Decreased respiratory drive	Medications (opioids, sedatives), brain or brainstem insults (traumatic brain injury, stroke, intracranial hemorrhage, brain tumors), central hypoventilation (Ondine's cutse)

ARDS = ; COPD = chronic obstructive pulmonary disease.

Table 51.5: Common indications for institution of mechanical ventilation in the NSU

Evaluate promptly and solve the problem

Glasgow Coma Scale score <8
Forced vital capacity (FVC) <15 ml./kg
Negative inspiratory force (NIF) <20 cm H,>0
Positive inspiratory force (PIF) <40 cm H_20
Respiratory rate >35/min
Pao_2 <fiO iinm Hg
$Pac:o_2$ >60 mm Hg
Cardiovascular shock
Upper airway obstruction not corrected by noninvasive methods
\piH\l

Bedside spirometry measurements are very useful for assessing respiratory muscle strength: forced vital capacity {F'VC, normal >60 mL/kg), negative inspiratory force (NIF, normal >70 cm H_20), and positive expiratory force (PEF, normal >100 cm H2O). Inadequate oxygenation can be diagnosed by obtaining arterial blood gas samples or noninvasive pulse oximetry (Sao_2). The former can also offer information regarding $C0_2$ retention. A chest roentgenogram (CXRay) may help elucidate the underlying disease such as pneumonia, atelectasis, or pneumothorax. In the presence of an unremarkable CXRay and hypoxemia, pulmonary embolism must be ruled out or treated.

Once the need for mechanical ventilation has been established, we usually proceed with rapid sequence intubation as described previously. Typical initial ventilatory settings used in the NSU are outlined in Table 51.6. The patient should be maintained with sedation (short-acting agents such as propofol or midazolam) and, if needed, neuromuscular blockade. As soon as the patient is intubated, treating physicians must start improving and treating the underlying condition that led to respiratory distress to ensure a quick and smooth weaning and ex tu bat ion.

Classes of Available Ventilators and Modes of Ventilation

Mechanical ventilators produce positive pressures at the airway opening, which can be cycled by volume, time, and flow. During volume cycling, the ventilator delivers a breath until a preselected volume has been delivered. These ventilators can potentially deliver a predetermined volume regardless of the airway pressure required to deliver it. Therefore to avoid excessive inhalation, a pressure relief valve is introduced. During time cycling, inspiration lasts for a preset interval and is therefore time-dependent. Exhalation begins at a preset time regardless of the volume delivered. During flow cycling, inspiration is terminated when a predetermined decrement of flow is achieved. With this type of cycling, patients exert more control over inspiratory and expiratory efforts.

Table 51.6: Initial ventilator settings for a typical patient requiring mechanical ventilation in the NSU

Start with this and then titrate down as soon as feasible

Mode: assist-control (AC)
Inspired fraction of oxygen ($FiC>_2$): 100%
Respiratory rate: 12-18/min
Tidal volume (Vt): 7-10 cc/kg
Positive end-expiratoty pressure (PEEP): 5 cm H,0

The four most common modes of ventilation used in the NSU are assist-control mode ventilation (ACMV), synchronized intermittent mandatory mode ventilation (SIMV), pressure support ventilation (PSV), and inverse ratio ventilation (IRV) (Shelledy, Ran, and Thomas-Goodfellow 1995; Stcnberg and Sahebjami 1994). In ACMV, a preset tidal volume (Vt) is given every time an inspiratory effort is sensed as a fall in the pressure at the airway opening, and a backup rate is set to avoid hypoventilation in patients with decreased respiratory drive or chemical paralysis. In SIMV, the ventilator delivers breaths that are triggered by the patient's inspiratory effort up to a preset rate. If the number of inspiratory efforts exceeds the preset rate, all the excess breaths will be unassisted. In this mode a backup rate is also given, and in order to exercise the patient, the rate of machine-delivered breaths or Vt is progressively decreased. In PSV, patients receive a preset pressure triggered by an inspiratory effort. Once the inspiratory flow falls below a certain threshold, the breath is terminated. Vt depends on lung compliance, chest wall compliance, status of respiratory muscles, and airway resistance. This mode can be used in isolation or as adjunct to SIMV or ACMV. To exercise the patient, the amount of pressure supplied is gradually reduced. In IRV, the inspiratory/expiratory ratio (I:E) is set at >1. The major application is in those critically ill neurological patients who have acute lung injury or ARDS and have failed to improve oxygenation with positive end expiratory pressure (PEEP). Because IRV is very uncomfortable for patients, they should be heavily sedated and paralyzed. Last, PEEP and continuous positive airway pressure (CPAP) are also often used. They are not separate modes of ventilation but are used together with other modes to improve arterial oxygenation. The benefits of PEEP may result from its ability to improve residual functional capacity, thus increasing lung compliance. Usual PEEP levels are 5-10 cm H_20, which may be increased by 2.5-5 cm H_20 to achieve the desired oxygenation, Disadvantages include risk of barotrauma, hypotension, and elevated ICP due to decreased cerebral venous return. However, clinical experience has shown that PEEP levels of 5-15 do not affect ICP or CPP in critically ill neurological patients (McGuire et al. 1997).

Once the patient has been intubated and a mode of ventilation chosen, it is important to monitor and assess

several parameters: ventilation and oxygenation, lung and chest wall mechanics, intrinsic PEEP, and muscle strength. Ventilation and oxygenation are followed through continuous Sa02 and end-tidal $C0_2$ recordings or intermittent arterial blood gas sampling. Lung and chest wall mechanics are integrated in the equation for dynamic compliance calculation, which is given by dividing Vt by peak inspiratory airway pressure minus PEEP ($Qv_n = Vt/(P,,i_{at}$ — PEEP), Auto PEEP is usually present in those patients with airway obstruction, with rapid respiratory rates, or with IRV. It refers to dynamic hyperinflation of the lungs when Vt is given before complete exhalation. Auto PEEP can be measured at the bedside by pausing the ventilator at the end of expiration and closing the expiratory circuit flow. Finally, muscle strength monitoring is usually accomplished by following FVC and NIF. These measurements provide information about respiratory muscle strength but not endurance.

Medical Management of Ventilated Patients

Medical management of critically ill neurological and neurosurgical patients who require mechanical ventilation concentrates on five points: chest physiotherapy, nutrition support, correction of electrolyte imbalance, gastrointestinal prophylaxis, and treatment of concurrent hospital-acquired infections. Although further data from controlled randomized studies are needed to provide more scientific validation, chest physiotherapeutics techniques have been used for the past 30 years and are widely accepted. These include manual hyperinflation, gravity-assisted drainage, and chest wall vibrations to improve airway secretion clearance (Denehy 1999; Langerderfer 1998). In patients with atelectasis or mucus plugging, aggressive chest physiotherapy should always be instituted before other procedures are performed (i.e., bronchoscopy). Nutrition support, whether enteral or parenteral, should be initiated as soon as feasible (Taylor et al. 1999). The enteral route is preferred and is discussed in a later section. There is scientific evidence that early feeding may be associated with enhanced neurological recovery in critically ill patients with intracranial lesions. In addition, from the ventilatory viewpoint, malnourished patients have weaker respiratory muscles and are therefore more difficult to wean (Moxham 1984}. Electrolyte imbalance, including hypomagnesemia and hypophosphatemia, may also be associated with prolonged need for artificial ventilation, especially in patients with other factors that may adversely affect weaning,

Prophylaxis against stress ulcers and aspiration pneumonia has always been recommended in mechanically ventilated patients (Markowicz et al. 2000). Our current recommendation is to administer ranitidine to all ventilated patients in the NSU except those with thrombocytopenia or renal failure who are treated with sucralfate (Cook et al. 1998; Cook etal. 1999).

Weaning Patients from Mechanical Ventilation

There are several issues that need to be resolved before starting a weaning trial in mechanically ventilated neurological and neurosurgical patients:

1. Resolution of the cause of respiratory failure
2. Presence of good oxygenation (Pao_2 >60 mm Hg with $Fi0_2$ <50% and PEEP <5 cm H_20)
3. Ability of patient to protect airway (normal bulbar function)
4. Establishment of adequate respiratory drive
5. Adequately strong respiratory muscles (vital capacity [VC] >15mL/kg)
6. Identification of adequate cough reflex
7. Maintenance of a minute ventilation <15 L/min
8. Rapid shallow breathing index (RSBI) <105 breaths per minute (see later discussion)
9. Secretion suctioning frequency less than every 2-3 hours
10. Hemodynamic stability and normal electrolytes

A number of individual parameters have been suggested as predictors of successful weaning, but most of them have limited predictive power in critically ill patients: NIF >-30 cm H_20, VC >10 mL/kg, minute volume <10 L/min (Sahn and Lkshminarayan 1973), and the airway occlusion pressure measured at 0.1 second of an inspiratory effort against an occluded airway (Po.i) <—2 cm H_20 (index of respiratory drive) (Whitelaw and Derennc 1993). Because respiratory failure is a multifactorial condition, indices including several parameters are probably more reliable at predicting successful weaning. The most commonly used one is the RSBI (Yang and Tobin 1991). RSBI appears to be the best predictor of all the indices published thus far and can be derived from the following equation:

$$RSBI = //Vt$$

where /is the respiratory rate and Vt the tidal volume.

This index has to be obtained while patients arc off ventilatory support. RSBI values <105 arc predictive of successful weaning. Once patients meet these criteria, a weaning trial is started, It is important to realize that there is no such thing as an ideal weaning method (Brochard et al. 1994; Esteban et al. 1995). The most accepted method of weaning consists of a gradual reduction of support using PSV, SIMV, a combination of both, or spontaneous breathing trials (SBT). Some authors found that PSV was better than SIMV or SBT, whereas others have reported better results with SBT, These differences may be related to differences in patient population.

Whatever weaning method is chosen, it should be executed early in the day, the patient should have received a good rest the night before, tube feedings should be held at least 4 hours before the trial, and treating physicians should be ready to reintubate if the patient fails extubation.

Chronic Ventilatory Care

The majority of patients placed on mechanical ventilation are extubated within 7 days. However, about 4-16% require prolonged ventilatory support (>15 days). Neurological patients represent a large proportion of these patients. After 14 days of intubation, the risk of rracheolaryngeal injury increases (Koh et al. 1997). It is generally accepted that such patients should undergo tracheostomy. In patients with neurological and neurosurgical diseases, the risk of extubation failure is high because of upper airway obstruction and tenacious secretions; thus early tracheostomy (sooner than 14 days) in this patient population has been advocated. Once patients have undergone tracheostomy, they can be classified into two groups: those who require mechanical ventilation for airway protection and those with parenchymal lung disease or dysfunction. The former will be able to come off the ventilator shortly after tracheostomy is performed, whereas the latter group may need to be cared for in a long-term ventilatory rehabilitation unit (Gluck 1996).

Cardiovascular Care in **the** NSU

Cardiac diseases are common comorbidities in patients with neurological illness and may present concomitantly or occasionally may precede the neurological insult. Acute neurological and neurosurgical insults may lead to different types of cardiac manifestations that pose a challenge to ncurointensivists {Rolak and Rokey 1999; Sakr, Ghosn, and Vincent 2002; Prieto, Eisenberg, and Thakur 2001; Ay, Arsava, and Saribas 2002; Lang, Borner, and Figulla 2000). Such cardiac manifestations may include acute coronary syndrome, cardiac arrhythmia, and fluid overload.

Acute Coronary Syndrome

When patients present after an acute brain injury {e.g., acute ischemic or hemorrhagic stroke or SAH or even large space occupying lesion) and develop elevated cardiac enzymes, it may be difficult to ascertain whether these cardiac abnormalities are primary or secondary. Acute coronary syndrome (ACS) in particular represents a significant challenge since cardiac enzymes can be elevated in patients with acute vascular and nonvascular disease such as status epilepticus in the NSU. In one study the elevation of serum creatinine kinase was not found to be cardiac in origin in ischemic stroke patients, whereas the troponin T elevation was more sensitive in detecting myocardial ischemia and damage (Ay, Arsava, and Saribas 2002; Lang, Borner, and Figulla 2000). The main mechanism is myocytolysis secondary to autonomic system overdrive leading to nonischemic ACS. Another possible mechanism is rupture of a coronary artery plaque following the acute ischemic stroke or neurological injury and subsequent myocardial ischemia. The EEG findings **may** vary from symmetrically inverted T waves to ST segment elevation.

When patients are found to have elevated troponin serum concentrations with or without acute electrocardiogram (ECC) changes, rhey should be considered as having ACS and appropriate treatment should be initiated. The management of these patients usually includes standard medications including antiplatelet agents, beta blockers, and nitroglycerin. An echocardiogram should be obtained to evaluate ventricular function. In general, medication dosages are usually adjusted to maintain adequate CPP while decreasing cardiac demands. MAP of or above 90 mm Hg is preferred. Angiotensin-convcrting enzyme inhibitors and beta blockers may be given at a lower than standard dose. Anticoagulation or intravenous GHb/IIla inhibitors should be avoided within the first week after large stroke or neurosurgical procedure and in cases of ICH for up to 2 weeks. Of course, thrombolyric therapy for ACS may not be administered, but interventional petcutancous angioplasty tteatment can be considered, Pain control with nitroglycerin intravenously or morphine may be given with prevention of excessive sedation. Fluid therapy guided by invasive cardiovascular techniques may be required since dehydrating neurologically damaged patients may be deleterious to brain function.

Cardiac Arrhythmia

Abnormalities in cardiac rhythm may occur after ischemic and hemorrhagic stroke, as well as in other diseases encountered in the NSU including GBS and status epilepticus. Different types of cardiac abnormalities may be seen and approach to treatment may vary according to the underlying rhythm subtypes. Atrial fibrillation with rapid ventricular response is better converted after transesophageal echocardiography has demonstrated absence of intracavitary clots and after it has been determined that the patient can be anticoagulated (Hebbar 2002). Medical or electrical conversion may be accomplished in the context of acute neurological injury, and the latter should not be an absolute contraindication. Sinus rhythm is preferred if possible since this will increase the cardiac output and ultimately CPP. If the patient cannot be converted and the heart rate still requires control, less hypotensive agents such as digitalis are preferred as the first drug of choice. Other drugs may be used, including beta blockers and calcium channel blockers.

The use of vasoactive drugs in the NSU may lead to worsening of the underlying rhythm and may induce cardiac arrhythmias. The vasopressors that are commonly used to manage patients with SAH may be problematic in elderly individuals with sensitive rhythm and underlying cardiovascular morbidities. Caution should be used when administering such medications.

Congestive Heart failure

Fluid overload and pulmonary edema are common in the NSU setting, where patients are routinely overloaded with intravenous fluid to maintain CBF and CPP as a standard therapy for certain conditions (e.g., vasospasm prophylaxis after SAH and hypervolemic therapy after acute ischemic stroke for penumbra salvaging}. In elderly neurocritical care patients with concomitant cardiac dysfunction the risk of congestive heart failure and pulmonary edema may be high. Up to 80% of patients with SAH experience varying degrees of severity of pulmonary edema (Vespa etal. 1994). The standard of care is to obtain a comprehensive cardiac evaluation with plain chest radiograph, echocardiography, and ECG at baseline and to monitor hypervolemic, hypertensive, and hcmodilutional therapy accordingly. If the cardiac function is compromised at baseline the fluid management may be tenuous and central venous catheters, including Swan-Ganz catheter, may be needed to guide this therapy.

Pulmonary capillary leak and pulmonary edema may occur secondary to massive brain insult (known as neurogenic pulmonary edema) in patients with brain mass, stroke, or SAH and hydrocephalus with sudden rise in ICP (Gluecker et al. 1999). The mainstay of treatment is to provide adequate and gentle diuresis and short periods of PEEP. Other therapeutic strategies may include albumin combined with diuretic therapy and agents to augment the cardiac output such as dobutamine or amrinone (Knudsen, Jensen, and Petersen 1991).

Gastrointestinal and Nutritional Management in the NSU

Gastrointestinal Abnormalities

Severe stress in the NSU population may frequently be accompanied by secondary deleterious effect on the gastrointestinal (GI) system. Common CI complications encountered in the NSU and their management are summarized in Table 51.7. Secondary CI manifestations that are related to acute neurological injury include gastric and colonic ulcers, bleeding, and ileus. The gastric stress ulcer may be related to sudden ICP elevations with GI ulceration and bleeding caused by catecholamine surge. The bleeding can be in the upper or lower tract and can be accompanied by hypovolemic-hypotensive shock, which may subsequently lead to a vicious cycle of cerebral ischemia and further increase in ICP with subsequent increase in the GI bleeding. This may be seen in the advanced stages of increased ICP and before death or cerebral herniation. Treatment involves emergency control of the ICP and immediate whole blood transfusion and volume resuscitation. Except for this extreme situation, the GI complications from acute ischemic stroke are usually mild and may be related to the concomitant use of medications (Wijdicks et al. 1994). GI prophylaxis in NSU patients is recommended with sucralfate or ranitidine, particularly in ventilated patients (Holland 2001).

Tabic 51.7: Gastrointestinal manifestations and management in NSU

GI manifestations	*Approach*
GI bleeding	Stop anticoagulation
	Administer protamine sulfate 1 mg/100 units of heparin or fresh frozen plasma for warfarin reversal
	Volume and blood resuscitation
	Gastric protection
	Look for underlying etiology
Ileus	Replete potassium
	Replete magnesium
	Bowel rest
	Decompression
	Discontinue offending agents
Diarrhea	Discontinue potential medications
	Fluid management
	Metronidazole if *Clostridium difficile* suspected

Elevated liver enzymes and hepatic encephalopathy secondary to the frequent use of hepatically metabolized anticonvulsants or antibiotics are common in the NSU. Valproic acid may be associated with elevation of the serum ammonia concentration with encephalopathy and occasional pancreatitis (Holland 2001). EEG can be useful to assess for hepatic encephalopathy versus asymptomatic elevation of the liver enzymes. Discontinuation of the offending agent and supportive care with lactulose and neomycin is the mainstay of treatment.

Gastrointestinal ischemia and angina can occur and should be considered in cases of hypotension in NSU patients who already suffer from increased tendency to thrombosis and clotting. Occlusive and nonocclusive types of mesenteric ischemia can be encountered in the NSU, although the former is more common than the latter. This is a medical and surgical emergency, which presents with a painful abdomen without sufficient corresponding physical signs on examination, the so-called "benign abdomen." This classical presentation may not be evident in the NSU, and it should be suspected in patients with recalcitrant sepsis who also have elevated serum lactate concentration. Diagnosis can be established with abdominal CT scanning, Immediate medical and possibly surgical evaluation is life saving (Greenwald 2001).

Another significant GI manifestation that is commonly encountered is intestinal ileus (Liolios, Oropcllo, and Benjamin 1999). Paralytic ileus may occur in a variety of neurological conditions and in the postoperative period in neurosurgical patients. GBS requiring NSU care is commonly if not universally complicated by some degree of abdominal distension and GI obstruction secondary to ileus. Treatment usually involves supportive care with intravenous fluid and electrolyte repletion while avoiding

oral feeding and removing any offending agents such as sedatives or analgesics that could worsen the intestinal dilatation. Decompressive nasogastric tube and rectal tube may be tried before surgical decompression in those who do not improve with suppottivc medical therapy.

An additional GI complication wotth mentioning that is commonly encountered in the NSU is diarrhea. Diarrhea can be related to the underlying neurological disease or may be secondary to the critical care management. Drugs used in the NSU known to induce diarrhea are mainly antibiotics and gastric protection medications. Enteral feeding is another common cause and should be stopped if all othct causes are excluded. Infectious etiologies such as *Clostridium difficile* (C. *diff)* and *vancomycin-resistant enterococci* (VRE) arc also common, particularly after long-term use of broad-spectrum antibiotics (30^10% may be associated with C. *diff).* Treatment of *C. diff* consists of discontinuation of the offending agents and administering metronidazole or vancomycin by entetal route (Liolios, Oropello, and Benjamin 1999).

Nutritional Requirements

Nutritional support is essential in patients with neutologi-;,;il insults. Daily requirements vary according in the underlying disease, the patient's ideal body weight adjusted formula, and the Harris Benedict equation used to calculate the daily calorie needs. This equation is often used to estimate Resting Energy Expenditure (REE):

$$\text{Male (kcal/day)} = 66.473 + (13.7516 \times W) + (5.0033 \times H) - (6.755 \times A)$$

$$\text{Female (kcal/day)} = 655.0955 + (9.5634 \times W) + (1.8496 \times H) - (4.6756 \times A)$$

For both equations, *W* is body weight in kilogtams, H is height in ccntimctets, and *A* is age in years. This may be operationally translated into approximately 25-30 kcal/kg/day. Nutritional requirement may be adjusted to the particulat disease and nutritional status indicatots. For instance, sepsis may require increased nutritional support by 30%, wheteas high caloric feeding should be avoided in GBS and myasthenia gravis. Nutritional support adequacy may be assessed using prealbumin {half-life of 2-3 days) rather than albumin (half-life of 20 days). Insulin growth factot-I is another promising nutritional assessment parameter (half-life of 24 hours) but it is not commonly used in clinical practice (Schears and Dcurschman 1997). Regarding the tomes of nutrition administration, enteral feeding is preferred whenever possible. Oral feeding in the NSU may not be feasible because of the patient's mental status and risk of aspiration with impaired swallowing mechanism. Feeding tubes should be placed in the distal stomach or first part of the duodenum to avoid the risk of aspiration. The risk of aspiration may be higher in those patients with gastroparesis; gastric motility agents may be added as necessary. The right timing to start feeding and nutritional support is not defined for neurological diseases, but early feeding is usually recommended based on preliminary evidence from head-trauma and surgical post-operative studies associating it with bettet outcomes (Schears and Deutschman 1997).

Renal and Electrolytes

Patients with acute neurological insult may have a concomitant underlying renal dysfunction. Primary renal diseases that may worsen while patients are in the NSU include acute or chronic renal failure secondary to renal hypoperfusion from the use of vasoactive drugs or antibiotics and urinary tract infection caused by indwelling catheters. The latter may also be a leading cause of fever, and antibiotics should be initiated appropriately.

Urinary retention may be seen after spinal neurosurgical procedures and can be managed with frequent intermittent catheterization. Uremia may supervene while the patient is in the intensive care unit; this should be considered in the differential diagnosis of delirium in the NSU. Furthermore, patients in the NSU for acute neurological emergency who arc receiving hemodialysis (HDj should have no heparin in their dialysis lines if ICH or a large cerebral infarct is ptesent. Blood pressure changes during HD should be attended to, and fluid balance at the end of the dialysis session should also be monitored closely. Drugs that may intetferc with renal function should be used with great caution to avoid nephrotoxicity. Whenever possible renal dose adjustment of anticonvulsants and antibiotics in those with renal dysfunction should be made and free unbound drug concentrations should be monitoted.

Electrolyte imbalance, including hyponatremia, may be encountered in the neurocritical care setting. Hyponattcmia can be caused by the syndrome of inappropriate anti-diuretic hormone secretion (SIADH) or cerebral salt wasting syndrome (CSWS). The formet can be seen in patients with SAH, massive stroke, GBS, IGH, and after pituitary adenoma resection. Stress, pain, and anxiety may also lead to incteased secretions of ADH. SIADH is usually managed with fluid restriction. CSWS may also lead to hyponatremia with normal-to-decreased total body volume and in the presence of nattiurcsis may require fluid therapy rather than restriction. Symptomatic acute hyponatremia may tequitc more aggressive therapy with hypertonic saline, but the latter should be avoided in patients with chronic hyponatremia because of the major risk of producing central pontine myelinolysis.

Hypernatremia can be secondary to diabetes insipidus (DI), which may occur with SAH, increased 1CP, cerebral edema, or following pituitary adenoma resection. Increase in the urine output to more than 250-300 cc/hour for 2 consecutive hours with low specific gtavity (less than 1.010) may be an early indication of DI. Setum and urine

osmolality and electrolytes should be monitored every 6 hours and results used to guide further therapy. Initial management in patients who are awake with intact thirst mechanism is merely by replacement with oral fluid in a volume equal to the urine output plus 20%. If patients are obtunded this can be supplemented with intravenous hypotonic solutions according to the calculated total body water deficit (TBWD). This is usually calculated using the following equation:

$$\text{TBWD in liters} = 0.6 \times \text{usual body weight in kg} \times \frac{\text{serum sodium} - 140\ \text{mEq/L}}{140\ \text{mEq/L}}$$

Shorter acting vasopressin may be given early on in doses "I 2-5 units 1\! nr SQ every 4 hours if the urine volume is more than 300 cc/hour for 2 consecutive hours. The advantage is that if DI is transient, the vasopressin effect is not long acting and will not carry over. Desmopressin or 1-desamino-D-arginine vasopressin (dDAVP) is preferred over vasopressin because of its longer duration of action. The dDAVP may be administered to patients with persistent hypernatremia not responding to fluid therapy or requiring constant short acting vasopressin therapy. An initial dose of 2.5-10 j.ig may be given intranasal!)' at bedtime or two times daily. Alternatively, 0.5-4 ug may be given intravenously, subcutaneously, or intramuscularly every 8-10 hours (Diringer 2001).

Hematological System

Several important hematological diseases that may be seen in NSU populations are worth mentioning. Patients are often paralyzed and fulfill all the criteria of Virchow's triad and are thus prone to thrombotic events. The incidence of deep venous thrombosis (DVT) in patients with stroke and neurosurgical patients may vary. In patients who have experienced acute stroke, the incidence of DVT may range between 11% and 17%, and pulmonary embolism (PE) may range between 3% and 39% (Hillbom ct al. 2002). In neurosurgical postoperative patients and in general critical care patients it may range between 22% and 80%, depending on the underlying disease (Attia et al. 2001; Warbel, Lewicki, and Lupica *1999).* NSU patients with a DVT may nor have leg pain and swelling. This diagnosis is mainly encountered either in routine screening or in the context of fever workup. Clinical findings in a case of PE can also be obscured by the patient's inability ro complain of shortness of breath. However, any difficulty in breathing should be taken very seriously. An arterial blood gas with high alveolar-arterial gradient should raise a red flag, and the diagnostic studies for PE should be obtained.

The main screening test for DVT is the noninvasive bedside vascular ultrasound; venography is rarely required. In cases of PE, spiral computed chest tomography, ventilation-perfusion scan, or pulmonary arteriography may be obtained to establish the diagnosis. Current data do not support increased risk of bleeding in the use of cither enoxaparin 40 mg daily or un fractions ted heparin 5000 units subcutaneously thrice daily in NSU patients for DVT and PE prophylaxis (Hillbom et al. 2002; Attia et al. 2001). Both animal and human studies have shown the safety of heparin or warfarin administration if started after 7 days from the time of craniotomy surgery. Thus the use of those agents for therapeutic management of DVT or PE can be recommended 1 week after neurosurgical procedures. Unfortunately, similar data are not available for ICH or large ischemic strokes. For patients with a high risk of developing bleeding complications from anticoagulation, a Greenfield filter should be placed in the inferior vena cava or rarely a thrombectomy can be performed.

Any patient with evidence of cerebral or systemic bleeding while on anticoagulation therapy needs prompt evaluation. Reversal of warfarin may be needed emergently because of possible life-threatening complications. The use of vitamin K a r a dose of 10 mg intravenously slowly every 8-12 hours for three doses may be required. If more urgent reversal is necessary, fresh frozen plasma (FFP) or prothrombin complex concentrate should be administered. The latter has been shown to be more effective than FFP and vitamin K at reversing the effect of warfarin (Cartmill et al. 2000). In cases where heparin has been given, protamine sulfate (1 mg/100 units of heparin) should be administered immediately after stopping the infusion.

SPECIFIC CLINICAL CONDITIONS

We will review important issues in the critical care of patients with certain neurological diseases whose course may sometimes involve acute phases requiring the need for *neitro-*critical care, I'll esc diseases include a cure ischemic stroke, cerebral edema, intracranial hypertension, ICH, SAH, myasthenia gravis crisis, GBS, and status epilepticus. These diseases are reviewed in general elsewhere in this text, but the purpose here is to emphasize the aspects of their neurocritical care. Other neurological diseases, such as congenital myopathies, spinal muscular atrophy, muscular dystrophies, and amyotrophic lateral sclerosis, may require intensive care. However, generally the problems patients with these diseases face which would require critical care fall within the spectrum of generalized intensive care. It is the need for specialized neurocritical care that chiefly concerns us here.

Acute Ischemic Stroke

There are several reasons for instituting intensive care of the acute ischemic stroke patient. These are both neurological and non-neurological. The neurological reasons depend on

whether the patient has received thrombolytic therapy. If a stroke patient is treated with thrombolytic therapy, the patient is at risk for hemorrhage into the infarct or even in noninfarcted areas of the brain (or even elsewhere in the body}. Such patients need careful monitoring with special attention to their neurological status. Should they in tact suffer intracranial bleeding, the risk of expansion of the hematoma and cerebral edema necessitate aggressive management of hematocrit and any coagulopathy and constant monitoring of blood pressure. Even without thrombolytic therapy, large infarcts such as a massive middle cerebral infarct (which generally produces profound neurological deficits and suggestive changes on head CT scans, as desctibed below) generally warrant close monitoring because of the high frequency of cardiac and pulmonary problems, as well as the high mortality associated with their tcsulting cerebral edema and consequent possible herniation. Other stroke-re la ted conditions that deserve neurocritical care management include crescendo transient ischemic attacks (because of the risk of impending ischemic stroke), progressive neurological decline in the setting of an acute ischemic stroke (for the purpose of induced hypertensive therapy), arterial dissection (hypervolemic and hypertensive therapy are necessary}, postendovascular procedure (because of the significant risk of embolization and reocclusion), and cerebral vasospasm following subarachnoid hemorrhage (sec later discussion). In addition, stroke victims can require intensive care for non-neurological reasons such as respiratory failure and subsequent mechanical ventilation, vasopressor administration for hypotension, therapy for critical hypertension, cardiac disease such as myocardial ischemia or arrhythmias, management of systemic bleeding complications due to thtombolytic therapy, or management of pulmonary complications {e.g., pulmonary edema).

The management of an acute ischemic stroke must begin with both clinical stabilization of the patient and an evaluation for thrombolytic therapy. If the patient presents within six hours of symptom onset, there is the possibility of administering a thrombolytic agent either intravenously (within first 3 hours) (National Institute of Neurological Disorders and Stroke 1995) or intra-arterially (from *3-6* hours) (Suarez et al. 1999). These patients arc evaluated with the National Institutes of Health Stroke Scale (NIHSS). The NIHSS scores the stroke severity through assessment of consciousness, visual fields, sensorimotor systems, and speech and language. The maximal score is 42 and represents the most devastating of strokes. Current guidelines qualify patients with an NIHSS score >4 as potential thrombolytic candidates. Patients with NIHSS scotes >18 have the worst clinical outcomes. In addition to the use of the NIHSS, imaging techniques such as CT, MR1, angiography, and TCD can assist in the evaluation of acute stroke patients. With the advent of rapid MRI technology, imaging can even help with the triage of acute stroke patients for treatment (Sunshine et al. 1999}.

However, before there can be any discussion of treating a patient, the stroke victim must be clinically stabilized. This brings us back to the "ABCs" of basic life support. For patients whose airway is at risk, who arc in respiratory distress, or whose GCS score is less than eight, immediate intubation and mechanical ventilation arc necessary. Acute stroke patients with evidence of Cushing's triad {systemic hypertension, bradycardia, and respiratory disturbances) raise the suspicion of elevated ICP and therefore require immediate intubation. Controlled hyperventilation for management of elevated ICP can then be performed {see later discussion). Rapid sequence intubation, the generally preferred method, is described previously (Peterson et al. 1998). Following intubation, optimization of patient comfort and the need to avoid elevations in intracranial pressure (caused by vasodilation as a result of abnormal cerebrovascular compliance that occurs in cerebral tissue damage) warrant sedation with short-acting agents such as propofol or midazolam.

If the patient is acutely hypotensive at presentation, aggressive fluid replacement must be initiated. Because of the need to avoid dextrose or hypotonic solutions that can worsen cerebral edema, 0.9% saline fluid is routinely used. Should vasopressors be necessary, phenylephrine is used because it is an *a*\ agonist, and cerebral vessels tend to have a very small population of al agonists. Dopamine is often used when bradycardia is present. Animal studies and clinical evidence suggest the benefit of increasing CPP through the ischemic penumbra that surrounds the core ischemic brain tissue. As a result it is recommended to aggressively hydrate all ischemic stroke patients (with due consideration for other factors such as heart failure). This is thought to increase the CPP by increasing total intravascular volume or truly increasing cerebrovascular ABP. Some clinicians try to achieve a systolic blood pressure between 140 and 180 mm Hg in acute ischemic stroke patients. Although it may not be necessary to induce hypertension in clinically stable patients, for patients with known stenoses of the cerebral arteries (both intracranial and extracranial vessels, such as the carotid and vertebral arteries), it has been shown to be safe and effective to do so.

Note also needs to be made about control of elevated ABP. Auto regulation following ischemic sttoke usually produces elevated ABP. This is in fact the inherent compensatory mechanism of the brain to maintain adequate CBF. It also forms part of the basis for the theory behind the efficacy of induced hypertension to improve clinical outcome in stroke by increasing CBF to the ischemic penumbra. But m the setting of the need to administer thrombolytic therapy, systemic hypertension can be dangerous. This is due to the increase in incidence of post-thrombolysis ICH seen with elevated ABP. Likewise, even in the absence of the use of thrombolytics, extremely elevated ABP can alone be a risk factor for hemorrhagic conversion of an infarct. Guidelines for the management of

elevated ABP in the setting of acute ischemic stroke have been established (Adams et al. 1996):

1. For diastolic blood pressure >140 mm Hg on two readings 5 minutes apart, administer IV infusion of sodium nitroprusside (0.5-10 jjg/kg/min) and titrate until diastolic blood pressure goes down by 20%.
2. For systolic blood pressure >230 mm Hg and/or diastolic blood pressure of 121-140 mm Hg, administer IV infusion of labetalol (10 mg delivered over 1-2 minutes; repeat this bolus or double the dose of labetalol successively every 10 minutes up to a total dose of 150 mg). If labetalol is still not effective, administer sodium nitroprusside.
3. For systolic blood pressure of 180-230 mm Hg and/or diastolic blood pressure of 105-120 mm Hg, administer IV infusion of labetalol as in (2), up to 150 mg total dosage.
4. After initial control of the elevated ABP, labetalol can be administered every 4-8 hours. For patients with asthma, bronchial hyper-re activity, heart failure, or severe cardiac conduction defects, labetalol is not the drug of choice, and other agents are indicated.

In addition to close monitoring of ABP, blood glucose must also be monitored closely. At a minimum blood glucose should be checked every six hours for all acute ischemic stroke patients, even nondiabetic ones. For serum concentration above 150 mg/dL serum glucose should be lowered, since hyperglycemia is known to exacerbate focal neurological deficits (Weir ct al. 1997}. T needs to be taken frequently and maintained at less than 37.5 C. F.levated T has also been associated with poor outcomes in acute stroke patients.

If a patient who has received thrombolytic therapy for an acute stroke is suspected to have bled, the hematocrit, hemoglobin, PTT, PT/INR, platelet count, and fibrinogen must be determined. Transfusion of blood products may be necessary. Because patients receiving thrombolytic therapy should be admitted to an NSU in the immediate post-thrombolysis phase, recommendations by the American Heart Association for management of bleeding are reviewed here:

1. Thrombolytic therapy should not be used unless there are readily available facilities to handle bleeding complications.
2. Until head CT scanning is available for a patient who experiences new or worsened neurological deficits, ICH must be suspected as the likely cause of deterioration of clinical status. In this case—as in all cases of suspected thrombolysis-associated bleeding—the infusion of the thrombolytic agent or any anti-coagulant therapy must be stopped, I lead CT scanning is obviously emergently necessary.
3. Surgical consultation should be considered.

For large ICH, any coagulopathy will have to be corrected. Cerebellar hematomas and large (>60 cc) lobar hemorrhages that have mass effect require emergent drainage.

Either in the case of ICH or simply because of large ischemic strokes (for example, complete MCA occlusion with poor collateral flow [has causing infarction of the complete MCA territory) or for other reasons, there can be so much cerebral edema that significant mass effect and elevation of ICP can occur. In these cases an intensive care environment, if the patient is not already in one, is critically important. Management of this condition is reviewed in the following section.

Cerebral Edema and Elevated Intracranial Pressure

Through a complex mechanism relating to multiple membrane proteins and transporters involved in the formation of the blood-brain barrier (BBB) and to several autacoids and proinflammatory proteins, under certain pathological conditions this barrier can break down. Once BBB is permeable there can be a net influx of water and solutes to the interstitium and intracellular spaces, thereby causing cerebral edema. Some of the conditions that can cause this are primary cerebral injuries such as ischemic infarcts, ICH, and traumatic brain injury. Cerebral edema can be worsened by such secondary factors in brain injuries as hypotension, hypoxemia, and seizures. Once an affected area of the brain is edematous, the potential for mass effect arises, because the intracranial volume is essentially fixed by the rigidity of the skull. In the setting of mass effect, ICP can rise and raise the grim prospect for the development of herniation syndromes. This is the profound danger of cerebral edema and explains the need for close monitoring of patients with the potential for cerebral edema who show neurological worsening or of parients with significant cerebral edema even without evidence of neurological worsening. An example of the latter is large lobar ischemic strokes that can develop cerebral edema up to 96 hours after the initial infarct.

The normal mean ICP is in the range of 5-10 mm Hg, Levels above 15 mm Hg are considered absolutely abnormal (see the previous discussion). Once ICP is elevated, it is considered an emergency and may require emergent treatment to lower it.

Management of elevated ICP involves both medical and surgical maneuvers (Suarez 1999). The first step (assuming the cervical spine is stable for flexion) is to place the patient's head and upper trunk at 30"; in many cases this is effective in reducing ICP (Frank 1993). Medical treatment then begins with evaluating the need for intubation. If the airway is unstable, if there is respiratory distress, or if the GCS is less than 8, the patient needs emergent intubation. However, elevated ICP alone can necessitate intubation to perform one of the primary means of treatment, which is controlled hyperventilation (HV). This means increasing

the respiratory rate of the intubated patient to blow off more $C0_2$. The goal Pa«>2 is between 28 and 33 mm Hg. Lowering the $Paco_2$ beyond this range carries a risk of inducing cerebral ischemia and therefore must be avoided. Hyperventilation is the fastest method of medical management for elevated ICP, and its effect lasts for several hours. Once the target Pact); has been achieved, recommended practice is to slowly decrease the ventilatory rate to allow the Paco2 to rise at about a rate of 2 mm Hg per hour up to the normal range. This will allow the treating physician to use hyperventilation later on, should it be necessary in a given patient.

The next step is to administer hyperosmolar solutions, most commonly mannitol. Generally mannitol is given as a bolus over 10-15 minutes at a dose of 0.5-2.0 g/kg. A phenomenon known as "rebound" cerebral edema has been described in the setting of continuous mannitol infusions, and thus continuous infusion is not advised. Serum osmolarity must be measured, usually every six hours, to adjust the requisite dose of mannitol to keep osmolarity above normal (usually 300-320 mOsm/L). If an intraventricular catheter is already in place, this can be used to draw off CSF to directly lower ICP.

When these methods fail to lower ICP, barbiturate coma is the next step. The commonly recommended technique is to induce coma with high-dose pentobarbital as a 40 mg/kg IV bolus followed by a continuous infusion at a dose of 1-2 mg/kg per hour. The coma should be maintained for 24-48 hours *after* achieving control of the elevated ICP. Several factors, especially the adverse effects of the treatment, must be kept in mind while using this therapy. These are summarized in Table 51.8. As with stroke patients, part of the neurocritical care of patients with elevated ICP is maintaining normothermia and normoglycemia, avoiding increased intrathoracic pressures, and monitoring closely for, as well as taking prophylactic measures against, seizures (including giving phenytoin). One of the alternative or adjunctive experimental therapies to barbiturate coma that is showing promise is hypertonic saline administration (Qureshi and Suarez 2000; Suarez et al. 1998). Other experimental therapies, such as induced hypothermia and the use of neuroprotective agents, are on the horizon.

Table 51.8: Protocol of care of patients treated with pentobarbital coma

Intubation/mechanical ventilation
Peripheral arterial line
Pulmonary artery catheter placement (Swan-Ganz catheter) to measure central venous, pulmonary capillary wedge pressure, and cardiac output
Aggressive IV hydration for a goal wedge pressure of 12-18 mm Hg
Use of vasopressors (phenylephrine, norepinephrine, or dopamine) to keep CPP >70 mm Hg
Normothermia: 35.5-37.5"C
Pulmonary toilet
DVT/GI prophylaxis
Adequate nutrition: ideally through enteral route; parenteral route if this is not possible
Avoid hypotonic solutions
Maintain normoglycemia: 100-150 mg/dl,
Monitor leukocyte count on peripheral blood smear (CBC) closely; pan culture and possible empiric antibiotics to be started at first sign of significant elevation
Bedside I'.I'C monitoring tor bursi suppression partem
Jugular bulb catheter for monitoring (and treatment) of cerebral venous oxygen saturation

Surgical management obviously involves treatment of surgically relevant lesions. Therefore tumors need to be resected or dcbulked, hematomas may need to be evacuated, and brain abscesses may need to be aspirated and drained. There are experimental surgical techniques of performing bifrontal craniectomy for head trauma to reduce ICP and performing hemicranicctomy for large cerebral infarcts (Schwab et al. 1998).

Subarachnoid Hemorrhage

Virtually all patients with SAH will need to be initially managed in an NSU setting because of the complications associated with this potentially devastating condition (Van Gijn and Rinkel 2001). The goal of management in the acute phase of SAH is to prevent rebleeding and the sequelae from the initial hemorrhage, such as vasospasm and consequent cerebral ischemia. As a result of autoregulation, as well as other systemic factors, hypertension in the immediate post-hemorrhage phase can be profound. Extreme hypertension must be treated in this phase to reduce the risk of rebleeding. While some argument exists as to what constitutes the level at which to treat elevated ABP, the recommendation is to keep systolic blood pressure below 160 mm Hg. Even mundane measures such as maintaining a quiet environment with few distractions can keep ABP low. Artificially lowering ABP should not cause problems with respect to vasospasm-induced ischemia because available evidence indicates this process does not take place until at least postbleed day 3. Patients will need continuous ABP monitoring, usually with an arterial blood pressure transducer. Once cerebral aneurysms are secured, aggressive fluid hydration with normal saline solution (often at twice maintenance rates) can help to prevent vasospasm and cerebral salt wasting.

Symptomatic cerebral vasospasm usually occurs between 4 and 14 days after SAH and manifests itself acutely as focal or diffuse neurological symptoms. Should vasospasm occur, hydration with intravenous normal saline is part of recommended hyperdynamic therapy or, as it is colloquially called, "triple H" therapy, for hypervolemia, hypertension, and Aemodilution (Egge et al. 2001). While demonstrated efficacy in controlled trials is currently lacking, the American Heart Association docs recommend use of aggressive hydration with crystalloid such as normal saline or 5% albumin to elevate central venous pressure

(Mayberg et al. 1994). The technique of induced hypertension is essentially the same as noted above for acute ischemic stroke, with the use of phenylephrine and possibly dopamine or other pressor agents.

Some of the other complications, which may complicate management of SAH in the neurocritical care setting, are hydrocephalus, hyponatremia, and seizures. Hyponatremia can be caused by increased levels of atrial natriuretic factor (ANF) or by SIADH. Distinguishing between the two causes can be difficult but is important because restricting fluid for SIADH mitigates the therapeutic effect of hypervolemia and precludes aggressive fluid hydration. While a full discussion of this issue is not possible here, it should be noted that measuring the patient's volume status (i.e., weight, fluid balance, central venous pressure, and pulmonary capillary wedge pressure) can be critical to distinguishing between these two causes. These measurements are low in cerebral salt wasting (due to diminished intravascular volume), but normal or elevated in SIADH. Thus placement of a central venous catheter may be necessary.

Communicating hydrocephalus (HCP) can present acutely (within 1 week) or subacutely (a few weeks) after SAH. Clinical presentation of these patients is usually diffuse brain dysfunction secondary to elevated ICP. HCP is usually treated with intraventricular catheters; some patients may require permanent ventticuloperitoneal shunts. Clinical seizures are seen in about 26% of SAH patients. Such patients should be managed as described in the following section.

Spontaneous Intracranial Hemorrhage

Our purpose here, as in the other sections, is to simply note issues in neurocritical care of patients with ICH. Most important is the fact that the risk of neurological deterioration and cardiovascular instability in patients with ICH achieves its highest level during the first 24 hours after the bleed {Qureshi et al. 2001). For this reason many experts recommend admitting such patients to an NSU setting for at least 24 hours after the onset of ICH (Broderick et al. 1999). However, such a decision is often based on the fact that around 30% of patients with supratentorial ICH and nearly all patients with brainstem or cerebellar ICH have impaired consciousness, require intubation, and thus require admission to an NSU. Once m the NSU, monitoring of various clinical parameters just as for acute ischemic stroke will apply to patients with ICH *except* for the issue of aggressive hydration and induced hypertension. Much controversy surrounds the question of whether elevated ABP causes expansion of the hematoma. Current guidelines from the American Heart Association recommend that patients with a mean ABP >130 mm Hg be treated with IV antihypertensive agents (but keeping CPP above 70 mm Hg) for 3 days. After this, oral hypotensive agents can be given as long as the patient is clinically stable. Other issues of neurocritical care that may come up for a patient with ICH are mass effect from the hematoma and surrounding cerebral edema resulting in elevated ICP. The principles of management are the same as described previously. In addition, some cases ol K I 1 involve intraventricular blood, which can predispose the patient to hydrocephalus.

Myasthenia Gravis Crisis

A myasthenia gravis crisis (MGC) is defined as myasthenia gravis (MG) weakness severe enough to require mechanical ventilation (Mayer 1997). In 74% of patients in whom MGC occurred, it did so within the first two years after disease onset, and MGC can occur in up to 20% of all patients with MG (Thomas et al. 1997). A number of factors have been identified as precipitants of MGC (Table 51.9), although up to 30-40% of patients with MGC do not have clearly identifiable predisposing factors. It is important to do as much as possible to identify these precipitants, because a fundamental principle of managing the MGC is to remove them. Because of the involvement of the oropharyngeal and respiratory muscles, as the weakness of these muscles progresses, the FVC declines, which allows atelectasis to develop and then lead to respiratory failure. As described in Chapter 84, serial monitoring of hospitalized MG pun cuts must he performed with close attention to physical examination evidence of respiratory distress, as well as ABG and bedside rests of respiratory function (namely, NIF and VC). It must be remembered that the ABG, NIF, and VC can become abnormal only very late in the progression towards MGC. Also, while a maximal NIF or VC may be apparently adequate in a one-time test, fatigue may reduce respiratory function to below a critical level shortly thereafter,

Rapid-sequence orotracheal intubation, as described previously, is preferred. Recommended ventilator settings are small tidal volumes at 7-8 cc/kg with more rapid respiratory rates at 12-16 breaths per minute. In addition, atelectasis can be avoided with intermittent sighs of 1.5 x tidal volume at a frequency of 3-4 times per hour.

Tahlc 51.9: Precipitants of myasthenia gravis crisis

Infections:
Most commonly upper and lower respiratory tract
Medications:
Corticosteroids
Antibiotics: aminoglycosides, ciprofloxacin, clindamycin
Antiarrhythmics: procainamide, propranolol, timolol
Neuropsychiatric drugs: phenytoin, trimethadione, lithium
Stress:
Recent surgery
Trauma
Botulinum toxin administration
Thymoma

Several conditions should be met to make a decision about readiness for extubation. The ability of the patient to withstand procedures producing respiratory or bulbar muscular fatigue is crucial. Proper care of the MGC in the NSU setting also involves attention to adequate nutritional support, maintenance of adequate hydration, careful attention to electrolytes, aggressive pulmonary toilet, and DVT and GI prophylaxis. Acute treatment of neuromuscular failure from MG includes plasma exchange or intravenous immunoglobulin and corticosteroid therapy {Qureshi et al. 1999),

Guillain-Barre Syndrome

As with patients with MG, those with GBS will need neurocritical care most commonly for difficulty with respiration, although other critical conditions such as cardiac arrhythmias, sepsis, and pulmonary embolus can complicate their hospital course and require admission to an NSU {Ropper 1992). For this reason, when patients with GBS are admitted to nonintensive care settings within the hospital, special attention must be given to pulmonary toilet (e.g., incentive spirometry and chest percussion), GI and DVT prophylaxis, hydration, adequate nutrition, and frequent neurological examinations to avoid complications and rapidly identify patients who are clinically decompensating. Inspiratory and expiratory weakness together with bulbar weakness, if present, forms the basis of the significant risk that patients with GBS have for respiratory failure, either directly because of the weakness or because of aspiration and pneumonia. It is precisely this risk that necessitates the frequent neurological monitoring, including measurement of NIF and FVC. Should FVC fall to 20 cc/kg or less, the patient needs to be transferred or admitted ditectly to the NSU. FVC less than or equal to 15 cc/kg necessitates intubation and mechanical ventilation. Corresponding levels exist for NIF, but because of effort dependence they are less reliable. Fatigue is as much of a factor in GBS as it is in MG. A study on vital capacity in GBS showed that a decrease of 50% in the vital capacity over 48 hours predicted the need for mechanical ventilation (Chevrolet and Deleamont 1991). Other clinical clues predicting a need for mechanical ventilation include severe bulbar weakness, tachycardia, tachypnea, staccato speech, inability to count from 1 to 20 in a single breath, use of accessory muscles for breathing, and paradoxical breathing. Hypoxemia and respiratory acidosis seen on ABG tend to be late findings. Should intubation be necessary, as with other neurological conditions, rapid-sequence intubation and avoidance of depolarizing agents are recommended. In addition, the risk of aspiration is significant in patients with GBS. Therefore extreme vigilance must be maintained for the earliest evidence of pneumonia to promptly initiate antibiotic therapy.

It has been well documented that patients with GBS may have autonomic dysfunction and even failure, in addition to muscle weakness. Thus in addition to respiratory reasons for neurocritical care, there can sometimes be cardiac reasons. Some of the reported cardiovascular abnormalities include ECG changes, bradycardia, labile ABP (both extreme hypotension and hypertension, brady-rachycardias, and even fatal arrhythmias). Therefore careful attention must be paid to an admission ECG and any evidence of cardiac rhythm changes or other evidence of autonomic dysfunction (such as orthostatic hypotension, pupillary abnormalities, sweating abnormalities, and gastrointestinal dysfunction). Depending on the clinical scenario, cardiac monitoring may be appropriate. In such settings vasoactive medications must be used with caution.

Status Epilepticus

With as many as an estimated 250,000 cases of status epilepticus (SE) in the United States annually and with a mortality as much as SO,000 annually, it is no wonder that it desetves aggressive neurocritical care (Fountain 2000). Currently SE is defined as either two consecutive seizures within five minutes without intervening recovery of consciousness or a prolonged seizure (with or without impaired consciousness) for 30 or more minutes (Lowenstein and Alldredge 1998). The patient in SE needs to be acutely stabilized. This involves attending to some of the same factors as in acute ischemic stroke: establishing airway patency, maintaining adequate breathing, and determining the need for intubation; delivering oxygen, providing intravenous hydration, and ensuring cardiovascular stability; and controlling the seizures.

We provide the following recommended protocol:

1. Lorazepam should be administered at 0.1-0.2 mg/kg IV at a rate of 2 mg per minute.
2. If seizures continue, if the etiology is known but not corrected, or a cause for the seizure activity is not known, the patient should be loaded with phenytoin 20 mg/kg IV at a rate of 50 mg per minute or fosphenytoin 20 mg/kg IV at a rate of 150 mg per minute. If IV access cannot be obtained, fosphenytoin can be administered intramuscularly. For patients allergic to phenytoin, valproic acid can be loaded at 20-25 mg/kg IV at a rate of 50-100 mg per minute.
3. For repeated seizures, additional lorazepam may be given (at above dose) or additional phenytoin or fosphenytoin can be administered at 10 mg/kg IV at a rate of 50 mg per minute.
4. Should seizures continue after this, the next step is essentially some kind of induced coma using one of the following agents:

    - Midazolam IV 0.2-0.3 mg/kg loading dose, with maintenance dose of 0.1-2 mg/kg per hour
    - Propofol IV 50-250 gg/kg per minute

Either of these agents requires that the patient be intubated and have central venous access, continuous cardiovascular monitoring, and continuous EEC monitoring for the purpose of titrating these medications to achieve a burst-suppression pattern. The medication must be continued for at least 12 hours after initiation of therapy. Other choices include phenobarbital 20 mg/kg IV at a rate of 50-75 mg/min and valproic acid as described previously.

As with the other conditions discussed, the neurocritical care of SE patients involves attention to proper pulmonary toilet, cardiac monitoring, electrolyte balance, GI and DVT prophylaxis, and adequate nutrition. Fxccpt in cases in which the specific cause of the seizures is unquestionably known. n is ;iKn r-c-ciiMiMiended to give thiamine 1 0(1 mg IV upon presentation and daily to cover for seizures in chronic alcoholics, while various etiologies are being explored.

Chapter 52
Principles of Neurosurgery

Roberto C. Heros, Deborah O. Heros, and James M. Schumacher

The practice of neurosurgery is founded in neurology, and a solid understanding of neurological diseases is fundamental to good clinical neurosurgical practice. Likewise, neurology cannot be practiced well without a basic knowledge of the surgical implications of neurological diseases. Most of the specific pathological entities that constitute the bulk of neurosurgical practice (e.g., head and spinal cord injury, brain tumors, aneurysms and arteriovenous malformations [AVMs], degenerative and neoplastic spinal disorders, central nervous system infections, peripheral nerve problems, and pain) are covered in detail in specific chapters elsewhere in this book. Therefore in this chapter, we concentrate on three particular aspects of current neurosurgical practice. The first section deals with some neurosurgical emergencies that can occur in patients who are generally cared for by neurologists. The second section deals with some specific neurosurgical considerations that arise frequently in patients cared for by neurologists. Finally, in the third section, we discuss briefly some recent technological developments that have had a significant impact on neurosurgical practice and that are of interest to neurologists.

NEUROSURGICAL EMERGENCIES IN THE NEUROLOGY PATIENT

Acute Hydrocephalus

Hydrocephalus is usually a relatively chronic problem, but it can result in very dramatic acute symptomatology in a number of clinical settings. An awake patient can rapidly become drowsy, sometimes preceded by agitation, and progress rapidly to stupor and coma with small, poorly-reactive pupils. The importance of considering acute hydrocephalus in this setting is that the condition can often be reversed by one of the simplest neurosurgical maneuvers, an emergency ventriculostomy. Any neurosurgeon can perform a ventriculostomy in a matter of minutes with simple equipment kept available in a sterile tray specifically designed for this purpose in almost all hospitals in which neurosurgery is practiced. Most frequently, a frontal "twist drill" trephination is performed through a small incision in the frontal region (11 cm behind the nasion and 3 cm lateral to the midline), and the anterior horn of the lateral ventricle is cannulated with a small ventricular catheter connected to external drainage. There

arc a number of specific instances in which this maneuver can be life saving,

Herniation after a lumbar puncture is indeed a rare event. Before computed tomographic (CT) scanners were available, this was seen more often when patients with large supra ten to rial or posterior fossa masses underwent lumbar puncture. However, there are still occasional instances of patients with conditions that are not diagnosed by an initial CT scan, which can result in herniation after a lumbar puncture, such as in patients with acute bacterial meningitis and in patients with basal meningitis due to either tuberculosis or sarcoidosis. A simple ventriculostomy can immediately reverse this situation.

Patients who have had a subarachnoid hemorrhage (SAH), usually from a ruptured aneurysm, can deteriorate abruptly and rapidly lapse into coma, usually as a result of rerupture of the aneurysm cither into the parenchyma of the brain or into the ventricles causing acute hydrocephalus. In these patients, we recommend an emergency ventriculostomy even before a CT scan is performed. We have seen several patients wake up within a few minutes of a ventriculostomy when the problem was intraventricular hemorrhage and acute hydrocephalus. Obviously, the patient with a massive intracerebral hemorrhage would not be helped by this maneuver, but even then nothing is lost except the time taken to do the ventriculostomy. Acute hydrocephalus from intraventricular hemorrhage can also be suspected as the cause of abrupt coma in patients known to have an AVM or a cavernous angioma in the periventricular region.

Patients with a lesion m the region of the anterior third ventricle and the foramen of Monro can deteriorate acutely, and in these instances, acute hydrocephalus musr be suspected. This is a common cause of sudden death in patients with colloid cysts of the third ventricle (Figure 52,1). These patients often have a history of abrupt headaches related to posture or to coughing or performing a Valsalva maneuver that produce an abrupt increase in intracranial pressures. An emergency ventriculostomy can be life saving in these cases.

Patients who have an in-dwelling shunt for hydrocephalus can deteriorate acutely as a result of shunt malfunction. Again, when this occurs and the patient has lapsed into coma, the first step should be a "shunt tap"; by placing a small needle in the shunt reservoir, cerebrospinal fluid (CSF) can be freely extracted if the obstruction is disral. If this fails, usually because the obstruction is proximal, an emergency ventriculostomy is indicated even before the CT scan is obtained.

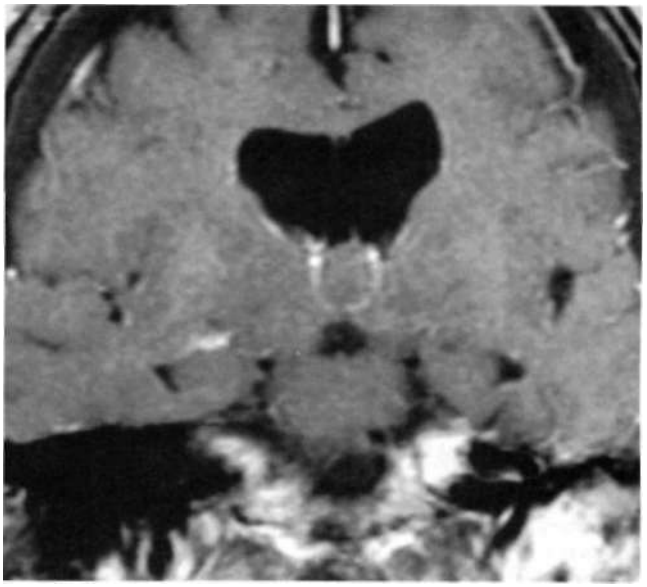

FIGURE 52.1 Colloid cyst of the third ventricle. Note the severe hydrocephalus caused by this small colloid cyst, which is blocking hoth foramina of Monro. The lesion was removed by a microsurgical transcallosal approach without neurological complications,

Cerebellar Hemorrhage and Infarction

Most patients with cerebellar infarction and many patients with cerebellar hemorrhage will be initially under the care of a neurologist. The diagnosis of either entity can almost invariably be made on clinical grounds alone and can be confirmed by a CT scan or magnetic resonance imaging (AlRIj. rhc neurologist must recognize when neurosurgical intervention, which is frequently life saving and function restoring for these patients, is indicated. For this reason, it is convenient ro classify the clinical stages seen in both of these conditions as follows: an initial "cerebellar" stage in which the only clinical deficits detected are referable to the cerebellum; an intermediate stage in which in addition to cerebellar signs, there are signs and symptoms referable to hydrocephalus; and the final stage of brainstem compression. We firmly believe that neurosurgical intervention is indicated when the earliest signs and symptoms of hydrocephalus develop. At this stage, the patient may be treated with a ventriculostomy alone; however, this carries the danger of upward herniation, which is seen frequently after the lateral ventricles are decompressed if the large posterior fossa mass is not dealt with. We prefer to use ventriculostomy cither to gain time to perform a definitive surgical decompression of the posterior fossa or to go directly to the operating room for surgical decompression without a preliminary ventriculostomy. Once definite signs of brainstem compression develop, emergency surgical decompression is mandatory if the patient's life and function are to be saved.

The patient with cerebellar hemorrhage usually presents with the classic history of a headache of relatively abrupt onset frequently accompanied by nausea and vomiting. Very commonly, the patient or his or her family members

will give a history of inability to walk due to instability that develops soon after the headache. When examined, these patients have striking truncal ataxia and often cannot even sit on the examining table to be examined; they can practically never walk. In addition, they frequently have nystagmus and signs of cerebellar appendicular ataxia. When the patient is wide awake and the hemorrhage is not too large (usually <3 cm in diameter by CT scan), surgery can be delayed and the patient can be observed in an intensive care setting. Drowsiness or agitation followed by drowsiness signals the onset of hydrocephalus and calls for surgical intervention. Surgery, in particular a paramedian suboccipital craniotomy with removal of the hematoma, is crucial at the earliest signs of brainstem compression such as an ipsilateral sixth nerve palsy that rapidly advances to a complete ipsilateral gaze palsy accompanied by a peripheral facial weakness on the same side.

With cerebellar infarction, the syndrome tends to progress more slowly than with cerebellar hemorrhage, and very often, the patient can be managed conservatively with careful neurological observation, preferably in an intensive care unit. As opposed to the case of cerebellar hemorrhage, headache may not be prominent at the onset in patients with cerebellar infarction; complaints of dizziness and difficulty walking may be the only signs of cerebellar dysfunction. It is important to remember that because symptomatic cerebellar infarction is most commonly due to occlusion of the vertebral artery at the origin of the posterior inferior cerebellar artery (PICA), a lateral medullary infarct may coexist. The signs and symptoms of intrinsic lateral medullary damage, of course, do not call for surgical intervention. It is therefore essential to differentiate brainstem infarction from brainstem compression resulting from the mass effect of the edema or hemorrhagic transformation of the infarct. The detailed clinical signs and MRI can differentiate the two conditions. The recommended surgical procedure is a bilateral suboccipital craniotomy extending through the foramen magnum. Because the infarction is most commonly in the territory of the PICA, the tonsil is often involved and herniates through the foramen magnum, which needs to be decompressed to relieve brainstem compression. Because the progression of cerebellar swelling is usually much slower with cerebellar infarction than with hemorrhage, it is possible to temporize with a ventriculostomy in patients who have signs and symptoms of hydrocephalus (confirmed by CT scan) but who do not have signs of direct brainstem compression. The syndrome often will gradually resolve without the need for suboccipital decompression in these patients (Camarata and Heros 1996).

The prognosis for good functional recovery is excellent in patients with cerebellar hemorrhage and infarction who had a timely suboccipital decompression before they lapsed into coma. Even comatose patients can make an excellent functional recovery provided that the decompression is performed expeditiously soon after the onset of coma. These patients often require a prolonged period of rehabilitation, sometimes with a tracheostomy and a gastrostomy, but eventually they improve and their intellectual function remains intact.

Intracerebral Hemorrhage

Intracerebral hemorrhage as a clinical entity is covered in detail in Chapter 57B. Here, we only refer to the fact that this entity may be a neurosurgical emergency. This is particularly true when any intracerebral hemorrhage breaks into the ventricle and results in acute obstructive hydrocephalus. As discussed earlier in this chapter, the situation can be significantly palliated with a unilateral or bilateral ventriculostomy if the ventricles are filled with blood. There is considerable evidence that in some circumstances, emergency surgical evacuation of intracerebral hematomas can not only be life saving but also function sparing. Much of the evidence comes from large, but uncontrolled, scries from Japan, where these patients arc often managed in neurosurgical units and considered true surgical emergencies.

Current practice in the United States is to treat patients with supratentorial intracerebral hemorrhage conservatively with maximal medical therapy for increased intracranial pressure (e.g., mannitol and hyperventilation). If they show significant neurological deterioration to the point of herniation, evacuation of the hemorrhage can be life saving, but frequently these patients are left devastated. The important question, which can only lie answered by a randomized controlled trial, is whether early intervention (during the first 6 hours aftet the hemorrhage) may be beneficial in terms of preserving or rcstotiug neurological function. There is clear experimental evidence that secondary changes occur over the first several hours as a result of direct local pressure, ischemia, focal vasospasm, and perhaps release of noxious substances from the clot (Mendelow 1991). These secondary changes in the experimental setting can be prevented by early evacuation of the clot.

For the more accessible lobar subcortical and putaminal hemorrhages, refined microsurgical techniques have been introduced to remove rhc clot with minimal trauma to the brain and with a better chance of achieving thorough hemosrasis. There are also surgical means of evacuating hematomas in less accessible locations like the thalamus that are relatively less invasive rhan direct surgical intervention. These techniques include a device that acts as an Archimides screw to aspirate the clot, the use of a nucleotome type of device to emulsify and then aspirate the clot, the stereotactic injection of lytic agents to liquefy the clot and then aspirate it, and the use of the endoscope to directly visualize and suction the clot. It is now more likely that the proper randomized study to answer the question of whether early surgery is beneficial will be conducted

because patients are seeking medical care sooner as a result of public education campaigns that emphasize the importance of treating stroke as an emergency (i.e., Brain Attack) (Camarata, Heros, and Latchaw 1994). A recent study, however, indicates that postoperative reblccding may be a problem in very early surgical evacuation (Morgenstern etal. 2001).

At the present time, because of lacking specific practice standards or guidelines, individual patient-specific treatment plans are developed. The ovetall medical health of the patient, age, and other issues of quality of life play an important role in the final decision. Emergency operations are often performed on patients who have a significant neurological deficit, who are seen soon after the onset of the symptoms, and who have a relatively accessible hematoma. Patients who were tteated conservatively initially, but who have failed maximal medical therapy and are showing signs of herniation, may also be good surgical candidates. In these patients, the operation is undertaken as a life-saving measure, with little hope of significant functional recovery. We are more conservative with thalamic hemorrhages and will operate only rarely as a life-saving procedure. In elderly patients in whom amyloid angiopathy may be suspected as the cause of hemorrhage (because of evidence of previous hemorrhages, subcortical location, and history of dementia), a conservative approach is advised, because operating on these patients can lead to catastrophe due to poor hemostasis resulting from the friability of the cerebral vasculature.

FIGURE 52.2 Brain abscess. Note the location of this abscess just behind the atrium of the ventricle. If not drained urgently, this lesion couki rupture into the ventricles wirh resulting ventriculitis, which could be fatal.

Intracranial Tumors

In general, intracranial tumors usually present as a neurosurgical emergency only if there is an acute hemorrhage into the tumor with abrupt deterioration. With intrinsic brain tumors, this is statistically most likely to occur with astrocytomas because they are so much more common; however, oligodendrogliomas and ependymomas have a relatively greater propensity for hemorthagc. Of the metastatic tumors, melanoma, hypernephroma, choriocarcinoma, and thyroid carcinoma are particularly prone to hemorrhage.

Some patients with intrinsic brain tumors and occasionally with meningiomas can develop rather massive cerebral edema to the point at which deterioration occurs abruptly. Although generally we try to manage most of these patients with corticosteroids, the neurological deterioration may be abrupt and severe enough to require immediate surgical decompression.

Brain Abscess

A brain abscess may present with acute neurological deterioration resulting from rupture of the abscess into the ventricular system. A brain abscess is suspected in a patient with signs of sepsis in whom the CT or MRI scan shows a parenchymal lesion that is "ring enhancing" (Figure 52.2). Such patients with either a relatively inaccessible brain abscess or multiple brain abscesses are primarily treated medically with antibiotics, usually after aspiration for cultures of at least one of the abscesses. Acute deterioration in these cases is suggestive of intraventricular rupture, particularly if one of the lesions is in the periventricular region. These situations call for immediate surgical drainage of the abscess and ventricular lavage, leaving a catheter for continuous drainage and intraventricular antibiotic injection.

Pituitary Abscess

A rare condition that often calls for emergency neurosurgical intervention is a pituitary abscess. These patients frequently have a history of meningitis, sinusitis, or rhinorrhea. Chronic headaches and signs and symptoms

of pituitary insufficiency are not uncommon. The presentation is usually acute with a sudden exacerbation of symptoms including visual loss, extraocular nerve dysfunction, and disturbance in the level of consciousness. When such a presentation is accompanied by signs of sepsis, a pituitary abscess must be suspected and ruled out. An emergency transsphenoidal debridement, accompanied by systemic administration of antibiotics and appropriate hormonal replacement therapy (including a large loading dose of corticosteroids) is indicated. We use dexamethasone at 10 mg intravenously, immediately followed by 4 mg every 6 hours. Others prefer hydrocortisone at a dose of 200-300 mg intravenously three to four times daily.

Pituitary Apoplexy

Patients with cither a known pituitary tumor or more commonly without such a history may present with an apoplectic attack that includes sudden severe headache, decreased vision, diplopia, and later drowsiness and coma. In these instances, pituitary apoplexy must be suspecred, particularly if the initial CT or MRI scan indicates an enlarged sella or a pituitary tumor. The apoplectic nature of the attack is usually due to infarction, hemorrhage, or hemorrhagic infarction within a pre-existing pituitary adenoma. Not uncommonly, the course is more subacute lasting several days and with less dramatic symptomatology. On examination, the patient may show photophobia and meningismus, bitemporal hemianopia and/or decreased visual acuity in either or both eyes, and deficits of extraocular motion, most commonly a partial or complete third nerve palsy unilaterally or bilarerally.

Pituitary apoplexy represents a medical and surgical emergency. These patients must be treated immediately with intravenous corticosteroids in the doses indicated earlier. A transsphenoidal operarion to remove as much of the tumor and/or hemorrhage as possible, and to decompress the optic apparatus, is mandatory and urgent. The results are excellent if the operation is performed promptly.

Spinal Cord Compression

Acute paraparesis or quadriparesis rapidly progressing to complete paralysis is a common situation in neurological practice. Although the diagnosis of acute demyelinating transverse myelitis is frequently entertained, this diagnosis is untenable without an imaging study thar rules out spinal cord compression. Such a syndrome of acute myelopathy can have a number of causes that require emergent neurosurgical decompression. Most commonly, the problem is due to merastatic tumors, though in this case, unless there has been hemorrhage within the tumor, the progression is usually over days and weeks rather than minutes or hours.

Nevertheless, sometimes the patient does not seek neurological consultation until unable to walk. If the progression has been rapid, emergency decompression or emergency irradiation is indicated depending on the clinical setting. Glucocorticosteroids are usually administered emergently in these instances. Surgery is the preferable recommendation in cases in which the primary tumor is known to be radioresistant, such as a hypernephroma. Lymphomas are very radiosensitive and radiation therapy is usually the preferred modality. When the pathological diagnosis of the tumor is not known, it must be established by open surgery or a percutaneous biopsy.

More dramaric causes of acute spinal cord compression are hematomas, which can be subdural, epidural, or intramedullary, and abscesses, which are mostly epidural but can also be subdural. Both conditions usually call for emergency surgical intervention. An epidural or subdural spinal hematoma can develop spontaneously, but more often, it develops in the setting of anticoagulation, blood dyscrasias, or trauma. Wc have seen a few cases develop after spinal puncture was unadvisedly performed in patients who were anticoagulated. An abscess should be suspected in any patient with a subacute paraplegia who has a history of recent sepsis or who is predisposed to infection either because of diabetes or immunodeficiency. An epidural abscess can also develop in a patient without any predisposing history, and in this instance, the primary event commonly is discitis (infection of the intervertebral disc). The results of emergency surgical decompression both in hematomas and in abscesses arc excellent provided thar the patient undergoes operation quickly after the onset of the symptoms of myelopathy. Even paraplegic patients can recover if operated on within the first few hours after the onset of paraplegia.

Acute spinal cord compression can also develop from compression fractures or fracture dislocations that can occur as a result of relatively minor trauma in patients with severe osteoporosis, metastatic bone disease, rheumatoid arthritis, or ankylosing spondylitis.

Of special consideration is acute cauda equina compression, which often requires emergency neurosurgical decompression. The causes of acute compression of the cauda equina are similar to those of spinal cord compression, However, when the cause is a neoplasm, the evolution of symptoms tends to be considerably slower and less dramatic. Subdural and epidural hematomas and abscesses can affect the cauda equina acutely, and because the potential for recovery of function is better for the cauda equina than for rhe spinal cord, even with a profound deficit, there is reason to perform decompression as rapidly as possible because of the correlation between delay in decompression and extent of recovery. This is particularly true when there is loss of bladder and bowel control; in these cases, full bowel and bladder function rarely returns if decompression is delayed more than a few hours after loss of function. The same is true when compression of the

cauda equina is caused by an acute disc extrusion. Although this can occur at any lumbar level, it is seen most commonly between the fourth and fifth lumbar vertebrae and most of these patients show a complete block to CSF flow at myelography, CT scanning, or MRI scanning. A common mistake is to attribute acute urinary retention in a patient with acute low back pain to the effect of the narcotics that these patients often require to control their acute pain. We teach our residents that acute urinary retention in a patient with a suspected ruptured disc calls for emergency neuroradiological investigation and emergency surgery if a large disc herniation causing cauda equina compression is found. In fact, even the acute development of a foordrop, which is a common and significant disabling neurological deficit, calls for at least urgent (within 24 hours) if not emergent investigation and possible surgery because again the probability of full recovery is related to the rapidity of decompression.

NEUROSURGICAL CONSIDERATIONS IN COMMON NEUROLOGICAL DISORDERS

Subarachnoid Hemorrhage

Patients with SAH may be initially cared for by the neurologist. Although these patients are frequently transferred at some point to a neurosurgical service, **the** neurologist must be aware of some surgical considerations (sec also Chapter 57C).

Timing of Angiography and Surgery

The mainstay of the initial diagnosis of SAH is the CT scan. The results of the CT scan may dicrate immediate neurosurgical intervention, for example, if there is acute hydrocephalus or a large intracerebral hematoma. The scan will also frequently suggest the site of the aneurysm, and the amount of blood is an excellent predictor of the likelihood of vasospasm. The likelihood of a patient developing vasospasm and the specific arteries involved in the spasm are closely correlated with the thickness and location of the clot seen in an early (within 48 hours) CT scan in the basal subarachnoid spaces. Intracerebral and/or intraventricular blood does not appear to correlate with vasospasm, although it does adversely influence the outcome.

Timing of angiography is the next aspect to be considered. Generally, unless the patient is in very bad neurological and medical condition, we recommend proceeding with angiography immediately, regardless of whether early surgery or cndovascular treatment is entertained. Early angiography has the advantage of establishing the diagnosis and the presence or absence of an aneurysm or an AVM and is helpful in establishing the plan of treatment. If endovascular treatment is chosen, sometimes it can be performed in the same angiographic session without need for recatheterization (see Chapter 37C). In addition, early angiography is extremely helpful in establishing the site of bleeding, which is important even if early surgery is not planned because the patient may suffer recurrent hemorrhage. This may result in the need for immediate surgical intervention, particularly if the subsequent hemorrhage is intracerebral. In such instances, there may be no time for angiography and the surgeon must intervene to evacuate the hematoma without delay. It is most helpful in these instances to know the details of the aneurysm. There is a recent tendency to substitute CT angiography for catheter arteriography (see Chapter 37B). This is particularly helpful in patients in bad neurological condition in whom emergency surgery can be planned using a CT angiogram demonstrating the aneurysm rather than catheter angiography.

To guide the timing of surgery, a number of grading systems of the patient's neurological condition and, particularly, level of consciousness have been developed. Generally, grade I and II patients are awake and oriented and in good neurological condition, whereas grade IV and V patients are stuporous or comatose and in very bad condition or are agonal. Grade III patients are awake but confused or drowsy and usually have a mild to moderate neurological deficit. Most neurosurgeons currently advocate early surgery or endovascular occlusion in most cases of ruptured aneurysm when the patient is in relatively good condition, that is, awake with or without a cranial nerve palsy, and either intact neurologically or with only a mild neurological deficit (grades I, II, and "good" grade III patients). The exception is in cases in which the aneurysm presents a major technical challenge such as with giant aneurysms in which open surgery is difficult and endovascular therapy is not likely to succeed. These patients may need to be treated with complicated clipping techniques, **which** may require temporary arterial occlusion or bypass grafting and arterial sacrifice. In these cases, brain relaxation is necessary for optimal exposure, and it may be preferable to wait until the increased intracranial pressure and hyperemia secondary to the initial hemorrhage subside. From the practical point of view, this means 12 or 14 days, and it may be longer in patients whose course is complicated by vasospasm. In patients in poor neurological condition (stupor, coma, and/or a major neurological deficit—grades IV and V), we personally prefer to use endovascular occlusion early or, if this is not feasible, to wait until the hemodynamic effects of the initial hemorrhage and the intracranial hypertension subside before entertaining open surgery. Clearly, having the aneurysm either clipped or completely obliterated by endovascular coiling eliminates the risk of early recurrent hemorrhage and allows the treatment of vasospasm with hypervolemia and hypertension, which augments the risk of rehemorrhage when the aneurysm is unsecured.

Hydrocephalus

Hydrocephalus frequently complicates SAH. Hydrocephalus after SAH is divided into three relatively different clinical syndromes (Heros 1989). The first is *acute, obstructive hydrocephalus,* which is discovered by CT scan in a patient who is in bad condition after the initial SAH. This calls for an emergency ventriculostomy (see Acute Hydrocephalus, earlier in this chapter). The second syndrome is *subacute hydrocephalus,* which characteristically develops after the first few days and results in increased headache and a gradually declining sensorium. We tend to be conservative with these patients and temporize with measures such as mannitol infusion and corticosteroid treatment, which may carry the patient through this stage without the need for a permanent shunting procedure. When the decrease in consciousness is severe, a ventriculostomy is necessary. We prefer to avoid this procedure in the awake patient, particularly if the aneurysm has not been secured, because there have been instances in which rcblecding has been induced by either ventricular drainage or a spinal tap withdrawing a substantial amount of spinal fluid. Some of these patients will eventually need a permanent shunt, but if this can be delayed until the CSF is completely clear, the chances of a successful shunt increase significantly. The third syndrome is *delayed hydrocephalus,* which presents as the syndrome of normal-pressure hydrocephalus. The typical setting is the patient who has recovered or is recovering gradually from an SAH, has had the aneurysm clipped or coiled, and then either fails to continue to improve or starts to deteriorate. The classic triad of symptoms, namely impairment of cognition, difficulty with gait, and incontinence, is frequently seen in these patients. In this clinical setting, when the CT scan shows that the ventricles arc larger than they were initially, we proceed with a shunting procedure without any other tests. These patients respond very well to shunting.

Vasospasm

Although there is no effective way of preventing vasospasm, calcium-channel blockers have proven effective in ameliorating its ischemic consequences, so most neurosurgeons currently use them from the onset in patients with SAH, The mainstay of the treatment of vasospasm remains the induction of hypervolemia, usually with colloids that result secondarily in hemodilution and the artificial induction of hypertension. We use hypervolemia prophylactically from the onset in those patients in whom the initial CT scan suggests a high likelihood of the future development of vasospasm. We also tallow ilu'se patients with daily transcranial Doppler examinations, which show increased flow velocities in arteries exhibiting vasospasm. At the earliest onset of ischemic symptoms presumably related to vasospasm, we perform a CT scan to rule out hydrocephalus and check the blood studies to make sure that abnormalities like hyponatremia and hyperglycemia are not the cause of the deterioration. If vasospasm is left as the probable cause, we proceed with vigorous medical treatment, raising the arterial pressure as necessary to reverse the neurological deficit, sometimes to 190-200 mm Hg systolic. If the patient does not respond promptly with resolution of the ischemic symptoms, an angiogram for possible angioplasty (sometimes preceded by intra-arterial papaverine injection) is obtained (Figure 52.3). It has been our impression, supported by recent anecdotal reports, that such treatment is most beneficial when instituted during the first hours after the onset of the symptoms. For this reason, we consider the treatment of vasospasm a relative emergency.

