channelopathies. These include hyperkalemic periodic paralysis and paramyotonia congenita. These disorders result in muscle paralysis and myotonia resulting from disorders of sodium channel inactivation. Some families with paramyotonia congenita have point mutations leading to a single amino acid change in the voltage-sensing fourth transmembrane sequence.

Calcium Channels

Pharmacological and electrophysiological characteristics of four distinct calcium channels are established, T, L, N, and P are the assigned names. The L and N types have been cloned. This suggests that greater molecular diversity exists than has been discovered functionally. Calcium channels are evolutionary descendants of, and share 50% homology with, sodium channels, primarily in the transmembrane regions. This structural similarity may account for the fact that some classes of compounds, such as hydantoins and calcium-entry blockers, bind to both sodium channels and calcium channels. Significant differences in the intracellular linkers between transmembrane domains are likely to account for the unique regulation and function of calcium channels. A long intracellular carboxy terminus of the L channel contains a sequence to which calcium must bind before dihydropyridines such as nifedipine or nimodipine can produce their pharmacological block. The intracellular loop connecting the second and third transmembrane domain of L-type channels in muscle T-tubules may be the voltage sensor signaling calcium release from sarcoplasmic reticulum in muscle. This loop differs in neuronal L-type

channels. By analogy to the sodium channel, the fourth transmembrane sequence of each domain contains multiple positively charged lysine and argmine residues, which appear to confer voltage sensitivity on channel opening.

The operating cycle of calcium channels is similar to that of the sodium channel and involves changing from resting to conducting and inactivated conformations. Frequency or use-dependence of blockade by certain drugs is crucial for calcium channels as well as sodium channels. A good example is use-dependent block of L channels by dihydropyridines. This feature confers activity-dependence on the effect of the drug and suggests the drug may be present with minimal effects at low activity levels.

Physiology and Pharmacology of Calcium Channels

Slight depolarization from rest may activate low-threshold T-type channels, which open briefly and inactivate relatively quickly. These channels probably underlie oscillatory behavior, which confers burst firing properties on neurons. As the membrane depolarizes sufficiently, the high-threshold types of calcium channels, namely L, N, and P, open. The opening of P-type channels is implicated in the production of dendritic calcium spikes, which propagate to the soma. Here, depolarization to threshold results in firing of sodium-dependent action potentials over the somatic membrane and axon hillock. Although sodium-dependent action potential firing accounts for propagation along axons, neurotransmitter release depends on the admission of calcium into the terminals through voltage-dependent calcium channels. Neurotransmitter release depends at least on N-type channel activation and probably also on activation of P-type channels. The peptide f3-conotoxin isolated from predatory cone snails selectively blocks the N-type channels. S-agatoxin, isolated from spider venom, blocks the P-type channels. Under some conditions, dihydropyridine-sensitivc L-type channels may be involved in transmitter release. However, transmission in most experimental paradigms is unaffected by dihydropyridines. In the experimental paradigm known as post-tetanic potentiation, a nerve is stimulated at high frequency. Following the tetanus, a single stimulus produces a markedly enhanced postsynaptic excitatory response. Fnhanced neurotransmitter release is responsible for the phenomenon, because of calcium accumulation in nerve terminals with repetitive activation. Phenytoin, which blocks both sodium channels and L-type calcium channels, inhibits post-tetanic potentiation.

Oscillatory activity appears to be important in both normal and abnormal activity of thalamic neurons. Low voltage-activated T-typc calcium channels appear to underlie this activity. Ethosuximide and dimethadionc, drugs used for absence epilepsy, block T-typc current at therapeutically relevant concentrations, but phenytoin and carbamazepinc do not. This difference may explain in part, the different efficacy of antiepileptic drugs. The broad-spectrum antiepileptic drug, valproic acid, blocks the T-type current only slightly at high concentrations in dorsal root ganglion neurons, but not in thalamic or human neocortical neurons. Ethosuximide does not block T-currcnt in human cortical neurons, suggesting regional and species differences in the pharmacology of this type of current.

Abnormalities of calcium channel operation underlie at least two disorders of muscle. In the Lambert-Faton myasthenic syndrome, plasma contains antibodies against synaptic voltage-sensitive calcium channels (see Chapter 84), F^xci tat ion -con traction coupling in skeletal muscle involves propagation of sodium action potentials along the sarcolemma, which excites voltage-sensitive calcium channels at the T-tubular triad. These are probably dihydropyridine-sensitive L-type channels. Calcium reuptake occurs through a second type of calcium channel, which ryanodine blocks. This is probably identical to the calcium channel activated by IP3 and subject to modulation by activation of phospholipase C. A point mutation in this channel is associated with malignant hyperthermia in swine and in some humans. The result of the mutation is that sarcoplasmic calcium concentrations remain elevated causing the myofibrillary lattice to remain contracted, Life-threatening heat production, rigidity, and muscle breakdown result.

Potassium Channels

Potassium channels share some structural features with other voltage-sensitive ion channels, including four subunit domains each with six transmembrane sequences. However, unlike sodium and calcium channels, the summits arc not covalcntly linked, and the polarity of the potassium channels is different. Potassium channel subunits are the most numerous and diverse of all voltage-sensitive ion channels. When the channels are opened, potassium ions move outward from the neuronal cytoplasm where the potassium concentration is high (approximately 140 mmol/1.) to the extracellular space where the potassium concentration is low (less than 5 mmol/L). Cloning of multiple potassium channels from a variety of species, especially *Drosophila,* has confirmed much of the behavior of the delayed rectifier channels responsible for action potential repolarization described by Hodgkin and Huxley. Other potassium channels responsible for oscillations in membrane potential and clamping of the membrane potential toward the resting level have also been characterized electrophysiologically and pharmacologically. Also, unlike sodium and calcium channels, the inactivation particle of the potassium channel is located at the end of the intracellular amino terminus and swings into the channel opened by voltage changes like a hall on the end oi a rope. Mutations in the pore-forming principal subunit of K channels are associated with benign neonatal familial convulsions.

The delayed rectifier channel, or K^R, initiates repolarization of the action potential. It turns on quickly with depolarization although not as quickly as the sodium current and is maximally active as the sodium current becomes inactivated. Persistence of potassium current after inactivation of the sodium current results in a hypcrpolarizing after-potential, which inactivates quickly and allows maximal firing rates in the range of several hundred per second. Mutation in K^R channels, so-called channelopathies, are associated with myokymia, episodic ataxia, and cardiac arrhythmias {long QT syndrome).

Depolarization, especially when it is prolonged in response to steady synaptic excitation, also activates the so-called A-current. This outward current hyperpolarizes the neuron and delays the onset of firing after a voltage change by driving the membrane potential away from threshold, back toward the resting potential. As the current inactivates, the membrane potential depolarizes to threshold, and firing commences.

A third potassium current, the M-current (IM)J is activated by depolarization. Activation of the IM opposes the tendency toward threshold and repetitive firing. A unique feature of this current is that it is not inactivating, and it causes depolarization to drift toward the resting potential. Neurotransmitters that block I_M, such as ACh or muscarine after which the I_M is named, promote increased firing frequencies. Normal excitation by multiple biogenic amine neurotransmitters involves blockade of KIR channels and calcium-dependent potassium conductances. M-current is carried by inwardly rectifying (KIR) channels connected by G proteins to the neurotransmitter receptors. Mutations in $K[_K$ channels can cause ataxia in mice. Mutations in ATP-sensitive $K_{[R}$ channels can result in salt-wasting (Bartton's syndrome). Modulation of these conductances may be important in the pathophysiology and control of epilepsy and in normal processes such as sleep,

Two calcium-dependent potassium channels contribute repolarizmg outward currents (IkCaj that are activated by depolarization. A kinetically fast I«Ca is activated with the delayed rectifier. A rise in intracellular free calcium resulting from transmembrane influx or release from intracellular stores is essential for activation of this current. A kinetically slower \&*Ca*, I^HP; contributes a slow component to the after-hyperpolarization. Tctraethylammonium blocks fast I_KCa more potently than it blocks IAHP. Other antagonists, such as apamin (extracted from the venom of the honeybee), charybdotoxin (a peptide toxin in scorpion venom), curare, and barium act preferentially on I A W

Hippocampal pyramidal neurons have all of these outward potassium channels. The overlap of function is insurance against sustained depolarization. In addition, these neurons have an inward potassium current (1Q) activated by hyperpolarization that causes the membrane potential to drift back toward the resting potential. This particular current probahly prevents reduction of spiking capacity by excessive hyperpolarization.

As important as potassium channel activity is in determining firing patterns and frequency, relatively little is known about the effects of medications on potassium channels. Perhaps the best example of modulation of potassium channels to control neurological disease is the use of aminopyridines and guanidine to treat the myasthenic syndrome and in some cases myasthenia gravis. Two aminopyridines, 4-aminopyridine and 3,4-diaminopyridine, have been used clinically. They are presumed to act by blocking potassium channels in nerve terminals to can si[1] depolarization, entry of calcium, and enhanced neurotransmitter release. Guanidine, which probably sensitizes nerve terminals to calcium in a similar manner, has been used in the treatment of these disorders and botulism. The availability of therapeutic agents to modulate potassium channel activity might be very useful in the treatment of epilepsy.

Chloride Channels

Multiple chloride channels are being discovered by cloning techniques. Nonetheless, our understanding of the role ⊳t voltage-dependent chloride channels in the brain **lags** behind that of the cationic channels already described. Chloride ions are involved in regulation of cell volume and must move to maintain charge neutrality when cations enter. Without electroneutrality, osmotic shifts would occur, and neurons would swell or shrink, depending on activity levels. The balance is accomplished through a leak channel. Neurons have a relatively low resting conductance to chloride. However, the chloride conductance in fast-twitch muscle at rest is high. In addition to the high leak conductance to chloride, a voltage-activated chloride channel or current contributes to sharp repolarization of action potentials in skeletal muscles. Experimentally, blockade of this current by aromatic monocarboxylic acids or zinc results in repetitive firing of action potentials in addition to a very slow repolarizing phase. This situation is mimicked in myotonic goats and in humans with myotonia congenita, an autosomal dominant disease with a mutation on chromosome 7q in the region of the skeletal muscle chloride-channel gene. With increased understanding of voltage-sensitive chloride channels, the development of therapeutic agents that activate chloride channels and repolarize muscle may be possible.

Cystic fibrosis is also associated with abnormal pulmonary chloride channels, resulting from single-gene mutation on the long arm of human chromosome 7q. Gene therapy for this illness is in the pioneering stages.

PRINCIPLES OF THERAPEUTICS

The art of administering medications is a complex product of the therapeutic alliance between a patient and the

physician and the availability of safe and effective medications. Ethical pharmaceutical companies coordinate the need for new medications with internal programs for identifying and testing candidate compounds at their own expense. Discovery programs are usually directed toward finding novel medications for a particular condition. Compounds are chosen based on efficacy and lack of significant toxicity in appropriate animal models. Compounds that emerge from these targeted programs were categorized by the use for which they were discovered historically. However, recognition of multiple uses after approval has resulted in a tendency toward testing for multiple uses during the preapproval phase of testing. Proof of efficacy and safety is the basis of regulatory approval. This establishes the claims that can be supported in the package insert. Meeting these criteria for multiple applications affords the company maximal exclusivity under patent protection after approval. Once a compound is identified, human clinical trials are designed in collaboration with regulatory agencies—the FDA in the United States. Ethical considerations are important in determining who should be admitted to the studies. This often results in the inclusion of adults with conditions refractory to available alternatives. The paramount concern for safety has resulted in the exclusion of children and women of child-bearing potential from many studies. As a result, guidelines for the use of many new medications are limited and drugs become used in these populations after approval despite the lack of specific indications. Many FDA-approved medications are prescribed for "off-label" uses. Some physicians adhere rigorously to approved uses, whereas others use familiar medications for alternative uses. This can have medicolegal implications.

Study designs result from collaboration between regulatory agencies and companies. In the United States, approval for marketing requires by law that the investigational compound is safe and superior to anorher treatment (usually a placebo or a low dose of a drug). This requires statistically significant outcomes. Recent changes in FDA regulations have made evaluation of devices more like that of pharmaceuticals. Clinical trials for regulatory review are conducted in three phases. Phase I studies determine pharmacokinetics of drugs, parameters for devices, and methodologies for procedures. Freedom from acute toxicity can also be assessed. Dose ranging during phase II studies provides the first information about efficacy and continues assessment of the safety of the compound. Based on these pilot studies, doses are chosen for the rigorous company-sponsored studies of phase III studies. Inclusion of subjects in such studies is always voluntary. Informed consent is an absolute entry criterion and study subjects may leave the trials at any time and for any reason. Approval of the study-protocol by rhe institutional review board for safety of human subjects at each participating institution is also required. Investigators may be at university medical centers or in private practice.

Study design is important in obtaining interpretable data. Inappropriate designs or choice of doses may result in an uninformative study. Inclusion and exclusion criteria ensure inclusion of subjects with accurate diagnoses. These criteria are important for selecting as homogeneous a study population as possible so that interindividual variation does not prevent an interpretable outcome. Sample size is predetermined by statistical power analysis so that sufficient data can be obtained to arrive at valid conclusions. Several hundred patients may be included in a placebo-controlled study. Study protocols include escape criteria for removal of patients from the study at the discretion of the investigators because of concerns about safety and noncompliance. Multicenter, double-blind, placebo-controlled trials are common, but details of the design are tailored to test the features under study. A baseline period allows determination of the frequency and severity of symptoms while the patient takes a constant amount of conventional medication before beginning the investigational compound. Well-defined clinical endpoints or outcome measures are predetermined so that appropriate assessments of efficacy and adverse events (side effects and systemic toxicities) can be obtained at repeated intervals throughout the blinded period and open-label extensions. The duration of the blinded observation period may be only a few months. This and the sample size limit the ability to assess long-term safety. For example, toxicities with an incidence of I in 2000-5000 may not be observed in the course of the preapproval studies. In the case of felbatol, aplastic anemia in this range of incidence was not detected until more than 100,000 individuals had been exposed to the drug. Assessments by the study subject and investigator of impact of the novel treatment on quality of life are often included. The investigator and the company are accountable for all participants and their safety and for quality control of data relating to efficacy and treatment-emergent adverse effects. Because these studies typically require rigid assignments to placebo or active medication and to a specific dose and titration schedule, practical knowledge of how to use the medication after approval may be lacking. Postapproval (phase IV) studies are sometimes conducted to extend knowledge of safety, tolerability, and efficacy. Phase IV studies may be open-label studies to learn how to optimize use of the new medication on an individual basis. Postmarketing surveillance is not regulated by law in the United States. It depends, in large part, on the reporting of adverse event to the company and FDA by treating physicians.

The treating physician must diagnose a condition correctly, select the most effective remedy, and teach the patient how to self-administer the medicine. Responsibility does not end with a prescription. Physician-patient contact must occur at intervals to confirm the diagnostic impression, determine the efficacy of treatment, and assess dose-related and idiosyncratic adverse reactions. The patient must be motivated to rake medications

as prescribed, often several times a day. Compliance depends on confidence in the physician, understanding of the disease process, a sense that the medicine is beneficial and tolerable, and a dosage regimen that is consistent with the individual's lifestyle. These factors comprise what can be called acceptability of the medication to the patient.

Desirable Properties of Medications

Anticonvulsant drugs exemplify what is good, bad, and acceptable in the development and use of pharmaceuticals. Their properties are reviewed in the framework of pharmacokinetic and pharmacodynamic principles that enter into the bedside decision-ma king process.

1. The selected medication must be appropriate for the disease. In the example of anticonvulsants, this means making a correct seizure diagnosis and selecting a medication with a clinical spectrum of efficacy that includes the specific seizure type. Some anticonvulsants are effective against partial seizures with or without secondary generalization; others are effective against primary generalized seizures such as generalized absence; and a few, such as valproate, have a broad spectrum of activity against partial seizures and both primary and secondary generalized seizures.
2. Knowledge of the therapeutic index and mechanism of action simplify drug selection. The therapeutic index is a ratio of the toxic dose to a measure of a therapeutically relevant dose. In practice, it equates to the ratio of the blood concentration at which limiting side effects appear, usually the top of the therapeutic range, to a minimally effective dose, the bottom of the therapeutic range. Potency may not be the most desirable property of anticonvulsants, and a drug with greater potency may have a lower therapeutic index. To some degree potency is a trade-off against therapeutic index. A drug with a very large therapeutic index may actually encompass several therapeutic ranges, which can be tailored to the severity of the seizure disorder.
3. A broad spectrum of clinical efficacy seems a desirable characteristic in anticonvulsant drugs. However, broad spectrum implies multiple mechanisms of action, some of which may actually contribute to toxicity in a given seizure disorder or individual. A reductionist corollary of this reasoning is that a compound requires the least number of actions to treat effectively a specific disorder should be used.

Preparations

Several factors determine if a compound is user-friendly for the patient and the physician. Ease of use ensures compliance but not efficacy. The following factors contribute to case of use:

1. Dosage forms that allow graduated dosing throughout the therapeutic range of the medication
2. Easy-to-swallow capsules or rablets and a liquid preparation for children, the aged, and the debilitated
3. Once- or twice-a-day dosing to avoid taking medicine at school or work
4. Parenteral preparations for unconscious patients and for emergency situations such as status epilepticus

Bioavailability

Bioavailability is the amount of a dose that enters the body. In practice, it is determined as the peak plasma level after oral ingestion divided by the peak after intravenous administration. Currently used anticonvulsant drugs are freely available after oral ingestion. Bioavailability of some compounds is dose-related and may decrease with increasing dosages. Nonetheless, blood levels rise, although less than expected, with dose increments. This implies that above a certain practical limit, further dosage increments will not raise the plasma level sufficiently to justify the cost of the higher dose. Bioavailability may be limited by an uptake mechanism. Optimal dosing requires knowledge of compounds that interfere with or augment uptake and the effects of food.

Titration Rate

Ideally, a therapeutic concentration should be present in the blood and brain as soon as possible after starting a new drug. In practice, this means that a loading dose can be given or that the titration rate should be fast. Loading doses can be given in urgent situations, such as frequent seizures with physical harm to the patient or status epilepticus.

A loading dose is a large dose, usually administered intravenously or by mouth that brings the plasma level into a therapeutically effective range after one or a few administrations. Loading doses cannot be given with many drugs because of limiting adverse effects or because parenteral preparations arc noi available-.

The titration rate is the speed at which dose increments can be made, and it is an inverse function of the elimination, or half-life, of the medication. A steady state should be reached before conclusions are drawn about the results of a dose increase and a decision about further increments is made. Steady state is reached in five half-lives after initiation of therapy or a dose increment. Further increments before achieving steady state may result in overdose, increased adverse effects, and even more seizures. Multiple doses smooth the oscillations in blood level between doses. The maximum tolerable daily dose may be increased by dividing the dose further. Thus

toxic effects encountered by giving a 1-g dose twice daily may be eliminated by giving the same drug 600 mg four times daily. Seizure control may improve at the higher dose.

Distribution

Drug distribution is commonly discussed in terms of volume of distribution and binding to plasma proteins. The volume of distribution is a virtual number; it can be computed as the amount of drug injected into the body divided by the plasma concentration. This value, in liters, is the fluid volume necessary to dilute the total amount of drug injected to the concentration found in plasma. It is affected by the degree of binding to plasma protein, hydrophobicity of the compound (its partition coefficient in fat), regional blood flow, and other physical factors. The volume of distribution is often reported as the computed volume divided by body weight in kilograms. A low volume of distribution of about 0.15 L/kg suggests distribution only within the vascular compartment, which consists of about 5,5 L total blood volume and 3 L of plasma in a normal 70-kg man. A value of 0.15 to 0.50 L/kg suggests distribution throughout extracellular fluid, which is about 12 L in the average man. Values of 0.5 to 0.6 L/kg indicate that the drug is distributed throughout total body water. Assuming no regional selectivity, total body water is a volume of about 42 L in a 70-kg man. Values in excess of 0.6 L/kg suggest that the drug is concentrated other than in body water at concentrations higher than those found in the **plasma.** This would be particularly true for highly lipophilic compounds, such as phenytoin, and compounds that are actively accumulated in the CNS, such as gabapentin.

Lipophilic compounds are bound significantly to plasma proteins (e.g., albumin). This may be a site for competition with other lipophilic compounds. Use of water-soluble compounds (e.g., gabapentin) avoids the potential for such interactions among drugs,

Biotransformation

The body metabolizes drugs to rid itself of them, as it would many harmful exogenous chemicals. In the case of highly lipid-soluble drugs such as phenytoin, carbamazepine, and valproic acid metabolism in the liver results in multiple metabolites, some of which are sufficiently water-soluble to be excreted efficiently by the kidney. To accomplish this, the liver uses four fundamental types of reactions: oxidation, reduction, hydrolysis, and conjugation. The first three reactions produce hydroxy!, carboxylic acid, and amine groups, which are polar. This is phase I of enzymatic catalysis in the liver. This step generally results in reduced activity of the metabolites, However, active metabolites are produced from caibamazepine and valproic acid (carbamazepine epoxide and *tratts-2-en* valproic acid). The active metabolites are subsequently modified to more water-soluble compounds for elimination.

In phase II, the polar groups are coupled to endogenous compounds such as glucuronic or acetic acid or inorganic sulfate to produce water-soluble conjugates. Most conjugates are inactive and are excreted in the urine or bile. We generally think of these reactions as taking place in the liver, but microsomal and cytosohc enzymes in other organs, including the brain, may actually metabolize drugs to some extent.

Ultimately, biotransformation accomplishes two tasks inactivation of exogenous chemical substances and their modification for elimination. The capacity of the body to transform drugs determines, m large part, the interval between subsequent doses required to sustain a therapeutic level. The standard antiepileptic medications are metabolized to varying degrees; gabapentin and vigatrim are not metabolized at all.

Pbarmacogen etics

Pharmacogenetics is the study of variations in rates and patterns of drug metabolism. Awareness of such variations is crucial in optimizing therapy for the individual patient. Phenytoin provides one of the best and earliest examples of pharmacogenetic variation. Variation of parahydroxylation of phenytoin results in variable nonlinearity of the relationship between oral dose and steady-state plasma concentrations of phenytoin. This is manifest as the well-known zero-order kinetic curve. The phenytoin blood level rises linearly, up to **a** break point above which a slight dose change causes a very large increase in plasma phenytoin concentration. The break point varies from individual to individual and with age. The elderly-experience this effect at lower doses than children. The break point represents saturation of the liver's capacity to metabolize phenytoin to the parahydroxy derivative. To a large extent, this phenomenon was responsible for the invention of therapeutic blood-level monitoring and for the evolution of models based on Mic ha el is -Me men kinetics to pharmacokinetically optimize dosing in individuals taking phenytoin.

The half-life of phenytoin is longer in slow hydroxylators, who achieve higher concentrations at lower doses than patients who are fast hydroxylators. Slow hydroxylation is an autosomal recessive trait that appears in about 1 in 500 individuals. In practice, unfortunately, these individuals are identified only empirically.

Predisposition to hepatotoxicity resulting from phenytoin is probably inherited as a genetic polymorphism, Patients with elevated liver enzymes during phenytoin therapy proved to be slow acetylators. Isoniazid is a noncompetitive inhibitor of phenytoin hydroxylation. Inhibiting phenytoin metabolism may result in toxic drug levels and hepatic injury resulting from effects on other liver en/ymes,

Drug Interactions. Interactions resulting from effects of concomitant medications on the metabolism of standard antiepileptic medications are among the most frequent problems complicating drug therapy of epilepsy. Addition of a second medication may increase, decrease, or not affect the plasma concentration of the first anticpilcptic medication. Phenytoin and carbamazepine induce hepatic microsomal enzymes of the P-450 system, which augment the metabolism of other antiepilepties and decrease their levels. These metabolic interactions may reduce efficacy of oral contraceptives by enhancing metabolism. Valproic acid, on the other hand, inhibits metabolism of other antiepilepties and may cause significant elevations in their concentration. Gabapentin and vigabatrin are not metabolized and do not alter metabolism of other antiepileptic drugs or oral contraceptives. Blood levels of these two amino acids are not affected by addition of other drugs. Use of medications without drug-drug interactions at the level of metabolism is desirable, bur optimal ust- of standard antiepilepties requires knowledge of these interactions and the art of miiiimi/,ing their consequences.

Physiological Variation

Several factors influence the rate of drug metabolism. Phenobarbital levels have been reported to be higher in males than in females, suggesting slower metabolism in the males. Whether this is due to induction of liver enzymes by female sex hormones or other factors is unclear. The rate of drug oxidation is higher in elderly men than women. Pregnancy introduces several variables. These include changes in steroidal hormones, a rise in body temperature, alteration in volume of distribution and reduced drug binding to plasma proteins, increased blood flow and rate of delivery of drug to the liver, and drug metabolism by the placenta.

Circadian variation in metabolic rates and gastric emptying may significantly alter drug disposition. Plasma-free fractions of phenytoin and valproate have been shown to vary throughout the day and in response to urinary pH changes, suggesting that the ionized fraction of drugs such as phenytoin may change and affect blood levels no matter how slightly. Awareness of these factors is increasing as studies of chronopharmacokinctics evolve.

Developmental factors also affect metabolic rates. Newborns generally have slower phase I reactions than adults, but the rate increases to a peak over several years and may exceed the adult metabolic capacity in older children. One of the best examples of this is difficulty of sustaining a significant blood level of phenytoin in children who often require very large doses. In general children in the range of 1-6 years of age require larger doses on a milligram per kilogram basis than adults to achieve therapeutic levels of phenytoin, carbamazepine, ethosuximide, and valproic acid. The effect of developmental factors on metabolism of novel antiepileptic medications has not yet been reported. Among the elderly, phase I reactions are much slower than in early adulthood. On the other hand, conjugation reactions arc not significantly different.

Elimination

Drug elimination is really a two-step process of biotransformation and excretion from the hody. One of the most important parameters guiding dosage adjustment and dosage intervals is the elimination half-life. After oral or intravenous administration, the plasma level of a drug rises to a maximum, then begins to fall. A curve describing plasma concentration against time after administration can be described by one or more exponential components. The elimination half-life is approximated by assessing the time required for the blood level to fall to 50% of the peak blood level. Clinically, this is very useful in determining the time to reach a steady state. In multiple dosing situations typically encountered in the treatment of epilepsy, the drug concentration in plasma (and at its receptor sites) will rise in a stepwise manner with successive doses after initiation or a change in dose. This process will continue until drug elimination matches drug delivery. This situation defines the steady state. A practical rule of thumb is that five half-lives are required to achieve a steady state after drug initiation or a dose change. Changing doses before achieving the steady state obfuscates evaluation of the effect of a dose change; hence the dictum that time should be allowed for steady state to be achieved before contemplating an additional dose change. Dosing intervals are greater for drugs with longer half-lives.

Half-life may vary with chronic dosing. This is particularly true of carbamazepine, which undergoes the process known as autoinduction of metabolism. After an initial steady state is achieved during the first week of therapy, the half-life may be as long as 24 hours. However, after an average of 1-2 months, hepatic enzyme metabolizing capacity increases, and the plasma level falls despite a constant medication regimen. Autoinduction of other standard antiepileptic medications is not significant.

Chapter 50
Principles of Pain Management

Paul L. Moots and Padmaja Kandula

NOCICEPTION

The management of pain requires a complete understanding of the afferent pathways that serve nociception. The localizing value of sensory deficits caused by disorders of the petipheral nerves and spinothalamic tracts has been appreciated for more than a century. Primary involvement of these tracts in conveying pain signals has been a fundamental element in the understanding of pain for over 100 years. In the last 30 years a more detailed and dynamic model of nociception has emerged. This model incorporates (1) knowledge of the descending pathways that modulate pain transmission, (2) biochemical information about the neurotransmitters involved in the pain pathways, and (3) new insights into the pathological mechanisms that underlie changes in the nervous system in relation to injury or chronic stimulation that alters the function of nociceptive systems. This model also incorporates information about the interaction of primary nociceptive systems with othet neural systems (limbic, hypothalamic, and other systems) that gives rise to aspects of pain experience that are not primarily sensory. Better understanding and use of currently available pain control methods and the development of new treatments for pain are emerging as the model of neural mechanisms subserving pain evolves.

Receptors and Primary Afferents

Nociceptors are formed by the peripheral ramification of certain finely myelinated and unmyelinated afferent axons. Their morphology is relatively simple. The most common nociceptive receptors are bare nerve endings. Nociceptors are subcategorized by tissue distribution, tcsponse to various types of potentially noxious stimuli, threshold of response, and changes in activity in response to prior stimulation (e.g., sensitization). Nociceptors are found in skin, intramuscular connective tissue, blood vessels, periosteum, and most thoracic and abdominal viscera.

The afferent fibers that convey nociceptive information are small myelinated fibers with conduction velocities of 5-30 m per second (A fibers) and unmyelinated axons with conduction velocities of 0.5-2.0 m per second (C fibers). Nociceptive fibers account for 10% of the myelinated and 90% of the unmyelinated fibers in cutaneous nerves. Visceral afferent fibers at any spinal level represent a smaller percentage of the total afferent fibers and contain a higher proportion of unmyelinated fibers than do cutaneous afferent fibers.

Cutaneous nociceptors include (1) high-threshold mechanical nociceptors (HTMs) associated with small myelinated axons (A fibers), (2) myelinated mechanothermal nociceptors (MTs) {A fibers), and (3) polymodal nociceptors associated with unmyelinated axons (C fibers). HTMs respond only to intense mechanical stimuli, and their thresholds are many times higher than those of non-nociccptive mechanoreceptors. Stimulation of single afferent A nociceptive fibers causes a sharp, well-localized pain sensation. The intensity of the perceived pain is roughly proportional to the frequency of discharge. The threshold and rate of response of HTMs and MTs can be altered by thermal injury. These sensitizing effects may be involved in the development of hyperpathia. Polymodal nociceptors respond to mechanical, chemical, and thermal stimuli. Stimulation of nociceptive C fibers is associated with a dull, burning, or aching quality that is less well localized than A fiber stimulation. Unlike HTMs, repeated stimulation and thetmal stimuli do not produce sensitization of polymodal nociceptors, but local inflammatory responses to tissue injury do lead to sensitization.

The deep somatic nociceptors associated with muscle, tendons, fascia, jomts, and periosteum are largely free nerve endings with A and C fibers. The extensive plexus of fibers investing the periosteum and joints gives hone the lowest pain threshold of the deep tissues. The effects of sensitizing stimuli and the distribution of central terminals from deep somatic afferents differ considerably from cutaneous afferents. These differences result in the aching rather than sharp nature of deep somatic pain and in its less well-defined localization.

Visceral pain contributes greatly to the symptomatology of many medical and surgical disorders. Unfortunately, the physiology and pathophysiology of visceral nociception are less well studied than that of somatic nociception. Many viscera] afferents are involved in reflex autonomic regulation and do not serve a sensory function. The lack of sensation other than pain, perceived on stimulation of many viscera, is an important distinction between visceral and somatic, particularly cutaneous, sensation. When compared with skin, the intestine is remarkably insensitive to direct tissue damage, such as cutting or burning. Visceral nociceptive stimulation generally produces a poorly localized aching or spasmodic, cramping pain. The terminals of the visceral afferents in the spinal cord tend to be more widely distributed than are cutaneous afferent terminals, which contributes to the poorly localized character of the pain. Visceral pain often is accompanied by perception of pain arising in somatic structures that share the same spinal level of innervation. This phenomenon, known as *referred pain*, results from the convergence of nociceptive fibers from different structures onto the same population of cells in the dorsal horn.

Visceral nociceptors are free nerve endings without obvious architectural specialization. The majority are related to unmyelinated C fibers. Lightly myelinated fibers also contribute to the population of nociceptive visceral afferents, but the proportion of nociceptive A fibers is lower than in cutaneous nerves. The visceral nociceptive afferents are divided into two general categories, based on their characteristics of activation. HTMs in many viscera function specifically as nociceptors and respond to distention or changes in intraluminal pressure. In addition, low-threshold receptors respond in a graded fashion, in proportion to stimulus intensities ranging from innocuous to noxious, contribute to nociceptive input at high levels of stimulation. Both types of nociceptive afferents are present in some organs {e.g., esophagus). Thus unlike cutaneous nociception, which predominantly results from the stimulation of fibers specifically nociceptive in nature, visceral nociception combines intensity-coded input from low-threshold receptors along with activation of specific nociceptors. The distinction between liber specificity and pattern or intensity coding of visceral nociceptive input is detailed by Cervero (1994).

Some visceral nociceptive afferents are also sensitive to chemical stimulation, for example, by bradykinin, and other physiological stimuli, such as hypoxia. **These** afferents demonstrate sensitization, particularly in the setting of mucosal inflammation. Through presumably centrally mediated mechanisms, cutaneous hypalgesia can occur in conjunction with visceral nociceptive input. The phenomenon may be analogous to referred pain.

Most of the visceral afferent nociceptive fibers travel via the sympathetic nerves into the thoracic spinal cord. They enter through both the dorsal and ventral roots and have a broader pattern of termination than somatic afferents. The visceral affercnts traveling in the vagus nerve convey some nociceptive information, including sensations of tightness in the chest and gastric distention. However, most afferent vagal fibers are regulatory and not primarily sensory or nociceptive. The afferent fibers in the lumbosacral parasympathetic nerves do convey important nociceptive information from the bladder and other pelvic viscera.

Alterations in primary sensory afferents result from peripheral nerve injury, inflammation, and other pathological processes. Such changes may affect nociception acutely and alter the perception of chronic pain. Changes in membrane cation channels (i.e., vanilloid receptors) and the subsequent alterations in the intracellular second messengers active in peripheral endings of nociceptive afferents are thought to underlie the sensitization following thermal, chemical, and inflammatory activation (Bolay and Moskowitz 2002), These peripheral sensitization phenomena are probably transient.

Alterations in the proximal elements of nociceptive and non-nociceptive afferents also contribute to changes in pain perception that may become chronic. Changes in voltage-gated sodium channels that arc relatively specific to C fibers occur with injury or inflammation. Changes that occur in non-nociceptive afferents, such as A-beta fibers, are also interesting. These fibers normally convey information about non-noxious mechanical stimuli. Following injury, neurotransmitter production may change and substance P is released. New synaptic connections may form within the superficial laminae of the dorsal horn. These alterations may explain the pain induced by non-nociceptive stimuli (e.g., allodynia),

Dorsal **Horn and Central Projections**

Tin.' central projections ot the primary nociceptive afferents, whose cell bodies are located in the dorsal root ganglia, are directed through the dorsal roots to the most superficial of Rexed's laminae (I and II) and to some of the deep laminae (V) of the dorsal horn over a vertical distance of one or two vertebral levels. The A fibers conveying input from HTMs and MTs terminate primarily in laminae I and V; C fibers terminate in lamina II. Visceral afferents included in the sympathetic nerves also terminate in laminae I and V, sometimes overlapping with somatic affercnts, and also terminate more widely in the lower laminae (VI, VII, and X),

The viscerosomatic convergence of nociceptive afferents is important in the genesis of referred pain. These terminals use multiple neurotransmitters, including excitatory amino acids and neuropeptides, particularly substance P. Postsynaptic modulation may result from substance P's long-term modulating effects. In addition, both presynaptic and postsynaptic events may be modified by supraspinal input involving monoamines and opioid neuropeptides.

The postsynaptic neurons in the dorsal horn include cells that respond only to noxious stimuli (e.g., nociceptive specific neurons) and others, *wide dynamic range neurons* that respond to both nociceptive and non-nociceptive sensory stimuli. These neurons project as a largely decussated pathway that projects in the contralateral antctolateral portion of the spinal cord comprising the principal spinothalamic tract. This tract is somatotypically organized with sacral elements situated posterolateral^ and cervical elements more anteromedially. included in this tract are fibers that project to the periaqueductal gray (spinoreticular pathway) and brainstem nuclei. These fibers, along with projections to the central or laminar nuclei of the thalamus, make up the paleospinothalamic tract. In humans, most of the spinothalamic tract projects to the ventral posterolateral nucleus of the thalamus as the neospinothalamic tract. The cortical projections of the paleospinothalamic tract are widespread, whereas the cortical projections of the neospinothalamic tract are directed to the primary sensory cortex.