Y.ndovascular vs. Direct Surgical Treatment of Intracranial Aneurysm

At the present time, there is no definitive answer as to whether endovascular or direct surgical treatment of an intracranial aneurysm is better. Our experience and review of the current literature indicate that endovascular aneurysmal obliteration, when possible, is an acceptable alternative to surgical clipping in terms of preventing early rehemorrhage (Figure 52.4). This form of treatment is generally feasible in patients with nongiant aneurysms whose aneurysmal configuration is "favorable" (narrow neck compared to the width of the dome). Of course, generally these aneurysms are also favorable for surgical intervention. However, some aneurysms, because of their location, are relatively more difficult to treat surgically. In these instances, the early morbidity of endovascular treatment may be less than the surgical morbidity; aneurysms at the top of the basilar artery are a good example of this situation. A recently completed randomized international study conducted at a number of centers in Europe, Australia, and Canada has confirmed that the early morbidity of open surgery is slightly greater than that of endovascular coiling in patients who were felt to have aneurysms that could be treated either surgically or cndovascularly (International Subarachnoid Aneurysm Trial 2002). In this important study, 9278 patients were eligible for randomization. The neurovascular team at each institution felt that in the majority, one or the other form of treatment was preferable, and in those patients who were not randomized, surgery was chosen more often than endovascular therapy. In 2143 patients, the neurovascular team could not he sure which treatment was preferable, so they were randomized. In this group, endovascular therapy showed an absolute risk reduction of 6.9% in terms of likelihood of a had outcome at 1 year. This is an important difference that was significant statistically. However, rebleeding was more common after coiling than after clipping (2,6% after coiling vs. 0.9% after clipping), and if that differential rare of rebleeding continues, it will not take

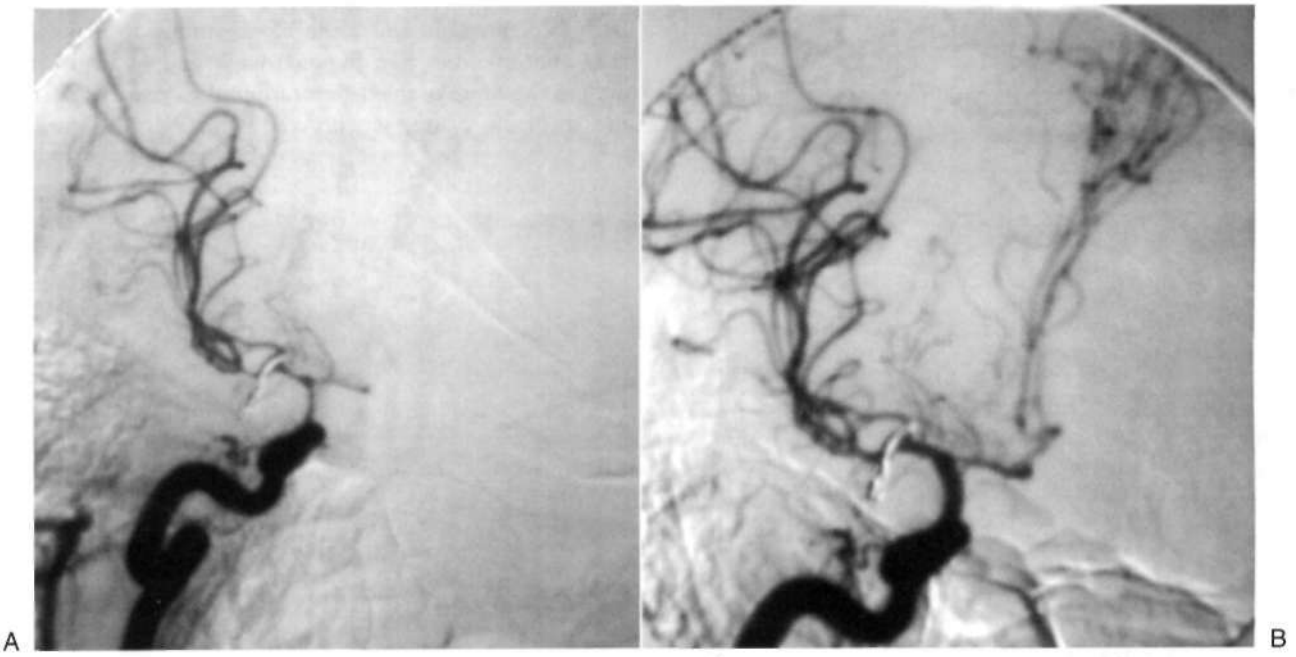

FIGURE 52.3 Vasospasm treated by endovascular balloon angioplasty. (A) Note the severe vasospasm present in the supraclinoid internal carotid artery and in the early segments of the middle cerebral and the anterior cerebral arteries. The partem had a subarachnoid hemorrhage *6* days before from a middle cerebral aneurysm rhat was successfully clipped the day after the hemorrhage. (B) Note the significant restoration to normal caliber of the previously spastic vessels by the endovascular angioplastic procedure. The anterior cerebral arteries, which practically did not fill before rhe angioplasty, now fill relatively well.

many years for the early advantages of coiling to be overcome. The ongoing follow-up study of these patients may give us a more definitive answer about which form of treatment is preferable for aneurysms amenable to borh forms of treatment. However, this study addressed only the group of parients who were felt ro be equally amenable to borh forms of treatment; because they were the minority of the patients evaluated, the results of rhe study cannot be generalized to all patients with aneurysms. Additionally, the study addressed only patients with SAH, and its results should not be extrapolated to patients with unruptured aneurysms.

Unfortunately, endovascular coiling is usually unsuccessful in most giant aneurysms or in aneurysms wirh very broad necks, or in fusiform or dissecting aneurysms. These are, of course, the aneurysms with which we also have the most surgical difficulty'. In these patients, we frequently have to consider other surgical alternatives such as proximal arrerial occlusion or rrapping (occlusion proximal and distal to the aneurysm) with or without a bypass graft, aneurysmorrhaphy (opening and decompressing the aneurysm under temporary trapping), or clipping under cardiac standstill using cardiopulmonary bypass {Figure 52.5).

In our institution, we continue to recommend microsurgical clipping for most accessible aneurysms of the anterior circulation and the vertebral artery when the patient is in relatively good neurological condition. Basilar aneurysms are considered on an individual basis, and currently most are treated by endovascular means. In patients in poor neurological grade, even if the aneurysm is surgically accessible, we prefer to at least attempt endovascular treatment initially. We then proceed to surgery, usually ar a later stage, if the endovascular trearment fails. For most patients with giant or dissecting aneurysms, or aneurysms with a very broad base, surgery remains the preferred option.

Vascular Malformations

Distinct pathological types of vascular malformations usually present as different clinical syndromes. In addition, it has become increasingly apparent that these different pathological entities are not always pure, and sometimes transitional forms and coexistence of different types of malformations are present. Because these patients are frequently cared for by the neurologist, it is pertinent to presenr rhe neurosurgical the rape uric perspective.

The first classic type of malformation, the *capillary telangiectasis,* is generally of no clinical significance and is seen only at autopsy. The second type of vascular malformation is the *venous angioma* (Figure 52.6). It seems clear that most of these lesions are clinically silent. However, occasionally there can be seizures that can be localized to the area of the venous angioma and, rarely, a hemorrhage. In the latter case, it is not uncommon to have

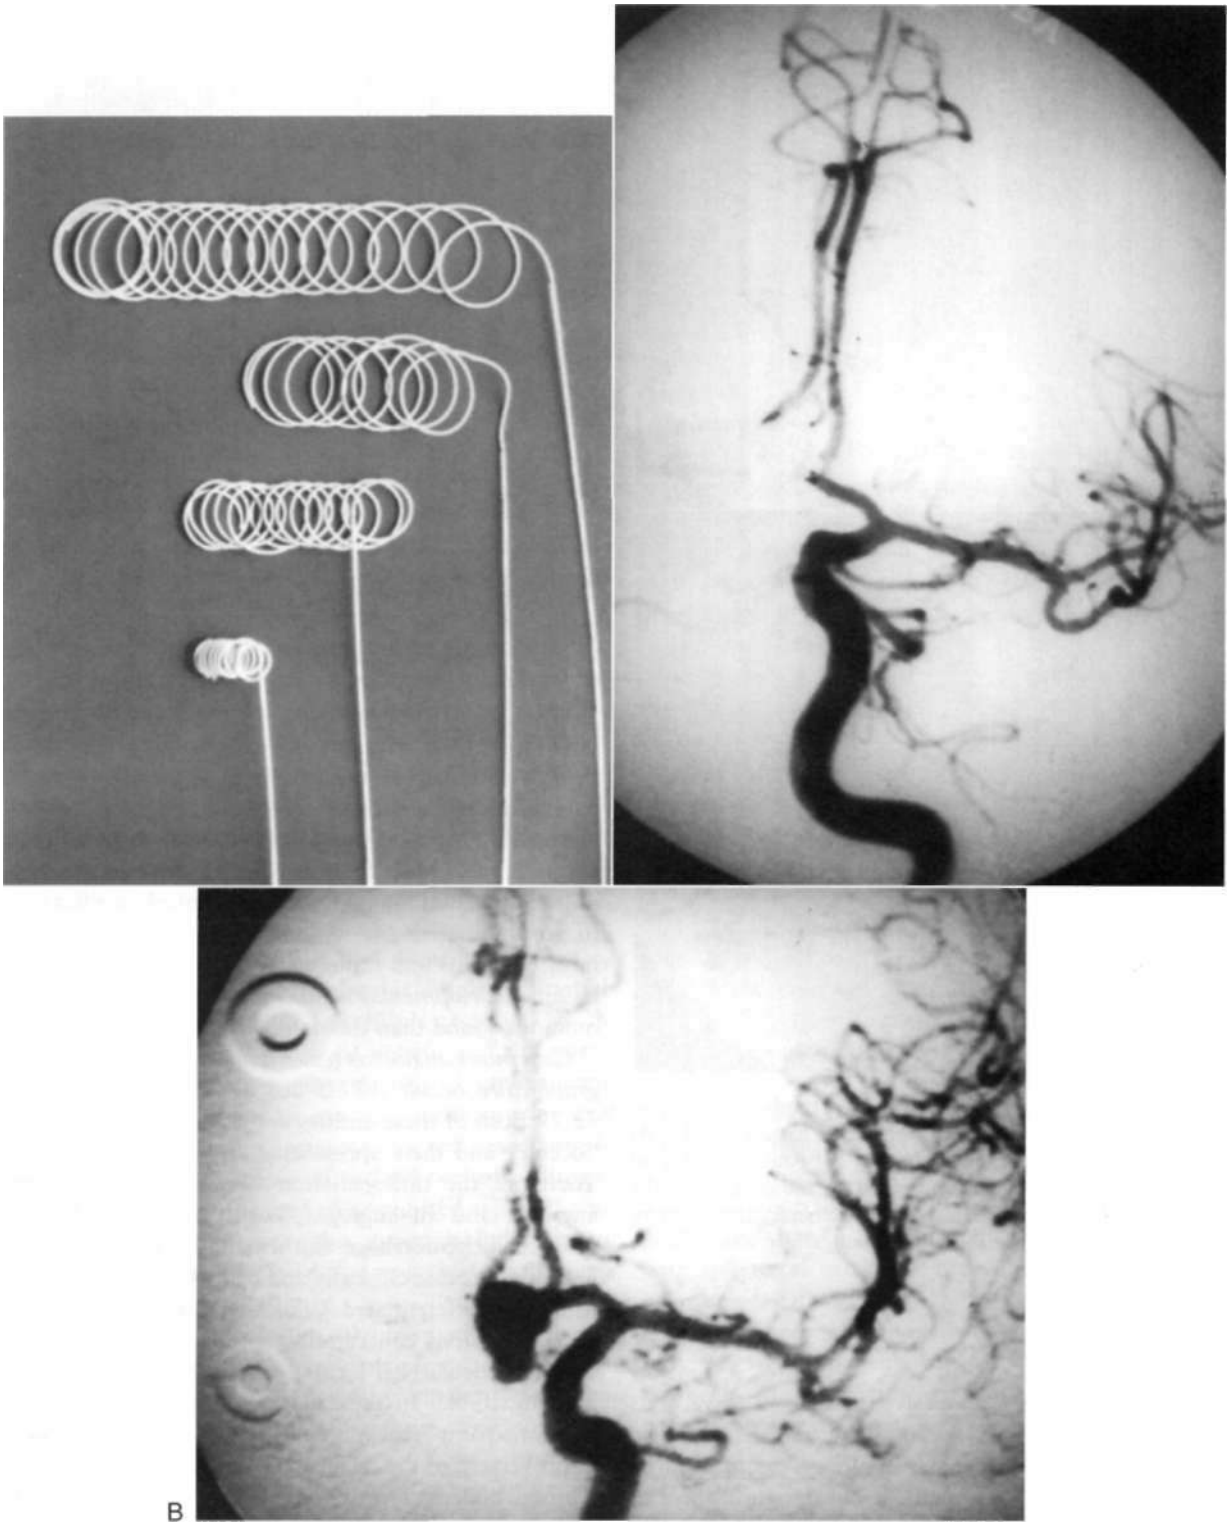

FIGURE 52.4 Endovasculat coil occlusion of aneurysms. (A) Detachable Guglielmi coils, which come in different sizes and can be detached by electrolysis from the carrier catheter once they are placed inside the aneurysm. (B) Ruptured anterior communicating artery aneurysm in a patient who had a poor neurological grade. Because of the grade, the decision was made to coil this aneurysm rather than clip it microsurgically. (C) Result after endovascniar coiling. Note that there is no filling of the aneurysm, which was Totally occluded by coiling.

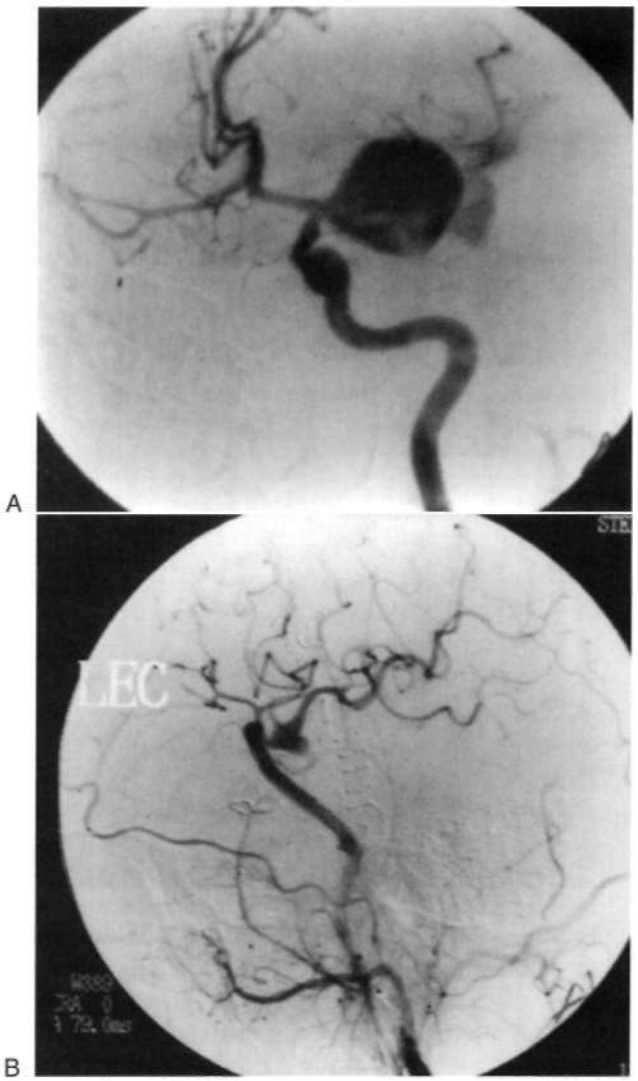

FIGURE 52.5 Unclippable giant middle cerebral aneurysm treated by middle cerebral occlusion after bypass graft. (A) Preoperative appearance of the aneurysm. (B) After occlusion of the middle cerebral artery just proximal to the aneurysm, the saphenous vein bypass graft between the external carotid artery and a distal division of the middle cerebral artery now fills the entire middle cerebral territory.

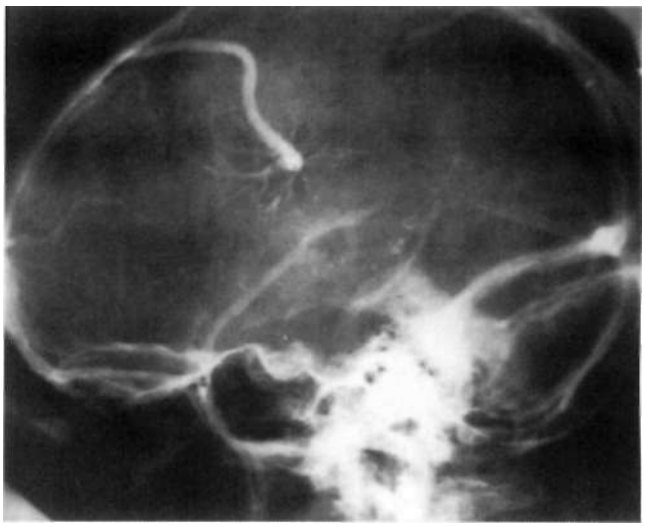

FIGURE 52.6 Venous angioma. Note the characteristic caput medusa appearance of small radial veins draining into a large venous channel. These lesions fill angiographically in the late venous phase, and they usually drain the normal brain, which makes their excision dangerous.

the lesion results in seizures, it is preferable to tteat the patient medically without surgery. When these patients are referred for surgical opinion, we prefer to reassure them and to tell them that they have not a pathological entity but a developmental anomaly of little clinical significance and to go about their life without restrictions. To this effect, most clinicians and radiologists are beginning to call these lesions *developmental venous anomalies,* which has a less ominous sound than the name *venous angioma.*

Cavernous angiomas (cavernomas) and *cryptic* or *angiographically occult AVMs* are a different matter (Figure 52.7). Both of these entities are generally angiographically "occult" and their appearance on MRI can be idenrical. Therefore the differentiation herween a true cavernous angioma and an angiographically occult AVM that has resulted in hemorrhage can usually be made only pathologically, because clinically and by MRI these lesions cannot usually be differentiated. Clinically, angiographically occult vascular lesions can certainly result in seizures, which at times, particularly if located in the medial tempotal lobe, are intractable. In these patients, resection of the lesion ("lesionectomy") most often results in resolution ot marked improvement of the seizures. Generally, we do not perform a formal epilepsy type of resection with electrophysiological recordings in these patients. In patients who present with well-controlled seizures without evidence of overt hemorrhage, a case for continuing medical treatment without sutgety can be made. However, surgical removal is very likely to result in a cure and eventual cessation of the need fot anticpilcptic medication. Because many of these lesions are located in accessible surgical regions and the surgery can be performed with little risk of morbidity, we gcnetally

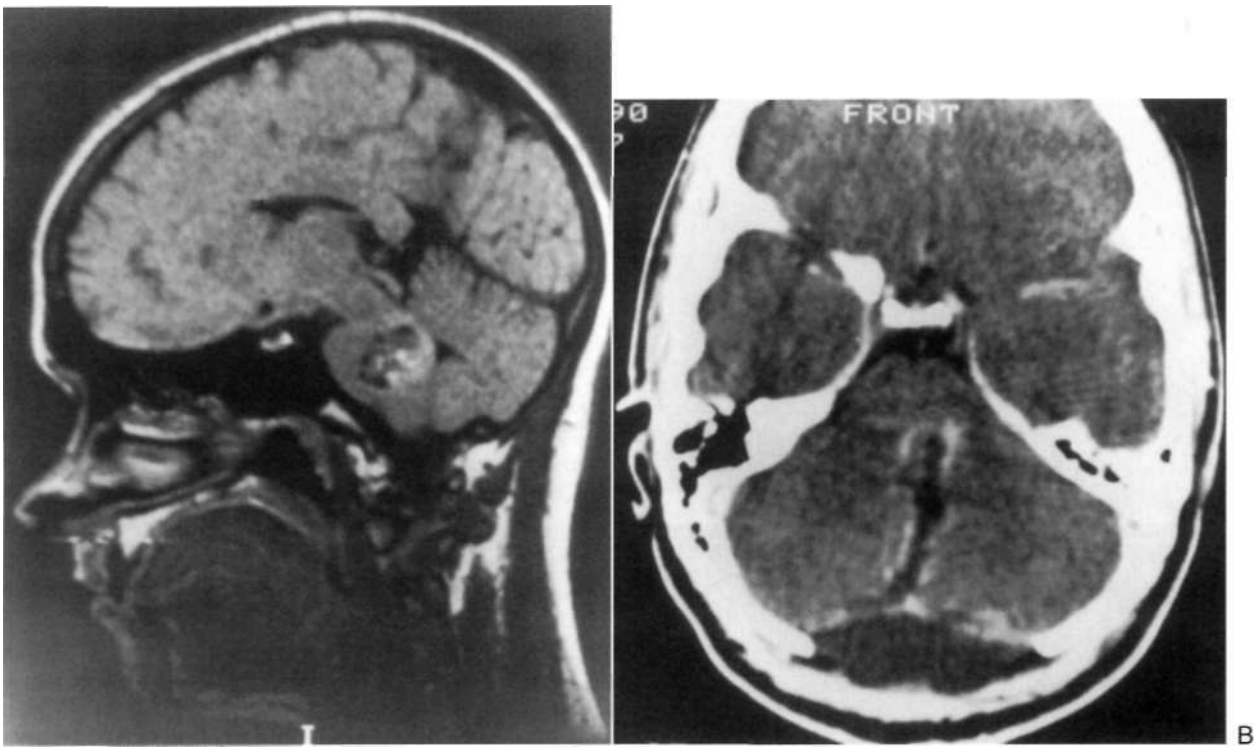

FIGURE 52.7 Cavernous angioma of the pons. (A) Note the typical appearance of the lesion in the pons, which happens to be a common location for cavernous angiomas. Because this patient had several episodes of neurological deterioration in the past related to small hemorrhages within the lesion, the decision was made tn excise the lesion surgically, (B) Postoperative computed tomographic scan showing complete removal of the lesion. There is some blood in the surgical bed and along the surgical track through the inferior vermis of the cerebellum.

advise surgery for these patients. Even in lesions in the motor and speech atea, particularly if the lesion is relatively superficial, surgery can be performed with very little risk of morbidity.

The issue is more complicated when the lesion is asymptomatic and detected on an MRI obtained for other reasons. In these cases, we tend to he conservative and **follow** the patient with pctiodic MRIs and advise surgery only if symptoms develop ot if the lesion shows significant growth, usually by focal hemorrhage, on MRI follow-up. When a lesion has resulted in a clinically overt hemorrhage, we generally recommend surgical excision for most supra-tcntorial and cerebellar lesions. Even deeply located mal formations can be accessed with traditional or framelcss stereotaxis through a trajectory that spares critical functional ateas. Once the surgeon reaches the lesion, it can usually be temoved without producing additional neurological damage,

Lesions of the brainstem are more difficult to resolve. Cavernomas are particularly common in the pons, and once they become symptomatic, almost always from the mass effect of a new hemorrhage, they tend to progress with tepeated intralesional hemorrhages and thus progressive growth of the mass. We recommend surgery in these patients if the lesion teaches a surgically approachable surface (floor of the fourth ventricle, lateral surface of the pons or medulla, anterolateral surface of the pons ot mesencephalon, or quadrigcminal plate) and the lesion can be accessed without ttavetsing normal brain. In deeper lesions that do not come to the surface, we recommend surgery only when the patient has become significantly and progtessively impaired from repeated hemorrhages. Unfortunately, radiosurgery appears to be ineffective for these lesions, although in some uncontrolled series, there is a suggestion of a slight improvement in the natural history in reference to future hemorrhage. However, the risk of significant morbidity from radiosurgery of lesions within the brainstem is high. Therefore most neurosurgeons do not recommend radiosurgery for angiographically occult malformations,

A better understanding of the natural history of these lesions is necessary to solidify indications for treatment. The available evidence indicates that lesions found incidentally have a very low (<1% per year) risk of future hemorrhage. This risk increases significantly, at least for the first few yeats after a hemorrhage, particularly in those lesions located in the brainstem. Nevertheless, our understanding of the long-term natural hisrory is still deficient because these lesions became diagnosable only after the MRI became widely available as a diagnostic tool.

The final and most important type of vascular malformation is the *true AVM* (Hcros 1995; Figure 52.8).

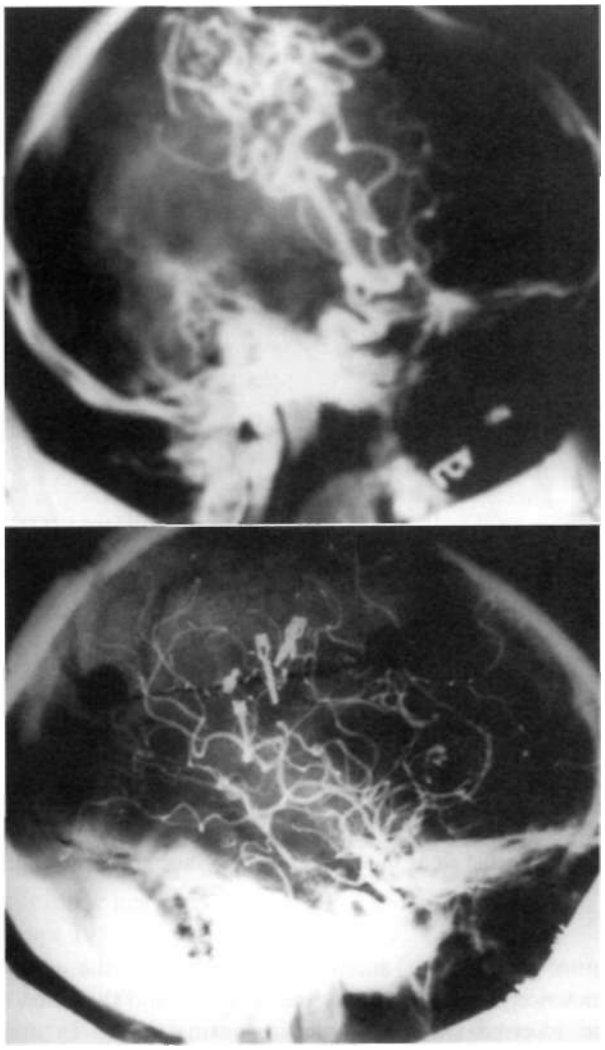

FIGURE 52.8 Arteriovenous malformation of the rolandic region. (A) Note the rapid filling of the lesion with poor filling of the rest of the middle cerebral territory. This patient was suffering from a progressive neurological deficit that we attributed to "stealing" of blood into the malformation from the surrounding brain. For this reason, we decided to recommend excision, despite that the patient would likely be at least temporarily worse after surgery. (B) Postoperative arteriogram showing complete removal of the lesion. The patient's pre-existing hemiparesis worsened significantly, but 6 months later, he was better than preoperatively. Note that after excision of the lesion, the middle cerebral vessels have returned to a more normal caliber and the rest of the middle cerebral territory fills well.

These lesions are well visualized angiographically. Their natural history is much better understood and they appear to have a risk of hemorrhage of approximately 3-4% per year regardless of whether they have bled previously. The risk of another hemorrhage after a hemorrhage increases slightly for the first 6 months {about 6%), but after that it settles to an identical rate of rebleeding as that in lesions that have never bled (3-4% per year). Each hemorrhage carries an average of 10% mortality and an additional 30% significant neurological morbidity. Therefore the natural history of a patient with an AVM of the brain is probably worse than that of a patient with an unruptured intracranial aneurysm. It is true that aneurysmal intracranial hemorrhage is much more dangerous than a hemorrhage from an AVM, because about half of patients with aneurysmal hemorrhage die. However, because the incidence of hemorrhage from an unruptured aneurysm is probably less than 1% per year and that of an AVM is 3-4% per year, calculations show that the prognosis is slightly worse for the patient with an unruptured AVM than for a patient with an unruptured aneurysm.

The therapeutic alternatives for a patient with an AVM include conservative observation, with medical treatment of seizures if necessary; surgical excision; embolization with or without subsequent surgical excision; and radiosurgery, which may be preceded by embolization in some cases. This is a complicated topic, and borderline cases are the subject of significant controversy. Currently, most experienced neurosurgeons advise surgical excision for patients who are relatively young and healthy and who harbor a surgically accessible AVM, which can be removed with relatively low surgical morbidity. What constitutes a surgically accessible AVM varies with the experience of the surgeon. Many classification schemes have been developed to help predict the surgical risk, In general, AVMs that are less than 6 cm in diameter and that are not located in an eloquent region of the brain (motor-sensory region, speech areas, basal ganglia, thalamus, and brainstem) can be removed with a surgical morbidity of less than 5% and negligible surgical mortality (<1%). For small lesions (generally <3^4 cm in diameter) located deeply in eloquent supratcntorial regions, we recommend radiosurgery. The appropriate treatment for patients with small AVMs of the brainstem is unclear; they respond to radiosurgery, but the morbidity from brainstem radiation necrosis is quite significant. Radiosurgery is recommended if they have had a major hemorrhage or if they have recurrent symptomatology from repeated small hemorrhages. For large AVMs located in critical areas of the brain, there is no good treatment. The surgical morbidity is extremely high in these patients and they generally do not respond to radiosurgery. Embolization is only palliative and embolization that does not eliminate the malformation completely appears not to improve the natural history in terms of future hemorrhage and may even significantly increase the chances of future hemorrhage from the AVM (Kwon et al. 2000). Embolization can cure some of the smaller accessible malformations, but these are the malformations that generally can he removed surgically with negligible morbidity. We do use embolization on larger lesions or on very high flow lesions to facilitate surgical removal, and there are some instances in which palliative embolization can be helpful (progressive neurological deficit from "steal," intractable headaches from very large meningeal feeders that can be obliterated by embolization, presence of

intranidal fistulas and aneurysms that probably carry higher risk of bleeding, etc.). Radiosurgery has been recommended over surgical excision of small accessible AVMs on the basis of cost. However, radiosurgical treatment is effective in only 70-80% of patients with small AVMs. In those in which it is eventually effective, it takes 1-3 years for the effect of tadiosurgery to be complete, so patients remain at risk of hemorrhage during this time. A long-term cost analysis indicates that in the long run, when the cost of predicted futute hemorrhages is taken into account, sutgical excision is the most cost effective form of treatment for these patients with surgically accessible small or medium-sized AVMs (Nussbaum, Heros, and Camarata 1994).

Brain Tumors

Brain tumors are covered in Chapter 58. Here, we review the neurosurgical approach to some specific brain tumors.

Gliomas

Pilocytic astrocytomas arc relatively well-demarcated tumors that can usually be removed completely and in general have a very good prognosis after total or subtotal surgical excision. The same can be said of the low-grade astrocytomas of the cerebellar hemisphere in children. These tumors generally do not require postoperative radiation therapy. Low-grade well-differentiated fibrillary astrocytomas generally arc not well demarcated and cannot be removed completely, particularly when they involve or are close to critical areas of the brain. Some techniques that are discussed such as intraoperative cortical mapping, frameless stereotaxis, and image-guided sutgety can help achieve a more thorough removal of these tumors. However, they are basically infiltrating tumors, and although the issue is still controversial, we generally recommend postsurgical radiation therapy unless the surgeon is satisfied with the completeness of the surgical removal. Many experts, however, prefer a policy of following these patients with periodic MRIs and using radiation therapy only when the tumor shows clinical and/or radiographic signs of progression. In the case of high-grade gliomas, it is still not clear that the extent of surgical removal affects the natural history, although there is considerable anecdotal evidence supporting the concept that when achievable without increasing morbidity, aggressive surgical removal improves overall prognosis. In addition, aggressive debulking may improve symptoms of mass effect and increased intracranial pressure and may allow the patient to tolerate radiation therapy, which might otherwise have exacerbated the symptoms.

Radiotherapy continues to be the most important adjuvant therapy for patients with malignant gliomas. Chemotherapy improves the prognosis slightly, but generally at the expense of some morbidity. We tend to recommend chemotherapy in younger patients with good functional status, especially in patients with anaplastic astrocytomas, mixed oligoastrocytomas, and oligodendrogliomas, where the evidence for the benefit of chemotherapy is more convincing. Additionally, we always consider chemotherapy as an option at the time of recurrence. Recently, intratumoral chemothciapy with implantation of carmustine-impregnated biodegradable wafers (Gliadel), whenever a good resection can be accomplished with low surgical morbidity, has become available as an option. Radiosurgery may be considered as a boost to conventional fractionated radiotherapy as initial therapy or in cases of recurrence. Young patients with unifocal, well-circumscribed tumors, who are in good neurological condition, tend to benefit the most from adjuvant radiosurgery,

Pituitary Tumors

Pituitary macroadenomas are most frequently nonsecreting and present with visual disturbances. Transsphenoidal resection can usually alleviate the visual symptomatology but is rarely curative in these cases. However, the benefit of postoperative irradiation has to be weighed against the side effects of radiation, including the late development of radiation-induced tumors, hypothalamic dysfunction, radiation encephalopathy, and visual deterioration. Fot these reasons, radiosurgery is increasingly being considered as a secondary treatment for these tumors. Simple observation with periodic MRIs is an option in many patients, particularly when they are older. Prolactinomas are now treated primarily medically with dopamine agonists, such as bromoctiptine, except in patients who are planning to become pregnanr soon, in which case ttanssphenoidal resection is usually recommended. Surgery is still the procedure of choice when the patient becomes refractory or intolerant to bromocriptine treatment or when rapid visual deterioration occurs, often as a result of pituitary apoplexy, (see Pituitary Apoplexy, earlier in this chapter}. Functional (secreting) tumors that result in acromegaly or Cushing's disease are still primarily treated surgically, with a high rate of success. However, the endocrinological definition of cure or control for these tumors has become increasingly strict, and radiosurgery is being considered an option in those patients who do not appear to have been completely cured by surgery,

Craniopharyngioma

Whether conservative surgery followed by radiation therapy, or radical surgery in an attempt to remove all the tumor, should be the preferred treatment for craniopharyngiomas is still unclear. Most surgeons nowadays will attempt a complete surgical removal if at the time of surgery this appears possible without inducing morbidity from hypothalamic or optic damage (Figure 52.9). With this principle in mind, a total microsurgical removal is

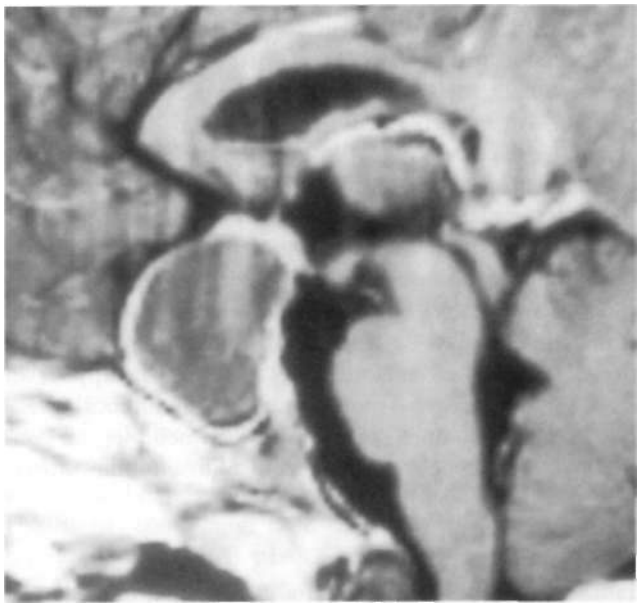

FIGURE 52.9 Craniopharyngioma. This is a rather typical appearance for a cystic craniopharyngioma. The lesion was removed completely by a microsurgical bifrontal interhemispheric approach.

possible in many patients, both children and adults, with craniopharyngiomas, and in these cases radiation therapy is not indicated. However, continuing observation with periodic MRIs is essential because even tumors that appear to have been totally removed can recur many years later. Most neurosurgeons will not attempt complete removal when the capsule of the tumor appears to be densely adherent to the hypothalamus, optic nerve, or important vascular structures and will prefer to leave some residual tumor rather than risk serious morbidity. In these instances, if the amount of residual tumor is relatively small, observation with periodic MRIs is appropriate. If a significant amount of tumor is left behind, radiation therapy is recommended for most patients unless they are elderly or very young. The radiation can be in the form of radiosutgery if the tumor is well localized. If there is a recurrence and the patient has not undergone radiation therapy, radiation should be considered as opposed to surgery unless there is progressive visual dysfunction. In that case, surgical decompression followed by radiation is appropriate. In cases of a relatively pure cystic recurrence, stereotactic aspiration with or without installation of radioactive material into the cyst can be entertained as an alternative to direct surgical decompression, followed by conventional fractionated radiation or radiosurgery.

Pineal Region Tumors

In an increasing number of patients, small asymptomatic tumors of the pineal region are being detected by MRI. Many of these patients have a typical pineal cyst. Unfortunately, this appearance can be confusing, because even though the bulk of the lesion may be cystic, there is usually some enhancement on the wall, which raises the question of a true neoplasm. In general, if the cyst is asymptomatic and relatively small (up to approximately 1 cm in diameter), we prefer to observe the patient with periodic MRIs to rule out growth, which would indicate a cystic pineal neoplasm as opposed to a true pineal cyst.

There has been an effort to make a definitive diagnosis of pineal region tumors by MRI and treat some of these tumors blindly with radiation therapy based on an MRI appearance suggestive of a pineal gcrminoma. Radiation therapy is clearly very effective for these tumors, and because these tumors are so prevalent in Japan, many-Japanese neurosurgeons use radiation as a therapeutic diagnostic test. In othet words, they will radiate the tumor, but if there is no prompt response to radiation demonstrated by significant shrinkage of the tumor, they will proceed with a biopsy. In the United States, the relative prevalence of germinomas is considerably lower than in Japan, and many other tumors of the pineal region may resemble a pineal germinoma, but they arc best tteated by total or subtotal surgical resection depending on the findings at surgery (Figure 52.10). In addition, even in malignant tumors that cannot be removed completely, establishing a pathological diagnosis by biopsy can be very helpful in terms of guiding treatment. This will vary significantly, not only in terms of the dose of radiotherapy but also in terms of whether chemotherapy may be

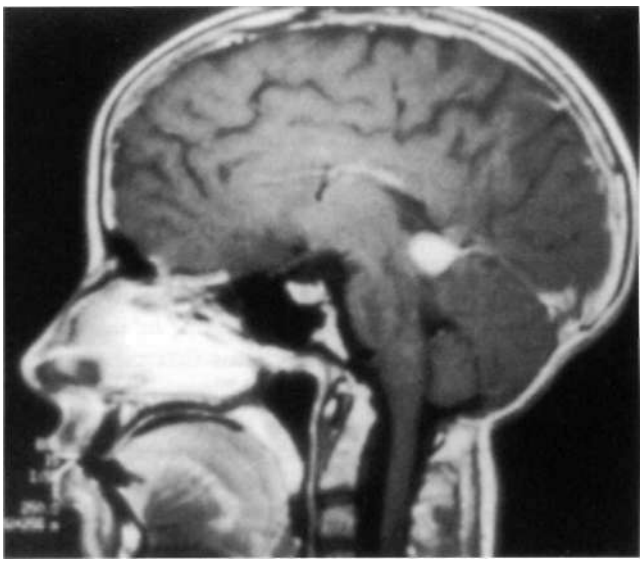

FIGURE 52.10 Pineal region tumor. This small lesion was removed completely by a microsurgical supraeerehcllar infrarcntorial approach. Pathologically, the lesion was a pinealoma, and because of the completeness of the surgical removal, the patient had no other treatment. Twelve years later, she is still intact neurologically, and the lesion has not recurred.

appropriate. For this reason, we recommend establishing a pathological diagnosis by surgical biopsy in most of these patients. There is controversy, however, over whether a stereotactic biopsy or a direct open surgical biopsy is preferable. Almost every large series of stereotactic tumor biopsy indicates that the morbidity of the procedure in the pineal region is higher than when such biopsies are performed for tumors elsewhere. This is undoubtedly related to the complicated venous anatomy in this region, which can lead to postoperative hemorrhage. For this reason, we prefer open surgical biopsy, most often by the infra tentorial supracerebellar route, in most of these patients. An open procedure has the advantage of allowing surgical resection during the same operation if such is indicated from a combination of the frozen section diagnosis and the appearance of the tumor at surgery. In our experience, about half of these patients have benefited substantially from surgical resection. These have been primarily patients with pineocytomas, meningiomas, low-grade exophytic astrocytomas of the pulvinar region, and benign teratomas. In the other half of the patients (with malignant tumors such as pineal germinomas, pineoblastomas, endodermal sinus tumors, and malignant teratomas), the surgical biopsy has been able to guide subsequent therapy. Only in cases in which the typical MRI appearance is accompanied by strong markers in the CSF of a choriocarcinoma *{fi* chain of human chorionic gonadotropin) or endodermal sinus tumor («-fetoprotein) would we entertain radiation therapy without surgical biopsy. Malignant teratomas and undifferentiated germ cell tumors can have elevation of both markers, but because the treatment of these tumors may differ, we prefer open biopsy when both markers are elevated. This may be accompanied by significant surgical dcbulking, particularly in the case of teratomas.

Acoustic Neurinomas

Schwannomas of the vestibular nerve are increasingly being diagnosed at a very early stage when they are still intracanalicular in location or have only a small intracranial extension, mainly because of decreased hearing and the availability of MRI. In these patients, radiosurgery has become an important therapeutic alternative to surgery. It appears clear that radiosurgery can achieve tumor control (i.e., no growth or shrinkage) in the majority of these patients, at least for a few years. This is an attractive option in older patients. Radiosurgery carries some risk of morbidity and many of these patients eventually do lose their hearing after radiosurgery, but at the present time, it is not clear whether facial function is better spared by careful microsurgical excision or by radiosurgery. Because the results of surgery have been very satisfactory in terms of permanent cure and preservation of facial function and hearing in patients with small tumors, we favor this option in relatively younger patients and consider radiosurgery or observation in the elderly. Patients with larger schwannomas of the cerebellopontine angle, who frequently present with brainstem symptomatology, continue to require surgical excision. Nowadays this can be achieved very safely in terms of neurological morbidity and with a high rate of success in terms of sparing facial function. Hearing, if present preoperatively, can be saved only infrequently in patients with larger tumors. In older patients or in younger patients who are adamant about having intact facial function postoperatively, it has become more common to perform a subtotal resection, leaving some tumor adherent to the facial nerve that can be either observed with periodic MRIs or treated with radiosurgery depending on the age of the patient.

Meningiomas and Other Tumors of the Base of the Skull

Benign tumors of the base of the skull have become more amenable to relatively complete surgical excision using skull base approaches (see Skull Base Techniques, later in this chapter) (Figure 52.11). These operations are typically performed by the neurosurgeon in collaboration with either a neuro-otologist or a head and neck surgeon. The same is true for more aggressive tumors of the base of the skull, such as esthesioneuroblastomas, chondrosarcomas,

FIGURE 52.11 Large petroclival meningioma. Lesions such as these can be removed at least radically and sometimes completely with relatively little morbidity using skull base techniques. This particular lesion was removed subtotally through a cranio-orbitozygomatk approach. A small remnant of tumor was left in the cavernous sinus because the patient was in her late 60s.

chordomas, and low-grade carcinomas. The latter tumors can rarely, it ever, he cured, hut surgery can otter very significant palliation with acceptable morbidity. Most meningiomas can be cured by surgical excision, but whether some of the invasive meningiomas, particularly those that invade the cavernous sinus, can really be eradicated completely is under controversy. More radical operations are increasingly achieving total tumor excision both by intraoperative inspection and by immediate postoperative CT or MRI scanning. However, such radical resections are most commonly accompanied by significant morbidity, particularly when the tumor invades the cavernous sinus or involves the carotid, middle cerebral or basilar arteries, and their branches. Long-term follow-up studies are necessary to know whether such radical operations and their resultant morbidity are justified by a significant improvement in longevity and tumor-free survival.

We prefer to allow a small amount of residual meningioma to remain in the cavernous sinus ot around the carotid artery and optic nerve or basilar artery when removal of this could be predicted to carry a significant surgical morbidity. This is particularly true in older patients, in which case, we do nothing but observe the tesidual tumor by periodic MRI. In younger patients, we tend to be more aggressive, and if it appears impossible to remove all the tumor without substantial morbidity, we consider postoperative irradiation, either by radiosurgery or fractionated radiotherapy, depending on size of the residual tumor and proximity of structures such as the optic nerve. Various chemotherapeutic agents, such as hydroxyurea, tamoxifen, and interferon-^, have been used with variable degrees of success as adjuvant treatment for aggressive and/or recurrent meningiomas.

Metastatic Tumors

The role of neurosurgery in metastatic disease of the brain was traditionally limited to excision of single metastatic lesions in patients who had a relatively good prognosis from their systemic cancer (an expected longevity of at least a few months). Additionally, in selected cases with multiple brain metastases, a large lesion that was producing progressive symptomatology or threatening life, such as is the case of a large cerebellar metastasis, was removed to relieve symptoms or to provide time for radiation therapy or chemotherapy to control the disease. These indications are still valid; however, radiosurgery has become a very attractive way of treating small asymptomatic brain metastases. This treatment carries very little early morbidity and can be used for several metastatic lesions, which may be treated in one or more sessions. The number of metastatic lesions that can be treated safely by radiosurgery has not been established, but most radiosurgical units arc reluctant to treat patients with more than four or five metastatic lesions, Some tumors are not sensitive to radiation, and when this is the case, particularly in the case of a single lesion that continues to grow after radiosurgery, surgical excision continues to be an important consideration. Whether to neat these patients with whole-brain radiation in addition to radiosurgery is still controversial, although there has been a tendency to move away from whole-brain irradiation.

Ischemic Ccrcbrovasculat Disease

Ischemic cerebrovascular disease is covered in detail in Chapter 57A. Here, we review a few points of relevance to cerebrovascular disease from a neurosurgical perspective.

Arterial dissections, both extracranial and inrracranial, are being increasingly recognized as a cause of stroke, particulatly in younger individuals. Dissection of the cervical portion of the carotid artery can occut both spontaneously and after neck trauma (Figure 52.12). It often presents with severe retromandibular pain, and on

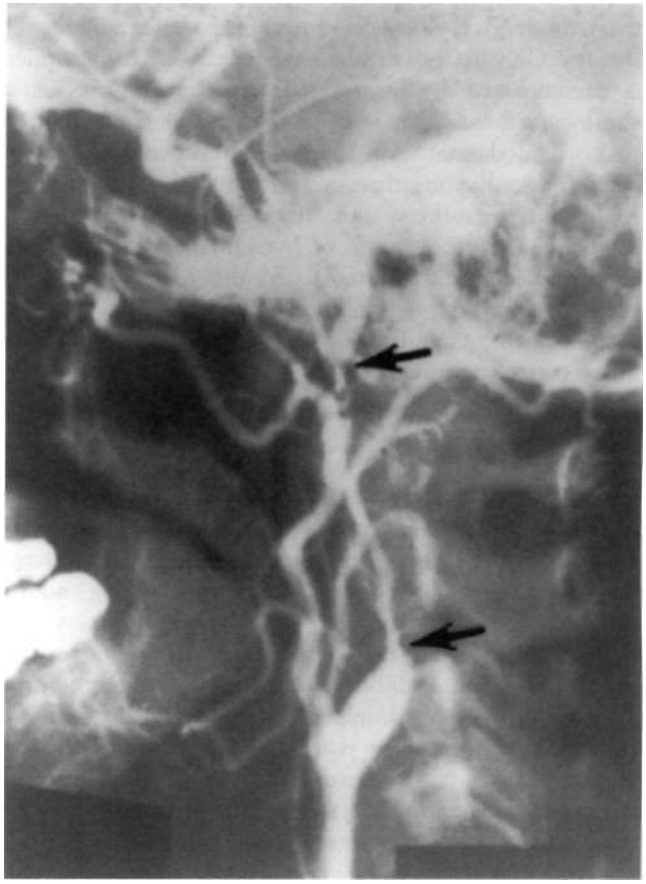

FIGURE 52.12 Dissection of the cervical portion of the internal carotid artery. Notice the typical appearance of the long, narrow segment (string sign), which begins approximately 1.5 cm distal to the bifurcation *(lower arrow)* and ends abruptly at the entrance of the internal cimrid into the hiise of the skull *[higher arrow).*

examination, it is common to detect an ipsilateral partial Horner's syndrome from involvement of rhe high cervical pericarotid sympathetic plexus. Typically, the dissection states 1-3 cm above the bifurcation and terminates abruptly where the internal carotid artery enters the base of the skull. The patient may have transient ischemic attacks (TIAs), a fixed stroke, or a fluctuating neurological deficit. Surgical intervention is rarely necessary because these patients respond well to anticoagulant treatment. Frequently the dissection heals and the artery returns to a fairly normal appearance after a few weeks. Persistent symptoms after coagulation may call for surgical intervention to directly repair the dissection, which is difficult, or to perform an extracranial to intracranial bypass graft, which at least anecdotally has been effective in some of these cases. More recently, angioplasty with stenting has become the preferred option.

Extracranial vertebral dissection presents with high cervical pain, sometimes radiating to the occipital region, as well as posterior circulation TIAs, or stroke. Again, vertebral dissection can occur spontaneously, but most commonly is due to trauma, which can be dramatic (cervical fractures and dislocation) or relatively subtle (abrupt turning of the neck, chiropractic manipulation, or simple hyperextension of the neck such as for shaving under the chin). Again, anticoagulation is the mainstay of treatment for extracranial vertebral dissection when there is ischemic symptomatology. The results are very good unless the patient has already had a major stroke.

Intracranial arterial dissections are more serious. They can result in ischemic symptoms usually from occlusion of small branches, or they can result in SAH, which can be devastating and recur frequently if untreated. The treatment is more complicated because of the risk of hemorrhage; however, when ischemic symptoms are predominant and there has been no evidence of hemorrhage, anticoagulation should still be considered.

Patients with TIAs arc most commonly seen initially by their primary care physicians, and then they may or may not be referred to a neurologist. It is important to keep in mind the difference between a patient who has had multiple TIAs over a period of months or years and the patient who has had the first TLA ever. In the former situation, the workup can be more relaxed, although still these patients should be investigated expediently. In the latter situation, however, it is important to act with urgency. After a first TIA, there appears to be an approximate 30-35% risk of a stroke in that arterial distribution over the next 3-5 years. However, most of that risk occurs during the first month and particularly during the first few days after the TIA, Important therapeutic considerations include anticoagulation and carotid endarterectomy. Other situations that require urgent evaluation are crescendo TIAs and major TIAs, where the patient develops a profound neurological deficit, usually involving the face, arm, and leg on one side with or without aphasia.

Carotid endarterectomy is an operation with winch many neurosurgeons have considerable experience. The indications have become much better defined over the last several years. At the present time, based on the results of the several excellent multi-institutional randomised studies that have addressed the issue of effectiveness of carotid endarterectomy, we recommend this operation to symptomatic patients (TIAs or a mild completed stroke) who have more than 70% stenosis of the ipsilateral carotid artery and who are in reasonably good condition in terms of medical comorbidity. In the group of patients with moderate stenosis (50-70%), we would consider endarterectomy only when the patient is relatively healthy in terms of medical comorbidity, particularly that of significant coronary disease, and when the estimated neurological morbidity of the procedure is estimated to be low. For asymptomatic patients, we consider endarrerectomy only when the stenosis is relatively severe, generally more than 75-80%, and when we can be relatively confident that the surgery can be performed wirh minimal morbidity (relatively young patient in relatively good health and no adverse risk factors, such as a very high bifurcation, contralateral occlusion, or intracranial stenosis, demonstrated by angiography). It is important for the neurologist to remember, however, that the indications for carotid endarterectomy vary not only according to the patient, but also according to the experience of the surgeon and the institution where the carotid endarterectomy is to be performed. Most experienced neurosurgeons and vascular surgeons who have a particular interest in carotid endarterectomy can perform the operation with an average combined mortality and serious morbidity of less than 5% (Table 52.1). In all the recent randomized studies that have established the general indications for carotid endarterectomy, the surgical morbidity was within this low range because the surgeons and the institutions invited to participate had considerable experience with the operation. These results may not be generally applicable, and each physician needs to consider this in terms of his or her own indications for endarterectomy. The role of angioplasty and stenting is gradually being defined. Presently, we consider this procedure in patients who are felt to be at high risk for carotid endarrerectomy, such as elderly patients with serious medical comorbidities, patients who have restenosed their artery after an endarterectomy, patients with angiographic risk factors such .is a very high bifurcation with a plaque extending to the base of the skull, patients with radiation-induced stenosis, and some patients with poor collateral circulation such as a contralateral carotid occlusion.

Moyamoya disease is an entity that has become more frequently recognized in the United States as an etiology for TIAs and stroke in children, adolescents, and young adults, and for intracerebral hemorrhage in older adult patients (Figure 52.13). This disease, which was first described in Japan, is much more common in the oriental races, but it

Table 52.1: Complications" of elective carotid endirterectomy

Indications for surgery	No. *of cases*	*Major stroke*	*Minor stroke*	*Other**	*Death*
Transient ischemic attacks	707	*6*	*5*	14	4
Stroke	108	3	3	3	3
Asymptomatic	172	1	1	2	0
TOTAL	987	10 (1%)	9 (0.9%)	19(1.9%)	7 (0.7%)

Note: These numbers include only elective operations. During this time, several endarterectomies were performed emergently for completed stroke; these results are nor included here.

"These are early complications that became evident or occurred during the immediate postoperative period.

[f]AII operations were performed by the senior author or under his direcr supervision from 1980 through 1995 at either the Massachusetts General Hospital or the University of Minnesota Hospital,

'Includes neck hematomas that required reoperation, nonfatal myocardial infarctions, and cranial nerve palsies that almost always resolved in time.

'Includes episodes of transient visual loss.

does occur with some frequency sporadically in any race. We mention this entity here because neurosurgical revascularization of the ischemic territories is a very effective way of ameliorating the symptoms and preventing stroke and hemorrhage in the future. Revascularization can be achieved in a number of different ways, such as with a direct anastomosis from the superficial temporal artery to a middle cerebral artery branch, direct apposition without anastomosis of the superficial temporal artery to the surface of the brain, or apposition of the temporalis muscle to the surface of the brain. All of these procedures can result in dramatic revascularization, as demonstrated angiographically, after a few months. Our results with approximately 25 such patients have been very rewarding.

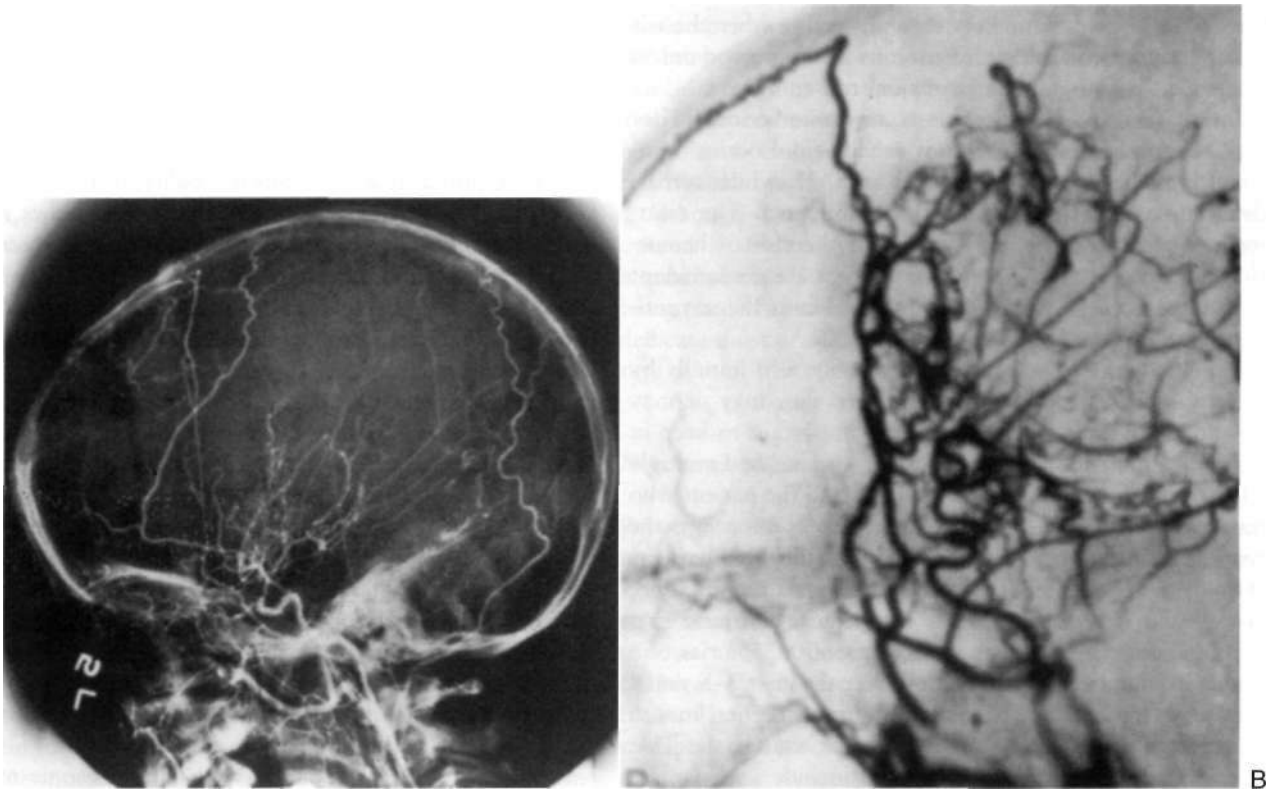

FIGURE 52.13 Moyamoya disease. (A) Note the virtual occlusion of the supraclinoid segment of the internal carotid artery and the origin of the middle cerebral artery with the moderately prominent conglomerate of small anastomotic vessels that attempt to teconstruct the middle cerebral artery distally. (B) Because the patient had recurrent ischemic symptoms, she was treated with an arterial myosynangiosis, which simply means laying the temporalis muscle, kept in continuity with its vascular supply, directly over the brain. Note the significant revascularization of the middle cerebral territory by external carotid collateral just 3 months after the operation.

Dementia

The diagnosis and management of dementia are almost always in the hands of the neurologist. Many forms of dementia are treatahle and the neurologist makes every effort to rule our such entities. One cause of dementia that deserves consideration from a neurosurgical perspective is normal-pressure hydrocephalus.

The diagnosis and the indications for CSF shunting in patients suspected of having normal-pressure hydrocephalus remain controversial (Epstein and Fried 1995). However, many patients who were incapacitated by a progressive gait difficulty, dementia, and urinary incontinence of variable severity have returned to a significantly improved functional status after placement of a CSF shunt. It is also clear that many other patients who have received a shunt with this diagnosis have not been helped. Therefore many tests have been devised to establish firmly this diagnosis and rule out the much more common diagnoses of Alzheimer's disease and multi-infarct disease. Unfortunately, no single test has been proven to be consistently reliable. The tests have been generally of two types. The first group includes rests thai attempt to measure physiologically or radiologically an impairment in CSF reabsorption. The other group includes tests that are functional and aim at testing clinically, in a variety of ways, the effects of withdrawing a significant amount of CSF.

In general, we have followed the advice of Dr. C. Miller Fisher to be guided primarily by the clinical syndrome. Patients who tespond well to shunting tend to have a history of gait difficulty that precedes and is out of proportion to the degree of dementia. These patients may have variable degrees of difficulty with sphincter control. In this clinical setting, when the CT scan or the MRI shows significant hydrocephalus, which is out of proportion to the degree of atrophy, we proceed with shunting without any further testing. We rarely consider shunting in patients who are markedly demented and who have developed some gait difficulty late in the course of their disease; such patients will almost always show atrophy out of proportion to the hydrocephalus on their CT scan, and they rarely, if ever, respond to shunting. This leaves a sizable group of patients in whom the situation is less clearly defined: (1) The gait disturbance and the dementia may have started more or less at the same time and may he of about the same severity, and the CT scan may show both significant atrophy and hydrocephalus, (2) the dementia may have preceded the gait difficulty, but the CT scan demonstrates significant hydrocephalus and only a modest degree of atrophy, or (3) there is a good clinical syndrome of gait disturbance with very little dementia, but the CT scan shows significant atrophy and only slight hydrocephalus. In these borderline cases, additional tests are indicated.

The simplest and perhaps most reliable way of testing for impaired reabsorption is still the conventional radioisotopic cisternogram. When we sec the typical pattern of retention of radioactivity in the ventricles for up to 48 hours and preferably for 72 hours, we are encouraged to proceed with shunting. On the other hand, if the test is negative with disappearance of the radioisotope from the ventricles within 24 hours, we do not recommend a shunt. When the results of the cisternogram are less clear-cut (some retention of radioactivity in the ventricles at 24 hours and disappearance at 48 hours), we proceed with a functional test of CSF withdrawal and clinical examination for improvement. If improvement is clearly documented, we proceed with shunting.

A shunting procedure is not without some risk of morbidity, particularly in patients with atrophy secondary to Alzheimer's disease, who could develop problems from overdrainage such as subdural hematomas and persistent headaches. Therefore every effort should be made to select patients carefully for surgery; when in doubt, we prefer to accept the relatively small morbidity of a shunt and proceed with this operation rather than risk leaving a patient untreated who could have been helped by a relatively-simple operation. Presently, we prefer to use programmable valves for all patients with norma I-pressure hydrocephalus. These valves can be regulated from the outside to drain at a set pressure without the need for an open surgical revision, as was necessary in the past. Thus if the patients fail to improve and the postoperative CT scan shows that the ventricles have not decreased in size, the pressure of the valve can be lowered very simply at an office visit. Likewise, if the patient complains of headaches and dizziness upon standing and the CT shows that the ventricles are now too small and/or there arc subdural hygromas on CT scan, the pressure can be raised.

Pseudotumor Cerebri

Pseudotumor cerebri is managed primarily medically. Surgical management should be reserved for the rare patient in whom maximal medical treatment of intracranial hypertension has failed. Persistent disabling headaches or progressive visual loss from papilledema in spite of maximal medical therapy mandates surgical intervention. The obvious procedure to relieve intracranial pressure is CSF shunting. This addresses the primary problem, and if successful, the papilledema should subside. However, these patients often have small ventricles, and it is difficult to insert and maintain a ventricular shunt. For this reason, lumboperitoneal shunting is usually considered in these patients. Although these patients are often obese and a lumboperitoneal shunt presents some technical difficulty, this treatment is needed at times. When the problem is primarily visual loss and the headaches can be controlled satisfactorily with analgesics, the optic nerve sheath fenestration procedure is considered, although studies have questioned the effectiveness of this procedure. In the very rare parient in whom these two procedures fail to

control the symptomatology, a subtemporal decompression may he required. This procedure was initially advocated by Dandy in the 1930s and it is still used occasionally, although we personally have no experience with it.

Pain

The neurosurgeon used to play a very prominent role in the treatment of chronic pain. This was because pharmacotherapy of pain was not as well developed, and ablative procedures, such as cordotomies, rhizotomies, midline myelotomies, and even medullary tractotomies, had a proven record of effectiveness, albeit at the price of significant surgical morbidity. Gradually, with improved pharmacological treatment of pain, and with the increased interest in this area of other specialties such as anesthesiology and physical medicine and rehabilitation, the neurosurgeon, and to some degree the neurologist, has lost interest in the treatment of chronic pain. Yet pain is a prominent and frequently the prevalent symptom in a large number of patients treated both by neurologists and by neurosurgeons. It is important then to keep in mind that there are still very valuable surgical options for patients incapacitated by chronic pain. Clearly, with sufficient amounts of narcotics, all pain can be controlled. However, this is not generally a satisfactory option for patients with chronic pain from nonmalignant disease who may have normal longevity. It may not be the preferred option even for patients with malignant pain, although for the latter group of patients, newer opioid preparations prolong pain amelioration with fewer effects on the sensorium and cognition than the traditional narcotics.

Spinothalamic cordotomy is still an attractive option for patients with pain due to malignant disease, particularly when that pain is unilateral. The early morbidity of a unilateral cordotomy in the thoracic or cervical area is relatively small. The problem with cordotomy is that the effect tends to fade with time and patients tend to develop late dysesthesias, which can become very painful and disabling over the years. Patients with cancer, however, often have a limited life expectancy and these late problems are less of a consideration. Therefore cordotomy is still a good option in patients who may not tolerate systemic natcotics and who are in good enough condition to withstand the stress of a relatively short surgical procedure. When the pain is bilateral, cordotomy becomes a less attractive option because the morbidity of bilateral cordotomies is significantly higher, particularly the risk of urinary incontinence.

Midline myelotomy, which aims at interrupting the segmental crossing pain fibers, is a particularly attractive option for patients with bilateral lower extremity and pelvic pain such as seen frequently with gastrointestinal, urological, and gynecological malignancies. This procedure carries some immediate morbidity, usually paresthesias from damage to the posterior columns, but these early paresthesias tend to subside, and when the pain is restricted to the lumhosactal region and lower extremities, the results are very good in terms of sparing strength and bladder function and controlling pain satisfactorily (Sourek 1997).

Dorsal rhizotomy for truncal pain, particularly in the chest wall, is still a useful procedure to consider in patients with malignant pain. A prerequisite is the ability to relieve the pain with appropriate nerve blocks, and the surgeon should always aim at dencrvating several segments above and below those indicated by the nerve blocks because of sensory overlap, the tendency for the analgesic area to shrink with time, and the likelihood of local spread of the disease. An open neurosurgical procedure can he done, but it is now usually done by a percutaneous radiofrcquency technique.

Intrathecal injection of morphine hy a number of the available implantable systems may be an alternative to the more invasive ablative surgical procedures for many patients. This form of treatment has obvious appeal, but many patients either do not respond to it or become tolerant to the drug, so very large doses are required to maintain pain control. Nevertheless, a large number of patients with cancer can be managed satisfactorily with these intrathecal systems.

Pain resulting from head and neck malignancies is a particularly difficult problem to treat. In these patients, the syndrome is often complicated by anxiety secondary to difficulties swallowing and breathing. If anxiety is a predominant component, bilateral cingulotomy, which can be performed stereo tactically with minimal morbidity, should be given setious considctation. In truly intractable patients, cortical or deep brain stimulation (DBS) by means of implanted electtodes can be considered, but these procedures are performed only at a few selected centers.

Intractable chronic pain from injuries or nonmalignant disease is a much more difficult problem to treat. Obviously, chronic narcotic administration is not an attractive option in these patients. Intrathecal morphine administration by implantable pump systems almost always fails eventually. Ablative procedures are not a good choice except fot rate instances. For example, dorsal rhizotomies are still a satisfactory procedure for chest wall pain after thoracotomy. Occasionally, rhizotomies have also tesulted in significant pain relief in cases of intractable radiculopathy after failed intervertebral disc surgery. More recently, dorsal root entry zone lesions, made either by open surgery or percutaneously, have shown some promise in the control of chronic pain caused by problems such as cervical root avulsions, postparaplegic pain, postherpetic neuralgia, and phantom limb pain. Relief has been reported in 50-70% of patients with these different chronic pain syndromes, and the procedure carries relatively little morbidity.

Electrical stimulation of peripheral nerves and spinal cord has been in and out of favor for the last several years.

There is no question that a number of patients can be palliated with percutaneous electrical stimulation, but in general, this treatment is only partially effective and the effect is temporary. For more chronic pain, neuroaugmentive procedures, which essentially consist of chronic stimulation by implanted electrodes, have become very attractive because they are nonablative and reversible. These procedures are particularly effective for treatment of neuroinjury (denervation) types of pain. When such pain is from peripheral dcafferentation, spinal cord stimulation with electrodes placed directly over the posterior column has been effective in well-selected patients. The more difficult central type of pain produced by spinal cord or brain **injury,** which is usually due to a stroke in the thalamus, can be treated by central stimulation, usually in the periaqueductal or periventricular gray matter. These targets have been well defined by stereotactic methodology. However, these procedures are difficult, expensive, and available at only a few centers.

Finally, hypophysectomy, which can be performed by open transsphenoidal microsurgical approach or much more frequently by the percutaneous technique using radiofrequency or absolute alcohol injection, is very effective for pain control in patients with intractable pain from metastatic disease to the bone due to hormonally dependent cancer (breast and prostate). This procedure may also be effective in a smaller percentage of patients with nonhormonally dependent cancers; however, in these cases, the effect is usually very transient. Thus the neurosurgeon still plays a role in the treatment of chronic intractable pain whether it is due to malignancy, injury, or a chronic nonmalignant disease process.

Trigeminal Neuralgia

Most patients with trigeminal neuralgia are initially treated by a neurologist. Carbamazepine and diphenylhydantoin continue to be the most effective medications to control this condition. However, patients sometimes do not tolerate these medications or the pain becomes refractory to them. With the introduction of newer drugs such as gabapentin and other antiseizure medications that have been shown to be somewhat effective in the treatment of trigeminal neuralgia, there is a tendency to continue to treat these patients indefinitely with a variety of medications, typically with inadequate control of this devastating type of pain.

Neurosurgical procedures are often very effective and frequently lead to complete disappearance of the pain in patients with typical trigeminal neuralgia. There are two types of neurosurgical procedures for the treatment of this condition. In relatively young patients, who are in good general condition and have no contraindication to general anesthesia, we generally recommend, as the first surgical line of treatment, a Jannetta microsurgical decompression operation designed to relieve the vascular compression of the trigeminal nerve at its entrance into the brainstem, which appears to be the cause of the condition in most patients with idiopathic trigeminal neuralgia (Jannetta 1996). In relatively healthy patients, this operation carries only a very minimal risk of serious neurological morbidity, The procedure is contraindicared in patients with known causes of trigeminal neuralgia such as multiple sclerosis and in patients who are elderly or who have systemic diseases that would increase the risk of general anesthesia. For the latter group of patients, which is probably the majority because this is a disease that affects mostly older people, a variety of destrucrive procedures are often effective. The most commonly used is a radiofrequency lesion, which is done percutaneously through the cheek, in the gasserian ganglion. A less effective way of achieving the same result is with an injection of glycerin into Meckel's cave. A **more** recently introduced method of producing some damage to the nerve is with a percutaneous introduction of an inflatable balloon, which can then be used to compress the trigeminal root. Radiosurgery has also been used with some success to damage the gasserian ganglion; however, its effect is delayed and frequently these patients are too incapacitated by their pain to wait several months for relief.

The destructive percutaneous procedures have the advantage of being much better tolerated and not requiring open surgery with general anesthesia. They also have the advantage that they can be repeated if the pain recurs. The disadvantage is that in general, these procedures achieve pain control only at the expense of significant hypalgesia, which, in some cases, is quite disagreeable to the patient. In addition, sometimes the lesions cannot be well controlled and the patient may develop complete analgesia with loss of the corneal reflex and subsequent visual complications from keratitis when the first division is affected. There is also the potential risk of *anesthesia dolorosa,* which is more intolerable than the pain of trigeminal neuralgia. In addition, particularly when the initial degree of hypalgesia achieved is only mild, the recurrence rate is very high with a significant initial failure rate. A last resort fur some ol these patients is open partial section of the trigeminal root, which can be accomplished by the subtemporal or suboccipital route. Open rhizotomy is rarely necessary these days, **although** historically it was the mainstay of the treatment of trigeminal neuralgia.

In brief, a neurosurgeon with an interest in the treatment of this condition should be consulted for any patient who fails to achieve acceptable pain relief without toxicity from the medications.

Hemifacial Spasm

Hemifacial spasm usually occurs as an isolated condition rather than as a manifestation of a more generalized dystonia, as is often the case with spasmodic torticollis.

These patients now can achieve significant palliation with periodic injections of botulinum toxin, a technique that has been mastered by many neurologists. The relief from these injections is temporary, lasting an average of 3-4 months, at which time they can be repeated. The long-term effects of chronic treatment with botulinum toxin remain unknown and many of these patients gradually develop some degree of facial weakness.

Most neurosurgeons have accepted the theory first postulated by Gardner and latet championed by Jannetta that in most patients, hemifacial spasm is caused by compression of the facial nerve by a vascular loop as it exits the brainstem, as most cases of trigeminal neuralgia are caused by compression of the trigeminal nerve by a vascular loop at the root entry zone in the brainstem. Therefore the decompressive procedure popularized by Jannetta, which consists of displacing the vascular loop from the facial nerve and holding it in a new position by a variety of means, has become very popular and has proven very successful in the treatment of this condition. More than 90% of the patients achieve either good control or complete resolution of their hemifacial spasm and the relief appears to be long lasting and usually permanent. The morbidity of the procedure in relatively young patients in good genctal condition is minimal. This operation is very attractive for patients with hemifacial spasm because destructive procedures that result in decreased facial function are intolerable to most patients (Jannetta 1996).

Spinal Arteriovenous Malformations

Though relatively rare, spinal AVM should be considered in the differential diagnosis of a number of neurological disorders that affect the spinal cord. Although these lesions have sometimes been subdivided into multiple types depending on their anatomical characteristics, it is sufficient to group them into three main types. The most common is the spinal dutal fistula, which is the most difficult to diagnose clinically and therefore can be confused with a number of neurological problems. The second type is the true AVM of the spinal cord, which can be strictly intramedullary or can extensively involve the spinal cord, the meninges, and even the vertebral bodies. These lesions occur at all ages and throughout the spinal cord. They can present either with acute myelopathy from intramedullary hemorrhage or with symptoms similar to those seen in the spinal dural fistulas from arterialization of the venous plexus that drains the spina! cord. Rarely, they present with spinal SAH, which may spread intracranially and simulate aneurysmal SAH. However, on close questioning, the pain in these patients almost always starts in the spinal area, and frequently they have a history of transient paraparesis or leg numbness at the onset. Therefore unless this history is obtained, there is no need to work up a patient with a typical history of intracranial aneurysmal SAH for a spinal AVM, The third group includes a variety of intradural, pcrimcdullary direct arteriovenous fistulas, which can either lead to very similar symptomatology as the spinal dural fistulas from venous hypertension or present with hemorrhage. The latter is often due to rupture of a venous aneurysm, which results from the high-pressure artcrialization of the perimedullary veins (Heros 1995).

Spinal dural fistulas occur in relation to the dural sleeve of one of the lower thoracic or lumbar roots. Less commonly, these lesions can also occur in the upper thoracic and cervical region. Typically, symptoms appear during mid and late adulthood and for this reason are thought to be acqmred legions, rather than congenital lesions. They arc more common in men than women. These lesions become symptomatic when they drain directly into the perimedullary coronal venous plexus, which normally drains the spinal cord (Figure 52.14), They rarely, if ever, result in hemorrhage and almost always become symptomatic as a result of pain and myelopathy. The pain may be radicular in nature, constant in the low back, or intermittent and frequently has a pattern suggestive of neurogenic claudication, where the pain occurs with ambulation and is relieved by rest. This is particularly pertinent because these lesions tend to occur in the same age-group as that in which lumbar spondylosis and neurogenic claudication are common. Therefore they must be entertained in the differential diagnosis of these conditions.

The myelopathy tesults from arterialization of the normal venous drainage of the spinal cord with secondaty venous hypertension. The patient may develop a progressive motor-sensory disturbance that can progress either steadily or sometimes with remissions and exacerbations that mimic multiple sclerosis. Sphincter disturbance eventually occurs, and, if untreated, the patients are usually wheelchair bound within 5 years from the onset of the leg weakness. The serious natural histoty of this disorder must be kept in mind, particularly in view of the fact that its surgical or endovascular treatment is relatively straightforward and almost always successful, provided that the neurological deficit is not profound or prolonged by the time of treatment.

In the past, diagnosis was made with a myelogram to demonstrate the dilated veins on the dorsal aspect of the spinal cotd (this tequired a complete lumbothoracic myelogram turning the patient in the supine position), Presently, the diagnosis can be made by cithct thin-cut CT myelography after injection of intrathecal contrast material or by spinal MRI. The latter can be problematic because unless it is done with special attention, the dilated veins in the surface of the spinal cord can be missed. Frequently, all that can be seen is an area of increased signal on T2-weighted images. Whenever such finding is seen without swelling of the spinal cord, this diagnosis must be suspected and confirmed by MRI with special technique. We use

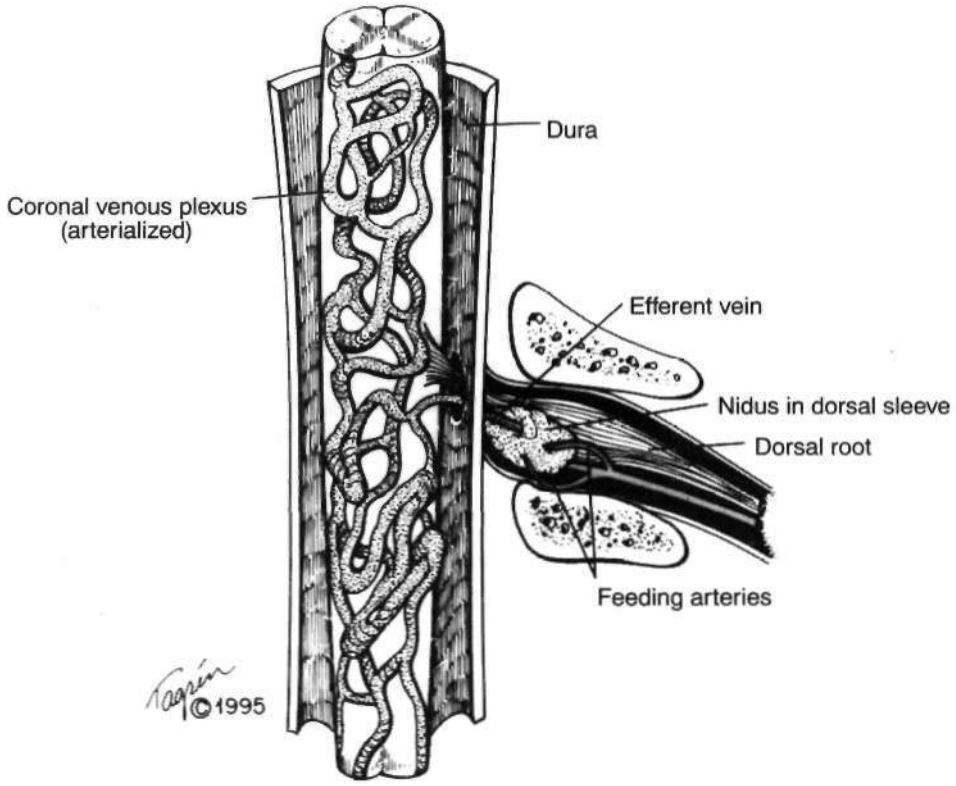

FIGURE 52.14 Schematic lvpri'smrmion ot .1 spinal Jural fistula. The actual fistula is located typically in the dural covering of one of the lower thoracic or lumbar nerve roots. The arterialized veins draining the fistula connect with the corona! venous plexus that normally drains the spinal cord. This venous plexus then becomes arterialized, thus increasing venous pressure and producing a venous hypertensive myelopathy. (Reprinted with permission from Heros, R. C. 1995, "Spinal arteriovenous malformations," in *Surgical Management of Neurovascular Disease*, eds R. C. Ojemann, C. S. Ogilvy, R. M. Crowd!, & R. C. Heros, Williams & Wilkins, Baltimore.)

standard T'l- and T2-weighted sagittal spin-echo images and T2-weighted axial gradient-echo images, as well as postcontrast three-dimensional MRI and Tl-weighted sagittal and axial images. With this technique, we have been able to reliably identify the fistula and its exact location (Bowcn ct a!. 1995). When there is no experience with these techniques and a spinal AVM is strongly suspected clinically, a spinal angiogram must be performed. This technique also requires considerable expertise and carries significant morbidity, and patients should not be indiscriminately subjected to it unless a spinal AVM is strongly suspected from the MRf or CT myelography study.

The treatment of dural venous fistulas consists either of eliminating the arteriovenous fistula completely or interrupting the arterialized venous communications (generally there is only one arterialized vein, although occasionally there arc two or three) from the fistula to the perimedullary coronal venous plexus of the spinal cord. This can be accomplished endovascularly in centers with the appropriate expertise. The procedure is difficult, and in less than very experienced hands, the morbidity of spinal angiography and endovascular therapy is quite significant. Unless the embolic material completely occludes the fistula and the beginning of the arterialized vein, recurrence is the rule. Nevertheless, in experienced hands, this is a very attractive option, particularly for older patients in whom surgery would carry a significant anesthetic risk, in most patients, we favor open surgical treatment, which consists of a small laminectomy with interruption of the arterialized vein usually with coagulation of the dural fistula in cases in which the fistula is located around a nerve root that can be sacrificed without consequences {e.g., the lower thoracic region). The results of treatment arc excellent and frequently dramatic with reversal of even very advanced paraparesis, particularly in cases in which the deterioration has been relatively acute and the treatment is undertaken early (Heros 1995).

It is important for the neurologist to include spinal AVMs in the differential diagnosis of any patient who presents with signs and symptoms of myelopathy, whether abrupt, slowly progressive, or with a pattern of remissions and exacerbations. In addition, whenever a patient in whom the diagnosis of lumbar spondylosis is entertained (frequently because of the pain pattern of neurogenic claudication), a spinal AVM should be considered. This is especially the case if there are signs of myelopathy, which obviously cannot be attributed to lumbar spondylosis, or if there is significant leg weakness or sphincteric disturbances, which are seen only very late in cases of lumbar spondylosis. We personally have operated on several patients with spinal AVMs who had been diagnosed as having multiple sclerosis. Several other patients have been operated on once or even twice before for lumbar spondylosis before the spinal AVM was eventually diagnosed and treated surgically.

Spasticity

Neurologists frequently treat patients in whom spasticity is either the predominant symptom or where it at least contributes significantly to the overall functional impairment of the patient. In children, this is most commonly due to cerebral palsy. **In adults,** stroke, multiple sclerosis, and myelopathy from spinal cord injury or other spinal cord diseases account for most of the patients in whom spasticity is an important problem. The first step in treating spasticity is pharmacological, and oral baclofen is the most common medication used. Frequently, however, the dose has to be increased to the point of intolerable drowsiness or other side effects. Other medicines such as ti/anidine, diazepam, and dantrolene may be used, but they may cause drowsiness or reduction in strength. At this stage, intrathecal administration of baclofen, usually by an implanted pump, can be very useful. When this fails, other more invasive ablative neurosurgical procedures may be considered. Dorsal rhizotomies are very effective in the treatment of spasticity. However, the side effects of complete dorsal rhizotomy are significant, and therefore more selective procedures have been developed. An open approach with intraoperative neurophysiologies! stimulation to select the dorsal rootlets involved in spasticity has been very effective, particularly in childten with cetebral palsy {Peacock and Standt 1991). Other, more invasive procedures such as a central myelotomy to interrupt the reflex arc and intrathecal phenol injections can be considered in the paraplegic patient who is severely incapacitated by spasticity. Intrathecal phenol causes loss of sensory input from the skin with the risk of decubitus ulcers and hence is rarely used other than for patients with terminal cancer.

Cervical Spondylosis

The neurosurgeon, who often operates on patients with cervical spondylosis for signs and symptoms of myelopathy and/or radiculopathy, must be intimately familiar with the nonsurgical differential diagnosis of cervical myelopathy, which includes motor system disease, subacute combined degeneration from vitamin B_{12} deficiency, demyelinating disease, tabes dorsalis, human T-lymphotropic virus type 1 (HTLV-l)-associated myelopathy and a number of other disorders. It is equally important for the neurologist to be aware that cervical spondylosis can result not only in neck pain and radicular symptoms, but also in myelopathy that may be painless and mimic these other diseases. When detected early, the myelopathy from cervical spondylosis can be either reversed completely or improved significantly with surgical correction. Even in the late stages, the patient's disease can be at least stabilized with surgery.

The early surgical treatment of cervical spondylotic myelopathy consisted of a posterior decompressive laminectomy or laminoplasty, which are still the best operations for many of these patients. However, we have become much more aware of the fact that cervical myelopathy is frequently a result of not just direct compression of the spinal cord, but also abnormal movement, Therefore depending on a careful study of each patient, other operations designed to decompress the cord anteriorly and/or posteriorly and then to fuse the spine when necessary have resulted in a considerable improvement in the treatment of these patients.