The integration of nociceptive input to the thalamus shares some similarities with those at the spinal level. The phylogenically distinct components of the spinothalamic tract probably convey qualitatively different information. The paleospinothalamic pathway serves arousal and the emotive or affective component of pain; the neospinothalamic component conveys discriminative and localizing information. Like dorsal horn neurons, thalamic neurons are activated as either nociception-specific or as polymodal wide dynamic range neurons. In addition, the convergence of somatic and visceral input at the thalamic level adds another possible source for referred pain,

The development of functional neuroimaging techniques, such as positron emission tomographic (PET) scanning and functional magnetic resonance imaging, has provided new information about the anatomy of central nociceptive processing. Methods that demonstrate regional activation based on changes in cerebral blood flow indicate that multiple areas are activated in conjunction with the perception of pain. Particularly interesting is the activation of the anterior cingulate gyrus, which may mediate attentional and affective aspects of pain perception. Primary and secondary somatosensory cortex, thalamus, periaqueductal gray, supplemental motor, inferior prefrontal, and insular cortex are also activated (ladarola et al. 1998). These regions provide the networks that subserve the various neural components (sensory-perceptual, behavioral, modulating) that comprise the complex experience of pain. Understanding the integration and chemical regulation of these components remains challenging (Jones 1998).

Central Modulation of Nociception

Afferent nociceptive input is modulated by peripheral mechanisms, such as sensitization of nociceptors by thermal or chemical stimuli. Central mechanisms that modulate nociceptive input also exist. At the spinal level, both local neuronal circuits and descending pathways originating in the brainstem modulate nociceptive transmission through the dorsal horn and the spinothalamic projections. This modulating effect is generally inhibitory and produces analgesia via endogenous opioid and aminergic systems. Studies of systems that facilitate nociceptive input are ongoing.

Intrasegmental and intersegmental projections arising from cells located in Rexed's laminae I and II (e.g., substantia gelatinosa) modulate both presynaptic and postsynaptic elements of primary nociceptive afferent terminals in laminae I, II, and V. These local circuits also serve to integrate nociceptive and other sensory inputs. Suppression of nociceptive transmission in the dorsal horn by non-nociceptive afferent stimulation was the hasis for the development of circuitry models referred to as the *gate control theory* of pain transmission. This model has influenced studies of nociceptive mechanisms for the last 30 years. Although the specific dorsal horn circuits originally hypothesized in gate control theory were never identified, the phenomenon of modulation of nociceptive input by peripheral and descending central influences remains a fundamental topic of study in the understanding of nociception.

Endogenous opioids serve as principal neurotransmitters in the local circuitry of the dorsal horn. Opioid receptors (mu- and kappa-receptors; see the section on endogenous opioids and opioid receptors later in this chapter) are found on both presynaptic and postsynaptic elements of primary nociceptive afferents in the substantia gelatinosa, which also contains a high density of enkcphalinergic terminals. These interneuron synapses are an important site of action for systemically administered opioid analgesics.

Descending influences on spinal nociceptive transmission were first demonstrated by producing analgesia sufficient to perform laparotomies on rats after electrical stimulation of the periaqueductal gray. Similar effects have been produced by local iontophoretic application of opioid analgesics on regions of the brainstem. The best established of the descending nociceptive modulating systems derives from cells in the midhrain periaqueductal gray that project to the nucleus raphe magnus (NRM) in the medulla. The NRM in turn projects to neurons in Rexed's laminae I, II, and V of the dorsal horn. Analgesia induced by stimulation of cither the midbrain or medullary region is sensitive to opioid antagonists (e.g., naloxone), and specific opioid receptors

exist at both sites. The descending pathway from the NRM travels through the dorsal lateral column of the spinal cord medial to the corticospinal tracts. Sectioning these tracts blocks the analgesic effect of stimulation of the periaqueductal gray or NRM. Electrophysiological studies indicate that stimulation of these descending pathways inhibits activity in wide dynamic range dorsal horn neurons that contribute to the spinothalamic tract. The fibers originating in the medullary nuclei, particularly the NRM, use serotonin as a principal neurotransmitter. Norepinephrine is the principal neurotransmitter of fibers from other medullary nuclei, such as the nucleus reticularis gigantocellularis, and from more rostral components of the monoaminergic system. These pathways specifically inhibit nociceptive input without affecting other somatic or visceral sensory input. They represent the principal supraspinal sites for the analgesic effects of endogenous and exogenous opiate action.

Activity in wide dynamic range neurons and nociceptive neurons of the dorsal horn are altered differently by supraspinal input. Chronic changes in the control of transmission through these paths, either by inhibition or facilitation, may contribute to the development of some chronic pain states (Millan 2002).

Transitory analgesia also can be produced by stimulating the somatosensory cortex and certain periventricular nuclei in the hypothalamus. This effect is mediated by direct fibers included in the corticospinal tracts that terminate in the dorsal horn and by polysynaptic pathways that may use the reticulospinal and raphe spinal pathways described earlier. The analgesic effect resulting from electrical stimulation at these supratentorial sites is less consistent than that achieved by stimulation of the periaqueductal gray.

Endogenous Opioids and Opioid Receptors

Two major neuroscience breakthroughs since the 1970s are (1} the identification of specific neuronal receptors that mediate the effects of opiates and (2) the identification of endogenous peptides that act as ligands for these receptors. In recent years, the number of opioid-rclatcd peptides has increased with the identification of endomorphins, nociceptin, and nocistatin. New types of opioid receptors have also been identified. Modulation of the endogenous opioid systems in the setting of inflammation, neurological disorders, and chronic pain has added greatly to insights and treatments in curtcnt pain therapy (Przewlocki and Przewlocka 2001).

Three families of endogenous opioid neuropeptides have been identified: enkephalins, dynorphins, and endorphins. Each family derives from a distinct gene, yet all active opioid species have in common the amino terminal sequence Tyr-Gly-Gly-Phe. In each family, the active peptides arise from the cleavage of a larger precursor protein. The two opioid precursors most closely associated with brainstem and spinal nociceptive transmission are pro-enkephalin A, the precursor of met- and leu-enkephalin, and pro-enkcphalin B (prodynorphin), the precursor of dynorphin. These precursors are concentrated heavily in those regions of the periaqueductal gray, medullary nuclei, and dorsal horn involved primarily with nociception. The principal member of the endorphin family of opioid peptides is /J-cndorphin, which is derived from pro-opiomelanocortin and is relatively restricted to the hypothalamus and pituitary. It is also the parent precursor of melanocyte-stimulating hormone, adrenocorticotropic hormone, and other peptides.

In the late 1990s, the *endomorphins,* peptides with mu-recepror agonist properties and a distinct terminal amino acid structure, were identified. Endomorphins I and 2 are found in brain regions that arc important in pain signaling, Endomorphin 2 colocalizes with substance P in some of the primary nociceptive afferents in the dorsal horn and appears to have an inhibitory effect on nociceptive transmission. Other peptides with analgesic properties, such as nociceptin, have also been found.

Opioid receptors, initially identified by the specific binding of ligands, such as morphine, are subcategorized by differing ligand affinities. The major subcategories are the mu-, kappa-, and delta-receptors. Each of the receptor subtypes has been cloned and sequenced. The receptors are membrane-spanning proteins that appear to be coupled by G proteins to adenyl cyclase, using cyclic adenosine monophosphate as the second messenger. They probably act by regulating K^+ and Ca^+ channels. Pharmacological evidence, based on ligand binding specificities, suggests that additional opioid receptor subtypes exist, but cloning data has not supported that view.

The mu-receptor, so named because of its high affinity for morphine, is present in the periaqueductal gray and dorsal horn. The analgesic potency of opiate compounds correlates well with the agonist-binding affinity to the mu-receptor. Genetically engineered mice lacking the mu opiate receptor demonstrate no analgesic effect from morphine. In addition, these mice fail to manifest behavioral evidence of physical dependence or naloxone-induced withdrawal symptoms after chronic morphine treatment. Thus mu-receptor expression is necessary and sufficient to explain all the pharmacological actions of motphine. Kappa-receptors also are distributed in the spinal and brainstem regions that are important in the modulation of nociception. These distributions clearly overlap those of the enkephalins and dynorphins.

Other receptors with sequence similarities to the opioid receptor have been identified. The orphan opioid-like receptor (ORE 1) was found, and an endogenous ligand nociceptin has also been discovered. This receptor is found in many brain regions including the dorsal horn of the spinal cord. Nociceptin is also widespread but heavily concentrated in the superficial laminae of the dorsal horn.

The endomorphins and nociccptin have analgesic actions when administered intrathecally in animals. However, in some experimental situations nociceptin and dynorphins can facilitate nociceptive transmission.

As in other neurotransmitter systems, changes in the level of activity within nociception-rclated pathways and other influences such as inflammation lead to alterations that modify the pathways both acutely and chronically (Przewlocki and Przewlocka 2001}, Systemic inflammation increases the nociceptive effect of endogenous opiates. These changes include an increase in potency of mu-receptor agonists probably because of changes in the mu receptor. The loss of afferent neurons resulting from peripheral nerve injury may decrease the presence of opioid receptors in the dorsal horn. This is suggested as an explanation for the relatively reduced efficacy of opiates against neuropathic as compared with somatic pain,

Chronic pain states may reflect long-term changes in the endogenous opioid systems. For example, increased levels of dynorphin in the spinal cord following segmental nerve injury result in a decrease in the analgesic efficacy of morphine (Malan ct a!. 2000). This may contribute acutely to hyperalgesia through N-methyl-D-aspartate (NMDA) receptor-related mechanisms because the effect can be prevented by NMDA receptor antagonists. Persistent effects attributed to NMDA-mcdiated excitatory neurotoxicity may then contribute to the development of chronic neuropathic pain.

The termination of opioid receptor activation depends on peptidases with active sites located on the extracellular surface of the cell membrane that cleave the peptides into inactive fragments. The so-called enkephalinascs may serve as a target for a new class of analgesics.

PAIN MECHANISMS

Nociceptive Pain

Nociceptive pain is a response to tissue injury that produces activation of nociceptors. The acute pain caused by tissue injury usually is divided into somatic and visceral pain, based iin their differences in character. Somatic pain is more clearly localized and described as sharp or dull, Visceral pain is less well localized and has a crampy, spasmodic, or aching character. Visceral and deep somatic pain more commonly arc associated with referred pain than is cutaneous pain.

Chronic nociceptive pain is usually similar in character to acute pain arising in the same area, but with time, the consequences of the modulation of nociceptive transmission and the affective components of pain become more important in the character of the pain syndrome. Depression, sleep disorders, and the sequelae of disuse (e.g., muscle atrophy and limited joint mobility} contribute to the disability of chronic pain disorders.

Although nociceptive pain usually arises from localized tissue injury, the distribution of perceived pain does not always directly identify the source of pain—that is, tissue injury occurring at one site may be felt as arising from another (referred pain}. The best known example is the association of left arm pain with angina. Other common examples arc listed in Table 50.1. In addition to the convergence of visceral and somatic input at the spinal level, other possible mechanisms of tefcrred pain include innervation of two structures by different branches of the same nociceptive afferent fiber and changes in the receptive field of thalamic neurons.

Neuropathic and Deafferentation Pain

Pain is an important consequence of direct injury to peripheral nerves; common examples are nerve and nerve root compression syndromes, acute and chronic pain after nerve transection, neuritis in association with infectious and inflammatory lesions (e.g., herpes zoster), and diffuse polyneuropathies.

Neuropathic pain often has several different qualities that are experienced concurrently. One common form is sharp, lancinating pains that are brief but very intense, or shocklike, and well localized. Typically, the pain radiates

Tahle 50.1: Common referred pain syndromes

Pain location	*Segmental distribution*	*Causes*
Frontal or vertex headache	Trigeminal nerve	Traction, inflammation, or other lesions involving the supra tentorial meninges
Ear pain	Glossopharyngeal and vagus nerves	Tumor, abscess, or inflammatory lesion in the oropharynx or hypopharynx
Right shoulder pain	Plireiiie IHTO (C.5-C5)	Cholecystitis or diaphragmatic irritation
Left chest/arm pain	T1-T4	Cardiac ischemia
Left upper abdominal wall pain	T8	Gastric diseases
Middle and lower abdominal wall pain	T10-T11	Small intestine and colon disorders
Testicle/inguinal region pain	T12-L2	Renal or perirenal abscess or tumor
Knee pain	L3-L4	Pelvic, acetabular, and femoral head disorders

in a pattern that suggests a dermatomal or peripheral nerve distrihution. In trigeminal neuralgia (see Chapter 75) or postherpetic neuralgia, a trigger zone exists such that stimulation applied to a specific area elicits intense, shock-like pains. A superimposed burning pain is common, and sensory stimulation of the affected region often exacerbates the burning pain far out of proportion to the intensity of the stimulus. A slight breeze or movement of a sheet over the skin is often sufficient to produce exquisite pain in patients with painful neuropathies. A variety of mechanisms are involved in pain accompanying nerve disease, and multiple mechanisms may be operating simultaneously in any given patient. These mechanisms include: (1) activation of normal nociceptors contained in a nerve (e.g., ncrvi nervorum), (2) spontaneous discharges in injured nociceptor afferents, (3) induced discharges in injured nociceptor afferents, (4) deafferentation with subsequent changes in dorsal horn or central nociceptive transmission leading to central pain generation, pj activation ot sensitized mechanoreceprors by efferent sympathetic activity (sympathetically maintained pain}, and (6) specific ion channel changes in primary afferents. The last of these, upregulation of voltage-gated sodium channels specific to sensory neurons following injury, raises the suggestion that chronic pain states may be a channelopathy (Waxman et al. 1999}. Alterations in the descending inhibitory and facilitatory modulation of nociceptive transmission are also important in the genesis of chronic pain syndromes, including those of neuropathic origin.

Histological evidence supports the presence of nociceptors in the perineural and epineural tissues investing peripheral nerves, the ncrvi nervorum; therefore nerve injury can cause nociceptive pain in the sense described in the section on nociceptive pain, earlier in this chapter. This likely contributes to pain resulting from nerve root compression and peripheral nerve entrapment.

Neuropathic pain can result from abnormal discharges in injured or regenerating sensory afferents. Injured nerve fibers sometimes develop spontaneous discharges, and afferent impulses may be evoked by electrical activity in surrounding axons (ephaptic transmission) in injured nerves both acutely and later, during axonal regeneration or neuroma formation.

The nature of some nerve disorders is to selectively affect small-caliber afferent fibers; examples are neuropathies associated with diabetes and amyloidosis (see Chapter 82). This selective effect generates abnormal activity in nociceptor afferents, resulting in neuropathic pain. More commonly, the damage to the afferent fibers is not selective, Abnormal activity in non-nociccptivc tactile afferent fibers also may take on a painful quality that is distinct from or superimposed on the pain produced by nociceptor afferent activity. Synaptic plasticity in the dorsal horn and changes in neurotransmitter production by injured non-nociceptor afferents contribute to this phenomenon (Boiay and Moskowitz 2002). In these situations, pain is produced by activity generated in the peripheral nervous system. However, the failure of peripheral nerve blockade by nerve transection or local anesthetic infiltration to relieve chronic neuropathic pain syndromes indicates that the pain related to peripheral nerve injury or disease also has a central nervous system (CNS) component.

The mechanisms of central pain generation are becoming better understood through studies elucidating the anatomical and synaptic plasticity, biochemical alterations in neurotransmitter systems, and changes in neural systems that modulate nociceptive transmission. Sensitization of dorsal horn cells may result from high frequency stimulation by nociceptive afferents, a phenomenon described as "wind up." Wide dynamic range neurons become sensitized in this manner such that repeated activation triggers a progressively stronger response. Some of the biochemical mechanisms important in this process include the activation of NMDA receptors resulting in prolonged depolarizarion of the postsynaptic membrane. Under pathological conditions the process may become persistent. Intense afferent activity may also lead to release of excitatory amino acid neurotransmitters with resultant loss of local neurons resulting from neurotoxic effects. Sprouting of afferent terminals may also contribute to chronic sequelae.

Chronic pain syndromes resulting from peripheral nerve injuries and from CNS disorders rhat involve the sensory pathways probably share mechanistic central changes. The distribution and character of pain associated with central lesions differ somewhat from those of peripheral lesions. However, central pain is usually more diffuse and less well defined in distribution. It is also less likely to be lancinating in quality or associated with a trigger zone. Similarities of central and peripheral induced pain are as follows: (1) both are usually distributed in a region of impaired tactile perception, (2) tactile input takes on a painful quality (hyperpathia) out of proportion to the intensity of stimulus applied, and (3) the pain often has a highly emotive burning quality.

The clinical and conceptual overlap between central and peripheral neuropathic pain syndromes has led many investigators to lump both types of pain syndromes under the category of deafferentation pain. Tricyclic antidepressants and anticonvulsant drugs can relieve both types of deafferentation pain.

In addition to nociceptive and deafferentation mechanisms, efferent peripheral nervous system activity may contribute to chronic neuropathic pain syndromes. Abnormal activation of adjacent peripheral axons by electrical coupling (ephapses) is seen in animal models, but its contribution to pain generation in humans is difficult to estimate. A second postulated efferent mechanism of neuropathic pain is that of *sympathetically maintained pain.*

Efferent sympathetic activity, or overactivity, may be generated in the CNS or as a reflex response to peripheral stimuli. Electrical stimulation of efferent sympathetic fibers

in cats induces spontaneous discharges in non-nociceptive cutaneous mechanorcceptors with subsequent activation of neurons of wide dynamic range in the dorsal horn. This is a proposed mechanism by which efferent sympathetic activity sustains chronic pain subsequent to pain originally induced by trauma. This proposal complemented several clinical observations regarding chronic pain syndromes with neuropathic features, including the related conditions formerly known as *causalgia* and *reflex sympathetic dystrophy* (RSD), However, the importance of sympathetic activity in these pain syndromes has been questioned (Max and Gilron 1999). These disorders illustrate the evolving nature of the understanding of neuropathic pain mechanisms and the limitations that persist in the treatment of neuropathic pain.

Complex Regional Pain Syndromes

In the 1870s, Weir Mitchell characterized a syndrome of severe progressive distal limb pain with swelling, changes in color and temperature, atrophy, and loss of use. It was based on his observation of soldiers whose wounds had resulted in major nerve injuries. He termed the condition *causalgia.* A process with very similar clinical features that often follows minor trauma in the absence of major nerve trunk injury has been termed RSD, RSD is much more frequent than causalgia, especially in civilian practice. Numerous labels have been applied over the years. In recent years, a substantial change in the understanding of these disorders has occurred, and the nomenclature has been revised to avoid terminology that implies specific postulated mechanisms of pain production. The currently used terms are (1) complex regional pain syndrome (CRPS) type I (formerly RSD) and (2) CRPS type II (formerly causalgia).

Although no accepted standard exists for the diagnosis of these syndromes, the clinical criteria for the diagnosis of CPRS type I have been refined. In 1994 the International Association for the Study of Pain (IASP) proposed the following diagnostic criteria: (1) the presence of and initiating noxious event or cause of immobilization, (2) continuing pain, allodyma, or hyperalgesia with which the pain is disproportionate to any inciting event, (3) evidence at some time of edema, changes in blood flow, or abnormal pscudomotor activity in the region of pain, and (4) the absence of conditions that would otherwise account for the degree of pain and dysfunction (Reinders et al. 2002; van de Beek et al. 2002). The critctia are vague in many respects, and even with attempts to define more rigorous criteria for research purposes it remains uncertain that the criteria define a uniform population of patients (Harden et al. 1999). In addition, despite attempts at defining diagnostic criteria, the recent literature continues to show wide variation in their application (van de Beek et al. 2002).

These syndromes are three rimes more common in women than in men, and most patients are in early- to mid-adulthood. The primary feature of these syndromes is pain, usually in the distal part of a limb, with the hand being more frequently involved than the foot. The pain generally has neuropathic qualities (burning, allodynia, and hyperalgesia) that with time spread proximally to involve areas that are not identifiable as the distribution of a single peripheral nerve or dermatome. This tendency to spread is one of the most characteristic features of the syndrome and gave rise to the descriptive term *spreading neuralgia.* In cases associated with major nerve injury {CRPS type II), the pain begins within days and is severe from the start. In the more common CRPS type I, weeks or months may elapse between the inciting injury and the development of pain, which tends to progress more gradually. The pain is characteristically worsened by activity and by placing the affected limb in a dependent position. CRPS type I is estimated to occur after 7% or more of Colles' fractures, 1-2% of other fractures, and 2-5% of minor peripheral nerve injuries. It may also occur after myocardial infarction. No identifiable precipitant is found in up to 25% of cases. Rarely, a similar syndrome may affect cranial or axial structures.

In addition to neuropathic pain, other characteristics include the presence of edema; changes in skin temperature; hyperhidrosis; and trophic changes in the skin, muscles, and bone. These features led to the impression that abnormal sympathetic function was fundamental to the development of the syndrome, including the pain. The observation that regional sympathetic blockade, either by pharmacological or surgical means, produced dramatic pain relief for most patients added greatly to this mechanistic interpretation. Mam experts felt that a favorable response to regional sympathetic blockade established the diagnosis as RSD. The observation that efferent sympathetic activity can activate nociceptive cells of wule dynamic range in the dorsal horn by stimulating polymodal sensory affcrcnts provided a mechanistic explanation {e.g., sympathetically maintained pain) that unified the diverse features of this syndrome.

Although the explanation is conceptually appealing, further research and clinical experience has indicated that the understanding of these neuropathic pain syndromes is far from complete. Attempts to show that sympathetic activation worsens pain produced by capsaicin-induced C fiber activation in normal humans have been negative (Baron et al. 1999; Max and Gilron 1999). Furthermore, microneurography has not demonstrated excessive sympathetic output in most CRPS patients. Several place bo - controlled studies have shown that regional sympathetic blockade is not superior to placebo treatment. Furthermore, regional sympathetic blockade may affect visceral afferent nociceptive fibers associated with vascular or other visceral elements, and its efficacy may not be entirely a

reflection of sympathetic efferent modulation. It is likely that a small percentage of CPRS patients may have sympathetically maintained pain, but current evidence suggests that the pain is usually independent of sympathetic activity. This evolution in the mechanistic understanding of these syndromes has led to revisions in nomenclature in an attempt to remove mechanistic inferences such as *reflex* and *sympathetic* from the names,

These disorders are often chronic and result in disabling changes in the affected limb. Thus in a descriptive sense, the term *dystrophy* provides a useful concept for the chronic aspects of the CRPSs. The skin tends to become taut and glossy, with loss of subcutaneous fat and trophic changes in the nails. Demineralization of bone, typically in the hand, can be identified radiographically. Decreased range of motion, muscle atrophy, and weakness are common. Unusual hand postures develop in half of patients. Some of these are contractures, but many represent dystonia and, like other neurological symptoms, they tend to be progressive. Progressive sensory loss, including anesthesia dolorosa and progressive hyperalgesia, may occur. **These** motor and sensory phenomena are an indication of the remarkable CNS changes that contribute to the development of the CRPSs. However, some patients experience a self-limited process without the development of chronic dystrophic features,

The natural evolution of CPRSs continues to be debated. The traditional descriprion is a progressive disorder with three stages: acute, dystrophic, and atrophic. However, a self-limited form is also thought to occur. A prospective trial to examine the natural history of early CPRS of the hand, with treatment limited to limb elevation and analgesic and anti-inflammatory medications, suggested that pain and swelling resolved much faster than vasomotor instability and trophic changes (Zyluk 1998). At 6 months, pain and swelling persisted in less than one third of patients, whereas persistent discoloration, trophic changes, and temperature changes were present in 50%. At 13 months, only 15% had pain and swelling, whereas 30% showed persistent discoloration and trophic and temperature changes. Approximately 85% obtained full finger flexion at 13 months. Overall, 70% of patients had a good result, defined as pain free with full finger flexion. However, nearly two thirds of patients had a grip strength ratio (affected vs. normal hand) of less than 50% indicating that, despite symptomatic improvement, the likelihood of long-term functional impairment was high.

The treatment of the CRPSs is often only partially successful. Recent models of neuropathic pain that suggest an analogy with the kindling-like changes of repeated seizures add to the rationale for aggressive early treatment. A trial of regional sympathetic blockade is still recommended as part of the early management by many practitioners, usually with the inclusion of placebo trials. The dichotomy of opinion about the efficacy of regional sympathetic blockade is apparent when one considers that only a few years ago, response to this procedure was considered fundamental to the diagnosis. The literature contains many citations in which complete pain relief was obtained in more than 80% of patients. The long-term efficacy of sympathectomy for chronic neuropathic pain is relatively poor, with less than one third of patients achieving sustained relief.

Physical therapy and analgesics including nonsteroidal anti-inflammatory drugs (NSAIDs) and agents fot neuropathic pain such as gabapentin are **also** common in the early management of CRPS. Although opioid analgesics are often considered less effective for chronic neuropathic pain, they add substantially to pain control for some patients. For chronic neuropathic pain of high intensity and for other late complications, such as dystonia and contracture, other specialized methods may be used.

The efficacy of implanted spinal cord stimulators for chronic neuropathic pain syndromes has been demonstrated. A randomized, controlled trial of spinal cord stimulation for CRPS I suggests a decrease in intensity of pain for patients in whom standard thctapics including physical therapy, sympathetic blockade, transcutaneous electrical nerve stimulation (TENS), and analgesics were ineffective (Kemler et al. 2000). Spinal cord stimulation is accomplished by means of an implanted electrode in the epidural space near the spinal level associated with the most intense dysesthesia. After a trial with an external generator, the electrode is connected to a subcutaneous pulse generator situated in the anterior abdominal wall. Compared with physical therapy alone, electrical stimulation resulted in considerable improvement in pain at 6 months with an average reduction of 2.4 cm on a 10-cm visual analogue pain scale. Unfortunately, concurrent analgesic use and changes in analgesic use were nor reported. The complication rate approached 25%, largely related to electrode placement, but most were easily managed. Despite improvements in pain control and global rating of benefit, no improvement in functional status was observed.

Contracture and dystonia also contribute to the pain and disability of CRPS I. Intrathecal baclofen markedly reduce dystonia and improve function in the affected limb of patients with multifocal or generalized dystonia from CRPS I (van Hilten et al. 2002). Some patients improved dramatically, regaining normal hand function or ability to walk. Myoclonic jerks and muscle spasms may also improve.

Botulinum toxin is another approach to dystonia treatment in CRPS. In a small study of four patients with dystonic clenched fist, including one with bilateral involvement, all patients experienced pain improvement. One obtained complete finger extension with functional improvement and a second experienced postural improvemenr with repeated botulinum toxin injections (Cordivari etal. 2001).

Idiopathic and Psychogenic Pain

Pain that occurs without a definable cause of nociceptor activation or any mechanism of neuropathic generation often is categorized as idiopathic or psychogenic. The terms, however, are not synonymous; not all apparently idiopathic pain problems prove to be psychogenic. Still, with rigorous evaluation and ample follow-up observation, many patients with chronic pain lacking a defined cause have psychological factors that promote or sustain the pain problem. This is a heterogeneous group, both in terms of the nature of the pain complaint and the nature of the psychological processes involved.

For many people, recurring pain complaints are related to the stresses and anxieties of work, family relations, and other aspects of daily life. Tension headaches and fibromyalgia syndromes commonly fall into this category. The supposition that emotional tension, fatigue, and other factors produce nociceptive somatic pain secondary to muscle contraction is simplistic. Psychogenic factors are suspected when such complaints become a major focus of concern or disability far out of proportion to any evidence of nociceptive stimuli.

Identifying specific psychological or psychiatric problems that promote and sustain pain problems is important in determining therapeutic strategies **(Eisendrath** 1995). Patients with anxiety disorders and those with obsessive or other personality traits associated with somatization must be identified so that appropriate therapy can be undertaken. Conversion disorders also present ftequently with pain complaints, particularly headache. Chronic analgesic thetapy is of little benefit and, in some cases, may worsen the pain problem.

Unexplained pain is not a common presenting complaint of a ma]or psychiatric disorder. Occasionally, somatic delusions that include pain occur as part of depression and resolve with antidepressant therapy. Headache is the most frequent pain complaint in patients with depression. Conversely, depression is relatively common among chronic pain patients, and the severity of pain from minor injuries or other lesions is often magnified. Using stringent criteria, major depression is present in about 5-10% of chronic pain patients. The frequency may reach 50% or more when evidence of mild affective disorders is included. Among patients with schizophrenia, somatic delusions and hallucinations that primarily involve pain arc relatively rare. Chronic headache is the most common pain complaint in these patients.

Malingering is feigning illness, such as a chronic pain syndrome, for the purpose of obtaining an obvious, often tangible, secondary gain. Malingering patients are dramatically and demonstratively incapacitated by their symptoms. They tend to be uncooperative during examinations and noncompliant in therapeutic efforts. Frank malingering is relatively uncommon; for example, less than 5% of patients with chtonic back pain are thought to be malingerers. However, many patients embellish minor deficits, and many coincidentally receive secondary gains for being ill. Thus in physician surveys, the frequency of reported malingerers in chronic pain clinics varies greatly. As a poorly defined and uncommon entity, malingering should be considered a diagnosis of exclusion in chronic pain patients. The psychological factors that contribute to the chronic pain problems described previously should be identified as potential avenues of therapy.

The pathophysiological basis of psychogenic pain remains speculative, and multiple mechanisms are probably involved. The fact that nociceptive pain is so strongly influenced by anxiety and other psychological factors suggests that the overlap between centtal pain mechanisms and emotive mechanisms, particularly in regard to the opioid and aminergic systems, is important in the production of psychogenic pain.

APPROACH TO THE PATIENT WITH PAIN

This chapter and most discussions of pain management focus on symptomatic control of pain by pharmacological, surgical, and other means. Successful pain management always is based on a clear understanding of the pain's cause. This requires a history of the nature of the pain, a full accounting of medical history, and a physical examination that often includes a detailed neurological assessment. On this basis, a pain complaint can be characterized as nociceptive (somatic or visceral), neuropathic, psychogenic, or including a combination of these features. This characterization directs the subsequent evaluation of the patient and guides the choice of therapy.

Acute Pain

History

When characterizing a new pain complaint, the most useful features arc location, character, mode of onset, factors that aggravate and relieve pain, and concurrent features (e.g., fever, dyspnea, and nausea). The complaint that "pain radiates" may be a valuable indicator of referred or neuropathic pain. From these elements of the history, a working differential diagnosis usually can be formulated and then further evaluated by physical examination and laboratory studies.

Even during the initial interview, an assessment must be made of the relationship between the pain's severity and the patient's emotional response and attributed disability. This assessment is difficult because the experience of pain is intensely subjective and highly variable among people. It is easy to dismiss a pain complaint as minor if the patient is not wincing or grimacing or to consider the patient histrionic if the complaint is accompanied by dramatic

crying, writhing, or posturing. The physician is wise to accept the patient's report of pain severity unless overwhelming evidence to the contrary exists.

Prior medical problems often explain current pain syndromes; for example, diabetes may be associated with limb pain as the result of ischemia or peripheral neuropathy. A history of cancer suggests vertebral or epidural metastasis as the cause of progressive back pain. A remote history of trauma, neuritis, sciatica, or shingles, elicited only after careful inquiry, may be the basis for neuropathic pain syndromes. Depression and psychological factors that may contribute to the pain syndrome also must be explored.

Physical Examination

The initial examination is directed mainly by the stated location of pain. The physician searches for evidence of local inflammation to help locate the source of pain: tenderness; warmth; swelling; limited joint mobility; and signs of pleural, peritoneal, or meningeal irritation. Observations of subtle changes in posture (e.g., slight hip flexion in patients with pelvic abscess) are often helpful. Maneuvers that elicit or relieve pain should be duplicated. These include direct pressure, coughing or sneezing, joint flexion, straight-leg raising, reverse straight-leg raising, and nerve percussion (Tinel's sign).

Establishing the cause of a pain complaint often provides a mechanistic explanation of somatic or visceral nociceptive pain, neuropathic pain, or some combination of the three. An understanding of cause and mechanism allows the best opportunity to develop a rational treatment plan. The symptomatic relief of a new pain complaint when the cause is not clearly identified is a common pitfall that may lead to permanent tissue damage. For example, most patients with neurological symptoms resulting from spinal epidural metastasis have experienced back pain that was not fully evaluated for weeks or months. This is not to recommend withholding symptomatic therapy for severe pain while waiting for results of diagnostic tests but rather to perform an investigation that is thorough enough to establish a specific cause. When a specific cause (i.e., infection, fracture, tumor) of a new pain complaint is not established and the diagnosis of a benign or self-limited problem is entertained by exclusion, the management plan must include reassessment.

Even with rigorous investigation, however, the pathophysiological basis of many pain complaints cannot be defined. Most people experience transitory aching in muscles or joints and occasionally brief lancinating or sharp pains without a previous history of injury or other explanation. The self-limited and generally mild nature of a pain, identifies it as part of the normal repertoire of sensations. Such complaints can become self-perpetuating, as in analgesic-rebound headache, for which regular use of mild analgesics prolongs rather than terminates headache. The coexistence of unexplained pain complaints along with a history of bona fide medical illness (e.g., a history of diabetes or cancer) is common. It may be difficult to determine whether the pain is causally related to the preexisting illness. Often, this problem can be solved only with patience, repeated examinations, and clinical insight into whether or not the nature of the pain is appropriate in the context of the underlying illness. Attributing a new pain complaint to a psychiatric disorder requires the rigorous exclusion of other causes.

Chronic Pain

Pain that lasts months or longer without a defined cause and is of sufficient severity to interfere with normal daily activities is a relatively common and often difficult problem. Chronic, incapacitating pain may follow relatively minor trauma or even occur without prior trauma, as seen in patients with CRPS or RSD. Several CNS disorders can produce chronic pain syndromes that pose difficult diagnostic problems (e.g., multiple sclerosis, thalamic tumors, or infarcts). Most chronic pain patients do not have a definable disturbance that remains unidentified after prolonged observation. Psychological factors appear to predominate in many of these patients, and a pharmacological approach to management is rarely useful when used alone. Treatment in clinics that specialize in a multidisciplinary approach to pain control, including pharmacological, behavioral, and psychological management, is more likely to be successful.

Pharmacological Approaches to Pain Management

A systematic pharmacological approach to pain management has been espoused for cancer patients, a group with a high frequency of both acute and chronic pain syndromes, This escalating analgesic approach, advocated by the World Health Organization, is most applicable to the patient with a defined lesion producing persistent somatic nociceptive pain but also provides a rational approach to the treatment of many pain problems. The main points of this approach are (1) the titration of analgesics in relation to severity of pain, (2) the superiority of regularly scheduled dosing over "as-needed" dosing for persistent pain, and (3) the use of adjuvant medications whose actions are not primarily analgesic to improve the efficacy of the principal analgesics.

NSAIDs are used first. If pain control is not achieved, a low-potency opiate, adjuvant agents (e.g., tricyclics), or both are added. If pain persists, more potent opiate analgesics are used while continuing adjuvant agents. Alternate routes of analgesic administration {i.e., intravenous, epidural) and surgical approaches are reserved for specialized situations in which pain control cannot be achieved or maintained with the first steps of the approach.

Placebo Therapy and Pain Relief

The placebo effect contributes to the therapeutic benefit derived from many types of pain treatment. In general, 15-30% of patients enrolled in placebo-controlled trials respond to placebo, irrespective of the nature of the pain. The response rates in psychogenic and nociceptive pain are the same; therefore a placebo response is not a diagnostic test for psychogenic pain or malingering. Even relatively severe pain states, such as CRPSs, may improve substantially with placebo treatment. The efficacy of placebo is sufficiently reproducible that pain control studies often are thought to have a flawed study design if the frequency of response to placebo is less than 10%.