The neurosurgeon must know that the diagnosis of motor system disease must be entertained in patients with cervical spondylosis with significant myelopathy but with no sensory deficits. It is extremely unusual for cervical spondylosis to result in significant motor myelopathy without at least subtle decrease in sensation in the lower extremities. Conversely, the diagnosis of motor system disease becomes suspect when significant sensory abnormalities exist, and in these instances, cervical spondylosis is usually the culprit. The diagnosis of subacute combined degeneration is often entertained in these patients. This disease, however, is frequently preceded or accompanied by a significant peripheral neuropathy, which is not present in patients with cervical spondylosis unless they have an intercurrent disease.

Two other uncommon syndromes in the patient with cervical spondylosis can confuse the neurologist and the neurosurgeon. The first is the presence of signs and symptoms in the hands suggestive of lower motor neuron involvement in patients with upper cervical compression from spondylosis. It is not uncommon to see patients with significant compression of the spinal cord at C2-C3 or C3-C4 who despite lack of compression of the spinal cord or the nerve roots at the lower cervical levels complain of clumsiness and weakness of the hands. Most of these patients have the numb, clumsy hand syndrome, with severe loss of joint position sense. Rarely, they may have weakness of intrinsic hand muscles and some evidence of atrophy. This is similar to the well-established clinical observation ol symptoms and signs that simulate lower motor neuron disease in the lower cervical cord with tumors at the foramen magnum and other processes that produce upper cervical cord compression. The hypothesis to explain this problem proposes that impairment of ascending venous drainage produces venous infarction in the lower cervical cord. The second, and probably related problem, is the fact that patients with cervical spondylotic myelopathy without imaging evidence of motor nerve root compression can have symptoms and signs suggestive of a motor radiculopathy. The most reasonable explanation for this is that there is damage to the anterior horn cells. Recognition of this problem is important because if this problem is not recognized, patients can be subjected to unnecessary foraminotomies to decompress nerve roots, which may lead to spinal instability and the need for fusion.

In brief, cervical spondylosis is extremely common in the older population and frequently leads to myelopathic signs and symptoms that can mimic other diseases. Because surgical treatment is very effective, this diagnosis should be entertained in all patients in the middle or older age-group who present with signs and symptoms of cervical myelopathy and/or radiculopathy.

Brain Biopsy

Fortunately, with the introduction of many new diagnostic techniques, it is rare to have to perform brain biopsy for neurological diagnoses. However, there is still a well-defined role for this procedure, and it can usually be carried out with minimal or no morbidity.

Infections

Brain biopsy is still used by some clinicians before the institution of antiviral therapy when the diagnosis of herpes simplex encephalitis is suspected. However, the clinical and radiographic picture nowadays is usually specific enough to lead to a therapeutic trial of antiviral drugs before considering a biopsy, particularly in view of the fact that these patients often have significant brain swelling and the morbidity of the biopsy may be significant. Certain fungal and bacterial infections such as mucormycosis, aspergillosis, and nocardiosis often require a brain biopsy for diagnosis. The definitive diagnosis of some slow viral diseases such as Creutzfeldt-Jakob disease (CJD) requires a brain biopsy, which must be done with extreme caution according to a specially developed protocol. Presently, because of the risks to medical and paramedical personnel and to future patients (at risk because of insufficient sterilization of surgical equipment), many centers avoid brain biopsy and depend on clinical diagnosis in patients with clinically typical CJD.

The indications for biopsy in patients with acquired immunodeficiency syndrome are decreasing as MRl and radioisotope studies have become more capable of differentiating tumors (lymphomas) from infection (usually toxoplasmosis) or progressive multifocal leukoencephalopathy (PML). When the appearance is consistent with toxoplasmosis, we prefer to treat these patients empirically for about 2 weeks and proceed with the biopsy only if they do not respond to medical treatment. If the appearance is consistent with either lymphoma or toxoplasmosis, we obtain a single-photon emission computed tomography (SPECT) study; if positive, we assume that the diagnosis is lymphoma, but we usually confirm this with a biopsy before the initiation of radiation therapy. If the SPECT study is negative, we treat the patient empirically for toxoplasmosis. MRl is usually specific enough in the diagnosis of PML to make biopsy rarely necessary.

Vascitlttides

Brain biopsy is still necessary for the definitive diagnosis ol some vasculitides, such as granulomatous or isolated angitis.

Pediatric Neurodegenerative Diseases

Brain biopsy remains important in the diagnosis of some of these rare disorders including Canavan's disease and Alexander's disease.

Neoplastic Disorders

Brain (or rather meningeal) biopsy may be necessary in some cases of primary meningeal carcinomatosis, lymphomatosis, and gliomatosis, in which there is no obvious primary site and no definitive diagnosis has been obtained through spinal fluid cytology.

Dementia

Most causes of dementia can be diagnosed or at least strongly suspected clinically. In atypical cases, a brain biopsy is indicated to rule out treatable conditions such as Whipple's disease or a vasculitis.

Seizures and Epilepsy

Abnormal synchrony of neurons underlies seizure activity. Trauma, brain tumors, infection, metabolic disturbances, or abnormal cerebral development can cause irritation and/or abnormal neuronal firing patterns and rhythms. When seizures become intractable to medications, neurosurgical methods can assist in seizure control. Since the pioneering work of Wilder Pcnfield, many surgical advances have been made, adding to safety and efficacy. Today, seizure cure or increased patient manageability can be achieved with surgery. Medial temporal and selected extratemporal resections can result in 70-80% of patients becoming seizure free (Spencer 1996). Cortical mapping techniques allow the surgeon to localize and preserve brain areas that generate language and movement. Patients with widespread electroencephalographic (KEG) abnormalities or multiple foci may benefit from techniques such as multiple subpial resections, callosotomy and vagal nerve stimulation. Newer techniques such as subthalamic nucleus stimulation, gene insertion, and cell transplantation are under investigation.

Patients with intractable seizures are screened for surgery with scalp or sphenoidal EEG and video monitoring, MRl, SPECT scans, neuropsychological testing, and occasionally depth electrodes. Surgery is usually performed if these diagnostic tests can pinpoint the seizure focus and it is in a predictably safe surgical area.

Seizure surgery has become safer and more effective because of improved diagnostic methods, such as high-field and functional MRI, improved SPECT scans, and MR1 Spectroscopy. Surgical planning software stations and neuronavigational systems display images of the patient's brain and predicted seizure foci on a screen near the operative field. Preoperative functional MRI data for motor, language, and EEG can be included on the navigation screen,

A modern multidisciplinary approach to epilepsy is recommended. Neurologists, neurosurgeons, psychologists, and social workers working together can result in the best possible patient management

Movement Disorders and Parkinson's Disease

For six decades neurologists and neurosurgeons have collaborated to treat movement disorders associated with Parkinson's disease, essential tremor, multiple sclerosis, Huntington's disease, trauma, vascular conditions, and infection. When associated symptoms become intractable to medical therapy, modern neurosurgical techniques can help bring dramatic and long-standing relief. The earliest indication of this opportunity came from the recognition that motor improvement occurred in some patients with Parkinson's disease and tremor after focal strokes in the basal ganglia. Russell Meyers and others used these observations to design lesions of subcortical motor areas. Before the discovery of L-dopa, thousands of patients were treated successfully by stereoencephalotomy (thalamotomy). Lesioning the brain came back into vogue in the early 1990s with the advent of better stereotactic methods and the realization that L-dopa's beneficial effects were not curative and did not prevent progression of illness, Radio frequency lesioning of the internal segment of the globus pallidus (pallidotomy) has proven effective in relieving many of the cardinal symptoms of Parkinson's disease and selected dystonias. Essential tremor can be treated by lesioning the ventral intermediate motor thalamus (Vim's thalamotomy) or even the dentate nucleus of the cerebellum (dentatectomy).

Brain lesions can also be made using radiosurgical techniques (X-knife, gamma knife, proton beam). This technique is not recommended in most centers because it requires a high dose of focal radiation and does not allow for real-time neurophysiological localization and assessment of the patient during the procedure. Lesion accuracy, size, and potential delayed complications from radiation necrosis are concerns.

Coincident with the revival of brain lesioning, DBS has been shown to mimic the effects of lesioning with minimal damage to brain circuitry. A quadrapolar electrode is placed stereotactically into the nucleus of interest. The electrode is connected to a pulse generator implanted in an infraclavicular subcutaneous pocket. Stimulation parameters can be modified in an office setting.

Bilateral high-frequency stimulation of the subthalamic nucleus or internal segment of the globus pallidus is currently the treatment of choice for patients with Parkinson's disease, who have advanced disease with troublesome "on-off" motor fluctuations, dyskinesias, dystonias, or tremor. Patients are chosen for surgery after careful neurological and neuropsychological screening. In some patients with Parkinson's disease, the "off time" can be reduced more than 70%. With DBS, many patients' medications may be reduced. DBS is also the favored surgical treatment for essential tremor and selected dystonias. Bilateral thalamotomies can carry a significant risk of causing permanent aphasia, although the effect is reversible with DBS. Studies are in progress to determine the value of DBS in epilepsy, pain, obsessive-compulsive disorders, and depression. As the rhythms and oscillations in the brain are better understood, improved modalities of stimulation are being developed.

Advances in localization have allowed greater safety and efficacy in functional neurosurgical procedures. Brain targets of interest are acquired using planning software platforms that use anatomical atlases and the fusion of the patient's MRI and CT images. Target coordinates are translated to a stereotactic frame. Procedures are performed under mild sedation. Microelectrode recording and microstimulation is used to identify characteristic neuronal firing patterns, receptive fields, and nuclear boundaries. Intraoperative neurological examinations record beneficial and negative effects of brain lesioning or stimulation. Frameless stereotactic techniques are being developed for these functional neurosurgical procedures.

RECENT NEUROSURGICAL DEVELOPMENTS

Finally, in this section, we mention briefly some recent neurosurgical developments that have had a significant impact on neurosurgical practice or will do so.

Microsurgery

The operating microscope was introduced to neurosurgical practice about three decades ago, so it is not a recent development. However, the impact of the microscope in neurosurgery has been so significant and recent mechanical improvements in the mobility of the microscope have made it such that the microscope itself can almost float with the eyes of the surgeon as he moves within the surgical field to obtain the best possible angle of vision. The safety of operating on lesions such as aneurysms, AVMs, spinal cord tumors, tumors of the base of the skull, and intraventricular tumors has been improved remarkably. The average

morbidity of operating in some of these conditions has been reduced by half or more since the introduction of the microscope.

Skull Base Techniques

The skull base used to be like an iron curtain dividing the surgical fields of the neurosurgeon, the head and neck surgeon, the orbital surgeon, and the neuro-otologist. Over the last 10 or 15 years, neurosurgeons have learned, frequently from their colleagues in these other specialties, the techniques of removing bone safely along the base of the skull to gain access to deeply situated lesions with minimal brain retraction, better visualization, and greater safety. These techniques include the basal bifrontal craniotomy, sometimes with removal of the orbital rim and the nasion, the basal frontotemporal craniotomy with removal of the orbitozygomatic bone, the combined subtemporal-suboccipital and presigmoid craniotomy with posterior petrosectomy, and the far lateral suboccipital transcondylar approach. Using these surgical approaches and frequently working with colleagues in head and neck surgery, otolaryngology, neuro-otology, and ophthalmology, we are able to perform combined procedures that allow us to perform at least grossly complete total removals of benign tumors that were once considered inoperable. In addition, significant palliation and even cure of many tumors of low-grade malignancy can be accomplished with these techniques, and the approach to other lesions such as difficult and giant aneurysms and lesions of the brainstem has been made feasible and relatively safer,

Endoscopy

Neurosurgeons have been relatively late in adopting endoscopic techniques. However, with newly designed rigid and flexible endoscopes, the neurosurgeon can visualize, through smaller incisions, structures and pathology where the access by direct vision is much more difficult and dangerous. Endoscopes are ideal for intraventricular surgery, but they have also been incorporated in general microsurgical practice to look behind and around areas that are not directly in the field of vision of the surgeon. Also a number of traditional neurosurgical procedures, such as thoracic discectomies and transsphenoidal pituitary operations, can be performed less invasively with the use of the endoscope.

Intraoperative Angiography

Modern refinements in digital subtraction angiography have made its use in the operating room practical. This has been aided by the introduction of operating room tables and head support systems that are radiolucent and therefore allow angiograms in whatever plane and angle is best suited for the particular situation at hand. We routinely use intraoperative angiography in the surgery of AVMs to confirm complete removal before closing the wound. We also use this technique routinely in patients with giant or large, complex aneurysms to confirm the visually observed results of clipping. Other surgeons use the technique routinely for the surgery of all aneurysms. Not uncommonly, the intraoperative angiogram leads to repositioning of the clip to prevent a potentially catastrophic complication. Another application of this technique is to check patency of a bypass graft during surgery,

Neurophysiological Monitoring

Significant advances in neurophysiological monitoring have decreased the risk of many neurosurgical procedures, Spinal cord surgery, for example, is now routinely done with some form of neurophysiological monitoring involving not only sensory evoked potentials, but also motor transmission by transcranial cortical stimulation. Almost every cranial nerve can now be monitored, making surgery in or around the brainstem considerably safer. Somatosensory evoked potentials, central conduction time, and direct cortical measurements of blood flow have introduced greater safety to intracranial surgery involving temporary or permanent occlusion of major cerebral arteries. Carotid surgery has been made safer by intraoperative monitoring with EEG, somatosensory evoked potentials, and transcranial Doppler studies,

Frameless Stereotaxis

A number of new sophisticated systems of surgical navigation that incorporate stereotactic concepts and arc based on digital images (MRI or CT) that can be incorporated into a dedicated computer system have been developed. These new systems of surgical navigation consist of a method of registering images, an intraoperative localization device, a computer video display of the images, and some method of real-time intraoperative feedback. These techniques have led to the design of smaller craniotomies and very accurate intraoperative localization of deeply located lesions through minimally invasive brain trajectories. They have been particularly-useful for the surgery of deep brain tumors, skull base tumors, brain cavernomas, and for certain types of spinal instrumentation such as pedicle screw fixation. An extension of these techniques is the development of surgical robotic devices, which undoubtedly will find an important place in the neurosurgeon's armamentarium within the near future.

Real-Time Image-Guided Surgery

Systems have been devised to perform actual neurosurgical operations, either stereotactically or by open craniotomy, directly in a CT scanner or an MRI machine. Magnetic resonance^compatible instruments have been developed for this purpose. These devices were designed specifically for use in the operating room and though cumbersome and expensive have provided the neurosurgeon with real-time surgical feedback. The eventual role of these imaging devices in the operating room is still uncertain but promises to be significant.

Radiosurgery

The concept of radiosurgery and the first dedicated radiosurgical unit (the gamma knife) was developed by a neurosurgeon, Professor Lars Leksell. Since then, neurosurgeons have been almost uniformly involved in the delivery of radiosurgery, which is based on neurosurgical stereotactic techniques. Radiosurgery has become an extremely important surgical technique in the primary or adjunctive treatment of many vascular and neoplastic lesions. In addition, from its inception, radiosurgery has been used to make discrete lesions in the brain and lately in cranial nerves (such as the trigeminal nerve for treatment of trigeminal neuralgia) as part of the armamentarium available for functional neurosurgery.

Radiosurgery is clearly the treatment of choice for small (usually <3 cm in diameter) AVMs located deeply in the brain, in critical areas where open surgery would carry an unacceptably high morbidity. It is also an acceptable alternative for patients with small accessible AVMs, who would carry an inordinately high surgical risk because of age or associated medical comorbidities. Unfortunately, cavernous angiomas respond poorly if at all to radiosurgery, and the treatment of these lesions, which are often in critical locations such as the brainstem, has carried unacceptably high morbidity.

Radiosurgery has also found an important role in the treatment of some surgically inaccessible but well-demarcated benign tumors such as meningiomas in the cavernous sinus or in other regions where perhaps the bulk of the tumor can be removed surgically, but a small remnant must be left to avoid serious neurological morbidity. It appears that with small acoustic neuromas, radiosurgery tends to control the disease; many of the tumors cithct shrink or remain static in size at least for a few years. Unfortunately, there is not enough long-term follow-up information on either meningiomas or acoustic neuromas as to the permanent effectiveness of radiosurgery. This treatment is very attractive in elderly or medically debilitated patients when the tumor can be encompassed within the radiosurgical field.

Earlier in this chapter, we mentioned the fact that small metastases in the brain can be treated quite effectively with tadiosurgcry, particularly when there is a single metastasis or only a few discrete lesions. The role of radiosurgery in the treatment of primary malignant brain tumors has not been adequately defined because most of these tumors are infiltrating. However, there may be a significant role for this modality in treating focal recurrence after conventional fractionated irradiation or as an initial adjunct to conventional radiotherapy.

Endovascular Surgery

Endovascular surgery is covered in Chapter 53, and we have discussed its role in the treatment of aneurysms earlier in this chapter. The role of endovascular techniques in the adjunctive treatment of AVMs and some very vascular tumors (preoperative embolization to decrease blood supply) is well defined. In addition, it is becoming clear that in certain instances, endovascular techniques are becoming an acceptable alternative to surgery as primary treatment. Such is the case with small AVMs and fistulas that can be obliterated completely with embolization, and with some intracranial aneurysms that have a particularly favorable anatomy for this technique. Endovascular embolization has already become the preferred form of treatment for most intracranial and spinal dural fistulas, including carotid cavernous fistulas. Many vein of Galen aneurysms and other complicated arteriovenous anomalies of newborns and children can be treated successfully with endovascular techniques.

Although presently most endovascular surgeons are trained in radiology and neuroradiology, an increasing number of neurosurgeons and neurologists have been or are being rrained as endovascular surgeons and are planning to dedicate most or all their time to performing endovascular surgery.

Neurotran splantation

Reconstruction and protection of neural tissue are the ultimate goals of therapy in neurodegenerative disease. Transplants of embryonic fetal tissue into the brain of patients with Parkinson's disease or in its animal models can survive and produce dopamine and effect mechanical, chemical, and electrical connections with the host brain. The disease process does not appear to affect the transplanted cells. Several human studies using embryonic mesencephalic tissue have shown some positive effects on the disease (Freed et al. 2001; Mendez et al. 2002) and postmortem studies have shown dopamine cell survival and graft-host integration. Similarly, xenografts of porcine cells have also shown positive effects in some patients and integration into host brain (Schumacher et al. 2000).

Transplantation of neurotrophins and genetically modified cells has shown potential in animal models of Parkinson's disease and other neurodegenerative diseases. Transfection of glial-derived neurotrophic factor genes via a lentiviral vector into the Parkinson's disease primate model have demonstrated dopamine cell protection (Kordowcr ct al. 2000). Fibroblasts genetically modified to produce nerve growth factor have been shown to protect against excitotoxic destruction of neurons (Schumacher etal. 1991).

Highly specialized embryonic stem cells have demonstrated the capability in animal models to repair and reconstruct the degenerated nigrostriatal system {Isacson et al. 2001). The methodology for generating functional dopamine progenitor cells for transplantation has advanced to the stage that human stem cell transplantation studies are under consideration. The limitation of stem cell technology is the ability to generate a purified neuronal cell line while suppressing other germ cell layers and/or tumor formation. This technology might allow transplantation of specific cells into the brain to effect repair and replacement without the need for immunosuppression.

Chapter 53
Principles of Endovascular Therapy

Ajay K. Wakhloo and Johnny S. Sandhu

Endovascular therapy (EVT) is one of the leading emerging neurological fields for the treatment of stroke, aneurysms, arteriovenous malformations (AVMs), brain tumors, and other such conditions. Over the past 20 years, it has evolved from a minimally invasive, alternative therapeutic approach to cerebrovascular diseases to a highly specialized field in its own right. EVT is now the primary approach for an increasing number of vascular diseases, with patients benefitting from better outcomes and shorter hospital stays.

The integration of new technologies, including neuroimaging and bioengineering, is likely to expand treatment indications. Significant advances in imaging technology (such as high-resolution angiography, flat-panel detectors, three-dimensional [3D] angiography, road-mapping capability, intravascular ultrasound, and interventional magnetic resonance imaging [MRIJ} are providing safer image guidance. Increased resources for biotechnology have resulted in the development of new materials and alloys using nanotechnology and micro-clcctromechanical systems (micromachinery).

Unlike the "extravascular" approach (open surgery) that involves an external approach to the outer layer of the vascular system (generally the adventitia), "endovascular" treatment focuses on the endothelium, which represents the largest receptor surface in the body that involves the coagulative system, platelets, vasodilatation processes (e.g., nitric oxide [NO]), vasoconstriction (e.g., endothclin-1), and biological responses to implanted materials. The endothelium is also sensitive to changes in blood composition and flow, including direction, velocity, and pressure. The next generation of endovascular therapies will involve the further development of newer materials, anticoagulation and antiplatelet agents, thrombolytics, growth inhibitors and promotors, and antiproliferative agents, as EVT moves from "microplumbing" to the delivery of growth factors and gene therapy.

Currently, the endovascular treatment of neurovascular diseases has two approaches: to close or devascularize (e.g., aneurysm obliteration or AVM embolization); and to open or revascularize (e.g., vascular stenting, thrombectomy, thrombolysis, and angioplasty). The key to a successful endovascular intervention is to understand basic vascular anatomy, pathology, classification of the pathology, materials, and imaging tools. In this chapter, we present the acute and elective endovascular treatment of selected disorders,

GENERAL CONSIDERATIONS

Before an intervention, one generally must perform angiograms of the posterior and anterior circulation, selective injection of external carotid arteries, and 3D angiograms (if needed). Angiograms help the interventionist to define the lesion and its architecture, classify the disease entity, and outline potential collaterals and dangerous anastomoses, as well as to plan the EVT, including device selection. Computed tomography (CT) and magnetic-resonance angiography (MRA), especially with contrast, are gradually replacing catheter angiographic diagnostic workup, although detailed information still requires digital subtraction angiography.

The femoral artery approach is the most common site of access for cerebral or spinal diagnostic angiography and intervention. When an intervention is planned together with diagnostic angiography, a large femoral artery sheath is placed to introduce a variety of specialized catheters and devices, which arc threaded into the area of interest using a coaxial technique under fluoroscopic guidance and often

road mapping. This involves obtaining an image of die vascular tree that is frozen and serves as a background map. Under real-time fluoroscopy, it is then possible to navigate the catheters, wires, and bioimplants, using the "road map" to the area of interest.

With newer devices, an intervention can also be done via direct access through the carotid artery or if deemed necessary through the brachial or radial artery (Fessler et al. 2000). Microcathcters can either be navigated safely over microwires or flow guided into most of the important vascular segments of the central nervous system (CNS). Development of high-resolution angiography, road-mappmg techniques, and iso-osmolar nonionic contrast materials has helped minimize complications of diagnostic neuroangiography, such as minor or major stroke, which in experienced hands should be less than 0.5%.

The most commonly used embolic agents include polyvinyl alcohol (PVA) particles of different sizes (PVA = 50-1000 urn), Gelfoam, collagen fibers, dehydrated (96%) ethanol, platinum (fibered) coils, polymer-coated coils, acrylatc, cellulose acetate, and detachable balloons.

Some important essentials for a safe embolization can be summarized as follows:

- Thorough understanding of normal cerebrovascular anatomy and pathology.
- Exclusion of dangerous anastomoses between the external carotid artery and vertebrobasilar system and the internal and ophthalmic arteries. Dangerous anastomoses can be visible during initial neurovascular imaging or can appear during embolization. If necessary, a provocative test can be undertaken with injection of amobarbital (Amytal) or lidocaine into the extracranial arterial branches.
- Understanding of the characteristics of biomaterial including catheters, wires, and bioimplants used, as well as available alternative options.
- Experience in the use of thrombolytics, anticoagulants, and antiplatelet agents,
- The use of supcrselcctivc catheterization, especially if liquid embolic agents are used. Protection of normal vessels may require their temporary occlusion with nondetachable balloons or Gelfoam. If permanent occlusion is desired, this may be achieved by the use of detachable balloons, coils, or acrylates.
- Embolization should be performed under fluoroscopic control. Gentle and controlled injection of embolic agents is necessary to avoid reflux into normal tissues.
- Frequent use of road mapping is required for safe catheterization.
- Treatment of arterial vasospasm induced by instrumentation is undertaken with lidocaine, papaverine, nitroglycerin, or mannitol.
- Prophylactic use of high-dose corticosteroids can avoid expanding mass effects resulting from tumor ischemia or necrosis.
- Frequent monitoring of neurological status during embolization.
- Patients should receive generous treatment with analgesics.
- Whenever feasible, conscious sedation should be used, rather than general anesthesia. However, general anesthesia should be used for embolization of AVMs, for aneurysms, complex vascular disease, children, and in extremely restless or uncooperative patients.

TUMOR EMBOLIZATION

Transarterial Embolization and Direct Tumor Puncture

Devascularization of extracranial head and neck or intracranial tumors can be performed preop era lively to reduce intraoperative blood loss, to facilitate surgical resection, and to reduce the time of surgery (Siniluoto et al. 1993). In selected patients who are not suitable for surgery, tumor embolization may be palliative to reduce tumor size and control tumor growth (Koike et al. 1990; Wakhloo et al. 1993). It has been suggested that preoperative embolization may reduce tumor recurrence after surgery, although this remains debated (Dean et al. 1994),

The tumors most commonly subjected to preoperative embolization are meningioma, glomus tumors, juvenile nasal angiofibroma, hemangioblastoma, sarcoma, and (renal) metastases (Richter and Schachenmayer 1983; Teasdale et al. 1984; Manelfe, Lasjaunias, and Ruscalleda 1986; Eskridge et al. 1996; Scholtz et al. 2001). Embolization is particularly valuable in skull base meningiomas (Jungreis 1991; Manelfe, Lasjaunias, and Ruscalleda 1986; Wakhloo et al. 1993).

In hemangioblastomas, preoperative embolization is extremely helpful, especially if the deeper parts of the tumor and the piaI arteries supplying the tumor can be approached. However, less than 50% tumor devascularization has proven not to reduce operative complications or morbidity (Takeuchi et al. 2001). Embolization is also a safe and effective method of controlling refractory epistaxis in patients irradiated for nasopharyngeal carcinoma (Mok etal. 1999).

The basic principles of tumor embolizations involve a complete assessment of tumor-supplying arteries and delineation of normal vascular structures including the venous drainage, a transarterial super selective catheterization of relevant arteries, followed by fluoroscopic-con trolled infusion of embolic agents. The most commonly used materials arc PVA, Gelfoam, acrylates, dehydrated ethanol, and fibrin glue (Manelfe, lasjaunias, and Ruscalleda 1986; Lonser, Heiss, and Oldfield 1998; Probst et al. 1999; Valavanis and Christoforidis 2000; Bendszus et al. 2000). The size of the embolic material must be tailored to the diameter of the supplying arteries to achieve a deep penetration of the embolic material into the tumor nidus for successful tumor

ischemia (Wakhloo et al. 1993). If supers elective catheterization is not feasible, for example, in tumor-supplying branches originating directly from the internal carotid or the vertebral artery, temporary occlusion of the internal carotid artery (ICA) distal to the feeders can he achieved when infusing particles or ethanol with a microcatheter that is positioned as close to the feeders as possible (Jungreis 1991; Wakhloo et al. 1993) (Figure 53.1).

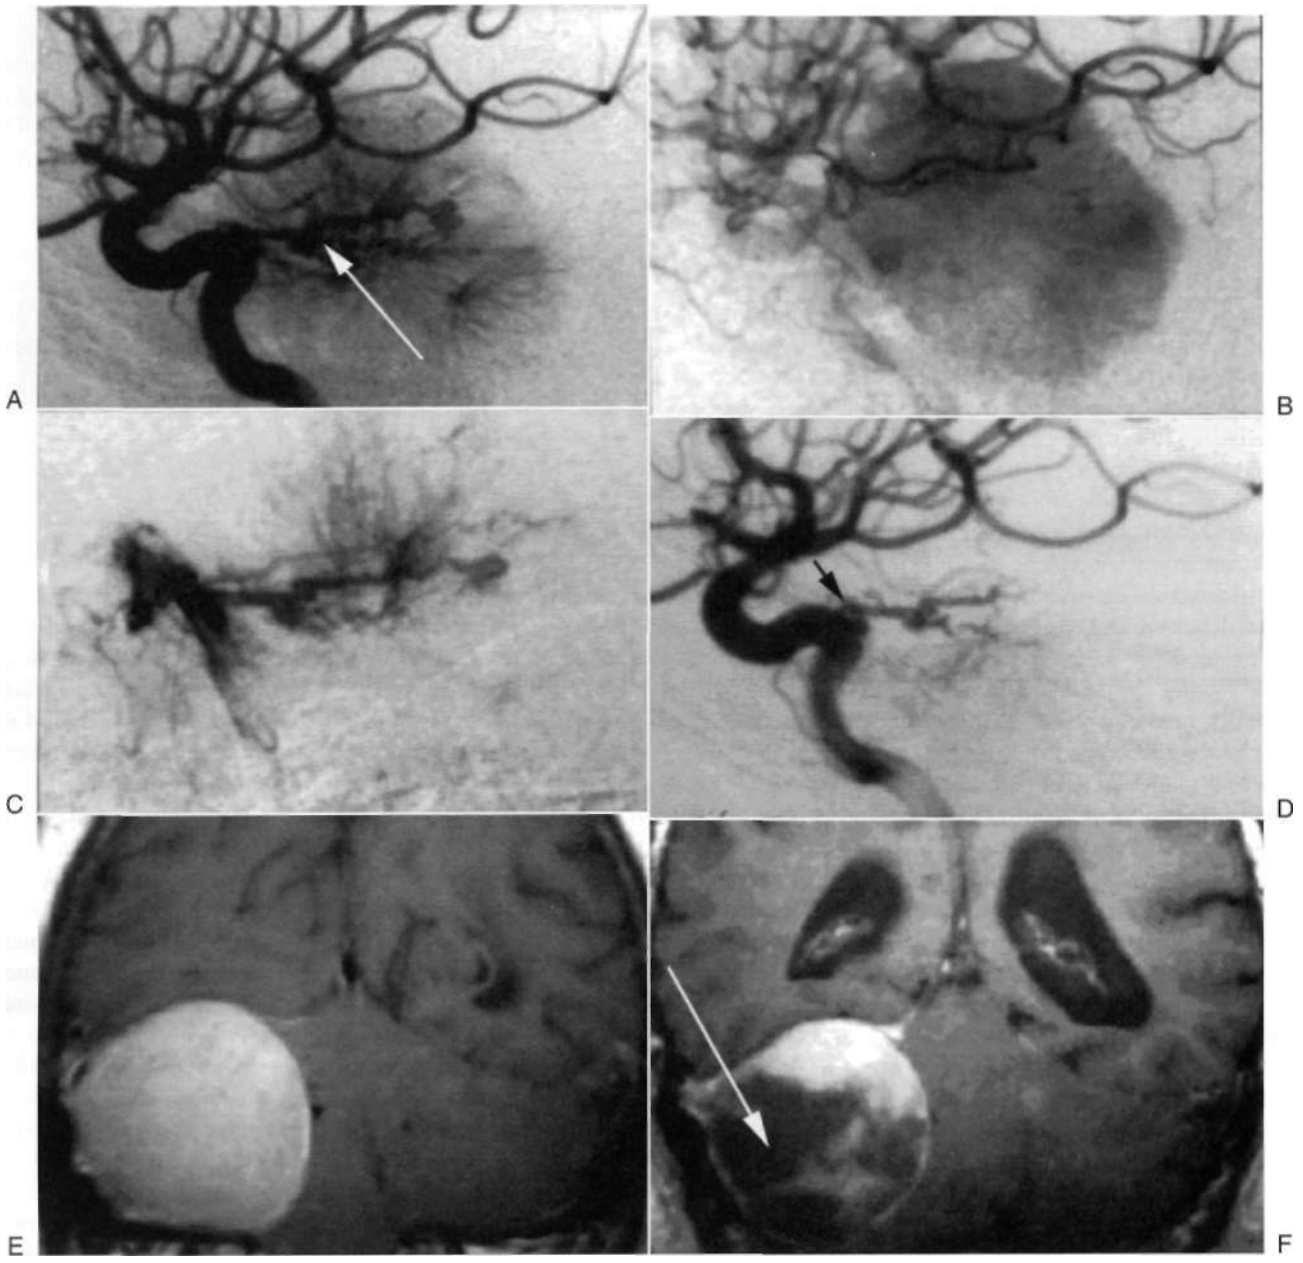

FIGURE 53.1 (A) internal carotid artery angiogram (ICA) (lateral projection) shows a hypervascular tumor at the skull base supplied via dilatated meningeal branches of the meningohypophyscaJ trunk (Bernasconi and Casanari). The centrifugal radial tumor vessel architecture is typical for a meningioma. (B) Homogenous tumor contrast enhancement with delayed washout is seen in the late arterial phase. The inferior portion of the meningioma is supplied through dural branches of the external carotid artery. (C) Supetselective catheterization of the men ingo hypophyseal artery and centrifugal polyvinyl alcohol (PVA) particle embolization. The control angiogram shows partially embolizcd tumor vessels with major central feeders perfused; dural and tumor enhancement at the clival region. (D) Postemholization ICA angiogram shows nearly complete devascularization with a patent meningohypophyscal trunk. (E) Contrast-enhanced coronal Tl-weighted magnetic resonance imaging (MRI) scan shows a large posterior fossa meningioma with attachment to the tent and mass effect on the brainstem. The extra-axial tumor shows homogenous enhancement and increased contrast uptake of the adjacent dura. Dilatated peritumor draining veins are visible. (F) MRI scan after embolization. Large areas of devascularization represent necrotic tissue. The remaining enhancing tissue is supplied via pial branches of the posterior circulation.

Postembolization gadolinium-enhanced MRI is an excellent imaging tool to evaluate the efficacy of embolization (Grand etal. 1993; Wakhloo et al. 1993). On MRI, marked tumor size reduction and a decrease in contrast uptake are associated with magnetic resonance spectroscopic (MRS) signs of a transient lactate peak, followed by a large aliphatic signal consistent with tumor necrosis. The necrosis as shown by proton spectroscopy is complete within 4 days (Jucngling, Wakhloo, and Hcnnig 1993; Bendszus et al. 2000).

As maximal tumor softening is seen, the optimal interval between embolization and surgery in 'meningiomas is proposed to be between 7 and 9 days. This facilitates a safer and easier tumor resection (Kai et al. 2002).

Attention must be paid to potential dangerous anastomoses between branches of the external carotid, internal carotid, and vertebral arteries, which may be present before embolization, adjacent to or within the tumor, or may open during embolization as a result of changes in vascular impedance (Casasco et al. 1999; Turner, Trobe, and Deveikis 2002). Facial palsy after preoperative embolization of glomus tumors has been described but is a rare complication (Marangos and Schumacher 1999). If an inappropriate particle size is chosen or embolization is performed from a proximal catheter position, lower cranial nerve deficits may be seen because of ischemia of vasa nervorum. Risk of embolization-induced increased endocrine activity of paragangliomas has been described but generally does not occur (Milewski, Eimannsberger, and Pflughaupt 1993).

Recently, a successful percutaneous or transnasal intratumoral injection of N-butylcyanoacrylate or ethanol has been described (Casasco et al. 1994). It may also be used in combination with transarterial embolization. It is a safe and effective method in the management of hypervascular neoplasms of the head and neck (Chaloupka et al. 1999).

Chemoinfusion with Blood-Brain Barrier Disruption

Primary treatment of brain tumors with neuroendovascular approaches has attempted to overcome the blood-brain barrier (BBB) by disrupting the BBB with the delivery of c he moth era pen tic agents. The tight junctions of microvessel endothelium have been a long-standing obstacle to delivering chemotherapeutic agents through the systemic circulation. Doses necessary to cross the BBB have typically been highly toxic to the rest of the body. Rapoport et al. (1970, 1972, 1976) first theorized the possibility of transiently opening the BBB with intra-artenal (IA) infusion'; of hyperosmotic agents. Mannitol was found to cause osmotic disruption with shrinkage of the endothelium and subsequent "opening" or "separation" of tight junctions. Neuwelt et al. (1979) first used osmotic disruption to subsequently deliver chemotherapy for brain tumors in a phase I trial in 1979. Since then, other agents such as vasoactive compounds have been studied to augment the local delivery of chemorherapy to brain tumors with varying degrees of success. These include leukotrienes, histamine, serotonin, interferon-^, hradykinin, and bradykinin analogues (RMP-7), A multicenter trial treated 221 adult patients with IA chemotherapy with or without BBB disruption. Patients had tumors that included primary CNS lymphoma (PCNSL), primitive neuroectodermal tumors (PNETs), germ cell tumors, cancer metastasis to the brain, or low- or high-grade gliomas. A total of 40 (75%) of 53 patients with PCNSL achieved complete response (CR). All patients with PNET, metastatic disease, or germ cell tumor achieved stable disease (SD) or better. Of the 57 evaluated patients with glioblastoma multiforme, 45 (79%) achieved SD or better. The study concluded that IA chemotherapy with or without osmotic opening of the BBB is feasible across multiple centers, with a low incidence of catheter-related complications (Doolittle et al. 2000).

ISCHEMIC STROKE

Prevention

Stroke remains a significant public health problem in the United States as the third leading cause of death and the number one cause of neurological disability {Weir 1987, 2002; Wolf and D'Agostino 1998). The American Heart Association (AHA) estimates that there are more than 4.6 million stroke survivors in this country, and more than 150,000 deaths annually are attributed to stroke {Wolf and D'Agostino 1998; AHA 2001). Recent studies estimate an incidence of 700,000 to 750,000 new strokes per year, with 83% of these secondary to ischemic events {Broderick et al. 1998; Rosamond et al. 1999; Williams et al. 1999). The most common etiology is the occlusion of an intracranial blood vessel that supplies a critical brain territory. Acute ischemic stroke results in death within 30 days for 7.6% of victims (Rosamond et al. 1999; AHA 2001).

The most effective treatment is prevention because of the nature of stroke and the difficulty in immediately identifying symptoms. Treatment is often delayed beyond the point of saving the ischemic penumbra—the salvageable area of brain tissue. Therefore prevention, especially in high-risk populations, may be an effective method in reducing the morbidity and mortality of stroke. Patient education, antiplatelet therapy and anticoagulation, carotid endarterectomy (CEA) and stenting, and intracranial stenting whenever indicated are all preventive medical measures that can be applied.

Carotid Artery Stenting

Large studies have estimated that 0.5% of people between the ages of 60 and 70 years and 10% of people older than 80 years have carotid artery stenosis. Atherosclerotic

occlusive disease of the carotid artery has been estimated to be responsible for 20-30% of all strokes (Timsit et al. 1992).

Age, race, gender, genetics, and family history are nonmodifiable factors that play a role in the development of carotid artery disease. Older age, African American and Hispanic descent, male gender, and a positive family history are all positive risk factors. Modifiable risk factors include the following: smoking, hyper)ipidemia, sedentary lifestyle, incteascd body mass index, oral contraceptive use, alcohol and substance abuse, diabetes mellitus, hypertension, prior transient ischemic attack (TIA) or stroke, elevated homocysteine levels, elevated anticardiolipin antibodies, presence of a carotid bruit, cardiac disease, increased fibrinogen, and low serum folate (Biller and Love 2000).

Indications for Treatment. Approximately half of the patients considered for endovascular treatment present with a symptomatic cerebrovascular event, cither a completed stroke or a single or multiple TIAs. The TIA syndrome resulting from ICA stenosis generally consists of ipsilateral amaurosis fugax, contralateral sensory or motor dysfunction, aphasia (if affecting the dominant hemisphere), contralateral homonymous hemianopia, or combinations thereof. Ocular symptoms are sudden, brief, and painless and last 1-5 minutes, rarely more than 30 minutes. Primary care physicians may also refer patients after auscultation of a carotid bruit, although this is not a very sensitive sign. Atherosclerotic occlusive disease is the most common etiology of carotid artery stenosis. However, stenoses can be caused by fibromuscular dysplasia, arterial dissection, arteritis (especially Takayasu's arteritis), which may produce stenoses of the great vessels and the intracranial circulation or neurofibromatosis. Long-standing hypertension may result in marked tortuosity of the proximal great vessels and intracranial small-vessel arteriopathy. Less common causes of carotid occlusive disease include tumor encasement, radiation-induced stenosis, and trauma. Revascularization in this group is indicated to improve hcmodynamic-related neurological symptoms secondary to high-grade stenosis.

Plaque Characteristics. Clinical observations and histopathological studies of the carotid plaque suggest that two different diseases of the carotid artery bifurcation can be distinguished: the "asymptomatic" and the "symptomatic" carotid plaque.

Carotid plaques can be distinguished as either homogenous or heterogenous. Diffuse intimal thickening or growth of the intima occurs through the migration of medial smooth muscle cells into the subendothelial space through the fenestrations of the internal elastic lamina, associated with increasing amounts of elastic fibers, collagen, and glycosaminoglycans. Homogenous plaques are stable and rarely show evidence of ulceration or hemorrhage. Homogenous plaques undergo the deposition of fat and fibrous tissue. Conversely, heterogenous plaques are unstable and contain lipid-laden macrophages, monocytes, leukocytes, necrotic debris, cholesterol crystals, and calcification. Plaques may harden with calcium, lipid, and cholesterol accumulations.

Several studies of plaque characteristics have revealed a correlation between the histological features of a plaque and its susceptibility to cause thromboembolic events. These findings have been mostly related to ultrasound findings. Plaques that are more likely to be related to stroke have a low echogenicity on ultrasound. This is because lipid and hemorrhage weakly reflect ultrasound, that is, show echoluccncy. These plaques are soft and friable. Irregularities of the surface (plaque ulceration) have been shown to be a risk factor for thromboembolic events. Ulcerated plaques arc often covered by soft, gelatinous clots that contain platelets, fibrin, white blood cells, and red blood cells. Heterogenous plaques have been shown to be an independent risk factor for stroke regardless of the degree of stenosis.

The cholesterol-rich, slightly raised fatty streak becomes a fibrous plaque. The complicated plaque may undergo rupture, intraplaque hemorrhage, extensive necrosis, calcification, and subsequent thrombosis. Infiltration of the fibrous cap of the plaque by foam cells may also contribute to the rupture. Symptomatic plaque shows a significantly higher incidence of rupture (74%) as compared with asymptomatic plaque (32%) (Carr et al. 1989; Bassiouny et al. 1997). Although there is no difference in the amount of necrotic core in the symptomatic versus the asymptomatic plaque (26% vs. 22%) or calcification (6% vs. 7%), a significantly higher number of macrophages are found in the symptomatic plaque (1114 vs. 385), indicative of the inflammatory nature of the disease.

Surgical and Endovascular Treatment. The North American Symptomatic Carotid Endartcrcctomy Trial (North American Symptomatic Carotid Endarterectomy Trial Collaborators 1991) was a randomized study that determined that CEA reduced the risk of stroke in patients with ipsilateral carotid stenosis and a recent cerebrovascular event. Patients treated with a high dose of aspirin over 24 months had a risk of ipsilateral stroke of 26%, whereas only 9% of the patients undergoing CEA presented with stroke in the same time period. Thus CEA became the standard of care for carotid disease with high-grade stenosis (70-99%). The periprocedural major stroke and death risk was 5.5% and 0.6%, respectively. Other surgical complications included cranial nerve injury, wound hematoma, and myocardial infarct, for a total periprocedural complication of *26%.* However, surgical high-risk patients were excluded from the study (Table 53.1).

The annual stroke event rate for asymptomatic patients with hemodynamically significant carotid artery stenosis ranges from 2-5% (Executive Committee for the Asymptomatic Carotid Atherosclerosis Study 1995). The

Table 53,T; Patients excluded from die North American Symptomatic Carotid Endartercctomy Trial

1. Mentally incompetent or unwilling to give informed consent
2. Inadequate angiographic visualization of both carotid arteries and their intracranial branches
3. Intracranial lesion that was more severe than the surgically accessible lesion
4. Organ failure of the kidney, liver, or lung, or cancer judged likely to cause death within 5 years
5. Cerebral infarction on either side that deprived the patient of all useful function in the affected territory
6. Symptoms that could be attributed to nonatherosclerotic disease
7. Cardiac valvular or rhythm disorder likely to be associated with cardiocmbolic symptoms
8. Previously undergone an ipsilateral carotid endarterectomy
9. Older than 79 years
10. Experienced angina or myocardial infarction in the previous 6 months
11. Progressing neurological signs
12. Conrralarcral carotid endarterectomy within 4 months
1.1. Underwent a major surgical procedure within 30 days

5-year stroke and death risk for an asymptomatic high-grade carotid stenosis with medical treatment was found to be 11%, whereas the surgical arm had a stroke risk of 5.1% (Executive Committee for the Asymptomaric Carotid Atherosclerosis Study 1995). The Asymptomatic Carotid Artery Stenosis (ACAS) trial found that CEA was justified in asymptomatic men with 60% or greater stenosis only if the perioperative morbidity and mortality rate of the procedure is less than 3%. The acceptable perioperative morbidity/mortality rate for symptomatic patients was 6%. Although the findings were not as clear for women, women also experienced a reduction in stroke risk with CEA.

Restenosis is not uncommon after CEA. Studies have reported an incidence of anywhere from 1.5% in symptomatic to 19% in asymptomatic patients (Healy et al. 1998). Furthermore, reoperation is often more difficult for restenosis after CEA, with higher rates of local and neuro logical complications.

The initial carotid stenting trials focused on patients who were not good candidates for CEA and continued to have TIAs on optimal medical therapy (Lanzino et al. 1999; Mericle et al. 1999; Lopes et al. 2002). Also, patients who fall into the following categories were considered for carotid artery angioplasty/stenting: lesions that were anatomically inaccessible to surgery, lesions with CEA restenosis, high-risk patients with severe comorbidities, radiation-induced stenosis, medically refractory patients, cases with arterial dissection and tumor-encased carotid arteries, and patients older than 80 years. Multiple current trials showed reduced peri procedural morbidity and mortality of endovascular treatment versus surgery if distal cerebral protection is used during carotid stenting I'CS). A randomized trial of stenting versus CEA in surgical high-risk paricnts showed that at 30-day postprocedure, stroke, myocardial infarction, and death were encountered in 12.6% in the surgical arm (N = 151) and only 7.8% in the stentcd group that used a cerebral protection device (N = 156) (Yadav 2002). The Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS) (CAVATAS Investigators 2001) was a randomized trial that sought to compare endovascular treatment with conventional carotid surgery. The multicenter trial in Europe, Australia, and Canada randomly selected 504 patients with carotid stenosis. Patients with stenosis of the common carotid artery, carotid bifurcation, or ICA that needed treatment were included only if both endovascular and surgical treatments were suitable. The CEA group had 253 patients, and the endovascular group had 251. Stenting was used in 55 patients (26%), and angioplasty alone was used in 158 patients (74%). The mean stenosis in the surgical group was 86.4%, and the 30-day stroke and death rate was *5.9%.* In the endovascular group, the mean stenosis was 85.1% and the 30-day stroke and death risk was 6.4%, No cerebral protection was used (Figure 53.2).

The Carotid Revascularization Endarterectomy Versus Stent Trial (CREST) is currently enrolling patients for a multicenter clinical trial to compare the efficacy of CEA and carotid angioplasty/stenting in symptomatic patients with stenosis of 50% or more. As of mid-2001, 47 centers had been selected (Hobson 2002). This study is evaluating whether carotid stenting, the new technology, is more or less efficacious than open surgery, the current standard treatment.

The latest update on the global carotid stent registry includes almost 11,000 stented patients with more than 12,000 carotid arteries stented (Wholey et al. 1998). Data show that the technical success with stenting was more than 98%. The minor and major stroke risk and mortality in the symptomatic group without the use of a distal cerebral protection device was almost 7%, whereas the use of a distal cerebral protecrion device reduced the risk to 3.25%. In the asymptomatic group, the minor and major stroke risk and mortality associated with carorid artery stenting was *4.7H"A,* but could be reduced significantly to 2.53% by using a distal cerebral protection device. The rate of restenosis (>50%) at 48 months was 5.5%. Other studies with follow-up of 1 year and less have reported in-stent restenosis rates after carotid angioplasty and stenting between 3.5% and 8.0% (Chakhtoura, Hobson, and Goldstein 2001). Stenting of vessels has been shown to overcome previously high rates of restenosis with angioplasty alone.

Cerebral protection devices are based either on balloon or on filter technology. The basic idea is to prevent embolic stroke during stenting. The cerebral protection device is placed distal to stenosis; once stenting is accomplished, the device is removed through a guiding catheter. Despite the use of a cerebral protection device, approximately 2-3% of symptomatic and asymptomatic patients suffer minor and major srroke. Generally, this is related to embolic debris

FIGURE 53,2 (A) Common carotid artery angiogram in lateral projection shows an ulcerated plaque and high-grade stenosis of the internal carotid artery (ICA) *[arrow).* (B) A balloon has been inflated within the ICA distal to the stenosis in preparation for stenting. The balloon serves as a cerebral protection device *{arrow).*

Continued

small enough to pass through the pores of the filter (<100 jam) or generated postprocedurally at the stented segment.

Other common complications of carotid stenting/ angioplasty include bradycardia and hypotension that can be prevented by applying slow inflation and lower pressures during percutaneous transluminal angioplasty (PTA) (Wakhloo et al., unpublished data).

Atropine (0.6-1.0 mg intravenously [IV]) and dopamine are rarely necessary to treat these complications yet are options if the need arises. Generally, vasospasm during catheterization, PTA, or stenting does not require any treatment because of its spontaneous resolution, although infrequently papaverine, mannitol, or sodium nitroprusside (Nipnde) may he used. Arterial dissection during catheter manipulation, PTA, or stenting may require extensive stenting to avoid vessel occlusion. After stenting, patients arc kept for 24 hours in a critical care or step-down unit before discharge. Special attention should be paid to hypotension and hypertension, renal function, the access site, and new neurological symptoms, including headaches, which can be related to hyperperfusion of the previously relatively ischemic distal vascular territory or cerebral hemorrhage. Patients should ambulate the next day and resume normal activities. Clinical follow-ups are recommended at 1 month, 3 months, *6* months, and 1 year, Patients should be carefully monitored for groin hematoma, fever, and neurological symptoms (e.g., amaurosis fugax, headaches, aphasia, and sensory or motor impairment). Doppler ultrasound to monitor restenosis is recommended at 6 months and 1 year.

Patients are put on clopidogrcl bisulfate (Plavix) at 75 mg per day orally and aspirin at 325 mg per day orally for 6" weeks after stenting. After 6 weeks, patients are instructed to take only aspirin at 81 mg per day orally for life,

In conclusion, carotid stenting with cerebral protection is safer than carotid surgery in symptomatic patients and in

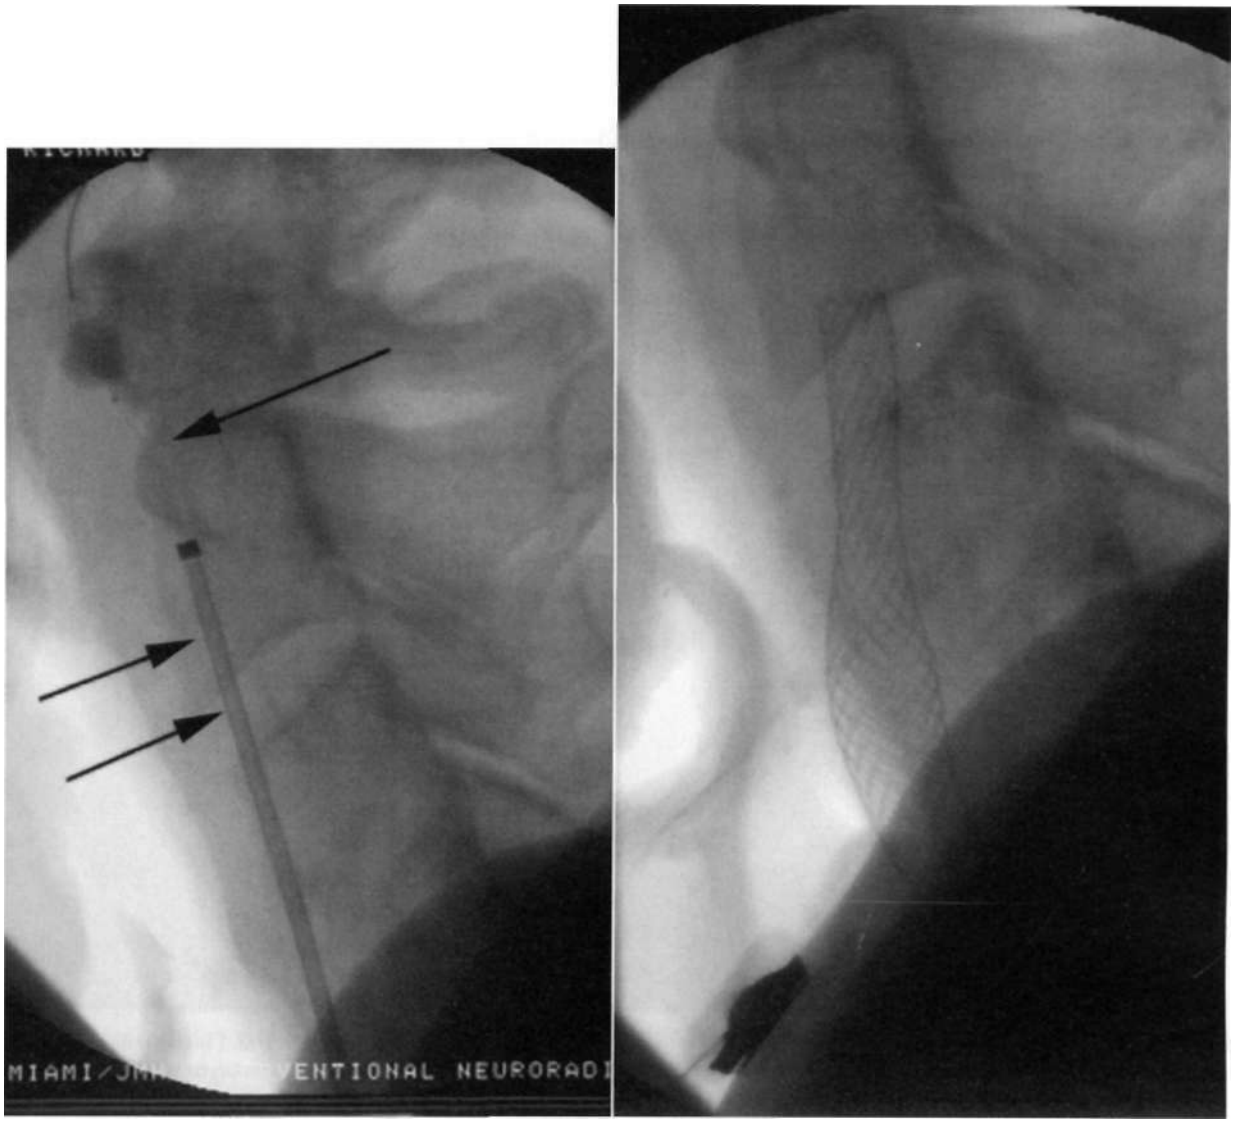

FIGURE 53.2, cont'd. (C) The stent delivery system (double arrows) is placed over the balloon wire *(arrow)* and positioned over the plaque while the balloon remains inflated. (D) Placement of a self-expanding stent. Before the delivery system is removed and the balloon is deflated, 50-60 mL of hlood is aspirated through the guide catheter to remove the potentially accumulated emboli. surgical high-risk symptomatic and asymptomatic patients. Surgical high-risk patients can be classified into those with anatomical factors that increase the risk of surgery and those with medical conditions that increase the risk of surgery (Tables 53.2 and 53.3). The exclusion criteria for stenting are listed in Table 53.4. In asymptomatic patients, stenting using a cerebral protection device is still associated with slightly higher morbidity than carotid surgery but may be used in selected patients.

Stenting in the United States remains an investigational procedure, but approval from the Food and Drug Administration (FDA) is expected in 2003. Carotid artery stenting will most likely grow safer, with fewer complications, as biomedical technology advances with new materials and devices that overcome current limitations. These include dedicated carotid stenting equipment with low-profile stent delivery systems and a variety of stent designs, better access sheaths, special balloons, and wires. MRI will also play a major role in the characterization of plaques, and more sophisticated interventional MRI will overcome current spatial and temporal resolution limitations. Various cerebral protective devices are being optimized to decrease the incidence of embolic events. Drug-coated stents will also play a role in carotid stent development.

Intracranial Stenting

Intracranial arterial stenosis plays a major role in cerebral ischemic disease and accounts for approximately 50,000-70,000 strokes per year (Chimowitz et al. 1995).

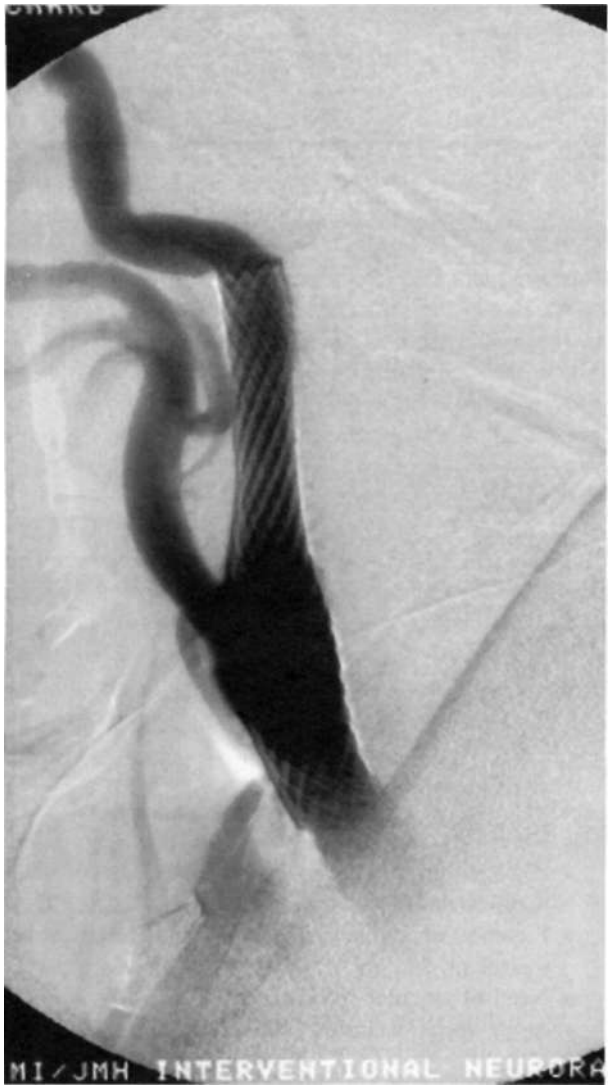

FIGURE 5 3.2, cont'd, (E) Control angiography shows stent placement and complete revascularization of the ICA.

The clinical impact of intracranial atherosclerosis is not yet fully understood, but reports have revealed that anywhere from 5-29% of all ischemic strokes are attributable to this disease (Hass et al. 1 968; Craig et al. 1982; Marzewski et al. 1982; Bogousslavsky and Regli 1983; Wechsler et al. 1986; Gorelick 1993; Chimowitz et al. 1995; Sacco et ai. 1995; Wityk et al. 1996; Akins et al. 1998; Connors and Wojak 1999; Thijs and Albets 2000; Lylyk et al. 2002). Previous studies have also reported an incidence of intracranial stenosis in 5-23% of all angiograms performed on stroke patients (Hass et al. 1968; Borozan et al. 1984; Keagy et al. 1986). Stenosis greater than 50% is considered hemodynamically and clinically significant.

Most patients with intracranial stenosis present with a stroke without the typical warnings of TIAs. The prognosis is even more ominous for patients with certain intracranial stenotic lesions, with mortality rates of 50% fot patients with an intracranial ICA stenosis (Matzewski et al. 1982). The distribution of intracranial stenosis is as follows: ICA 49%, middle cerebral artery (MCA) 20%, posterior cerebral artery (PCA) 11%, vertebrobasilar circulation (VB) 11%, and anterior cerebral artery (ACA) 9% (Akins etal. 1998).

Stroke associated with a stenosis of the MCA has been reported to occur at a rate of 8% per year (Bogousslavsky et al. 1986; EC/IC Bypass Study Group 1985). Other studies have reported an annual stroke rate of 4-12% per year for the anterior circulation and 2.5-15% per year for rhe posterior circulation (Craig et al. 1982; Marzewski et al. 1982; Botozan 1984; EC/IC Bypass Study Group 1985; Bogousslavsky et al. 1986; Wechsler et al. 1986; Thijs and Albers 2000).

Previous treatment modalities for inttactanial stenosis have been limited. The Watfarin Aspirin Symptomatic Intracranial Disease (WASID) study suggested that patients with vertebral, basilat, and posterior cerebral or posterior inferior cerebellar artery stenosis who were treated medically had annual stroke rates of 7.8%, 10.7%, and

Tabic 53.2: Anatomical high-risk population for surgery

Surgically inaccessible lesion above C2 or below the clavicle
Previous head or neck radiation therapy
Previous surgery [hat included the area of stenosis/repair
Previous ipsilateral neck dissection for cancer surgery
Spinal immobility of the neck resulting from cervical disorders
Restenosis after previous or unsuccessful carotid endarterectomy
Presence of recurrent laryngeal nerve palsy
Presence of tracheotomy
Contralateral total occlusion of the carotid artery
Tandem lesions (e.g., internal carotid artery stenosis at its origin and at the siphon)

Table 533: Medical high-risk population for surgery-

Congestive heart failure (New York Heart Association classification III/IV)
Unstable angina (Canadian Cardiovascular Society classification III/IV)
Pre-coronary artery bypass graft or valve-replacement procedure
Chronic obstructive pulinonarj disease :forced etpirarorv volume <30%)
Left ventricular ejection fraction <30%
Age older than 79 years
Recent myocardial infarction
Two or more coronary arteries with more than 70% stenosis

Table 53.4: Exclusion criteria for carotid artery stenting

Patients with bleeding disofdeis that preclude antiplatelet medication
Allergy to antiplatelet medication
Positive blood cultures/sepsis
[riiiiiimotompromised stare
Recent history of intracranial hemorrhage
Acute large middle cerebral artery stroke (<4-6-week-old infatct) fresh clot within the stenosis

6.0%, respectively (Chimowitz et al. 1995). The stroke rates in patients with carotid siphon or MCA stenosis who were medically treated were 8% and 10% (EC/IC Bypass Study Group 1985; Bogousslavsky et al. 1986). This indicates the need for more effective primary treatment of intracranial atherosclerosis. In the initial WASID study that recruited 151 patients, over a follow-up period of less than 2 years, the rates of stroke were 10.4 per 100 patient-years for those taking aspirin and 3.6 per 100 patient-years for those taking warfarin (Chimowitz et al. 1995). The National Institutes of Health is currently funding a larger study with more than 800 patients.

Extracranial-intracranial (EC-IC) bypass surgery that uses the superficial temporal artery to MCA anastomosis was once thought to offer an alternative treatment for patients with intracranial atherosclerosis. However, the EC/IC Bypass Study revealed that surgery did not reduce the risk of stroke compared with medical therapy (aspirin) (EC/IC Bypass Study Group 1985).

Atherosclerosis is the most common cause of intracranial arterial stenoses. Other etiologies of intracranial stenoses and occlusions include arteritis, radiation changes, drug abuse (methamphetamine and cocaine), vasospasm following subarachnoid hemorrhage (SAH), arterial dissection, sickle cell disease, neurofibromatosis, Menkes' kinky hair syndrome, idiopathic progressive arteriopathy of childhood, and metabolic disorders (e.g., homocystinuria). High-grade stenosis or occlusion of the supraclinoid ICA and Ml and Al segments may result in a pseudoangiomarous angiographic appearance of multiple lenticulostriate, thalamoperforating, choroidal, and leptomeningeal collateral vessels providing collateral flow to M2 and A2 branches. The term *moyatnaya* (Japanese for *puff of smoke)* syndrome is applied to this angiographic pattern.

PTA for intracranial stenosis was first attempted in the early 1980s (Sundt et al. 1980) but was later abandoned because of complications that included dissection, recoil, vasospasm, platelet aggregation, and acute occlusion. These high rates of morbidity and mortality continued until the mid-1990s (Higashida et al. 1993; Takis et al. 1997). Stenting and angioplasty have been limited by stroke from distal embolization, arterial dissection, arterial rupture (Purdy et al. 1990; Clark et al. 1995; Al-Mubarak et al. 1998), and acute vessel occlusion secondary to platelet aggregation (Clark et al. 1995; Takis et al. 1997).

Analogous to the development in occlusive disease of the extracranial carotid artery, primary stenting may replace angioplasty for the treatment of intracranial arterial stenosis. The downfall of angioplasty has been the lack of appropriate devices (Mori et al. 2000}. Recent advances in biotechnology, imaging, coagulativc and platelet pharmacotherapy, and catheter technology have addressed previous limitations of treating intracranial stenosis. Many cases of successful angioplasty have been reported (Honda et al. 1994; Clark et al. 1995; Connors and Wojak 1999; Marks ct al. 1999}.

Low-profile, more flexible, and highly trackable stents are capable of reaching and treating small distal tortuous arterial segments (Clark et al. 1995; Feldman et al. 1996; Callahan and Berger 1997; Al-Mubarak et al. 1998; Kellogg et al. 1998; Horowitz et al. 1999; Lanzino et al, 1999; Malek et al. 1999; Morris et al. 1999; Mori et al. 2000; Phatouros et al. 2000; Koenigsberg et al. 2000; Gomez and Orr 2001; Lylyk et al. 2002). Results have suggested its safety and efficacy.

We have our own experience in 30 patients with intracranial stenting (N = 25) and angioplasty (N = 5). The procedure-related major and minor complications were 6%, with no deaths (Wakhloo et al. 2003). Out of 13 patients studied angiographically approximately 12 months after the procedure, we have seen in-stent stenosis in one patient only.

Indications. Patients who are selected for intracranial stenting and angioplasty are generally refractory to optimal medical management. Inclusion criteria are as follows:

- Patients with greater than 50% stenosis of a major intracranial vessel (minimum vessel diameter of 2.5 mm)
- Previous stroke
- TIA
- Neurological symptoms referable to the target lesion
- High-grade stenosis or total occlusion of another major artery
- Presence of symptoms during the 6 months before treatment
- Need of vascular reconstruction
- Acute vessel occlusion or dissection after PTA

Common exclusion criteria are as follows;

- Severe neurological deficit from stroke
- Chronic total occlusion
- History of intracranial hemorrhage, hemorrhagic stroke, major stroke, or any stroke with mass effect within 6 weeks of procedure

The FDA has not approved any of the existing stents for use in the intracranial vascular system. Several stents are being investigated in feasibility studies for the treatment of intracranial aneurysms and intracranial atherosclerotic occlusive disease.

The technical success with intracranial stent ing/angioplasty is high. Connors and Wojak (1999) reported greater than 90% successful revascularization with PTA. The restenosis rate at 6 months was less than 10% in 44 patients and approximately 30% after 24-36 months. The complication rate of dissection, stroke, TIA, and other like conditions was between 10% and 15% (Connors and Wojak 1999).

In another scries of 10 patients with 12 intracranial stenotic lesions, the use of flexible balloon-expandable

coronary stents was attempted. Ten lesions in eight patients were treated; navigation difficulties prevented treatment of the other two. The mean pretreatment stenosis was 80% and decreased to 7% immediately after stenting. Three months later, the average stenosis was 19%. There were no reports of TIA, stroke, or orher morbidity or mortality during the mean follow-up period of 11 months (Mori et al. 2000).

In a series of patients with symptomatic intracranial stenosis or dissection, I.ylyk ct al. {2002) stented 34 lesions with a mean stenosis of 75%. The average stenosis was 30% after treatment. The peri procedural morbidity was 12%, and one patient died from hemorrhagic transformation of the stroke after reperfusion (Lylyk et al. 2002).

In summary, intracranial stenting provides a basis for treating the diseased arterial segment through stabilization of the local flow dynamics and biomechanics of the vascular wall. It serves as a matrix for new endothelial growth. Current medical treatment of atherosclerotic disease might prevent TIA or stroke but does not have significant reparative capability for the diseased vascular segments (Figure 53.3).

Further refinement of intracranial stents may be drug-eluting stents, covered stents, and stents with a lower profile and higher flexibility. Currently used neurostents are MRI compatible; therefore iteming docs not preclude an MRI investigation of the brain or even possibly an intraluminal evaluation of the stented arterial segment. The obliteration of perforators is a commonly perceived limitation of intracranial stenting. However, the fate of the "jailed" side branches depends on the fraction of the ostium surface area that is covered by the stent struts. In canine and rabbit models, these branches remain patent if less than 50% of the ostial diameter is covered by the stent (Wakhloo et al. 1995; Masuo et al. 2002). Recently, a report on a wide-necked persistent trigeminal artery aneurysm treated with stent-assisted coiling, wherein the trigeminal artery was "jailed," showed that the trigeminal

Continued

artery remained patent after 2 years, with no evidence of embolic stroke in its vascular distribution (Mohammed, Sandhu, and Wakhloo. 2002). Moreover, there have been multiple cases of the endovascular treatment of basilar trunk aneurysms and stenoses using stents {Horowitz et al. 1999; Lanzino et al. 1999) with favorable outcomes.

Acute Treatment

The development of several treatment options for acute stroke has changed the historical perception that stroke was untreatablc into the realization that stroke is a medical emergency with potential treatments. The time-sensitive window of opportunity for the treatment of stroke is due to the characteristics of the ischemic penumbra. Neuronal function is affected in two stages during ischemia. Neuronal electrical function is lost when the blood flow falls below a critical threshold of approximately 20 ml. of blood per 100 g of brain tissue per minute (normal = 50 mL of blood per 100 g of brain tissue per minute). At this level, brain tissue is thought to be revivablc, with the potential to reverse ischemic damage. However, irreversible damage occurs when blood flow falls below 10 mL of blood per 100 g of brain tissue per minute. Inefficient anaerobic metabolism of glucose commences, which rapidly leads to lactic acidosis and failure of the normal energy-dependent cellular ion homeostasis. Potassium leaves the cell, and sodium and water enter the cell and lead to cytotoxic edema. Calcium also entets the cell and sets a cascade of molecular events into motion that eventually leads to neuronal death, hence the urgency to treat the patient with acute stroke.

The treatment goals of acute thromboembolic stroke are to diagnose early, initiate rapid thrombolysis and treatment, restore normal cerebral blood flow (CBF), prevent iatrogenic hemorrhagic events, and thus to preserve human life and function. We discuss neurointerventional procedures for acute stroke that consist of IA administration of thrombolytics, mechanical thrombectomy, hypothermic devices, and future potential therapies.

Thrombolysis

Thrombolytic therapy has been proposed as a potential stroke therapy for many years. The first randomised trial was conducted in 1963 but was inconclusive.

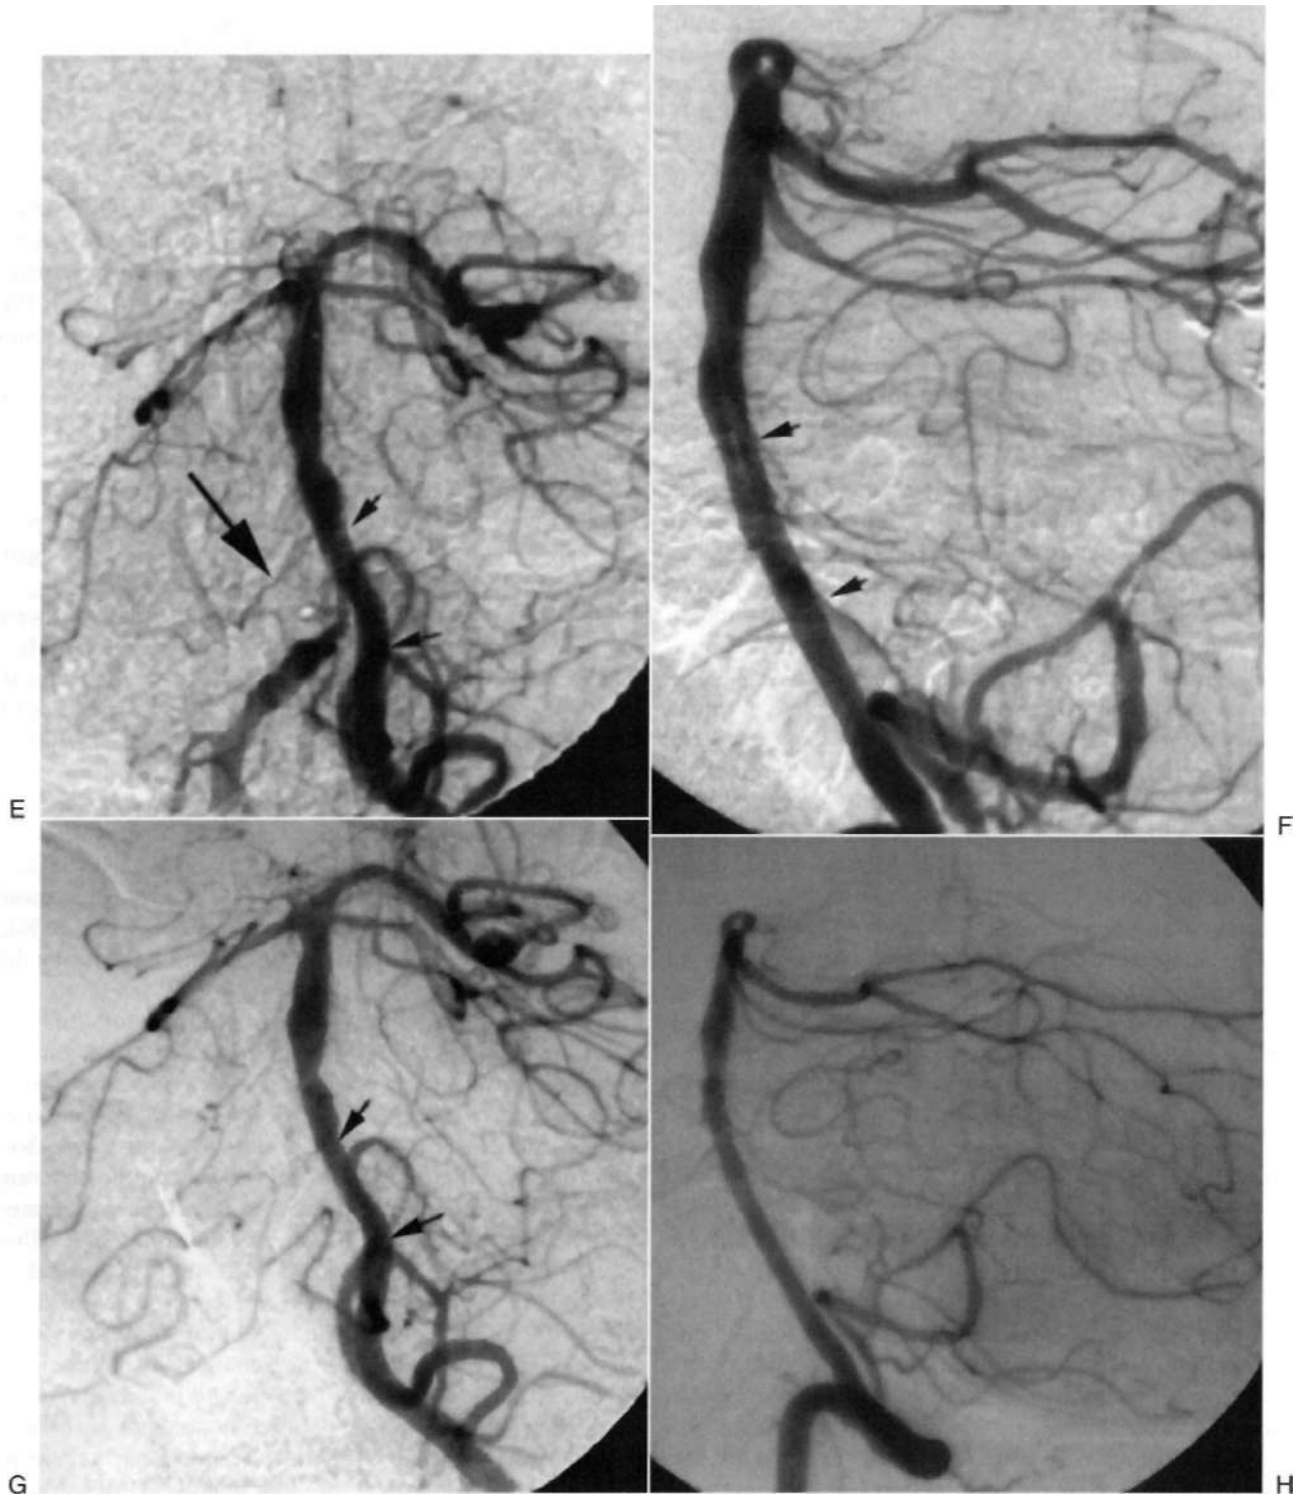

FIGURE 53.3, cont'd. (E, F) Control angiography after stent placement reveals improved flow of contrast in the left vertebral artery and basilar arteries. Note that the right anterior inferior cerebellar artery *{arrow)* remains parent after being "jailed" by the struts of the stent. The right distal vertebtal artery was not treated. (G, H) No evidence of in-stent stenosis seen on the 14-monrh follow-up angiography.

Six randomized studies were conducted from then until 1992 but were again inconclusive because of small numbers of patients, wide range of symptoms, and diversity of medications used (tissue plasminogen activator [t-PA], urokinase, streptokinase, fibrinolysin). In 1993, the PDA approved the use of IV t-PA, which is currently the only FDA approved therapy for stroke. Zcumer, Hacke, and Ringelstcin (1983) first proposed IA thrombolysis in 1983.

Neuroprotection. Hyperacute treatment has mainly focused on thrombolysis. However, neuroprotective agents have been shown to be effective in animal models. Agents considered include calcium-channel antagonists, N-methyl-D-aspartate (NMDA) antagonists, AMPA antagonists, y-aminobutyric agonists, lubeluzole, statins, antibodies to adhesion molecules, inhibitors of cytokines, and free radical scavengers (Fisher and Schacbitz 2000). However, they have not been shown to be effective in clinical trials. These trials have had problems of insufficient statistical power, excessive time delay in starting therapy (>2 hours}, inadequate dosing, and poor patient selection. Unfortunately, animal models have not correlated well with clinical realities, and neuroprotective agents have not been effective because of the very limited time window to block the calcium influx cascade. Nevertheless, promise remains for neuroprotection. Citicoline is a choline precursor that forms phosphatidylcholine, an important neuronal membrane lipid. Meta-analyses have revealed its potential use in small human trials. (Saver and Wiltcrdink 2002; Warach, Harnett, and the Citicoline 010 and 018 Investigators 2002). Another study has determined the feasibility of emergency paramedics administering magnesium in the field to combat delay in using neuroprotection (Saver et al. 2002). Hypothermia can also be applied as a form of neuroprotection, and many new devices have been developed specifically for this purpose.

Intravenous and Intra-Arterial Thrombolysis. A brief overview of the basic concepts of thrombolysis should precede the discussion of thrombolytic therapy. A balance of the coagulation and fibrinolytic systems is maintained through several mechanisms that may be altered in the treatment of acute stroke. Thrombus formation and thrombolysis are on opposite ends of the spectrum. This homeostasis maintains a balance in between thrombosis and hemorrhage. Fibrin and plasmin play key roles in this balance. Thrombin is also important to link platelet aggregation and coagulation and intrinsic and extrinsic pathways. It is sensitive to outside factors such as flow and is used in feedback control of fibrinolysis. Fibrinogen is cleaved into fibrin in the presence of thrombin.

Plasmin is key to thrombus dissolution. It acts on fibrinogen and fibrin in plasma, works on reactive surfaces (thrombi and cells), and mediates the proteolytic cleavage of matrix ligands. Plasminogen is converted into plasmin through the presence of t-PA, which is an endogenous plasminogen activator that is secreted from endothelium and other cells. It has fibrin and thrombus specificity'. Recombinant t-PA (rt-PA) is used as an exogenous source that has increased clot specificity and involves different mechanisms of action. It also affects platelet function and aggregation. There are novel forms of rt-PA with genetic-alterations to its half-life, specificity, and lower binding to plasminogen activator inhibitors. Genetically engineered rt-PA has advanced the treatment of stroke with pharma-cotherapy. Genetically altered derivatives of native t-PA include tenecteplase, which has three amino acid substitutions that have increased resistance to plasminogen activator inhibitor-1 (PAI-1). Tenecteplase has increased fibrin binding and decreased plasma clearance. It binds to fibrin and converts plasminogen to plasmin (Keyt et al. 1994). Other promising agents include *Dcsmodus rotundus* salivary plasminogen activators (DSPAs) from the vampire bat saliva that is selective for fibrin-bound plasminogen (Figure 53.4).

Platelet glycoprotein Ilb/IIla receptor blockers have been used in acute myocardial infarction. Preliminary studies have revealed a potential to increase the 3-hour treatment window in acute stroke using Ilb/IIla receptor blockers to block platelet aggregation (Bogousslavsky et al. 2001). Twenty-four patients were treated with combined IV lib/Ilia receptor blocker (cptifibatide) and IA t-PA. Patients were compared with historical controls treated with IA t-PA alone. The combined treatment patients had higher recanalization rates (58% vs. 31%) and better good outcome rates (Rankin Scale score 0-2, 38% vs. 27%), with no increase in hemorrhagic complications (McDonald et al. 2002).

The FDA approved thrombolytic treatment for stroke in 1996 after the IV t-PA trial sponsored by the National Institutes for Neurological Disorders and Stroke (NINDS) was published in 1995. The NINDS trial using IV t-PA was a multicenter, randomized, double-blinded, placebo-controlled study of 624 patients. Patients enrolled had an acute ischemic stroke, with clearly defined time of onset and measurable deficit on National Institutes of Health Stroke Scale (NIHSS) (Table 53.5). All patients had a baseline CT with no evidence of intracerebral hemorrhage (ICH). IV t-PA was given within 3 hours at a dose of 0.9 mg/kg. Treated patients were 30% more likely to have little or no neurological disability (3, 6, and 12 months). Treated patients were less likely to be severely disabled or to have died when compared with the placebo group at 1-ycar follow-up.