The mechanism of placebo action is probably central modulation of nociceptive input and alterations in other CNS functions, such as those associated with arousal and anxiety. Despite its efficacy, placebo therapy is often foregone because it appears deceptive and, more appropriately, because many analgesic drugs are more efficacious. Establishing the efficacy of certain treatments (e.g., a peripheral nerve or sympathetic blockade) in a given patient, however, requires the use of some placebo trials, in addition, placebo-controlled studies remain the standard for testing both pharmacological and nonpharmacological methods of pain control.

Nonopioid Analgesics

Nonopioid analgesics include acetaminophen and NSAIDs (e.g., salicylates, propionic acids [e.g., ibuprofen, naproxen sodium], and acetic acids [e.g., indomethacin, sulindac, and ketorolac)) (Table 50.2). As a group, these agents are indicated for mild-to-moderate nociceptive pain and arc particularly useful in the treatment of pain originating in bone and joints. They are generally less useful in the management of neuropathic pain syndromes. In addition to their analgesic action, NSAIDs arc anti-inflammatory and antipyretic. The predominant mechanism of action is probably inhibition of prostaglandin synthesis at the site of tissue injury, thus directly decreasing nociceptor stimulation. Although these agents have CNS effects (particularly antipyretic), it is unclear how much they contribute to the analgesic action, NSAIDs may be useful in combination with opiates for more severe pain. Unlike opioid use, NSAID use is not associated with tolerance or physical dependence. Also unlike opioids, progressive increments of NSAIDs beyond a certain dosage often fail to provide improved pain control (i.e., there is a "ceiling effect" to the analgesia produced by NSAIDs).

Acetaminophen has a 2- to 4-hour duration of action. A relative lack of gastrointestinal (GI) toxicity has led to its widespread use as an over-the-counter analgesic and antipyretic. Acetaminophen is a much less potent inhibitor of peripheral prostaglandin synthesis than aspirin or other NSAIDs and lacks clinically significant anti-inflammatory and antiplatelet effects. The mechanism of analgesia is not established but may be predominantly a CNS action. Formulations combining acetaminophen with mild opiates, such as codeine or oxycodone, have become widely used. Dose escalation with these formulations is limited by the risk of hepatic toxicity associated with the chronic use of acetaminophen in amounrs greater than 3-4 g per day. Severe and sometimes fatal hepatotoxicity may result from ingestion of more than 200 mg/kg at once.

Aspirin remains one of the most commonly used pain medications. The duration of action is generally 2-4 hours, although the plasma half-life increases significantly (threc- to fivefold) with increasing dosage. Despite the relatively common occurrence of nausea and GI irritation, many people tolerate chronic administration of *2-A* g per day, and it remains an important drug in the treatment of chronic inflammatory disorders, such as rheumatoid arthritis. Antiplatelet effects, resulting from irreversible inhibition of platelet cyclo-oxygcnasc, limit its use in patients with coagulopathies or thrombocytopenias, which often include cancer patients receiving chemotherapy. Choline magnesium trisalicylate, acetaminophen, and selective COX-2 inhibitors are notable for their lack of antiplatelet activity. The anticoagulant action of warfarin is accentuated by aspirin at high doses and by some of the other NSAIDs because of interference with plasma-protein binding and decreased metabolism. Other dose-dependent aspirin toxicities are tinnitus, vomiting, encephalopathy, and acidosis. Idiosyncratic reactions, notably acute asthma or anaphylaxis and Reye's syndrome, are the most serious adverse reactions but are relatively uncommon.

The propionic acid NSAIDs, ibuprofen and naproxen, are being used increasingly as short-term or as-needed analgesics for mild-to-moderate nociceptive pain; both are available in the United States without prescription. Ibuprofen has a relatively short half-life of 3-4 hours, whereas the longer half-life of naproxen (12 hours) makes it advantageous for persistent or chronic pain. GI toxicity is the main adverse effect limiting their use, although propionic acids are generally better tolerated than other NSAIDs. Ten percent to 15% of people taking ibuprofen discontinue the drug because of GI intolerance. Antiplatelet actions occur, but unlike aspirin the cyclo-oxygcnasc inhibition is reversible. The interaction of propionic acids with warfarin is usually insignificant. Uncommon adverse effects arc renal toxicity and aseptic meningitis.

The acetic acid NSAIDs, including indomethacin and sulindac, have been available longer than propionic acid NSAIDs. The half-life of indomethacin is variable, ranging from 2 to 11 hours. Sulindac is a prodrug whose major active metabolites have a half-life of 18 hours. The primary use of these NSAIDs is to treat chronic arthritis, such as rheumatoid arthritis and osteoarthritis. Acetic acid NSAIDs have a higher incidence of adverse effects than other NSAIDs; 20% of patients discontinue indomethacin because of toxicity. The main toxic effects are

Tabic 50.2: Selected nonopioid analgesics

Class	*Dnifi*	*Half-life (in hrs)*	*Dose range*	*Major toxicities*
Paraminophenol derivative	Acetaminophen	3	650-1000 mg q4-6h	Hcpatotoxicity with high doses
Salicylates (carboxylic acids)	Aspirin	0.5	650-1000 mg q4-6h	GI, including dyspepsia, gastritis, ulceration Increased bleeding time CNS toxicity at high doses Hypersensitivity reaction (may occur with all NSAIDs)
	Diflunisal (Dolobid)	13	500-750 mg ql2h	No antiplatelet effects GI toxicity less common than aspirin
	Choline magnesium trisal icy late (Trilisate)	215	1000-1500 mg q8-12h	No antiplatelet effects
Nonselective COX-1 and COX-2 inhibitors				
Propionic acids	Ibuprofcn (Motrin)		400-1000 mg q6-8h	GI toxicity, may be less common than with acetic acid NSAIDs Renal toxicity, particularly in combination with diuretics May aggravate hypertension CNS toxicities include dizziness, headache, drowsiness, fatigue
	roxen (Naprosyn)	14	250-500 mg ql2h	Similar to ibuprofen
Acetic acids	imethacin (Indocin)	45	25-50 mg q8-12h	GI toxicity CNS toxicity, particularly headache Renal toxicity, particularly with triamterene May produce hyperkalemia
	Sulindac (Clinoril)	**14**	150-200 mg ql2h	GI and CNS effects are less common than with indomethacin; may have less renal toxicity
	Ketorolac (Toradol)	**47**	15-30 mg IM or 10mgPOq6h	GI toxicity; for short-term therapy only
Enolic acid	Piroxicam (Feldene)	57	20-10 mg da ily	GI toxicity
Fenamic acid	Mefenamic acid (Meclomen)	2	100-250 mg q6-8h	For short-term use only; GI toxicity and diarrhea
COX-2 inhibitors				
	Celecoxib (Celebrex)	11	100-200 mg RID	No antiplatelet effects; possibly fewer GI side effects than nonselective COX-1 and COX-2 inhibitors
	Rofecoxib (Vioxx)	17	12.5-25 mg daily	No antiplatelet effects; possibly fewer GI side effects than nonselective COX-1 ,md COX-2 inhibitors
	Valdecoxib (Bextra)	8	10-20 mg daily	No antiplatelet effects; possibly fewer GI side effects than nonselective COX-1 and COX-2 inhibitors

CNS = central nervous system; GI = gastrointestinal; NSAIDs = nonsteroidal anti-inflammatory drugs.

GI discomfort, frontal headache, drowsiness, and dizziness, A third acetic acid NSAID is ketorolac, which can be administered orally or parenterally and has a half-life of 5-6 hours. It is one of the most potent NSAIDs, with an analgesic effect similar to morphine. It is not recommended for chronic therapy because of the risk of gastric ulceration.

Several other NSAIDs are available for analgesic and anti-inflammatory purposes. Piroxicam has an analgesic potency similar to aspirin but can be taken once daily

because it has a relatively long half-life and enterohepatic recirculation. The first dose of piroxicam and other long-duration NSAIDs may be double the recommended maintenance dose to increase the rate of onset of analgesia.

Selective COX-2 inhibitors have become an important addition to the NSAIDs in recent years. These are potent anti-inflammatory agents that also exert analgesic and antipyretic actions. They have relatively long half-lives and can be dosed once or twice daily. Osteoarthritis and rheumatoid arthritis are the principal pain indications. The toxicity profile is in many ways similar to that of nonselective COX-1 and COX-2 inhibiting NSAIDs with some important exceptions. Toxicity data indicates a smaller risk of gastric ulcers, although with prolonged therapy and at higher doses the differences in incidence may not be as great, and GI complaints remain an important part of their toxicity profile. The selective COX-2 inhibitors do not impair platelet aggregation.

The initial choice of an NSAID is based on the type of pain, the drug's toxicity profile in relation to the patient's underlying medical condition, the patient's prior experience with NSAIDs, and drug cost. For minor or self-limited somatic pain, the first choice should be a short-acting agent with a low likelihood of side effects, usually ibuprofen. For persistent or chronic pain, an agent with a longer half-life, such as naproxen, sulindac, or piroxicam, may be chosen to reduce the dosing frequency.

For many patients with chronic pain, serial trials of different agents are needed to determine the most effective NSAID. A 2-week trial is required to properly assess the response to a given dose. If pain control is inadequate and significant toxicity has not occurred, dose escalation is appropriate. The limiting dosage is determined by drug toxicity and the ceiling effect in regard to analgesia; for most NSAIDs, little additional analgesic effect is achieved by further escalation at the high end of the dose range (see Table 50.2). If one NSAID fails to relieve pain at a reasonable dose or is poorly tolerated, it should be replaced by another NSAID from a different chemical class. Failure to benefit from one NSAID does not predict the response to others. Therefore a working knowledge of one or two drugs from each class of NSAIDs is important.

Opioid Analgesics

Opioid analgesics differ from NSAIDs in their mechanism of action, pharmacological features of the analgesia produced, and toxicity profiles. These differences have led to the common approach of simultaneous administration of opioid and nonopioid analgesics, often in a combined formulation.

Opioids are divided into the mild and strong analgesics, based on their relative potency (Table 50.3). This distinction is somewhat arbitrary, and potency *per $e* is not a good indicator of efficacy. Codeine is the prototype of the mild opioid analgesics. The duration of action (2—4 hours} is similar to that of aspirin and acetaminophen. It is used for acute or persistent pain of moderate severity, generally when NSAIDs alone have proved ineffective or are contraindicated. Codeine works better for nociceptive than neuropathic pain. The impression that neuropathic and deafferentation pains are not responsive to opioids is incorrect; opioids are an important option for patients with refractory neuropathic pain syndromes. Nausea is one of the more common and limiting side effects of codeine. If it occurs, switching to a different opioid may relieve the problem. Autonomic side effects, particularly constipation, are sufficiently common that they should be anticipated by prescribing stool softeners. Dysphoria is another common side effect. Oxycodone, propoxyphene, and meperidine are other mild opioid analgesics. Meperidine is particularly likely to cause dysphoria or less commonly to cause myoclonus, encephalopathy, and seizures. These toxic effects result from metabolites that accumulate with repeated dosing. Meperidine therefore should be avoided in patients requiring chronic treatment.

Morphine and hydromorphone are the prototypes of high-potency opioid analgesics. Morphine has a relatively rapid onset, especially when administered pa renters lly and a short duration of action, about 2-4 hours. A sustained-release oral preparation (MS Contin) with a duration of action of 8-12 hours is useful for patients who require chronic therapy. High-potency opioids, like mild opioids, may cause nausea, constipation, and dysphoria. Sedation and respiratory depression also may occur. Tolerance (tachyphylaxis) to the side effects develops over 1-2 weeks. Tolerance also develops to the analgesic effects of opioids, but this is not always clinically significant, lor example, many patients with metastatic cancer who achieve good pain relief with opioids can be maintained on stable doses over prolonged periods. In these patients, recurrence of pain, particularly when rapid, is more commonly caused by tumor progression than by the loss of analgesic efficacy because of tolerance.

Chronic opioid use is associated with physical dependence, in which a typical pattern of symptoms develop after rapid withdrawal, including irritability, chills, salivation, diaphoresis, and abdominal discomfort with nausea and vomiting. The time course and severity are a function of the opioid's potency and half-life. The onset of withdrawal symptoms is approximately 6-12 hours after stopping treatment with morphine, as opposed to 36—48 hours for methadone. To avoid acute withdrawal symptoms and exacerbating pain symptoms, care must be taken in discontinuing opiates or switching from one opiate to another. The use of opioids with mixed agonist-antagonist properties, such as pentazocine, may precipitate withdrawal or lead to deteriorating pain control when substituted for a potent mu-receptor agonist, such as morphine. Similarly, the use of naloxone, a potent mu-rcccptor antagonist used to treat serious CNS toxicity, must be undertaken very

Table 50.3: Commonly used opioid analgesics

	Drug	*Half-life*	*Dose equianalgesk to morphine 10 mg IM*		*Typical dasage*	*Comments*
			IM	PO		
Mild						
	Codeine	3 hrs	120	200	30-60 mg PO q4-6h	Often coadministered with acetaminophen Nausea, constipation, and dysphoria common
	Oxycodone (+ acetaminophen = Percocet) (+ aspirin = Percodan)	2-3 hrs		30	5 mg PO q4-6h	Often useful when codeine is not well tolerated
	I [ydrocodoiie (+acetaminophen = Lortab or Vicodin)	4 hrs		30	2.5-7.5 mg PO q4-6h	Same as oxycodone
	Propoxyphene (Darvon)	6-12 hrs		150-200	65 mg PO q4h	Active metabolite (norpropoxyphene) with long half-life (30-36 hrs)
	Meperidine (Demerol)	2 hrs	75	300	50-100 mg IM	Encephalopathy, myoclonus, and seizures due to metabolite (normeperidine) limit chronic use Contra indicated in patients taking monoamine oxidase inhibitors
Strong						
	Morphine	2-3 hrs	10	30-60	2-10 mg IM/IV 30-60 mg POq4h	With chronic use the IM:PO ratio falls from 1:6 to 1:3 Available in slow release preparation (MS Contin)
	Hydromorphone (Dilaudid)	2-3 hrs	1.5	7,5	1-4 mg POq4h	Good choice for chronic therapy due to high potency and short half-life
	Pentazocine (Talwin)	2-3 hrs	60	180	50-100 mg PO q4h	Mixed agonist-antagonist Ceiling effect for analgesia May precipitate withdrawal in opioid-dependent patients Encephalopathy with dose escalation
	Methadone (Dolophine)	15-30 hrs	10	20	10-20 mg PO q4-8h	Duration of analgesia is highly variable, often only 4-K hrs Long half-life leads to drug accumulation and prolonged CNS toxicity
	Lcvorphanol (Levo-Dromoran)	12-16 hrs	2 mg IM	4 mg PO	2-4 mg PO q4h	Like methadone
	Fentanyl transdermal (Dnragesic)	3-12 hrs when given IV	*	*	25-100 ug/hr transdermal patch every 3 days	CNS toxicities like morphine Slow onser with peak concentration at 24-72 hrs Reservoir effect leads to prolonged toxicity Slow titration

CNS = central nervous system.
*Dosc equivalence is not well defined, but the ratio of fentanyl (transdermal) to parenteral morphine is approximately 1:30.

judiciously for chronic pain patients. Only respiratory depression should be treated with naloxone, and the required dosage is only one tenth of that used for an acute overdose.

The development of psychological dependence, or addictive behaviors, such as craving, drug seeking, and other maladaptive behaviors, is a concern for patients and physicians alike with regard to chronic opioid therapy. These concerns are heightened by the great impact of drug abuse in modern society, but they also may interfere with the delivery of effective and appropriate pain treatment. In cancer patients, for example, fear of developing dependence has contributed to the undertrcarment of pain syndromes. The actual risk of developing psychological dependence has been addressed in two types of studies. Studies of **drug** addicts in the first half of this century indicated that up to

10% of addicts first received narcotics for medical purposes. More recent studies analyzing the rate of development of psychological dependence in large populations of medical patients receiving narcotics indicate that the risk is less than 1 %. For the purpose of defining the rate of an adverse outcome, the more recent studies arc more informative. These results also support the current view that physical dependence and psychological dependence are distinct phenomena. Advances in the understanding of addiction including the neural and biochemical basis of reward systems in the brain suggest that genetic factors are important in the likelihood of developing addiction (Lingford-Hughes and Nutt 2003). Dopaminergic and glutaminergic actions in the nucleus accumbens are important in the development of addiction. Polymorphic variations in the endogenous opioids and opioid receptors are common, but their role in addiction remains unclear (Mayer and Holt 2001}. The risk of addiction is increased in patients with depression and personality disorders as a relatively common comorbidity. For these reasons the risk of addiction may be higher in patients with psychogenic pain syndromes as opposed to those with nociceptive or neuropathic pain. A prior history of drug abuse or other addictions also influences the risk of developing psychological dependence to prescribed medications. In practice, the principal adverse effects of chronic opiate therapy are dysphoria, nausea, autonomic effects, and the risk of withdrawal symptoms; however, prescribing practices and patient acceptance remain heavily influenced by the potential for psychological dependence and abuse.

As with NSAIDs, the initial choice of an opioid analgesic is empirical, based on the nature and severity of the pain, the potential side effects, and the individual's medication history. In most cases, a short-acting opioid is the initial choice. The most common regimen is to start with a mild-potency opioid analgesic, either codeine, hydrocodone or oxycodone, often combined with acetaminophen, on a 4- to 6-hour dosing schedule. For persistent and chronic pain symptoms, regularly scheduled (i.e., around-the-clock) dosing with supplemental dosing for breakthrough pain is more effective than as-needed dosing. The dose is escalated until pain is controlled or toxicities occur. Using short-acting opioids, titration can be achieved in hours to days, unlike using NSAIDs, which may require weeks. Incremental dosing changes of less than 25% seldom produce significantly improved pain control for patients on chronic opioid therapy. During initial titration, however, larger increments often produce nausea, dysphoria, or sedation. Unlike the NSAIDs, opioid analgesics do not have a ceiling effect, and patients with chronic pain taking opioid analgesics who are tolerant to the sedative and respiratory depressant effects occasionally require grams of morphine per day to maintain good pain control.