The Prolyse in Acute Cerebral Thromboembolism (PROACT I) was a double-blinded, placebo-controlled, centralized, randomized trial of IA thrombolysis in patients within 6 hours of onset of symptoms suggestive of MCA occlusion. It was the first trial to compare the safety, recanalization frequency, and clinical efficacy of direct IA infusion of recombinant prourokinase (rpro-UK) with placebo (del Zoppo et al. 1998). Forty patients were treated

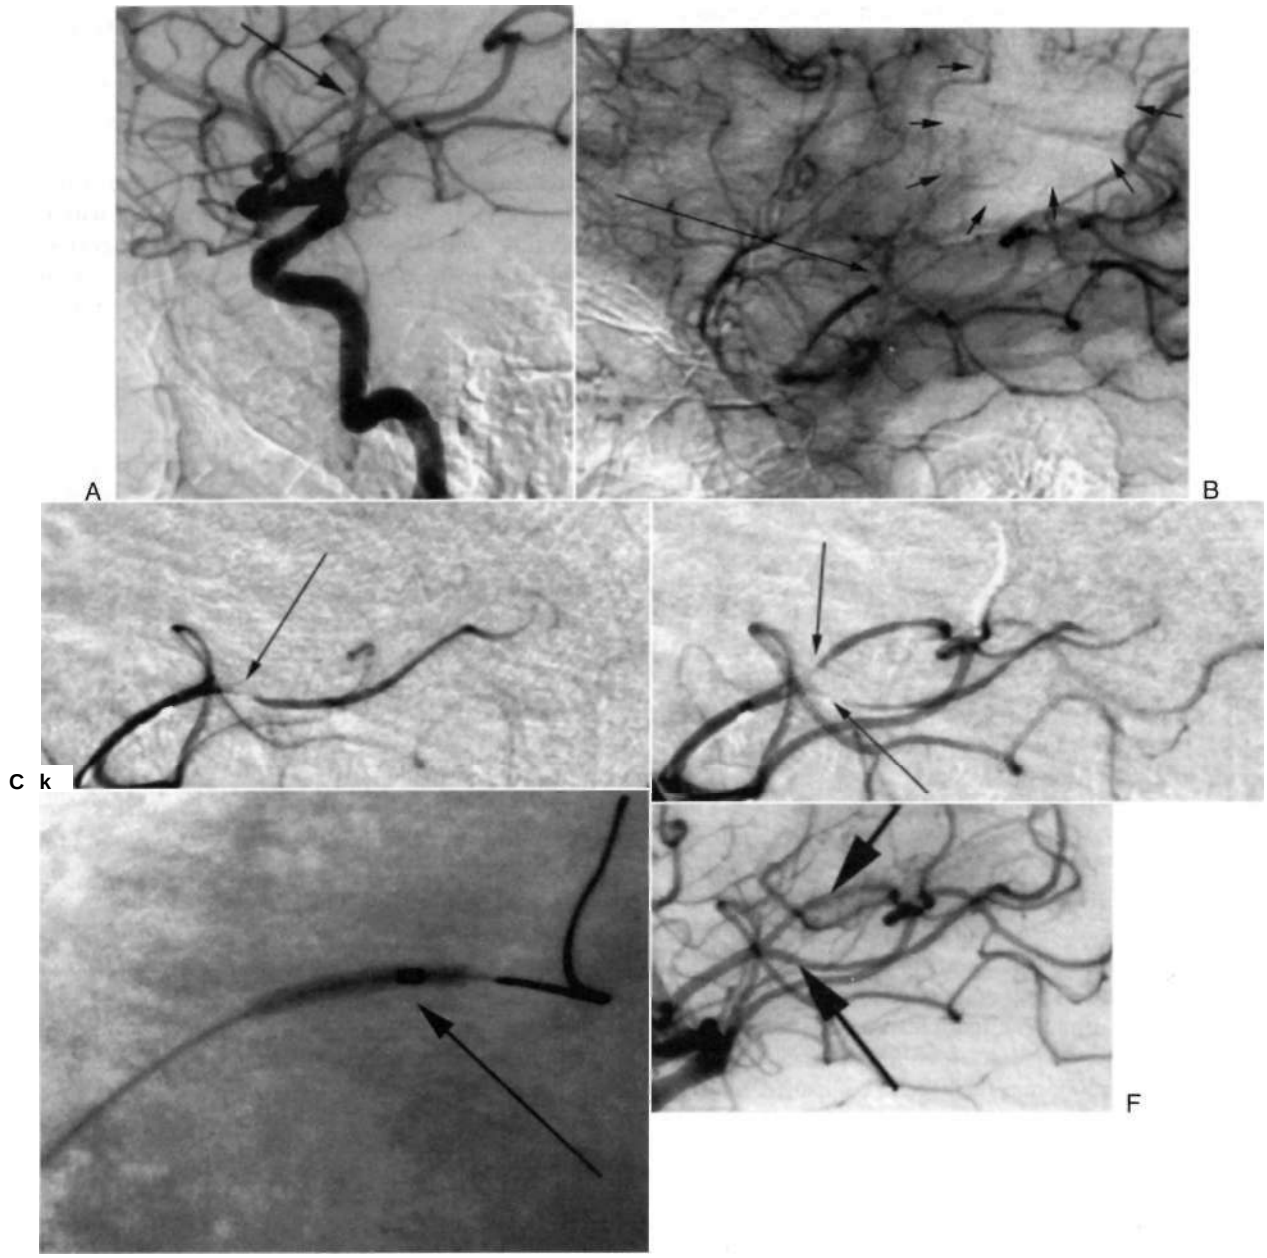

FIGURE 53.4 (A) An acute left angular artery thromboembolic occlusion *{arrow)* in a patient with a National Institutes of Health (NIH) Stroke Scale score of 12 was treated with intra-artcrial tissue plasminogen activator (t-PA). (B) Late arterial phase shows a large area of hypoperfusion *{arrows).* (C, D) Partial recanalization of superior and inferior divisions after a bolus of inrra-arterial local 5 mg of t-PA and an infusion of 10 mg over 1 hour. (E) Mechanical revascularization with a 1.5-mm balloon catheter of upper and lower branches. (F) Immediate recanalization of the entire angular artery occurred after percutaneous transluminal angioplasty. The patient improved neurologically within a few hours and had an NIH Stroke Scale score of less than 5.

with rpro-UK (« = 26) or placebo *(n* = 14) at a mean of *5.5* hours after the onset of symptoms. Recanalization was significantly associated with rpro-UK. Hemorrhagic transformation that caused neurological deterioration was no different between the two groups at 24 hours and 90 days.

The PROACT II study was undertaken to determine the clinical efficacy and safety of IA rpro-UK therapy in patients with acute stroke less than 6 hours in duration caused by MCA occlusion. PROACT II was a multiccntcr, randomized, and controlled, open-label clinical trial with blinded follow-up. Patients received either *9* mg of IA rpro-UK with heparin *{n* = 121) or heparin alone (w = 59). In the primary outcome analysis, 40% of treated patients and 25% of control patients had a modified Rankin Scale score of 2 or less at 90 days *[p* = .04), The pro-UK group had a mortality rate of 25%, and the control group had a mortality rate of 27%. The recanalization rate in the

pro-UK group was *66%* and only 18% in the control group *(p* < 0.001). Intracranial hemorrhage at 24 hours was observed in 10% of the pro-UK group and only 2% of the control patients *(/>* = .06). The investigators concluded that IA rpro-UK significantly improved clinical outcomes at 90 days, despite increased frequency of early symptomatic intracranial hemorrhage (Furlan et al. 1999).

The Emergency Managemenr of Stroke (EMS) Bridging Trial was a pilot study that suggested combined IV and IA therapies are feasible and safe and lead to higher rates of recanalization. The feasibility, safety, and efficacy of combined IV rt-PA and IA rt-PA were evaluated in this multicenter, randomized, placebo-controlled, double-blinded trial (Lcwandowski et al. 1999}. Thirty-five patients were enrolled, with eighteen in the IV/IA group and seventeen in the placebo/IA group. Outcomes were measured by the Barthel Index, NIHSS, and modified Rankin Scale. There were no significant differences in outcomes between the two groups at 7 days, 10 days, and 3 months. Recanalization was better in the IV/IA group with statistical significance. It was determined that IV/IA rt-PA was feasible to use and had better recanalization rates. However, the combined therapy did not reveal improved clinical outcomes. There was not a statistically significant difference in the rate of symptomatic ICH between the two groups.

In a study to determine the safety and efficacy of local IA thrombolysis with urokinase, Arnold et al. (2002) followed 100 consecutive patients with stroke caused by MCA occlusion. They found that the median NIHSS was 14 on admission. Excellent or good outcomes, a modified Rankin Scale score of 2 or less, were found in 59% of patients with an Ml or M2 occlusion and 95% of patients with an M3 or M4 occlusion. Fifty-six percent of patients had a recanalization score (Thrombolysis in Myocardial Infarction [TIMI1 score) of 2, and twenty percent had a score of 3 (complete recanalization). They concluded that local IA thrombolysis with urokinase can be safe and efficacious (Arnold et al. 2002).

As the randomized NINDS trial showed the beneficial effect of IV given t-PA in patients who present within the 3-hour time window for treatment, in most centers IA thrombolysis is frequently reserved for patients presenting with symptoms 3-6 hours after the onset of the ictus. For the IA use of thrombolytics, a superselectivc positioning of a microcathetcr adjacent to the clot is recommended. The endovascular approach allows fibrinolytic agents to be infused ptoximally, disrally, and within clots in main cerebral arteries. A higher local concentration of fibrinolytic agents is achieved, thus reducing systemic exposure to thrombolytics. In addition, a mechanical disruption of the clot with the microwirc and catheter can be accomplished. The collateral blood supply and the vascular system distal to the occluded atca can be visualized simultaneously, and a sense for the degree of recanalization gained (Saver 2001). IA thrombolysis has provided better early recanalization rates (60-80%) than IV therapy (20-60%) (del Zoppo 1997; Jahan et al. 1999; Saver 2001). Recanalization is graded according to the TIMI grade (T1M1 Study Group 1985). Grade 0 no recanalization; grade 1 minimal recanalization; grade 2 partial recanalization; and grade 3 complete recanalization. Modified Rankin Scale scores, Barthel indices, and NIHSS may all be used to assess patient outcomes over follow-up periods. Inclusion and exclusion criteria for IA thrombolysis are listed in Tables 53.6 and 53.7.

Conventional IV or IA chemical thrombolysis is time consuming, with a significant risk of hemorrhagic transformation of ischemic strokes.

Mechanical thrombolysis may afford more rapid and complete relief of cerebral ischemia, with decreased hemorrhagic transformation. Devices for revascularization in acute stroke have the potential risks of producing showers of distal emboli, vessel perforation, and damage to vessel walls with secondary platelet aggregation. Other strategies that may play a larger role in the future include various devices to remove clots, such as laser energy,

Table 53.6: Acute stroke intra-arterial thrombolysis inclusion criteria

Clinical diagnosis of ischemic stroke
Computed tomographic exclusion of hemorrhagic stroke
Four-vessel angiography that reveals vessel occlusion that correlates to clinical stroke
Significant long-term neurological deficit can be expected without treatment
lime from symptoms to intervention is less than 6 hours
No contraindications {laboratory findings) against the use of thrombolytics

Tabic 53.7: Acute stroke mtra-arterial thrombolysis exclusion criteria

Mild symptoms (deficits that are quickly resolving)
Sustained hypertension of > 180/100 mm Hg
Hemorrhage on computed tomography or magnetic resonance imaging
Known vascular malformation or tumor
Recent history of stroke, trauma, or surgery

ultrasound, photo acoustic laser energy, rheolytic thrombectomy, clot retticvers (including snarclikc devices, excision and aspiration), and suction thrombectomy.

Cathetet-hascd methodologies include hypothermia for neuroprotection, with heat exchangers placed in the inferior vena cava and systems that provide controlled induction, maintenance, and reversal of hypothermia. Other devices provide increased cerebral perfusion with intra-aortic balloons, hyperoxygenated perfusion using fluorocarbon and othct major oxygen carriers. Functional recovery of stroke includes rehabilitation with physical, occupational, and speech therapy. Stem cell research is ongoing with human bone matrow stem cell gtafting and neuronal growth hormones to replace neuronal loss.

It is apparent the histotical perspective on the treatment of acute sttoke has dramatically changed over the last decade and will continue to expand with neuroendovascular technologies. National analysis was reported by Nilasena and coworkers (Nilasena et al. 2002) from the National Stroke Project of the U.S. Centers for Medicare and Medicaid Service. They analyzed 14,295 inpatient Medicare medical records from a national sample of patients with acute stroke who were treated between April 1998 and March 1999. Fibrinolytic therapy was employed in only 1,7% of patients. In a study of Cleveland hospitals, only 1.8% of patients received IV t-PA (Kat/an et al. 2000). Furthermore, the 5-year recurrence rate for stroke has been reported anywhere from 24-42% (Sacco et al. 1982, 1994; Petty et al. 1998; Stapf and Mohr 2002). The etiology of the stroke must be addressed to minimize the risk of an additional stroke.

Vasospasm

Vasospasm associated with SAH accounts for major morbidity and mortality in approximately 20% of patients who initially survive an aneurysm rupture. It is considered one of the most preventable types of ischemic brain injury by prevention care and newer interventional techniques. It typically presents within 3-14 days after the initial hemorrhage and is usually greatest in severity at 7 days posthemorrhage. It can result in extensive cerebral and brainstem infarction and death. The etiology of cetebral vasospasm is directly related to the rupture of an aneurysm and hemosiderin products. However, a cascade of events results in a decrease in CBF. The events are likely related to the disturbed balance between vasoconstriction (mediated by endorhclin-1) and vasodilatation (mediated by NO), but have not been clearly elucidated. Compensatory mechanisms of autoregulation, collateral flow, and increased oxygen extraction eventually become exhausted and ischemic neurological damage ensues. The potential end result of prolonged vasospasm is cerebral infarction. Smooth muscle cells in the arterial wall undergo sustained contraction between 4 and 14 days (peak 7 days) after the initial hemorrhagic event. Subsequently, collagen is deposited in the adventiria and there is thickening of the intima, which may last for several weeks (Chan et al. 1995). Cerebral vasospasm has been reported to occur in 60-80% of all patients with SAH. Almost 30% of patients are thought to have symptomatic manifestations (Heros, Zervas, and Varsos 1983; Kassell et al. 1985, 1990; Srinivasan et al. 2002).

Patients with vasospasm may present with symptoms, and transcranial Doppler studies may reliably determine vasospasm at the patient's bedside in a noninvasive fashion, Conventional angiography is the gold standard for determining vasospasm. Several other studies have been proposed to evaluate regional CBF that include single-photon emission CT (SPECT), positron emission tomography (PET), xenon CT scan, and radioactive xenon clearance.

Prevention of vasospasm is attempted through maintaining normovolemia, normothermia, and normal oxygenarion. Volume contraction can predispose patients to vasospasm; hence, careful monitoring of fluid status is paramount.

Prophylactically, an oral calcium-channel blocker, nimodipiue, is given for 21 days following SAH to prevent vasospasm (Allen et al. 1983; Pickard et al. 1989). Other preventive modalities being investigated include thrombolytic therapy via intracisternal injections, aspiration and irrigation at time of craniotomy, intraoperative sodium chloride lavage, and early ventriculostomy to control intracranial pressure (Newton, Krawczyk, and Lavine 2002).

When patients become symptomatic and vasospasm is suspected as the culprit, hypertensive, hypervolemic, and /jemodilution (triple H) therapy is most commonly administered, However, symptoms may coincide with rebleeding or hemorrhage and should be distinguished with head CT. The role of endovascular approaches to the treatment of vasospasm becomes foremost in the case of failure of conventional therapies. In patients at risk for pulmonary edema, myocardial infarction, or other medical risk factors preventing triple-H therapy, endovascular techniques including mechanical and/or pharmacological treatment options should be initiated.

Mechanical Therapies. Balloon angioplasty has been shown to be effective in the treatment of vasospasm secondary to SAH. Zubkov, Nikiforov, and Shustin

(1984) first described this technique in 1984, As with other treatment options in the endovascular field, advances in balloon, catheter, microcatheter, and imaging technologies have expanded the application, efficacy, and safety of this technique over the course of the last several years **(Figure** 53.5).

Before treatment, a CT scan should be obtained to rule out hemorrhage or large infarct that could potentially be enhanced through repcrfusion. Intracranial pressure and arterial blood pressure are monitored throughout the procedure. Balloon angioplasty is performed with a low-pressure (2 atm), soft, compliant silicon microballoon. Angioplasty has been shown to have long-lasting effects, possibly due to stretched and torn collagen fibers (Yamamoro, Smith, and Klag 1992), rupture of the internal elastic lamina, and stretched smooth muscle fibers (Chan et al. 1995; Srinivasan et al. 2002). Many investigators have reported improved clinical outcomes after mechanical angioplasty for vasospasm (Higashida et al. 1989; Newell et al. 1989; Eskridge et al. 1990; McDougall et al. 1997; Maybcrg 1998). Transluminal balloon angioplasty has been shown to improve neurological outcomes in 60-70% of treated patients (Eskridge et al. 1998; Rosenwasser et al. 1999). Furthermore, complete vessel revascularization is

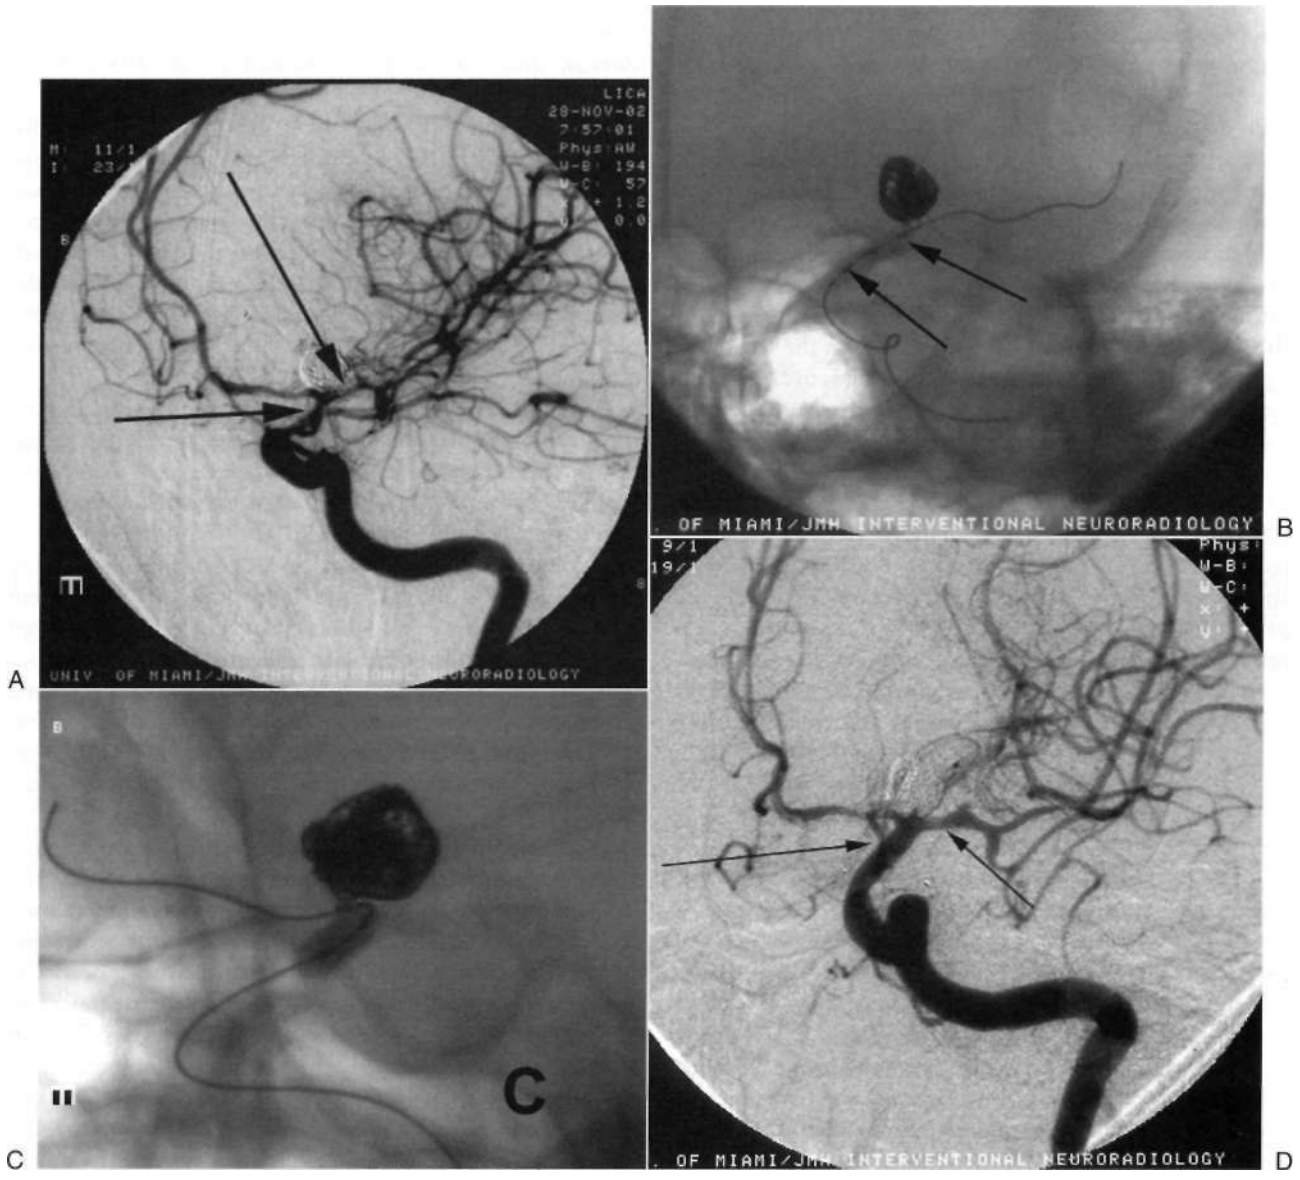

FIGURE 53.5 (A) Right hemiparcsis and aphasia associated with moderate to severe vasospasm of the CI and C2 segments of the internal carotid artery (ICA), and the Ml segment of the middle cerebral artery (MCA), and Al segment of the anterior ccrchral artery after coiling of a ruptured ICA terminus aneurysm *{arrows). {Arrows* in [A| reveal the extent of spasm. Note the decreased caliber of the ICA.) (B, C) Balloon angioplasty of the distal ICA and the Ml segment *(arrows).* (D) Improved distal perfusion after angioplasty of the ICA and Ml *{arrows).*

seen in virtually all cases and imaging studies, such as SPEC! and transcranial Doppler, correlate with clinical improvement (Mayberg 1998).

Currently, however, angioplasty can address only larger proximal vessels (>1.5 mm in diameter). Improved microcirculation is seen due to removal of the proximal increased impedance, with subsequent increased perfusion pressure. The potential complications of angioplasty include vessel rupture, dissection, or occlusion, as well as ICH, which is extremely rare in experienced centers and if appropriate material is used (American Society of Interventional and Therapeutic Neuroradiology 2001; Newton et al. 2002). Hypetplasia with subsequent narrowing of the artery is not seen.

Vasospasm of the smallet caliber distal vessels is not amenable to angioplasty. However, the most commonly used pharmacotherapy has been the use of IA papaverine. Papaverine is a phosphodiesterase inhibitot that causes smooth muscle telation possibly through decreasing the level of intracellular calcium (Mathis, Jensen, and Dion 1997; Milburn et al. 1998; Srinivasan et al. 2002).

Superselective injections of 100-300 mg of papaverine (3% solution) ovet 30-60 minutes may be delivered close to the target vessel. Its effect has been observed only transiently, which requires repeated injections. Infusions should be avoided below the ophthalmic artery to avoid pupillary dilatation, which may be misconsttued as evidence of neurological decompensation. Other side effects of papaverine include seizure, respiratory depression (if the infusion is given below the posterior inferior cerebellar artery), and increased intracranial pressure. Therefore intracranial pressure and arterial blood pressure should be monitored during its administration.

HEMORRHAGIC STROKE

Aneurysms

Intracranial Aneurysms

Studies have shown overall prevalence rates of intracranial aneurysms that vaty from 0.2-9.9%. The mean of 5% would correlate to nearly 15,000,000 Americans with an intracranial aneurysm. Approximately 10 of every 100,000 aneurysms will rupture per year, which equates to nearly 30,000 cases in the United States per year. The vast majority of aneurysms do not rupture, thereby presenting the need to classify patients into two gtoups: those with ruptured inttacranial aneurysms and those with unruptured intracranial aneurysms. The clinical management of these patient groups is evolving with the advent of ncuro-endovascular therapeutics.

Unruptured Intracranial Aneurysm. Patients with unruptured intracranial aneurysms far outnumber those with ruptured aneurysms. Most patients have a single unruptured aneurysm that is identified incidentally during the workup of conditions such as headache, cerebrovascular ischemic event, cranial nerve deficits, convulsive disorder, ill-defined spells, aneurysm mass effect, subdural hemorrhage or ICH, brain tumor, and neurological degenerative disease. The diagnosis of an unruptuted inttactanial aneurysm is made after suggestive findings on CT (40%) and MRI (37%) (International Study of Unruptured Intracranial Aneurysms Investigators 1998). The various types of imaging modalities and their utility in detecting aneurysms are listed in Table 53.8.

Juvela, Porras, and Poussa (2000) followed the natural history of intracranial aneurysms for an average of nearly 20 years in 142 patients with 181 unruptured aneurysms. The average annual incidence rate of ruptute was 1.3%, and the relative risk of rupture increased with the size of aneurysms. Smoking, size of aneutysm, and patient age were the most important risk factors for rupture. The International Study of Unruptured Intracranial Aneurysm (LSUIA) investigarots provided the most comprehensive study on the natural history of unruptured aneurysms. They reported a retrospective study of 1449 patients with 1937 aneurysms. Patients without a history of SAH (group 1, « = 727) were separated from those with a histoty of SAH from a separate aneurysm (group 2, *n* — 722), In group 1, the study revealed a cumulative tate of rupture of 0.05% per year for aneurysms that were less than 10 mm in diameter at the time of diagnosis. The tate was 20 times higher for aneurysms greater than 10 mm in diameter {nearly 1% per year). The rate of rupture in group 1 was 6% for the first year for giant aneurysms (>25 mm). Size and location of aneurysms were predictive factots of future rupture in group 1. Posterior circulation aneurysms were more likely to rupture independent of size.

Group 2 included patients with a history of SAH who had the ruptured aneurysm properly treated and a second nonruptured aneurysm. The rupture rate for the untreated

Table S3.8: Diagnostic studies for detection of intracranial aneurysms

CT examinations with slice thicknesses of 5-10 mm; however, small aneurysms may not be visible even with IV contrast (Hsiang et al. 1396; Bederson et al. 2000)
CT angiography shows aneurysm sizes as small as 2 mm with sensitivity of 77% and specificity of 87%
CT angiography for size >3 mm has specificity of 97% and 100%, respectively (Hope et al. 1996)
MRl/MRA: Good for screening with sensitivity of 69-93%, particularly for aneurysms >3 mm (Korogi et al. 1996)
Intra-arte Ha I angiography: Gold standard, but risks include complication rate of about 5%, neurological event of about 1%, and permanent neurological deficit of about 0.5% (Rinneetal. 1993; Ronkainen et al. 1998)

CT = computed tomography; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging.

aneurysm was 11-fold higher at 0.5% per year for aneurysms less than 10 mm in diameter than for similar aneurysms in patients who had not suffered an SAH. The rupture rate was less than 1% per year for aneurysms greater than 10 mm in diameter in both groups. Surprisingly, the size was not an independent risk factor for group 2 aneurysms. The location of the aneurysm and the age of patients were independent factors for rupture; specifically, basilar tip aneurysms provided a 5.1 relative risk and older age was ,i 1 .3 1 relative risk for rupture. Since the publication of this report, Wiebers et al. (unpublished data) have prospectively studied a larger cohort and the critical aneurysm size has now been redefined as 6 mm. This confirms the earlier observation made by McCormick and Acosta-Rua (1970) that 5-mm aneurysm size seems to be critical for an increased risk of rupture,

Indications for the treatment of unruptured intracranial aneurysms are listed in Table 53.9 (Bederson, Awad, and Wicbcrs 2000, revised by authors).

Surgical Treatment. Surgical outcomes were prospectively studied in the ISUIA report; 972 patients underwent intracranial surgery in group 1, and 198 patients in group 2, The overall morbidity and mortality rate at 1 month for patients in group 1 was 17,5%. At 1 year, the overall rate was 15.7%, with only 15.6% of patients at their baseline neurological status. Furthermore, 3,8% of patients died from surgical-related complications.

Mortality rates of direct surgical treatment of unruptured intracranial aneurysms have been reported as low as 0% and as high as 7%. Morbidity rates have been reported as low as 4% and as high as 15.3%. Unfortunately, various studies have established different criteria for morbidity and even mortality, depending on the time period of follow-up. The ISUIA study has been recognized as the most comprehensive study on this issue (International Study of Unruptured Intracranial Aneurysms Investigators 1998). Specific risk factors for poor surgical outcomes have been grouped into the following categories and subcategories: patient characteristics (age, symptoms, and medical condition), aneurysm characteristics (size, location, and morphology), and other factors (hospital and surgical team experience).

Endovascular Treatment of Unruptured Intracranial Aneurysms. Preliminary results of endovascularly treated unruptured intracranial aneurysms have revealed lower morbidity and mortality rates when compared with surgery. However, the rates of incomplete aneurysm obliteration and re-canalization arc current challenges tin this field. More than 120,000 aneurysms have been treated with the Guglielmi detachable coil (GDC) system. In a case series of 42 unruptured aneurysms that were treated with an endovascular approach, Wanke et al. (2002) found a morbidity rate of 4.8% and a mortality rate of 0%, with a follow-up range of *6-S3* months. Murayama et al. (1999) reported a morbidity rate of 4.3% in 109 treated patients. In a blinded review of patients with aneurysms that were deemed amenable to both coiling and clipping, 68 patients were treated with surgery and 62 were treated with endovascular coil embolization. The rates of complications were 34% in the surgical arm and 8% in the endovascular arm (Johnston et al. 2000). A retrospective study of patients with unruptured intracranial aneurysms in California reported the outcomes of surgically treated patients versus endovascularly treated patients. Adverse outcomes were more common in patients treated with surgery (25%, *n = 1699)* than in those with EVT (10%, *n* = 370). Remarkably, a testimony to improved procedures and materials, the frequency of adverse outcomes declined with statistical significance from 1991 to 1998, whereas the surgical adverse outcomes did not decline. Deaths occurred in 3.5% of surgeries and 0.5% of endovascular treatments (Johnston et al. 2001) (Figure *55.6).*

A cohort study of patients with unruptured intracranial aneurysms from 1994 to 1997 were evaluated and found to have significantly more adverse outcomes with surgery (18.5%, *n* = 2357) versus EVT (10.6%, *n* = 255). Adverse outcomes were defined as death or transfer to a rehabilitation hospital or nursing home at the time of discharge. The results were not altered after adjustments were made for age, sex, race, transfer admissions, emergency room admissions, and year of treatment (Johnston et al, 1999).

In the infancy of endovascular neuroradiology, it was widely believed that only posterior circulation aneurysms were amenable to coiling. It was also thought that aneurysms with mass effect would suffer great effects from the mass of platinum coils. However, the last 10 years have brought exponential growth in the field in terms of biotechnology, materials, and the understanding of fluid flow. A call has been made for a randomized controlled trial for unruptured intracranial aneurysms with surgical

Table 5.1.9: Indications for the treatment and management of unruptured aneurysms

1. Treatment of small intra caver nous internal carotid artery aneurysms generally is not indicated. Treatment of large symptomatic ones should be individualized based on patient age, severity, and progression, in addition to alternatives.
2. Symptomatic intradural aneurysms of all sizes should he-considered for treatment, with large or giant carrying higher risks for surgery.
.). Cdtxisiiiij; aneurysms nf all sizes in patients with subarachnoid hemorrhage from a separate aneurysm warrant treatment. Aneurysms at the basilar tip have high risk of rupture. Patient age, medical condition, and neurological status and relative risks should he considered.
4. Young patients with aneurysms approaching .5-6 mm should receive special consideration. Also, unique characteristics include aneurysms with daughter sacs, hemodynamic features (high-flow impingement zone, for example, internal carotid artery terminus aneurysm); familial considerations deserve special treatment consideration,
5. Asymptomatic aneurysms >5 mm should be strongly considered for treatment.

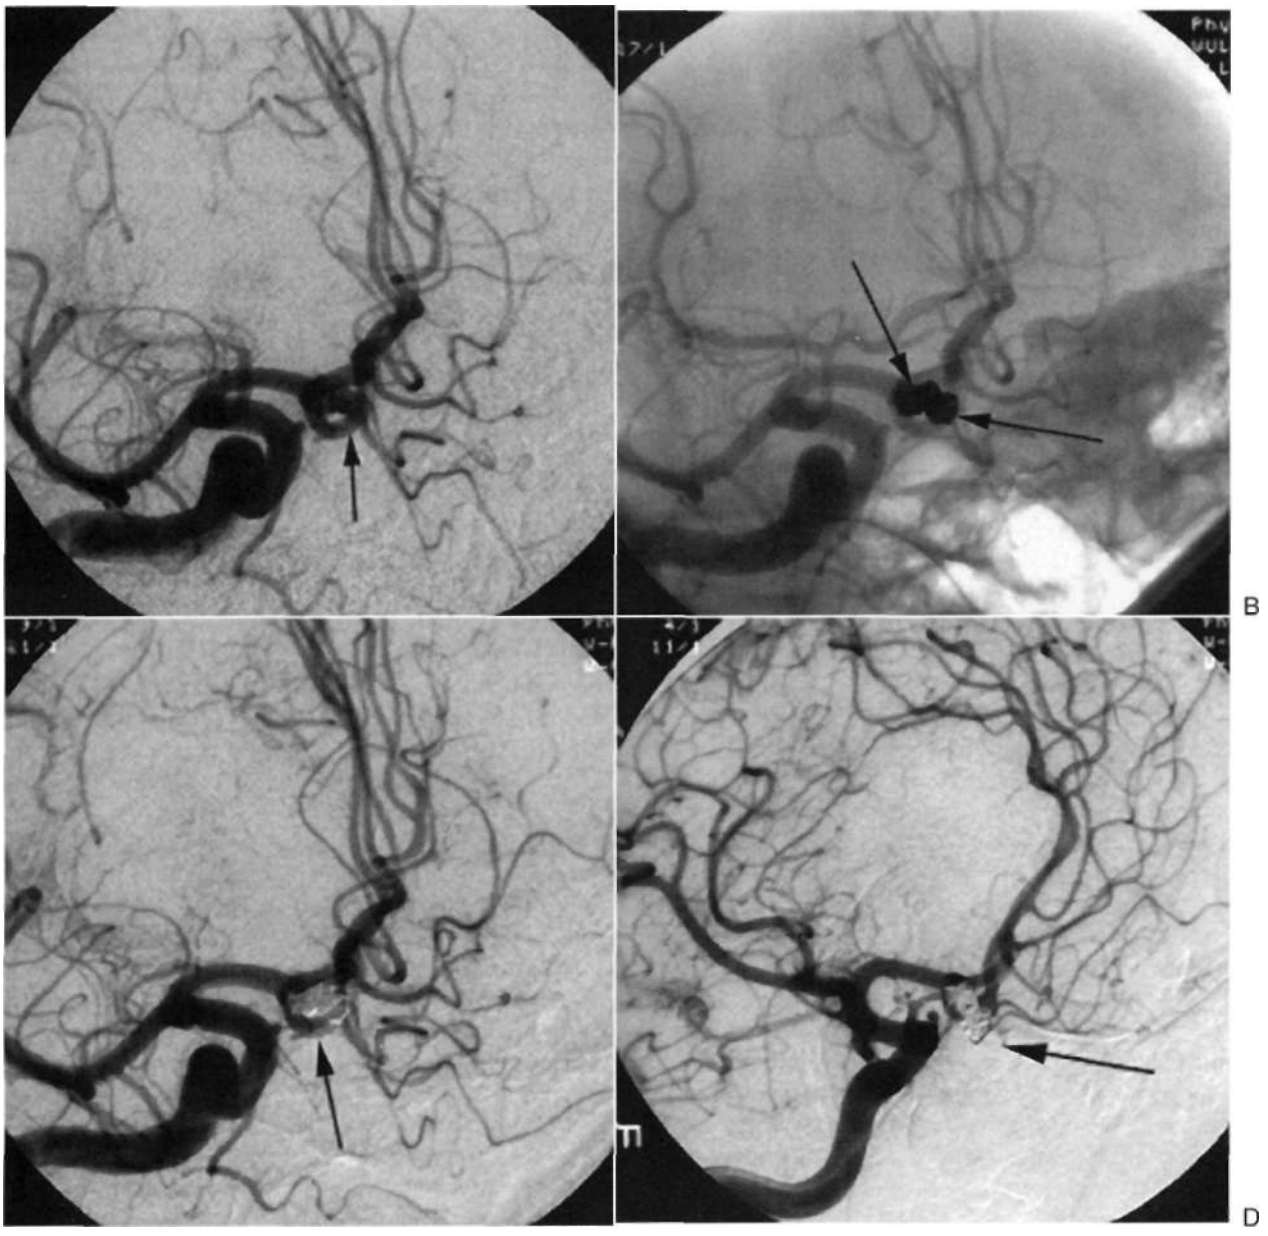

FIGURE 53.6 (A) Twice-ruptured .5-mm bilobed anterior communicating artery aneurysm in a 51 -year-old man who presented with a Hunt and Hess grade of 1. (B, C) Coiling of the aneurysm with complete obliteration *[arrows).* (D) The aneurysm remains completely occluded on 6-month follow-up angiography.

clipping, endovascular coiling, or medical management Oohnston et al. 1999, 2001; Broderick 2000).

The American Society of Interventional and Therapeutic Neuroradiology has, for management purposes, categorized aneurysms as either ruptured or unruptured. This classification can be further expanded to indicate endovascular treatment for therapeutic purposes, including treatment with parent vessel sparing or parent vessel occlusion (Tables 53.10, 53.11, and 53.12). The indications for endovascular treatment of aneurysms follow general guidelines based on aneurysm morphology, medical stability of the patient, and the risks of endovascular procedure versus clipping. The overall goal is to prevent aneurysm rupture or rebleed, or to stabilize or decrease the symptoms of mass effect caused by large or giant aneurysms. Successful outcomes are dependent on the degree of aneurysm exclusion from the overall circulation. Degree of exclusion

Table 53.10: Indications for endovascular treatment in unruptured aneurysm

Poor surgical candidate due to medical risk factors
High surgical clipping risk due to location or size
Failed clipping attempt
Patient/family refusal of open surgery
Multiple aneurysms that would require several craniotomies

Table 53.11: Indications for endovascular treatment with parent vessel sparing in ruptured aneurysm

Poor surgical candidate due to medical risk factors
Poor clinical grade
High surgical clipping risk due ro location or size
Failed clipping attempt
Significant vasospasm in vascular distribution removed from aneurysm location

by coiling will be based on the anatomy of the circulation (access and tortuosity leading to aneurysm), aneurysm morphology (specifically neck size), and collateral circulation. Aneurysms with a small neck (<4 mm) and small dome (<10 mm) have the highest potential success rate.

The onset of new more conforming coils with bioactivity, hydraulic detachment, hydrocoils, balloon and stent assistance, and experience have led to the exponential growth in this field, which has caused a major decrease in the recanali/ation rates to an overall less than 10%. Post-GDC bleeding of large aneurysms has been reported (based on a literature review of 48 studies over 7 years) to occur in 4% of cases and 33% of giant aneurysm cases. Brilstra et al. (1999) found a low permanent complication rate (3.7%) of both ruptured and unruptured aneurysms.

A case-controlled randomized prospective trial is required to determine whether open surgery or endovascular treatment results in better outcomes in unruptured intracranial aneurysms. However, the International Subarachnoid Aneurysm Trial (ISAT) has clearly defined the better clinical outcome to be after endovascular treatment of ruptured cerebral aneurysms at 1 year (Molyneux et al. 2002).

Ruptured Intracranial Aneurysm. The ruptured intracranial aneurysm is one of the most devastating events for patients with hemorrhagic stroke today. Nearly 30,000 Americans suffer annually from ,SAH associated with a ruptured aneurysm. Anywhere between 5% and 15% of all strokes can be attributed to SAH from a ruptured aneurysm. The most staggering statistic is that the 30-day aneurysmal SAH mortality rate is 45%, Half of the survivors will suffer from irreversible brain damage (Graves 1990; AHA 2001) (Figure 53.7).

The ISAT has provided a randomized, controlled trial of surgical clipping versus endovascular coiling of ruptured intracranial aneurysms (Molyneux et al. 2002). The multicenter trial enrolled 2143 patients with aneurysms who were deemed suitable for either treatment modality.

Table 53.12: Indications for endovascular treatment with parent vessel occlusion (ruptured or unruptured)

Fusiform ain'mysm
Pseudoaneurysm secondary to trauma, infection, neoplasm, or dissection
Some large or giant aneurysms

Random assignment included 1070 patients for clipping and 1073 patients for coiling. Most of the aneurysms (>50%) were less than 6 mm in diameter. Most of the aneurysms were located in the ACA (50.5%), followed by the ICA (mostly a posterior communicating artery aneurysm). Only a small number of aneurysms were located in the posterior circulation (2.7%), which is considered the most amenable for endovascular treatment. Most of the patients were in excellent condition before the intervention. Clinical outcomes were assessed based on modified Rankin Scale scores at 2 months and 1 year. Recruitment into the trial was stopped by the steering committee after an interim analysis per protocol revealed survival free of disability that was significantly better with endovascular coiling. In the surgical arm, 31.1% of patients were significantly restricted, partly or fully dependent, or dead (modified Rankin Scale score of 3-6} at 1 year (N = 758), compared to 23.5% in the endovascular arm (N = 770). The absolute risk reduction was 7.6% (relative risk reduction 24.3%, p = .00082). With more patients being evaluated at 1 year, the absolute risk reduction in endovascular treatment is becoming more obvious. The annual risk of rebleed of endovascularly treated aneurysms at 1 year was 0.12%, slightly higher than in the surgical arm because of incomplete endovascular aneurysm obliteration and the use of thrombolytics during the intervention.

Endovascular treatment of aneurysms is a genuine alternative to surgery for ruptured and unruptured anterior and posterior circulation aneurysms. The key component for a successful and permanent aneurysm occlusion and for a reduction in the rebleed risk is the initial complete aneurysm obliteration, I'eriprocedural morbidity and mortality for endovascular treatment are superior to surgery. Currently, a follow-up angiography (or a contrast-enhanced MRA in selected patients) is recommended at 3-6 months, and 1 and 3 years to rule out a reopening of the aneurysm resulting from coil compaction. The initial results with bioactive coils and other biologically active implants are promising and should further reduce the risk of aneurysm regrowth or recanalization, further reducing the rebleed rate.

Arteriovenous Malformations

AVMs are almost exclusively congenital; a few casts oJ familial occurrence have been described. The prevalence of AVMs is in the range of 1.4-4,3%, and most of them are located supratentorially (90%). Spontaneous thrombosis occurs in about 2-3% of patients. Symptoms typically present before the age of 40 years; AVMs arc uncommon in children. Sixty-five percent of patients present with intracranial hemorrhage, which can be intracerebral, subarachnoid, intraventricular, or a combination thereof. A new-onset seizure may be the presenting reason for hospitalization in about 15-35% of patients. Fifteen percent

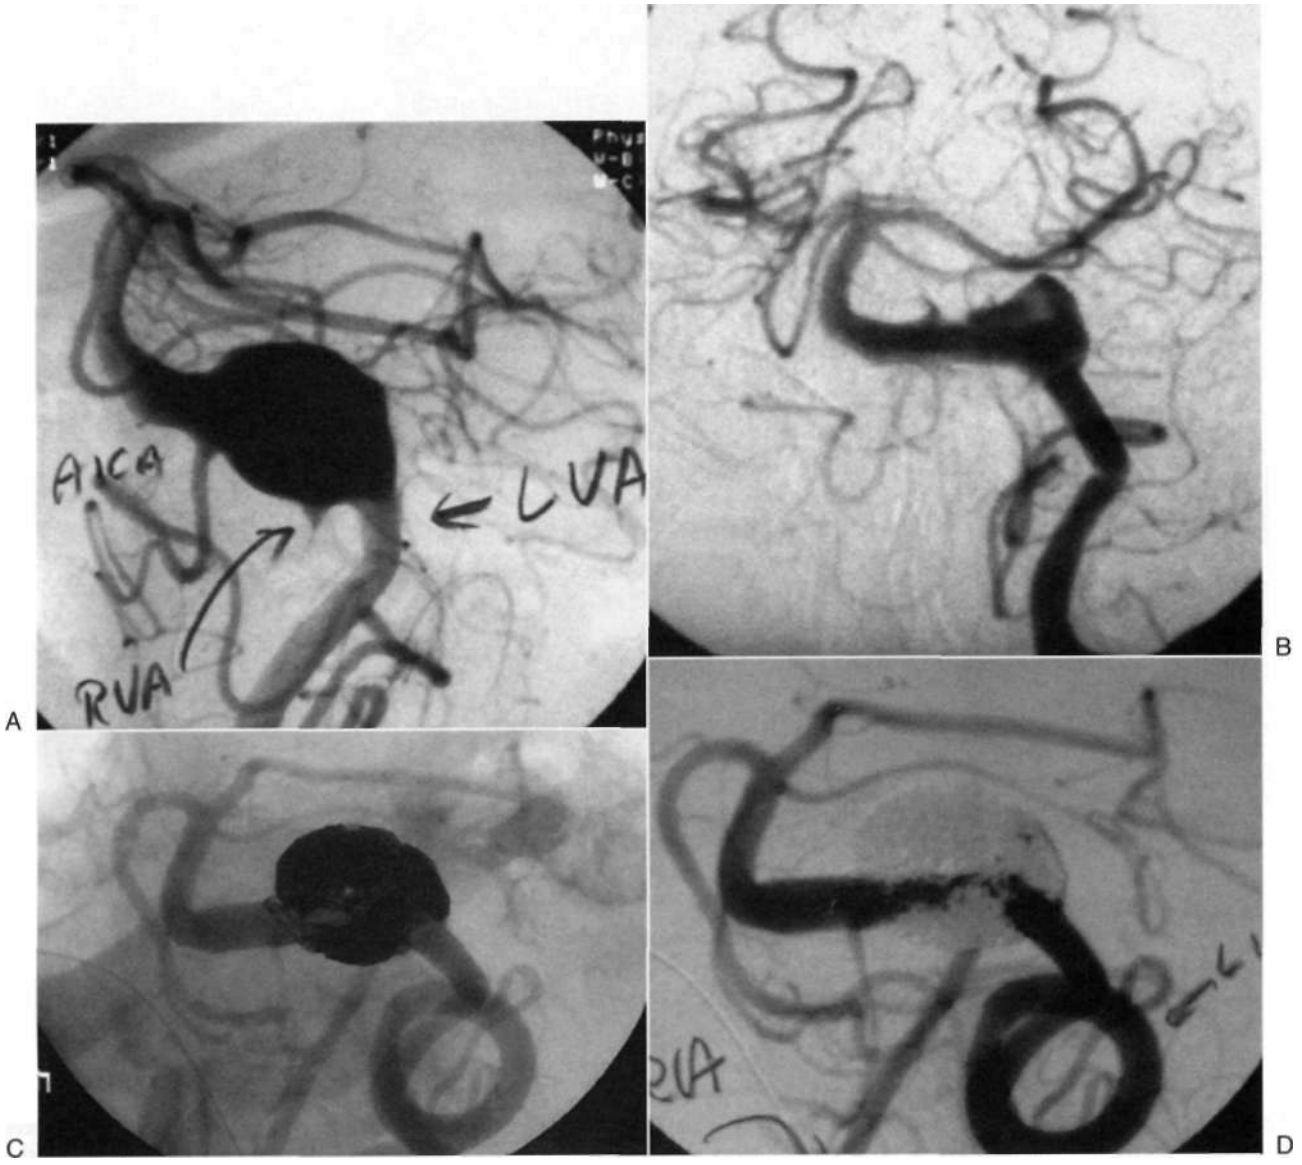

FIGURE 53.7 (A) Fusiform aneurysm of the vertebrobasilar junction. (B) Four-week follow-up angiography after placement of three overlapping noncovered stents *(arrows)* shows partial closure of the aneurysm. (C, D) Coiling of the aneurysm through the stent struts *(arrows).*

Continued

of patients complain of headaches. The annual hemorrhage risk has been described as 2-3%. ICH occurs in 60-65% of the cases, ICH combined with intraventricular hemorrhage in about 26%, pure intraventricular hemorrhage in about 8%, and pure SAH in 4%, The mortality for the first hemorthage is 29%, and the long-term disability is approximately 23%. After the first bleed, there is a 1-year recurrence risk of 6%, which then drops back to 2-3% in the following ycats. Thirty-four percent of patients have a risk of recurrent hemorrhage with 13% mottality {Graf, Perret, and Tomer 1983; Crawford et al. 1986; Brown etal. 1988; Ondra et al. 1990; Hartmann et al. 1998).

Radiographic features predictive of hemorrhage arc size, location, deep versus cortical venous drainage, impaired venous drainage, the nature of arterial feeders, and the presence of intranidal aneutysms. Approximately 3.7-17.0% of AVMs are associated with aneurysms. Aneurysms can be located distant and unrelated to the AVM, within the AVM feeding artery, in the AVM pedicle, or in the AVM nidus. Endovascular treatment also has a role in an AVM-associated aneutysm if it represents the site of rupture (Figure 53.8).

Treatment options include surgery, presurgical embolization, and radiosurgery, a combination of embolization and radiosurgery, and embolization alone. Endovascular embolization with liquid embolic agents such as dehydrated ethanol or M-butyl-2-cyanoacrylate has shown a cure rate with embolization alone in about 40% of Sperzer-Martin

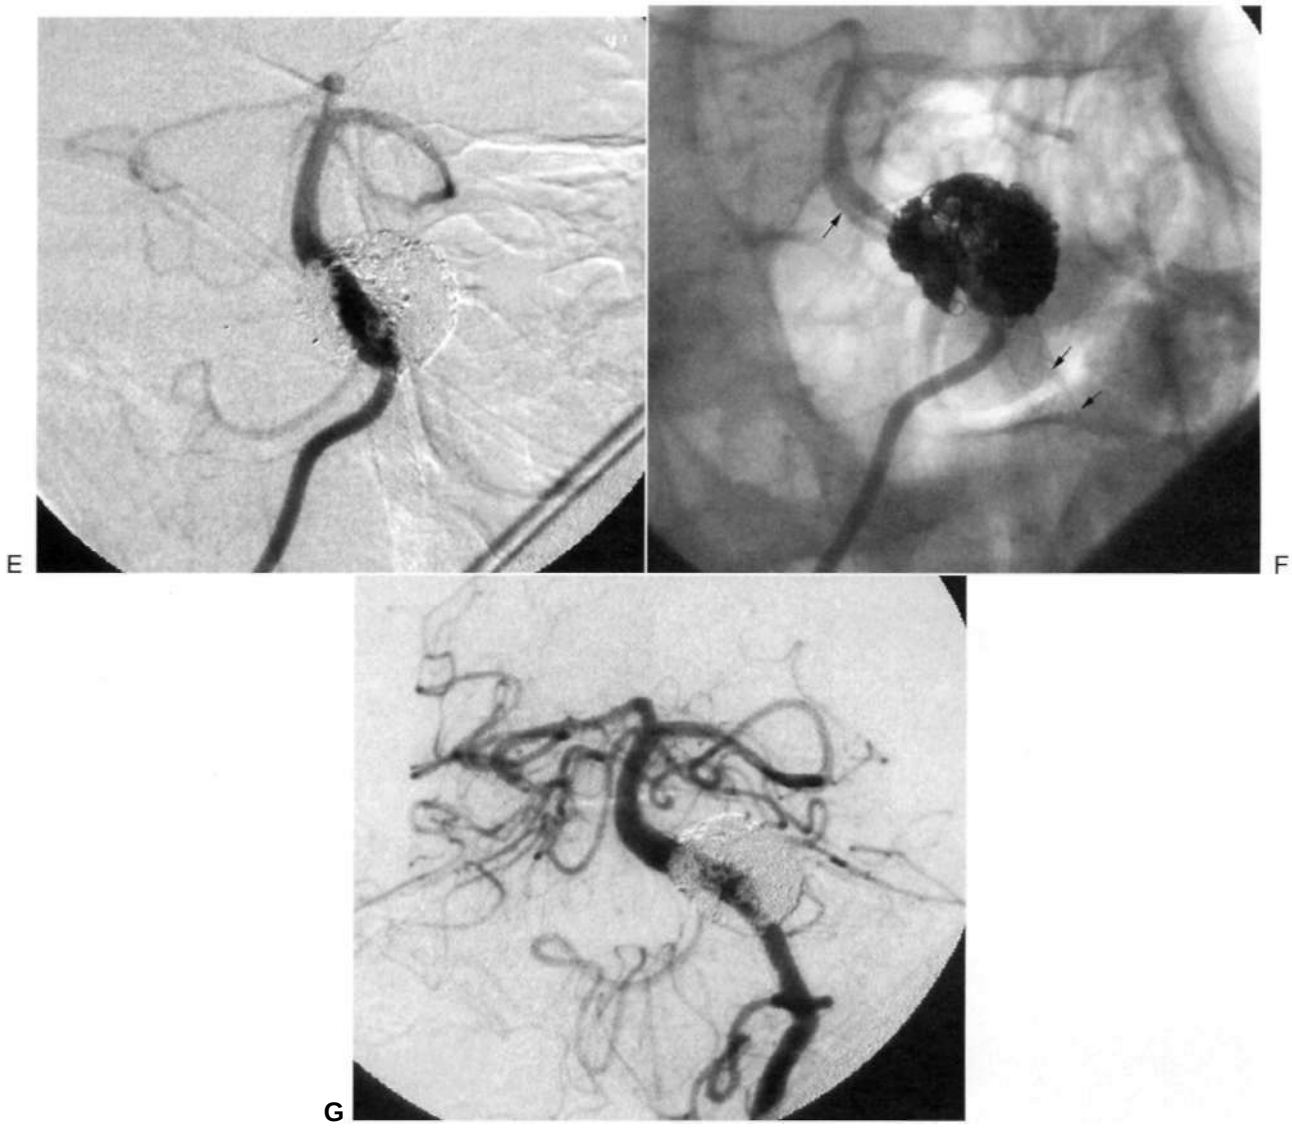

FIGURE 53.7, cont'd. (E, F) No filling of the aneurysm at 8-month follow-up angiography. Flow from the right vertebral artery enters the basilar artery through the stent struts. (G) The left vertebral artery supplies the basilar artery. The patient was asymptomatic after the procedure.

grade 1 AVMs, 30% of grade 2, and 10% of grade 3 AVMs smaller than 3 cm (Wikholm, Lundqvist, and Svendsen 1996; Debrun et al. 1997; Willinsky et al. 1999). In AVMs larger than 3 cm, cure with endovascular treatment is generally not possible, although embolization can downgrade the AVM before surgery or radiosurgery. Embolization has morbidity with a permanent neurological deficit of 6-8% and a mortality of 1-2% (Frizzel and Hsher 1995; Wikholm, Lundqvist, and Svendsen 1996; Debrun et al. 1997).

Successful endovascular treatment of an associated aneurysm that may be the source of AVM hemorrhage can decrease the risk of rebleed for 2-3 years, until radiosurgery is fully effective. In addition, reduction of flow can decrease venous congestion and occasionally reduce the frequency of seizures and other neurological symptoms. The Spetzler and Martin grading system was developed for surgical treatment strategies and is not useful for determining appropriate types of endovascular treatment. Certain aspects of the grading system such as deep venous drainage may negatively categorize an AVM into a higher grade in the Spetzlcr and Martin system but are helpful for endovascular treatment (Figure 53.9).

Recent improvements in endovascular techniques such as microwircs, flow-guided microcatheters, and liquid embolic agents have increased the cure rate to 40%. Longer follow-up studies are promising and show no recanalization or regrowth after complete embolization of AVM with acrylates (Lasjaunias et al. 1986, 1988; Wikholm, Lundqvist, and Svendsen 2001). Radiation therapy or surgery should be considered only if complete obliteration of an AVM cannot be accomplished.

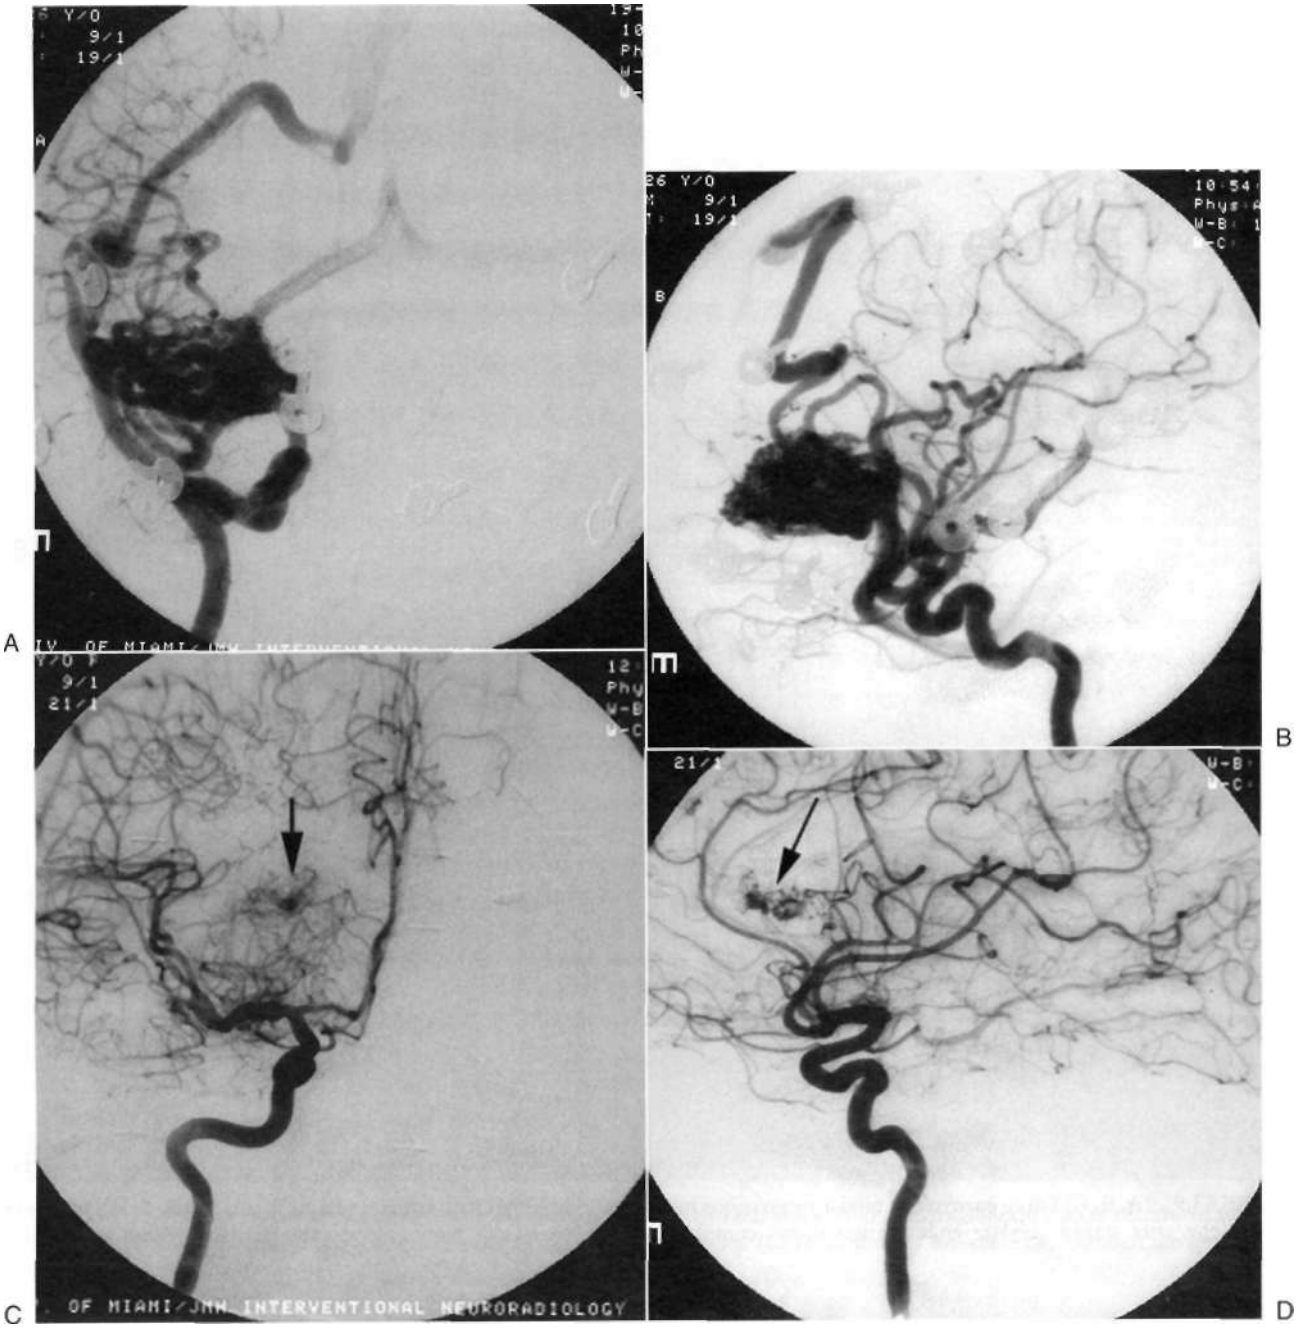

FIGURE 53.8 (A, B) Anteroposterior and lateral views of a right frontal arteriovenous malformation (AVM). (C, D) Control angiography after partial acrylatc embolization of the malformation. The remaining deep parts of the AVM *(arrows)* were treated with gamma-knife radiation.

Carotid Cavernous Fistula

Carotid cavernous fistulas (CCFs) are the abnormal connections between the carotid artery and the cavernous sinus. CCFs make up 10-15% of all intracranial arterial venous malformations. Fistulas arc generally categorized based on the following factors: direct or indirect (dural), spontaneous or traumatic, high or low flow, and anatomy (internal carotid or external carotid ot both). Most fistulas are of the direct type, Barrow type A, which are characterized by direct flow from the cavernous segment of the ICA to the venous circulation. These are most commonly associated with trauma. The remaining fistulas are indirect or dural fistulas classified into Barrow types B through D. These are shunts between the meningeal branches of the ICA and the cavernous sinus (type B), meningeal branches of the external carotid artery (type C),

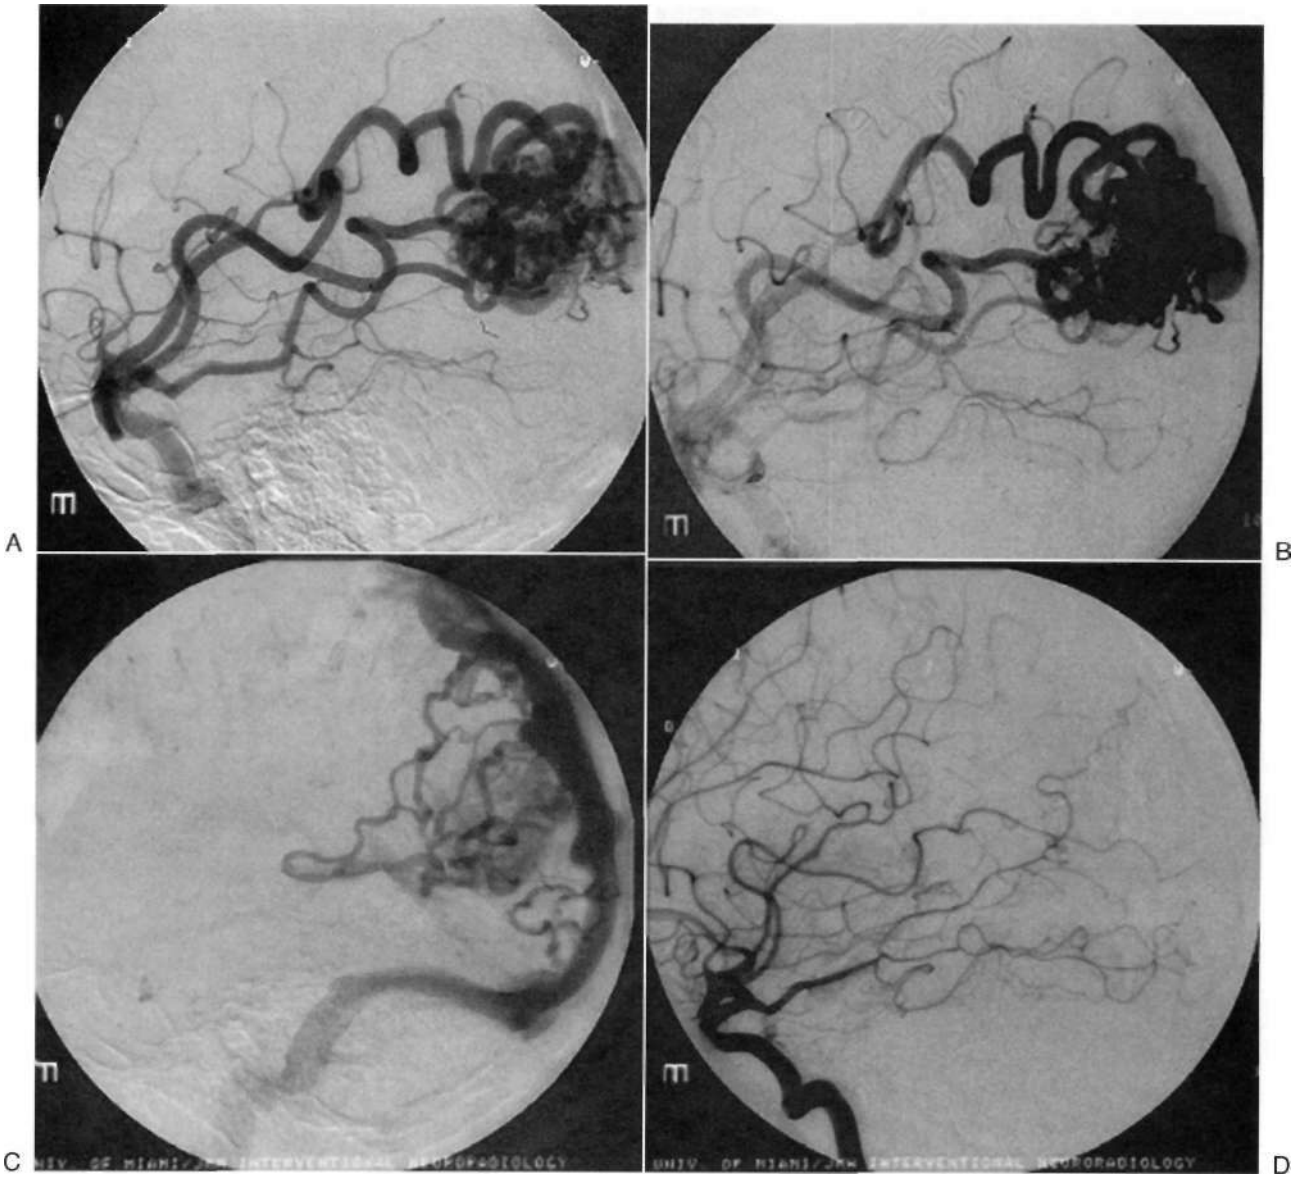

FIGURE 53.9 (A, B, C) Large parietooccipital arteriovenous malformation (AVM) with cortical venous drainage. (D, E, F) Follow-up angiography after staged acrylate embolization shows complete AVM obliteration. Note angiographic artifact created by acrylate *[arrows).* *Continued*

or the meningeal branches of both the internal and the external carotid artery (typeD) (Barrow et al. 19H5) (Figure 53.10).

Previous treatments included closure of the fistula with flow-guided balloons. Although balloons would successfully occlude the fistula and preserve carotid artery patency, several complications, albeit transitory, occurred such as worsened orbital congestions and ocular motor nerve paresis (Hedges 1999). Curative embolization of type A CCF involves the obliteration of the arteriovenous fistula, generally accomplished by using platinum fibered coils or dctachable balloons. In indirect CCFs, embolization of the cavernous sinus is generally required. This can be accomplished using a transvenous approach and obliteration of the affected part of the cavernous sinus with cither fibered coils or acrylates. The obliteration of the cavernous sinus is generally very well tolerated in patients with CCF. The ocular symptoms generally resolve within a few weeks.

Venous Occlusive Disease

Stenoses may occur within major dural sinuses, causing varying degrees of cerebral venous obstruction. These stenoses may be associated with chronic headache syndromes. Dural sinus and cerebral vein thrombosis may be associated with hypercoagulable conditions (including pregnancy and malignant disease), infection (e.g., mastoi-

ditis), or dehydration. Occlusive thrombophlebitis of a dura] sinus can result as a complication of mastoiditis or as a result of intracranial spread from a facial infection, transmitted by draining veins of the face into the cavernous sinus. The dural sinuses also may be invaded and occluded by tumyrs, especially meningiomas.

Increased intracranial pressure and venous infarctions (with or without intracranial hemorrhage) can result. If initiated early enough after onset, local thrombolysis using urokinase or percutaneous endovascular thrombectomy has shown some success in the management of sinus and cerebral vein thrombosis,

OTHER

The petrous ICA may cake an aberrant course through the middle ear cleft, rather than through the petrous temporal bone. In that case, it may cause pulsatile tinnitus and a blue tympanic membrane. Biopsy of the "mass" behind the tympanic membrane may injure the ICA or create a pseudoaneurysm. Aneurysms of the petrous ICA are uncommon and are usually traumatic or congenital. They may be a source of intracranial embolization and thus warrant either occlusion of the ICA with detachable balloons or endovascular bypass using a vascular (covered) stent. Similar approaches are used in treating deceleration or penetrating injuries that result in arteriovenous fistulas between the ICA and the internal jugular vein.

Aneurysms of the cavernous ICA present a lower risk than those present in the supraclinoid region (subarachnoid space) because rupture into the cavernous sinus is far less devastating than intracranial hemorrhage, although it does result in a direct carotid-cavernous fistula. Very large aneurysms may cause mass effects on adjacent cranial nerves. Symptomatic inoperable fusiform aneurysms of the cavernous and supraclinoid ICA may be treated by occlusion of the parent ICA using detachable balloons.

Chapter 54
Principles and Practices of Neurological Rehabilitation

Bruce H. Dobkin

Neurological rehabilitation extends its assessments and ptaetices into every aspect of the cate of patients with acute and chronic disabilities, regardless of the location of a lesion or its cause. Conducting patient rehabilitation becomes a high priority for the physician who wants to provide more than diagnostic setvices and short-tetm care. To best assist patients, the clinician must determine what tasks patients can and cannot perform, determine what skills are most important for them to tegain, apply skill learning principles based on an understanding of neuro-plasticiry mechanisms, work with allied health professionals to lessen disabilities, and anticipate and manage neuro-medical and psychosocial complications of immobility, loss of motot control, cognitive impairment, and functional dependence (Dobkin 2003).

GOALS AND STRUCTURE OF REHABILITATION

Rehabilitation can be defined as an educational process that aims to reduce disability and improve functional independence and quality of life. An alternative definition, perhaps a little more dynamic, describes rehabilitation as an active process of change by which a petson who has become disabled acquires and uses the knowledge and skills necessary for optimal physical, psychological, and social function. It is important to remember that neurological impairment (the presence of abnormal neurological signs) is the basis of the diagnosis. Impairment may in turn cause disability. These definitions inttoduce a number of concepts that will be dealt with more fully later in this chapter, but they underscore the fact that rehabilitation is an active educational and learning ptocess and that patient in-volvement is crucial.

Aims

Rehabilitation aims to improve functional and cognitive skills such as walking and language, reduce disability in petsonal care and other daily activities, prevent and manage com plications such as aspiration, contractures, pressure sores, and depression, lessen the burden of care needed by disabled people, and enhance health-related quality of life by maximizing functional independence and participation in home and community putsuits.

Disabled people and their families and caregivers should be intrinsically involved in the rehabilitation process. Therapies can be carried out only by or with disabled people, not at them.

Rehabilitation includes the following aims:

- Promote physical, psychological, and social adaptation to disability.
- Facilitate independence in daily self-care and community activities.
- Prevent secondary health complications.
- Encourage self-management.

To achieve these aims, the process differs from the usual medical model of care by including personnel from multiple disciplines, goal-directed assessments and interventions, outcome evaluation, and organization of community services to meet the patient's needs.

Personnel

A team approach to inpatient and outpatient care is necessary to manage the diverse problems faced by disabled patients and their families (Figure 54.1), In a mulridisciplinary model, each member with specialty training treats particular disabilities. In an interdisciplinary model, roles blend. An interdisciplinary approach orients toward problem-solving to improve functional outcomes rather than being bound by guild-oriented disciplines. For example, training procedures for motor and cognitive learning or behavioral modification are reinforced by all members of an interdisciplinary group, using agreed-upon strategies. Moreover, an interdisciplinary structure sets its goals with a view toward dealing with a patient's disabilities and returning him or her to a usual role in daily life activities. These interaction styles are not mutually exclusive, Most teams move between the two models when they formally meet to discuss the patient's progress and to adjust goals and treatments.

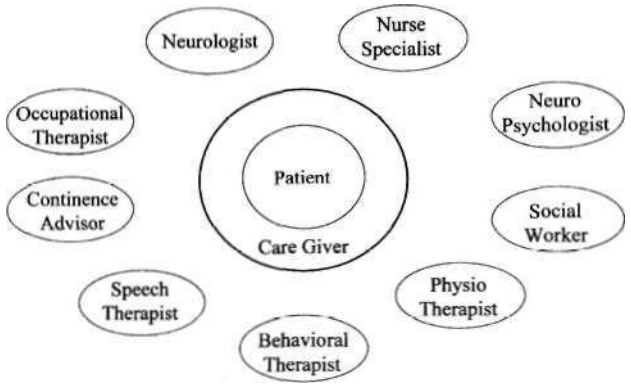

FIGURE 54.1 The mulridiscipJinary team centered around patient and caregiver.

The care milieu created by the team of therapists, nurses, social workers, neuropsychologists, and physicians, with its emphasis on lessening disability, is one of rehabilitation's most powerful tools. The team approach to neurological rehabilitation has come under remarkably little scrutiny, however. Studies of inpatient stroke rehabilitation support the approach primarily as an efficient way to organize services for patients with functional disabilities. For otbet neurological diseases, almost no well-designed trials about how to provide a system of care exist.

Physicians

An understanding of the underlying disorder, including the mechanisms of disability, potential outcomes, and natural history of the disease being managed, is critical in planning the rehabilitation program, particularly for chronic and progressive neurological disorders. This expertise may be provided by the growing number of neurologists with expertise in neurorehabilitation, who can bring principles from their growing storehouse of knowledge to bear on recovery, and by rehabilitation physicians or physiatrists, who also have broad experience in musculoskeletal, orthopedic, and cardiopulmonary rehabilitation issues. Podiatrists and other physicians, including orthopedists, urologists, psychiatrists, plastic surgeons, and neurosurgeons, often are consulted during rehabilitation and long-term management of disabled patients.

The clinician superimposes the contributions of neurological, musculoskeletal, cardiopulmonary, and other impairments on a map of the patient's functional abilities and disabilities. For example, docs spasticity or palpably tender musculoligamentous tissue cause pain or limit movement? Does a medication or episodic orthostatic hypotension lessen attention span and endurance for exercise? Rehabilitation physicians tend to be the facilitators of the team, especially in an inpatient service. Here, the physician leads a weekly team conference that reviews the patient's progress in reaching the functional goals that will permit a discharge to the home. To do this well, the physician must help build the team's infrastructure and understand the practices of its disciplines. With a backgtound in general medicine, neuromedicine, neuroscience, mechanisms of plasticity, and scientific experimentation, rehabilitation physicians should serve as clinician-scientists. The physician can encourage therapists to weigh, formulate, and test strategics. Drawing on current literature and collaborating with basic and clinical researchers, the neurological rehabilitation specialist assesses and develops interventions (Dobkin 2003).

Physicians should explain to both patient and primary care doctor the indications for medications, measures for secondary prevention of complications, management of risk factors for recurrence or exacerbation of the disease, and the type and duration of rehabilitative interventions. During outpatient care, physicians must develop their

counseling skills in matters such as exercise and specific directions about home practice for motor and cognitive retraining. The clinician reviews the details of how the patient is practicing to improve walking, the functional use of an affected upper extremity, language and memory skills, and socialization. Education should he offered about how task-specific practice may alter the brain's representations of these activities and improve the patient's abilities, even years after the initial neurological illness. For patients with chronic diseases that progress, practice is perhaps even more important because it may spur gradual neural reorganization to maintain function.

Rehabilitation Nursing

Traditionally, the nursing role has been one of providing care and support during a phase of illness and doing for others the things they would normally do for themselves. Nurses have particular expertise in bowel and bladder management and have developed the post of continence advisor, particularly for teaching chronic intermittent self-catheter ization (CISC). They are also the acknowledged experts on skin care and pressure sore management. In an inpatient unit, nurses are in constant contact with the patient undergoing rehabilitation. The nurse's extended contact with patients allows him or her to address the issue of carryover of skills from physical and occupational therapy sessions to other areas fundamental for discharge into the community. Each activity is integrated with others; for instance, continence management through CISC may require improvements in upper limb coordination, trunk control, mobility, lower limb tone, medications to optimi/.e bladder and sphincter control, and strategies to facilitate learning. Similarly, the therapy schedule depends on the success of these management strategies. Nurses have also become involved in the management of individual chronic diseases, including multiple sclerosis (MS), amyotrophic lateral sclerosis (ALS), and Parkinson's disease, especially attending to gaps in services needed by patients. A nurse practitioner can be a great asset to the physician and team in a busy inpatient service, especially in a university hospital, where patients tend have complex medical illnesses and needs. The Association of Rehabilitation Nurses has excellent resources for continuing education (www.rehabnurse.org).

Physical Therapist

Physical therapists or physiotherapists (PTs) contribute especially to the rehabilitation of bed mobility, transfers to a chair or toilet, stance, and ambulation. Their assessments emphasize measures of voluntary movement, sensory appreciation, range of motion, strength, balance, fatigability, bed and wheelchair mobility, and gait. The clinician's goals for neurological rehabilitation aim toward compensatory strategies for carrying out activities of daily living (ADLs), such as the use of a wheelchair, as well as interventions to lessen specific impairments when time allows. PTs play a primary role in managing musculoskeletal and radicular pain, contractures, spasticity, and deconditioning.

Two broad categories of exercise programs, therapeutic exercise and the so-called neurophysiological and neurodevelopmental approaches, have received the most attention in the past (Table 54.1). Newer concepts related to neuroplasticiry, motor control, and motor skill learning arc merging with these approaches. Traditional exercise programs emphasize repetitive passive and active joint-by-joint exercises and resistance exercises in anatomical planes to optimize strength and range of motion. The approach aims to prevent the complications of immobilization, such as contractures, muscle atrophy, and spasticity.

Exercise and Compensatory Functional Training. Most therapy programs emphasize education about impairments and disabilities, compensatory techniques for ADLs and mobility, and repetitive passive and active exercises to build from less complex to more functional movements. In the therapeutic exercise approach to stroke, spinal cord injury (SCI), and other upper motor neuron (UMN) diseases, residual motor skills in affected and unaffected extremities are used to compensate for impairments. The acquisition of self-care and mobility skills may take precedence over the quality of movement as long as patients are safe. Upper and lower extremity orthotics and assistive devices tend to be used early to promote functional compensation. Therapists also use breathing and general conditioning exercises and energy conservation techniques, particularly to reduce the energy cost of a pathological gait.

Conditioning and Strengthening. Light resistance exercises across UMN diseases and diseases of the motor unit, from the postpolio syndrome and ALS to myasthenia gravis and some of the muscular dystrophics, are generally safe and effective in improving strength and, sometimes,

function. Strength can be increased without an increase in spasticity in patients with U\t\ diseases ami without evidence of muscle injury in those with neuromuscular diseases. Concern about falls, disabihty, and muscle atrophy in older adults has led to many studies that show that a strengthening program can benefit any sedentary person. Resistance training can lead to an increase in strength before any muscle hypertrophy occurs, probably by augmenting the amount of supraspinal input that is brought into the task. Thus strengthening can be considered a form of motor learning. Isometric resistance exercises probably arc the safest approach for weak patients and can be performed without equipment. For example, flexing the elbow of one arm about 60 degrees and pressing down on that forearm with the palm of the other arm to reach an equilibrium of tension in each arm will enhance strength in the shoulder girdle, elbow flexors and extensors, and forearm groups.

Medications that act on the neuromuscular junction, such as pyridostigmine, those that work on muscle, such as 02 adrenergic agonists, those that work on demyelinatcd axons, such as the aminopyridines, and hormones such as androgens and human growth factor that limit disuse-atrophy may come into clinical use along with specific retraining programs.

Fitness training is valuable in LIMN, extrapyramidal, and motor unit diseases. Treadmill walking can be used as an aerobic workout for the older adult with hemiparetie stroke. After a complete SCI, cardiovascular conditioning can be limited by the use of only the upper body's small muscle mass, by pooling of blood in the leg muscles that reduces cardiac preloading, and by impaired cardiovascular reflexes. Functional electrical stimulation (FES) of the lower extremities during cycle ergometry can improve both peripheral muscular and central cardiovascular fitness. FES exercise in sets of 5 to 15 repetitions against an increasing load resistance of 1 to 15 kg over 12 weeks will increase muscle bulk, improve strength, and reduce fatigability for the FES activity. Although psychological and other physiological benefits have been attributed to FES in paraplegic subjects, long-term home programs require much motivation.

Neurophysiological Schools. Many schools of physical therapy have developed approaches that focus on enhancing the movement of paretic limbs affected by UMN lesions. They use sensory stimuli and reflexes to facilitate or inhibit tone and single- and whole-limb muscle movements in and out of mass actions called synergies. Most try to sequence therapy in a progression reminiscent of the neurodevclopmental evolution from reflexive to more complex movements. They emphasize normal postural alignment before any movement. Some techniques permit mass movement patterns early in treatment; others inhibit spastic, overflow, synergistic movements. Mobility activities might proceed in a developmental pattern from rolling onto the side with arm and leg flexion on the same side, followed by extension of the neck and legs while prone, then lying prone while supported by the elbows, and then doing static and weight-shifting movements while crawling on all four extremities. These mat activities are followed by sitting, standing, and finally walking. This progression is used most often in children with cerebral palsy, but some therapists also apply it to stroke and traumatic brain injury (TBI) rehabilitation. Different schools vary in their attempts to activate or minimize reflexive movements and in their use of training functional movements in ordinary activities. These schools have underused strengthening exercises.

The schools' use of reflexive movements, vibration to stimulate a muscle contraction, and cutaneous stimulation to facilitate a voluntary contraction is reasonable from a physiological point of view, but any carryover of responses into functional or volitional movement is uncertain. When these approaches have been compared for patients with stroke and cerebral palsy, as noted earlier, no real differences in outcomes related to gains in ADLs have been shown. However, these approaches teach movement, not specific ADLs, so perhaps the outcome measures have been inappropriate. More importantly, studies in neuroplasticity suggest that therapy structured around learning new sensorimotor relationships in the wake of altered motor control will be more effective than methods that aim to foster a developmental sequence. Over the past 10 years, practitioners have shown more flexibility in their approach to neurorchabilitation and have incorporated more recent concepts of motor learning and neuroplasticity.

Neurodcvclopmental techniques attempt to reproduce the developmental sequence shown by infants as they evolve motor control. Practitioners believe that normal movement requires normal postural responses, that abnormal motor behaviors are compensatory and that the quality of motor experiences helps train patients for normal movement. The Bobath approach is a particularly popular neurophysiological technique. It aims to facilitate normal movement and desired automatic reactions and to restore postural control while inhibiting abnormal rone and reflex activity using specific motor patterns. Bobath therapists avoid provoking mass flexor shoulder, elbow, and wrist synergies of the arm and extensor knee and plantarflexor ankle synergistic movements of the leg. Coordination of patterns of muscle group activity is viewed as more important than the actions of individual muscles. A typical exercise routine may work on stance and trunk control with a large ball and careful hand placement by the therapist to evoke movements out of synergy (Figure 54.2). These methods were originally developed for children with cerebral palsy but have been adapted for stroke and other neurological disorders.

Motor Learning Approaches. Over the past 10 years, several trends have emerged. The bases for motor control

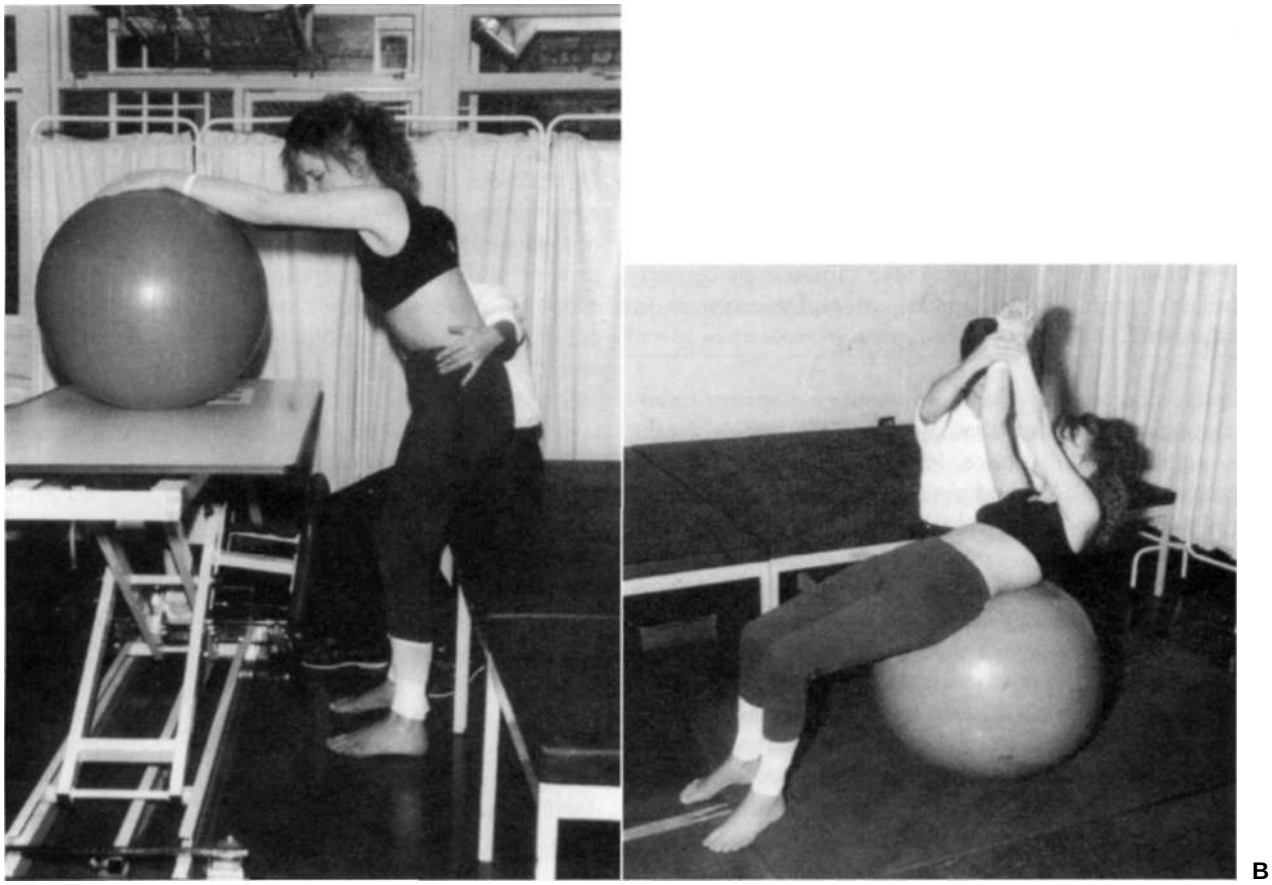

FIGURE 54.2 Gymnastic ball used to facilitate (A) standing and postural adjustments for standing up and (B) flexion and extension of the trunk and reaching.

have become key concepts for understanding normal movement and analyzing motor dysfunction. The motor control approach may incorporate techniques to eliminate unnecessary muscle activity, feedback of information about performance and practice, and task-specific or task-oriented therapies that promote practice with optimal reinforcement. In rehabilitation settings, little attention has been paid to whether training procedures—not what is taught but how it is taught—optimize gains in cognitive skills, motor functions, and self-care and community activities. The essence of therapy for any disability, as for acquiring any novel motor skill, is practice. However, a practice session can have a powerful but only temporary effect. A positive effect on performance during a training session may not lead to long-term learning. The goal of practice should be a permanent effect. Studies of interventions should include a dose-response curve to establish how much practice is needed to achieve a retraining goal. In 24 subjects with chronic stroke, random practice of functional activities using the hemiparetic left or right arm for reaching and grasping items led to better retention over time than blocked practice. Despite the contextual interference of intermixing other tasks such as pointing and touching during learning in the random practice group, both groups acquired their learning in the same number of trials. Thus random practice did not impede the rate of gains and still increased retention. Motor learning that prevents simple massed practice may be impeded in patients with striatal lesions that interfere with procedural memory and in mentally retarded subjects, but in most studies learning proceeds after a unilateral stroke and leads to adaptations in motor networks.

Task-Orientcd Practice. Motor learning emphasizes visual, verbal, and other sensory feedback to achieve task-specific movements, in contrast to neurophysiological techniques that rely on cutaneous, ptoprioccptive, and other sensory stimuli to elicit facilitation and inhibition of movement patterns. Constraint-induced movement therapy for the upper extremity and body weight-supported treadmill training for walking, discussed later, are among the task-oriented approaches to regaining movement. Mental practice, electromyography (EMG) and other forms of biofeedback (BFB), EMG-triggcrcd clecttical stimulation of a muscle group, and virtual reality training are potential therapeutic tools.

Studies of the efficacy of particular schools of therapy have not revealed differences between approaches.

These studies, primarily in patients with stroke, used outcome measures that emphasize independence in ADLs and not an outcome directly related to the primary focus of the specific technique of physiotherapy, which is motor performance and patterns of movement. Studies of efficacy should concentrate on the best well-defined practice for an important goal, such as reaching, grasping items, and walking that may, in theory, be modulated by the intervention. Most therapists take an eclectic experimentalist's approach, not unlike what physicians do in daily practice.

Adaptive Equipment. Canes and walkers improve stability through a lever arm that can share the body's weight between the leg and device, keep the pelvis level during stance on the weak leg, and generate a moment to assist the hip abductors and reduce loading on the knee. Devices must be fitted properly. For example, handgrips should be at a height that allows about 20-30 degrees of elbow flexion. The cane should swing forward with the involved limb and bear most weight during stance on that leg.

Light and very light wheelchairs must be fitted with at least a dozen characteristics in mind (Table 54.2). Severe spasticity, poor head or trunk control, the amount of upper extremity function, and the type of work and sports engaged in necessitate additional modifications. Motorized wheelchairs can be maneuvered by joystick switches and chin or sip-and-puff mouth controls. The high cost of custom-designed wheelchairs means that therapists, vendors, patients, and families need to work together to obtain what is most apptoptiate.

Occupational Therapist

Occupational therapists (OTs) facilitate the practical management of disability. The philosophical foundation of occupational therapy is that purposeful activity helps prevent and remediate dysfunction and elicits maximum adaptation. These goal-oriented tasks are meant to be culturally meaningful and important to the needs of clients and their families. Activities include daily life and work skills, exercise, recreation, and crafts. Occupational therapy is also concerned with improving the patient's interaction with the environment and maximizing the patient's role in society in terms of relationships, occupation, and personal standing. The OT implements a program to enable patients to leatn or relcarn specific activities, develop new or compensatory skills, adapt their behavior to what is feasible, make adjustments to increase the accessibility of their environment, and perform leisure activities.

A ptogram may include the use of appliances (Table 54.3) to improve independence, ranging from simple devices (e.g., a thickened gtip to better grasp cutlery or

  - Book holder; page turner (electronic or by a mouth stick)
  - Holder for one-handed cutting
  - Long-reach jaw grabbers

a pen) to complex ones (e.g., use of an environmental control unit). Hemicuff and Bobath slings are used to reduce shoulder subluxation and prevent pain (Figure 54.3), A balanced forearm orthosis supports the upper arm and allows a modest activation at the shoulder or elbow to swing the arm over a table, which may be especially effective for the patient with a C5 level SCI. Figures 54.4 and 54.5 show standing devices that allow subjects to do some tasks upright while they load joints to lessen the likelihood of developing contractures in hypertonic legs.

For patients with stroke and brain injury, OTs work closely with the neuropsychologist to address visuospatial inattention, memory loss, apraxia, difficulties in problem solving, and the skills needed to return these patients to school or employment. Many OTs manage dysphagia and interpret modified barium swallow (MBS) studies.

Task-oriented and motor learning strategies have gained attention in formal occupational therapy research. Using this approach, the OT presents activities in a way that elicits the retention and transfer of particular skills for use in a functional setting. For example, in one study, limb kinematics improved in normal and hemiparetic subjects when training included purposeful goals with objects of interest. Thus practice in object-related tasks, rather than simple repetition of reaching and grasping items that bear no significance to a person, may provide more concrete sensory information and offer rewards that motivate performance.

Speech and Cognitive Therapist

Speech and language therapists are trained in all aspects of communication, including phonetics and linguistics, audiology, and developmental psychology, and provide expertise in the investigation and management of

FIGURE 54.3 A cuff support to prevent pain and lessen the subluxation of die glcnohumeral shoulder joint in a patient with left hemiplegia sifter stroke.

FIGURE 54.4 This fabricated ankle-foot orthosis is designed for ankle and knee control of a hemiparetie patient who has minimal hypcrtonicity. A wider lateral flange and Velcro straps across the trout ot tin- ankle would provide greater ankle control,

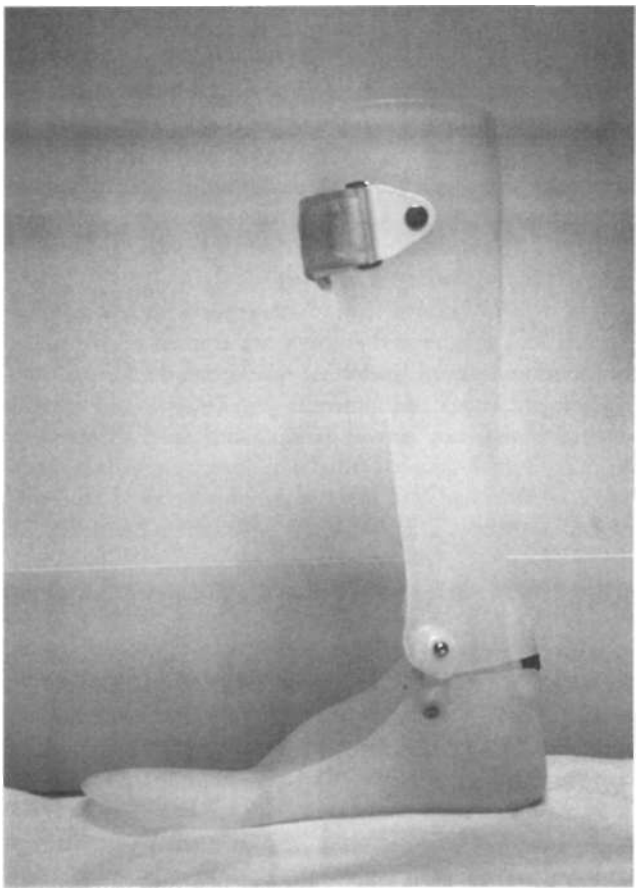

FIGURE 54.5 This thermoplastic orthotic includes a hinged ankle with a stop to allow about 5 degrees of dorsiflexion when the subject goes from sitting to standing and in portions of the srimce prme.

dysphagia. The therapists treat primarily patients with dysarthria and aphasia.

Therapies to improve the patient's speech intelligibility, volume, and fluidity include exercises of affected structures. For example, patients may be trained to slow their articulation, use shorter sentences, maximize breath support, extend jaw motion, and purposefully place the tongue or exaggerate articulatory movements. Therapists advise patients, relatives, and staff and recommend appropriate communication aids when necessary. They also provide assessment and guidance for those with swallowing difficulties; assessment includes the MBS with videofluoroscopy.

Treatment for aphasia is based on the clinical evaluation of the patient's cognitive and linguistic assets and deficits. The thetapy plan is fine-tuned by standardized language and neuropsychological tests, knowledge of the cortical and subcortical structures damaged, and the ongoing response to specific therapies. Speech therapists attempt to circumvent, deblock, or help the patient compensate for defective language behaviors. Stimulation-facilitation approaches are the most common (Table 54.4). Interventions for specific syndromes are applied as appropriate, For example, melodic intonation therapy is a

Table 54.4: Stimulation-facilitation approaches for aphasia therapy

Gestural expression and pointing
Word to picture matching
Yes-no response reliability
Oral-motor imitation
Phoneme, then word repetition
Verbal cueing for words and sentence completion
Contextual cueing
Phonemic and semantic word retrieval strategies
Priming for responses
Auditory processing at the phrase, then sentence level
Word-, phrase-, then sentence-level reading
Melodic stimulation

well-defined treatment for Broca's aphasia, in which patients have sparse or stereotyped speech and good auditory comprehension. Therapists and patients melodically intone multisyllabic words and commonly used short phrases while the therapist taps the patient's left hand to mark each syllable, Words are spoken with an exaggerated prosody that includes high and low pitches at short and longer durations. Gradually, the continuous voicing and rapping arc withdrawn. A positron-emission tomography **(PET)** study showed that the technique induces a systematic change in how the acoustic features of spoken and perceived speech are engaged by the brain after a left hemispheric stroke. Views on the value of speech therapy for aphasia vary. Most randomized controlled trials demonstrate a significant benefit.

Recreational Therapist

These therapists involve patients on an inpatient unit in group games, crafts, cooking, playing with pets, and other activities to help them socialize, practice skills, and enjoy the physical and emotional value of recreation despite new disabilities. In addition, the recreational therapist joins with the PTs and OTs to teach patients how to reintegrate into the home and community. Outpatient recreational activities carried out in a wheelchair or one-handed also foster socialization and fitness. More than 200 local, national, and international organizations have developed rules and equipment for at least 75 sports and recrearional activities that take into account a range of functional abilities.

Psychologist

Neuropsychologists with skills in clinical psychology help to define and manage cognitive impairments and mood and behavioral disorders. Detailed psychometric testing is

fundamental to establishing a rehabilitation program for a patient with cognitive impairment. The neuropsychologist often takes the lead in the management of sevetc brain injury resulting from trauma ot sttoke and plays an important tolc in counseling patients, caregivers, and staff. When working with patients after TBI, the neuropsychologist establishes operant conditioning patadigms or a token economy to reinforce appropriate social interactions and learning. The neuropsychologist also develops relaxation techniques for anxiety states and behavioral approaches for chronic pain management.

Social Worker

Social workers deal with the psychosocial aspects of disability and provide counseling and often brief psychotherapy. Their concerns extend to the ability of the patient and family to cope with disability in and out of the hospital. They play a key role in apprising the rehabilitation team about family issues, supports needed by the disabled patient, and appropriate care providers in the community. The close interactions of social workcts and patients or caregivers often provide great insighi into the dynamics of family involvement and the adequacy of resources. They act as a liaison to a wide range of agencies and to case managers from insurance companies. Smooth discharge planning from an inpatient service usually includes their assistance.

Ortbotist

Expertise in the manufacture, selection, and application of orthotic devices is another key component of a rehabilitation service. The PT or OT works with an otthotist to select external devices that apply or remove forces to ot from the body in a controlled manner. Although many orthotic devices are mass-produced, the expertise of a trained orthotist is often invaluable in choosing and constructing orthoses and supervising theit fitting and adjustment. Orthoses include ankle and ankle-knee braces, hand and shoulder splints, spinal braces, collars, and corsets. Materials are most often a type of plastic, but leathet and metals may be used, depending on mechanical needs. The effects of pressure, shear forces, and heat retention with sweating must also be considered to protect the skin.

With shortened inpatient stays, ankle-foot orthoses (AFOs) that fit inside a shoe tend to be used eatly to achieve ambulation in patients with a central or peripheral lesion. Observation of gait usually is enough to determine the need for a trial with an AFO. Indications include inadequate dorsiflexion for initial heel contact or for toe clearance during midswing, excessive hip-hiking during swing, media I-lateral subtalar instability during stance, tibial instability during stance, uncontrolled foot placement caused by sensory loss, and an operative heel cotd lengthening. If the knee of the hemiplegic buckles during stance, angling the AFO in slight plantatflcxion will extend the knee catlicr. Dorsiflcxing the AFO by 5 degrees can decrease knee hyperextension and help prevent the snapping back that causes instability and pain in midstance. Ankle inversion may necessitate greater rigidity and longer anterior foot trim. Figure 54.4 shows a thermoplastic AFO that fits in a shoe to limit plantar flexion and rotation and help control the knee. Orthoses may be static, such as a rest splint worn at night, or dynamic with joints that may be lockable or free moving. Figure 54.5 shows a thermoplastic AFO with a hinged joint that allows some flexibility when a patient goes to stand, and some give at heel strike to start the stance phase of the gait cycle. Toe clawing can be managed with a metatarsal pad that spreads the toes. The ankle can be articulated with a stop that permits greater flexion during stance. The brace can also be spring loaded for dorsiflexion of a drop foot in eatly stance.

A metal double-upright brace can offer greater rigidity for mediolateral instability and allows more versatility in adjustments for the amount of plantar and dorsiflexion but can be more expensive, too heavy, and cosmetically unappealing to the hemiplegic patient. Metal bracing systems are used more often by select subjects with pataplcgia from spinal injuries and in those with polio. Lightweight plastic knee-ankle-foot orthoses (KAFOs) with locking metal knee joints can also assist patients with profound polyneuropathy, muscular dystrophy, meningomyelocele, or SCI. Reciprocal gait orthoses (RGOs) with wire cables that link flexion of one hip to extension of the opposite hip are available for paraplegics. Short-distance ambulation for exercise can also be aided in the patient with SCI by vatiations on a KAFO and other devices. Bracing in people with SCI has been combined with FES to improve stepping and decrease its energy cost.

The thoracolumbar support shown in Figure 54.6 was molded to the patient to lessen neck motion after a high thoracic vertebral injury and surgical stabilization. Static orthoses allow no motion of the primary joint. Solid wrist-hand orthoses usually are set between neutral and 30 degrees of extension. Dynamic orthoses use elastic, wire or powered levers that compensate for weakness or an imbalance in strength and allow some controlled movement, Figure 54.7 shows the paretic left hand of a patient with a C6 SCI holding a card with the aid of a thumb opposition splint. The weaker right hand needs wrist extension to mechanically oppose the thumb to the second and third digits. Such custom-made devices can be produced with lightweight metals and plastics.

Process of Rehabilitation

Assessment

The quality of cate is only as good as the assessment on which it is based, particularly in relation to the complex difficulties encountered by patients with neurological

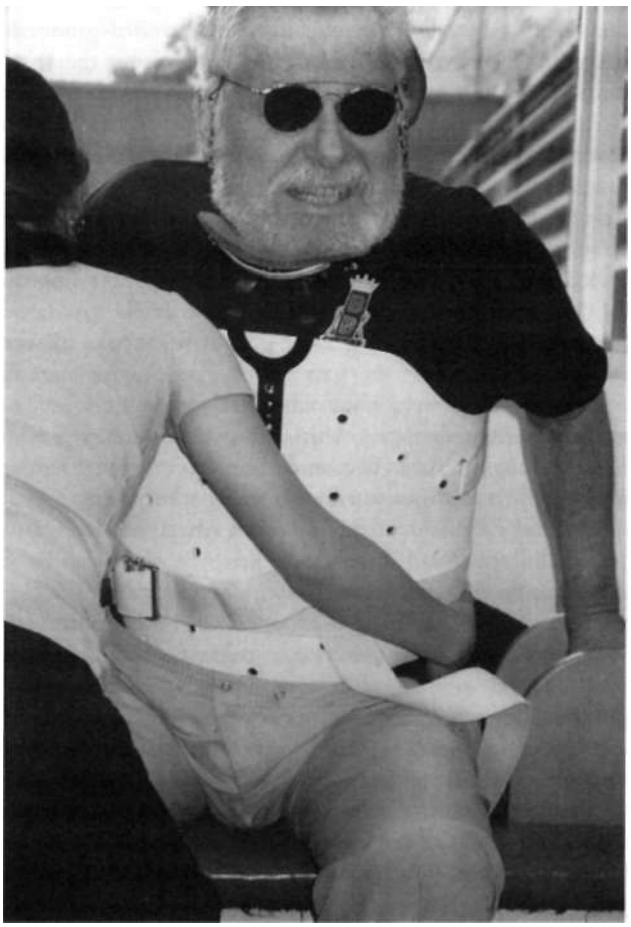

FIGURE 54.6 Tins thoracolumbar support orthotic was molded to the patient's chest to limit upper thoracic vertebral motion after a high spinal cord injury and surgical fusion. The chin brace and stiffness of the jacket limit early progress in mobility tasks for transfers. The riser grips he holds make it easier to practice pushing down into the mat to raise his buttocks.

disability. Accurate assessment means getting to the bottom of the mechanisms behind problems that affect patient functioning. It is the only sound basis for care plans, individual treatment, and effective advice. Assessment incorporates analysis, synthesis, and evaluation. Neurorehabilitation assessment involves identifying the most productive focus for interventions and the most appropriate setting in which they can be achieved and predicting anticipated outcomes and time frames. Assessment in neurorehabilitation may also be described as formative, that is, an ongoing process to target and develop appropriate interventions. In this respect the rehabilitation process is unusual in that assessment and treatment are an integral process: Assessmenr initiates a treatment program that i[1]- continually revised in li^ht ot successive assessments.

duiit Selling

An expert assessment should provide sufficient information to allow a reasonably accurate prediction of the potential

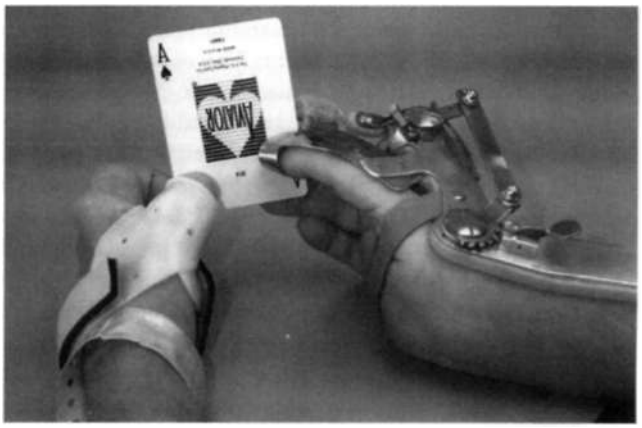

FIGURE 54.7 This card-playing patient with a C6 spinal cord injury uses a molded thumb opposition splint to pinch better with the right hand and a lightweight metal tenodesis orthotic that pinches the thumb to the next two fingers when he dorsiflexes his wrist.

outcome for the patient after a course of rehabilitation. Both short-term and long-term goals take into account the amount of likely neurological recovery and the amount of residual disability. The long-term goal must be broken down into logical, measurable steps that move steadily toward the final outcome. Goal-setting serves as an encouragement ro the patient as the short term goals are achieved, as a way to monitor rehabilitation, and as a way to identify newly emerging problems. Short-term goals must be relevant and motivating, express explicitly what is to be accomplished, and be functional, attainable, realistic, and measurable. They should be discussed with the patient and agreed upon.

Evaluation: What to Measure in Neurological Rehabilitation

In the past decade there has been a major increase in inrerest in outcome measurement as a method of demonstrating the effectiveness of an intervention, an essential prerequisite for evidence-based clinical decision making. What is especially important to measure, and how are these measures taken?

Measures

What to measure depends on the clinical setting and must be based on the anticipated effect of the intervention. Crude, quantitative clinical endpoints such as mortality and survival duration may be important in evaluating early interventions in acute spina! cord or brain injury and stroke but would tell little about disability and quality of life of survivors. For progressive neurological disorders such as Parkinson's disease or MS, qualitative measures are far more valuable for testing interventions than mortality rates.

To provide a comprehensive assessment of the impact of disease, outcomes may be considered at four levels:

- Pathophysiological parameters of disease such as magnetic resonance imaging, PET, and transcranial magnetic stimulation
- Crude clinical endpoints such as relapse rate in MS, seizure frequency in epilepsy, and mortality in stroke
- Relevant aspects of health status, such as disability
- Health-related quality of life

Each of these levels addresses distinct aspects of the disease process. The relationships between them are complex, The first two levels entail physician-oriented outcomes, whereas those at the third and fourth levels are more accurately called patient-based outcomes, although only the fourth incorporates the patient's perspective. Rehabilitation is especially interested in measures of the impact of disease, which is contained within the World Health Organization (WHO) International Classification of Impairments, Disabilities and Handicap. As shown in Table 54.5, the focus is on the consequences of the disease or health condition rathet than the disease alone (i.e., a classification of disablements and functioning). A classification available on the WHO Web site (www.who.int/icidh/) examines activities that disabled people can and cannot do and indicates whether people actually perform these activities. The dimensions of the WHO classification also include personal and environmental factors that affect functioning. The emphasis on activities, participation, and contextual factors interacting with impairments and disabilities may influence the design of new measurement tools.

Two types of measures exist for each of these domains: measures that arc specific to a given disease and generic ones that may, with caution, be applied across a range of diseases (sec Table 54.5). The former may be more sensitive in detecting changes particular to the effects of an individual disease, whereas the latter may allow comparisons across different diseases and serve as an off-the-shelf tool. Examples of generic measures of disability include the 10-item Barthel Index (BI), which can be totaled to a maximum score of 20 or 100 (Table 54,6), and the 18-item Functional Independence Measute (FIM), which includes a modestly responsive cognitive component for a total of 126 points (Tables 54.7 and 54.8). The FIM is used more often in America than in Europe or Asia. Although it has been applied to many neurological diseases, more than a few investigators have questioned this applicability. The FIM and BI and two other scales (Tables 54.9 and 54.10) are commonly used in clinical trials. They correlate closely with each other. In many respects, they reflect the burden of care needed by patients. These and most scales have floor or ceiling effects, dubious meaning when applied to a

Table 54.5; World Health Organization system of classification

		Exemplar outcome measures	
Term	*Definition*	*General*	*Disease specific*

10. Controlling bladder	5	10

disease for which no validity and reliability data have been obtained, and variable sensitivity to change, especially when used during outpatient care. Useful measures with an assessment of their applicability for neurological rehabilitation can be found (Dobkin 2003).

How to Measure

Irrespective of what is to be measured, two essential issues must be addressed if the data are to be clinically meaningful. The outcome measure must be clinically useful and scientifically sound.

Clinical Usefulness. Factors that determine whether an instrument can be successfully incorporated into clinical practice and is appropriate to the study sample are the method of administration, appropriateness, user acceptability, and score distributions. The most widely used methods of administration are patient completion (Medical Outcome Study 36 Item Shore Form [SF-36] Survey;

Table 54.7: Functional Independence Measure (FIM)

Items
Self-care
- Eating
- Grooming
- Bathing
- Dressing upper body

- Memory

Burden of Care Rating
7 = Complete independence (timely, safely)
6 = Modified independence (device)
5 = Supervision
4 = Minimal assistance (subject = 75% +)
3 = Moderate assistance (subject = 50% +)
2 = Maximal assistance (subject = 25% +)
1 = Total assistance (subject = 0% +)

Table 54.8: Description of functional independence measure levels of function

Independent
Another person is not needed for the activity (no helper).
7. Complete independence: All tasks desctibed as making up the activity typically are performed safely without modification, assistive devices, or aids and within a reasonable time.
6. Modified independence: The activity involves one or more of the following: an assistive device is needed, more than a reasonable time is needed, or there are safety (risk) considerations.

Dependent
Another person is needed for supervision or physical assistance for the activity to be performed, or it is not performed (requires helper).

Modified Dependence: The patient expends half (50%) or more of the effort. The levels of assistance needed are the following:
5. Supervision or setup: The patient needs no more help than standby assistance, cueing, or coaxing, without physical contact, or the helper sets up needed items or applies orthoses.
4. Minimal contact assistance: With physical contact, the patient needs no more help than touching and expends 75% or more of the effort.
3. Moderate assistance: The patient needs no more help than touching or expends half (50%) or more {up to 75%) of the effort.

Complete Dependence: The patient expends less than 50% of the effort. Maximal or total assistance is needed, or the activity is not performed. The levels of assistance needed are the following:
2. Maximal assistance: The patient expends less than 50% of the effort but at least 25%.
1. Total assistance: The patient expends less than 2.5% of the effort.

Table 54.9: Glasgow outcome scale

Score	*Outcome*
1	Death
2	Vegetative: unresponsive and speechless
3	Severe disability: dependent on others for all or part of care or supervision because of mental or physical disability
4	Moderate disability: disabled but independent in activities of daily living and community
5	Good recovery: resumption of normal life; may have minor neurological or psychological deficits

Ware et al. 1993), interview rating {standard neuropsychological testing), behavioral observation (BI), examination rating (Ashworth Scale), and raring by team consensus by trained observers (FIM). The method of administration has important implications for the design of clinical studies and for cost.

Appropriareness of a measurement tool takes into account the anticipated effect of the intervention and of the patient population, including factors such as disease type and severity. Considering the area of neurorchabilitation, it may be anticipated that intervention will result in change in disability and health-related quality of life, and have an impact on mood, emotional well-being, coping skills, and self-efficacy. Each of these outcomes may need to be measured because they may change independently of each other; that is, a rehabilitation intervention may have a different effect on disability than on general well-being or affect mobility but not disabilities related to functional use of the upper extremities.

User acceptability is equally important. If an instrument is to be clinically useful and acceptable so it can be incorporated into daily practices, it must be brief, user friendly, practical to administer, and cost-effective. Unwieldy, time-consuming, or re source-heavy instruments have limited use in clinical practice.

Finally, if an instrument is to be a useful measure of an attribute such as disability, it must adequately represent the true distribution of that attribute in the study, must discriminate between individuals in the study sample, and must detect change in the attribute being measured. These issues can be addressed by examining the score distribution in the sample of interest, that is the range of scores, mean score and standard deviation, and floor and ceiling effects. Ideally, the range of the sample should approximate the possible range of the scale, and the mean score should be near the midpoint of the possible scale range. Floor and ceiling effects are calculated as the percentage of subjects scoring the minimum and maximum possible scores, respectively, and should not exceed 15%. Higher deviations may compromise the sensitivity of an instrument to detect change in the attribute being measured.

Table 54.10: The Rankin Disability Scale

Score	*Disability*
1	No disability
2	Slight disability: unable to carry out some previous activities but looks after own affairs without assistance
3	Moderate disability: needs some help but walks without assistance
4	Moderately severe disability: unable to walk and do bodily care without help
5	Severe disability: bedridden, incontinent; constant nursing care needed

Scientific Soundness. Clinical usefulness docs not guarantee scientific soundness in terms of rigorous measurement. The outcome measure must contain three essential and intimately related scientific properties: reliability, validity, and responsiveness. A reliable measure produces results that are accurare, consistent, stable over time, and reproducible. The purpose of reliability testing is to determine the extent to which random measurement error is present. Random error includes all chance factors of produced variations on repeated measurement. The potential sources of random error include errors in the measure itself, the person doing the measuring, and the person being measured. Measures have four types of reliability: internal consistency, test-retest, interrater and intraratcr reliability, and parallel test forms. Reliability is also necessary for an instrument to be valid.

Validity concerns the relationship between the concept being measured and the instrument being used to assess that concept. It is broadly defined as the extent to which the instrument measures the concept it purports or is intended to measure. Three rypes of evidence support validity: content related, criterion related, and construct related.

Responsiveness is the ability of an instrument to measure clinically important change and change over time. It is essential in evaluating the relative benefits of differing interventions. Sensitivity to change is particularly important when treatments are associated with small but significant differences that may be undetected by insensitive measures. Responsiveness often is reported in the form of an effect size that is most commonly defined as the mean change score divided by the standard deviation of the baseline score.

Measures and Designs for Clinical Trials

Rehabilitation interventions have been slow to conform to scientifically designed clinical trials. Although general rehabilitation has been the subject of trials in patients with stroke, MS, aphasia, and other diseases and disabilities, trials are especially needed to assess a particular intervention for subjects with a particular set of disabilities **that** are the target of the well-defined intervention. Physical interventions arc far more difficult to provide in a

reproducible fashion than drug therapies. Outcome measures are also less easy to develop and apply when the primary outcome is levels of disability or of a specific disability rather then outcomes such as mortality, morbidity, survival time, or subjects who survive without disability, which are typical measures of drug and surgical studies. Ongoing multicenter randomized trials of locomotor training with body weight support for acute SCI and of constraint-induced movement therapy for patients with subacute stroke will help determine the feasibility of complicated but defined physical treatment strategies provided by many therapists. A variety of designs for rehabilitation studies have been summarized (Dobkin 2003).

General Organization for Neurorehahilitation

Rehabilitation is a complex, multifaceted entity in that it attempts to address a wide range of needs across diverse conditions and involves multiple disciplines that must interact effectively if the outcome is to be optimal. Such complexity requires a clearly articulated structure supported by appropriate documentation.

The development of a comprehensive, shared system of documentation that reflects the process of the rehabilitation unit's activity from initial assessment to discharge can provide clear evidence of unit practice and reflect its underlying philosophy about patient care and team work. From this commonly agreed baseline, proposed innovations can be analyzed in terms of their relative value and how they may affect other aspects of unit activity. If the documentation is regularly reviewed and accurately reflects current practice, new staff from all disciplines can quickly orient themselves to the agreed system without relying on subjective interpretations of routine. A comprehensive system of unit documentation may include integrated care pathways or the latest version of inpatient rehabilitation payment created for Medicare in the United States. An integrated pathway details the expected interventions occurring during a given episode of clinical care. Departures from the expected pathway are documented, coded, and analyzed after an agreed number of patients have been through the pathway. This identifies areas in the service that need improvement. In addition to documenting the process of care, rehabilitation pathways incorporate the long-term and short-term goals that form rhe basis of most rehabiliration programs. This audit can have a reciprocal role in describing, guiding, and promoting effective unit practice.

Service Provision

The way in which services are organized depends to some extent on the disease being managed. The most fundamental differentiation is between acute events such as brain and spinal cord trauma and stroke, mostly static conditions in which disability might increase with aging and overuse of muscles and joints such as cerebral **palsy** and polio, and progressive disorders such as MS and Parkinson's disease. Service provision should also be driven by the acknowledged philosophy underlying rehabilitation: to optimize home and community activities and return the patient to the community as soon as possible. The speed with which this is done depends as much on the services available in the community as on the severity of the disability and the capacity of the family and caregivers to look after the patient. Some tension arises between inpatient services, in which all the necessary ingredients may be gathered under one roof, and community services, which may be less centralized but support patients in their own environment. More important is the smooth interface between these two settings,

Inpatient Rehabilitation Unit. The most efficient rehabilitation setting is an inpatient unit designed and staffed specifically for this purpose. The value of such dedicated units was first appreciated in the acute management of SCI by Sir laid wig Guttman after World War II and has been applied to other diseases such as polio after epidemics. The benefits of acute units in stroke management have been convincingly demonstrated. Patients treated in stroke units are significantly less likely to die than those cared for on ordinary wards. Death, institutionalization, and dependency are all significantly less common in stroke unit patients, in part because of a reduction in secondary complications of stroke and a milieu dedicated to managing disability. Parly functionally oriented therapies by an organized team tend to get patients independent enough to return home sooner than sporadic therapy that does not articulate specific attainable goals for mobility, self-care, and family training. These benefits persist for up to 5 years after discharge and improve quality of life (Jorgensen et al. 2000).

Several studies of TBI suggest the benefit of coordinated care starting during the inpatient stay. Investigators randomly assigned 120 active-duty military personnel who suffered moderate TBI to a standardized, inpatient milieu-based cognitive rehabilitation program or to a home program with weekly phone support from a nurse and mental and physical exercises carried out on their own for about 30 minutes a day (Salazar et al. 2000). The inpatient program used both a didactic cognitive and functional experiential approaches. Treatment lasted 8 weeks. Outcomes did not differ 1 year later in standard cognitive tests, social adaptation, mood, behavior, or fitness for military duty. More than 90% returned to work. Aggression increased in both groups, suggesting the need for ongoing support.

The role of inpatient rehabilitation units in managing progressive conditions such as MS and Parkinson's disease is much less well defined, although some evidence suggests

a benefit in progressive MS. Inpatient care may also return patients home at a higher level of functioning after implantation of a deep brain stimulator for Parkinson's disease or after an exacerbation of walking disability caused by a hip fracture in a patient with a chronic hemiparesis.

Community Setting. Although community-based rehabilitation is often mentioned and appears to have a number of advantages from the perspective of the disabled patient, few studies have addressed its efficacy. This may relate at least in part to the methodological difficulties in defining the training team's level of expertise, the patient's level of disability, and the frequency, duration, and type of therapy. One large randomized trial compared rehabilitation at home after an average 12-day inpatient stay with another week of inpatient care followed by hospital-based outpatient treatment. Patients who lived alone were independent in transfers when they left the hospital, or they needed to be assisted by a caregiver. Similar outcomes 12 months after a stroke were achieved at lower cost because of less use of hospital beds by the early discharge group. An intention-to-treat randomized trial with 250 subjects showed that rehabilitation in an inpatient unit after a brief stay in an acute stroke unit or general medical ward produced better outcomes in moderate to severely disabled patients (BI score <50) compared with rehabilitation treatment in the community. No differences in quality of life were found, and levels of activity outside the home were not measured. Smaller trials confirm similar positive outcomes at 3-6 months for home compared with various forms of outpatient care, with the home group having fewer in-hospital days and greater gains in instrumental ADLs.

A day treatment program for about 100 patients who were unable to work 1-2 years after TBI provided a range of interventions during group therapy for a mean of 190 days. The investigators found a significant reduction in physical disability, increased self-awareness and emotional self-regulation, and more effective participation in interpersonal activities. One year after completion, 72% lived independently and 57% were employed.

A brief stint of outpatient therapy for a well-defined goal, such as to improve transfers in a patient who declines from MS or to make walking safe again after an illness that causes dcconditioning in a patient with chronic hemiparesis, is an invaluable means for patients to maintain their highest level of independence. A few therapy sessions a week for a few weeks plus a home program accomplishes this limited task-specific goal and relieves caregivers of new burdens. For example, a bout of therapy for aerobic conditioning and muscle strengthening lessened disability in patients with chronic stroke. A randomized trial entered 110 patients with mostly chronic TBI to an outreach program in rhe community or to provision of written material about resources for patients and families (Powell ct al. 2002). The outreach group met about twice a week for a mean of 27 weeks. The outreach group made modest but significant gains in scores on the BI and a brain injury outcome measure 2 years after the start of this late intervention,

Organization of Services

The most efficient structure for rehabilitation services in many countries includes a two-tiered system of service delivery. Regional specialists can manage complex and profound disabilities, and local community services provide neurological disability teams from local hospitals or directly in the community. Regional neurological rehabilitation centers provide experts familiar with the management of complex and severe disabilities, act as a focus for education, training, and research, and should be linked to university teaching centers. Such centers can offer care for patients with high SCIs and severe traumatic brain injuries, manage specialized orthopedic and plastic surgery procedures, and provide wheelchair and special seating needs, custom orthotics and prosthetics, rehabilitation engineering, functional electrical stimulation devices for walking and upper extremity movement, neuroprostheses, communication aids and environmental controllers for quadriparetic patients, and driving assessments.

Most disability services can be provided locally, which is likely to be both cost efficient and effective. Services provided by a multidisciplinary neurological disability team based in a local hospital can develop community outreach into clinical centers and homes. Resources arc often not adequate for this approach, and in some situations serious consideration should be given to the community-based rehabilitation model developed by the WHO, which allows communities to develop their own support mechanisms for disabled people, often with locally trained workers supervised by qualified staff providing basic rehabilitation treatment and advice. Tclerchabilitation services may prove especially useful in supporting patients who live far from available services or are too disabled to leave the home.

Service for Chronic and Progressive Neurological Disorders

Rehabilitation services for patients with chronic or slowly progressive neurological disorders ofren are inadequate. Services must anticipate and manage exacerbations and worsening disability, support self-management, and keep the patient in the community, reducing the need for hospital or nursing home admissions. Services must meet a broad range of needs that change over time. Patients after stroke may develop a painful joint or hip fracture that causes walking skills to decline. A bout of locomotor retraining can reverse this disability. Patients with MS have increasing disability and handicap over three or four decades with

little effect on longevity. For patients with muscle disorders, peripheral neuropathies, motor neuron disease, and Parkinson's disease, close surveillance can anticipate and reduce the burden of these diseases through specific goal-oriented therapies, caregiver training, and assistive devices.

BIOLOGICAL BASES FOR REHABILITATIVE INTERVENTIONS

The potential to enhance neurological recovery by manipulating the biological adaptability of the brain and spinal cord has become relevant to clinical practice. Basic ncuroscience studies suggest that physical and pharmacological interventions, along with natural biological reactions to injury, could inhibit or enhance the restoration of motor and cognitive functions. Table 54.11 outlines some of the potential mechanisms that contribute to changes in impairments and disabilities. These arc not discrete mechanisms. They overlap and many depend on each other over varying intervals of time. In addition, biological therapeutic-approaches such as tissue implants may enhance these mechanisms when applied to human studies of recovery in the near future. These potential mechanisms, drawn mostly from in vitro and in vivo experiments with invertebrates and vertebrates, are the subject of much ongoing investigation. Although care must be taken in extrapolating from animal studies of recovery to their implications for human interventions , at least a few of these potential mechanisms suggest strategies that the rehabilitation team can use to improve outcomes.

Table 54.11: Mechanisms that may support recovery of function

Net work Plasticity
Recovery of neuronal excitability
Resolve cell and axon ionic dysequilibrium and conduction block
Resolve edema, resorb blood products
Reverse diaschisis
Increased activity in neurons adjacent to injured ones and in partially spared pathways
Representational adaptations in neuronal assemblies
Expansion of representational maps
Recruitment of cells not ordinarily involved in an activity
Recruitment of parallel and subcomponent pathways
Altered activity in distributed cortical and subcortical networks
Activation of pattern generators (e.g., for stepping)
Recruitment of networks not ordinarily involved in an activity
Modulation of excitability by neurotransmitters
Use of alternative behavioral strategies
Neuronal Plasticity
Altered efficacy of synaptic activity
Activity-dependent unmasking of previously ineffective synapses
Learning tied to activity-de pendent changes (e.g., long-term potentiation, long-term depression) in synaptic strength in perilnjury and remote regions
Increased neuronal responsiveness from denervation hypersensitivity
Delayed decline in number of neurons (e.g., from apoptosis)
Change in number or variety of receptors
Change in neurotransmitter release and uptake
Regeneration and sprouting from injured and uninjured axons and dendrites
Signaling gene expression for cell viability, growth, and remodeling proteins
Modulation by neurotrophic factors
Actions of chemoattractants and inhibitors in the milieu
Remyelination
Transsynaptic degeneration
Actions of neurotransmitters and neuromodulators on cell functions
Neurogenesis

Recovery of Neuronal Excitability

Reversal of toxic-metabolic insults to neurons, axons, and glia plays an early role in recovery of function. Recovery of impairments could be delayed until intracellular and extracellular edema, acidosis, and ion fluxes resolve and until protein synthesis restarts, the mass and toxic effects of blood from a hemorrhage lessen, and other cellular functions return to normal. Some of the gains in the first days to few weeks after TBI, SCI, and stroke seem related to these mechanisms. Acute medical interventions to spare the penumbra of hypometabolic tissue on the edge of an infarction have been a mainstay of approaches to neuroprotection in stroke. The extent of the recovery of penumbra! tissue has been correlated with recovery of hmcrion in patients after stroke. The surviving penumbra may be a substrate for long-term potentiation (LTP) and synaptogenesis, which predisposes it to activity-dependent learning and reorganization.

Remote effects of an injury, caused by a lack of transsynaptic activity along a neural pathway after one of its links has been damaged or by loss of modulation by noradrenergic, serotonergic, dopaminergic, or cholinergic neurotransmission, could also transiently limit recovery. This transsynaptic functional deactivation, called diaschisis, has been demonstrated in autoradiography and PET studies. After a thalamic infarct, for example, hypometabolism of frontoparietal cortex that had received input from this complex is often found, as is hypometaholism of the dorsolateral frontal cortex after a stroke in the caudate and anterior limb of the internal capsule. Although resolution of remote functional deactivation has been suggested as a mechanism of motor recovery in animal studies, human studies with functional imaging have not clearly revealed a relationship between the degree of impairment of recovery and regions of anatomically remote hypometabolism.

Activity in Partially Spared Pathways

Partial sparing of neuronal clusters, as in peri-infarct tissue, or in tracts such as the posterior limb of the internal capsule, probably would permit a lessening ot impairment and disability over days ro a few months after injury. Many experimental studies reveal that as little as 20% sparing can provide the minimal residual structure necessary for near-normal functioning. For example, symptoms of Parkinson's disease evolve after about 75% of dopamine-containing neurons have died, and locomotor function decompensates when 95% are lost. In a classic human study, Bucy relieved hemiballismus by incising a portion of the cerebral peduncle. Within 24 hours, the patient's flaccid hemiplegia began to improve. By 7 months, the patient plateaued with a very mild hemiparesis, independent gait, and the ability to hop on the contralateral leg. At autopsy only 17% of the axons in the medullary pyramid persisted, and an estimated 90% of precentral giant cells of Betz suffered retrograde degeneration.

Partial wallerian degeneration of the corticospinal tract can sometimes be seen on magnetic resonance imaging after stroke (Figure 54.8). By computed tomography, sparing of more than 60% of the cerebral peduncle, including the medial portion, predicts the recovery of a precision grip and, to a lesser degree, the force of the grip (Figure 54.8A). Greater sparing of the primary motor cortex (Ml) and less wallerian degeneration are associated with better hand function in studies that involved functional neuroimaging (Feydy et al. 2002). The typical hemiplegic posture of elbow, wrist, and finger flexion followed 60% shrinkage, which roughly corresponds to a loss of 88% of the descending fibers. Better motor and functional outcomes have also been associated with sparing of metabolic activity in the thalamic and basal ganglia-frontal network and with sparing of the basal ganglia ipsilateral to the stroke. About 20% sparing of the ventral or ventrolateral funiculi after SCI permits fair motor function, and *$5%* sparing of the dorsal funiculus allows appreciation of dorsal column sensory inputs.

FIGURE 54.8 Magnetic resonance imaging 6 months after a left hemisphere stroke reveals atrophy of the ipsilateral cerebral peduncle of about 40% compared with its homologous peduncle on the right and wallerian degeneration of the basis pontis involving a moderate amount of the corticospinal tract. After an initial hemiparesis, the patient was able to oppose his thumb to all fingers, use the hand in activities of daily living, and walk 50 feet in 14 seconds (normal) with minimal gait deviations. The imaging is consistent with enough pathway sparing to have allowed retraining of residual sensorimotor pathways for this functional gain.

The recovery of vision after an occipital stroke may depend on spared parts of the vision-associated areas of the cortex. Patients who recover from a hemianopsia tend to activate bilateral extrastriatal cortex during hemifield stimulation to the affected occipital lobe. Involvement of primary and extrastriatal cortex leaves a persistent field loss.

Residual neurons and axons of an injured tract may need rehabilitative training to help drive activity-dependent plasticity and permit success in carrying out tasks. When the number of corticospinal fibers that synapse with spinal motor pools is too small to generate adequate excitatory postsynaptic potentials, a descending volley will not excite the spinal neurons. Recovery of an adequate excitatory postsynaptic potential might follow practice that strengthens synaptic efficacy. Other contributors to spared pathway functioning brought on by relearning and associated adaptations include changes in ion channels, increased strength of output from undamaged cortical and brainstem neurons that also descend onto spinal neurons, dendritic sprouting, and uprcgulation of the number of motor neuron and interneuron excitatory receptors. In addition, the ipsilateral motor cortex, via the uncrossed ventral corticospinal tract, has often been invoked as a pathway that might provide some of this input and compensate for a contralateral cerebral injury. The fibers of the ventral tract synapse especially with motoneurons for axial and limb girdle muscles. Functional neuroimaging studies that involve training of the upper extremity, the leg for walking, and language after aphasia suggest that better gains are associated with greater contralateral cortical activation rather than with ipsilateral homologous regional activity.

Alternative Behavioral Strategies

Many functional activities can be accomplished without the use of an affected extremity. Behavioral adaptation and compensation often allow greater independence in ADLs

despite persistent impairments. Motor functions can appear to have fully recovered when in fact residual neural activity is supporting behavioral plasticity. For example, after a unilateral pyramidal lesion in the rodent or monkey, reaching for a pellet of food gradually improves and at first glance may appear to have recovered fully. A closer analysis of the movement reveals better control of the proximal than the distal limb. The animal reaches with a grasp, brings the pellet to its mouth without the normal supination of the hand and forearm, turns its head to chase after the food, and cannot easily release its grip. The hand-to-mouth movement pattern of the hemiparetic patient is similar to the lesioned animal's strategy. Functional ambulation often improves, in part, by compensatory gait deviations and with assistive devices. For example, most patients in rehabilitation who had a full middle cerebral artery distribution infarction cannot ambulate 150 feet independently by 6 months after stroke, but more than 75% can with assistance as defined by the BI. Behavioral plasticity itself has a neural substrate that includes training-induced cortical representational reorganization and increased efficiency of residual pathways.

Rehabilitation efforts often train patients to substitute for a lost motor function or to use compensatory movements to accomplish the movement. Alternative strategies, rather than real restitution, arc emphasized. With behavioral compensation, patients learn techniques to adapt ro their new sensory, motor, and cognitive impairments. 1 lowever, substitution may prevent the activity-dependent nervous system reorganization that is needed to encourage greater recovery of a specific impairment.

Distributed Networks

A distributed system is a collection of processing units (i.e., dynamic neuronal assemblies with similar functional properties and anatomic connections), that are spatially separate and exchange messages. Hierarchical, parallel, and quasiserial linking operations arc made with the afferent and efferent systems of the brain (Table 54,12). The nodes in such systems cooperate to manage the diverse information necessary for the rapid and highly flexible control of, for example, cognition and multijoint movements. These circuits lend themselves to an understanding of the neuroplasticity that might contribute to spontaneous and training-induced recovery of function.

Tahlc 54.12: Characteristics of distributed systems

Signal flow follows a number of pathways.
Action may be initiated at any of the modal loci in a system.
Local lesions in a system may degrade but not completely eliminate a function.
Dynamic reorganization may be more important than modification of structural connections.
In a reentrant system, nodes are open to externally and internally generated signals.

The executive motor system has been the subject of recovery-related studies. The primate primary motor cortex (Ml) has separate clusters of output neurons that can facilitate the activity of a single spinal motoneuron. Also, a single cortical motor neuron can project to the spinal motoneurons for several muscles, even those that might act across a joint. In addition, neurons in overlapping Ml territories are activated to produce movements of different body parts. This overlapping organization contributes to the control of the complex muscle synergies for voluntary movement of the arm and leg within the ordinary work-space of the body (Graziano et al. 2002). Multiple representations also have been demonstrated in non-primary motor regions. They are found in the premotor cortex of Brodmann's area (BA) 6, the supplementary motor area and immediately rostral to it, and in BA 23 and BA 24 by the cingulate sulcus. These motor regions have interrelated and overlapping functions with direct and indirect anatomical connections. Each area has an independent set of inputs from adjacent and remote regions, and most have parallel but separate outputs to the brain-stem and spinal cord. The effective unit of operation in such a distributed system is not a particular neuron and its axon but groups of cells with similar functional properties and anatomical connections,

The capacity of motor-related cortices to redistribute their function is apparent from PET and functional magnetic resonance imaging (fMRI) studies that have looked at subjects with recovered hand function after a stroke. For example, after a striatocapsular infarction in patients who recovered finger tapping and hand squeezing, bilateral rather than just contralateral activation of cortical motor neurons was found, along with greater involvement of motor areas that would not ordinarily be visibly activated for that task. Other regions related to selective attention and intention also show increases in blood flow and metabolism, which suggests that they must play a larger role when the substrates for a movement reorganize. Regions that are activated in normal subjects when greater force is exerted, such as insular, premotor, and anterior opercular cortex, may also be activated during movement of a hemiparetic limb (Dettmers et al. 1997), in parallel with the increased effort needed to move that some patients describe.

Parallel, segregated circuits process different variables for movement throughout their integrated pathways, as in the striatum, thalamus, and cerebellum. One study showed that the stimulus parameters in sensory cortex for producing LTP in the motor cortex were within the range of discharges of neurons in the sensory cortex when they respond to peripheral stimulation. The authors proposed that repeated practice of a particular movement increases the excitability of a selected group of terminals in the ventrolateral thalamus so that its untrained, diffuse input

becomes able, with training, to excite selected cortical efferent zones without further input from the sensory cortex. This helps explain how loop circuits form between the motor cortex and periphery, via the sensory cortex and thalamus. They hypothesized that circuits are initially diffuse, leading to excessive muscle contractions during a new movement, but become more specific as LTP is induced by practice. They also showed that repetitive activity of the pyramidal tract neurons in response to sensory input can produce LTP in spinal interneurons.

The cerebellum receives and modulates locomotor cycle-related signals. The neocerebellum monitors the outcome of every movement and optimizes movements using proprioceptive feedback. Given the great computational interest the cerebellum has in the details of afferent information from joints and muscles, rehabilitation therapies for walking and upper extremity actions should aim to provide this key motor center with the sensory feedback that the spinal cord and cerebellum recognize as typical of normal walking and reaching-related inputs. The motor functions that the cerebellar inputs and outputs attend to, such as timing and error correction for accuracy as the hand approaches an object, are especially important for patients to practice when a lesion undermines motor control. Thus individual channels can control separate functional units of motor cortex, and in turn each is independent in its control of subcortical motor nuclei. After an injury, the balance of activities of these networks is reset. Although these systems are not likely to be highly redundant, they may provide a partially reiterative capacity for some sparing or compensation after a sensorimotor network injury. The intact parallel systems from cortical and subcortical areas may partially compensate or substitute for nonfunctional ones when their activity is enhanced by specific cognitive and motor rehabilitative retraining. For example, if the premotor cortex were damaged, compromising visually cued movements, the patient might be taught to use an internally cued strategy mediated especially by the spared supplementary motor area.

The brainstem and spinal cord also contain important subcomponents of distributed motor functions. For example, they contain their own intrinsic networks tor aspects of locomotion. The descending message for the initiation of locomotion seems to be carried by reticulospinal pathways from dorsal areas of the midbrain and pons that synapse with lumbar spinal neurons. Although cortical and peripheral sensory input is essential for normal locomotion under disparate environmental conditions, the timing of synergist and antagonist muscle activity for stepping appears to be primarily the task of a self-oscillating lumbar interneuronal network. Even an isolated section of lumbar spinal cord in mammals can produce cyclical outputs that rhythmically flex and extend a joint. This locomotor circuit is called a central pattern generator and especially depends on glutamate and glycine for alternating excitation and inhibition.

After a complete lower thoracic spinal cord transection, adult cats and other mammals can be trained on a treadmill so that their paralyzed hindlimbs fully support their weight, to rhythmically step, and to increase their walking speed toward what a normal cat can do. Additional studies on adult spinal transected cats that were trained only to stand and then encouraged to step on a moving treadmill showed that postural support alone was detrimental to subsequent locomotion. Thus the details of basic locomotor movements can be carried out by subcomponent nodes of the more complex neural networks for stepping. Evidence of spinal cord learning during step training and by modulation of the H-reflex has been shown in patients with SCI. This activity-dependent plasticity has potential value in rehabilitation. Studies of patients with spinal injury and stroke have used body weight support and treadmill training to take advantage of residual descending controls and spinal mechanisms for stepping (Dobkin 1999).

Chemical and electrical microstimulation in the ventral gray matter of the spinal cord elicits a convergence of the leg from different starting positions to a single position in the body's workspace. In each volume of spinal cord studied, a discrete set of synergistic limb muscle contractions directs the limb toward an equilibrium point across a range of muscle forces. These modules of separable force fields have been called spmal primitives by Bizzi and colleagues (Bizzi et al. 2000). This intrinsic organizarion, combined with central pattern generators, may simplify the work of the supraspinal controllers for common movements such as the synergies that compose stepping. Given the synergies elicited by Ml and premoror cortical microstimulation (Graziano ct al. 2002), it seems likely that a modest amount of residual descending input to the cord from motor areas may be able to trigger spinal synergies for reaching and stepping movements. In addition, segmental sensory inputs to the spinal cord arc likely to be critical modulators of a spinal locomotor control system.

Studies with spinal transected cats and patients with a clinically complete SCI suggest that important sensory inputs associated with stepping include the rate and degtce of hip extension, the level of weight bearing, the timing of hip extension and unloading of the leg at the end of stance for the transition to swing, the increase in loading of the stance leg at onset of swing of the opposite leg, the intensity of practice, and treadmill speed (Dobkin 1999). Normal human walking with the entire ensemble of sensory inputs and descending inputs present may be less dependent on hip position and stance-to-swing group 1 afferent activity. However, proprioceptive feedback related to movement, especially from the lengthening antagonist muscle, is an important signal for the step cycle. Sensory inputs have task-specific effects as well. The same sensory input from the foot that increases hip and knee flexion if applied during the swing phase of the gait cycle increases activation of the extensor muscles if applied during the stance phase.

Therefore to retrain a patient to walk, strategies should be directed to incorporating optimal step-related sensory inputs.

Although we have emphasized aspects of motor recovery, both distributed and hierarchical organization and plasticity are jusr as evident for higher cortical functions. Cognitive domains appear to be mapped at multiple sites that arc highly connected with feedback connections. PET and fMRI studies have begun to reveal changes in the organization ot these interactions tor particular tasks after a cerebral injury. Cognitive rehabilitation strategics have been developed based on the notion that recovery might be mediated by tapping into the locali/.able and distributed grids ot connectivity that are intact.

Cortical and Subcortical Representational Adaptations

Cortical motor and sensory neurons are not permanently fixed in the way in which they subserve their limb functions. In the adult and developing animal and in humans, these representations are distributed, dynamic, .\m\ capable ot much physiological ..\m\ perhaps structural reorganization. Many lines of animal research suggest that compensation after a central or peripheral injury can result from a functional shift to neighboring neurons. As noted earlier, the neurons of the ischemic penumbra of an acute cerebral infarction may play an important role in functional gains. Very early overuse of these neurons was shown to cause greater injury in rat models of stroke and trauma. Such overuse is unlikely in human subjects, however. Indeed, early practice appears important. A primate model of a less than 1-rara injury to the hand area of Ml found that perilesional representations for the digits decreased when the monkey failed to practice using the hand to scoop pellets out of a narrow well. Neighboring representations for the digits, wrist, and forearm increased with practice. Thus cortical representational changes are especially likely to arise during training paradigms that involve learning and the acquisition of specific skills. This plasticity probably arises from the unmasking of previously silent synapses and increases in synaptic efficacy in thalamocortical and intracortical circuits. Over weeks and months, it might arise from sprouting of dendrites over short distances. In animal studies of recovcty of forclimb function, only 12 hours of a specific therapy for the affected limb leads to behavioral gains and cortical representational changes. In human subjects after stroke, representational plasticity for the ankle movers can be shown after intensive practice in step training in patients with chtonic hemiparesis, similar to the evolution of changes observed with massed practice in patients with upper extremity paresis.

The combination of mutable neuronal assemblies that represent movements and sensation and multiple representational maps in a parallel, distributed system offers the opportunity for exploration by those involved in rehabilitation. Behaviorally relevant tasks that arc shaped by an optimal schedule of practice and feedback on neural networks might increase functional gains. The optimal duration and intensity of training are uncettain for human rehabilitation strategies, but greater intensity of practice seems to enhance subsequent performance (Kwakkel et al. 1999; Sullivan et al. 2002}. Unfortunately, most patients get only a few months of formal inpatient and outpatient retraining of modest intensity that is spread across many tasks.

Biological Interventions

The molecular processes that are induced by activity in neurons, axons, and dendrites are under intense investigation, both during normal learning and after an injury. Morphological changes such as axonal regeneration over short distances, dendritic arborization, and synaptogenesis have been observed after a brain injury or SCI. When inputs from one pathway to the dendritic tree of a neuron are lost, intact axons can sprout and form synapses on denervated receptors. The net effect of this change in the weight ol inputs could have a positive or a detrimental effect on neural function. Can such changes be manipulated? Basic neuroscience studies of biological approaches offer some exciting approaches to complement ncurorehabilitation strategies.

Regeneration of injured axons in the central nervous system occurs over very short distances. It depends in part on molecules on the surface of cells and in the extracellular matrix. Tissue culture and vertebrate models have shown that substances in the extracellular matrix and on the surface of oligodendrocytes inhibit elongation of the axonal gtowth cone. Antibodies and receptor blockers have been made to these substances, including to the inhibitor Nogo, leading to growth of axons in the rat after a partial spinal and brain injuries, When they are combined with a growth factor, such as neurotrophin-3, axonal growth further improves. Neurotrophic factors have been used to protect neurons from apoptosis and to signal neuronal machinery to make the substances necessary for neurite outgrowth. Cultured Schwann cells, transplanted olfactory ensheathing cells, embryonic tissue implants, neurotrophic factors delivered by implanted, engineered fibroblasts, and peripheral nerve bridge implants, with a combination of other biological manipulations, have also met with some success in permitting several populations of axons to regenerate across or around a rodent SCI. Bone marrow stromal cells have been injected into the blood after experimental stroke and seem to produce a trophic factor or other support for enhancing plasticity. Cottical and subcortical transplants of stem cells, engineered cells, human embryonal cells that take on the characteristics of local neurons, and progenitor cells for neurons and glia have also been introduced into the brain to promote recovery in animal models.

Physical activity alone can regulate the expression of neurotrophic factors in the cortex and spinal cord and induce neurogenesis, especially in the hippocampus and spinal cord.

Reported cell transplant experiments in humans include numerous interventions for Parkinson's disease that have so far been unsuccessful, safety studies of implantation of a human cell line after chronic subcortical stroke, and embryonic tissue placed in the syrinx of patients with chronic SCI. Several safety studies have failed, including the use of porcine cells. Studies with neuronal and oligodendroglial progenitors arc promising but face many difficulties. A review of biological interventions for rehabilitation and the applicability of animal models to human translational tesearch suggests that clinicians will need to put models into perspective and participate with basic neuroscientists in combining training and transplant technologies (Dobkin2003).

Pharmacological Interventions

Drugs that affect neurotransmission, intracellular second messenger signaling, excitation and inhibition, and the cascades associated with long-term potentiation and long-term depression are candidates to enhance learning and the reacquisition of skills after a brain injury or SCI. At least five neurotransmitter projections have modulating effects on wide regions of the cortex and spinal cord. A lesion may transsynaptically interrupt this neurotransmitter output to cortex and cord, limiting the drive to uninjured regions and producing behavioral deficits. For example, dextroamphetamine augments specific cognitive processes by increasing the signal-to-noise ratio; cholinergic projections serve as a gate for behaviorally relevant sensory information. Animal studies have provided preliminary evidence that a vatiety of pharmacological agents may facilitate or inhibit the rate or degree of recovery of sensorimotor function and walking after a cerebral injury. After being given dextroamphetamine, both rats and cats that underwent a unilateral or bilateral ablation of the sensorimotor or frontal cortex exhibited an accelerated rate of recovery, though not necessarily greater gains than the controls, in the ability to walk across a beam. This endured well pasr the single or intermittent dosing schedule of the drug. Amphetamine and other drugs to be discussed have shown promise in small human trials. Thus specific training paradigms combined with agents might enhance gains. Functional imaging studies with transcranial magnetic stimulation (Boroojerdi et al. 2001) and fMRI may aid in rhe selection of drugs to combine with rehabilitation.

Some drugs have more clear-cut mechanisms of action, For example, the conduction of action potentials along demyelinated axons may be increased by pharmacological agents such as 4-aminopyndine, which block potassium channels and improve impulse conduction. This approach has met with some success in MS treatment. In some patients with motor neuron disease and Guillain-Barre syndrome, anticholinesterase-inhibiting medications, acting on neuromuscular junctions with altered structure and function, have reduced fatigability and improved strength in a modest way.

Drug studies in humans pose confounding problems. The type, location, extent, and age of the lesion and the specific drug, its dosage, time of initiation, duration of use, and adverse effects and the accompanying physical or cognitive therapy that might add to a drug's effect must be determined. What is clear is that clinicians should select medications with special care in the months after a cerebral injury and monitor for effects that seem to impede recovery.

NEUROMEDICAL PROBLEMS DURING REHABILITATION

Neurological and systemic complications often interfere with inpatient and outpatient rehabilitation. With shorter acute hospital and inpatient rehabilitation stays, physicians, nurses, and therapists must anticipate and treat medical problems. Some will arise from new neurological impairments and immobility; others are comorbid conditions that might have caused the acute illness. In addition, patients and caregivers must be trained in the errors of omission and commission and in the risk factors for recurrence of, say, a stroke that leads to late morbidity.

As noted, some but not all studies suggest that specialized stroke, SCI, and TBI hospital programs appear to lead to better early outcomes than does treatment on general medical units. Differences in morbidity, mortality, and length of hospital stay have been associated with more organized services. For example, protocols that use prophylactic subcutaneous heparin, hold oral intake until completion of a screening test for safety of swallowing, limit indwelling bladder catheters to those in coma, and assess posrvoid residuals by ulrrasound to avoid unnecessary intermittent catheterizations can reduce medical complications.

Frequency of Complications

Complications in Patients with Stroke

Medical complications often interfere with a patient's ability to participate in therapy (Table 54.13). About 4 medical and 0.6 neurological complications per patient occur during an average course of inpatient rehabilitation. About one third of patients have a urinary tract infection, urinary retention, musculoskeletal pain, or depression. Up to 20% fall, develop a rash, or need continuous management of blood pressure, hydration, nutrition, ot glucose levels. About 10% develop a transient toxic-metabolic

Table 54.13: General frequency of inpatient stroke rehabilitation neuromedical complications

Complication	*Percentage of patients*
Urinary tract infection	40
Musculoskeletal pain	*M)*
Depression	30
Urine retention	2^
hills	25

encephalopathy, pneumonia, cardiac arrhythmias, pressure sores, or thrombophlebitis. Up to 5% have a pulmonary embolus, seizures, gastrointestinal bleeding, heart failure, or other systemic complications. Where feasible, prophylactic measures for these potential problems are essential. Because many patients arc transferred from the acute hospital to a rehabilitation unit less than 10 days after a stroke, neuromedical complications may he higher at some centers and include the side effects of starting new medications during the acute stay and recurrent stroke. Across rehabilitation centers, 5-15% of patients must be transferred back to an acute hospital setting.

Complications in Patients with SCI

Medical complications of a somewhat different nature are common in the acute and chronic phases after SCI. In this younger group, chronic comorbid systemic medical problems are less common than in patients with stroke. However, prior substance abuse and emotional and behavioral disorders can complicate therapy. In the first 6 weeks aftet SCI, operative procedures affect what can be done in rehabilitation. About one half of patients get a spinal fusion and internal fixation. Acute spinal care also entails the use of externa) stabilization techniques, such as halo vest and Philadelphia collar for cervical injuries and a thermoplastic, custom molded brace for thoracolumbar

Table 54.14: Medical complications within 6 weeks of acute spinal cord Injury

Complication	*Percentage of patients*

fixation (see Figure 54.6). These devices limit head and trunk mobility, which makes self-care tasks that involve balance, management of the lower extremities, and CISC; more difficult. Lower extremity fractures, especially of the femur, occur in about 5% of patients with acute SCI, which could further limit mobility and increase the risk of deep vein thrombosis (DVT) and skin breakdown, 'fable 54.14 lists the complications found during a prospective clinical trial of methylprcdnisolone for acute SCI in 487 patients,

Early morbidity is greater with cervical and upper thoracic injuries and with complete lesions than with lower or incomplete lesions. Ventilatory dysfunction, aspiration, dysautonomia with upright hypotension or paroxysmal hypertension, a neurogenic bowel with impactions, a neurogenic bladder with retention and infections, a catabolic state, and gastric atony are especially likely to complicate early inpatient rehabilitation. Hypercalcuria or hypercalcemia related to immobilization may also necessitate therapy. Central and musculoskeletal pain and grief reactions warrant immediate attention,

Complications in Patients with TBI

Systemic and neurological complications are common after serious **TBI,** The older patient carries more systemic comorbidity, whereas the younger patient may have alcohol or drug abuse as a comorbidity. In addition to other bodily injuries and any of the complications that can accompany stroke and SCI, physicians must monitor for pituitary-hypothalamic dysfunction with endocrinopathies and disorders of homeostasis, salt-wasting and inappropriate secretion of antidiuretic hormone, cerebral hygromas, hydrocephalus, and the persistent vegetative state, Ventticular enlargement develops in .30-70% of patients with severe TBI. Most have hydrocephalus ex vacuo, which is passive enlargement of the ventricles from the loss of gray and white matter. In the patient with enlarging ventricles who reaches an early plateau or declines in mobility and cognition, symptomatic normal- or high-pressure hydrocephalus must be considered.

Table 54.15: Glasgow outcome scale classification for recovery of consciousness and function in adults in a persistent vegetative state (PVS) beyond 1 month

Outcome	*3 Months (%)*	6 *Months (%)*	*12 Months (%}*
Traumatic Brain Injury			
Death	15	24	r,
PVS	52	30	15
Conscious	33	46	52
Seven' disability	—	—	2S
Moderate disability	—	—	17
Good recovery	—	—	7
Nontraumatic Brain Injury			
Death	24	40	53
PVS	65	45	32
Conscious	11	15	15
Severe disability	—	—	11
Moderate disability	—	—	3
Good recovery	—	—	1

Patients who are in a persistent vegetative state often ate evaluated by the rehabilitation team for prognostication and for a trial of stimulation. After TBI, the prognosis is not quite as grim as aftct hypoxic-ischemic coma unless hypotension accompanied the TBI. Table 54.15 shows the outcomes during the first year after brain injury determined by a 1994 study of the Multi-Society Task Force on Petsistent Vegetative State.

Management of Ncuromedical Problems

Dysphagia

Neurogenic dysphagia is the potential cause of a pulmonary infection in any patient with stroke, TBI, motor neuron disease, MS, advanced Parkinson's disease, cervico-medullary disorders such as a syrinx, Guillain-Barre syndrome, myasthenia gravis, and most neuromuscular diseases. Indeed, swallowing disorders affect 10% of acutely hospitalized older adults and 30% of nursing home dwellers. Even transient dysphagia can lead to malnutrition, dehydration, aspiration pneumonia, and airway obstruction with asphyxiation. It increases the patient's risk of death and institutionalization.

The natural history of recovery from dysphagia after sttokc and TBI is good. For example, a Brirish study diagnosed dysphagia in 30% of 357 conscious patients within 48 hours of a unilateral hemispheric stroke; the patients wete rated as being impaired if swallowing was delayed or they coughed on 10 mL of watet. Lethargy, gaze paresis, and sensory inattention were present more often than in those who swallowed normally. By 1 week, 16% had dysphagia. At 1 month only 2% and at *6* months only 0.4% of survivors were still impaired.

Symptoms and signs that suggest a tisk of aspiration include lethargy, coughing or a hoarse and gurgly voice after feeding, slow eating or drinking (less than 10 mL per second of watet ftom a cup), dysphonia, and poor oropharyngeal movement. The limitations of bedside indicators have led to the use of the MBS with video-fluoroscopy as the method of choice to rule out silent aspiration. The telationship between small amounts of aspiration by MBS and clinical complications is moot, however, and requires clinical judgment. The MBS also visualizes the effects of dietary texture and compensatory techniques. In attentive sttoke rehabilitation inpatients, coughing or a wet-hoarse quality of the voice within 1 minute of continuously swallowing 90 mL of watet from a cup had a sensitivity of 80% and specificity of 54% for aspiration detected by an MBS study. The bedside test had a sensitivity of 88% and specificity of 44% fot large amounts of aspiration that may be clinically more significant.

Dysphagia management must be addressed through all phases of recovery from stroke and TBI and duting the progression of diseases such as Parkinson's, ALS, and myasthenia gtavis (see Chapter 13). Lesions in the pathways for swallowing interfere with the oral, oral preparatory, and reflex or pharyngeal phases of deglutition. The initial emphasis for care is placed on protecting the airway and maintaining adequate alimentation and hydration, using a nasopharyngeal feeding tube if necessary. Oral pooling of secretions and drooling that predispose to aspiration can be managed with a low, titrated dosage of an anticholinergic drug such as glycopyrrolate. Good oral hygiene and management of tooth caries by oral rinsing with chlorhcxidinc gluconate and stannous fluoride can lessen the likelihood of bacterial infection being carried into the lungs by otal secretions. Therapeutic efforts focus on the use of stimulation and compensatory approaches designed to reduce the swallowing impairment or to minimize the functional disability resulting from that impairment (Table 54.16). For example, postural adjustments may be made based on the MBS. A chin tuck narrows the airway opening, tilting the head to the stronger

Tabic 54.16: General therapies for dysphagia

Compensation	*Sensorimotor exercises*	*Direct interventions*
Head positioning	Oral sensory stimulation (thermal, vibration)	Palatal prosthesis
Chin tuck	Resistance and placement exercises of tongue and jaw	Surgery
Head rotation to weak pharyngeal side	Chewing, oral manipulation of bolus	Cricopharyngeal myotomy
Softer food	Laryngeal adduction	Epiglottopexy
Thicker liquids	Biofeedback	
Lower intake volume		
Slower intake pace		
Compensatory maneuvers		
Double swallow		
Supraglottic swallow		
Laryngeal elevation		

side of the pharynx directs a bolus away from the weak side, and head rotation inward the weak pharyngeal muscle channels a bolus toward the stronger side. Modification of diet texture includes thickened or gelled liquids that are less likely to be aspirated than thin liquids. Purees and formable solids such as applesauce or mashed potatoes usually are safer than foods requiring chewing and oral manipulation. Pharyngeal stimulation by the therapist may help drive representational plasticity for these muscles on the unaffected side of the brain after stroke to improve swallowing.

Gastrostomy, whether percutaneous endoscopic gastrostomy or a tube inserted radiologically, may not lessen the risk of reflux aspiration any more than a nasopharyngeal feeding tube for patients with persisting aphagia. A percutaneous endoscopic gasttostomy can be complicated b\ gastric pci'loration, peritonitis, hematoma, fistula formation with the lung, stomal infection, cellulitis, and bleeding at the insertion site. Jejunostomy may lessen the risk oi reflux Inn increase the risk ot the dumping s\ ndrome. Rarely, esophagosromy or pharyngostomy is better suited for the patient with neurological dysfunction and prior gastrointestinal disease or surgery. Clinical trials related to the efficacy of types of tube feedings and other interventions for dysphagia are monitored by the Cochrane Review (www.updatc-softwarc.com/cochranc.htm). Dysphagia therapies provided by the family under the guidance of a therapist may be as efficacious as hands-on therapy by a professional. With outpatient care, patients and family members assume greater responsibility for integrating and adapting recommended procedures to suit their individual needs and priorities.

Skin Ulcers,

Education in skin management during rehabilitation provides an important opportunity for preventing later morbidity and mortality. Ischemia of the skin and underlying tissues occurs particularly in weight-bearing areas adjacent to bony prominences. The American Model Systems data for patients admitted within 24 hours of traumatic SCI showed that 4% subsequently developed pressure sores and 13% of these were graded as severe. They occurred over the sacrum, heel, scapula, foot, and greater trochanter of the hip. Lower-grade skin lesions developed over the genitals. Sores related to sitting arc most often located over the ischial tuberosiries, where tissue pressure can exceed 300 mm Hg on an unpadded scat. A 2-inch-thick foam pad decreases the local pressure to 150 mm Hg. Even with the use of cushions designed to distribute weight-bearing skin surfaces, pressures in the sitting position are far above the 11- to 33-mm Hg pressures in the capillaries and venules. Raising the head of the bed by only a few inches especially increases shearing forces over the sacrum.

A standard classification for degrees of integument breakdown, prophylactic measures, and wound care is available from the Agency for Health Care Policy and Research in Washington, D.C. Rubor, induration, and blistering arc signs that precede a break in the skin. Pressure relief is the best approach, performed every half hour after a complete SCI and every 2 to 3 hours in patients with intact sensation after stroke or other disabling injuries. Patients must develop a skin care program based on their general health, nutrition, continence, the toughness of their skin, the most used positions, type of wheelchair seat, presence of old skin scars, and other factors.

DVT and Pulmonary Embolus

In controlled trials of prophylaxis, DVT has been found in 20-75% of untreated patients within 2 weeks of stroke; 5-20% suffered a pulmonary embolus (PE), which was fatal in about 10%. Intermittent calf compression for the paretic leg, intermittent low-dose heparin given as 5000 units every 8 or 12 hours, and low-molecular-wcighr heparinoid are far more effective than no intervention ot the use of antiembolism hose alone. Across several studies, anticoagulants have reduced DVT by a factor of 2- to 7-fold and PE by about 2- to 4-fold. If a DVT is diagnosed, patients usually can restart activities out of bed after 2 days of intravenous heparin.

For those with spinal cord or head injury complicated by bone fractures, the incidence of DVT and PE is particularly high. After an SCI without a fracture, the risk of DVT,

detected by a radiolabeled fibrinogen scan, impedance plethysmography, or Dopplcr blood flow, appears greatest in the first 12 weeks, especially in combination with paraplegia and flaccidity. Symptomatic thrombophlebitis and PF. are less common. In one study, thromboembolism was detected in 31% of plegic patients, who were randomized to 5000 units of subcutaneous heparin twice a day within 72 hours of injury. It was found in only 7% of those whose activated partial thromboplastin time was prolonged to one and a half times control values by dosage adjustment every 12 houts. Over 7 weeks of anticoagulation, bleeding complications were greater in the adjusted-dosage gtoup, especially at trauma sites. Most patients with uncomplicated SCI continue anticoagulation until discharge from inpatient rehabilitation.

Contractures

Across studies, about 15% of patients with SCI admitted for rehabilitation and 80% admitted after moderate to severe TBI lost more than 15% of the normal range of motion of at least one joint. Hemiparetic patients with stroke fall between these extremes. Contractures are found especially in the lower extremities in neuromuscular diseases, affecting at least 70% of outpatients with Duchenne's muscular dystrophy. They can limit functional use of a limb and impair hygiene, mobility, and self-care. Serious contractures can cause pressure sores, pain, and, especially in youngsters, emotional distress when odd postures distort their body. After an acute UMN lesion, proper positioning "I the arm in abduction and hand in extension and of the leg in hip abduction with knee flexed and ankle in neutral position can protect the affected extremities. Serial casting and surgeries are occasionally necessary for contractures that interfere with skin care or functional use of a limb.