Rapid titration of opioids for severe pain is best achieved with parenteral administration. Inability to tolerate oral medications is another reason to use parenteral opioids. Repeated intravenous boluses may be used, although continuous intravenous infusion has certain advantages in terms of efficacy, toxicity (i.e., lack bolus effects), and ease of administration. A short-acting agent, such as morphine or hydromorphone, is preferable for parenteral thctapy. Aside from trauma and surgery, the need for parenteral opioids usually arises in patients with long-standing pain syndromes, such as metastatic bone lesions, who have been using oral opioids. Determining the correct parenteral dosage requires a change in dosage to compensate for differences in potency between drugs and for the difference in oral versus parenteral efficacy (see Table 50.3).

If a continuous intravenous infusion is chosen, the total opioid dose of the prior 24 hours is converted to the milligram equivalent of parenteral morphine, which, divided over 24 hours, becomes the basal hourly rate. A loading dose approximately equivalent to 1 hour's dose (up to 30 mg of morphine) is given as a bolus. If parenteral therapy involves switching from one opioid to another in a patient whose pain is well controlled, the newly calculated dose should be decreased by 25-50% because the efficacy and cross-tolerance between opioids are incomplete. If pain control has been poor, only a 25% reduction is made. In addition to a basal rate, as-needed doses for persistent or breakthrough pain should be administered, often accomplished by a patient-controlled delivery pump. In this way, rapid titration can be achieved by recalculating the hourly basal rate, based on the combined basal and as-needed requirements. For rapid titration, a bolus is given each time the basal rate is increased.

The need for rapid intravenous titration of opioids often arises in patients with advanced cancer. In this group and in all patients with chronic pain syndromes that become rapidly worse, symptomatic relief must be achieved concurrently with attempts to define the exact reasons that pain control is being lost. Treatment of the underlying process, such as a bone or epidural metastasis or abscess, remains one of the most important aspects of pain management. The judicious use of radiotherapy for painful metastases often reduces the need for analgesics.

The approach to the patient requiring moderate- to high-dose chronic opioid therapy has evolved considerably. Frequent doses of short-acting agents become impractical at high doses because of the large amounts of medication needed. Switching to a long-acting opioid, such as methadone, is an effective approach for some patients, although methadone's analgesic effect is often much shorter than its pharmacological half-life. In addition, titration must be done slowly to avoid excessive steady-state levels that cause prolonged sedation and other adverse reactions. Newer approaches are based on the use of short-acting agents formulated for relatively slow or prolonged release.

MS Contin, the sustained-release oral preparation of morphine, provides relatively stable serum levels of morphine that can be supplemented with standard oral morphine on an as-needed basis for breakthrough pain.

Titration, with initial dosing based on the milligram equivalent of morphine taken in the prior 24 hours, is relatively easy to accomplish, A slow release oxycodone preparation, Oxycontin, can he used similarly.

Transdermal fcntanyl is another approach to continuous, chronic opioid therapy. Fcntanyl is an extremely porent synthetic opioid agonist with a very short half-life when administered intravenously. The transdermal system delivers doses ranging from 25 to 100 pg per hour for 2-3 days through the development of a subcutaneous reservoir at the site of the transdermal patch. The continuous release provides the long duration of analgesia. Because of the reservoir effect, however, the attainment of effective analgesia is delayed 24—48 hours, titration must be performed over several days, and the management of adverse effects is complicated by the persistence of active blood levels for 2 or more days after the transdermal patch has been removed. As with MS Contin, most patients on fcntanyl require a short-acting opioid, such as morphine or hydromorphonc, for breakthrough pain.

With increasing opioid dosage, the adverse autonomic and CNS effects become dose limiting for many patients. This is particularly true of patients with CNS metastasis or those who are concurrently taking orher sedative-depressant medications. Several approaches are available for patients with poor pain control in the setting of significant opioid toxicity. One approach is to switch to an equally potent analgesic dose of a different opioid, recalling that cross-tolerance is incomplere and effective analgesia may be obtained with a modest decrease in the equivalent dose of a different opioid. In addition, optimizing the use of nonopioid analgesics and other adjuvanr medications may allow a decrease in opioid requirements. The addition ot methylphenidate (Ritalin) is another way of reducing drowsiness when that symptom limits dose escalation with chronic opioid treatment. If drowsiness or other opioid toxicities remain unacceptable, pain control is poor, or both, regional administration of opioids via intrathecal or epidural catheters and neurosurgical approaches to pain control should be considered.

Both epidural and intrathecal administration of morphine provide relatively high concentrations of opioids in the cerebrospinal fluid, producing analgesia by direct action on opiate receptors in the spinal cord. The amount of opioid reaching systemic circulation is usually considerably decreased. These approaches generally are limited to patients with pelvic or lower extremity pain. Side effects include pruritus, urinary retention, nausea, and vomiting. Respiratory depression and other CNS side effects (e.g., sedation, confusion) may occur. Factors that predispose patients to adverse reactions are advanced age, the use of water-soluble opioids (e.g., morphine), high intrathecal doses, the concurrent systemic administration of opioids or anesthetics, and lack of opioid tolerance. Unlike the administration of local anesthetics, epidural opioids rarely cause transitory weakness.

Adjuvant Medications Useful in Pain Management

Opioids and NSAIDs often are used together because their mechanisms of action are different and complementary, and their side-effect profiles do not overlap. The opioid requirements are reduced, as is the likelihood of clinically significant opioid tolerance or dependence. Several other drugs with primary actions that are not analgesic have been used to improve pain control, including anticonvulsants, tricyclic antidepressants, benzodiazepines, stimulants, corticosteroids, topical capsaicin, and anesthetics.

Anticonvulsants

Phenytoin, carbamazepine, gabapentin, and occasionally valproate are used to treat neuropathic pain syndromes, including focal (e.g., postherpetic neuralgia or trigeminal neuralgia) and diffuse neuropathies (e.g., diabetic neuropathy) (Backonja 2002; Kingery 1997). Controlled trials have demonstrated that gabapentin is superior to placebo and equivalent in efficacy to amitriptyline (Backonja et al. 1998; Morello et al. 1999; Rowbotham et al. 1998). Lancinating pains, presumably arising from abnormal neuronal discharge, respond best. Anticonvulsants are also useful for central deaf fere ntation pain syndromes. The dose required to achieve pain control is not necessarily the same as that required to produce therapeutic levels for anticonvulsant purposes, and gradual titration, usually over weeks, is required. Responses are difficult to predict, and serial trials often arc required in attempts to find an effective agent for these pain syndromes.

Tricyclic Antidepressants

Amitriptyline and several other tricyclic antidepressants improve pain control when used with other analgesics for nociceptive pain and when used alone for neuropathic pain syndromes. The analgesic effect is independent of the presence of depression or any effect on mood. Blockade of serotonin and norepinephrine reuptake is probably the mechanism by which analgesia is produced; however, rhe analgesic activity of newer and more selective serotonin reuptake inhibitors (e.g., fluoxetine) is not established. The commonly used tricyclic compounds all have considerable anticholinergic activity, and some of the common toxic effects, such as constipation, overlap with the autonomic side effects related to opioid analgesics.

Benzodiazepines and Baclofen

Diazepam and baclofen are useful in managing spasticity, which occasionally is accompanied by muscle pain. Baclofen is also beneficial in some patients with trigeminal neuralgia that is refractory to other drugs and may be beneficial for other neuropathic pain syndromes. For most patients, however, benzodiazepines add lirrle or no benefit

fot analgesic purposes but, rather, add significantly to the problems of sedation and dysphoria. Avoidance of CNS depressants is an important part of minimizing opioid toxicity.

Stimulants

Convctscly, the judicious use of stimulants can improve pain control and reduce opioid toxicities. For example, dextroamphetamine and methylphcnidatc enhance morphine-induced analgesia and reduce the sedation associated with opioid treatment. Caffeine also improves analgesia and reduces sedation from opioids.

Corticosteroids

Corticosteroids contribute substantially to pain control caused by (1) inflammatory lesions of bone, joints, muscle, or blood vessels; (2) nerve root or spinal cord compression, particularly in relation to epidural mass lesions; and (3) headaches from cerebral edema, elevated intracranial pressure, and meningeal irritation. Corticostctoids are the primary treatment lor some inflammatory conditions, such as temporal arteritis. Their use as an adjunct for pain control generally is limited to short-term treatment because of the niaiiv side effects associated with chronic therapy. Rheumatic pain complaints may follow cessation of corticosteroids.

Capsaicin

Topical capsaicin produces depletion of substance P from primary nociceptor afferents and provides satisfactory pain relief in more than 30% of patients with posthctpctic neuralgia for whom other medical treatments were unsuccessful. Unfortunately, initiation of treatment often causes severe burning pain that may prevent continuation of treatment.

Others

Several other drugs are used infrequently for refractory pain syndromes, usually neuropathic and deafferentation syndromes. These include anesthetic and antiarrhythmic agents, such as mexiletine; neuroleptics, such as flupbenazine, and a-adrenergic agents, such as clonidinc.

Nonpharmacological Approaches to Pain Management

Ablative Procedures

Regional Nerve Blockade. Nerve blocks with local anesthetics, such as lidocaine, commonly are used to manage transitory, severe, localized pain. Epidural blockade for obstetric and gynecological procedures is the most common application of a regional nerve block. Other uses are to treat postoperative incisional pain and delayed operative pain that may occur after thoracotomy. Epidural blockade is particularly useful when pain is localized to one or two dermatomal segments on the trunk. Localized neuropathic pain, such as with acute herpes zoster or traumatic neuroma, also can he controlled with nerve blocks.

Phenol can be injected to produce permanent neurolysis in patients with cancer who are expected to survive less than 1 year and in patients with intractable and severe pain who obtain significant relief with temporary nerve blockade. Burning, dysesthetic pain from deafferentation (anesthesia dolorosa) often develops months after neurolysis and may he more troublesome than the original pain complaint. The list' of temporary blockade and neurolysis is limited by their nonselective effect on all nerve fibers. Blockade of nerves to the limbs and sacral segments usually is avoided because sensory and motor deficits accompany analgesia.

Sympathetic blockade is an important component in the treatment of causalgia and related disorders. It usually is accomplished by serial blocks with local anesthetics and occasionally by neurolytic blockade. Pain relief may last long beyond the anesthetic agent's duration of action. Stellate ganglion blockade is performed for arm pain; celiac plexus blockade, for upper abdominal pain, such as that occurring with pancreatic cancer; and the lumbar sympathetic ganglia blockade, for pelvic, rectal, and leg pain. Fluoroscopic or computed tomographic guidance often is required for accurate injection placement.

Peripheral Surgical Approaches. The use of peripheral nerve and dorsal nerve root transection generally is confined to patients with well-localized or truly segmental truncal pain syndromes that have responded to nerve blockade. As with neurolysis, the late occurrence of painful dysesthesia is common and limits enthusiasm for this approach. Sympathetic ganglionectomy occasionally is performed in patients with causalgia and related syndromes who benefit transiently from sympathetic blockade.

Central Surgical Approaches. The most common central ablative surgical procedure for pain management is an anterolateral spinal cordotomy, producing transection of the latetal spinothalamic tract. As with other surgical procedures for pain management, strict criteria for patient selection—including failure of appropriate pharmacological means—must be established. Patients whose life expectancy is 12 months or longer generally are not appropriate because the analgesic benefit declines with time, and painful dysesthesia is a late complication. Thus the procedure is largely limited to patients with cancer. The best candidates are patients with unilateral somatic, nociceptive pain in one leg or the trunk. Visceral and neuropathic or deafferentation pain syndromes are not effectively controlled. Bilateral thoracic cordotomies sometimes are performed for midline lower abdominal, pelvic, or bilateral leg pain, but urinary and fecal incontinence are frequent complications. Initial

pain control is achieved in about 80% but lost in half after 6-12 months. Painful dysesthesia develops in 20% or more by 1 year. Corticospinal tract deficits are uncommon. In rare patients on very high doses of narcotics, the acute abolition of pain by surgical means or nerve blockade is accompanied by acute respiratory failure, which may be caused by an acute change in opioid tolerance and can be reversed with naloxone. Bilateral cervical cordotomies are associated with apnea resulting from the interruption of fibers subserving ventilation in about 5% of patients.

Other targets for ablative pain control procedures include the periaqueductal gray, trigeminal nucleus, thalamus, primary sensory cortex, frontal lobes, and portions of the limbic system such as the cingulate gyrus. Although few comparative data are available, no pain control procedure appears to be superior to cordotomy for pain syndromes originating below the cervical level. Analgesia tends to be transitory, and late dysesthesia is common to all procedures involving the spinothalamic tract, the thalamus, and its primary sensory projections. Destructive lesions in the cingulate gyrus interfere with the emotional experience associated with chronic pain without producing analgesia.

Another procedure used primarily to treat pain from disseminated bone metastases of hormonally sensitive cancers (i.e., breast and prostatic carcinoma) is pituitary ablation, which usually is performed by alcohol instillation via a transsphenoidal approach.

Modulating Procedures

The concept that nociceptive input can be reduced by peripheral stimulation is fundamental to the gate theory of pain transmission. In practice, this is accomplished most often by electrical stimulation using TENS. Placebo effect contributes substantially to the analgesic efficacy of TENS, although some studies of acute pain syndromes, such as postoperative pain, indicate benefit greater than obtained with sham stimulation. TENS also is used for chronic pain syndromes, particularly neuropathic pain, although studies have provided mixed results. Although some controlled studies demonstrate benefit, a randomized comparison between TENS and exercise for chronic lumbosacral pain demonstrated no difference between TENS treatment and placebo. The combination of percutaneous electrical stimulation using acupuncture-like needles for electrodes (PENS) was compared in a randomized trial with TENS, simple exercises, and a sham procedure for patients with chronic low back pain. PENS was associated with a reduction in analgesic usage, improved physical activity, and improved sense of well-being (Ghoname et al. 1999). Additional controlled trials arc needed to define the role ot these methods in acute and chronic pain management; however, it is clear that some patients obtain substantial improvement from these nonpharmacological approaches.

Stimulation of dorsal root fibers and the dorsal columns using epidural electrodes has been performed for 20 years. Clear indications arc debated but generally include (1) poor efficacy of standard medical therapy; (2) an identified cause for the pain syndrome, usually with a neuropathic component and without a primary central cause of deafferentation; and (3) a dermatomal distribution of pain that can be effectively included in a region of stimulation-induced paresthesias. Areas that are difficult to cover include the C2 vertebra; posterior axial structures, including the neck and lumbosacral spine; and the perineum. An array of electrodes, usually on a single wire, is inserted in the dorsal epidural space cither by laminectomy or percutaneously in the low- or midthoracic region. A trial period of 4-7 days of stimulation is performed to assess pain relief. If benefit is observed, the electrodes are permanently implanted.

Most series are dominated by patients with chronic lumbosacral pain after laminectomy, the so-called failed back syndrome, which is often attributed to arachnoiditis. Next most common are patients with other neuropathic pain syndromes, such as neuropathies. Fifty percent to 70% of patients show initial improvement. Long-term pain relief occurs in 40%, however, and many continue to require some analgesic medication. Mechanical problems, such as electrode breakage, have been a common cause of failure. Although these results appear hopeful, given the chronic, refractory nature of the pain syndromes addressed, prospective studies with carefully focused indications and rigorous follow-up assessment are required. One such study, a controlled trial of epidural stimulation and physical therapy versus physical therapy alone for patients with CRPS, did demonstrate a substantial reduction in pain intensity with epidural stimulation. However, no improvement in functional status was observed (Kemler et al. 2000).

Stimulation of the periaqueductal gray and primary nuclei of termination of the spinothalamic and trigeminothalamic pathways (i.e., ventral posterolateral and ventral posteromedial nuclei, respectively) has been employed for chronic neuropathic pain syndromes, including many with deafferentation components. Tic douloureux, postherpetic neuralgia involving the face, pain after cerebral infarction, postcordotomy pain, and brachial plexus avulsion have been approached in this way. As with spinal cord stimulation of the patients who have a good initial response, only about 50% report long-term benefit. Other areas used for pain control by neurostimutation include the motor cortex and the septal area. Lacking well-defined indications and controlled trials with rigorous assessment of outcome, central neurostimulation for chronic pain is an optional treatment for those whom medical therapy does not help.

CONCLUSION

Pain, the most common of all medical complaints, is becoming increasingly well understood. It is a complex

group of neurophysiologies! processes that may arise from (1) the normal response of the nervous system to tissue injury; (2) pathological alterations in neural activity in nociceptive, sensory, and other pathways; or (3) no identifiable pathology. In practice, treatmenr is based on defining the mechanisms by which the pain symptom is generated. A relatively high likelihood of therapeutic success is achieved in the case of nociceptive pain, but only a modest rate of success is obtained in the treatment of neuropathic and idiopathic pain syndromes. The understanding of pain mechanisms, both in terms of basic science and as clinical phenomena, remains incomplete. Nonetheless, this mechanistic approach is central to formulating a rational therapeutic strategy. Treatment applied without an understanding of the mechanisms involved has a high likelihood of failure, unnecessary toxicity, and potential for irreversible tissue injury.

The goal of pain management is complete pain relief. Too often, pain relief is not pursued aggressively, so that the symptom can he used as an indicator of disease activity (e.g., in patients with cancer). In comparison with the array of other clinical, laboratory, and radiographic measures of disease activity available for neoplastic, infectious, and inflammatory diseases, progressive pain as an isolated symptom is generally a moderately sensitive and modestly to moderately specific indicator of disease activity. Thus using pain as an indicator should be considered secondary to relief of the symptom, assuming that the cause of the pain is understood. The most significant factor limiting complete relief of nociceptive and neuropathic pain is analgesic toxicity. Much of pain management beyond knowledge of basic analgesic pharmacology centers on this issue.

Another reason to treat both acute and chronic pain aggressively is that for some patients intense or recurring pain leads to chronic changes in the nervous system. It is likely that these changes contribute to the development of some chronic pain syndromes. Similarities between pain and epilepsy in this regard have been pointed out recently. Some of rhe neurophysiological and neurochemical changes that underlie epilepsy are operative in the genesis of chronic neuropathic pain disorders including kindling-related phenomena, inherited and acquired membrane ion channel abnormalities, and excitatory amino acid-related neuronal injury (Post 2002).