Ectopic bone formation may cause functional impairment in up to 20% of patients with SCI below their neurological level, usually in the first 4 months after injury. Those with a complete lesion, pressure sores, spasticity, and age greater than 30 years may be at gtcatest risk. After TBI, heterotopic ossification (HO) especially tends to affect the proximal joints of comatose patients. During rehabilitation of less responsive and cognitively impaired or aphasic patients, pain caused by undetected musculoskeletal injury and HO can add greatly to agitation and limit participation. HO develops when multipotential connective tissue cells transform into chondroblasts and osteoblasts, presumably under the influence of locally induced growth factors. The hips, knees, and shoulders are most often affected. Swelling, erythema, and decreasing range of motion are among the first clinical signs. A three-phase technetium-99m-labelcd methylene-diphosphonate bone scan reveals focal uptake befote radiographic visualization of bone. Early treatment with disodium etidronate suppresses mineralization of the osteoid. Range-of-motion exercises, aspirin, nonsteroidal anti-inflammatory drugs, and a wedge resection of mature heterotopic bone can decrease pain and immobility.

Seizures

A seizure may complicate inpatient care, and new antiepileptic drugs given for prophylaxis (Haltiner et al. 1999) may affect patients' ability to attend to instructions. Seizures occur in 5-8% of patients within 24 hours to 2 weeks of an ischemic stroke. The risk of epilepsy after TBI varies with the severity of injury and time after onset of injury. In a population study of more than 2700 patients with mostly nonpenetrating TBI, 2% had a seizure in the first 2 weeks after injury. Those with brain contusions, hematomas, or 24 hours of unconsciousness or amnesia had a 7% 1-year and 11.5% 5-year risk of seizures. Within the fitst 2 weeks in these sevctc cases, children under age 15 had a rate of 30% compared with 10% in adults. After a moderate injury, defined as a skull fracture or 30 minutes to 24 hours of unconsciousness or amnesia, 0.7% at 1 year and 1.6% at 5 years had a seizure. The risk after a mild injury with briefer unconsciousness or amnesia was 0.1-0.6%, the same as for the general population. With a 25% rate of fitst seizures regardless of anticonvulsant prophylaxis beyond the first week after serious brain injury, it does not seem productive to continue anticonvulsant therapy beyond the firsr 2 weeks after a serious TBI, especially because an anticonvulsant medication can increase cognitive impairment.

Dysautonomia

Bedrest, dehydtation, cardiac and antihypertensive medications, antidepressants, and autonomic reflex dysfunction from diabetes mcllitus contribute to postural hypotension in the patient with stroke and TBI. The supine and standing blood pressure should be checked as mobilization proceeds during rehabilitation. Autonomic reflexes may fail in patients with SCI levels above T6. Symptomatic postural hypotension is common in the first weeks after injury and may persist in quadriplegic patients.

Initial therapies include gradual reconditioning of postural reflexes on a tilt table, sleeping in a reverse Trendelenburg position, full leg hose, and an abdominal binder. In the inpatient setting, fluid loading with saline or albumin may aid the effort to compensate for venous pooling, decreased cardiac output, and impaired vasoconstriction and venoeonstriction from interruption of sympathetic outflow. Fludrocortisone increases the intravascular volume and peripheral vascular resistance. The dosage can be pushed gradually to 1 mg per day. Salt tablets should be added to the diet. Hypokalemia and edema with pressure sores can complicate use of mineral ocorricoids. While the patient is upright, ephedrine 25 to 100 mg up to every 3 hours, ergotamine 2 mg up to several

times daily, or midodrine up to 10 mg 3 times a day can be rried.

Episodic autonomic hyper-reflexia related to uninhibited sympathetic outflow may affect 50-90% of SCI patients with high-level SCI, usually beginning several months after injury. It is instigated by visceral and joint pain, HO, pressure sores, bowel and bladder distention, fecal impaction, urinary infection and cystitis, ingrown toenails, pregnancy and labor, venous thrombosis, late development of a syrinx, and tight clothing, a patticular supine position, or oropharyngeal suctioning, which can also cause bradyarrhythmias, and sometimes it has no evident cause, Hypertension, headache, diaphoresis, anxiety, reflexive bradycardia, nasal congestion, flushing above and pallor below the SCI level, extensor spasms, and piloerection can result. The instigating agent must be removed. Acute therapies include upright positioning, search for an unemptied bladder or rectum using lidoeaine on a catheter or finger when probing, and treatment of a blood pressure that exceeds 180/100 mm Hg. A beta blocker such as labetalol, a short-acting calcium channel blocker, vasodilators such as hydralazine and nitroprusside, and occasionally phenoxybenzamine, prazosin, clonidine, or nitroglycerine usually lower the pressure safely. Some quadriplegic patients have very labile responses to antihypertensive drugs and suddenly become hypotensive with these treatments. For frequent bouts (it hypertension, maintenance therapy includes lowdosages of any of these oral agents but with dosage adjustments based on the finding of supine hypertension compared to sitting hypotension. For paroxysmal bradycardia, propantheline or a pacemaker may be needed. Scopolamine and propantheline can prevent bouts of sweating.

Bowel and Bladder Dysfunction

Urinary incontinence occurs in up to 60% of patients in the first week after a stroke but tends to improve without a specific medical treatment. This must be considered in the context of an incidence of urinary dribbling and involuntary emptying of about 30% in the healthy, noninstitutionalized population over age 65. Across studies, about 18% of those who were incontinent at 6 weeks aftet a stroke are still so at 1 yeat. By the end of inpatient rehabilitation, the incidence is about 10% in patients with a motor-only stroke and about 30% with large hemispheric strokes,

After SCI, the bladder detrusor reflex may not return for 6 weeks to 12 months. In the absence of spontaneous bladder emptying, intetmittent catheterization is done on a schedule that prevents the accumulation of more than 400 niL. Patients should measure their output from time to time and develop a voiding schedule that takes into account variations in fluid intake and the use of alcohol and caffeine. Catheters can be washed, stored in a plastic bag, and reused. If sensorimotor impairments persist, nearly all patients with an SCI lesion that spares the S2-S4 micturition center develop dyssynergia between the detrusor and the external sphincter. These uncoordinated contractions lead to incontinence and intermittent outlet obstruction.

Urodynamic studies and an intravenous pyelogram are indicated as a baseline and to assist in therapy (see Chaptet 42). Obstruction can cause recurrent infections, urosepsis, vesicourethral reflux, urolithiasis, and hydronephrosis. The person with SCI should learn his or her signs of bladder fullness, such as sweating, changes in temperature, increased spasticity, and an increase in heart rate. Some palpate the area of the bladder to determine fullness. Once awareness of fullness develops, the person can aid in initiating or completing micturition by tapping over the bladder, rubbing the skin over the pubis or on the innet thighs, pressing on the abdominal wall (Crede's maneuver), and hearing down or coughing. These maneuvers are particularly helpful in those with a lower motor neuron bladder with an open sphincter. Most patients also **learn** the signs of an early bladder infection and work out a system with their physician to obtain antibiotics immediately.

Pharmacological treatment can be understood in relation to problems in bladder filling, storage, and bladder-emptying (Table 54.17). Urodynamic studies often aid in the choice of drug trial. The goals are continence and regular emptying that occurs without high intravesicular pressure and with less than 100 mL of residual volume after voiding. If this is not achieved, there are several alternatives to the use of an indwelling catheter on a long-term basis. To prevent inadequate emptying at low pressure at the price of external sphincterotomy and resultant incontinence,

Tabic 54.17: Pharmacological manipulation of bladder dysfunction

Medication	*Indications*	*Mechanism of action*
Bcthaneehol 25 mg bid—50 mg qid	Facilitate emptying	Increase detrusor contraction
Prazosin 1 mg bid—2 mg tid or Tamsuiosin 0.4 mg qd	Decrease outlet obstruction Prostatic hypertrophy	AI pli a-blockade of external sphincter to decrease tone
Hyoseyamine 0.125 mg hs-0.25 mg tid, Oxybutynin 2.5 mg hs-5 mg qid, or Detrol 2 mg qd	Urge incontinence Frequency	Relax detrusor, increase internal sphincter tone
Imipramine 25-100 mg hs	Urge incontinence Enuresis	Increase internal sphincter tone, decrease detrusor contractions

long-term CISC can be used in combination with anticholinergic medications to paralyze detrusor function. This procedure has become increasingly accepted as an effective alternative in the management of low intravesicular pressure. An external collecting device can also be used to ensure dryness. The patient must be trained to adjust fluid intake and the timing of catheterization to meet the flexible needs of community living. The absence of an effective external collecting device for female patients makes it necessary to continue long-term intermittent catheterization if there is paralysis of detrusor function. A waterproof undergarment may be worn between catheterizations to avoid embarrassment. The difficulties of this regimen cause many women to choose constant indwelling catheter drainage despite its drawbacks. Augmentation enterocystoplasty, reservoirs, conduits, and electrical stimulation techniques are less often needed. The VOCARE Bladder System (NeuroControl, Ohio) for patients with upper motor neuron SCI allows patients to stimulate sacral nerves that have been implanted with electrodes to empty the bladder and bowel.

The optimal management of spina bifida in children includes self-catheterization. Through cartoons and drawings, children must be taught how to prevent germs from growing in the bladder. Intermittent self-catheterization of the bladder usually can begin by age 5 years or by the time the child starts school.

Bowel evacuation can be brought under control in the majority of cases of SCI or other causes of myelopathy or cauda equina injury. The goals include continence, the prevention of impaction and discomfort caused by inadequate elimination, prevention of rectal bleeding, and a reasonable amount of time for bowel care. Some people with SCI can identify a signal of rectal distension, such as sweating or an increase in spasticity. It is particularly useful to establish a fixed time, usually after a meal, for evacuation. Once a pattern has been established with stimulatory suppositories, patients often get by with dilatation of the anal sphincter, either digitally or by a glycerin suppository. Those who cannot develop enough intra-abdominal pressure to void may need manual evacuation several times a week.

Central Pain

A major source of disability can be pain from a thalamoparietal stroke or SCI. One of the most common patient complaints a year or more after SCI is burning pain at and below the level of the lesion. Approximately half gauge their symptoms as moderate or severe. Some patients only need assurance that the pain does not represent a serious complication or a warning signal of another stroke. Others need to help the physician set goals about moderating the severity, frequency, duration, and time of day of the pain. Tricyclic and selective serotonin reuptake inhibitor antidepressants, carbamazepinc, clonidine, gabapentin, benzodiazepines, and baclofen are among the drugs that diminish dysesthetic or lancinating pain in some patients. Intrathecal baclofen and morphine can be efficacious when oral approaches fail {see Chapter 50).

Sleep Disorders

During rehabilitation, insomnia, sleep apnea, and excessive daytime sleepiness can interfere with attention, learning, and carryover. Stimulants, alcohol, medications, pain, anxiety, depression, and chronically poor sleep habits contribute. Central and obstructive sleep apneas have been associated with a higher risk of stroke. Pharyngeal muscle weakness and impaired neural control during sleep of the nasopharyngeal and pharyngolaryngeal muscles caused by a stroke or TBI contribute to the risk of obstructive apnea. Up to one third of stroke inpatients may have a sleep disorder. Polysomnography is indicated when the rehabilitation team observes a hypersomnolent, confused, and snoring or apneic patient. One study found an average of 52 sleep-disordered breathing events per hour in selected subjects within 1 year of stroke. The number of oxygen desaturation events and the oximetry measures during sleep-disordered breathing correlated with poorer functional recovery scores at 1 and 12 months after stroke. It is especially important to address the possibility of apnea with outpatients with :iu> type ol neurological disease, especially stroke, TBI, thoracic SCI, and myasthenia gravis.

Spasticity

Mechanisms. The most important UMN problems that cause disability are the decrement in motor control associated with dyssynergic patterns of muscle activation and the coactivation of agonist and antagonist groups during movements, as well as paresis, slow movements, loss of dexterity, and fatigability. During rehabilitation, the signs that tend to be treated include the flexor posture of the arm and extensor posture of the leg, sometimes with dystonia, rigidity, and contractures; and exaggerated cutaneous and autonomic reflexes with involuntary flexor and extensor spasms.

Hypertonicity can also be the consequence of interactions between central and peripheral factors. The mechanical resistance to a passive change in a joint angle arises from the elastic and viscous properties of muscle, tendon, and connective tissue and from reflexively mediated stiffness. Some investigators have proposed that secondary changes in spastic muscle, such as an increase in connective tissue and loss of muscle fibers or change in their properties, explain at least some of the increased stiffness in patients. Hyperexcilability of motoneurons probably plays a larger role. A number of ill-defined mechanisms could alter membrane properties and morphologically and physiologically reorganize spinal circuits, leading to hypertonicity. A variety of neurotransmitters act within these

Table 54.18: Clinical measures of spasticity

Ash worth Scale	
1	No increase in tone
2	Slight increase, producing a catch when joint is moved in flexion or extension
3	More marked increase in tone hut easily flexed
4	Considerable increase; passive movement difficult
5	Affected part rigid in flexion or extension
Spasm Score	
0	No spasms
1	Mild spasms induced by stimulation
2	Spasms less than 1/hr
3	Spasms more than 1/hr
4	Spasms more than 10/hr

systems, although their net effects are uncertain. Thus drug interventions produce hard-to-predict changes in tone and spasms.

Assessments. For routine assessments and for clinical trials of a uti spasticity interventions, a mini her of measures of hypcrtonicity have been used. The Ashworth Scale (Table 54.18) has had good interrater reliability in studies of stroke, SCI, and MS. The relationship between this score and disability is not so evident. A clenched, plegic hand may lead to disability if pain ot maceration of the palm develops, but a treatment that changes the Ashworth score from 4 to 3, and certainly from 3 to a lower score, is unlikely to offer any benefit. Other measurement techniques require instrumentation (Dobkin 2003).

Treatment of Spasticity

Therapists usually can manage pathologically increased tone in patients with hemiplegia by aiming to maintain notmal length of the muscle and soft tissue across a joint and helping patients to avoid abnormal flexor and extensor patterns at rest and during movement. Spasticity should be treated more aggressively when it interferes with nursing care and perineal hygiene or contributes to contractures and pressure sores. Treatment is often needed for patients with myelopathies, who endure painful spasms or involuntary flexor or extensor trunk and leg movements during transfers and after minor cutaneous stimulation. After SCI, spasticity is more prominent with incomplete than complete motor and sensory impairments, especially with cervical and upper thoracic lesions. It can be useful to lessen spasticity when ir appears to restrain voluntary upper or lower limb movements by co-contraction of agonist and antagonist groups. Hypertonicity has potential value. For example, spasms can dceteasc muscle atrophy and bone dcmineralization and increase venous return. An extensor thrust can provide the rigidity needed for weight-bearing stance. Learning to induce an extensor spasm can assist bed transfers in patients with a myelopathy. Determining how and when hypertonicity interferes with a patient's activities is the most useful way to determine whether an intervention is needed. Bouts of clonus and flexor and extensor spasms during ambulation, driving, wheelchair push-up pressure releases, transfers, self-care activities, bed mobility, sleep, and sexual activities can be counted over the course of a day or week. Any intervention should aim to greatly lessen recurrences.

Nociception can exacerbate hypcrtonicity and trigger flexor and extensor spasms and dystonic postures. A painful shoulder can cause the hemiplegic arm to flex at the elbow and wrist. Even an ordinarily innocuous stimulus, such as tight clothing or sunburn, can abruptly increase tone, much as it can cause autonomic dysreflexia in the patient with a cervicothoracic SCI. Treatable pain stimuli include bowel and bladder distention, urinary tract infection, epididymitis, joint pain especially on range of motion, unrecognized fractures, pressure sores, ingrown toenails, and deep venous thrombosis. Resistance exercises, though generally useful during rehabilitation, can increase flexor or extensor tone, especially if the exercise brings out associated movements.

An overall approach to the management of pathological hypertonicity and spasms includes reversing any noxious stimulus, using physical interventions before adding drug trials, and reserving more invasive techniques such as nerve blocks and orthopedic or neurosurgical procedures to a few recalcitrant situations.

Physical Modalities. Slow stretching movements and daily passive range-of-motion exercises reduce motion-sensitive symptoms of spasticity. Static stretching with splints and serial casting can reduce stretch reflex activity and contractures. Muscle cooling, tendon vibration, pressure exerted over a tight muscle belly, postural adjustments, loading a limb by weight-bearing on an extended arm or, for paraplegics, standing in a support frame (Figure 54.9), and EMG BFB can complement a stretching program. Electrical stimulation of motor and sensory nerves, muscles, and dermatomes by a variety of paradigms may reduce tone at the ankle and knee and in the forearm and finger flexors. A single session of stimulation usually decreases resistance and clonus for a few hours.

Pharmacotherapy. Conttolled trials of antispasticity agents have varied widely in the target symptoms managed and the outcome assessments used. Usually, only a particular neurological disease is considered. Functional gains related to locomotion and upper limb use for any UMN disease often are marginal. However, a medication that prevents disabling spasms may improve quality of life. Table 54.19 lists useful first- and second-line drugs.

After a SCI, about 25% of patients arc discharged with an antispasticity agent, and half use medication by 1 year. Patients with American Spinal Injury Society (ASIA) gtades A and D (see Chapter 56C, Table 56C.2) are less likely to have been treated than those with grades B and C. Baclofen, tizanidine, and clonidine are especially useful in reducing

FIGURE 54.9 A patient with quadnplegia from a spinal cord injury uses a standing wheelchair to try to reduce ankle and knee contractures and overall muscle tone. Subjects who can use their upper extremities may use a wheelchair like this to perform tasks while upright, such as washing dishes.

clonus and extensor spasms caused by myelopathy. The latter two drugs are *a-2* agonists that inhibit the excitatory influences of peripheral sensory inputs on motoneurons. Medications with short-lasting effects such as tizanidine may be especially useful in limiting spasms during sleep or brief activities, such as ttansferring from wheelchair to bed. For refractory spasms and pain, intrathecal baclofen given by an implanted, programmable pump infusion has generally replaced a surgical myelotomy, intrathecal morphine, and electrical spinal stimulation. It has also replaced selective dorsal rhizotomy, except in some children with spastic diplegia from cerebral palsy. Dantrolene tends to be most useful in managing hypertoniaty of the upper extremity after stroke and TBI. Less than 0.5% of users develop hepatotoxicity after several months of intake.

Baclofen, dantrolene, and the benzodiazepines can cause muscular weakness and difficulty with weight-bearing. Children with cerebral palsy and patients with hemiplegic stroke often need their by perron icity to ambulate on a

Tabic 54.19: Dosages of medications for symptomatic spasticity

Drug	*Dosage*
First-Line Use	
Diazepam	2 mg bid—15 mg qid
Dantrolene	25 mg bid—100 mg qid
Baclofen	5 mg bid-40 mg qid
Clonidine	**0.05 mg qd-**0.2 mg tid
Ti/.anidine	2 mg bid—8 tug qiu
Gabapentin	400 mg tid-900 mg qid
Occasionally Useful Additions	
Intrathecal baclofen	50-150 pg rrial dosages
L-dopa or carbidopa	25 or 100 mg bid, respectively
Phcnytoin	Serum concentration 10-20 ng/dl.
Phenobarbital	Serum concentration 10-30 ug/dL
Threonine	500 mg-2.5 m tid
Cyprobepradine	4 mg bid—H mg qid
Chlorpromazinc	10 mg qd-50 mg tid
Mannol	2.5 mg qd-tid

paretic leg. L-dopa may be of value in these patients and in selected adults after stroke or SCI. These drugs can also cause sedation, confusion, hypotension, bowel and bladder dysfunction, and other central and systemic side effects. Great care must be taken when using them in the patient who has a pseudobulbar palsy and is at risk for aspiration. Whenever a drug appears to be useful, it is worth tapering the dosage down from time to time so that the patient can help reassess continued benefits.

Chemical Blocks. Chemical agents, such as phenol, have been injected into the lumbar theca, nerve, motor point, or muscle to lessen inappropriate muscle co-contraction, spasms, and dystonic postures. Because motor point blocks can partially spare voluntary movement and could reduce reciprocal inhibition when given to an antagonist muscle, they could improve some aspects of motor control. Intramuscular infiltrative injections of 50% cthanol or botulinum toxin reduce features of spasticity for about 3 months.

Botulinum injections have seemed most efficacious for the wrist and finger flexors and plantar flexors of the ankle. Interpretation of the results of clinical trials using botulinum toxin requires attention to how well the outcome measure reflects clinical effectiveness for an important problem. Is a change in ease of passive range of motion, as in the Ashworth Scale, as meaningful as an increase in functional use of the limb? A few trials in children with cerebral palsy and spastic diplegia reveal modest *0%* increases in walking speed after injections. The great majority of studies report a 1 - or 2-point decrease in the Ashworth Scale score and support this finding by offering a global physician score that, in reality, probably reflects a perception of a decrease in tone around one or more joints. A randomized trial compared injection of type A toxin into forearm muscles with vehicle injection in patients after stroke who scored 3 or more for the wrist and

2 or more for the fingers (Brashear et al. 2002). A statistically significant decrease in the Ashworth score occurred at 6 and 12 weeks (e.g., a change from 0.1 in controls to 0.8 in the finger flexors of the treated group). Significant changes were also found in the Disability Assessment Scale, which was said to reflect functional disability. This disability is only a subjective measure of change in hand hygiene, pain, positioning, and dressing that does not require use of the hand. It would be easy to misinterpret the data as revealing better functional use of the hand after botulinum toxin injection, but the real meaning is that with the wrist and finger flexors loosened, the hand was easier to keep open passively. Trials of botulinum toxin that are sponsored by the industry have not included a conttol intervention that uses rehabilitative passive or active range-of-motion or treatments for pain that may decrease tone. Also, these studies have not tried to maintain the effect of greater passive ranging by adding physical therapy after an injection to try to prolong benefit.

Surgical Interventions. A variety of surgical procedures, including tendon lengthening, tenotomy, and tendon transfer, can correct deformities induced by spasticity and improve function. A gait analysis with EMG helps determine which procedure might aid mobility. Physical therapy must follow any surgery. Tenotomy of the hip adductors and iliopsoas and tendon lengthening of the hamstrings, Achilles, and toe or finger and wrist flexors are among the more common interventions. Lower-extremity surgeries are performed most often in children with cerebral palsy, although the data are difficult to interpret in terms of meaningful clinical gains. Achilles tenotomies for Duchenne's muscular dystrophy and a variety of foot surgeries, including triple arthrodesis, for Gharcot-Marie-Tooth disease may be beneficial.

Posterior rhizotomy has been carried out especially in children with spastic diplegia. Selective division of posterior nerve rootlets of the second lumbar to second sacral level is based on intraoperative EMG responses of lower extremity muscles to posterior nerve rootlet stimulation. Youngsters with the most dramatic functional improvements are bright, ambulatory patients with spastic diplegia who have minimal fixed contractures and good strength. Some clinicians argue that such patients would do well with any intensive therapy. Indeed, controlled trials suggest that the intervention is no better than routine physical therapy in terms of functional walking (McLaughlin et al. 2002).

THERAPIES FOR IMPAIRMENTS AND **DISABILITIES**

Therapeutic exercise and the neurodevelopmcnral approaches have traditionally received the most attention from PTs and OTs. Newer approaches, developed from concepts related to neuroplasticity, motor control, and motor learning, arc merging with these. Success in retraining during rehabilitation, regardless of the primary approach, requires attention to many confounding variables. These include the characteristics of a task; how learning is reinforced; the patient's mood, motivation, attention, and memory for carryover of what is taught; environmental distractions; and family support. All can influence how motor and cognitive programs are built, shaped, and refined as the patient acquires a new skill. The daily practices of most individual neurological therapists reveal an eclectic, problem-oriented approach, A few well-specified approaches to therapy are being assessed in clinical trials.

Locomotor Training

Observation of rhe gait cycle for temporal asymmetries of the legs and kinematics at the hip, knee, and ankle during the stance and swing phases reveals deviations that the clinician can identify and use to help train patients (Dobkin 2003). Table 54.20 lists the easiest ones to look for as the patient walks on a flat surface. The timing of loading the stance leg and flexing the swing leg from its 10 degrees of extension is one of the important sensory inputs to the spinal cord for initiating the swing phase of gait.

The notion of task-oriented training has led to small trials of treadmill training and related walking activities in patients with hemiplegic stroke. The specificity of the training improves the speed of walking, leg strength, and fitness and may reduce the energy cost of walking. The addition of partial body weight support to treadmill training (BWSTT) has shown promise in patients with stroke and SGI and in patients with Parkinson's disease and cerebral palsy. Subjects wear a mountain climbing harness that is attached to an overhead lift. The amount of weight borne by the lower extremities is adjusted to optimize the stance and swing phases of gait. One or more therapists

Table 54.20: Easily observed components of the gait cycle-

Stance Phase	
Pelvis	Lateral and horizontal shift to the stance leg
Hip	Extension to about II)
Knee	Slight flexion upon loading
	Extension at midstance
	Flexion at foot pushoff
Ankle	Dorsiflexion to 10" at heel contact
	Dorsiflexion as the lower leg moves over the foot
	Plantarflexion to 20 with a propulsive rocker motion of the foot for pushoff
Swing Phase	
Pelvis	Drop at toe off, then forward rotation
Hip	Flexion to 20° to "shorten" the leg
Knee	Flexion to 65° to "shorten" the leg, then extension just before heel contact
Ankle	Dorsiflexion to 10^{s} for heel strike

may manually assist the lower extremities and pelvis during step training to optimize the step pattern.

In theory, BWSTT allows the spinal cord and supraspinal locomotor regions to experience sensory inputs that are more like ordinary stepping than the atypical locomotor inputs created by compensatory gait deviations and difficulty with loading a paretic limb (Dobkin 1999). More normal proprioceptive and cutaneous input may improve the timing and increase the activation of residual descending locomotor outputs on the motor pools. In patients with complete SCI, FMG activity appears to he derived from the neural circuitry of the lumbosacral motor pools that recognize the sensory inputs provided by BWSTT, Sensory inputs related to the level of loading and to treadmill speed have been shown to modulate the EMG output during BWSTT in which the legs arc fully assisted during the step cycle. Most important, BWSTT allows massed practice with many repetitions guided by the cues of the therapist. This approach should enhance motor re lea ruing.

In patients with stroke, single case studies and small clinical trials also suggest that BWSTT can increase the likelihood of achieving more independent ambulation and at greater speeds than by conventional therapy (Dobkin 1999). Gait symmetry clearly improves during treadmill step training. A Canadian randomized trial compared BWSTT with treadmill training without support during inpatient rehabilitation starting an average of 70 days after a stroke in 100 patients who could flex the affected hip. Average treadmill speeds did not exceed 1 mph. The trial showed a significantly greater overground speed in those managed with BWSTT (34 cm per second compared with 25 cm per second). Patient selection, duration of support before full weight bearing is allowed at faster treadmill speeds, practice paradigms, and the associated use of orthotics must In: better defined. Aims of this task-specific intervention include greater independence in walking and attaining walking speeds that permit home and community ambulation. The threshold velocity for home ambulation is 40 cm per second (45 cm per second equals 1 mph). Therapy ought to aim for faster walking speeds and for more energy-efficient traveling distances to permit unlimited community activities. Commtinin ambulation requires a walking velocity of 60 to 80 cm per second, or more than 1.5 mph. Therefore task-oriented training on a treadmill must exceed 1.5 mph. Note that typical disability measures such as the FIM and BI assess only the level of independence to walk 150 feet at any velocity. BWSTT did not improve overall locomotor-related outcomes in several randomized inpatient trials. The great range in time of onset of stroke to entry, slow treadmill training speeds for the BWSTT group, variations in the duration of therapy across patients, and lack of an intention-to-treat analysis make these trials less valuable. Training at treadmill speeds of about 2 mph lead to faster overground walking speeds than training at slower speeds, regardless of the initial overground walking velocity of a patient with stroke (Sullivan et al. 2002).

BWSTT is also being combined with functional neuromuscular stimulation (FNS) with surface or implanted electrodes for patients will) chronic stroke. The results to date show modest improvements in walking speed and kinematics within subjects, but the design of clinical trials with the combined approach seems premature, given that the optimal use of BWSTT has not yet been demonstrated. Robotic devices may prove useful in assisting patients and taking the physical burden of step training off therapists. Multiccntcr trials of BWSTT are in progress for acute SCI (Dobkin 1999) and stroke using faster treadmill training speeds and better-defined training strategics than in previous trials.

Temporal features of the gait cycle in patients with stroke and Parkinson's disease have been enhanced by bicycling and by rhythmic auditory stimulation that seems to entrain stepping.

Constraint-Induced Movement Therapy

This strategy calls for forced use of the affected upper extremity and gradual shaping of a variety of functional movements to overcome what is theorized as learned nonuse of the paretic limb. Learned nonuse might derive from unsuccessful early attempts to use the affected limb after a stroke. The primary intervention uses a variety of techniques that prevent the use of the unaffected arm by-placing it in a sling or glove and having the patient practice skills and ADLs with the affected arm. The first rendition of this approach for the upper extremity has been promoted by Taub ct al. (1999) with a course of 6-7 hours of massed practice with the affected arm and the restraint for 2 weeks. In these patients with chronic stroke who could dorsiflex the wrist at least 10 degrees and extend the fingers of the paretic arm, about half of the improvement in daily use was evident within the first several days of restraint of the unaffected arm combined with therapy, which suggests that a latent capability had succumbed to learned nonuse. Gains in the amount of hand use are accompanied by cortical reorganization of the hand region, consistent with the effects of practice. Other investigators have been working to eliminate the restraint and decrease the intensity of practice with a therapist. One acute trial of the approach showed positive results (Dromerick et al. 2000), and a multiccnter trial called EXCITE for patients who are 3-9 months post-stroke is in progress. The most important aspect of this approach is massed practice. Styles of practice, such as the use of shaping and reinforcement schedules and the most cost-effective practice intensity, are works in progress.

The notion of constraint with therapy has been invoked for a few treatments for walking and aphasia because the underlying style of therapy aims for massed practice of

specified activities and attempts to optimize responses and limit patient errors (Pulvermuller et al. 2001). The practice paradigm seems more important than concerns about restricting the use of an unaffected arm, leg, or language response.

Instrumented Biofeedback

BFB includes a variety of instrumented techniques that try to make the treated subject aware of physiological information that can be used to better train an activity. Electromyographic BFB to improve upper and lower extremity muscle activity, decrease co-contraction of muscles, and increase functional movements has been used across many upper and lower moroneuron diseases. Its efficacy usually is modest at best. Across controlled trials of ambulation after stroke, electromyographic BFB seems most useful as a way to increase **ankle** dorsiflexion. EMG-triggcred neuromuscular stimulation initiated by a voluntary movement such as slight wrist extension of a paretic hand has led to functional gains for hand grip in some studies. BFB can improve performance during training but not necessarily when visual or auditory guidance is stopped.

Acupuncture

A variety of acupuncture methods are widely used in China and Korea after stroke. Reports from these countries are impossible to interpret in terms of efficacy. Several small Western trials that treated subjects who had moderate hand paresis after a pure motor stroke showed gains in speed of hand manipulation or ADLs with the intervention. Better-controlled trials have not shown clear benefit (Johansson et al. 2001). A review of nine Western controlled trials with *53$* patients, carried out by investigators from a department of complementary medicine in Britain, concluded that no compelling evidence shows acupuncture to be effective for stroke rehabilitation. Despite 12 positive randomized trials reported in the Chinese literature, the results of very well-designed clinical trials do not support the use of acupuncture as a general intervention during stroke rehabilitation. Studies focused on particular types of dysfunction have yet to be carried out in a well-designed fashion.

Robotics

In addition to robotic trainers to assist stepping ptactice, unilateral and bimanual practice with the upper extremities may be enhanced with robotic and mechanical assistive devices. Devices aim to allow subjects to ptactice movements to increase motor control and functional use of the arm with only intermittent therapist oversight. The MIT-MANUS manipulates a patient's pareric elbow and shoulder much as a therapist might provide hand-over-hand therapy for reaching in a plane over a Moror. Power and control at the shoulder and elbow improve with robotic training, consistent with the greater intensity of practice using those muscle groups. A device that allows movement in multiple planes and incorporates the hand may be of greater value for training.

Functional Neuromuscular Stimulation

FNS systems can provide a hand grasp and release in C5 and C6 quadriplegics (Peckham et al. 2001). The commercially available FrecHand (NeuroConrrol, Ohio) ncuroprosthesis uses electrodes implanted in muscles of the opposite shoulder to control an external device that allows patients to complete upper limb grasp, pinch, and release tasks. The device has been less successful in reaching potential users than one might have expected. The first commercial surface electrode-driven device for grasping is the Handmastcr (NESS Ltd. Ra'anana, Israel), which has found some use in quadriplegic patients with at least *CS* intact and in hemipJcgic patients with poor hand function, FJectrodcs attached to a molded forearm orthosis that teaches across rhe wrist stimulate the wrist and finger flexors and extensors in synchrony. The external conttol unit operates from a button managed by the patient for the level of output that allows grasp, holding, or release.

FNS sysrems have been used more often to aid standing and ambulation. Used alone or combined with an RGO or with other assistive and bracing devices, these systems can allow walking as an exercise and in some instances permit stepping for distances involved in movement indoots. However, a lengthy strengthening and fitness program must precede the use of these devices. The only commercial device to assist stepping, the Patastep System (Sigmetics, Inc.}, uses six surface electrodes to stimulate the gait cycle as subjects hold onto a rolling walker. Stimulation of the quadriceps muscles and pushoff with the arms permits standing up. Constant stimulation maintains standing. A step button on the walker stops quadriceps firing as one leg srarts its swing phase and activates a triple flexion response by peroneal nerve stimulation. The patient releases the button after the hip flexes and switches on the quadriceps stimulator for stance. The other leg is then stimulated to aid swing. Other patients with a complete UMN SCI may exercise with a bicycle ergometer called the ERGYS (Therapeutic Technologies, Inc., Tampa, Florida), which uses bilateral surface electrodes over the quadriceps, hamstrings, and gluteal muscles to sequentially activate leg forces on the pedals. As muscle strength increases, contractions are made against greater ergometer resistance, and muscle bulk builds.

Neural Prostheses

Direct electrical stimulation of the brain and spinal cord and the use of neural signals to control brain-computer interfaces have become increasingly feasible.

Spinal cord stimulators placed over the dorsal spinal cord in the epidural space reduce some types of central pain and hypertonicity after SCI. Stimulation of the upper lumbar cord has also produced rhythmic leg movements in subjects with complete SCI. Stimulation with four dorsally placed lumbar electrodes reportedly improved the gait pattern of a patient with spastic quadriparcsis. Walking speed and endurance increased beyond what had been accomplished with BWSTT alone. Electrode microarrays are in experimental stages for direct spinal cord stimulation, perhaps of spinal primitive modules described earlier, Nerve cuffs placed around a portion of a peripheral nerve provide a permanent electrochemical interface to selectively initiate or record electrical signals or modulate the nerve's responses. Their initial experimental use has been for ankle dorsiflexor stimulation during walking.

Some estimates suggest that up to 2 million Americans may currently be without any voluntary control due to ALS, a locked-in syndrome after stroke or trauma, MS, cerebral palsy, or muscular dystrophy. A direct brain-computer interface can be configured to substitute for neural control of muscles. Many of the technical challenges have been addressed or clever solutions are in the making to take command signals derived from brain electrical activity to control a neuroprosthesis or robotic device (Wolpaw et al. 2002). Signals are acquired from field potentials over the surface of the scalp, dura, or subdural regions or from the spike potentials of small clusters of neurons picked up by microelcctrode arrays from motor cortex or cognitive planning regions. Selected signals are digitized and processed by algorithms to extract specific features, such as the amplitude of an evoked potential or of a specific rhythm from sensorimotor cortex, or the firing rate of cortical spikes. A translation algorithm takes the particular electrophysiological features chosen to give simple commands to a device, such as a word processor or keyboard, a Web site, or an upper extremity neuroprosthesis.

Pharmacological Adjuncts

Neurotransmitters and neuromodulators given in pharmacological dosages may augment the activation of a network during a specific task, but determining the dose-response ratio that has positive effects and no adverse effects takes much study. Human clinical trials have been small, and most investigators screen 10-50 subjects to meet entry criteria. Several trials of dextroamphetamine, methyl-phenidate, and i.-threodopa have revealed motor gains when combined with motor therapies, but others have not; a trial with l.-dopa revealed modest gains in motor function (Scheidtmann et al. 2001). A promising approach is to use functional imaging to help detect changes in response to a drug and other therapy (Boroojerdi et al. 2001).

THERAPIES FOR COGNITIVE AND BEHAVIORAL DISABILITIES

Overview of Cognitive Therapy

Cognitive and behavioral disorders are common with a recent stroke or TBI and in MS, Parkinson's disease, and degenerative diseases. Table 54.21 lists some of the cognitive impairments dealt with by the rehabilitation team. These can seriously impede gains in mobility, ADLs, and community reintegration. Prospective studies of patients with an acute stroke reveal that 15-35% have greater memory impairments 3 months to 1 year after onset than age-matched controls. Cognitive dysfunction is

especially common after TBI. Greater severity and duration of impairments are associated with a lower Glasgow Coma Score on acute admission and longer duration of post-traumatic amnesia. Up to one half of patients with an SCI have cognitive impairments from an associated TBI that may not be obvious early in their care.

The amount and rate of recovery of neuropsychological functions vary with the sophistication of the measures used; type and severity of impairment; type, severity, and distribution of lesions; time since onset; and age at onset and follow-up. More subtle factors such as the interactions of diseases, associated sensorimotor and cognitive impairments, and premorbid intellect and education can affect the efficacy of a particular therapeutic approach and the natural history of gains. Comparisons between interventions often are confounded by the intensity and duration of treatment, lack of specification of the treatment methods, personal infractions between the therapist and patient, and success of the family's ability to reinforce desired behaviors.

General management approaches include training in particular functional adaptive skills, behavioral modification, and remediation of specific cognitive processes (Cicerone et al. 2000). In the adaptive approach, therapy tries to circumvent the effects of cognitive impairments on targeted daily activities. Repetition, cues that are both internal and environmental, and cognitive assistive devices are used for training. Learning to do a particular task usually does not generalize to other tasks that are not closely telatcd. Behavioral modification techniques are most often used in acute and transitional living settings for patients with TBI. Rewards are given for accomplishing a task or reducing antisocial actions. In the cognitive remediation approach, the subcomponents or hierarchical organization of a given cognitive skill are addressed. Tbe strategy assumes that at least some of the parallel and hierarchical neural networks for cognitive processes are understood. More often, the techniques used emphasize interventions meant to boost intact domains to help compensate for more impaired ones. Few studies show the benefit of a particular approach or combination of approaches over another interventional style for most cognitive impairments. Techniques usually merge as the team experiments with interventions that address the most deleterious problems. Indeed, outpatients *wkh* a TBI are the most likely group to need multimodal programs that stress ttaining in task-specific skills by remediative techniques, awareness about impairments and limitations, and skills needed for independent living and work,

Aphasia

The incidence of language disorders has varied across studies of patients with stroke and TBI. In a British health districr of 250,000 people, new cases of aphasia numbered 202 yearly. By one month after stroke, 165 survivors were potential candidates for speech therapy, A prospective, community-based Danish study of acute stroke found that 38% of 881 patients were aphasic on admission, with 20% of the admissions rated as severe on the Scandinavian Stroke Score. Nearly one half of the severe aphasics died soon after onset, and one half of the mild aphasics recovered by 1 week. Only 18% of community survivors were srill aphasic at the time of their rehabilitation hospital discharge. Up to 28% received early speech therapy as needed. Patients were retested for 6 months. Ninety-five percent with a mild aphasia reached their best level of recovery at 2 weeks, those with a moderate aphasia peaked at 6 weeks, and patients with severe aphasia reached best language function within 10 weeks. Only 8% of the severe aphasics fully recovered by 6 months on the scoring system used. The best predictor of recovery was less severe aphasia close to the time of the stroke.

Treatments

Treatments for aphasia average 45-60 minutes, arc provided up to three times a week in most studies, and rarely exceed this number in community practices. The family tries to continue what therapists recommend at home.

Twenty percent to 50% of aphasic patients have partial features of rhe rraditional aphasia subtypes (see Chapter 12). For rehabilitation therapy, the broadly defined features used to classify patients often do not address in enough detail tbe underlying disturbances of language, so they may not be optimal for directing treatment. A neuro-linguistic assessment of aphasia aims to specify the types of representations or units of language, such as simple words, word formation, sentences, and discourse that arc abnormally processed during speech, auditory comprehension, reading, and writing. For each unit, the therapist ascertains how the disturbance affects linguistic forms such as phonemes, syntactic structures, and semantic meanings.

Speech therapists most often attempt to find ways to circumvent, deblock, or help the patient compensate for defective language function by using a great variety of stimulation-facilitation techniques (see Table 54.4). These include visual and verbal cueing techniques, such as picture matching and sentence completion tasks, along with frequent repetition and positive reinforcement as the patient approaches the desired responses. Initial treatments also use tasks that relate to self-care, the immediate environment, and emotionally positive experiences. To prevent withdrawal and isolation, ir is especially important to quickly find a way to obtain reliable verbal or gestural "yes-no" responses. Behavioral techniques, particularly for patients with TBI, can be used to improve skills in maintaining eye contact, initiating and staying on a topic, turn-taking

during conversation, adapting to listener needs, and using speech to warn, assert, request, acknowledge, or comment.

Beyond the stimulation-facilitation approach to therapy, a variety of theoretical models for therapy have been proposed, such as the modality, linguistic, processing, functional communication, and minor hemisphere mediation models. Therapy techniques have been designed for specific aphasia syndromes and neurolinguistic impairments as well. Examples of a few of the available specific-approaches for particular problems follow.

The efficacy of melodic intonation thcrapv (MIT) has been especially good. In MIT, therapists and patients meiodically intone multisyllabic words and commonly use short phrases while the therapist taps the patient's left hand to mark each syllable. Gradually, the continuous voicing and tapping are withdrawn. MIT works best in Broca's aphasics with sparse or stereotyped nonsense speech and good auditory comprehension. If a single sound, word, or phrase overwhelms any other attempted output, the Voluntary Control of Involuntary Utterance Program can help the patient gain control over perseverative intrusions.

The agrammatism of Broca's aphasia has been treated with the Helm Elicited Language Program for Syntax Stimulation, which tries to build increasingly more difficult syntactic constructions. The therapist uses a standard series of drawings of common activities and provides a brief verbal description that ends with a question. The question contains a target sentence. As the patient's responses with target words improve, the patient is asked to complete the story without having heard the target sentence. Some patients with minimal or stereotyped output and impaired comprehension have improved with multiple input phoneme therapy. This 22-step hierarchical program huilds from an analysis of phonemes produced spontaneously by the patient to attempts at eliciting a target phoneme, followed by blends of consonants, then multisyllabic words, and eventually simple sentences. Some mute or nonfluent aphasics can acquire a limited but useful repertoire of gestures using, for example, American Sign Language.

Comprehension in global and Wernicke's aphasics has been managed with the Sentence Level Auditory Comprehension Program. It trains patients to discriminate consonant-vowel-consonant words that are the same or differ by only one phoneme (e.g. "bill, pill, fill"). They then try to associate the word sounds with the written word and later try to identify the target word embedded in a sentence. For global aphasics, nonverbal communication using pantomime has decreased limb apraxia and improved auditory comprehension through a technique called Visual Action Therapy. The technique called Promoting Aphasics' Communicative Effectiveness emphasizes the ideas that need to be conveyed in face-to-face interactions rather than linguistic accuracy. It aims to develop any modality that can be used to transmit a message, including hand and facial gestures and drawing. The handbook and program called Supported Conversation for Aphasic Adults (Pictographic Communications Resources, Aphasia Centre, North York, Ontario, Canada) was designed for the nonaphasic conversation partner to facilitate interaction with global and nonfluent people. Electronic devices that provide delayed auditory feedback by about 200 milliseconds after the aphasic person makes each phoneme can be tried to improve awareness of paraphasic errors and intelligibility.

Pharmacological Adjuncts

A few studies suggest that intensive therapy combined with a drug that enhances vigilance or learning may **benefit** patients who have adequate language comprehension. Piracetam, a derivative of y-aminobutyric acid but with no GABA activity, may facilitate cholinergic and aminergic neurorransmission. A randomized, placebo-controlled trial included 50 moderately aphasic patients who had a stroke a mean of 10 months before starting the 6-week intervention of 10 hours of speech therapy weekly. The drug-treated group had a significantly better total score on the Aachen Aphasia Test, alrhough the clinical impact is not clear. In a randomized trial of 24 patients, use of piracetam was also associated with some language subtest gains and higher cerebral blood flow in left hemisphere language regions during a word repetition task. Other cholinergic agents have improved naming in patients with moderately severe Wernicke's aphasia or dysnomia, especially by reducing perseveration. Amphetamine and dopaminergic agents have improved aspects of language in several small studies but not all. Short-term trials of such agents can be carried out with parallel therapy and standardized tests in individual patients.

Outcomes

A metaanalysis was performed on *55* trials of speech therapy in aphasics with a stroke. Significant effects were found for treated patients at all stages of recovery, with the greatest outcome found when therapy was started in the acute stage. Treatments of more than 2 hours per week gave greater gains than lesser amounts of therapy. Severe aphasics showed large gams when treated by a speech-language pathologist. An inadequate number of studies were found to allow demonstration of any difference in treatment effects for differing types of aphasia. The Cochrane Library's systematic review of group trials in stroke (http://update-software.com/cochrane.htm) concludes that speech and language therapy for aphasic people after stroke has not been shown to be clearly effective or ineffective in a randomized clinical trial. Still, even a delayed pulse of a specific language therapy often improves a goal-directed aspect of aphasic communication in individual patients.

Memory Disturbances

Memory disturbances can have a profoundly negative influence on compensation and new learning in the patient undergoing neurorehabilitation. An inpatient team depends on teaching that can he encoded and retrieved. When sustained attention is impaired, even motor and functional gains may be affected.

Frequency of Memory Disturbance Across Diseases

The frequency and risk factors for memory toss and dementia caused by one or more strokes have become increasingly appreciated. The prevalence of memory disturbance in population- and community-based studies is nine times greater in the first year after a stroke than in an age-controlled group and twice as great each subsequent year. Other studies find a risk of about 20% 3 months after a stroke. The frequency of dementia rises with increasing age and varies with the definition used. Even a mild aphasia may affect verbal memory and can interfere with verbal learning during rehabilitation.

Memory impairments after TBI have been related to the time between injury and assessment, to the nature of the memory task, and to the severity of the injury. Tasks that require divided attention are especially useful to tease out executive dysfunction caused by a TBI. Natural history studies have reported varying outcomes. For example, in a group of 102 patients with TBI (ages 10-60 years) who were hospitalized for any period of unconsciousness, for post-trauma tic amnesia (PTA) of more than 1 hour, or for evidence of cerebral trauma, at 1 month the TBI group performed significantly worse on the Wcchsler Memory Scale and the Selective Reminding Test than a control group. Those who could not follow a command for the longest times beyond 24 hours after injury scored below the controls on more subtests of the Wechsler Memory Scale. Tests of orientation and short-term memory were inferior in their ability to reveal memory deficits compared with tests that required storage of new information for later use. At 1 year, patients performed better than they had at 1 month after onset.

Treatments

Most rehabilitative efforts to improve attention and to encode new information or recognize and retrieve memories are used for people with TBI. Previous exposure to verbal and especially to nonverbal information, with cues and prompts, can allow many amnestic patients after TBI to recall that information, a phenomenon called priming. Priming does not require semantic processing for encoding. It is specific to the properties of the input and relies on perceptual representations stored by modaliry-speeific memory subsystems, such as those that process word forms and visual objects. Tests of recognition memory are especially sensitive methods for detecting residual memory in patients with severe amnesia. This implicit memory neocortical mechanism can even support the rapid acquisition of novel verbal and nonverbal material. It is independent of the hippocampal and diencephalic structures that relate to amnesia. Priming seems especially useful during rehabilitation to enhance procedural memory for skill acquisition.

Cognitive remediation of amnestic disorders aims to train paricnts in using the subcomponent processes that underlie declarative and nondcelarative memory. Therapists can then take a restorative or compensatory approach to affect particular memory skills for functionally important activities, For example, therapists may address attentional impairments that could interfere with memory training by strategies for improving focused, sustained, selective, alternating, and then divided attention. Impairments in encoding and recall of information are then addressed. This approach uses associative and external cues that arc meant to prompt an action after increasingly longer intervals. It also uses aids such as memory notebooks.

Some patients with TBI underestimate their memory and emotional impairments, even as they acknowledge physical and other cognitive problems. Without insight or concern, they deny having the impairment and withdraw or become angry with attempts at rehabilitation. The rehabilitation team must provide the counseling and insight therapy needed to overcome this.

After a moderate to severe TBI, repetitive driils can have little impact on general recall or on memory outside of the training session. External aids such as a calendar and appointment diary and internal strategies such as rehearsal and visual imagery help most patients. The devices listed in Table 54.22 are helpful if patients can be cued to use them.

Computers have been used extensively in cognitive remediation and skill training. Although software programs abound for working on reaction times, aspects of attention, language, problem solving, and other cognitive tasks, almost no data demonstrate the efficacy of this approach. Some patients have learned tasks such as data entry, database management, and word processing by taking advantage oi preserved cognitive abilities, including [In-ability to respond to partial cues and acquire procedural information, even in the presence of a marked amnestic syndrome. This knowledge often does not generalize to even modest changes in the tasks. Through procedural memory, verbal and visual mnemonic strategies have been used to teach subjects a computer graphics program. Cooking and vocational tasks were taught with an interactive guidance system that cued each subtask to build up to the desired task.

Pharmacological Adjuncts

Studies of single subjects and small groups suggest that the drugs in Table 54.2.3 may benefit some patients with

amnestic and attentional impairments. TBI may lead to damage in a particular neurotransmitter system, such as cholinergic neurons. Presynaptic cholinctgic neurotransmission was abnormal in a human postmortem study of TBI. Therefore rehabilitation trials of cholinergic enhancing drugs such as donepezil and cytidme diphosphocholine

seem warranted. Replacement therapies fotr other neurotransmittets, such as bromocriptine and noradrenergic agents, have a few human case studies to commend them. The divetsity of lesions after TBI (e.g., diffuse axonal injury, dorsolateral prefrontal cortex, hippocampus) necessitates an empiric, often individualized approach to pharmacotherapy.

Outcomes

Although memory-related processes are found to improve over the first 3 months after a stroke, reports on the natural history of ongoing cognitive sequelae suggest that both inpatient and outpatient rehabilitation efforts must pay ongoing attention to the need for compensatory aids and other strategies for these patients. After mild TBI, memoty usually recovers by 3 months. This varies with the test used to measure severity, the time from injury to testing, and the comparison group. The most impaired patients 1 year after a serious TBI are initially unable to follow a command finmore than a day and have post-traumatic amnesia for more than 14 days and a Glasgow Coma Score of 8 or less. One year after a severe closed head injury, patients followed in the Traumatic Coma Data Bank had greater impairments in vetbal and visual memoty and in other neurobehaviors, such as naming to confrontation and block construction, compared with normal controls. Selective rather than global cognitive impairments were likely at 1 year. Memory was disproportionately impaired compared with overall intellectual functioning in 15% of the moderately injuted and 30% of the severely injured patients. After moderate to severe TBI, children plateau in recovery by 1 year after onset, with little change in the next 2 years, and do not catch up to their peers in tetms of memoty, problem-solving ability, and academic performance. Late changes do evolve in some. In a long-term outcome study of mostly young adults, Wilson and colleagues reassessed 26 patients who had a TBI causing 1 hour to 24 weeks of coma, followed by rehabilitation. Five to 10 years later, 58% wete unchanged, 31% performed better, and 11% did worse on the Rivermead Behavioral Memory Test and Wechsler Memory Scale. Many needed to tcly on memory aids.

Hem i-In attention

Hennattentional disorders can arise from any node in the cottical-limbic-reticLilar network, which directs attention and integrates the localization and identification of a stimulus and its importance to the person. Unilateral neglect arises from injuries of the posterior parietal cortex; the ptefrontal cortex, which encompasses the frontal eye fields; and the cingulare gyrus. These regions include representations for sensation, for motor activities such as visual scanning and limb explotation, and for motivational televance, respectively. Subcortical areas such

as the thalamus, striatum, and superior colliculus coordinate the distribution of attention. Atrophy of frontal white matter and the diencephalon contributes to persistent anosognosia. The anterior and posterior extent of a lesion may also produce impairments in attentional and intentional processes that contribute to neglect. Therefore the most severe and subtle hcmiattentional disorders can be expected in focal stroke and more diffuse TBI.

Frequency of Hetni-lnattention Across Diseases

Community-based studies of stroke survivors detect visual neglect in 10-30% of patients. The neglect is modestly associated with poorer ADL scores and slower recovery, although severe neglect is rare beyond 6 months. Visual neglect is greater in right than left hemisphete strokes. Right-sided inattention, when looked for, has been detected in 15—40% of nonaphasic patients with acute left cerebral infarcts, although it is clinically most prominent after right brain injury. Patients with anosognosia, visual neglect, tactile extinction, motor inipersistence, or auditory neglect have the lowest BI scores at 1 year, even after the data are adjusted for initial ADL scores and for poststroke rehabilitation.

Recovery across reports has been most rapid in the first 2 weeks, regardless of the side of stroke, and has plateaued at 3 months, when most patients have little visual neglect. Severe visual neglect and anosognosia in the first week tend to predict some level of persistent impairment at 6 months. Many patients have more subtle and lingering impairments that depend on the test used to detect them. ¥*OT* example, early after a right hemisphere stroke, a group of patients showed a strong and consistent rightward attentional bias in addition to an inability to reorient their attention leftward. Twelve months later, the attentional bias continued, but they could fully reorient to left hemispacc when performing line bisection and cancellation tasks.

Treatments

The initial choice of an intervention may depend on the proposed mechanism of unilateral neglect or hemispatial inattention. For example, the patient can be treated for an underaroused right hemisphere that has difficulty processing sensory inputs. After a right brain injury, a powerful bias of the left hemisphere for attention to contralateral space could lead to an imbalance and necessitate a way to lessen the bias. A selective inability to disengage from inputs from ipsilatcral space might need to be addressed. Other strategies might have to be developed if the mental representation of contralesional space has been degraded or if a unilateral impairment m the activation of motor programs delays or prevents the intention to move to the contralesional side. If the initial theory-based intervention is not successful, then others should be tried. Table 54.24 lists some of the traditional and clever ways rehabilitationists have tried to manage hemi-inattcntion. For example, prisms have been used to transform sensorimotor coordinates, and passive prosthetics can be worn during tabletop activities. A 10-degree prism that shifts objects to the right in a patient with left hemi-inattention causes the patient to reach to the left when the glasses are removed. After adaptation to wearing the prism for 5 minutes, the patient's internal visual and proprioceptive map apparently realigns in the direction opposite to the optical deviation. The aftereffects of the prism may include significant improvement in drawing objects and performing cancellation tasks in left hemispace and in ADLs for days or more (Frassinetti et al. 2002). Noradrenergic and dopaminergic stimulants including methylphenidate and bromocriptine are especially worth trying in recalcitrant cases.

Behavioral Disorders

A great variety of behavioral changes can follow any hypoxic-ischemic injury or TBI. Alterations in personality have been reported in up to 75% of patients 1-15 years after a TBI and tend not to improve beyond 2 years after onset. Table 54.25 lists some of the more common changes. Agitated motor and verbal behaviors, though not easy to define or treat after TBI, are found in more than 10% and restlessness in 35% of patients during acute inpatient rehabilitation. As cognition improves, agitation declines, but directed and nondirected aggressive, impulsive behavior may evolve. Persistent aggression and emotional dyscontrol suggest premorbid mood and behavioral disorders.

Interventions include a medical assessment for exacerbating problems such as pain and drug-induced confusion, behavioral modification with positive and consistently applied reinforcements, a structured milieu, individual and group psychotherapy, and medication {Table 54.26).

Table 54.25: Potential changes in behavior and personality after traumatic brain injury and cerebral hypoxia

Blunted emotional responses
Poor self-worth
Passive dependent)

Hypoarousal sometimes improves with stimulants such as methylphenidate and amphetamine or with dopamine agonists. Aggressive behavior sometimes is decreased dopaminergic or noradrenergic receptor blockade. Beta blockers can decrease irritability. A randomized trial of propranolol with a dosage escalation to 420 mg a day showed a reduction in the intensity of agitation, but not the frequency of episodes, compared with placebo. Hypomaiiic behavior may respond to lithium. Anticonvulsants such as carhamazepine sometimes prevent outbursts related to episodic dyscontrol.

Affective Disorders

Incidence

Depression is very common after a stroke. The community-based Framingham Study diagnosed depression in 47% of 6-month stroke survivors, with no difference found in the incidence between those with left- and right-sided lesions, and in 25% of age- and sex-matched controls. In a population-based cohort of Swedish stroke patients whose mean age was 73 years, the prevalence of maior depression was 25% at hospital discharge, 30% at 3 months after sttoke, 16% at 1 year, 19% at 2 years, and 29% at 3 years. In this and many other studies, a left anterior infarct, dysphasia, and living alone contributed to the prediction of depression upon discharge. At 3 months, greater dependence in ADLs and relative social isolation were associated with depression. Few social contacts at 1 and 2 years contributed.

Anxiety is another stroke-related affective disotder. Although less often studied, a generalized anxiety disorder was present in 28% of recent stroke victims and was associated with greater social isolation and greater dependence in ADLs. Apathy was found in about one quarter of patients within 10 days of a stroke, associated with greater cognitive impairment, poorer ADLs, and some cases of major but not minor depression.

Depressed people with an SCI report spending more time in bed and fewer days out of the house and receiving more personal care assistance than better-adjusted patients with SCI at 2-7 years after injury. Suicide rates may be 2-4 times that of the general population within 5 years of SCI. Anxiety and depression can also arise from a post-traumatic stress disorder associated with the event that led to the SCI.

Of patients with TBI, 25-60% ate diagnosed with depression. Left anterior injuries, as in unilateral stroke, are associated with an early, ttansient depression. However, other focal and diffuse injuries make it difficult to relate mood disorders to specific diseases. Late-onset depression has been associated with premorbid psychiatric history and lower psychosocial function. Poor social adjustment can cause long-term depression and anxiety.

[able 54.26: Drut; interventions for aggressive behavior, restlessness, and episodic dyscontrol

Anticonvulsants (carhamazepine, valproate, gabapentin)
Beta blockers (e.g., propanolol)
Lithium
Antidepressants (e.g., amitriptyline, fluoxetine)
Stimulants (e.g., methylphenidate, pemoline)
Neuroleptics (e.g., risperidone)
Benzodiazepines (e.g., clonazepam)
Clonidine
Calcium channel blockers

Treatment

Clinicians should manage mood disorders aggressively, especially when progress in rehabilitation falls short of expectations. In general, patients with depression respond to all classes of antidepressant medications and can be managed with the judicious care in dosing that is usually taken with an older adult. For example, by 6 weeks after starting fluoxetine or citalopram, two thitds of depressed subjects after a stroke recover, compared with about 15% given placebo. The same medications can help alleviate pseudobulbar emotional incontinence with its involuntary weeping, grimacing, and laughing. Close clinical monitoring for adverse reactions to the antidepressants is important during inpatient and outpatient rehabilitation. These include sedation, insomnia, anticholinergic effects on bowel, bladder, and salivation, orthostatic hypotension, cardiac arrhythmias, anxiety, extrapyramidal symptoms, and a serotonin svndrome.

FUNCTIONAL OUTCOMES **WITH REHABILITATION**

The most important outcomes for the rehabilitation team include the degree of independence in ADLs and community living. Thus functional measures that reflect the burden of care needed and the quality of life achieved by people with neurological disabilities are used in outcome studies more often than measures of change in sensorimotor and cognitive impairments. The scores on the FIM at admission for inpatient rehabilitation and at discharge offer an interesting snapshot of a large number of patients with stroke, **TBI,** and SCI from American institutions that participate in the Uniform Data System for Medical Rehabilitation. Over the past 10 years, the time from onset of neurological illness to transfer for rehabilitation has dropped about 25%, and the length of stay in rehabilitation has followed a similar course in the United States.

Table 54.27: Typical uniform data system for medical rehabilitation data for first stroke admissions, 2000

	Admission	*Discharge*
Mean Subs cores		
Self-care	3.5	5.2

Stay (days)		20
Discharge (%)		
Community	76	76
Long-term care	15	14
Acute care	7	6

Stroke

A metaanalysis of 36 trials carried out before 1992 showed that the average patient who received a program of focused stroke rehabilitation or a particular procedure performed better than about *65%* of the patients in the comparison group. Larger treatment effect sizes were associated with earlier timing of the intervention and younger age. This trend has continued over the past 10 years. Specific interventions for a well-defined functional disability, such as for improving functional use of an affected hand, walking, strength of a muscle group, balance, speech intelligibility, or community activities, show a moderate benefit.

Rehabilitation studies of patients with stroke generally show that 50% of 6-month survivors have no motor impairment, 70-80% can walk 150 feet alone, and 50-70% are independent in ADLs using the BI. These gains in subjects with the best outcomes do not imply that they can walk efficiently in the community. However, most studies suggest that 50-75% of survivors do not return to their prestroke level of activities in the community. Table 54.27 shows admission and discharge data about ADLs measured by the 7-part FIM, compiled from publications from the Uniform Data System.

Ambulation

A community-based population study in Copenhagen prospectively followed 800 acute stroke survivors. On admission, 51% were unable to walk, 12% walked with assistance, and 37% were independent. In the same facility, all who needed rehabilitation received services for an average total stay of 35 ± 41 days. At discharge, 22% could not walk, 14% walked with human assistance, and 64% of survivors walked independently by BI criteria. Recovery of ambulation correlated directly with leg strength. About 80% of those who were initially non-walkers reached their best walking function within 6 weeks, and 95% achieved this within 11 weeks. If patients walked with assistance at stroke onset, 80% reached their best function within 3 weeks and 95% within 5 weeks. With rehabilitation, 34% of the survivors who had been dependent and 60% of those who initially needed assistance achieved independent walking for at least 150 feet.

Life table analysis of patients from different impairment groups reveals a somewhat different pattern of gains. During their rehabilitation, 90% of patients with a pure motor (M) deficit become independent in walking 150 feet by week 14 after stroke onset, but only 35% of those with motor and proprioceptive (SM) loss by week 24, and 3% of those with motor, sensory, and hemianopic deficits (SMH) by week 30. The probability of walking more than 150 feet with assistance increases to 100% with M impairment by week 14. It increases to 90% in those with SM loss by week 26 and with SMH deficits by 28 weeks. At 1 month and 6 months after stroke for all survivors, 50% and 85%, respectively, of M subjects recover walking, 48% and 72% of SM subjects recover, and 16% and 38% of SMH subjects walk without human assistance (Patel et al. 2000).

Although many patients become independent in gait, sttoke patients who needed rehabilitation most often have self-selected walking speeds that peak in *3-6* months at one third to one half of normal for age. Speed is a good reflection of the overall gait pattern and, as noted earlier, reflects capabilities for walking in the home and community.

Self-Care Skills

In the Copenhagen Stroke Study, ADLs measured by the **BI** were assessed weekly in the hospital and at 6 months.

Twenty percent of survivors had a severe disability and 8% a moderate disability after a mean hospital stay of 37 days. Functional recovery peaked by 13 weeks after stroke onset in *95%.* The highest BI score was reached within 13 weeks by those with moderate impairments and within 20 weeks in those with severe impairments by the Scandinavian Stroke Scale. A Bl score greater than 60 is associated with a home discharge. Using the impairment grouping schema, the cumulative probability of reaching a BI score greater than 60 and greater than 90 at 6 months after stroke is 95% and 70%, respectively, for M subjects, 85% and 62% for SM subjects, and 52% and 35% for SMH patients (Patel et al. 2000). Similarly, about *65%* of inpatients during rehabilitation achieve a BI score greater than *95* by 15 weeks if they have only M deficits and by 26 weeks with SM loss. Only 10% score that high with SMH deficits after 18 to 30 weeks. However, 100% achieve a score greater than 60 by 14 weeks with M loss only, 75% by 23 weeks with SM deficits, and 60% by 29 weeks with SMH loss.

For patients admitted for stroke rehabilitation, the admission BI or FIM score predicts later burden of care. The FIM score on admission positively correlates with discharge FIM and negatively correlates with length of stay, except in patients under age 50. The largest FIM change over time occurs in patients with admission FIM scores of 40 to 80. Patients with admission scores grearer than 80 and age less than *55* years routinely return home. A score of less than 40 and age greater than 65 leads to a nursing home discharge for 60%.

Spinal Cord Injury

The Uniform Data System database shows that the average age of patients with traumatic SCI is 43 years old. The mean rime from onset to admission for rehabilitation is 22 days, and length of stay is about 33 days. The FIM score increases from about 63 to 89. ASIA A (sensorimotor complete) and B (sensory present) subjects from trauma become ASIA C (less than useful motor return) in only about 10% of patients during inpatient rehabilitation after a cervical or thoracic SCI. These patients tend to regain some sensorimotor function one level below the initial level of impairment. Gains may be a bit better for these ASIA-lcvcl patients with conus and cauda equina injuries. A clinical trial of CM, ganglioside found the following changes in 760 patients between 72 hours after a traumatic SCI of the cervical or thoracic cord and 26 weeks. About 80% of patients with a central cord injury were able to walk at least 25 feet. Only 4% of ASIA A patients at onset recovered any ability to walk, whereas 40% of ASIA B subjects regained this function. At least 70% of ASIA C subjects recovered unlimited walking. ASIA A patients almost never recovered normal bowel and bladder function. Overall, about 15% of subjects recovered these functions.

Self-care skills depend especially on the level and completeness of an SCI. For patients with complete lesions at C4 or above, ventilatory support and assistive devices are needed along with physical help. With C5 intact, self-feeding is achieved with devices such as a balanced forearm orthosis and wrist splints with attachments for utensils. Patients use a power wheelchair by a hand control. With C6 intact, wrist extension allows the thumb and fingers to oppose without or, better, with a tenodesis orthosis. Upper extremity dressing, self-carheterization, manual wheelchair propulsion, and sliding board transfers are feasible. With C7 intact, these activities are performed more efficiently, and use of a suppository for the bowel program is feasible. With C8 intact, long finger flexion permits most ADLs to lie accomplished from a wheelchair.

The strength of the lower extremities determines the amount of work that must be performed by the upper extremities for support, which in turn determines the energy cost and feasibility of ambulation. A study using the ASIA Motor Score found rhat 20 of 23 incomplete tetraplcgics who had an ASIA lower extremity motor score of 10 or more (the maximum normal score is 50 for five muscle groups of each leg on a 5-poinr scale of strength) at 1 month after injury became community ambulators with crutches and orthoses by 1 year. They subsequently achieved nearly effortless community ambulation if the lower extremity motor score improved to at least 30. In comparison, scores of 20 or less were associated with limited ambulation at slower average velocities, highct heart rates, greater energy expenditure, and greater peak axial loads on assistive devices. Paraparetic community ambulators usually need to have pelvic control with at least movement against gravity in the hip flexors and at one knee extensor so that they need no more than one KAFO for a reciprocal gait pattern.

Patients need encouragement and resources to be able to return to work or school. Those with education beyond high school are far more likely to return to work and stay employed. Aging with SCI poses problems for many. One fourth of patients who sustained their injuries 20 or more years ago evolve a greater need for physical assistance over the years, especially for help with transfers. They report shoulder pain, fatigue, weakness, weight gain, and a decline in the quality of life more often than patients who do not need more assistance. Clinical surveillance is needed to anticipate when a pulse of therapy for an increasing impairment or disability or a change in assistive devices or wheelchair is needed.

Traumatic Brain Injury

In general, after moderate to severe TBI, self-care and mobility improve from admission to inpatient rehabilitation to discharge, and gains are maintained or continue to increase for about 6 months. About 50% return to work at

6 months. Socialization and leisure activities generally do not return to premorbid levels. Table 54.28 shows some of the characteristics of injury and rehabilitation in a well-defined group of American patients that did not include children.

In a group of 24i consecutive admissions to a rehabilitation unit, a significant inverse relationship was found between the Glasgow Coma Score and the duration of coma, along with a strong positive relationship between the duration of coma and post-traumatic amnesia (PTA). Of 119 patients with diffuse axonal injury, no one in a coma for more than 2 weeks or with PTA for more than 12 weeks had a good recovery by the Glasgow Outcome Score at 1 year after injury. Two thirds of the small subgroup with coma for more than 2 weeks improved to moderate disability when the coma lasted 2-4 weeks. Only one third achieved this level if in coma for more than 4 weeks. Eighty percent of patients with PTA for less than *1* weeks had a good recovery, and half with PTA lasting 2-8 weeks were moderately disabled 1 year after admission. At another inpatient facility, patients who had a Glasgow Coma Score of 3-7 within 24 hours of onset had lower admission and discharge FIM scores for motor and cognitive function duting their rehabilitation. In many communities, about 10% of patients return to former jobs, and fewer than 30% are employed 2 years after severe TBI.

Parkinson's Disease

Perhaps even more than with other chronic and progressive neurological diseases, with Parkinson's disease an exercise prescription can help patients maintain range of motion, flexibility, proximal strength, mobility, and fitness. Parkinsonian patients can reduce their symptoms and improve their function with focused physical and occupational rehabilitation therapies. Speech therapy improves prosody, breath support for speaking, and intelligibility. Patients have been trained to increase the speed of a skilled movement such as buttoning, although with more practice than normal controls need. Also, twice-a-weck practice for 3 months in whole body movements such as sitting, kneeling, standing up, and throwing, along with problem-solving for these activities, improves the speed of movements needed for mobility in moderately disabled Parkinsonian patients. A randomized crossover study compared regular activity with 1 hour of repetitive stretching, endurance, balance, gait, and fine motor exer cises in moderately disabled patients. Exercises were performed three times a week for 4 weeks with a progressive increase in the number of repetitions. The total United Parkinson's Disease Rating Scale score and the ADL and motor subscores, particularly the bradykinesia and rigidity components, significantly improved with exercise. Without an ongoing formal exercise program, these gains were lost 6 months later.

Multiple Sclerosis

Evaluating the impact of rehabilitation in MS presents difficulties because it is a chronic condition continuing over many decades that is variable, unpredictable, and subject to spontaneous improvement during the first 15 years in many patients. A study of patients with rclapsing-and-remitting MS at onset found that the median time to reach a score of 4, 6, and 7 on the Kurtzke Disability Status Scale was 11, 23, and 33 years, respectively. The scores represent a change from limited walking up to 500 m (EDSS 4), to walking with unilateral support no more than 100 m

Table 54.28: Traumatic Brain Injury Model Systems Project, 1989-2000 (2553 cases)

Variable	*Onset*	*Rehabilitation discharge*	1 *Year after injury*

without rest (EDSS 5), to walking no more than 10 m while holding objects for support (EDSS 6). Patients with progressive disease from onset declined at 0, 7, and 13 years, respectively. Thus plenty of opportunities arise for rehabilitative interventions for specific disabilities.

Quasi-experimental studies suggest a benefit from inpatient rehabilitation in MS. For example, in a srratified, randomized, wait list, controlled study involving 66 patients with progressive MS, the treatment group underwent a mean of 25 days of multidisciplinary inpatient rehabilitation. At *6* weeks, the neurological status in both groups remained the same. The treated group showed significantly lower levels of disability than the control group. Despite a decline in neurological status over the following year, the group maintained its gains in disability for *6* months and in quality of life for 10 months. A randomized trial compared 3 weeks of inpatient rehabilitation with a home exercise program in 50 patients. No change in impairment was seen in either group. However, the rehabilitation arm showed a benefit in disability in the FIM motor domain for self-care and locomotion (which could include wheelchair use), which persisted for 15 weeks. Improvement in quality of life (SF-36) in the mental composite score was also present for 9 weeks. These results emphasize the importance of continuity of care between the rehabilitation environment and the community and social service sectors, if the needs of the person with MS or with other chronic neurological diseases are to be met effectively over the longer term.

The effect of an extended outpatient rehabilitation program on symptom frequency, fatigue, and functional status was studied in 46 patients with progressive MS. The 26 patients in the nonrandomized treatment arm received rehabilitation day services for 5 hours, 1 day per week. Although this program did not have any effect on functional status, significant benefits were seen in both in a reduction of symptom frequency at 1-year follow-up and in the incidence of fatigue compared with that of a wait-listed group. Although not yet studied by a scientific design, a day program may include general physical fitness exercises, practice in ADLs, group recreation, gardening, and local travel that help maintain or build self-care and community skills, along with psychosocial supports for clients and caregivers.

Other Diseases

Critical illness polyneuropathy and myopathy from sepsis and organ transplantation have become a common cause of diffuse weakness, deconditioning, and disability that necessitates inpatient rehabilitation. Exercise management is similar to that of patients with Guillain-Barre syndrome. Nearly all patients with critical illness-induced weakness improve their strength from movement only against gravity at admission to offering resistance in proximal muscles within 3 weeks of the inpatient stay. As soon as feasible, these patients need to enter a milieu that encourages them to assist themselves, stay out of bed, and do light resistance exercises throughout the day. Patients are encouraged to work their arms and legs against the resistance of a stretchablc rubber Theraband for 10 repetitions in various planes every hour, even when resting in bed, or to do isometric exercise with a family member. The average length of stay needed to achieve the ability to stand up and walk 50 feet or more with an assistive device is about 18 days. Light resistance and conditioning exercises ought to be part of any maintenance program for people with diseases of the motor unit as well, along with instruction from therapists if greater disability evolves.

SUMMARY

The essence of neurological rehabilitation is the ability to recognize and solve problems in everyday he a 1th-related activities faced by patients and their caregivers. Rehabilitation efforts attend to the details of the physical and cognitive impairments and disabilities of patients and their desire to participate more independently. The clinician must survey the patient's needs and anticipate complications by promoting prophylactic measures. Physical and cognitive interventions, supplemented by psychosocial supports and drug trials, aim to extend the quality of life of disabled patients. The design and institution of clinical trials for theory-based interventions have progressed more in the past 5 years than at any time in the past 50 years. These trials will lead to a solid base of therapies for specific needs. The success of incorporating biological interventions for neural repair and pharmacological memory-enhancing molecules into clinical practice will depend heavily on clinicians' ability to offer well-defined treatments that foster activity-dependent plasticity during the retraining of important skills.

Chapter 55
Neurological Complications of Systemic Disease

A. IN ADULTS

Michael J. Aminoff

This chapter discusses neurological complications of systemic disease in adults. Chapter 55B discusses the same subject in children. Some disorders are discussed in both chapters but with a different emphasis.

CARDIAC; DISORDERS AND THE NERVOUS SYSTEM

Neurological complications arc an important cause of morbidity in patients with cardiac disease. Cardiogenic

emboli may result from cardiac disease or its surgical treatment, and cardiac dysfunction can cause global cerebral hypoperfusion leading to syncope, stroke, or death, depending on the severity and duration of cerebral ischemia.

Cardiogenic Embolism

Cardiogenic emboli are most prevalent in patients with mitral stenosis and atrial fibrillation, intramural thrombi, prosthetic cardiac valves, atrial myxoma, infective endocarditis, sick sinus syndrome, and atrial fibrillation. Other causes include recent myocardial infarct, left atrial thrombus or turbulence, mitral valve prolapse, mitral annulus calcification, atrial fluttct, hypokinetic left ventricular segments, and congestive cardiac failure. Emboli from congenita) heart disease are discussed in Chapter 55B. The possibility of cardiac emboli must be considered in young people with either valvular heart disease or mitral valve prolapse.

Echocardiography is an important investigative procedure when cardiogenic emboli arc suspected. Transesophageal echocardiography is preferable to the transthoracic approach in the evaluation of suspected atrial disease, such as myxoma or thrombus, and to demonstrate a patent foramen ovale, but transthoracic echocardiography is an important method of visualizing the ventricular apex, mitrai or aortic valvular disease, and left ventricular thrombus.

Transesophageal echocardiography is an appropriate method to investigate people younger than 45 years with suspected cardiogenic emboii who may need anticoagulation or surgery and older people without signs of cardiac-disease, but transthoracic echocardiography is generally adequate when clinical evidence of cardiac disease is present.

Emboli are more likely when atrial fibrillation is associated with valvular heart disease. The incidence of stroke among patients with atrial fibrillation is increased 17-fold or 5-fold, respectively, depending on the presence or absence of rheumatic heart disease. Atrial fibrillation, in the absence ol cardiovascular disease or other predisposing illness, has a considerably lower risk of neurological complications. The neurological prognosis of paroxysmal atrial fibrillation is not established, but the risk of embolism is probably less than with chronic atrial fibrillation.

The benefit of anticoagulation in reducing the risk of stroke in people with atrial fibrillation is established. A consensus has developed that long-term oral warfarin therapy for atrial fibrillation unless there were specific contraindications or the atrial fibrillation was an isolated finding in people younger than 60 years without other evidence of cardiovascular disease. Aspirin (325 mg per day) is recommended when warfarin is contraindicated. Warfarin is usually started at least 3 weeks before elective cardioversion in people with atrial fibrillation of more than 2 days' duration and continued until normal rhythm has been maintained for 4 weeks.

Myocardial infarcts, especially apical, anterolateral, or large infarcts, have a risk of embolic stroke. Most occur within a week, but the risk persists for approximately 2 months. Therefore patients not on thrombolytic therapy arc heparinized after myocardial infarction and then treated for 3 months with warfarin if they have an increased risk of embolism. The groups with increased risk are those with congestive heart failure, previous emboli, evidence of a mural thrombus, left ventricular dysfunction, or atrial fibrillation.

Emboli are an important cause of death in people with rheumatic valvular disease. The risk of embolism is increased in the presence of atrial fibrillation, intra-attial thrombus, ot a histoty of emboli, and long-term warfarin treatment is recommended. Aspirin (160-325 mg per day) is added for recurrent systemic emboli despite adequate warfarin therapy.

Mitral valve prolapse is a common anomaly, especially among young women, and its relationship to cerebral emboli is now recognized. The risk of emboli is relatively small, and long-term warfarin therapy is recommended only tor people who have had previous embolic phenomena or are in atrial fibrillation. Eong-term aspirin therapy (325-975 mg per day) is recommended for people with mitral valve prolapse and transient cerebral ischemic attacks of uncertain nature.

Among patients with a history of cardiogenic emboli, recurrent stroke is more likely in those with cardiac valve disease and congestive heart failure. Nevertheless, the main cause of death in such patients is from the heart disease rather than neurological complications. The conversion of a cerebral infarct into a hemorrhage is a concern when patients with stroke from cardiogenic emboli are anticoagulatcd. The concern is especially justified in patients with large infarcts or when imaging studies suggest pre-existing hemorrhagic transformation. It is good practice to delay anticoagulation therapy after a small infarct for at least 24 hours, and then to initiate u only if computed tomographj shows no evidence of major hemorrhagic transformation. Anticoagulation is best delayed for 7 days after large infarcts. Atrial fibrillation is associated with an increased mortality during the acute phase of a stroke and in the subsequent year.

Syncope

Transitory global cerebral ischemia secondary to cardiac-arrhythmia causes syncope, sometimes preceded by non-specific premonitory symptoms such as visual disturbances, paresthesias, and lightheadedness (Sotcriades et al. 2002). Syncope is usually associated with loss of muscle tone, but prolonged ischemia causes tonic posturing and irregular jerking movements that are easily mistaken for seizures

(Adams-Stokes attacks). The syncopal patient is pale, and postictal confusion is either absent or short lived, usually lasting for less than 30 seconds. Obstructed outflow from aortic stenosis or left atrial tumor or thrombus is one cardiac cause of syncope; other causes are arrhythmias, especially from ventricular tachycardia or fibrillation, chronic sinoatrial disorder or sick sinus syndrome, and paroxysmal tachycardia. Additional causes of syncope are central and peripheral dysautonomias, postural hypotension, and endocrine and metabolic disorders. Vasovagal syncope, the most common variety, and the prolonged QT-interval syndrome are discussed in Chapter 55B.

Cardiac Arrest

Brain function is critically dependent on the cerebral circulation. The brain receives approximately 15% of the total cardiac output. Ventricular fibrillation or asystole causes circulatory failure that depending on its duration can cause irreversible anoxic-ischemic brain damage. The prognosis generally depends on age, the duration of the arrest before cardiopulmonary resuscitation is started, and the interval before starting defibriHating procedures. The prognosis is better when circulatory arrest is caused by ventricular fibrillation rather than asystole.

The pathophysiology of neurological damage caused by transitory interruption of cerebral blood flow is unclear. Suspected mechanisms are the accumulation of intracellular calcium, increased extracellular concentrations of glutamate and aspartate, and increased concentrations of free radicals.

In the mature brain, gray marter is generally more sensitive to ischemia than white matter, and the cerebral cortex is more sensitive than the brainstem. The premature brain has the reverse pattern of sensitivity (see Chapter 86). Cerebral or spinal regions lying between the territories supplied by the major arteries (watershed areas} are especially vulnerable to ischemic injury.

The severity of neurological complications of circulatory arrest correlarcs with the duration of the arrest. Brief (<5 minute) arrests cause temporary loss of consciousness and impaired cognitive function. Recovery may be followed by a demyelinating encephalopathy 7-10 days later, characterized by increasing cerebral dysfunction with cognitive disturbances and pyramidal or extrapyramidal abnormalities that may lead to a fatal outcome. Thus some patients regain consciousness after several hours and then develop progressive neurological deficits affecting cognitive and cortical function: intellectual decline, seizures, visual agnosia, cortical blindness, amnestic syndromes, and personality changes. Less common residua are rhe lockcd-in syndrome, parkinsonism or other extrapyramidal syndromes, abnormal ocular movements, bilateral brachial paresis, or action myoclonus. Spinal cord dysfuncrion is unusual and usually involves the watershed region at T5: Flaccid paraplegia with sensory loss, areflexia, and sphincter dysfunction are the immediate findings.

Prolonged cardiac arrest causes widespread and irreversible brain damage characterized by prolonged coma or a persistent vegetative state. Prolonged coma and loss of brainstem reflexes indicate a poor prognosis for survival or useful recovery. Absence of the pupillary response to light is perhaps the most useful clinical guide to prognosis; its absence even on initial examination indicates a poor prognosis for useful recovery (see Chapter 5 for further discussion).

Complications of Cardiac Catheterization and Surgery

Comments pertinent to children are provided in Chapter 55B. Cardiac catheterization causes cerebral emboli in fewer than 1% of cases; for unexplained reasons, these more often involve the posterior than the anterior circulation. The frequency of cerebral emboli following percutaneous transluminal coronary angioplasty is generally also less than 1% and may involve either the carotid or the vertebral circulation. However, the risk of stroke is greater in patients with acute myocardial infarction treated by angioplasty.

Encephalopathy, seizures, and cerebral infarction after cardiac surgery are usually caused by hypoxia or emboli. Postoperative psychoses or encephalopathies may be caused by metabolic disturbances, medication, infection, or multiorgan failure. Intracranial infection should be suspected when behavioral disturbances develop several weeks postoperatively in patients receiving immunosuppressive agents. Postoperative seizures are usually caused by focal or generalized cerebral ischemia, electrolyte or metabolic disturbances, or multiorgan failure. Intracranial hemorrhage is a rare complication of cardiopulmonary bypass. It is usually attributed to diminished platelet adhesiveness and reduced coagulation factors. Cognitive changes after cardiac bypass surgery are detectable in 53% of patients at discharge and 42% after 5 years. Patients without cognitive decline initially maintained their cognitive function at 5 years (Newman et al. 2001). Some patients with early cognitive deficits had initial improvement and later decline for uncertain reasons. Thus early cognitive changes cannot be assumed to be purely temporary.

Compression or traction injuries to the brachial plexus, especially the lower trunk, and phrenic and recurrent laryngeal nerves may occur during cardiac surgery.

Other common early complications of cardiac transplantation are organ rejection with consequent cardiac failure and side effects of immunosuppressive drugs. Cerebral air embolism may require hyperbaric oxygen therapy combined with aggressive resuscitation (Hinkle et al. 2001). Infections (meningitis, meningoencephalitis, or cerebral abscess) secondary to immunosuppressive therapy are the most important late complications. The infecting organisms include *Aspergillus, Toxoplasma, Cryptococcus, Candida,*

Nocardia, and viruses. The risk of lymphoma and reticulum cell sarcoma is increased also in patients on long-term immunosuppressive agents. Primary central nervous system (CNS) lymphoma may be impossible to distinguish clinically or radiologically from infection (see Chapter 5&).

Stroke occurs in approximately 5% of patients undergoing coronary artery bypass surgery. The risk is increasing because of the tendency to opetatc on older patients with more severe vascular disease or to undertake complicated, combined procedures such as bypass surgery plus valve replacement (Nussmeier 2002); other risk factors include proximal aortic atherosclerosis, hypertension, diabetes, and female gender. The mechanism is eithet embolic or less commonly a watershed infarction from hypoperfusion. A history of previous stroke also increases the risk, but a carotid bruit or radiological evidence of atherosclerotic disease of the carotid artery does not, and carotid endarterccctomy before the cardiac surgery is not justified.

A few patients who fail to recover consciousness after surgery despite the absence ol any identified metabolic cause have probably suttered diffuse cerebral ischemia or hypoxia. Hemispheric or multifocal infarction (Figure 55A. 1) is responsible in some cases. In evaluating patients with postoperative neurological deficits, diffusion-weighted magnetic resonance imaging (MRI) is more sensitive to ischemic change than computed tomography (CT) and most often reveals multiple embolic infarcts (Wityk et al. 2001).

Neurological Complications of Medication

The infectious and neoplastic complications of immunosuppressive agents are discussed in the previous section. The othct adverse events associated with corticosteroids are behavioral disturbances, psychoses, proximal weakness with type II muscle fiber atrophy, postural tremor, cataracts, and osteoporotic fractures. Benign intracranial hypertension may occur during treatment with or on withdrawal of corticosteroids. Neurological complications of cyclosporinc include tremor, seizures, focal deficits, paresthesias, encephalopathy, and ataxia.

Among antiarrhythmic agents, amiodarone causes tremor, sensorimotor peripheral neuropathy, myopathy, ataxia, optic neuropathy, and pseudotumor cerebri. Procainamide may unmask latent myasthenia gravis or precipitate a lupus-like syndrome with secondary vascular

FIGURE 5SA.1 A noncontrasr computed tomographic scan performed to evaluate persistent coma 2 days after coronary artery bypass graft. Multiple bilateral ischemic lesions can be seen.

occlusive complications that are probably associated with lupus anticoagulant and antiphospholipid antibodies. Quinidine has neurological side effects similar to those of procainamide and causes headache, tinnitus, and syncope.

Lidocaine and related agents may cause seizures, tremor, paresthesias, and confusional states. Calcium-channel-blocking agents occasionally cause encephalopathy. Beta blockers are associated with mental changes, paresthesias, **and** disturbances of neuromuscular transmission, and digoxin and thiazide diuretics with an encephalopathy and disturbances of color vision.

Infective Endocarditis

The incidence of infective endocarditis has been increasing because of intravenous substance abuse and the increasing use of prosthetic cardiac valves. The overall incidence of neurological complications of infective endocarditis is approximately 25-35% but varies with the infecting organism. Such complications are the first sign or major complaint in 25-50% of instances and are associated with a significantly higher mortality. Neurological manifestations arc especially common in patients with mitral valve abnormalities and consist of embolic or hemorrhagic stroke and infections such as meningitis or brain abscess.

Cerebral mycotic aneurysms (Figure 55A.2) are recognized complications of infective endocarditis and may result in intracranial hemorrhage. They generally develop at the point of bifurcation of peripheral arteries and have a more distal location than congenital berry aneurysms. The pathogenesis of mycotic aneurysms is unclear. The most likely cause is impaction of infected material in the vasa vasorum, with resulting destruction of the wall of an artery. Intraluminal occlusion of the vessel by infected material, wiih subsequent aneurysmal formation, is less likely but has been documented in some cases. Mycotic aneurysms may be clinically silent and sometimes resolve with antibiotic therapy. They are less common but occur earlier in acute than in subacute bacterial endocarditis. Their natural history is poorly defined.

Intracranial hemorrhage is caused also by septic arteritis that destroys the vessel wall without causing aneurysm and by hemorrhagic transformation of cerebral infarcts. Arteriography is needed in patients with intracranial hemorrhage to distinguish mycotic aneurysm from septic arteritis.

Intracranial bleeding from a ruptured mycotic aneurysm can be the initial feature of an underlying cardiac disorder or may occur during the management of previously recognized infective endocarditis. Four-vessel arteriography is indicated in every patient with infective endocarditis who develops focal neurological deficits or has a subarachnoid hemorrhage. Arteriography should be performed before starting anticoagulation therapy in infective endocarditis unless an appropriate course of antibiotics has been completed without the development of neurological symptoms.

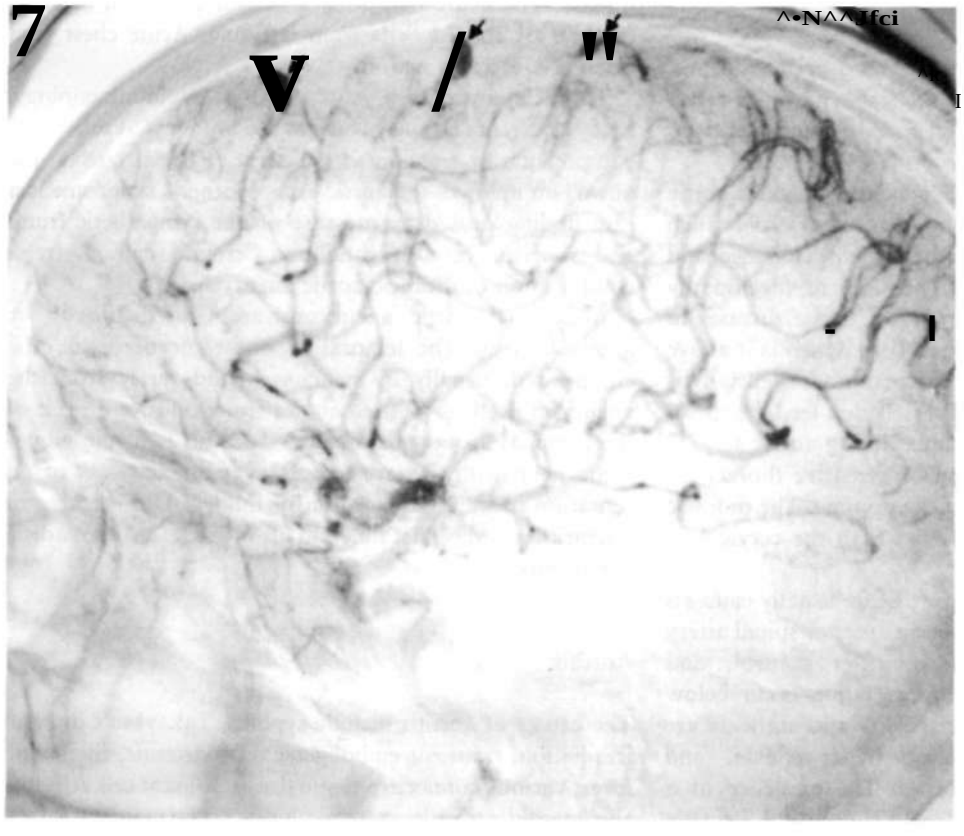

FIGURE 55A.2 Carotid angiogram, lateral view with subtraction, in a 48-year-old man with multiple peripheral mycotic aneurysms (*arrows*) verified at autopsy.

Embolization of infected material causes cerebral microabscesses and meningitis. Multiple septic emboli may cause meningoencephalitis or a diffuse encephalopathy that is characterized by a confusmnal state, headache, meningismus, and a cerebrospinal fluid (CSF) profile suggesting an aseptic process. The basis of these symptoms is probably multifactorial: infection, vascular occlusion, metabolic abnormalities, and mycotic aneurysms.

Antibiotic therapy to resolve the cardiac infection is the mainstay of treatment and is important in preventing neurological complications (Heiro et al. 2000). Neurological abnormalities usually resolve. Imaging studies are indicated in patients with progressive or persistent neurological deficits or an abnormal CSF. Arteriography is needed when MRI suggests mycotic aneurysm. Whether mycotic aneurysms require surgical resection or should be treated with antibiotics alone is unclear. Resection is recommended when cardiac valve replacement is planned, to reduce the risk of rupture from anticoagulants used during cardiopulmonary bypass. Anticoagulants are usually withheld from patients with infective endocarditis and cerebral embolism because of the risk of rupture of an unrecognized mycotic aneurysm. Moreover, control of the underlying infection with antibiotics reduces the risk of further embolism sufficiently to make anticoagulation unnecessary. Anticoagulation also may increase the risk of hemorrhagic transformation of embolic infarcts.

DISEASES OF THE AORTA

The aorta supplies blood to the CNS and peripheral nervous system (PNS). Several neurological syndromes result from aortic disease, depending on the site and severity of obstruction.

Spinal cord ischemia may result from congenital aortic abnormalities such as coarctation, acquired disorders such as aortic aneurysm or occlusive atherosclerotic disease, and aortic surgery or aortography. The level of myelopathy depends to some extent on the site of aortic disease. In general, aortic pathology that causes cord ischemia is above the origin of the renal arteries; obstruction more distally is less likely to affect the segmental vessels that feed the spinal cord. Risk factors for cord ischemia during aortic surgery include the presence of dissection or extensive thoracoabdominal disease, and a long cross-ciamp time. The thoracic cord is more susceptible to ischemia than the cervical or lumbosacral regions.

Spinal cord ischemia from aortic disease usually causes a complete transverse myelopathy or an anterior spinal artery syndrome. Weakness, loss of sphincter control, and impaired pain and temperature appreciation occur below the level of myelopathy. Initial flaccidity and areflexia are eventually replaced by spasticity, hyᵣper-ref!exia, and bilateral extensor plantar responses. The exisrence of a true posterior spinal artery syndrome is doubtful, because the posterior spinal arteries have multiple feeding vessels along their length. Occasional reports of a clinical disorder resembling progressive spinal muscular atrophy have been attributed to cord ischemia from aortic disease affecting the anterior horn cells especially.

Neurogenic claudication may be caused by ischemia of the nerve roots or cauda equina (as by a protruded lumbar disc in spinal stenosis), by intermittent cord ischemia from spinal vascular malformations, or by aortic disease. Pain, weakness, or a sensory disturbance develops in one or both legs while walking or in relation to certain postures. Symptoms are relieved by rest or change of posture. Neurogenic claudication must be distinguished from the intermittent claudication of peripheral vascular disease, because their treatments are different.

Disease of the aortic arch or its main branches also may lead to transient cerebral ischemic attacks or strokes. The risk of embolization from the aortic arch has been grossly underestimated until recently, especially in patients older than 60 years. Transesophageal echocardiography is an important means of evaluating the aortic arch.

Aortic Aneurysms

In Marfan's syndrome, there is an unusually high incidence of dissecting aneurysm ot (he ascending aorta that is associated with a dilated aortic root, but dissecting aortic aneurysms also occur in the absence of connective tissue disease. The neurological features usually consist of acute cerebral or cord deficirs from ischemia. Acute chest pain often is associated with it.

Thoracic aortic aneurysms suggest a syphilitic etiology. Left recurrent laryngeal nerve palsy may result from compression or traction of the nerve, especially when the aneurysm involves the aortic arch. Horner's syndrome is a rare finding caused by pressure on the sympathetic trunk and superior cervical ganglion. Cerebral emboli are a complication of thoracic aortic aneurysms.

Abdominal aortic aneurysms are caused usually by atherosclerosis. The femoral or obturator nerve may be compressed, usually by hematoma and rarely from the aneurysm itself, or injured at surgery. Occlusive disease of the terminal aorta sometimes leads to an ischemic monomelic neuropathy, characrerized by pain and loss of all sensation in the distal portion of the leg. Disturbances of micturition and sexual function also may result from aortic aneurysms.

Aortitis

The causes of aortitis include syphilis, Takayasu's disease, irradiation, transient emboligenic aortoarteritis, rheumatic fever, various connective tissue diseases (giant cell arteritis, rheumatoid arthritis, systemic lupus erythematosus [SLE],

scleroderma), ankylosing spondylitis, and Reirer's syndrome. Neurological complications occur when arteries are involved rhar perfuse neural tissues or in relarion to secondary aortic pathology such as an aneurysm.

Takayasu's disease is primarily a disease of young women. Nonspecific symptoms are fever, weight loss, myalgias, and arthralgia. Obstruction of major vessels of the aortic arch causes loss of pulses in the neck and arms, hypertension, and aortic tcgurgitation. Less common symptoms are headache, seizures, transient cerebral ischemic attacks, and stroke. Corticosteroids are the treatment of choice.

Transient emboligenic aortoarreritis is an inflammatory process affecting the aorta and other central elastic arteries, bur not the more peripheral vessels. It is a cause of stroke or transient ischemic attacks in young people.

Coarctation of the Aorta

Congenital coarctarion of the aorta is a narrowing of the thoracic aorta just after the origin of the left subclavian artery. Acquired coarctation may follow irradiation during infancy; the narrowing is in the irradiated region. A narrowed segment that is atypically located for congcniral coarctation and unrelated to prior irradiation should suggest Takayasu's disease.

Headache occurs in more than 25% of parients with coarctation. Subarachnoid hemorrhage may occur when an associared cerebral aneurysm ruptures, and episodic loss of consciousness of uncertain basis is reported also. Spinal cord dysfunction occurs when rhe lower part of the cord, supplied by vessels arising from the aorra beyond the narrowed Moment, becomes ischemic. Neurogenic inter mittent claudication may result from the stealing of blood from the cord by retrograde flow through the anterior spinal artery, a part of the collateral circulation bypassing the narrowed segment. Marked enlargement of collateral vessels wirhin rhe spinal canal may compress rhe cervicothoracic cord and cause myelopathy. Enlargement of the anterior spinal artety or one of its feeders may lead to aneurysmal distention and rupture, resulting in spinal subarachnoid hemorrhage. Treatment is by correction of the underlying coarctation.

Subclavian Steal Syndrome

Occlusion of either the innominate or the left subclavian artery before the origin of the vertebral artery reverses the direction of blood flow in the vertebral artery on the affected side. This often causes no symptoms but may cause ischemia in the posterior cerebral circulation. Neurological fearures are weakness, vertigo, visual complaints, and syncope. The pulse is typically diminished or absent in the affected arm, and sysrolic pressure is reduced usually by at least 20 mm Hg compared with the opposite arm. Reconsrrucrive surgery is sometimes helpful but is unnecessaty in most patients.

Complications of Aortic Surgery

Spinal cord infarction remains the most serious neurological complication of aortic surgery. CSF drainage and distal aortic perfusion may be important adjuncts to corrective surgery for thoracic and thoracoabdominal aortic aneurysms, reducing significantly the incidence of paraplegia and paraparesis (Estrera et al. 2001). Other complicarions are neuropathy, radiculopathy, postsympathectomy neuralgia when rhe sympathetic chain is surgically divided, and disrurbances of penile erection or ejaculation when the superior hypogastric plexus is divided surgically (Dougherty andCalligaro 2001).

CONNECTIVE TISSUE DISEASES AND VASCUL1TIDES

Neurological complications may be ditect consequences of connective tissue diseases, secondary to other organ involvement, or secondary to treatment. The adverse effects of corticosteroids and immunosuppressive agents were discussed earlier. Connective tissue disorders are characterized by an autoimmune inflammatory response, especially nccrorizing vasculiris. The mechanism of vasculitis is uncertain but may involve the deposition of immune complexes in vessel walls or cell-mediated immunity and release of lymphokines; autoantibodies also may be important in some instances. The common direct CNS manifestations of connective tissue diseases are cognitive or behavioral changes and focal neurological deficits. Peripheral neuropathies also occur and may take the form of a vasculitic neuropathy, distal axonal polyneuropathy, compression neuropathy, sensory neuronopathy, trigeminal sensory neuropathy, acute or chronic demyelinating polyneuropathy, or plexopathy.

Vasculitic neuropathy is caused by nerve infarction from occlusion of the vasa nervorum. It is a mononeuropathy multiplex that becomes increasingly confluent as more nerves are affecred until it resembles a disral symmetrical polyneuropathy. Nerves tend to be affected in watershed regions that lie between different vascular tctritorics, such as the mid thigh or mid upper arm.

Polyarteritis Nodosa, Churg-Strauss Syndrome, **and** Overlap Syndrome

Peripheral neuropathy occurs in up to 60% of patients with polyarreritis nodosa, Churg-Strauss syndrome, or overlap syndrome. It is usually a painful mononeuropathy multiplex that at least in polyarteritis often develops during the first year. As more nerves are affected, the deficits become

more confluent and come to resemble a polyneuropathy. A few patients exhibit only patchy hypesthetic areas; others develop a secondary polyneuropathy, for instance, from renal failure, a plcxopathy, radiculopathy, or cauda equina syndrome. Electrophysiological studies and nerve histology are often abnormal even when there is no clinical evidence of peripheral nerve involvement.

CNS involvement usually occurs later in the course than peripheral involvement. Common features are headache, which sometimes indicates aseptic meningitis, and behavioral disturbances such as cognitive decline, acute confusion, and affective or psychotic disorders. The electroencephalogram (EEG) is sometimes diffusely slow, but neuroimaging studies are generally normal. Focal CNS deficits are uncommon, are typically sudden in onset, and may be caused by infarction (Figure 55A.3) or hemorrhage. Angiography may not show the underlying vasculitis. Ischemic or compressive myelopathies from extradural hematomas are rare complications.

The 6-month survival rare of patients with untreated polyarteritis nodosa is only 35%. Prompt diagnosis and treatment arc critical. Weight loss, fever, cutaneous abnormalities, and arthralgias are common, and there may he hypertension and renal, cardiac, pulmonary, or gastrointestinal involvement. Laboratory studies show multiorgan involvement and immunological abnormalities. Common abnormalities are an increased erythrocyte sedimentation rate (ESR), anemia, and a peripheral leukocytosis. Hepatitis E surface antigen, hypocomplementemia, and uremia each occur in at least 20% of cases. Nerve or muscle biopsy often shows the necrotizing vasculitis, and angiography shows segmental narrowing or aneurysmal distention, especially in the renal, mesenteric, or hepatic vessels. Treatment is with corticosteroids, sometimes combined with cyclophosphamide.

Giant Cell Arteritis

i Icadache is the most common initial complaint of patients with giant cell arteritis, some of whom also complain of masticatory claudication. The temporal and other scalp arteries are often eryrhematous, tender, and nodular. A more serious initial symptom is acute transitory or permanent blindness, affecting one or both eyes, caused by ischemic optic neuropathy. Other CNS complications are rare, but neuropsychiatric disturbances, srrokes, diplopia, or seizures are occasionally the presenting feature. Peripheral neuropathies occur in up to 15% of patients, half of which are generalized.

One half of all patients have an elevated ESR, and polymyalgia rheumatica is often associated. High-dose corticosteroid treatment should be started once the diagnosis is suspected, without waiting to perform a temporal anew biopsy; any delay increases the risk of vision loss. Treatment is monitored by the clinical response and the ESR, but corticosteroid dose should be increased if clinical signs of disease activity occur, regardless of test results (Turbin and Kupersmith 1999). The dose of corticosteroids is gradually tapered with time, but treatment is usually required for 18-24 months.

Wegener's Granulomatosis

Neurological involvement occurs in up to 50% of patients with Wegener's granulomatosis. Peripheral involvement is manifest usually by a mononeuropathy multiplex or, less often, a symmetrical polyneuropathy. The brain may be affected directly by vasculitis or by extension of granulomas from the upper respiratory tract; the associated clinical syndromes are basal meningitis, temporal lobe dysfunction, crania] neuropathies, cerebral infarction, or venous sinus obstruction.

In one study of 109 patients with neurological complications, 53 had a peripheral neuropathy. The neuropathy consisted of mononeuropathy multiplex in 42, symmetrical polyneuropathy in 6, and unclassified involvement in 5 (Nishino et al. 1993). Cranial neuropathy was found in 21 patients (usually second, sixth, and seventh nerve involvement); 8 had multiple cranial neuropathies. Other neurological features were external ophthalmoplegia from orbital pseudotumor in 16, cerebrovascular events in 13, seizures (from metabolic, septic, or other complications, or from vasculitis) in 10, cerebritis in 5, and miscellaneous abnormalities in 25.

Isolated Angiitis of the Nervous System

Isolated angiitis (granulomatous angiitis) of the CNS is discussed in Chapter 57G, and that of the PNS is discussed in Chapter 82.

Rheumatoid Arthritis

Rheumatoid arthritis is the most common of the connective tissue diseases. Juvenile rheumatoid arthritis is discussed in Chapter 55B. Systemic vasculitis occurs in up to 25% of adult patients, but the CNS is rarely affecred. Pathological involvement of the cervical spine (Figure 55A.4), or atlantoaxial dislocation, may cause a myelopathy, headaches, or hydrocephalus or lead to brainsrem and cranial nerve deficits from compression or vertebral artery involvement. Special care is needed when hypcrcxtending the neck, as during endotracheal intubation, in patients with rheumatoid arthritis. Surgical fixation of subluxation is usually unnecessary unless displacement is marked or an associated myelopathy is severe or progressive.

Peripheral nerve involvement is common in rheumatoid arthritis. A distal sensory or sensorimotor polyneuropathy is

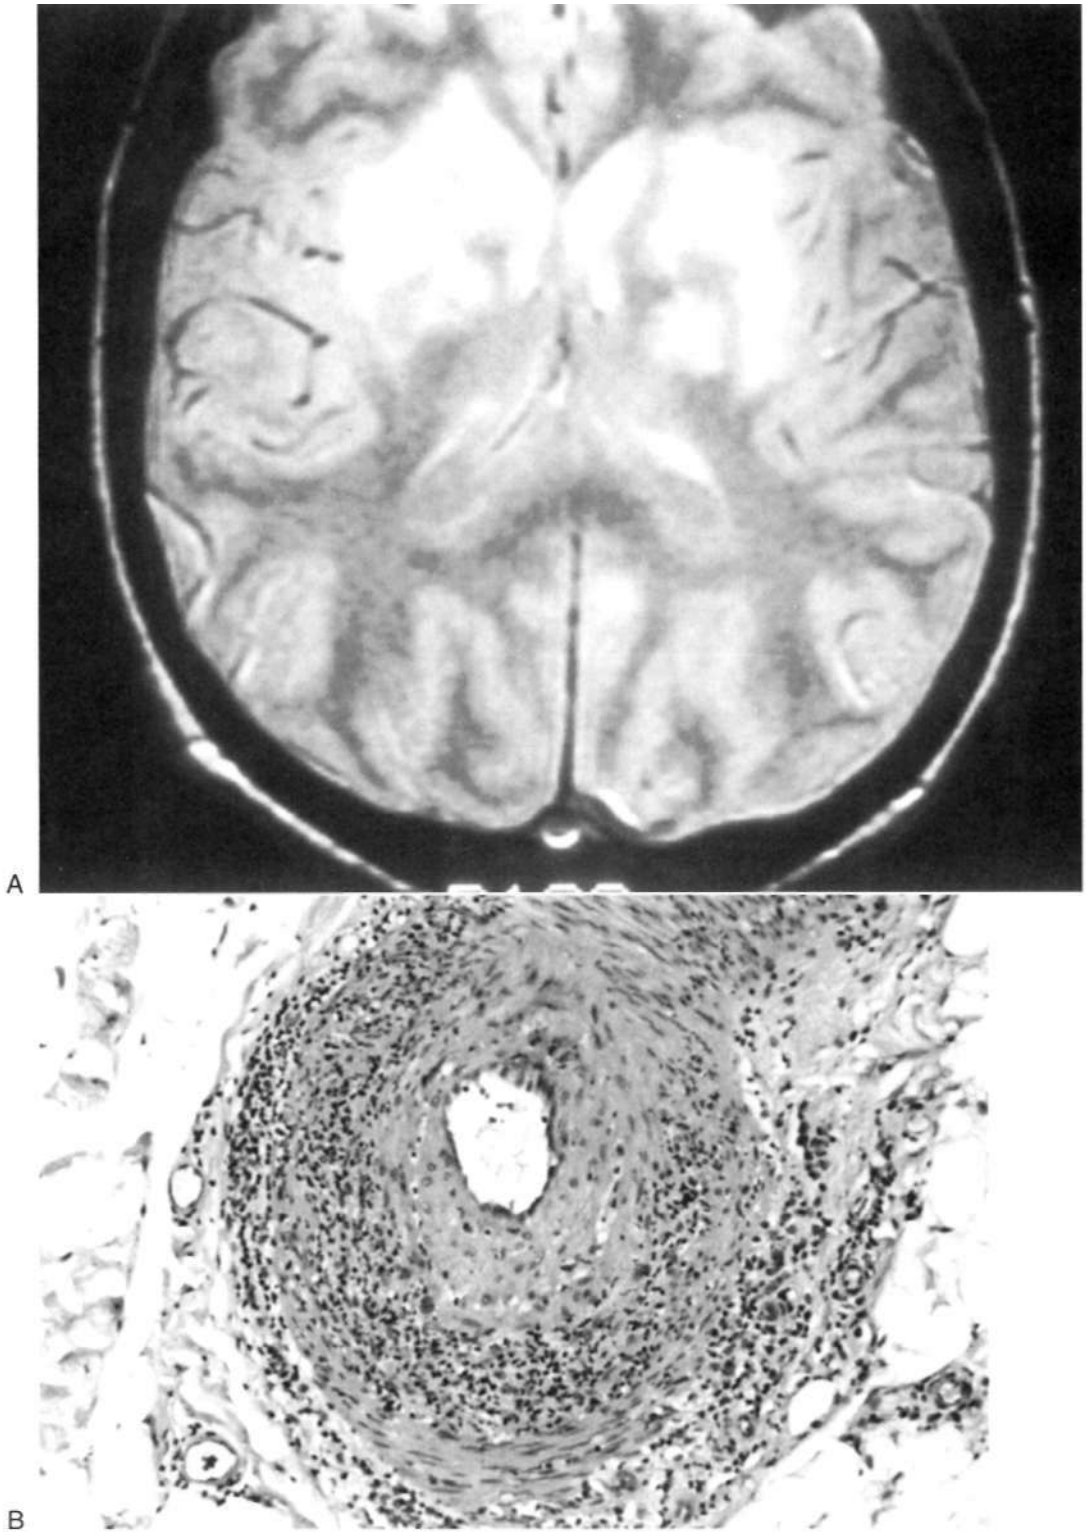

FIGURE 55A.3 (A) Proton-density-weighted magnetic resonance imaging scan showing patchy high signal in the basal ganglia bilaterally. (B) Microscopic section of a biopsied blood vessel showing marked thickening and inflammatory infiltrates indicative of a vasculitis in this patient with polyarteritis nodosa (hematoxylin and eosin, x 120).

FIGURE 5SA.4 Two contiguous sagittal magnetic resonance images of the craniocervical region in a patient with rheumatoid arthritis. (A) T2-weighted and (B) Tl-weighted gadolinium-en ha need images. Arrows show pannus formation at CI, causing narrowing of the subarachnoid space and a suggestion of posterior displacement of the upper cervical cord.

common; clinical or electrophysiological evidence of sensory dysfunction is found in up to 75% of patients. Mononeuropathy multiplex and entrapment or compression neuropathies are also common. Compression injuries occur to the median nerve in the carpal tunnel, medial plantar nerve in the tarsal tunnel, ulnar nerve in the cubital tunnel or canal of Guyon, and peroneal nerve at the fibular head.

Several antitheumatic agents have adverse effects on the neuromuscular system. Gold treatment causes petipheral neuropathy in up to 1% of cases. Its onset is rapid and the evolution of weakness and the CSF profile may suggest Guillain-Barre syndrome. Chloroquine can cause neuropathy, myopathy, or both, and D-pcnicillamine causes disturbances of taste, an inflammatory myopathy, and a reversible form of myasthenia gravis.

Systemic Lupus Erythematosus

As many as 75% of patients with SLE have neutological involvement at some point during their course, often during the firsr year. Neurological complications may lead to a

fatal outcome. The mechanism of CNS involvement is unknown. Neither the presence of antineuronal and anti-astrocytic antibodies nor the deposition of antibody in the choroid plexus correlates with CNS involvement.

The most common neurological manifestations are episodic affective or psychotic disorders that may be difficult to distinguish from corticostcrokl-iiidiiL-cd mental changes. Cognitive dysfunction is often temporary. Multiple sclerosis is sometimes simulated. Treatment is empirical, depending on presentation and the probable underlying pathophysiology. Disturbances of consciousness sometimes occur, especially in patients with systemic infections. Focal neurological deficits may result from strokes, the pathogenesis of which in SLE includes cardiac valvular disease, thrombosis associated with antiphospho-lipid antibodies, and cerebral vasculitis. Anticoagulant or fibrinolytic therapy may prevent stroke recurrence. Dyskinesias, especially chorea, occur in some patients with SLE, but underlying structural pathology of the basal ganglia cannot be detected usually; chorea is associated with the presence of antiphospholipid anti-bodies. The occurrence of generalized or partial seizures is probably caused by microinfarcts, metabolic disturbances, and systemic infections (see Chapter 55B for additional information on the pediatric aspects of SLE).

PNS involvement occurs less often and is characterized usually by a distal sensory or sensorimotor polyneuropathy (Roscnhaum 2001). Other forms of neuropathy include an acute or chronic demyelinating polyneuropathy that resembles Guillain-Barre syndrome, single or multiple mononeuropathies, and optic neuropathy. Corticosteroids, immunosuppressive agents, and plasmapheresis are bene-ficial when neuropathy is caused by necrotizing vasculitis but are of less certain value in other circumstances.

Sjogren's Syndrome

Sjogren's syndrome may be a primary disorder or secondary to other connective tissue diseases. The main features are xerostomia and xerophthalmia. Women are more often affected than men. Definite diagnosis requires a positive result of the rose bengal dye test for keratocon-junctivitis, evidence of diminished salivary gland flow, abnormalities on biopsy of a minor salivary gland, and an abnormal test result for rheumatoid factor or antinuclcar antibody. Neurological complications are not common but include psychiatric disturbances, late-onset migrainous episodes, aseptic meningitis, meningoencephalitis, focal neurological deficits, and, in rare instances, an acute or chrome myelopathy. Cranial MRI may show hyperintense, small subcortical lesions. Polyneuropathy is the most common peripheral manifestation, bur mononeuropathy multiplex may occur also. Sensory ncuronopathy is unusual but is more characteristic of Sjogren's syndrome than other connective tissue diseases (Roscnbaum 2001).

Progressive Systemic Sclerosis

Progressive systemic sclerosis (i.e., scleroderma) was believed to affect the nervous system only rarely, but Avcrbueh-Heller, Steincr, and Abramsky in 1992 suggested there is neurological involvement in as many as 40% of patients. The PNS is usually affected: Distal sensorimotor polyneuropathy, entrapment mononeuropathy, trigeminal neuropathy, myopathy, or myositis may occur.

Behcet's Disease

Behcet's disease, of unknown etiology, is defined by the combination of uveitis and oral and genital ulcers. Aseptic-meningitis or meningoencephalitis occurs in 20% of cases. Focal or multifocal deficits also may occur and are caused by ischemic disease of the brain or spinal cord, related to small venous inflammatory disease. In other instances, cerebral venous sinus thrombosis occurs (Siva and Fresko 2000). The CSF commonly shows a mild pieocytosis, and the protein concentration may be increased. Peripheral nerve involvement is rare and takes the form of polyneu-ropathy or mononeuropathy multiplex, Treatment is with corticosteroids. Cerebral venous sinus thrombosis is treated with heparin (see Chapter 57A).

Relapsing Polychondritis

Relapsing polychondritis is an infrequently diagnosed inflammatory condition of cartilage such as that of the nose, ears, trachea, and joints. Episodes of ear or nose inflammation typically last 1-4 weeks, then either resolve completely or leave deformities because of cartilage destruction. Both genders are affected equally, with peak age at incidence between 30 and 60 years. Eye inflam-mation, especially episcleritis or conjunctivitis, may be associated with the attacks. Systemic vasculitis or features of other connective tissue disorders may develop. The diagnosis requires a typical clinical picture of chondritis. The ESR is elevated usually. Although autoimmunity against type II collagen may play a role in pathogenesis, only one half of patients have serological evidence of anti-type II collagen antibodies,

Auditory or vestibular dysfunction occurs in nearly one half of patients. The mechanism is usually otic rather than eighth nerve inflammation. Other cranial neuropathies, such as optic or facial neuropathy, may be associated. Headache, when it occurs, is more often caused by extracranial chondritis than intracranial inflammation. Aseptic meningitis, which may be recurrent, and vasculitic meningoencephalitis are sometimes associated.

Corticosteroids arc the traditional treatment, and other inflammatory or immunosuppressive drugs have been tried in some cases. The efficacy of treatment is difficult to assess

because of the remitting and relapsing pattern of the disease.

RESPIRATORY DISEASES

Ventilation requires the integrity of the CNS and PNS to support its coordinated motor activity. Diseases of the forcbrain, brainstem, and spinal cord cause abnormal ventilatory patterns or ventilatory arrest, and diseases of the motor unit cause hypoventilation and ventilatory failure. This section is concerned with the neurological consequences of respiratory abnormalities rather than the neurological causes of ventilatory disturbances.

Hypoxia

The neurological manifestations of hypoxia depend on its rate of onset, duration, and severity. Hypoxia may be complicated by acid-base imbalance and leads to other hematological and biochemical changes that affect cerebral function. The precise mechanisms responsible for the neurological abnormalities discussed here are therefore complex.

Encephalopathies caused by chronic pulmonary insufficiency are characterized by headache, disorientation, confusion, and depressed cognitive function. Postural tremor, myoclonus, asterixis, and brisk tendon reflexes are found commonly on examination, and papilledema is present sometimes. These features are caused not only by cerebral hypoxia but also by hypercapnia, which leads to cerebral vasodilatation, increased CSE pressure, and altered pH of the CSF.

Sleep apnea syndromes cause chronic nocturnal hypoxia and become symptomatic as excessive daytime sleepiness. Many affected patients are obese, plethoric, and snore heavily. Treatment is summarized in Chapter 74.

High-altitude sickness is characterized by headache, lassitude, anorexia, nausea, difficulty in concentration, and disturbances of sleep. Symptoms begin within hours or days of ascending higher than 10,000 feet. At even higher altitudes, consciousness may be disturbed; coma occurs in severe cases and may lead to a fatal outcome. Cerebral edema of uncertain cause is the major underlying feature that causes papilledema, retinal hemorrhages, cranial neuropathies, focal or multifocal motor and sensory deficits, and behavioral disturbances. Corticosteroids avert or relieve the syndrome.

Hypercapnia

Ventilatory impairment causes hypercapnia and hypoxemia, and the neurological manifestations of each are difficult to distinguish.

Hypocapnia

The hypocapnia that results from hyperventilation causes cerebral vasoconstriction, a shift of the oxyhemoglobin dissociation curve so that peripheral availability of oxygen is reduced, and an alteration in the ionic balance of calcium. The clinical features arc lightheadedness, paresthesias, visual disturbances, headache, unsteadiness, tremor, nausea, palpitations, muscle cramps, carpopedal spasms, and loss of consciousness.

Hyperventilation occurs in hepatic and diabetic coma, with certain brainstem lesions, with various cardiopulmonary diseases, with certain drugs causing acidosis, and on an iatrogenic basis. Episodic hyperventilation often occurs without any identifiable systemic disease.

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

\"e urn logical complications may occur when infection and trauma have induced a systemic inflammatory response affecting the microcirculation to multiple organs. For example, patients with sepsis and multiorgan (including respiratory) failure sometimes develop an axonal neuropathy that only comes to attention when attempts arc made to withdraw ventilatory support. The neuropathy, which is called *critical illness neuropathy,* improves only slowly as the critical illness subsides.

Corticosteroids and neuromuscular blocking drugs may induce a myopathy, especially in patients with obstructive airway diseases. Its highest prevalence is among asthmatics who require ventilatory support in addition to corticosteroids and who have also received the neuromuscular blocking agent vecuronium. It sometimes occurs in patients who have received either corticosteroids or neuromuscular blockers, but not both. Muscle biopsy may show muscle fibers with specific loss of myosin (thick filaments).

A diffuse encephalopathy is a complication of sepsis and is most likely in patients with respiratory distress syndrome. Its pathogenesis is probably multifactorial and may relate to reduced cerebral blood flow, cerebral edema, disruption of the blood-brain barrier, direct cerebral infection, toxins produced by infecting organisms, metabolic abnormalities, and the effects of medication (Papadopoulos et al. 2000). The encephalopathy tends to fluctuate in severity, is often worse at night, and is associated with marked abnormalities of the EEC Treatment is of the underlying sepsis; no specific treatment exists for the encephalopathy.

SARCOIDOSIS

Sarcoidosis is a disorder of unknown cause with multiorgan involvement and many different clinical presentations. It is more common in blacks than in whites and in women than

in men. The disease is often discovered incidentally on routine chest roentgenography. The prevalence of neurological involvement in any series varies with case selection and diagnostic criteria but may be as high as 5%. The nervous system may be involved directly by the disease or secondary to opportunistic infections associated with abnormalities of the immune system. Only direct involvement (Figure 55A.5) is considered in this section.

Cranial neuropathies from chronic basal meningitis are the most common neurological manifestations of sarcoidosis. The facial nerve is affected most often, sometimes bilaterally. The optic nerve may be swollen or atrophied. Increased intracranial pressure from a space-occupying lesion, meningeal involvement, or obstructive hydrocephalus may cause papilledema. Visual changes are caused also by direct involvement of the optic nerves or their meningeal covering, or by uveitis. Unilateral or bilateral recurrent laryngeal, trigeminal, or auditory nerve involvement is also common, and multiple cranial neuropathies may occur.

Disturbances of the hypothalamic region are associated with diabetes insipidus, abnormalities in thermoregulation, amenorrhea, impotence, hypoglycemia, disturbances of sleep, obesity, personality changes, and evidence of hypopituitarism.

Other neurological features depend on intracranial or intraspinal meningeal or parenchymal involvement. Diffuse meningoencephalitis causes cognitive abnormalities or affective disorders. An enlarging granuloma may mimic a cerebral tumor and lead to seizures and focal neurological deficits.

Peripheral nerve involvement may take the form of a symmetrical polyneuropathy or an asymmetrical mononeuropathy multiplex. This may result from polyradicular involvement by extension of meningeal sarcoidosis or from direct involvement of the nerves by sarcoid granulomas. Muscle granulomas may cause clinical features of a myopathy and are found commonly in clinically unaffected muscles.

Neurosarcoidosis often remits spontaneously, but progressive neurological disease occurs in approximately 30% of cases. The diagnosis of neurosarcoidosis is difficult in the absence of systemic disease, especially cutaneous or pulmonary involvement. Histological confirmation often requires biopsy of seemingly unaffected tissue (e.g., muscle or conjunctiva) if other lesions are not accessible. Neither the tuberculin skin test nor the blood concentration of angiotensin-converting enzyme is definitive in establishing the diagnosis. Corticosteroid treatment is recommended generally, but its long-term value is not established. The

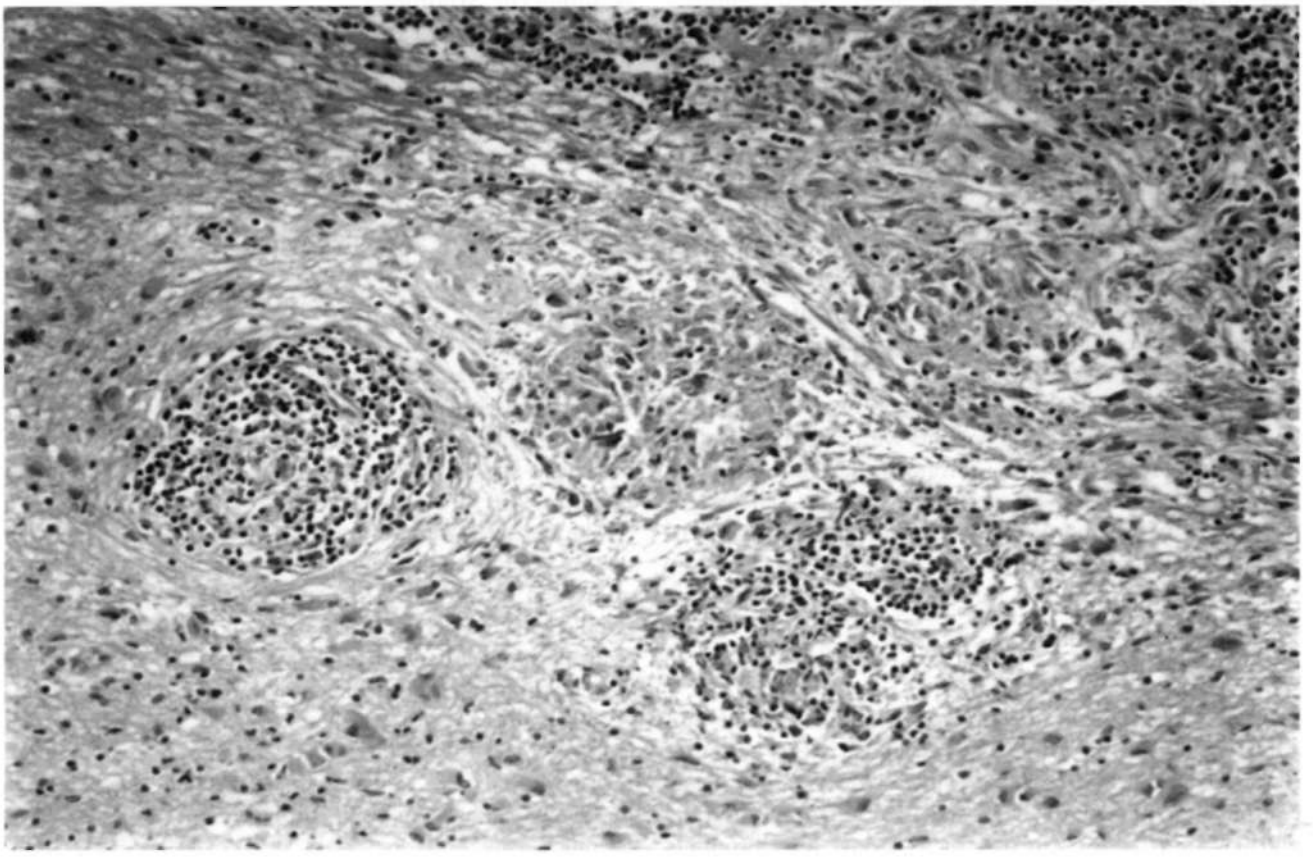

FIGURE 5SA.5 Photomicrograph showing sharply delimited granulomas without necrosis in hypothalamus of a patient with sarcoidosis (hematoxylin and eosin, x40).

initial dose of prednisone is 60 mg per day, and the dose is adjusted depending on clinical response. Irradiation of a focal lesion or cyclosporine is beneficial in some cases. Useful surgical measures arc the excision of focal, enlarging granulomas and the placement of a shunt to relieve hydrocephalus.

HEMATOLOGICAL DISORDERS WITH ANEMIA

Anemia often causes nonspecific behavioral symptoms such as lassitude, lightheadedness, inattentiveness, irritability, headache, and unsteadiness. Iron-deficiency anemia is associated with pica, restless legs syndrome, and benign intracranial hypertension, and with an increased risk of stroke or transient cerebral ischemic attacks because of thrombocytosis. Severe anemia may rarely cause focal neurological deficits in patients with pre-existing cerebral atherosclerotic disease. Pancytopenia may cause hemorrhagic CNS complications.

Megaloblastic Anemia

Vitamin B_{12} deficiency causes myelopathy, encephalopathy, optic neuropathy, peripheral neuropathy, or some combination of these disorders. The neurological complications do not necessarily correlate with the presence or severity of associated megaloblastic anemia. Folic acid masks the anemia without preventing the neurological complications. Nitrous oxide anesthesia may unmask a subclinical cobalamin deficiency (Marie et a). 2000), The food supply in the United States was fortified with folic acid beginning in 1994 to prevent spina bifida, so anemia is no longer a marker of vitamin Bi_2 deficiency.

The Schilling test is an important means of diagnosing the most common cause of vitamin B12 deficiency, impaired absorption from deficiency of intrinsic factor. Vitamin B12 is absorbed exclusively by the terminal ileum, and deficiency may occur also in patients with urinary intestinal diversion. Treatment with intramuscular injections of vitamin Bi_2 reverses the neurological disorder. The extent of residua correlates with the severity and duration of symptoms before treatment.

Sickle Cell Disease

Sickle cell disease causes vasculopathy of both large and small vessels as a result of a genetic point mutation (Prengler et al. 2002). Sickled cells adhere to the vascular endothelium, and a cascade of activated inflammatory cells and clotting factors leads to a nidus for thrombus formation. Sickling is aggravated by hypoxia, infection, inflammation, dehydration, and acidosis.

The most common neurological complication of sickle cell disease is stroke, which occurs more often in children than in adults. Other complications are convulsions, intracranial (usually subarachnoid) hemorrhage, behavioral disturbances, and alteration in consciousness. The cause of intracranial hemorrhage cannot always be determined despite detailed investigation, but some cases are caused by rupture of an aneurysm that may be surgically accessible. Blindness sometimes results from proliferarive retinopathy; retinal detachment or infarction also occurs. Spinal cord infarction is rare.

Thalassemias

Extramedullar hematopoiesis occurs in the liver, spleen, and lymph nodes of patients with severe forms of /^-thalassemia, but it may also occur in the spinal epidutal space and cause a compressive myelopathy. Treatment includes local irradiation, surgical decompression, corticosteroids, and repeated blood transfusions. Bone marrow hypertrophy also causes facial deformity, nerve root compression, and auditory impairment. Surgical decompression or radiation therapy is beneficial in some cases.

Acanthocytic Syndromes

Acanthocytes, or spiny red cells, are associated with abcralipoproteiiiemia [sec Chapter 68), neuroacanthocytosis (see Chapter 77), and McLeod's syndrome (see Chapter 85),

PROLIFERATIVE HEMATOLOGICAL DISORDERS

Leukemias

The neurological complications of leukemia are caused by leukemic infiltration of the nervous system, hemorrhage, infection, electrolyte disturbances, hyperviscosity, and complications of treatment. Localized leukemic deposits are more likely to affect the brain than the spinal cord; peripheral nerve involvement is rare.

The clinical features of meningeal leukemia are headache, nausea and vomiting, somnolence, irritability, convulsions, and coma. Obstructive or communicating hydrocephalus, papilledema, and meningismus may be associated. Cranial neuropathies and spinal radiculopathies are common, and their multifocal distribution should always suggest meningeal leukemia. Examination of the CSF shows abnormal leukemic cells, especially if cytospin techniques arc used, but a normal CSF result does not exclude the diagnosis of meningeal leukemia. Treatment is with intrathecal chemotherapy.

Intracerebral hemorrhage is more common than subarachnoid or subdural hemorrhage. It is associated with

platelet counts less than 20,000 cells/uL. The hemorrhage is often multifocal and varies in severity from microscopic to fatal. Spinal subdural or subarachnoid hemorrhage is less common than intracranial bleeding but is a potentially serious complication of lumbar puncture, sometimes requiring surgical decompression.

The hyperviscosity syndrome occurs when resistance to blood flow is increased markedly, so that transit through the microcirculatory system is impaired. It is characterized by headache, somnolence, impaired consciousness, stroke or transient cerebral ischemia, and visual disturbances. Venous sinus thrombosis, nonbacterial thrombotic endocarditis, and disseminated intravascular coagulation (DIC), discussed later in this chapter, may occur also. The most common cause of this syndrome is an increase in the concentration of -circulating gamma globulins, which is discussed in the following section.

Infection is a common complication of chemotherapy or corticosteroid therapy. The use of broad-spectrum antibiotics often encourages infection by unusual organisms. Progressive multifocal leukoencephalopathy is an uncommon complication of leukemia (see Chapter 60}.

Plasma Cell Dyscrasias

Plasma cell dyscrasias are classified on the basis of the protein synthesized. They may be complicated by para neoplastic syndromes {sec Chapter *58)* and by an increased susceptibility to infections that may involve the C\'S.

Myelomatosis

Multiple myeloma, the most common plasma cell dyscrasia, is associated with a monoclonal immunoglobulin G (IgG) or immunoglobulin A (IgA) paraprotein in the serum or urine. The clinical features are pain, fracture, and destruction of bone. Tumor infiltration of the vertebrae causes compression of the spinal cord or nerve roots. Back pain is conspicuous, radicular pain is common, and cord or root dysfunction may be present. Treatment by local irradiation and high-dose corticosteroids prevents or minimizes residual neurological deficits, but urgent decompressive surgery is required if the diagnosis is uncertain. Cranial involvement is less common than spinal involvement. Cranial neuropathies, especially of nerves II, V, VI, VII, and VIII, may occur. A reversible optic neuropathy of uncertain etiology, but probably not caused by infiltration, has been described.

Increased intracranial pressure does not necessarily indicate intracranial infiltration: Pseudotumor cerebri sometimes occurs without evidence of intracranial myeloma or hyperviscosity syndromes.

Peripheral neuropathy is a well-recognized complication of myeloma. A symmetrical axonal sensory or sensorimotor polyneuropathy occurs as a complication of the circulating immunoglobulin, and a predominantly motor neuropathy resembling chronic inflammatory demyelinating polyradiculoneuropathy may occur with osteosclerotic myeloma. Treatment with cytotoxic agents and plasmapheresis sometimes slows or reverses the neuropathy, as may irradiation of bony lesions. Tumor infiltration of nerves leads to an asymmetrical neuropathy that has the features of mononeuropathy multiplex. Amyloidosis is sometimes associated with myeloma and causes a neuro pathy characterized by dysautonomia, marked loss of pain and temperature appreciation, and weakness.

The POEMS syndrome consists of polyneuropathy, organomegaly, endoermoparhy, M protein, and skin changes in patients with plasma cell dyscrasia. It is most often associated with osteosclerotic myeloma but also occurs with osteolytic myeloma accompanied by only minor sclerotic changes and in patients without myeloma. Osteosclerotic myeloma usually is considered a variant of solitary or early multiple myeloma but may be a distinct entity. The neuropathy is a distal, sensorimotor polyneuropathy with both axonal degeneration and segmental demyelination. Other clinical features are papilledema; lymphadenopathy; hepatosplenomegaly; impotence; gynecomastia; amenorrhea; glucose intolerance; peripheral edema; ascites; pleural effusions; and cutaneous pigmentation, thickening, and hypertrichosis. Corticosteroids, cyclophosphamide, and irradiation of solitary osteosclerotic lesions may be beneficial.

Other neurological manifestations are caused by infections related to immunodeficiency, hypercalcemia, uremia, and hyperviscosity. The hyperviscosity syndrome is characterized by headache, visual disturbances, and encephalopathy. Hemorrhages, exudates, and venous engorgement are seen on funduscopic examination.

Waldenstrom's Macraglobulinemia

Waldenstrom's macroglobulinemia is a plasma cell dyscrasia associated with IgM gammopathy. Neurological complications are common. A progressive sensorimotor polyneuropathy is attributed to binding of monoclonal immunoglobulin *M* (IgM) to peripheral nerves or results from lymphocytic infiltration of the nerves. Other neurological complications relate to hyperviscosity or a bleeding tendency resulting from platelet abnormalities. Presentation is with a diffuse encephalopathy or focal neurological deficits. Common manifestations are fatigue, lassitude, lethargy, confusion, altered consciousness, and seizures. Visual, auditory, and vestibular disturbances also occur.

Neurological examination shows pyramidal, cerebellar, or brainstem abnormalities, and funduscopic examination may reveal papillitis, venous engorgement, hemorrhages, and exudates. Plasmapheresis relieves symptoms caused by hyperviscosity and helps the peripheral neuropathy in some cases.

Monoclonal Gammopathy of Undetermined Significance

Many patients with a monoclonal gammopathy have no evidence of serious underlying pathology, but some eventually develop a malignant plasma cell dyscrasia. Chronic inflammatory demyelinating polyradiculoneuropathy is the characteristic polyneuropathy associated with monoclonal gammopathy of undetermined significance. IgM autoanribodies that react with myelin-associated glycoproteins or with other target antigens may be present in the blood. Short-term treatment with intermittent cyclophosphamide and prednisone may provide long-term benefit.

Amyloidosis

Amyloidosis may occur as a familial disorder with dominant inheritance. Portuguese, Japanese, Swedish, and other varieties are described. The main neurological complication is a small-fiber sensory neuropathy, with marked impairment of pain and temperature appreciation and lesser involvement of other sensory modalities (see Chapter 82). An associated dysautonomia is conspicuous. Weakness develops later.

Nonfamilial amyloidosis is divided into primary and secondary varieties. Primary amyloidosis occurs in the absence of other disorders (except multiple myeloma), whereas secondary amyloidosis occurs in association with such disorders as chronic infection. Peripheral neuropathy is a common feature of primary but not secondary amyloidosis. It is characterized by a progressive sensory or sensorimotor polyneuropathy with autonomic involvement or by carpal tunnel syndrome. Cranial neuropathy is uncommon; cranial nerves III, V, and VII are most often affected. Cardiovascular and renal dysfunction are common, and other organ systems also may be involved. The diagnosis is suggested by the clinical findings and the presence, in most cases, of a monoclonal protein in the serum. No effective treatment is available. Death usually results from systemic complications.

Accumulation of /$_2$-microglobulin-associated amyloid in patients undergoing long-term hemodialysis may cause carpal tunnel syndrome, a cervical myelopathy, or a cauda equina syndrome. Surgical decompression may be helpful in such circumstances.

Cryoglobulinemia

Cryoglobulins are proteins that precipitate in the cold and dissolve when heated. They are classified as monoclonal IgM, IgG, IgA, or light chains (type 1), mixed but with one monoclonal immunoglobulin (type 2), and polyclonal, without any monoclonal protein (type 3).

Primary cryoglobulinemia occurs in the absence of other disease. Secondary cryoglobulinemia occurs in association with disorders such as myelomatosis or macroglobulinemia with monoclonal protein production or disorders with polyclonal protein production, such as vasculitis or chronic inflammatory disease. Cryoglobulinemia is associated with transient cerebral ischemic attacks, strokes, and a peripheral neuropathy that is probably ischemic in origin. The extent to which neurological complications arc caused by the cryoglobulinemia, as opposed to the accompanying vasculitis, is unclear. Treatment with corticosteroids, plasmapheresis, or both may be beneficial.

Lymphoma

Neurological complications of lymphoma can be caused by direct spread of tumor, compression of the nervous system by extrinsic tumor, or paraneoplastic syndromes (see Chapter 58). They may also result from irradiation or chemotherapy, thrombocytopenic hemorrhage, or opportunistic infections. Primary CNS lymphoma is a known complication of immunosuppression and occurs most often in patients with acquired immunodeficiency syndrome (see Chapter 58) and less frequently in transplant recipients.

Polycythemia

The thrombotic and hemorrhagic complications of polycythemia often affect the nervous system. Occlusion of small or large arteries or venous channels may cause cerebral infarcts that arc sometimes recurrent and fatal. This thrombotic tendency has been attributed to increased blood viscosity, thrombocytosis, and possibly chronic disseminated intravascular clotting. Intracranial hemorrhage is caused by abnormalities of clot retraction, thromboplastin generation, and platelet function. Spinal cord infarction is rare. Patients with polycythemia often complain of headache, poor concentration, unsteadiness, tinnitus, blurred vision, dysesthesias, and other nonspecific symptoms. The basis of such symptoms is unclear, but disturbances in the retinal circulation may account for the visual complaints. Pseudotumor cerebri and chorea may occur with polycythemia. Chorea reverses when the underlying hematological disorder is treated.

HEMORRHAGIC DISEASES

Hemophilia

Intracranial hemorrhage is a major cause of death in patients with hemophilia. Hemorrhages may be epidural, subdural, subarachnoid, or intracerebral and may occur spontaneously or following trivial head injury. Neurological symptoms may not develop for several days after injury. The severity of bleeding generally correlates with the severity of coagulopathy. Spinal subdural or epidural

hemorrhage may occur but is uncommon; the clinical features are back or neck pain and a progressive painful paraparesis or quadriparesis. Surgical decompression is necessary to preserve neurological function, and the deficient factor VIII must he provided as well.

Peripheral neuropathies secondary to compression of individual nerves by intramuscular or retroperitoneal hematomas are a common complication. Urgent operative decompression may be needed to preserve function,

Seizures may result from brain injury caused by previous intracranial hemorrhage. Their control with anticonvulsant agents helps prevent further bleeding.

Other Hemorrhagic Disorders

Other coagulopathies have a lower frequency of neurological complications than hemophilia, hut these are similar to those already described.

Disseminated intravascular Coagulation

DIG is characterized by thrombotic occlusion of small vessels and concomitant hemorrhagic complications because clotting factors (including fibrinogen and factors V and VIII) and platelets ate consumed in the thrombotic process. DIC occurs in association with primary brain disease, diseases of other organs, septicemia, immune-mediated disorders, diabetic ketoacidosis, neoplastic disease, and obstetrical complications. Several organs may be affected, but the brain is commonly involved. The underlying cause, rate of onset, and severity of DIC influence the clinical features, as do the organs affected and the predominance of thrombosis or hemorrhage.

Neurological features fluctuate in severity. Encephalopathy is common and varies in severity from a mild confusional state to coma. Comatose patients may recover completely, and continuing support is therefore indicated. The prothrombin time is usually prolonged, the serum level of fibrin-degradation products is increased, and thrombocytopenia may be present. The serum fibrinogen concentration is sometimes normal. Neuroimaging shows multifocal cerebral hematomas and infarctions. Treatment is directed at the underlying cause of DIC. Heparin may limit thrombotic complications but can worsen hemorrhagic complications; its value is uncertain. The same can be said of antiplatelet agents and antithrombin concentrates.

Thrombocytopenia

Thrombocytopenia, which is caused by reduced production or increased breakdown of platelets, may lead to hemorrhage. Intracerebral hemorrhage is usually from capillaries and is characterized first by clinically silent petechial hemorrhages and later by symptomatic hematomas. Spinal or peripheral nerve involvement by hemorrhage is uncommon. Platelet transfusions arrest further bleeding. Corticosteroids may be beneficial when platelet function is abnormal; splenectomy is sometimes indicated.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura is a disorder of uncertain cause, possibly immune mediated, that often has a fatal outcome. It is sometimes associated with the use of certain medications, especially quinine (Kojouri, Vesely, and George 2001). The clinical features are thrombocytopenic purpura, hemolytic anemia, fever, neurological abnormalities, and renal disease. The neurological features may include headache, mental changes, altered states of consciousness, seizures, and focal deficits. Treatment options are plasma exchange or infusion, splenectomy, and administration of corticosteroids ot antiplatelet agents. Rapid administration of platelets may lead to a fatal outcome and must be avoided.

Iatrogenic Hemorrhagic Disorders

Patients treated with heparin or warfarin may develop intracranial or spinal hemorrhage. The bleeding may be parenchymal, subarachnoid, subdural, or extradural. It can occur spontaneously or after injury and cause the acute or subacute onset of a neurological deficit. Treatment includes reversal of the coagulopathy, definition of the pathology by neuroimaging studies, and urgent decompressive surgery if necessary. Intramuscular hemorrhage may cause a plexopathy or peripheral neuropathy that requires urgent decompression.

Antiphospholipid Antibody Syndromes

Antiphospholipid antibodies (the lupus anticoagulant and anticardiolipin antibodies) are detectable in several disorders, but especially in SLE, Sneddon's syndrome (Figure 55A.6), and other connective tissue disorders (Cervcra et al. 2002). They are found also in patients taking certain medications, with some infections and obstetrical complications, and as an incidental finding in healthy people. The presence of antiphospholipid antibodies increases the risk of thrombotic disease. Cerebral ischemia is caused by either arterial or venous occlusion. Visual abnormalities include amautosis fugax and ischemic optic neuropathy or retinopathy. The occurrence of migraine-like headaches may be fortuitous. An acute ischemic encephalopathy, characterized by confusion, obtundation, quadriparesis, and bilateral pyramidal signs, may occur. Dementia, chorea, transient global amnesia, transverse myelopathy, Guillain-Barrc syndrome, and seizures have been described. Multiple

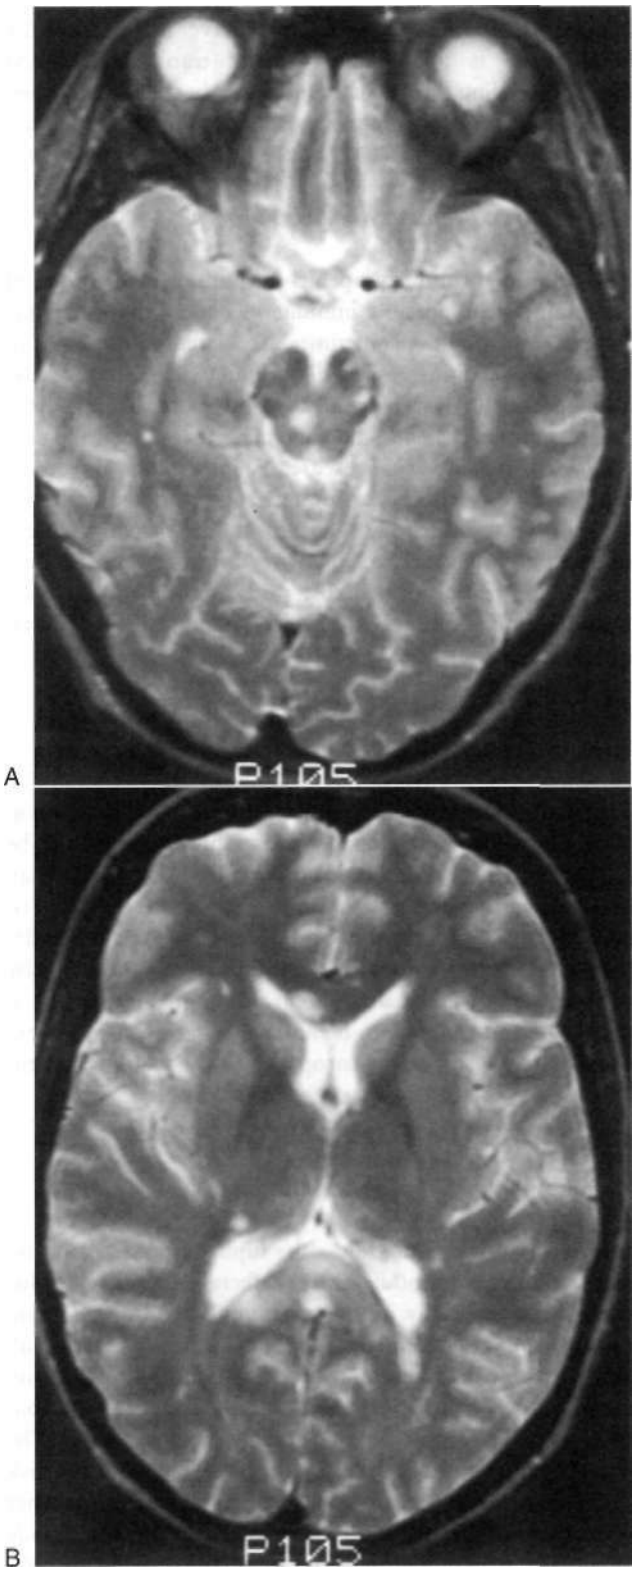

FIGURE S5A.6 A 27-year-old woman with Sneddon's syndrome (livedo reticularis and cerebrovascular disease). T2-weighted magnetic resonance imaging scan showing multiple foci of high-signal intensity in the mesencephalon (A) and in the corpus callosum and periventricular white matter (B).

sclerosis may be simulated clinically and on MRI (Cuadrado et al. 2000).

The pathogenesis of the thrombotic tendency is not established. The presence of antiphospholipid antibodies does not require immunosuppression. Cerebral thrombosis is managed in the same way as that from other causes.

LIVER DISEASE

Patients with acute hepatic failure often develop severe cerebral edema (Figure 55A.7). Several other neurological manifestations occur with chronic hepatic disorders.

Portal Systemic Encephalopathy

Chronic liver disease causes a portal systemic encephalopathy, characterized by an abnormal mental status (see Chapter 62). Points to emphasize here are that the encephalopathy may have an insidious onset, delaying its clinical recognition and treatment; a flapping tremor (asterixis) may be the only other neurological sign; and

FIGURE 5SA.7 A 15-year-old girl with fulminant viral hepatitis. Computed tomographic scan without contrast shows severe diffuse cerebral edema. (The two diagonal dark bands represent artifact from an intracranial pressure monitor.)

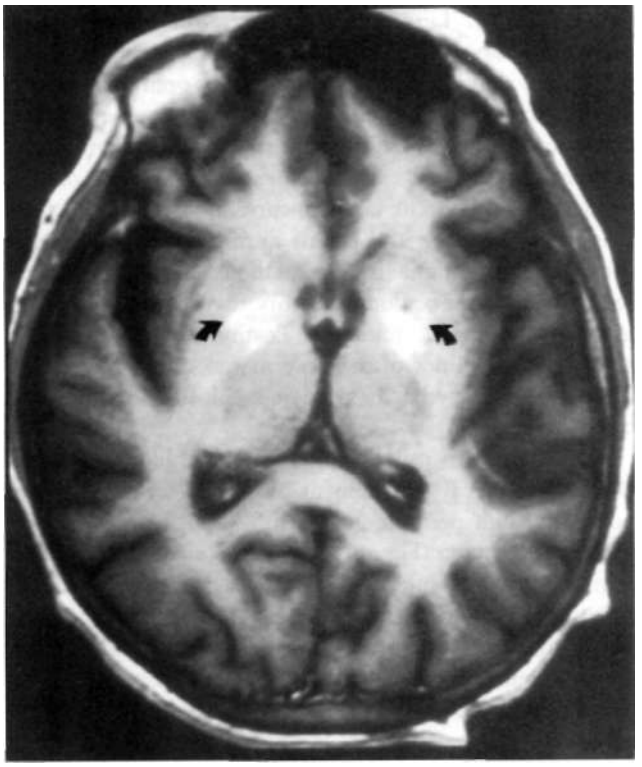

FIGURE 55A.8 Patient with chronic liver disease related to ethanol abuse. Tl-weighted magnetic resonance imaging scan, without contrast, shows bright signal in the region of the globus pallidus bilaterally *{arrows),* T2-weighted images (not shown) were normal,

liver function test results, other than the fasting arterial ammonia concentration, do not always correlate with the severity of the clinical disturbance. Focal neurological signs may be present but have no prognostic significance (Cadranel et al. 2001). EEG abnormalities also correlate with the severity of encephalopathy. MRI may show abnormal signal intensities in the basal ganglia on Tl-weighted images (Figure 55A.8). The mechanism of the encephalopathy is unknown. Treatment is discussed in Chapter 62.

Chronic Non-Wilsonian Hepatocerebral Degeneration

Some patients with chronic liver disease develop a permanent neurological deficit, even in the absence of prior portal systemic encephalopathy. The neurological features are similar to those of Wilson's disease (see Chapter 68): Intention tremor, ataxia, dysarthria, and choreoathetosis are common. As with portal systemic encephalopathy, the severity of the neurological disorder correlates best with the fasting arterial ammonia level. Neuroimaging studies may be abnormal. Specific treatment is not available.

Liver Transplantation

The neurological consequences of liver transplantation are similar to those of other organ transplants. The earliest postoperative disturbances are caused by organ rejection {with worsening hepatic encephalopathy), cerebral anoxia, cerebrovascular disease, or the side effects of immunosuppressant drugs, especially cyclosporine. Seizures are common. They result from metabolic disturbances, cerebrovascular disease, CNS infections, or adverse effects of treatment. Coagulopathies are also a complication and may cause fatal cerebral hemorrhage. Late complications are usually caused by infections or malignancies affecting the nervous system.

Pancreatic Encephalopathy

Whether acute pancreatitis is associated with a transitory encephalopathy is not established. The symptoms are nonspecific and similar to those of other metabolic encephalopathies, which must be excluded.

Gastrointestinal Diseases

Nutritional deficiency is the usual cause of neurological complications from gastrointestinal disorders (see Chapter 63). Several different dietary components are simultaneously deficient, and a single responsible nutrient is rarely defined.

Gastric Surgery

Neurological complications occur in 10—15% of patients after gastric resection. Because of the loss of gastric intrinsic factor, impaired vitamin BJ2 absorption may be responsible in part for neuropathy or myelopathy (Chaudhry, Umapathi, and Ravicb 2002). However, postgastrectomy neuropathy does not usually respond to vitamin $B|_2$ replacement alone. The myopathy that sometimes occurs is probably caused by vitamin D deficiency.

Gastric plication has been associated with encephalopathy, myelopathy, polyneuropathy, Wernicke's syndrome, and a nutritional amblyopia, but the precise nutritional deficiencies responsible remain to be established.

Smalt Bowel Disease

Neuropathy and myelopathy are associated with the malabsorption syndromes caused by small bowel disease, biliary atresia, or blind loop syndrome, or with previous extensive gastrointestinal resection. The findings may include pigmentary retinal degeneration, external ophthalmoplegia, dysarthria, peripheral neuropathy, and

pyramidal and cerebral signs in the limbs. Ataxia may be an especially conspicuous feature, so the neurological disorder resembles a spinocerebellar degeneration with an associated polyneuropathy. The syndrome is caused by vitamin E deficiency and responds to supplementation.

Chronic gluten enteropathy may cause a progressive and sometimes fatal CNS disorder in whieh there is some combination of encephalopathy, myelopathy, and cerebellar disturbance. Peripheral neuropathy is sometimes associated. An axonal neuropathy also occurs alone and without a measurable vitamin deficiency; restriction of dietary gluten leads to gradual resolution of neuropathic symptoms.

Whipple's Disease

Whipple's disease is a multiple system disorder that is believed to he caused by infection with the bacillus *Tropberyma wbtppeltt.* It is characterized clinically by steatorrhea, abdominal pain, weight loss, arthritis, lymphadenopathy, and a variety of systemic complaints. Neurological involvement is rare hut may occur in the absence of gastrointestinal symptoms. The most common neurological feature is dementia (Manzel, Tranel, and Cooper 2000). Less common are seizures, myoclonus, cerebellar ataxia, clouding of consciousness, visual disturbances, papilledema, supranuclear ophthalmoplegia, myelopathy, and hypothalamic dysfunction. A characteristic movement disorder, oculomasticatory myorhythmia, is peculiar to Whipple's disease; pcndular vergenee oscillations of the eyes occur with concurrent contractions of the masticatory muscles and persist during sleep. Oeulofacial-skeletal myorhythmia is also pathognomonic when present; it resembles oculomasticatory myorhythmia hut also involves nonfacial muscles. Postmortem examination shows abnormalities of the gray matter of the hypothalamus, cingulate gyrus, basal ganglia, insular cortex, and cerebellum.

The diagnosis is usually made by jejunal biopsy. Patients with neurological involvement also show cells that stain positively with periodic acid-Schiff stain in the CSF and brain parenchyma (Figure 55A.9}. Polymerase chain reaction analysis of intestinal tissue is sometimes helpful. Treatment is with antibiotic drugs such as trimethoprim-sulfamethoxazole, penicillin, tetracycline, or erythromycin, which should be prescribed in patients with a compatible clinical syndrome even when the jejunal biopsy result is negative.

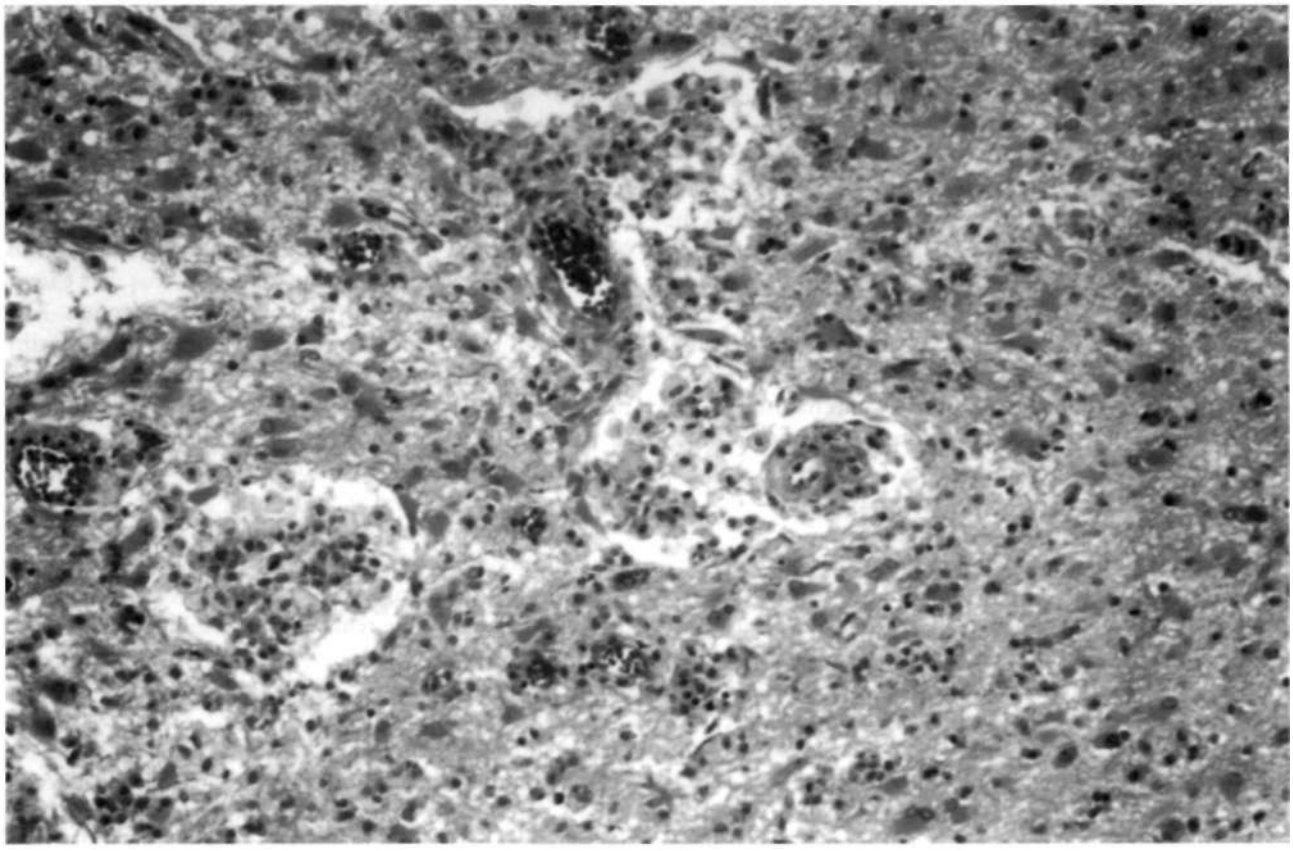

FIGURE 55A.9 Photomicrograph showing macrophages in brain tissue and around blood vessels, with prominent astrogliosis in involved brain, in a patient with Whipple's disease (hematoxylin and cosm, x40).

RENAL FAILURE

Renal failure is associated with sevetal neurological manifestations. Uremic encephalopathy is discussed in Chapter 62. Its clinical features resemble other metabolic encephalopathies, and its severity docs not correlate well with any single laboratory abnormality. The mechanism of encephalopathy is not established but has been attributed to the accumulation of toxic organic acids in the CNS or to direct toxic effects on the CNS of parathyroid hormone.

A length-dependent, symmetrical, sensorimotor polyneuropathy is a common complication of uremia. It usually worsens over several months but may progress more rapidly until the patient is profoundly disabled. Dysesthesias, muscle cramps, and restless legs are common early features. The neuropathy may stabilize or improve with long-tetm dialysis. Renal transplantation produces progressive improvement over the following year or longer, and complete recovery is possible. The neuropathy has been attributed to the accumulation of metabolites that have a molecular weight of 500-2000 daltons, but its precise pathogenesis is not established.

Autonomic dysfunction leads to postural hypotension, sudomotor abnormalities, impotence, and gastrointestinal disturbances. Dysautonomia may be important in the development of hypotension during hemodialysis, but other factors, such as volume depletion, are undoubtedly involved as well,

Uremic optic neuropathy causes a rapidly progressive vision loss that responds to hemodialysis and corticosteroid treatment. Isolated peripheral mononeuropathies occur in uremic patients from compression or entrapment, or from intramuscular hemorrhage. Hyperkalemia is sometimes responsible for a flaccid quadriparesis that responds to electrolyte correction. Treatment of uremic patients with aminoglycoside antibiotics can lead to cochlear, vestibular, or neuromuscular junction disturbances, and a myopathy sometimes results from electrolyte disturbances or corticosteroid treatment.

Neurological Complications of Dialysis

Hemodialysis requires an arteriovenous shunt in the forearm that sometimes causes a carpal tunnel syndrome attributed either to ischemia and venous congestion or to *fiz*-microglobulin amyloidosis.

The dialysis disequilibrium syndrome is probably caused by shifts of water into the brain. It is characterized by headache, irritability, agitation, somnolence, seizures, muscle cramps, and nausea during or after hemodialysis or peritoneal dialysis. Less common features are exophthalmos, increased intraocular pressure, increased intracranial pressure, and papilledema.

Patients undergoing dialysis for longer than 1 year may develop a fatal encephalopathy called *dialysis dementia*, Hesitancy of speech, leading to speech arrest, is a characteristic early feature. Intellectual function declines with time, and delusions, hallucinations, seizures, myoclonic jerking, asterixis, gait disturbances, and other neurological abnormalities ultimately develop. Death usually occurs within 6-12 months of onset of symptoms. The cause of dialysis dementia is uncertain, but aluminum intoxication was suggested by increased cerebral concentrations of aluminum at postmortem examination. Dialysis dementia has become less common since aluminum was removed from dialysates (Rob, Niederstadt, and Reusche 2001). Treatment with deferoxamine, a chelating agent that binds aluminum, is often prescribed for patients with dialysis dementia, but the optimum duration of treatment is unclear. Deferoxamine may actually exacerbate or pre cipiratc encephalopathy in patients with very high serum aluminum concentrations, and it also causes visual and auditory disturbances.

Another cause of encephalopathy in patients undergoing dialysis is Wernicke's disease. Thiamine, a water-soluble vitamin, is removed by dialysis and must be replaced by thiamine supplementation.

Neurological Complications of Renal Transplantation

The placement of the transplanted kidney close to the inguinal ligament increases the risk of retraction injury or hematoma formation around the femoral nerve. The result can be a postoperative femoral neuropathy that often resolves completely. Dysfunction of the ipsi lateral lateral femoral cutaneous nerve also may be caused by retraction or hematoma. The neurological complications associated with long-term immunosuppressive treatment are the same as those for other organ transplants.

ELECTROLYTE DISTURBANCES

Sodium

Serum osmolarity is primarily determined by the serum sodium concentration. Rapid changes in serum sodium concentration cause CNS dysfunction by altering the osmotic equilibrium between the brain and body fluids. The typical clinical features are disturbances of cognition and arousal that can progress to coma. Myoclonus, asterixis, and tremulousness are common. Seizures, when they occur, are often refractory to anticonvulsant medications until the underlying metabolic disturbance is corrected. Local symptoms (such as a hemiparesis) may occur during hyponatremia without any demonstrable structural basis but may indicate a prior or subclinical focal abnormality that is aggravated by the metabolic disturbance.

Focal abnormalities associated with hypernatremia often reflect intracerebral or subdural hemorrhage. The

hemorrhage is caused by brain shrinkage from osmotic forces, with secondary tearing of blood vessels, Hypernatremia, a common consequence of dehydration, may occur in patients receiving inadequate parenteral fluid replacement. It also occurs with diabetes insipidus, pathological involvement of the hypothalamic thirst center by tumor, and excessive salt intake.