Pain management has improved significantly as the result of systematic education programs for medical students, house officers, fellows, physicians, and other health care providers about pain assessment and the basic principles of analgesic therapy (see recommendations of the American Pain Society Quality of Care Committee 1995). However, pain management training in neurology residencies tends to be very limited, and a large majority of practicing neurologists report being inadequately trained in this area (Galer et al. 1999).

Advances in pain management also have been fueled by important basic neuroscience developments, such as the elucidation of the endogenous opioid systems, and increasingly sophisticated clinical analysis of pain syndromes. Clinical necessity will continue to fuel the development of better ways to treat patients with pain.

Chapter 51
Principles of Neurointensive Care

Eliahu S. Feen, Osama O. Zaidat, and Jose I. Suarez

A neurointensivist is a physician with special training in caring for critically ill patients. There are child neurologists with this specialization for children and adult neurologists who care for adolescent, adult, and geriatric neurology and neurosurgery patients. This chapter concentrates on the adult population. Such patients require specialized intensive nursing and medical care in modern specialized Neurosciences Critical Care Units (NSUs). The creation of NSUs stemmed from the realization that neurocritically ill patients have special and different needs, which can only be met by a team of physicians and nurses acutely aware of the interactions between systemic and central nervous system (CNS) alterations.

Neurologists and neurosurgeons have been involved in providing critical care since the beginning of the twentieth century. During the polio epidemics neurologists became the primary caregivers for affected patients, including critical care administration. However, the advent of massive vaccination campaigns and eventual eradication of poliomyelitis in developed countries led to a decline in clinical ncuroscicntists' participation in critical care delivery. This was followed by the birth of general critical care units in the 1960s to care for patients with acute and complex respiratory and cardiovascular issues. These units were mostly direcred by physicians with internal medicine training. A notable and important exception was Dr. David Jackson, a neurologist at the University Hospitals of Cleveland (Case Western Reserve University), who took an active part in and eventually became the director of a general medical intensive care unit in the 1970s. He can certainly be credited with being the first practitioner to have demonstrated that clinical neuroscientists can effectively care for critically ill patients. However, the resurgence of NSUs proper can be traced to the beginning of the 1980s when a few NSUs were set up at major academic centers in the United States. These units were directed by physicians, who were double-boarded in neurology and internal medicine. By the mid 1980s and early 1990s neurosurgical techniques and neuromoniroring devices had furrher advanced allowing for better management of complex neurocritically ill patients.

The establishment of NSUs brought along the need for a critical care subspecialty made up of intensivists from different medical and surgical backgrounds who had a keen interest in affecting the neurological outcome of patients. This subspecialty has been called *neuracritical care* or *critical care neurology and neurosurgery,* and the specialist is a *neurointensivist.* The role of the neuroinrensivist primarily involves caring for and the management of cririeally ill neurological and neurosurgical patients and discussing their clinical condition and prognosis with family members. They also actively participate in the teaching and training of medical and nursing staff, consult in other critical care areas to prognosticate on neurological outcome and to determine brain death, and participate in institutional critical care committees to develop and monitor policies pertaining to neurocritical care.

This chapter discusses the basic principles of neurocritical care as it is delivered in the United States. We will present general principles of NSU organization, neuromoniroring, and general management of neurocritically ill patients. It concludes with descriptions of the most common neurological conditions, emphasizing management in the NSU. Because of the complexity of the topic, a detailed presentation of netirocririeal care is beyond rhe scope of this chapter.

ORGANIZATION OF A NEUROSCIENCES CRITICAL CARE UNIT

NSU care is expensive and resources are scarce. Therefore appropriate selection of patients is important. In general, patients admitted to the NSU should include those that are likely to benefit from this level of care. This implies that those patients who are not sick enough to warrant critical care or who have catastrophic conditions that result in impending death may not be good candidates for admission to NSU. The Society of Critical Care Medicine has provided guidelines for admission criteria to an ICU (Task Force of the American College of Critical Care Medicine 1999). However, we should emphasize that no definite data are available to validate the utility of such criteria. Therefore neurointensivists should create policies and mission statements specific to each hospital and level of expertise available.

In general, we have determined at the University Hospitals of Cleveland at Case Western Reserve University that patients admitted to NSUs, regardless of the underlying pathology, should fall into one or more of the following broad categories:

1. Being at risk of serious event as a result of the disease process
2. Requiring highly specialized and concentrated nursing and medical care
3. Requiring specific and unique interventions or techniques not appropriate or not available for use on the other in-patient divisions

Table 51.1 presents a summary of admission criteria as they are currently maintained in our NSU.

Upon arrival at the NSU patients are treated and monitored for any signs of either medical or neurological instability. Once such signs arc deemed stable, patients are usually discharged from the NSU to a less intensive environment for continued care (see Table 51.1). A clear and detailed plan of such continued care must be outlined and discussed with the primary neurological or neurosurgical teams to minimize the number of further complications and readmissions.

The other important aspects are the environment and physical appearance of the NSU. The Society of Critical Care Medicine has put forth recommendations for ICU design that should also be observed when planning an NSU (Task force on Guidelines Society ot Critical ("are Medicine 1988; American College of Critical Care Medicine 1999). These arc suminarized in Tabic 51.2, A physician NSU director is required. The director ideally should be a neurointensivist who will be heavily involved in the care of patients, the administrative aspects of the NSU, and development and implementation of educational activities for both medical and nursing staff. Other neurointensivists can also participate in the overall organization of the NSU under the guidance of the director. A nurse manager should be appointed to help with management of the delivery of the highest-quality care possible. This nurse manager should have both RN and MSN degrees and have the ability to foster cooperation and participate in all administrative and academic activities in the NSU. The best care is provided when an atmosphere of cooperation and camaraderie is achieved by all participating health care providers.

Table 51.1: Summary of NSU admission and discharge criteria as they are enforced in our institution

Admission criteria
Acute respiratory failure
Hemodynamic instability
Hypertensive crisis
Massive gastrointestinal bleeding
Drug overdose
Metabolic emergencies (severe hyperkalemia; hypercalcemia; acute hyponatremia; addisonian crisis; diabetic ketoacidosis; or hyperosmolar states)
Coma of any etiology in need of intensive care
Status epileptic us
Cranio-spinal post-operative patient, including endovascular procedures
Untreated cranio-spinal mass effect
Acute ischemic stroke undergoing thrombolysis
Intracranial hemorrhage
Acute, treatable, or diagnostically uncertain unstable neuromuscular disease
Critical, reversible cerebral ischemia
Severe traumatic head and spinal cord injury
Need for external ventricular drainage or neutornonitoring that can only be provided in the NSU
Discharge criteria
Respiratory stability[7]
Hemodynamic stability
Neurologic system and signs are without unexpected change
Nursing needs that can be met in less intensive environment
Terminal illnesses in whom NSU care has been deemed inappropriate

NEUROLOGICAL AND SYSTEMIC MONITORING

The most important and simplest form of monitoring in the NSU is the serial neurological examination, which can be performed by nursing staff and physicians. Despite its importance, a carefully performed neurological exam in neurocritical care has limitations. These include limitation of neurological assessment by pharmacological interventions (e.g., neuromuscular blockade, propofol or midazolam sedation, or barbiturate coma); difficulty with recognizing certain pathological conditions (e.g., nonconvulsive status epilepticus, vasospasm, early increased intracranial prcs sure |ICP| or cerebral reactive hyperemia); interobserver variability (i.e., the neurological exam is quite operator-dependent); qualitative rather than quantitative assessment (e.g., an impression of elevated 1CP may be accurate yet it

Table 51.2: Guidelines for NSU design and organization

Physical appearance
Floor plan should be designed by a multidisciplinary team (NSU director, RN manager, architects, administrators, and engineers)
Patient bed area should have ample space and provide a supportive environment
Patient bed area should provide for direct or indirect visualization of patients to facilitate detection of patients' status
Necessary equipment to support the needs of the patients and the NSU medical and nursing personnel should be available and meet regulatory requirements
All physiological continuous monitoring should be available (display of waveforms and digital values for cardiac, arterial, venous, intracardiac, and intracranial pressures and respiratory monitoring)
Computer applications should be available for data input, retrieval, and analysis
Isolation rooms should be installed
Work areas and storage of critical care data and supplies should easily accessible to the staff
Separate clean and dirty utility rooms with separate access doors should be available
A staff lounge with toilet facilities should be provided
A nourishment preparation area should be provided
A conference room should be available
A visitor's lounge should be provided near the NSU
Transportation of patients to and From the unit should be easily-carried out
Physician on-call room should be next to the NSU
Neurocritical Care Personnel
A physician NSU direcror
Other neurointensivists
A nurse manager
Other nursing staff with special training in neurocritical care
Twenty-four hour in-house coverage by medical staff
Physician subspecia lists available for consults
Rcspitatory therapists at all times
Pharmacy services at all tunes
Other personnel: unit clerks, physical and occupational therapists, pastoral care specialists, social workers, dietary specialists, and biomedical en gin nee rs
A clinical laboratory available 24-hours a day with tapid transport systems

cannot quantify the severity of the elevation); and finally the tendency to recognize problems after they have occurred rather than foreseeing them. Different monitoring techniques are currently used to complement the neurological examination in the neurocritically ill patient. These include systemic and brain monitoring methods. The latter methods are capable of providing information regarding whole or regional brain functions, as is discussed later. Despite the availability of multiple monitoring modalities, there is not enough literature to support the use of one over the others. In fact, the current trend is for neurointensivists to use so-called "multi-modality neuromonitoring," which involves combining several systemic and brain monitoring techniques in the hope of achieving the best possible neurological outcome (Kirkpatrick, Czosnyka, and Pickard *1996;* Andrews 2000; Alvarez del Castillo 2001).

Nonbrain Monitoring

Systemic or nonbrain monitoring comprises continuous or intermittent measurement of arterial blood pressure (ABP), core body temperature (T), and arterial blood oxygenation iZimmerman and Dcllinger 1996; Cnuliano et al. 2000: Fallis 2000). Continuous ABP monitoring is preferred and is easily accomplished by the insertion of an indwelling cannula into a medium caliber artery, which allows for a visual display of arterial waveforms. Such continuous monitoring is very important to ensure proper ABP management in the NSU. The most common examples of benefits include avoiding lowering ABP, which may exacerbate ischemic injury in patients with acute ischemic stroke; controlling excessive elevations of ABP, which may lead to hematoma expansion in patients with intracranial hemorrhage (ICH) or may increase the risk of ICH following thrombolysis for acute ischemic stroke; guiding induced hypertension in patients with vasospasm after subarachnoid hemorrhage (SAH) and in those with critical vascular stenosis; helping to control ABP in patients at risk for autonomic instability (e.g., G-uillain-Barre syndrome [GBS]) and septic shock (e.g., bacterial septicemia or meningitis); and maintaining adequate cerebral perfusion pressure (CPP) in patients with elevated ICP.

The main purpose of T monitoring in the NSU is twofold: detection of hyperthermia in patients with systemic or brain infections, and maintenance of normothermia or hypothermia to protect the brain from further insult (Busto and Ginsberg 1998). The most accurate way to measure T is via recordings from a pulmonary artery catheter (PAC) thermistor. However, this method is invasive and can only be carried out in those patients with specific indications for PAC insertion. More practical approaches include oral and tympanic methods. **The** former appears to be more reliable, less subjected to operator variability, and may be useful even in patients with endotracheal tube placement. Bladder and rectal probes correlate well with PAC thermistor readings. Their main drawback is that there is a lag between T change detection by PAC thermistor and bladder probe, which may delay interventions.

Continuous arterial blood gas determination has undergone significant refinement in the past few years. Newer intra-arterial fiberoptic catheters are capable of providing reliable measurements of pH, PaOz, Paco2. This allows for early detection of abnormalities and prompt recognition and intervention.

Brain Monitoring

Brain monitoring techniques have been developed and refined over the past twenty years to include a variety of methods that are available for use in the NSU. These techniques are divided into two main categories: whole- and

regional-brain monitoring. Whole-brain monitoring techniques measure ICP, electrical potentials, and venous oxygen saturation. Regional-brain monitoring focuses on cerebral blood flow (CBK), cerebral blood flow velocities (CBFV), brain tissue metabolism, and oxygenation.

Whole-Brain Monitoring

Intracranial Pressure Monitoring. The Monro-Kellie Doctrine, one of the most basic principles of intracranial physiology, states that as a result of the rigid skull the intracranial space represents a fixed volume, and that an increase in the volume of any of its three constituent compartments (brain, CSF, blood) must be met by a corresponding decrease in the volume of other compartments or ICP will rise. This is clinically relevant in brain matter herniation from an expanding lesion and in the use of hyperventilation to reduce the volume of the blood compartment in elevated ICP states. Normal mean ICP is less than 10 mm Hg, and levels exceeding 15 mm Hg are generally considered abnormally elevated. However, it has been suggested that levels greater than 20 mm Hg for at least 2 minutes be used as a treatment threshold. CPP is telatcd to ICP and to mean arterial pressure (MAP) by the equation: CPP—MAP — ICP. Thus assuming a relatively constant MAP, an elevation of ICP will be paralleled by a reduction of CPP. It has also been argued that the main purpose of ICP monitoring is maintenance of normal CPP {normal >70 mm Hg), because the lattet may be more telatcd to secondary ischemic injury (Rosner 1993).

ICP is pulsatile and has systolic and diastolic components (Lang and Chestnut 1994). In addition to the value of mean ICP, these components also need to be evaluated carefully. The normal ICP waveform consists of a 3-pcakcd wave (Figure 51.1). PI, the first and generally the tallest peak, is also known as the percussion wave and corresponds to the transmitted systolic blood ptcssure. P2 (the tidal wave) and P3 (the dictotic wave) are normally smaller peaks, and the notch between them corresponds to the dicrotic notch of the arterial waveform. As ICP increases, P2 and P3 rise to the level of and then surpass PI, and ultimately with continued elevation of ICP the waveform loses distinct peaks and assumes a triangular morphology. During pathologic states of sustained elevations of ICP, the so-called "plateau wave (or A-wave) of Lundberg" can be observed. This A-wave has a plateau motphology that reflects a sudden dramatic sustained elevation in ICP to levels of 50-100 mm Hg. Plateau waves indicate critically low intracranial compliance, such that vety minor variations in intracranial volume result in marked changes in ICP.

Since the 1950s several ICP monitoring devices have been marketed. These include intraventricular, epidural, subarachnoid, and inttaparenchymal fiberoptic catheters

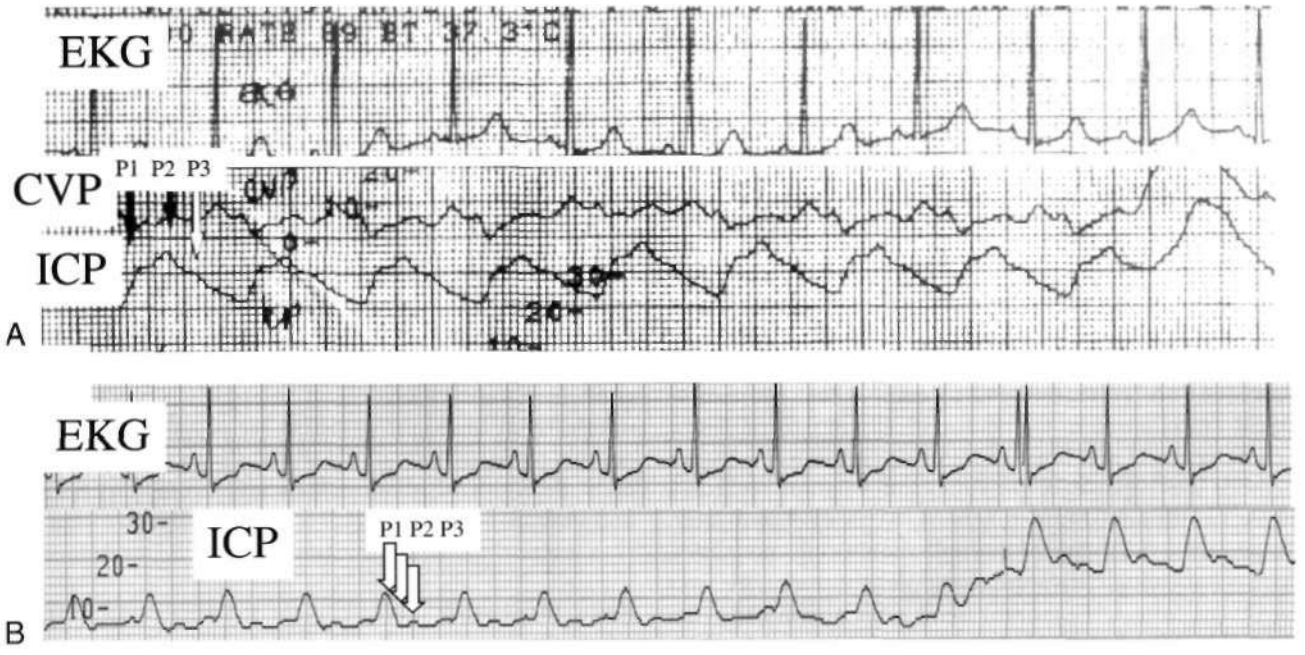

FIGURE 51.1 (A) A composite tracing of systemic and cerebral hemodynamic waveforms shows the electrocardiogram (ECG), central venous pressure (CVP), arterial blood pressure, ."id intracranial pressure (ICP). The PI, P2, and P3 waves of the ICP are outlined. P2 is equal to or higher than PI in this patient with an elevated ICP of 22 mm Hg. (B) Normal ICP with PI higher than P2, which is buried in the downslope of PI.

("Recommendations for intracranial pressure monitoring technology" 2000). A thorough review of these devices is beyond the scope of this chapter. However, in general the intraventricular cathetets remain the gold standard but are associated with the highest rate of infectious and mechanical complications. The most common indications for ICP monitoring in patienrs after traumatic head injury include patients in coma (Glasgow Coma Score [GCS| of 8 or less) with an abnormal head computed tomography (CT) findings; patients in coma with a normal head CT findings but at least two other risk factors for elevated ICP (age older than 40, abnormal posturing to pain, systolic blood pressure [BP] under 90 mmHg); and other head-injured patients at the physician's discretion (American Association of Neurological Surgeons, Joint Section on Neurotrauma and Critical Care 2000). In general, NSU patients with hemispheric processes associated with midline shift and depressed consciousness should also be considered for ICP monitoring,

Jugular Bulb Oximetry, Jugular bulb oximetry measures the oxygen saturation of venous return from the brain (normal >50%) (Feldman and Robertson 1997; Robertson et al. 1989; Cruz ct al. 1991). The fundamental goal of jugular venous oxygen saturation ($Sjv0_2$) monitoring is to provide a continuous index of the changing balance between cerebral oxygen delivery and cerebral oxygen consumption or metabolic requirement. Simultaneous determination of SjvOi using the jugular bulb catheter and arterial oxygen saturation (Sao_2) allows for the calculation of the intracranial arteriovenous oxygen difference (AVDO2) (normal 24^42%). From this parameter cerebral o\yju'ii con si 1111 prion :.ilso ruicn'cd to as cerebral metabolic rate) can be calculated as the product of $AVD0_2$ and CBE. The cerebral oxygen extraction rate (0_2ER) can then be derived as the ratio of cerebral oxygen consumption to cerebral oxygen delivery.

Indications for $Sjv0_2$ monitoring in the NSU have included head injury particularly but also include SAH, cere lira 1 infarction, and perioperative monitoring for various intracranial procedures. Advantages of the jugular bulb catheter as a monitoring modality include the practicality of continuous bedside monitoring, the capability to confirm the oximeter by drawing blood through the catheter, and the numerous physiological parameters that can be derived from the $Sjv0_2$ to arrive at a picture of cerebral oxygen balance. Disadvantages of the catheter include its susceptibility to artifacts of positioning and its invasiveness (Latronico et al. 2000).

Electrophysiological Monitoring: Electroencephalography and Evoked Potentials. The use of electroencephalography (EEG) in the NSU setting has dramatically affected patient care. This section discusses its salient applications relevant to the care of the neurocritically ill patient. Readers are referred to an excellent review by Jordan (1995) delineating the use of EEG as a monitoring tool. The utilization of continuous EFG monitoring is based on four major neurobiological rationales: (1) its close relationship to cerebral metabolic rate; (2) its sensitivity in detecting hypoxic-ischemic neuronal dysfunction at an early stage; (3) its obvious primacy as a monitor of seizure activity; and (4) its value in cerebral localization. Thus continuous EEG has been advocated as another routine tool for all NSU patients.

Despite the fact that the technical aspects of EEG application in the NSU do not differ greatly from the standard outpatient EEG, some factors arc relatively unique to the NSU setting. The main differences are the abundance of artifact sources (ventilators, intravenous pumps, dialysis pumps, other electrical machinery, suctioning) and the inability of the patient to cooperate secondary to various degrees of encephalopathy.

The most common indication for EEG monitoring includes generalized convulsive status epilepticus (GCSE) because the clinical ascertainment of ongoing seizure activity is often obliterated by the administration of various sedatives and analgesics in the NSU. Once such ongoing seizures arc found, the EEG becomes essential for monitoring the effects of further aggressive management, including the administration of barbiturates or general anesthetics to achieve a burst-suppression pattern. Detection of nonconvulsive seizures and nonconvulsive status epilepticus (NGSE) is equally important and can only be accomplished by EEG monitoring (Young, Jordan, and Doig 1996). Continuous EEG monitoring has revealed nonconvulsive seizures in *35%* of NSU patients in one study with a 76% incidence of NCSE. Other applications of continuous EEG monitoring, especially in patients in coma, include confirmation of metabolic encephalopathy, psychogenic unresponsiveness, locked-in state, and brain death (Diringer 1992; Synek 1988; Wijdicks 1995).

Evoked potentials have a more restricted role in the NSU (Moulton, Brown, and Konasiewicz 1998). The median nerve somatosensory evoked potential (SEP) has been mostly used. The technical details are discussed in Chapter 36A. Bilateral absence of the N20-P22 response has been associated with poor prognosis in coma in several studies, generally indicating outcome no better than a persistent vegetative state. SEPs, like EEG, have also been proposed as a confirmatory test to support a clinical diagnosis of brain death, again based on bilateral absence of the N20-P22 response.

Regional'/Focal-Brain Monitoring

Transcranial Dopplcr Ultrasonography, Transcranial Doppler ulttasouography (TCD) is a noninvasive technique to evaluate the mean cerebral blood flow velocity (MCBFV) in the large intracranial arteries. TCD can easily be done at the bedside (Manno 1997). TCD takes advantage of the principles of ultrasound and Doppler shift to image

erythrocyte flow in the basal cerebral arteries. This allows the operator to determine the presence or absence, velocity (systolic, diastolic, and mean), and direction of blood flow. The graphic waveform depicted on the screen will indicate depth of insonation, MCBFV, angle of insonation, and the so-called "pulsatility index" (PI). The latter is calculated as peak velocity minus end diastolic velociry divided by mean velocity and represents downstream resistance such as that found during ICP elevations. Another commonly followed parameter is the ratio of middle cerebral artery (MCA) to extracranial internal carotid artery (ICA) MCBFV (hemispheric index or Lindegaard's ratio), which is used to distinguish vasospasm (ratio >3) from hyperemia (ratio <3).

Three approaches are routinely used to in son ate the cerebral vessels: transtemporal, transorbital, and suboccipital. The transtemporal approach is used to insonate the proximal segments of the MCA and the anterior cerebral artery (ACA), the ACA/MCA bifurcation, the posterior cerebral artery (PCA) and a portion of the carotid siphon. The main constraint with this approach is that in about 10% of patients, particularly elderly females, it is difficult to insonate any of the cerebral vessels due to skull thickness. The transorbital approach iusonates the ophthalmic artery and most of the carotid siphon. The suboccipital approach insonatcs the vertebrobasilar system,

The major indications for TCD in the NSU are determination of vessel patency (absence or presence of MCBFV); identification of focal vessel stenosis (elevated MCBFV); cerebral vasospasm monitoring after SAH (MCBFV>120 cm/sec, Lindegaard's ratio >3, and MCBFV increments >50 cm per second within a 24-hour period) (Suarez et al. 2002); verification of cerebral hyperemia after traumatic brain injury (elevated MCBFV with Lindegaard's ratio <3); and confirmation of the clinical diagnosis of brain death (severely diminished MCBFV, absent diastolic flow, reverberating flow, and severely elevated PI) (Hassler, Steinmetz, and Gawlowski 1988).

Near-Infrared Spectroscopy (Cerebral Oximetry). Although the technology is not yet in widespread use, near-infrared spectroscopy (NIRS) potentially fills a significant void in the NSU by providing a noninvasive means of monitoring cerebral oxygen availability (Jobsis 1977; Lewis et al. 1996). NIRS is based on the ability of incident light of 700-1000 nra wavelength to pass through tissues into all components of the vascular tree, indicating by its absorption characteristics trends in the oxygenation state of hemoglobin. This provides a noninvasive picture of the adequacy of tissue oxygenation.

NIRS has been used for cerebral oximetry in head injury, epilepsy, cerebral venous thrombosis undergoing endovascular thrombolysis, and ischemic stroke. However, the reliability of NIRS has also been called into question because normal readings have been obtained over areas of hemispheric infarction. In addition to this, NIRS is sensitivity to extraneous light, susceptible to motion artifacts and signal drift. Moreover, there are frequently problems obtaining a signal through intracranial hematomas or through blood in the CSF, and it usually monitors focal regions. The main advantages of NIRS are that it is noninvasive, safe, can be performed at the bedside, and has the potential to be used as a trend monitor, particularly when used in conjunction with other monitoring modalities.

Regional Cerebral Blood Flow Techniques. Thtee methods have been introduced into clinical practice to measure regional cerebral blood flow (rCBF): Xenon-133 (Xel33) scans, laser Doppler flowmetry (LDF) (Haberl, Villringer, and Dirnagl 1993), and thermal diffusion flowmetry (TDF) (Carter 1996; Martin and Doberstcin 1994). Of the three, Xel33 scan is the most commonly used (Anderson 1996). Xel33 is a radioisotope that, after administration by various routes, is briefly taken up by the brain but docs not undergo metabolism. It is then cleared by the venous system and exhaled with a 90% first-pass clearance from the body. Using multiple stationary scintillation detectors, the cerebral uptake and elimination of Xel33 can be measured and expressed as a two-dimensional rCBF map with emphasis on cortical CBF. Xel33 has been used extensively to determine rCBF in severe head injury and SAH and has been employed intraoperatively during carotid endarterectomy and during carotid occlusion for cerebral aneurysms. The main advantages of the Xel33 method are its long track record as a reliable, reproducible gauge of rCBF; its minimally invasive nature and rapid clearance; and its portability, permitting bedside use in the NSU.

Microdialysis. The basic concept of microdialysis involves the insertion of a fine catheter into the brain parenchyma, followed by perfusion of the catheter with a physiological solution such as Ringer's solution, thereby facilitating the exchange of molecules between the perfusate and the extracellular fluid (ECF) across a dialysis membrane located within the catheter tip. The dialysate is sterilcly sampled at hourly or other regular intervals in vials, which arc placed in a microdialysis analyzer at the bedside. In this manner the clinician may monitor semi-on-line pH, lactate and pyruvate, glucose, glycerol, glutamate, urea, and potentially other soluble molecules of interest (Nilsson et al. 1999; Vespa et al. 1998; Landolt, Langemann, and Alessandti 1996). Changes in lactate and the lactate/pyruvate ratio have been used as indices of cerebral ischemia, as has elevations in the concentrations of excitotoxic amino acid glutamate. Rises in glycerol are believed most likely to reflect phospholipid breakdown as a result of cell membrane damage. Because of this, cerebral microdialysis has been employed in the NSU to monitor for cerebral vasospasm and delayed cerebral ischemia in SAH, to identify indicators of secondary brain injury after severe brain trauma, and to

follow ECF glutamate concentration peri-ictally in patients with epilepsy,

Controversy exists regarding some aspects of microdialytic analysis, such as whether lactate alone or the lactate/pyruvate ratio is a better indicator of early cerebral ischemia, and the technology is not yet in widespread clinical use. Other problems are the invasiveness of the procedure and the inability to foresee what areas of the brain should be sampled,

Tissue Monitoring. Another recently introduced invasive cerebral monitor is the implantable microsensor catheter for the measurement of brain Po_2, Pco_2, pH, and temperature (van den Brink ct al, 2000). As with many other monitoring technologies described here, the tissue Po_2 probe has been applied most extensively in the head injury population (normal >15 mm Hg), As a means of detecting cerebral ischemia in this setting, it has compared favorably to SjvOi and may aid in prognostication. The main risks associated with tins technique are those encountered with other invasive monitors (i.e., ICH and infection).

GENERAL MANAGEMENT OF NEUROCRITICALLY ILL PATIENTS

Care of the critically ill neurological and neurosurgical patient encompasses knowledge and awareness of the general medical management in the context of CNS pathology. The balance between the two presents a real challenge to the neurointensivist and creares a real dilemma when caring for and treating such patients. This section discusses several approaches to managing each of the body systems, bearing in mind the underlying severe neurological and neurosurgical diseases with special attention to the ICP and ischemic penumbra. The main goals of treatment of NSU patients are amelioration of primary insults and prevention or correction of secondary insults (e.g., seizures, cerebral edema, fever, and elevated ICP) to guarantee the best possible outcome.

Basic Critical Care Approach

The standard of care in the NSU, like in any other ICU, begins with securing the airway and establishing adequate breathing and circulation ("ABC"). Caution must be used when evaluating the ABC, Neurointensivists should pay particular attention to the possible complications associated with endotracheal intubation (ETI) in the NSU population to prevent increasing neurological problems. Two important elements need to be considered when handling the airway: cervical spine stability and ICP. Neck extension and flexion may aggravate an already existing cervical spine injury. In such cases, nasotracheal intubation with fiberoptic techniques may be preferred over orotracheal route. An equally important issue is that many of the NSU patients present with space-occupying brain lesions, which may trigger subsequent reflex elevation in the ICP during ETI, Administration of adequate sedatives and neuromuscular blockade agenrs in addition to lidocaine {either intravenously or orotracheally) may help in blunting such increases in ICP. This may he best achieved by the so-called "rapid sequence intubation" (RSI) (Talucci, Shaikh, and Schwab 1998). RSI consists of preoxygenation followed by administration of a short-acting sedative agent, such as etomidate at a dose of 0.1-0.3 mg/kg, and a nondepolarizing neuromuscular blocking agent, such as vecuronium at a dose of 0.1 mg/kg, in addition ro applying cricoid pressure (Sellick's maneuver) to prevent aspiration when consciousness is lost. To blunt the cough reflex during ETI, lidocaine (1-1.5 mg/kg) is administered 1-2 minutes prior to laryngoscopy (Helfman et al, 1991). Hyperkalemia and worsening of the underlying weakness may occur after administering depolarizing paralyric agents, particularly in those patients with renal impairment or focal neurological weakness of 3-90 day duration. Continuous cardiac monitoring and determination of potassium serum concenttation are routinely checked after such agents are given,

Once the ABC has been stabilized, patients are closely followed and neuroprotective measures are instituted (Table 51.3). MAP should be maintained at 100-120 mmHg in ischemic brain and spinal cord injury to maintain a CPP around 70 mmHg (Rosner, Rosner, and Johnson 1995), Other measures include maintaining at all times in NSU patients a T below 37,0-37.5^{J}C, a serum glucose concenrration between 80 and 120 mg/dL, and adequate hydration (Rodorf et al. 2000).

Another important aspect of care in NSU is the neurointeusivist-family relationship. Emphasis should be placed on early institution of direct contact between the treating physician and the patient's family. Identifying a spokesperson and all legally authorized nexr of kin is crucial and will allow for a more effective decision-making process. This is particularly important when end-of-life decisions and organ donation need to be addressed. Withdrawal of care in patients who have suffered catastrophic brain injuries can be difficult to approach. The establishment of good rapport between families and sensitive and well-trained health care personnel will accomplish a rate of up to 96.5% family satisfaction (Mayer and Kossoff 1999).

Respiratory Care in the NSU

One of the major reasons for the development of critical care units was the institution of acute respiratory care. Such care includes mechanical ventilation, aggressive suctioning, chest therapy, and maintenance of airway patency. Currently, mulriple indications exist for critically ill

Table 513: Basic considerations in NSU

Respiratory and airway protection	Perform rapid sequence orotracheal intubation
	Nasotracheal intubation in head and spinal trauma
	Eromidate 0,3 mg/kg followed by Jidocaine 1-2 mg/kg IV, 2 minutes prior to intubation
Cardiovascular	Maintain euvolemia in cases of increased ICP
	Maintain hypervolemia in cases of ischemic brain injury and SAH
	Use isotonic and occasionally hypertonic solutions
	Keep MAP 100-120 mm Hg
Renal	Maintain: Magnesium >2,0 mg/dL
	Calcium >8.5 mg/dL
	Phosphorus >2.5 mg/dL
	Potassium >4.0 meg/L
Pain/sedation	Morphine sulfate 2-4 mg IV/IM q 4 hr
	Codeine ."50-60 mg IM q 6 hr
	Midazolam 0.1 mg/kg in divided IV doses for sedation
	Clonidine 0,1 mg orally bid or tid
	Ativan 1-2 mg IV/IM/PO qid
	Olanzapine 5—10 mg orally bid
Neuroprotective measures	Keep glucose 80-120 mg/dL (use insulin drip if needed)
	Keep core body temperature <37.5°C
	Institute early nutrition

neurological and neurosurgical patients to be admitted to the NSU for respiratory care (Table 51.4). This section discusses basic principles of respiratory and ventilatory care, spanning indications for endotracheal intubation, weaning process, cxrubation, and chronic ventilatory care,

Indications for Mechanical Ventilation: A Life-Sustaining Treatment

When patients are admitted in respiratory distress they need a fast and safe assessment. Mechanical ventilation should be instituted in those patients meeting certain criteria, as outlined in Table 51.5 (Banner et al. 1997). Acute respiratory failure (ARF) implies that the respiratory system has failed to meet the patient's oxygenation, ventilation, or metabolic requirements. ARF has been classified into types I and II. Type I is the so-called "hypoxemic ARF" and is defined by a Pao_2 <60 mm Hg. This is commonly seen in patients with lung parenchyma processes such as pneumonia, pulmonary embolism, or acute respiratory distress syndrome (ARDS). Type II is the so-called "hypercapnic ARF" with or without hypoxemia and is defined by a $Paco_2$ >50 mm Hg. This type is usually seen in those patients with neuromuscular disorders such as myasthenia gravis and GBS. In many occasions neuro-intensivists are faced with patients who have both types I and II ARF (Gujjar et al. 1998).

Airway integrity depends on the patient's level of consciousness (LOG) and lower brainstem reflexes (gag, swallow, and cough). When one of these factors is affected, patients are at greater risk of upper airway obstruction or aspiration pneumonia. The threshold LOC is usually given by a GCS <8. Breathing patterns can be easily evaluated by observing thoracic and abdominal breathing movements. Paradoxical movements of the abdomen and rib cage, increased respiratory rate, and use of accessory muscles of ventilation arc an indication that the patient is iti impending respiratory failure secondary to weak respiratory muscles,

Table S1.4: Most common indications for admission to the NSU of critically ill neurological and neurosurgical patients with respiratory problems

Factor	*Underlying process*
Muscle weakness	Neuromuscular disease (MG, GBS, polymyositis)
	Cervical spine injury
	Critical care myopathy and polyneuropathy
Poor oxygenation with abnormal work of breathing	Aspiration pneumonia, lung collapse, pulmonary edema, ARDS, COPD, neuromuscular disease, upper airway obstruction
Inability to protect airway	Dysphagia, brainstem disorders, Glasgow Coma Scale <8, poor cough