Hyponatremia, defined as a serum sodium concentration less than 132 mKq/liter, is associated with hypo-osmolarity, except in patients with hypcrlipidcmia or hyperglycemia. It occurs in several pathological states: excessive salt loss from the kidney or gastrointestinal tract, impaired water excretion, the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), adrenocortical insufficiency, and iatrogenic water intoxication.

Hyponatremia in patients with acute brain syndromes, such as subarachnoid hemorrhage, is often attributed to SIADH. In fact, hyponatremia in this circumstance is more likely ro he caused by salt wasting than SIADH, and patients have a reduced plasma volume, rather than a normal or increased plasma volume as expected with SIADH. In such cases, fluid restriction further exacerbates the hypovolemia and may cause cerebral ischemia.

The rapid correction of hyponatremia may cause central pontine myclinolysis, a disorder initially associated with alcoholism or malnutrition but now more often iatrogenic in origin. Neurological diiriKii.uion from central pontine myeliuolysis may obscure or follow the resolution of hyponatremic encephalopathy. Severe cases are characterized by a spastic or flaccid quadriparesis, pseudobulbar palsy, and decreased states of consciousness. In some patients, the clinical features arc minimal compared with the abnormalities seen on MRI. Central pontine myelinolysis is prevented when hyponatremia is corrected at a rate of less than 12 mKq/liter per day.

Potassium

The difference in the concentration of intracellular and extracellular potassium creates the resting membrane potential of nerve and muscle cells. Disturbances of serum potassium concentrations adversely affect cardiac and neuromuscular function. The hereditary periodic paralyses are discussed in Chapter 85.

Hyperkalemia usually causes cardiac arrhythmia before disturbing neurological function. The arrhythmia is sometimes associated with rapidly progressive flaccid paralysis and depressed tendon reflexes. Weakness may **last** for several hours, may be preceded by burning paresthesias, and is sometimes accompanied by mental changes. Treatment is determined by the underlying cause, severity of the hyperkalemia, and electrocardiographic findings.

Hypokalemia usually causes neuromuscular disturbances rather than encephalopathy. Mild hypokalemia causes myalgia, fatigability, and proximal weakness that spares the bulbar muscles. Severe hypokalemia causes rbabdomyolysis and myoglobinuria, and hypokalemic alkalosis causes tetany. All symptoms remit when normokalemia is re-established.

Calcium

Hypercalcemia is associated with metastatic disease, myeloma, paraneoplastic syndromes, primary or secondary hyperparathyroidism, vitamin D intoxication, and milk-alkali syndrome. Its main CNS complication is an encephalopathy, characterized by altered state of consciousness, apathy or agitation, depression or mania, headache, and in rare instances seizures that may be a result of vascular occlusive complications. In the PNS, there is muscle weakness and fatigability, especially in patients with hyperparathyroidism, who may develop myopathy.

Hypocalcemia may follow thyroid or parathyroid surgery and is a recognized feature of hypoparathyroidism, malabsorption syndromes, vitamin D deficiency, and acute pancreatitis. Tetany is the main symptom of hypo-calcemia. Perioral and distal limb paresthesias arc the initial feature and are followed by muscle cramps, a feeling of muscle spasms, and then actual spasm of the hands and feet.

CNS complications of hypocalcemia are focal or generalized seizures and an encephalopathy characterized by hallucinations, delusions, psychosis, altered states of consciousness, and cognitive impairment. The seizures respond poorly to anticonvulsant drugs but stop when hypocalcemia is corrected. Other CNS complications of hypocalcemia are parkinsonism or chorea that responds to correction of the calcium abnormality, increased intracranial pressure (in patients with hypoparathyroidism), and myelopathy.

Magnesium

Intracellular magnesium is involved in the activation of several enzymatic reactions, and extracellular magnesium is important in synaptic transmission.

Hypomagnesemia is caused by reduced intake or absorption of magnesium or by excessive loss from diuretics, kidney disorders such as renal tubular acidosis, and diabetic acidosis. Serum concentrations do not reflect accurately the severity of magnesium depletion, because magnesium is predominantly an intracellular ion.

The neurological complications of hypomagnesemia are similar to those of hypocalcemia, and the two often coexist. The possibility of concurrent hypomagnesemia must be considered when managing hypocalcemia, especially when parenteral calcium supplementation fails to provide the expected response. Complaints of weakness in patients with hypomagnesemia may be caused by magnesium deficiency

alone or with other electrolyte abnormalities. Hypomagnesemia is treated with magnesium sulfate given orally, unless there is an absorptive defect, when it is given intramuscularly or intravenously.

Hypermagnesemia is caused by excessive intake or impaired excretion of magnesium. The usual cause is renal failure. Clinical features are drowsiness and diminished responsiveness, confusion, and depressed or absent tendon reflexes. Other features are hypotension, respiratory depression, and weakness from impaired neuromuscular transmission. Severe hypermagnesemia causes coma and may be fatal.

PITUITARY DISEASE

Pituitary Adenomas

The initial features of pro lac tin-see re ting pituitary adenomas are amenorrhea and galactorrhea in women and impotence in men. However, the diagnosis of prolactinoma is often not considered until patients develop symptoms of increased intracranial pressure originating in the scllar region. The treatment choices are transsphenoidal surgery or dopaminergic agonists such as bromocriptine. Radiation therapy is used when these choices are either unhelpful or not feasible. Tension pneumocranium is a rare complication of transsphenoidal surgery: Impaired mental status, seizures, and headaches, sometimes associated with systemic hypertension and bradycardia, occur in the early postoperative period and necessitate surgical drainage of the pneumocranium (Sawka et al. *1999),*

Growth hormone-secreting pituitary tumors cause acromegaly; gigantism occurs in children, and enlargement of the jaw, extremities, and skull in adults. Approximately 50% of patients have a myopathy, which improves over many months when the underlying hormonal disorder is treated. Carpal tunnel syndrome in patients with acromegaly is from hypertrophy of the transverse carpal ligament. Symptoms usually resolve 2-3 months after Surgical excision of the pituitary tumor, but electrophysiological abnormalities may persist for longer. Patients with acromegaly also may develop a mild, usually subclinical, polyneuropathy.

Cushing's Disease and Syndrome

Cushing's disease is caused by excessive secretion of adrenocorticotropic hormone from the pituitary gland. The clinical features are truncal obesity, hypertension, acne, hirsutism, osteoporosis, diabetes mellitus, and menstrual irregularities. Mental changes are common and include anxiety, agitation, insomnia, depression, euphoria, mania, and psychoses. Proximal muscle weakness and wasting are common, especially in the legs. Muscle biopsy shows type II fiber atrophy, a characteristic feature of muscle in patients treated with corticosteroids (see Chapter 85); electromyography is generally normal. The constellation of clinical features that constitutes Cushing's syndrome is seen also as a paraneoplastic syndrome, in association with adrenal adenomas, and after long-term corticosteroid treatment.

An enlarging pituitary adenoma may cause a visual field defect {Figure 55A.10). Treatment of Cushing's disease by bilateral adrenalectomy sometimes leads to rapid expansion of the underlying pituitary adenoma (Nelson's syndrome), with compression of other cranial nerves, especially cranial nerve III. Intracranial hypertension is a recognized complication of Cushing's syndrome and occurs particularly after the pituitary adenoma is resected,

Hypopituitarism

Hypopituitarism results from diseases of the pituitary gland or hypothalamus. The neurological features depend on the severity of secretory impairment and on the hormones affected. Common features arc apathy and intellectual decline, which are often difficult to attribute to a single hormone deficiency because several are affected concurrently.

Diabetes Insipidus

Diabetes insipidus, the inability to conserve water, results from disorders of the hypothalamus or pituitary gland or from **interruption** of the neurohypophyseal tract. Transitory diabetes insipidus is often a complication of head injury or intracranial surgery and may occur without explanation in previously well patients. Nephrogenic diabetes insipidus is caused by impaired renal responsiveness to vasopressin, which is synthesized in the hypothalamus and transported to the posterior pituitary gland. The main neurological feature is an encephalopathy that varies in severity from irritability to somnolence and ultimately to coma. Hypotension and hyperthermia also occur. Treatment is with vasopressin or a long-acting vasopressin analogue.

THYROID DISEASE

Hyperthyroidism

The features of hyperthyroidism are anxiety, restlessness, irritability, emotional lability, impaired concentration, headaches, and insomnia. Elderly patients may become depressed and lethargic, a condition designated *apathetic hyperthyroidism.* An enhanced physiological tremor and generalized hyper-rcflexia are common. Hyperthyroidism itself may cause seizures or may trigger a pre-existing

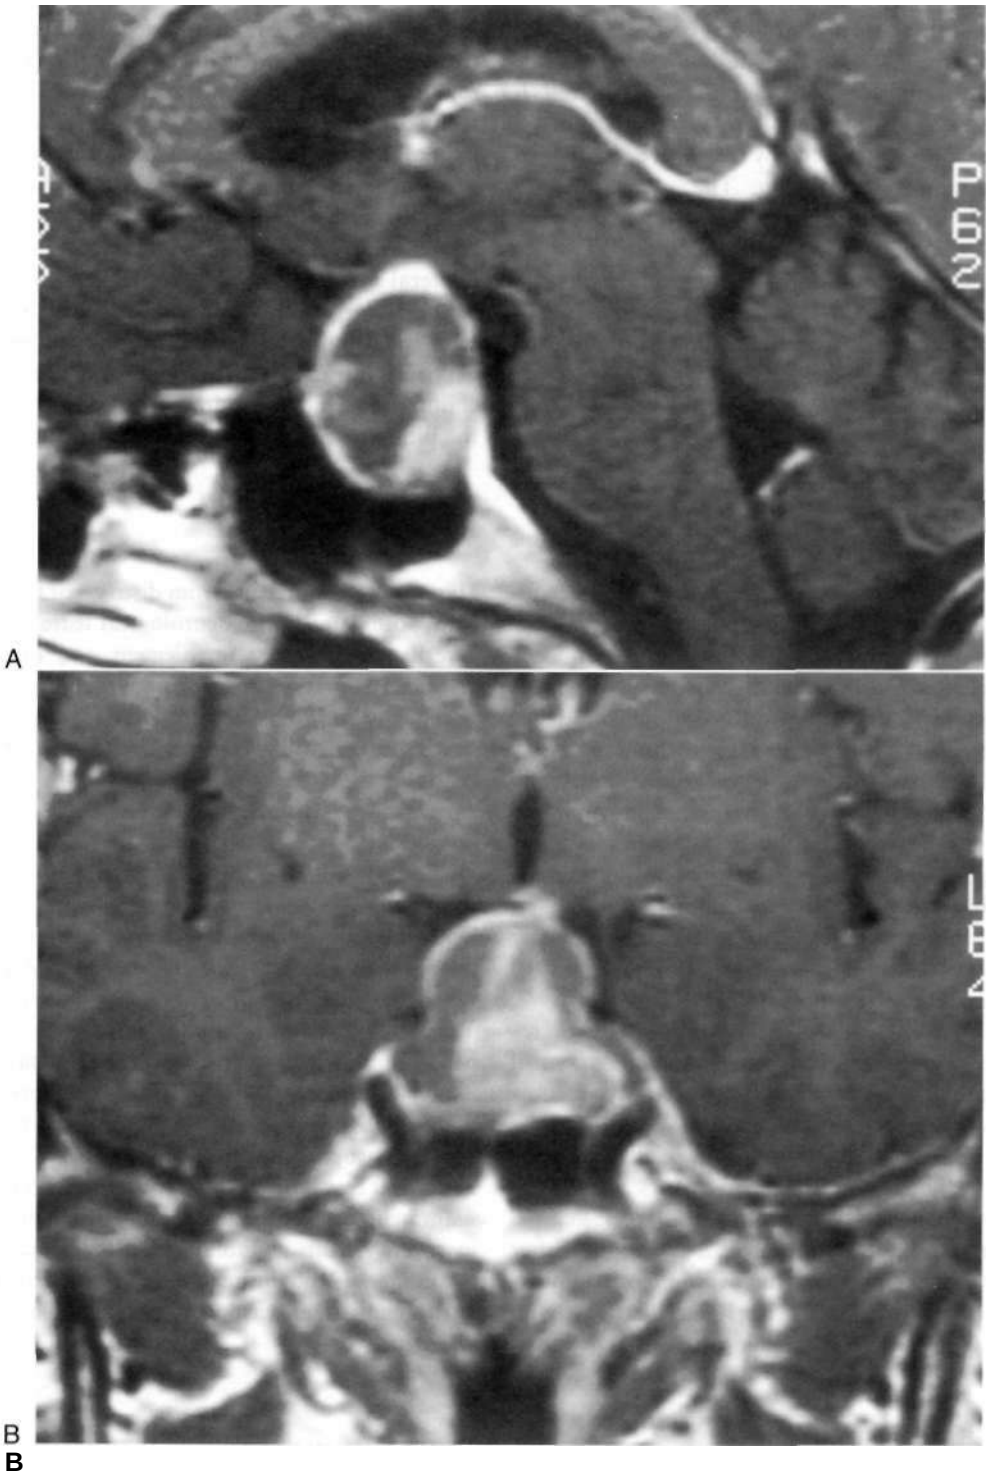

FIGURE 5SA.10 Tl-weighted gadolinium-enhanced magnetic resonance imaging. (A) Sagittal view. (B) Coronal view, A heterogeneously enhancing mass arises out of the sella turcica and extends up to involve the region of the optic chiasm. Surgery confirmed a pituitary adenoma.

seizure disorder. Chorea and paroxysmal choreoathetosis also have been described,

Thyrotoxic crisis is characterized by confusion and agitation leading to coma. Fever, cardiac arrhythmias, diarrhea and vomiting, and other systemic disturbances are associated. Treatment consists of hydration and cooling, beta-blocking drugs, corticosteroids, and in some cases plasmapheresis.

Dysthyroid orbitopathy (ophthalmic Graves' disease), characterized by exophthalmos and ophthalmoplegia, is common. Orbital edema and infiltration by inflammatory cells lead to orbital fullness, conjunctival edema and

hyperemia, proptosis, and some limitation of ocular movements. Eyelid retraction may be caused by sympathetic overactivity affecting Miillcr's muscle in the upper lids and fibrosis of the levator muscle. The occasional occurrence of optic neuropathy is related to infiltration of the optic nerve, crowding of the orbital apex, and enlargement of the extraocular muscles. Dysthyroidorbitopathy may occur in patients without a history of thyroid disease or clinical signs of hyperthyroidism. Treatment options include corticosteroids, radiation therapy, and orbital decompression.

Compression of the recurrent laryngeal nerve or cervical sympathetic fibers by an enlarged thyroid gland, commonly neoplastic, may lead to vocal cord paralysis or Horner's syndrome, respectively.

Several neuromuscular disorders are associated with hyperthyroidism. Most common is a proximal myopathy accompanied by fasciculations. Its mechanism is unknown, but the severity of myopathy does not correlate with the severity of thyroid abnormality. Scrum creatine kinase levels are generally normal. Improvement occurs with treatment of the underlying thyroid disorder. Hyperthyroidism and myasthenia gravis often coexist. Both are immune-mediated disorders (see Chapter 84). Treatment of one disorder, however, does not have any predictable effect on the other.

Thyrotoxic periodic paralysis is similar to familial hypokalemic period paralysis (see Chapter 85). It is particularly seen in Asians, and the hyperthyroidism may be clinically silent. Episodes of weakness occur after activity or after meals with high-carbohydrate content. Potassium administration treats the acute attacks, and correction of the thyroid disorder cures the periodic paralysis as well.

A sensorimotor polyneuropathy has been reported in hyperthyroidism, but the association may be fortuitous.

Hypothyroidism

Mental changes are common in hypothyroidism. Apathy, somnolence, and impaired concentration are typical *And* arc often attributed to depression. Confusion, delirium, and psychosis (myxedema madness) may occur also and improve with treatment of the underlying thyroid disorder. In severe hypothyroidism, decreased states of consciousness are associated with hypotension, hypothermia, respiratory failure, hypoglycemia, and other metabolic derangements; untreated, the disorder progresses to coma and sometimes death.

Other features of hypothyroidism are an increased incidence of seizures, truncal ataxia caused by a cerebellar degeneration, hearing loss, and cranial neuropathies. Hoarseness of the voice is caused by structural changes m the vocal cords, rather than neurological disease. The neurological complications of hypothyroidism usually recover with thyroid replacement, especially if the deficiency is not long standing.

The PNS is often involved in hypothyroidism. Most common is a proximal myopathy accompanied by myalgia and muscle stiffness. The affected muscles may be enlarged (Hoffmann's syndrome) and have my oedema (transient local mounding when a muscle is percussed).

Carpal tunnel syndrome occurs in as many as 30% of patients and usually responds to correction of the thyroid disorder. Less common is a sensory or sensorimotor neuropathy; both segmental demyelination and axonal degeneration have been implicated. There may be slow relaxation of tendon reflexes. Myasthenia gravis is associated also but occurs less commonly than in hyperthyroidism.

Hashimoto's Thyroiditis

Hashimoto's thyroiditis has been associated with myasthenia gravis and less clearly with giant cell arteritis and vasculitic peripheral neuropathy. In addition, a relapsing encephalopathy may occur in association with Hashimoto's thyroiditis and high titers of antithyroid antibodies. Clinical presentation is with confusion, altered conscious level, and sei/.ures. Tremulousness and myoclonus may be conspicuous, and strokelike episodes of deterioration are common. The EEC is diffusely abnormal, the CSE protein concentration is increased without any associated pleocytosis, and neuroimaging studies are normal except for patchy abnormal uptake on isotope brain scan. Treatment is with corticosteroids. The long-term prognosis is good.

PARATHYROID DISEASE

Hyperparathyroidism

Neurological manifestations of hyperparathyroidism are common. They are essentially those of hypercalcemia (see Calcium, earlier in this chapter). A mild proximal myopathy may occur also and improves with surgical treatment of the parathyroid disorder. A picture like that of amyotrophic lateral sclerosis has also been described.

Hypoparathyroidism

I lypoparathyroidism commonly follows thyroidectomy or has an idiopathic basis. Pseudohypoparathyroidism is caused by peripheral resistance to the effects of parathyroid hormone rather than to any deficiency of hormone secretion. The neurological manifestations of these disorders relate primarily to the effects of hypocalcemia on the nervous system. Intracranial calcification is common in patients with hypoparathyroidism and occurs especially in the basal ganglia; it is usually asymptomatic. Benign intracranial hypertension also may be associated with

hypoparathyroidism and is reversed by correction of the underlying metabolic disorder.

ADRENAL GLANDS

Pheochromocytoma

Pheochromocytoma is associated with neurofibromatosis and von Hippel-Lindau disease (see Chapter 71). The initial features of pheochromocytoma are paroxysmal symptoms of excessive catecholamine secretion; headache, hyperhidrosis, palpitations, cardiac arrhythmias, tremulousness, and anxiety. Most patients have hypertension, and seizures occur in approximately 5%. Malignant pheochromocytomas are rare, and metastatic tumors may respond to radiation therapy.

Addison's Disease

Adrenal failure results from diseases of the pituitary or adrenal gland or from adrenal suppression by long-term use of exogenous corticosteroids. The major features are generalized weakness, fatigability, lassitude, depression, headache, weight loss, anorexia, and hyperpigmentation of the skin. Increased intracranial pressure may be present. Adrenal failure is a feature of X-linked adrenomyeloleukodystrophy.

Diabetes Mellitus

Peripheral Nervous System

In developed countries, diabetes is the most common cause of polyneuropathy (see Chapter 82). The mechanism of neuropathy is not established but may be either metabolic or vascular.

Diabetic polyneuropathy has both axonal degeneration and demyelination. It may be asymptomatic; the diagnosis is suggested by depressed tendon reflexes and impaired vibratory sense in the legs. When the neuropathy becomes symptomatic, the feet are affected more than the hands. The initial symptoms are pain, paresthesias, or numbness. Profound weight loss sometimes precedes the development of an acute painful neuropathy. Progressive neuropathy is characterized by distal sensory loss and weakness in the limbs and arreflexia. Severe impairment of pain and temperature appreciation occurs occasionally and results in distal ulceration and arthropathy (acrodystrophic neuropathy).

Autonomic neuropathy is an important feature of diabetes mellitus. The clinical features range from lack of symptoms to a syndrome that includes postural hypotension, abnormal cardiovascular and thermoregulatory control, and impotence. Pupillary abnormalities, gastroparesis, and diarrhea from intestinal dysmotility may occur also, and responses to hypoglycemia may be blunted.

Diabetic polyradiculoneuropathy is characterized by pain and asymmetrical limb weakness, usually involving the thighs and often accompanied by weight loss. A diabetic plexopathy or polyradiculopathy, rather than a femoral neuropathy, probably accounts for most cases of diabetic amyotrophy (Dyck and Windebank 2002). Symptoms are rapidly progressive but stabilize after a few weeks; gradual but often incomplete recovery occurs over the following months or years.

The typical syndrome of diabetic thoracoabdominal polyradiculopathy consists of nonradicular truncal pain that may initially suggest intra-abdominal or intrathoracic pathology requiring surgical exploration. Sensory loss and weakness are mild.

Diabetic mononeuropathy multiplex has a vascular basis. Simple mononeuropathies are also common in diabetics. Entrapment neuropathies, especially carpal tunnel syndrome, occur with an increased incidence. Cranial neuropathies, usually isolated involvement of nerves III, IV, and VI, cause a painful extraocular palsy. Diabetes-induced palsies of cranial nerve IN are generally distinguished from compressive lesions by sparing of the pupillary reflex. Cranial nerve VII may also be affected, causing unilateral facial weakness. Specific treatment for diabetic neuropathy is not available, but it is important to ensure that the diabetes itself is well controlled.

Central Nervous System

Stroke is more common in diabetics than in the general population, because of an increased incidence of hypertension and atherosclerosis. Diabetes increases stroke severity and mortality and predisposes to deep subcortical infarcts.

Diabetic ketoacidosis, an important cause of morbidity and mortality, may be the presenting feature of previously unrecognized diabetes. Severe hyperglycemia and a metabolic acidosis cause an osmotic diuresis that dehydrates the patient. Clinical presentation includes an altered state of consciousness that progresses to coma. Focal or lateralizing signs are absent usually unless the patient has underlying brain disease. The pathogenesis of diabetic coma is poorly understood and probably multifactorial. Serum hyperosmolality and acidosis are probably important contributing factors. Postmortem examination in some patients with severe diabetic ketoacidosis shows evidence of DIG, which may contribute to the altered level of consciousness. Potential contributory factors are other metabolic derangements, infection, vascular occlusive phenomena, and cerebral edema.

Nonketotic hypetosmolat coma may be precipitated in diabetic patients by an acute medical complication, such as

a myocardial infarction. Affected patients are typically elderly with mild disease. Hyperglycemia and hypcrosmolality occur without significant ketosis. Progressive obtundation is the principal feature, but seizures and focal deficits may develop. Treatment includes fluid, potassium, and phosphate replacement as necessary and correction of hyperglycemia.

Hypoglycemia

Hypoglycemia can cause an acute metabolic encephalopathy, with initial features of tremuloiisncss, anxiety, confusion, stupor, or coma, depending on the level of hypoglycemia. Later features are brainstem dysfunction and transitory focal neurological deficits that resemble strokes but either resolve or alternate from side to side. Seizures are sometimes the only manifestation of hypoglycemia. Administration of glucose reverses the symptoms. Severe hypoglycemic cerebral injury causes MR1 abnormalities localized to the basal ganglia, cetebral cortex, substantia nigta, and hippocampus, suggesting a patticular vulnerability of these areas (Fujioka et al. 1997). Neuromuscular syndromes resembling *a* peripheral sensorimotor polyneuropathy or lower motor neuron degeneration have been described in patients with insulinomas or who receive excessive insulin for therapeutic purposes.

Chapter 55
Neurological Complications of Systemic Disease

B. IN CHILDREN

Bruce O. Berg

The clinical features of many neurological complications of systemic diseases are somewhat different in children than adults depending on the child's age and stage of development. This section of the chapter considers those differences.

CARDIAC DISORDERS AND **THE** NERVOUS SYSTEM

Congenital Heatr Disease

The possible neurological complications of congenital heart disease (CHD) in childten include cerebral hypoxia, neurological abnormalities sccoiuUm to the cardiac anomaly, associated cerebral malformations, and complications of diagnostic and therapeutic interventions. The incidence of CHD is about 1% of live births but would probably be highet if adequate data wete available on stillbirths and abortions. It seems likely that the cause of CHD is an intetaction of genetic and environmental factors. Chronic hypoxia, polycythemia, cerebrovascular accidents, and brain abscesses were the main causes of the neurological disorders associated with CHD. Howevet, the advenr of modem diagnostic and therapeutic techniques have resulted in earlier surgery with reduced mortality and increased survival. Both the sutgety and the longer sutvival have resulted in a greater variety of neurological disturbances.

Patients with acyanotic CHD have left-to-tight shunts. The main anomalies are atrial septal defects, ventricular septal defects, and patent ductus arteriosus. These children are not usually at risk for neurological complications from emboli or bacterial abscess, because blood flow traverses the pulmonary vascular bed, which protects the brain from blood-borne injury. Under some circumstances, a reversal of shunt flow occurs that can result in cerebral emboli. Congenita] stenosis of the great vessels does not cause cyanosis and tarely contributes to thrombi fotmation with subsequent cetebtal and peripheral emboli (see the discussion of bacterial endocarditis, later in this section). This gtoup of malformations includes aortic stenosis, pulmonary stenosis, and coarctation of the aorta. Aortic stenosis is occasionally responsible for decreased cardiac output with secondary

cardiac arrhythmia, cerebral hypoxia, and seizures. Pulmonary stenosis rarely causes neurological complications. Coarctation of the aorta, however, may be associated with cerebral aneurysms and accounts for about one fourth of all cerebral aneurysms in children.

In contrast, the cardiac anomalies that characterize cyanotic CHD facilitate blood flow to the heart and brain without first traversing the pulmonary vascular bed. These can ultimately result in the direct transport of a nidus of peripheral infection to the brain, resulting in cerebritis, brain abscess, or stroke. This group includes tetralogy of Fallot, transposition of the great vessels, truncus arteriosus, tricuspid atresia, and complete anomalous pulmonary venous return.

Hrain abscesses had been common in children with CI II) older than 2 years. Improved diagnostic techniques that allow the early identification and repair of complex congenital heart lesions have greatly diminished their incidence. Children with inoperable cyanotic congenital heart lesions remain at risk for stroke from cerebral emboli (Carlin and Chanmugam 2002). After excluding the neurological complications of cardiac surgery, interventional diagnostic studies, and therapeutic measures, the remaining neurological morbidity of CHD is infection and cerebral dysgenesis. Early diagnosis and treatment, as well as vigorous prophylactic treatment for bacterial infections and dental surgery, have greatly reduced the risk of bacterial endocarditis and hrain abscesses (Tak et al. 2002). The neurological disorders resulting from septic emboli secondary to bacterial endocarditis include meningitis, brain abscess, stroke, and seizures. Systemic emboli occur in 50% of children with bacterial endocarditis and represent as many as *65%* of all emboli to the brain.

The clinical features of cerebral embolization are sudden alteration of consciousness, dysphasia and/or aphasia, seizures, and hemiparesis. The diagnosis of bacterial endocarditis relies on determining and documenting sepsis by multiple repeated blood cultures. Transthoracic echocardiography is used to demonstrate cardiac vegetations and magnetic resonance imaging (MRl) to show cerebral ischemia. Antibiotics are the mainstay of treatment.

Most children with CHD have normal intellectual development; however, the incidence of developmental delay is increased in children with cyanotic CHD, particularly when surgical repair is delayed until late childhood. The potential reasons for developmental delay include brain malformations, chronic hypoxia, cerebral infarction, and seizure disorders. Patients with congenital heart defects arc at greater risk for prenatal and perinatal cerebral injury. Van Houten, Rothman, and Be jar (1996) reviewed cranial ultrasound scans of 49 full-term infants with CHD and compared them with 42 healthy full-term control infants. Infants with congenital heart defects have a higher incidence of cranial ultrasound abnormalities than control infants (0.6% vs. 14%; $p < ,0001$). The most common sonographic findings are cerebral atrophy and linear eehodensities in the basal ganglia and thalamus, particularly in those infants with coarctation of the aorta or ventricular septal defect. The incidence of intraventricular hemorrhage was greater in infants with acyanotic CHD than in those with cyanotic CHD. In some autopsy studies of CHD, the incidence of cerebral dysgenesis is about 30% and some cardiac anomalies carry a greater risk than others.

In a review of 41 infants with hypoplastic left heart syndrome, Glauser et al. (1990) found that 29% of infants had either a major or a minor malformation of the central nervous system (CNS). Microcephaly occurred in 27%, an immature cortical mantle in 21%, and the remainder had a variety of other malformations including one case of holoprosencephaly. The phenotype of some chromosomal abnormalities includes both cardiac and nervous system malformations. Down syndrome (trisomy 21) is characterized by developmental delay and congenital heart defects, particularly endocardial cushion defects. Trisomy 13 with ventricular septal defect and other organ anomalies including holoprosencephaly and varying degrees of incomplete division of the cerebral hemispheres and basal ganglia occur in about 80% of cases. Patients with trisomy 18 have renal anomalies, ventricular septal defect, redundant cardiac valve leaflets, agenesis of the corpus callosum, Chiari malformation, Dandy-Walker syndrome, and heterotopias. Williams syndrome is characterized by developmental delay, supravalvular aortic stenosis, and sometimes other aortic lesions. The genetic defect is a deletion at 7q11.23, the locus for clastin. The phenotypical spectrum associated wirh deletions in the region of 22ql 1, Di George and velocardiofacial syndromes, includes a variety of cardiac abnormalities, unusual fades, cleft palate, varying degrees of hypoplasia of the thymus and parathyroid glands, and hypocalcemia.

Acquired Heart Disease

Neurological complications are associated with several acquired cardiac disorders of childhood including cardiomyopathy, arrhythmias, and hypertension. Cardiomyopathies can be idiopathic or result from myocarditis. In every case, the ventricles are abnormally dilatated and unable to function properly. The chronically dilatated heart, lacking normal pulsatile activity, causes the stasis of intraventricular blood, which results in thrombi formation and dispersion of emboli. Decreased ventricular output may cause reduced coronary blood flow, arrhythmia, and syncope.

Ventricular arrhythmia can occur in CHD before surgical manipulation but is more likely to occur during or after surgical manipulation at the time of heart surgery or in the postoperative period (Walsh 2002). The result of embolization to the cerebrovascular system is stroke.

The main neurological complication of hypertension in children is hypertensive encephalopathy. It is an uncommon occurrence in children. The most common presenting

symptoms arc seizures, headache, and cortical blindness, Hypertension is associated with neurofibromatosis type 1 and von Hippei-Lindau syndrome, because of the associated pheochromocytoma, in children with Guillain-Barre syndrome with autonomic nervous system involvement, and in bronchopulmonary dysplasia,

Neurological Complications of Diagnostic and Surgical Intervention

The techniques of cardiac catheterization have improved during the last several decades, but nonetheless, the introduction of catheters, balloons, or other devices into the vascular system has an inherent risk of causing injury to the endothelial lining of the vessel in question. Although the incidence of neurological complications associated with cardiac catheterization is low, the main risk is the possibility of thrombus formation and the subsequent dispersion of emboli to the brain and other organs.

Improved cardiac surgical techniques allow the successful repair of complex congenital heart at an earlier age; this has increased survival but also increased morbidity. In the early postoperative period, the occurrence of seizures varies from 5-25%. The use of electroencephalographic monitoring may reveal that the incidence is even higher. In the evaluation of seizures in the postoperative cardiac surgery period, cerebral dysgenesis and metabolic abnormalities such as hypoglycemia, hypomagnesemia, and hypocalcemia are important considerations. The causes of most postoperative seizures remain undefined but are presumed secondary to hypoxic-ischemic events and possibly the untoward events related to repcrfusion. Prospective studies have suggested a correlation between recurring postoperative seizures and neurodevclopmcntal delay. Previous reports have suggested that 20% of children with CHD had evidence of cerebrovascular disease. Such reports were at a time that the major cause of stroke in children was CHD, The incidence varied from 25-30% of cases. The modern diagnosis and surgical repair of complex congenital lesions has lowered the incidence of stroke, but an increased risk still exists because the mechanics of cardiopulmonary bypass increases the likelihood of cerebrovascular occlusion and emboli. The risk of stroke remains increased during the postoperative period because of altered intravascular endothelial surfaces and because prosthetic devices facilitate thrombus formation and embolization by decreasing blood flow. This increased risk of stroke necessitates the use of postoperative anticoagulation.

Reports of choreoathetosis following hypothermic heart surgery first appeared in I960. Since that time, other less common movement disorders have been recognized including oculogyric crises and parkinsonism. Movement disorders occur in 1% or fewer children following such surgery. The typical course is an uncomplicated postoperative period lasting about 7 days. The child then seems confused and irritable. The onset of abnormal movements of the head, neck, limbs, or trunk follows, which are present when awake and disappear during sleep. The abnormal movements persist for several weeks to months. The underlying mechanism of the movement disorder is not understood.

Neuroimaging studies have been nonspecific, although single-photon emission computed tomography (CT) has suggested defects of cortical and subcortical perfusion. The dyskinesias are recalcitrant to treatment. Reducing external stimulation and careful administration of sedation improves the sleep cycle,

Cardiac Transplantation

Hcatt transplantation is becoming an important procedure for children with profound and irreversible cardiomyopathy, for CHD, and for end-stage heart failure (Marelli et al. 2002}. Improved use of immunosuppressive agents has increased survival, but their long-term use facilitates opportunistic infection, and the drugs are themselves a source of neurological complications. The entire period of immunosuppression, from before to after surgery, is a time of risk. Other neurological complications continue to occur including hypoxic-ischemic episodes, stroke, drug neurotoxicity, and psychosis. The possibility of infection, the long-term effects of rejection, and the drugs used to treat these complications are important factors in morbidity and mortality. Hypertension and renal disease are usually present and coronary artery disease and lymphoproliferative disease arc major causes of dearh.

CONNECTIVE TISSUE DISEASES AND VASCULITIDES

Polyarteritis Nodosa

Systemic necrotizing vasculitis of small and medium-sized vessels characterizes polyarteritis nodosa (PN). PN occurs more often in adults than in children, but adolescents can be affected. An infantile form has been described, which is probably the same or similar to Kawasaki disease. Clinical manifestations include fatigue, anorexia, weight loss, malar skm rash, myalgia, and arthritis. Renal disease, often associated with hypertension, can occur any time during the course of the disease.

A specific diagnostic test is not available, but an elevated sedimentation rate, positive C-reactive protein and complement levels, and a positive antineutrophil cytoplasmic antibody (ANCA) each suppott the diagnosis.

Several neurological complications are associated. Headache occurs as part of aseptic meningitis. Neuroimaging studies performed at the time of the headache are usually normal. Symptoms of CNS involvement occur early in the course of disease and include behavioral changes,

disturbances of cognition, and seizures that can progress to status epilepticus. Ocular involvement is manifest by decreased visual acuity, loss of visual fields, and sco to ma ta from proliferative retinitis and retinal hemorrhage. Sudden hemiplegia is characteristic of stroke. Neuroimaging studies such as MRI and magnetic resonance angiography (MRA) are required but cerebral angiography may be required to specifically demonstrate the vascular lesion(s) for the diagnosis of angitis. Among children with diffuse myalgia and elevated blood creatine kinase concentrations, about 50% show typical electromyographic (EMG) findings of myopathy. Mononeuritis multiplex is characteristic of PN and may have a remitting and relapsing course. The clinical picture begins to resemble a polyneuropathy as an increasing number of nerves are affected. Young children with PN-associatcd neuropathy arc unable to describe symptoms of paresthesias or numbness and may not respond to the examiner's questions.

Angiography can show segmental narrowing of vessels, particularly in the renal, mesenteric, and hepatic vessels. Muscle or nerve biopsy reveals a necrotizing vasculitis. In addition to general supportive care, corticosteroids are administered and in some cases in combination with cyclophosphamide.

Takayasu's Arteritis

Takayasu's arteritis, sometimes known as "the pulseless disease," is a rare arteritis involving the aorta and its branches. Females are affected more often than males, and in children, the abdominal aorta and its branches are more often affected than the aortic arch. Clinical features before the "pulseless" phase include fever, anorexia, weight loss, myalgia, and arthralgia. Aortic arch involvement can result in aortic insufficiency or aneurysm. Dyspnea, claudication, and loss of radial pulses are the main features of aortic arch involvement. The presenting features of involvement of the abdominal aorta are abdominal mass and discomfort, congestive heart failure, hypertension, and symptoms and signs of an acute abdomen.

Neurological complications of Takayasu's arteritis are uncommon but can include transitory visual loss, vertigo, and syncope. Other features are recurring headache, seizures, and hemiplegia. Treatment consists of administration of corticosteroids, immunosuppressive agents, or both in combination. Surgical graft procedures and angioplasty are beneficial in selected cases.

Churg-Strauss Syndrome

Churg-Strauss syndrome (CSS) is an allergic angiitis characterized by peripheral neuropathy, asthma, fever, eosinophilia, heart failure, and pulmonary disease. The American College of Rheumatology has outlined the criteria for diagnosis. Four of the following six conditions must be met: asthma, eosinophilia more than 10%, mononeuropathy or polyneuropathy, nonfixed pulmonary infiltrates on radiograph, paranasal sinus abnormalities, and blood vessel biopsy with extravascular eosinophilia. Fibrinoid necrosis of the media of small arteries and veins characterizes the vascular histopathology.

Neurological manifestations of CSS in children are limited almost entirely to the peripheral nerves secondary to involvement of the vasa nervorum. Adult patients have behavioral disturbances, intracranial hemorrhage, seizures, and cranial neuropathies. Treatment of CSS, as in other vasculitides, includes corticosteroids and immunosuppressive agents.

Juvenile Rheumatoid Arthritis

The characteristics of juvenile rheumatoid arthritis (JRA) is chronic inflammation of one or more joints in patients younger than 16 years in whom other causes for the arthritis are excluded. All of the different features of JRA are attributable to complex autoimmune disease. No identifiable infectious agent causes JRA.

About 10% of children with JRA have a systemic form. The clinical manifestations of systemic JRA are difficult to manage effectively. Affected children usually have recurrent fevers, a faint evanescent skin rash, irritability, malaise, and anorexia. Some complain of severe joint pain and myalgia even before the appearance of joint involvement. Pericarditis and myocarditis are common and can be life threatening. Laboratory studies (in systemic JRA) show anemia and thrombocytosis. Children with systemic JRA are typically seronegative for rheumatoid factor (RF) and antinuclear antibodies (ANAs). An acute encephalopathy may be associated. Those affected can have abnormal liver function, hyperammonemia, and increased intracranial pressure, Flectroencephalographic studies are abnormal with or without the presence of clinical seizures.

Other types of JRA include pauciarticular form in which one or several joints are affected and a polyarticular form in which five or more joints are involved (Al-Matar et al. 2002). More females than males are affected, and female bias is greatest in the polyarticular form. Iridocyclitis is a complication of JRA, especially the pauciarticular form, which may occur at any time in the course. Periodic ophthalmologica) examinations are recommended. Focal neurological findings are uncommon and can be secondary to soft tissue involvement. Occasional sensorimotor polyneuropathies occur but less commonly than in adults. Scrum creatine kinase concentrations are elevated in one third of children with JRA, but proximal weakness or histological evidence of myositis is uncommon. Rare immune-mediated abnormalities of the neuromuscular system include inflammatory neuropathy, myositis, and myasthenia gravis.

Decreased mobility of the neck, secondary to fusion of the cervical vertebrae, can occur in both the systemic or polyarticular forms of JRA. Torticollis may be the presenting feature. Cervical myelopathy from atlantoaxial dislocation is a rare event in children.

The management of JRA is usually with aspirin or nonsteroidal anti-inflammatory agents. Some require corticosteroids, intravenous immunoglobulin (IVIG), immunosuppressive agents, or parenteral gold salts. Physical and occupational therapy lessen the discomfort of joint or muscle stiffness and may prevent the development of peripheral nerve entrapment syndromes.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is an immune-mediated multisystem disorder. Onset is at all ages, and multiple organ symptoms are involved, particularly the kidneys. The fcmale-to-male gender bias is 8:1. General clinical features include fever, weight loss, malar rash, arthritis, and musculoskeletal symptoms. No single diagnostic test is confirmatory, but almost all patients show a positive immunofluorescent ANA test result.

The incidence of neurological complications varies from 20-40%, and half of these are neuropsychiatric symptoms: cognitive and behavioral disorders and psychosis. Depression and anxiety are common and often occur early in the course. Confusion, disorientation, memory loss, and even dementia characterize impaired cognition. Headache and seizures, partial and secondarily generalized, occur and are usually self-limited. These manifestations may he directly attributable to the disease or may be secondary to hypertensive encephalopathy, electrolyte disturbances, or corticosteroid treatment. Focal neurological abnormalities may involve the cranial nerves or the limbs. Cerebral thromboses secondary to vasculitis or more often immunccornpntind deposition is causative. Specific features include visual loss, optic neuritis, ophthalmoplegia, pseudotumor cerebri, facial palsy, deafness, vertigo, vocal cord paralysis, ataxia, and transverse myeloparhy. Chorea and other dyskinesias occur in about 4% of affected children. Peripheral nerve involvement occurs in 5%, characterized by numbness and distal weakness, either as mononeuritis multiplex or as an acute dcmycliuating polyneuropathy similar to the Guillain-Barre syndrome. Management includes corticosteroids, IVIG, immunosuppressive agents, and plasmapheresis.

Mixed Connective Tissue Disease

Mixed connective tissue disease (MCTD), a disorder of unknown etiology, is similar to other syndromes of small-vessel vasculitis such as SLE, scleroderma, dermatomyositis, and Sjogren's syndrome. Few children show involvement of larger vessels. Children wirh MCTD have autoantibodies to a nuclear rihonuclear protein (anti-RNI[1]), which is present in rihonuclear labile-cxtractable nuclear antigen. Fever, lymphadenopathy, and hepatosplenomegaly characterize the disorder. Poly arthritis is a common feature, as well as skin rash, myositis, and cardiomyopathy.

Neurological complications include proximal muscle weakness associated with increased scrum creatine kinase concentration, and histological findings of myositis, headache, aseptic meningitis with increased cerebrospinal fluid (CSF) protein concentrations, occlusion of the internal carotid artery, and intracerebral hemorrhage. Treatment consists of the administration of hydroxychloroquine for the management of the skin rash and nonsteroidal anti-inflammatory agents for symptoms of joint involvement. The efficacy of corticosteroids has not been established.

Wegener's Granulomatosis

Wegner's granulomatosis is a rare vasculitis of unknown origin characterized by necrotizing granulomatosis affecting small arteries and veins. The onset is usually in adult life but may begin in infancy. The major findings are rhinorrhea, nasal mucosal ulceration, sinusitis, pulmonary disease (cough and hemoptysis), and glomerulonephritis. Fever, malaise, and anorexia are associated. In a comparative study of clinical features in children and adults, subglottic stenosis occurred five times more often in children than adults, and nasal septal deformities were twice as common. One third of children have arthritis, skin ulcerations, conjunctivitis, corneal ulceration, exophthalmos, and micnigraiiiilomatous hepatitis. Increased ANCA titers are present in most cases. Neurological manifestations include mononeuritis, multiplex or polyneuropathy, cranial nerve palsies, optic nerve granuloma, and orbital pseudotumor. Management is by administration of corticosteroids and cyclophosphamide. Long-term therapy with cyclophosphamide and azathioprine is beneficial.

licheet[1]s Disease

Uveitis and oral and genital ulcers characterize Behcet's disease. It is rare in children. The current diagnostic criteria, as determined by the International Group for Behcet disease, include recurrent aphthous stomatitis and two of the following: recurrent genital ulcers, uveitis or retinal vasculitis, erythema nodosum or pustules, or abnormal reaction to allergens. Meningoencephalitis, dementia or psychosis, ischemic lesions of the brainstem or spinal cord, and thrombosis of the dural sinus or intracranial veins are the neurological complications. Mononeuritis multiplex or poKiiL-uropath} are rare. The CSF protein concentration

may be elevated. Treatment is generally supportive, but corticosteroids and immunosuppressive agents are recommended.

Cogan's Syndrome

Cogan's syndrome is a chronic vasculitis of unknown etiology that rarely affects children. Photophobia, interstitial keratitis, and vestibular acoustic symptoms (tinnitus and hearing impairment) are characteristic. Systemic manifestations may include lymphadenopathy, splenomegaly, and musculoskeletal complaints. A systemic vasculitis, when present, may involve the aorta and result in aortitis and aortic insufficiency. The coronary and renal arteries may be involved. Corticosteroids have a short-term benefit; immunosuppressive agents may also be effective.

Sjogren's Syndrome

Sjogren's syndrome is a chronic disorder characterized by recurrent lymphocytic inflammation of the salivary glands, xerostomia, and keratoconjunctivitis sicca. The primary form is rare in childhood; the secondary form is a complication of SLK, JKA, MCTD, or dermaromyositis, The disease mainly affects females.

The main features are a nonspecific anemia, leukopenia, and hypergammaglobulinemia. Several autoantibodies are positive including ANA, anti-SSA, and rheumatoid factor. Lymphoid infiltration of the minor salivary glands of the lower lip is characteristic of Sjogren's syndrome. Neurological complications are limited and may include optic neuritis, aseptic meningitis, and cerebrovascular occlusion. MRI studies show regions of increased signal intensity on T2-weighted images in the internal capsule and periventricular white matter. Treatment is generally supportive, but corticosteroids and immunosuppressive agents arc used in life-threatening circumstances.

RESPIRATORY DISEASES

Periodic Breathing and Apnea

Periodic breathing is a pause in respiration that persists 3 seconds or more, followed by a normal respiratory pattern for 20 seconds, and then repeats at least three more times. This pattern is common in the premature infant. Supplemental oxygen is required if arterial oxygen saturation is significantly decreased or the infant becomes bradycardia Neurological sequelae do not occur unless hypoxemia is significant and prolonged.

Apnea, the cessation of respiration and flow of air for more than 20 seconds, can be secondary to airway obstruction, lack of respiratory effort (central apnea), or both. The most common type of apnea is that which occurs in the premature infant of about 35 weeks beginning during the first several days of life and then decreasing in frequency and severity over the succeeding months. All potential causes of recurring apnea should be excluded utilizing interventional diagnostic and therapeutic measures. Episodes of apnea are seldom associated with gastroesophageal reflux.

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia is a chronic progressive lung disorder that affects infants who had hyaline membrane disease and were mechanically ventilated while receiving high-oxygen concentration. The pathogenesis is not clearly established. Neurological complications include impaired vision, hypotonia, delayed development, particularly fine and gross motor performance, postural control, and balance. The acquisition of speech and language are impaired and articulation is impaired.

Chronic hypoventilation may cause brainstem gliosis. A movement disorder affecting the head, neck, trunk, limbs, and oral-buccal-Ungual musculature can develop during the second or third postnatal month. Episodes of respiratory failure exacerbate the movement, and sleep reduces them. Feeding is difficult because of the oral movements. Although the management of ventilation and nutrition of infants has improved during the last several decades, the mortality of bronchopulmonary dysplasia remains high. Fifteen percent do not survive the first year. Symptoms gradually resolve in those who survive.

Cystic Fibrosis

As in other chronic pulmonary disorders, neurological features of cystic fibrosis arc secondary to chronic hypoxia and retention of carbon dioxide. Lethargy, and sometimes coma, results as pulmonary function declines. Chiari type I malformation is more common in children with cystic fibrosis than the general population. Symptoms and signs are reversed with the improvement of hypoxia.

SARCOIDOSIS

Sarcoidosis is a systemic disease of unknown etiology characterized by small noncaseating epithelial granulomas affecting multiple organs. When the nervous system is involved the disorder is called *neurosarcoidosis.* Children of African heritage arc affected more commonly than those of European heritage, and females more often than males. Childhood sarcoidosis is rare, comprising about 6% of cases. In children younger than 4 years, the features are a painless arthropathy with intact range of motion,

uveitis, and cutaneous lesions. Older children have a clinical course similar to that of adults with pulmonary involvement, fever, lymphadenopathy, and weight loss. Given the vagaries of clinical identification and reporting, the prevalence of nervous system involvement in adults may be as high as 5% and as high as *9%* in children (see Chapter 55A).

HEMATOLOGICAL DISORDERS

Congenital Aplastic Anemia (Fanconi's syndrome)

Fanconi's syndrome, inherited as an autosomal recessive trait, is genetically heterogeneous. At least eight genes have been identified. Three fourths of affected children have congenital anomalies. The pathophysiology is disordered proliferation and differentiation of hematopoietic stem cells. A single cytopenia progresses to pancytopenia. The typical characteristics are microcephaly, short stature, abnormal thumbs and radii, hyperpigmented and hypopigmented spots, and structural renal anomalies. The congenital aplastic anemia can occur in children who have no other physical abnormalities usually associated with the disorder.

Hemolytic Disease of the Newborn (Kernicterus)

Hemolytic disease was once the most common perinatal hematological disorder of infancy. The incidence has significantly declined by the administration of anti D antibody (Rho U) immune globulin to mothers within 2 hours. It is an alloimmune hemolytic anemia of the fetus secondary to the transplacental passage of mother's anti-Rh antibody. The worst result is erythroblastosis fetalis and in many cases kernicterus in survivors. Until the last decade, kernicterus was uncommon, but for unclear reasons, the frequency is now increasing.

Over 2 to 7 days, the jaundiced infant developing kernicterus is initially drowsy, does not feed well, often has a high-pitched cry, and loses transitory neonatal reflexes. Muscle tone increases gradually resulting in opisthotonus and on occasion extensor spasms. During the next several months, the infant becomes hypotonic, and in the ensuing years, the full scope of neurological abnormalities become apparent. These include gaze palsies, particularly impaired upward gaze, high-frequency hearing loss or other auditory impairments, athetosis, dystonia, and developmental delay.

The cerebral areas most affected by the bilirubin encephalopathy are the basal ganglia, especially the globus pallidus and subthalamic nucleus, the cerebellar vermis, and dentate nuclei. Other affected sites include the hippocampi and some cranial nerve nuclei, especially the oculomotor and acoustic vestibular nerves.

Aside from prevention, treatment is supportive, using physical and occupational therapy, as well as potential orthopedic procedures.

Sickle Cell Disease

Sickle cell disease occurs as the result of structurally altered hemoglobin molecule in which a neutral amino acid is substituted for one that is acidic, altering the physical properties of the molecule. The most common forms of sickle cell disease include sickle cell anemia, sickle ^-thalassemia, and sickle hemoglobin C. Sickle cell anemia occurs in about 1 per 600 newborn African Americans in the United States; sickle hemoglobin C in 1 per 800, and sickle ^-thalassemia in 1 per 1700. Clinical manifestations can affect most organ systems but involvement of the CNS can be life threatening. The occurrence of neurological complications are higher in the homozygous form SS or in sickle ^-thalassemia and occurs less often in sickle hemoglobin C.

Acute and chronic neurological complications exist. Emergency diagnostic and therapeutic measures are needed in episodes of acute neurological dysfunction. Children with sickle cell disease are unusually susceptible to infections with *Streptococcus pneumoniae, Haemophilus influenzae,* and *Mycoplasma pneumoniae.* CNS infection can provoke stroke, the most common neurological complication of sickle cell disease. The symptoms of stroke may be headache, seizures, hemiparesis, or speech and language dysfunction. Abnormalities of the spinal cord and peripheral nerves also occur. The initial symptoms may be transitory but require immediate diagnostic and therapeutic attention to prevent permanent sequelae. Chronic symptoms of silent stroke can be manifested by recurring headache, seizures, abnormalities of speech and language, and learning disabilities.

Children with sickle cell disease are at high risk for stroke syndromes from cerebral infarction and may develop disorders of higher cortical function from neurologically silent small cerebral infarcts. The baseline prevalence of silent infarcts was 21.8% among 266 children, ages 6 through 19 years, in the Cooperative Study of Sickle Cell Disease. Most lesions occurred in girls before the age of *6* years, whereas boys remained at risk until the age of 10 years.

Transcranial Doppler ultrasonography is a useful screening technique to demonstrate vascular narrowing. Neuroimaging studies arc useful, but the use of prophylactic partial exchange transfusions should be considered before performing any procedure that requires infusion of hypertonic contrast material. Cerebral angiography is contraindicated because of the risk of provoking vascular occlusion. Partial exchange transfusions may be beneficial in terminating an occlusive crisis in children who had a clinical stroke and evidence of cerebral infarcts on neuroimaging studies. Sufficient packed red cells is given to reduce the hemoglobin S to no more than 30-35%.

Higher levels are associated with a significant risk of recurrent stroke.

Hemophilia

Hemophilia is a genetic disorder of deficient or abnormal coagulation proteins. The main clinical feature is frequent and excessive bleeding. The most common type is deficiency of factor VIII, accounting for about 75% of patients. The incidence is 1 in 7500 live male births. About half have increased bleeding at circumcision, but it is not until the child becomes active at about age 2 years that easy bleeding becomes apparent, usually affecting the ankles, knees, or elbows. Intracranial bleeding occurs without obvious preceding head trauma. Hemorrhage affecting the CNS, gastrointestinal'tract, or retroperitoneal space can be life threatening. In one Swedish study of 117 children with moderate or severe hemophilia type A or B, 13 were delivered by cesarean section and the remainder were delivered vaginally. Subgaleal bleeding was the most common hemorrhagic complication of those delivered vaginally and most of these were associated with vacuum extraction. Their conclusion was that the risk of vaginal deliveries of hemophiliac patients was small, but the use of vacuum extraction should be avoided. Symptoms or signs of intracranial bleeding may not be immediately apparent. Therefore all hemophilic children who sustain trauma or show features of CNS disturbance should undergo head CT to delineate the location and extent of intracranial bleeding. In one report, four of seven hemophilic patients who suffered eight episodes of intracranial bleeding died despite replacement of factor VIII. The authors strenuously suggest that administration of factor VIII is often therapeutically insufficient and that surgical intervention is required if the CNS disturbance does not resolve within hours.

Neonatal Polycythemia

Neonatal polycythemia, defined as a hematocrit of more than 65%, occurs in 5% of newborns during the first several days postpartum. The hyperviscosity may cause vascular injury to the brain and kidneys. Reducing the hematocrit prevents and may reverse venous thrombosis. Even renal vein thrombosis is usually lessened or cleared within the first weeks. No long-term studies are available of newborns, who have had renal involvement from polycythemia. In one follow-up controlled study of 111 consecutive newborns with neonatal polycythemia and hyperviscosity, a higher incidence of motor and neurological abnormalities (38% vs. 11%) was observed at 1-3 years among infants with neonatal hyperviscosity. Moreover, concurrent hypoglycemia increased the risk of poor neurological outcome in hyperviscous infants to *55%.* Of *76* infants with neonatal polycythemia and hyperviscosity, I I bad spastic diplegia, 5 were hypotonic, and hemiparesis, athetosis, and nonfebrile seizure disorder were observed in each of 3 children. In the control group, two patients were abnormal. One patient had spastic diplegia and a second was hypotonic. Other studies have reported that intracranial hemorrhage can occur.

Thrombocytopenic Purpura

Thrombocytopenic purpura is an autoimmune disorder that can have its onset from early childhood to adulthood. Males and females arc equally affected. It presents as an acute illness with bleeding into the skin, which occurs cither spontaneously or following minor trauma. The bleeds can vary from pctcchiae to large eechymoses. Purpuric lesions are particularly seen in pressure areas such as around the neck or in areas of tight-fitting clothing.

Neurological complications affect fewer than 10% of affected children. Intracranial bleeding is unusual, but headache, behavioral and learning disorders, speech abnormalities, hemiparesis, and disorders of movement are described in the chronic form of the disease. Though acute in onset, the course is usually self-limited but can relapse at the time of an acute infection. Mononcuropathy and polyneuropathy can be associated.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (IIP) is a familial microangiopathic disorder characterized by hemolytic anemia and thrombocytopenia with platelet aggregation of the microvasculature and adjacent arterioles distributed throughout the brain. Larger cerebral vessels art' rarely affected. Hemolytic-uremic syndrome, a related disorder is acute and self-limited and affects only children, whereas TTP affects adults, is chronic, and can be relapsing.

Clinical findings include fever, abdominal pain, and arthralgia. Neurological findings include headache, disorientation, visual abnormalities, and sometimes disorders of speech and language. Plasma exchange is generally effective for management.

Hemorrhagic Disease of the Newborn

Hemorrhagic disease of the newborn is caused by vitamin K deficiency and is usually apparent within the first days postpartum, although it may occur as late as several months of age. It usually occurs in infants fed only breast milk and who have not received supplementary vitamin K in the nursery. The initial features are intracranial or gastrointestinal hemorrhage. Mothers who receive anticpilcptic drugs, especially phenytoin, are more likely to have infants with hemorrhagic disease.

Neurological complications are secondary to hemorrhage into the subarachnoid space or cerebral parenchyma. The clinical features may include cortical blindness, hemiparesis, ataxia, and disorders of movement.

GASTROINTESTINAL DISEASES

Hepatic Encephalopathy

The syndrome of hepatic encephalopathy is characterized by behavioral and neurological abnormalities that occur secondary to acute or chronic liver disease. The pathogenesis is unknown, but substances that have not been cleared by the liver cause CNS intoxication. The onset of encephalopathy can be acute, subacute, or chronic (Tessier, Villeneuve, and Villeneuve 2002}. With acute liver failure, hepatic encephalopathy becomes apparent within *8* weeks. The hepatic encephalopathy associated with subacute or chronic liver diseases can be episodic and less severe. The clinical features include changes of behavior, impaired attention span, and lack of concern regarding personal hygiene and appearance. Abnormal motor findings include change of muscle tone and posture, paratonia, asterixis, and hyperactive tendon reflexes. The clinical findings are summarized in Table 55B.1.

Symptoms are subtle during the first stage of hepatic encephalopathy and can go unnoticed. As the process continues, mental status declines and asterixis may be present. In the third stage, the patient may become lethargic or somnolent, and incontinence and seizures may be present. In stage 4, response to painful stimuli is decreased and decerebrate or decorticate posturing can occur. Despite severe liver disease, jaundice, hepatomegaly, ascites, or edema may not be clinically apparent. Laboratoty documentation of livet disease is not difficult in patients with an acute fulminating hepatic failure. However, the diagnosis is more difficult to establish when hepatic involvement is milder. Elevated plasma ammonia concentrations ate helpful to confirm the diagnosis, but normal concentrations are not exclusionary and CSF ammonia concentrations do not correlate with disease severity. CSF glutamine concentrations correlate with the scvetity of hepatic encephalopathy and ate the most sensitive laboratory test. The EEG findings are abnormal but nonspecific. Triphasic slow waves, often attributed to hepatic encephalopathy, are also seen m encephalopathy of othet causes.

Table S5B.1: Signs and symptoms of hepatic encephalopathy

Stage	*Mental status/behavior*	*Motor/reflexes*
	Anxiety/confusion Irritability/agitation Impaired attention Altered sleep patterns Depression	Fine postural tremor Impaired coordination
	Lethargy Behavioral/ personality changes Disorientation/ poor recall	Asterixis Dysarthria Primitive reflexes (suck, gasp) Paratonia/ataxia

Management includes treating the precipitating event, restricting dietary protein intake, and altering the intestinal flora. Liver transplantation is a consideration and is successful in 55-89% of patients.

liver Transplantation

In one review of complications associated with (all ot livet) organ transplantation, neurological complications occurred in 30-60% of patients of adult ages. Neurological complications occurred in 20-30% of children undergoing liver transplantation (Ghaus, Bohlega, and Rczeig 2001). Complications of organ transplantation may be considered in terms of (1) the underlying disease, (2) the transplantation ptoccdure, (3) the effects of associated infection, and (4) the adverse effects of immunosuppressive agents.

Congenital biliary atresia is the most common reason for liver transplantation in children. Other causes are biliary micronodular cirrhosis, viral hepatitis, Alagille syndrome, and several rare genetic disorders. The main potential surgical complication of liver transplantation is excessive blood loss. Prolonged periods of hypotension may result in hypoxic-ischemic brain injury in watershed areas. Peripheral nerve and brachial plexus injuries can occur intraoperativcly. After organ transplantation, a steteotyped pattern of infection may occur at three different times: the first month after transplant; 1-6 months post-transplant; and 6 months or longer after transplantation. Infection with *Mycobacterium tuberculosis, Strongyloides stercorals,* and systemic mycoses characterizes the immediate postoperative period. The greatest tisk for infection is the second period. The responsible agents are viruses, especially herpesviruses and hepatitis virus, and opportunistic pathogens such as *Listeria monocytogenes, Nocardia asteroides,* and *Aspergillus fumlgatus.* Six months post-transplant, the risk is from infection secondaty to immunosuppression. The infectious agents include *Cryptococcus, L. monocytogenes,* and *Mycobacterium tuberculosis.*

Adverse neurological complications occur as a direct effect of immunosuppressive agents. The most commonly administered agents are cyclosporin A, corticosteroids,

methotrexate, high-dose cytarabine (ara-C), and OKT3 monoclonal antibody. Neurological complications occur in 10-25% of children treated with cyclosporin A. Seizures are the most common complication. Others arc tremor, burning dysesthesias of the palms and soles, ataxia, quadriparesis, behavioral disorders, and leukocncephalopathy.

The adverse neurological effects of corticosteroids are mental status changes, myopathy, hypertension, and abnormalities of fat metabolism. Methotrexate, an antifolate metabolite, causes aseptic meningitis in 10—38% of children treated intrathecally. Other symptoms are headache, photophobia, fever, meningismus, vomiting, and lethargy. Transverse myelopathy is a rare complication. Leukoencephalopathy, the most serious complication, is usually the consequence of repeated doses of intravenous high-dose methotrexate, or intrathecal methotrexate.

Intravenous and intrathecal administration of ara-C may cause myelopathy, peripheral neuropathy, encephalopathy, and cerebellar dysfunction. The cerebellar syndrome is characterized by dysarthria and both truncal and limb ataxia. High-dose ara-C administration is a potential cause of a Guillain-Barrc-like syndrome and a sensorimotor neuropathy. OKT3 administration is associated with fever, headache, and photophobia, which resolve when the drug is discontinued. Intracranial hemorrhage developed in 6 of 30 children treated with OLTx. One child had a basilar artery thrombosis and four developed pituitary gland necrosis. On postmortem examination, 22 had Alzheimer type II astrocytes and two had central pontine myelinolysis. Other neuropathological findings included neuraxonal dystrophy and phagocytic nodules, thought to represent disseminated fungal or viral infections.

Whipple's Disease

Whipple's disease is mainly an adult multisystem disorder. Early clinical features include fever and arthralgia, followed by features of intestinal malabsorption. Small intestine biopsy shows an accumulation of periodic-acid-Schiff staining histiocytes, which also occur in the brain and spinal cord. Neurological complications include intellectual impairment, ophthalmoplegia, ataxia, and spastic paraparesis. Polydipsia and abnormalities of the sleep-wake cycle indicate hypothalamic involvement.

ENDOCRINE DISORDERS

Thyroid Disorders

The thyroid gland and brain are intimately associated through the anterior hypothalamus. The hypothalamus regulates thyroxine levels by producing thyroid-stimulating hormone. Thyroid hormone is involved in the early neurodevelopment of dendritic growth and arborization, neural migration, and synaptogencsis. The clinical features of thyroid deficiency depend on the age at onset. Two syndromes, each with subtypes, are defined: congenital hypothyroidism and acquired juvenile hypothyroidism. The incidence of congenital hypothyroidism is 1 in 4000 live births. Affected newborns have little or no clinical evidence of thyroid hormone deficiency, and the diagnosis depends on newborn screening programs. These are mandatory in the United States and much of the Western world.

Most children with congenital hypothyroidism have thyroid dysgenesis of unknown etiology. The disorder is sporadic and the female-to-male ratio is 2:1. The thyroid is hypoplastic, ectopic, or absent. Affected infants usually have a rather pale skin, a hoarse cry, an enlarged protruding tongue, prolonged neonatal jaundice, umbilical hernia, and large anterior and posterior fontanelles. They often appear lethargic and have difficulty feeding, constipation, and diminished spontaneous movements. Within 1 or 2 months, it becomes increasingly apparent that these infants are inordinately apathetic and hypotonic and have a hoarse cry. Sensorineural deafness is common and early testing and diagnosis avoids potential problems in speech and language development. Delayed psychomotor development and ataxia are sometimes associated (Morin et al. 2002). One form of congenital hypothyroidism (Kocher-Dcbre-Semelaigne syndrome) is associated with muscular enlargement, weakness, and slow movements.

Acquired hypothyroidism develops at any age in previously normal children. Females are more often affected than males. Circulating antithyroid antibodies are present in a significant number, reflecting an immune-mediated process (I lashimoto's thyroiditis). Nonimmune causes include exposure to goitrogenic factors, inborn errors of thyroid metabolism, and acquired hypothalamic or pituitary disease. Pcndrcd described two deaf sisters with goiter from a nonendemic goiter area and this condition, now known as Pendrcd's syndrome, has a prevalence of 1.5-3 per 100,000 school-age children. Affected children have high-frequency or complete sensorineural deafness and goiter and arc either euthyroid or mildly hypothyroid. The pathogenesis is not established.

Endemic cretinism is the most severe form of dietary iodine deficiency. Neurological features include mental retardation and pyramidal and extrapyramidal dysfunction. The gait is unusual and thought to result from pyramidal and extrapyramidal dysfunction, as well as joint laxity. Deafness is common in children with endemic cretinism and significantly improves after iodine prophylaxis. Lcvothyroxine is the treatment of choice and results in normal growth and development if treatment commences within the first weeks postpartum (Selva et al. 2002). The ultimate intellectual development depends on the time of diagnosis and treatment and the severity of hypothyroidism (Hopwood 2002).

Hyperthyroidism (Graves' disease) usually results from autonomous thyroid stimulation by thyroid-stimulating

immunoglobulin. The thyroid is diffusely hyperplastic. A rare form of congenital hyperthyroidism has an insidious onset and the female-to-male ration is 6:1. Affected patients become increasingly irritahle and have a short attention span, difficulty concentrating, and an increased appetite. Behavioral problems at home or in school are common. The most common physical sign is unilateral or bilateral exophthalmos. Other ocular signs that are common in adults such as lid lag, difficulty with convergence, infrequent blinking, and the appearance of staring are uncommon in children. The thyroid gland is enlarged and easily palpable. Tremor and increased tendon reflexes are common and chorea may be present. Neuromuscular diseases (e.g., weakness, myasthenia, and hypokalemic periodic paralysis) arc less common in children than in adults.

Serum concentrations of Tj and T_4 are elevated. Propylthiouracil is the usual treatment of thyrotoxicosis. Neurological symptoms and signs resolve when the patient becomes euthyroid.

Parathyroid Disorders

Hypoparathyroidism results from deficiency of parathyroid hormone {PTH} or lack of responsiveness of the end organs to PTH (pseudohypoparathyroidism). The typical feature is hypocalcemia. In adults, deficiency of PTH is usually the result of inadvertent removal of the parathyroid glands during thyroid surgery or other surgical procedures about the neck. The Di George's syndrome is a congenital form of hypoparathyroidism resulting from abnormal embryogenesis. The characteristic features are thymic hypoplasia, congenital heart defects, and structural abnormalities of the brain.

Hypercalcemia as a consequence of hyperparathyroidism is uncommon in children. Nausea, vomiting, weight loss, lethargy, and weakness occur when serum calcium levels exceed 12 mg/dL. Attention deficit, depression, weakness, and hyper-reflexia may be associated.

Adrenal Gland Dysfunction

Excessive production of glucocorticoids occurs in adrenocorticotropic ic hormone (ACTH)-secreting pituitary adenomas, other intracerebral tumors, and adrenal adenomas. Excessive weight gain and proximal weakness follows initial growth failure. Tendon reflexes are decreased and electrophysiological studies show normal or low-amplitude, short-duration motor unit potentials. Muscle biopsy reveals type II atrophy. A cushingoid appearance is typical, with adipose tissue over the posterior neck (bison hump), thinning of skin with prominent capillaries, increased pigmentation of flexor skin creases, and sometimes purple striae on the trunk. Pubic hair may appear early. The measurement of serum Cortisol, ACTH, and their metabolites before and after dexamethasone suppression establishes the diagnosis.

High-dose glucocorticoids are used to treat acute head injury and some intractable myoclonic epilepsies such as infantile spasms. The mechanism of action is unknown. Pseudotumor cerebri (idiopathic increased intracranial pressure) can occur during the administration of high-dose glucocorticoids. The characteristic syndrome is headache, papilledema, and enlargement of the blind spot on visual field testing. Transitory visual obscurations may be associated. Some children develop reversible behavioral disturbances during the time of steroid administration. Withdrawal of ACTH should be carried out slowly and periods of stress are covered by exogenous corticosteroid administration.

Glucocorticoid Deficiency

Glucocorticoid and mineralocorticoid deficiency characterizes Addison's disease, originally described as a complication of adrenal gland tuberculosis. Adrenal failure can also result from pituitary diseases, prolonged administration of exogenous corticosteroids, or other destructive disorders of the adrenal such as hemorrhage, infection, or tumor. Hyperpigmcntation of the flexor surfaces, gingival, and mucous membranes occurs secondary to excess ACTH production. Affected children experience anorexia, vomiting, weight loss, apathy, irritability, and headache. Some children develop confusion, seizures, and coma.

Pituitary Disorders

Neurological disorders secondary to pituitary gland dysfunction can result from pathological processes of the gland, the pituitary stalk, or the pcriscllar region. The main features result from increased intracranial pressure and disorders of endocrine function.

The characteristic features of septo-optic dysplasia (De Morsier's syndrome) are absence of the septum pellucidum and other midline structures and failure of the interhemisphcric commissures (corpus callosum and anterior commissure) to form. Other midline anomalies include optic nerve hypoplasia and neuroendocrine disorders. Associated neurological abnormalities include mental retardation, microcephaly, visual impairment, nystagmus, spasticity, and seizures. Children with mild forms of the syndrome may have normal intelligence.

The Laurence-Moon-Biedl syndrome is thought to be associated with pituitary dysfunction. It is characterized by mental retardation, retinitis pigmentosa, syndactyly and Polydactyly, hypoplastic genitalia, and obesity. This syndrome, and similar syndromes, is probably a genetic disorder transmitted as an autosomal recessive trait. The mechanism of hypogonadism was considered unresponsiveness of target organs to gonadal hormones

(primary end-organ failure), hypothalamic dysfunction, or pituitary fail Lire, The pituitary is morphologically normal and the numbers and immunoreactivity of adenohypophyseal cells is normal.

Cerebral gigantism (Sotos' syndrome) is characterized by large body weight at birth and in early childhood, mental retardation, macroccphaly, and an unusual face with a broad forehead and a sharp chin. Bone age is advanced, the hands and feet are enlarged, and rapid growth occurs during infancy that slows by late childhood. Serum growth hormone concentrations are normal. Most cases are sporadic, but some show autosomal recessive inheritance.

Diabetes Mcllitus

Diabetes mcllitus is the most common endocrine disorder of childhood. Late complications include abnormalities of higher cortical function and disorders of the peripheral nerves, eyes, and kidneys. Insulin-dependent diabetes mellitus (IDDM) is the most common type of diabetes mcllitus encountered in children. Inadequate insulin production is secondary to circulating antibodies against pancreatic cell components. It occurs in association with other autoimmune diseases. A tendency to develop ketosis exists that may lead to ketoacidosis.

Peripheral neuropathy is the most common neurological complication of IDDM and is thought to affect 10% of children with chronic diabetes mellitus. The polyneuropathy is usually asymptomatic, but careful neurological examination often reveals mild weakness of distal muscles and decreased stretch reflexes. In one prospective study, nerve conduction and autonomic function was evaluated in 144 diabetic children. Neurophysiologies! recording of nerve conduction and parasympathetic function (R-R variations) were determined after 2, 5, and 10 years. Low sensory nerve conduction velocities and autonomic dysfunction were found in 25% of children at the onset of diabetes when patients were not in remission. An initial improvement of sensory conduction velocities was found from 0-2 years, hut after 2 years, sensory and motor nerve conduction velocities and autonomic nerve function deteriorated. A correlation existed between peripheral nerve conduction velocities and control of blood sugar concentration. Spinal somatosensory evoked potentials and peripheral nerve conduction velocities were measured in 46 neurologically normal, insulin-dependent juvenile diabetics. These children, without clinical evidence of neurological involvement, showed defects in spinal afferent transmission. In general, a correlation exists with the existence of neuropathy and the duration of the diabetes mellitus and the degree of blood sugar conttol.

Although adult patients with IDDM can develop cranial neuropathies, particularly cranial nerves III, IV, and VI, this is rare in children. Polyradiculopathy, a well-documented complication of diabetes in adults, is rarely encountered in children, usually juveniles, with diabetes mcllitus.

A small group of children with IDDM who had experienced hypoglycemic seizures were evaluated at 1, 3, and 7 years. They showed significant decline in verbal but not visuospatial skills. Later assessment showed deficits in perceptual, motor, memory, and attention tasks. Other studies have found no effect on cognitive performance from diabetes or from severe hypoglycemia in children with late-onset diabetes, whereas early onset diabetes was associated with psychomotor efficiency and attention.

Diabetes mellitus can result in a severe metabolic encephalopathy from diabetic ketoacidosis (DKA). DKA is the most serious complication of IDDM and the most common cause of death. The pathogenesis is unknown. Severe cerebral edema can occur even after administration of appropriate insulin and fluid correction and at a time when glucose levels are decreasing and circulation seems normal. Severe and abrupt clinical deterioration occurs secondary to cerebral edema resulting in central or uncal herniation. Emergency treatment includes the administration of mannitol, endotracheal intubation, and hyperventilation.

RENAL DISORDERS

Renal Failure

Renal failure results in an encephalopathy with clinical features similar to those of other metabolic encephalopathies. The pathogenesis is unknown. Several compounds including urea, creatinine, guanidine, and parathyroid hormone have been considered at least partially responsible for the neurological disorder, but the specific explanation is not established. The clinical manifestations of uremic encephalopathy are characterized by disturbances of cognition and motor function, which are usually accompanied by electroencephalographic abnormalities (Palmer 2002). Awareness of the environment is diminished and the child appears apathetic, if not preoccupied, and lethargic. Concentration is impaired and simple arithmetic becomes difficult. As the encephalopathy worsens, recent memory is impaired and the child becomes confused if dialysis is not instituted. Further deterioration results in lethargy, stupor, and apnea. Motor features include tremor, asterixis, muscle cramps, neuromuscular excitability, and weakness. Seizures and myoclonus are present in advanced uremic encephalopathy. Peripheral nerve involvement is common and can result in sensory or sensorimotor polyneuropathy. Clinical evidence of polyneuropathy is common before dialysis. Peroneal motor nerve conduction velocities are reduced in children undergoing chronic hemodialysis even without clinical evidence of peripheral nerve involvement. The velocities did not improve during the next 6-12 months. Nerve biopsies from children with chronic renal failure show acute axonal neuropathy, progressive axonal

neuropathy with secondary segmental demyelination, and a primary demyelinative polyneuropathy.

The degree of renal function does not correlate with cognitive function in children with chronic renal failure since infancy, who had early dialysis (mean age of 18 months) and early transplantation (mean age of 28 months). Although head circumference was normal at hi nil, mosi had microccphaK by 1 year of age. As a rule. neurodcvclopmcntal outcome tends to be better when renal impairment begins at an older age. The median intelligence quotient scores of children who experienced onset of chronic renal failure before the age of 1 year are lower than those whose diagnoses were made after the age ol 3 years (Qvist et al. 2002).

Treatment of children with chronic renal failure demands management and control of fluid and electrolyte balance, use of peritoneal or hemodialysis, and in some cases renal transplantation (Smith, Ho, and McDonald 2002). Seizures are best managed by using phenobarbital or phenytoin at the usual therapeutic doses, recognizing that protein binding is decreased in uremic patients.

Neurological Complications of Dialysis and Transplant

The neurological complications of dialysis and renal transplantation in children are the same as those described in Chapter *55A,*

Chapter 56
Trauma of the Nervous System

A. BASIC NEUROSCIENCE OF NEUROTRAUMA

W. Dalton Dietrich and Helen M. Bramlett

Traumatic brain injury (TBI) is a leading cause of death and disability among children and young adults. In addition head injury in older adults as a result of falls is a growing clinical concern. To investigate the pathophysiology of brain injury and to develop novel thetapcutic strategies to treat this condition, experimental models of TBI have been established. Although no experimental model completely mimics the human condition, individual models produce many features of human brain injury. Based on these models, therapeutic strategies directed at specific pathomcchanisms have been initiated. This chapter reviews the basic science of neurotrauma and summarizes the various experimental strategics used to investigate and treat TBI.

EXPERIMENTAL MODELS OF TRAUMATIC BRAIN INJURY

Severe closed-head injury produces a range of cerebral lesions that may be divided into four general categories: (1) diffuse axonal injury; (2) vascular lesions, including subdural hematoma; (3) contusion; and (4) neuronal degeneration in selectively vulnerable regions. In a review of animal models of head injury, Gennarelli (1994) classified models of head injury according to the method of producing injury. Fluid percussion (FP) and rigid indentation models are characterized as percussion concussion, whereas inertial injury models and impact acceleration models are considered acceleration concussion. In an attempt to investigate the effects of mechanical deformation on specific cell types, in vitro models of stretch-induced injury have also been developed.

Percussion Concussion

The central, lateral, and parasagittal FP models are characterized by brief behavioral responsiveness (e.g., coma), metabolic alterations, changes in local cerebral blood flow (LCBF) and blood-brain barrier (BBB) permeability, and behavioral deficits. The central FP model tends to have variable and small contusions in the vicinity of the fluid pulse and scattered axonal damage, mostly limited to the brainstem. In contrast, lateral and parasagittal FP is characterized by a lateral cortical contusion that is remote from the impact site. Evidence of axonal damage is seen throughout the white matter tracts in the ipsilateral cerebral hemisphere, and tissue tears are seen at gray matter-white matter interfaces. Hippocampal damage is pronounced in the lateral and parasagittal IP injury models with little brainstem damage. The FP injury model thus produces a range of disorders, including contusion, widespread axonal injury, and selective neuronal necrosis. In addition, varying injury severity, including mild (1.1-1.3 atm), moderate (2.0-2.3 atm), and severe (2.4—2,6 atm), can be studied in a reproducible fashion. This is an important model

characteristic because of the heterogeneous nature of human TBI and the possibility that treatment strategies may vary with injury seventy,

Another commonly used rodent TBI model is controlled cortical impact injury. In this model, a bone flap is removed and the impact device is vertically driven into the cerebral cortex to produce tissue displacement. This model produces a well-demarcated cortical contusion with variable degrees of hippocampal involvement dependent on velocity and defotmation depth. An advantage of the controlled cortical impact model is that it can be used in mice and allows the testing of genetically altered mice to help determine the cause-and-effect relationships between gene expression and cell injury.

Acceleration Concussion

Inertia! acceleration models can produce pure acute subdural hematomas and diffuse axonal injury. Tissue tear hemorrhages occur in the central white matter, and gliding contusions occur in the parasagittal gray matter-white matter junctions. These models ate characterized by a variable period of coma and axonal damage in the upper brainstem and cetebellum. Impact acceleration models produce prolonged coma and widespread axonal damage. These models are characterized by variable and somewhat uncontrolled skull fractures.

Cerebral contusion is the most common head injury. In this regard, both acceleration and concussion models reproduce this histopathological outcome. Diffuse brain injury is an important phenomenon with regard to patients who die or remain in a persistent vegetative state. The parasagittal FP model produces widespread axonal perturbations in forcbrain structures and tissue tears in white matter. An optic nerve model of traumatic axonal injury has also been investigated. This approach produces axonal injury by a rapid elongation of the nerve in situ. First developed in guinea pigs, rats, and mice, this model is advantageous for clarifying the pathophysiology of traumatic axonal injury. Human head injury is never as pure as an experimental model, and the total human injury condition may not be addressed adequately with a single animal model. However, once a particular feature of human brain injury is produced in an experimental model, the pathogenesis of the injury can be critically investigated.

In Vitro Models

A shortcoming of animal models is that they preclude a critical assessment of individual cell responses to trauma. In animal experiments, for example, the initial cellular response to injury may be a consequence of both ptimary and secondary events initiated by a complex cascade of cellular interactions. Therefore to critically investigate the consequences of injury on a specific cell type in the absence of confounding cellular and systemic factors, several in vitro cell culture models have been developed. Models range from scratching the culture with a pipette tip to inducing cellular deformation by stretching cultured cells.

Using these apptoaches, investigators have found that trauma induces a wide range of primary cellular alterations. Astrocytic responses include hyperplasia, hypertrophy, and increased glial fibrillary acidic protein content. Increases in intracellular calcium occur, which arc blocked by specific-receptor antagonists. Traumatized astrocytes also produce interleukins and neurotrophic factors. Neonatal cottical neurons that arc stretched undetgo delayed depolarization that depends on the activation of specific teceptor populations. Combined mechanical trauma and metabolic impairment in vivo also induces N-methyl-o-aspartate receptor-dependent neuronal cell death and caspase-3-dcpcndent apoptosis. In vitro experimental approaches provide novel data concerning mechanisms underlying cellular responses to trauma and the role of specific cell types in the pathophysiology of brain trauma.

NEURONAL DAMAGE AFTER TRAUMATIC BRAIN INJURY

Temporal Patterns of Neuronal Death

The ncuropathological sequelae of human TBI have been well described. In experimental TBI, temporal patterns of neuronal damage have also been characterized. As early as 6 hours after cortical contusion injury, the contused tissue appears edematous, and pyknotic neurons are apparent at the injury site (Cortez, Mcintosh, and Oble 1989). By 8 days, a cortical cavity has developed that is surrounded by a border containing necrotic tissue, a glial scar, or both. The temporal profile of neuronal damage after parasagittal FP brain injury has also been assessed with light and electron microscopy (Dietrich, Alonso, and Hallcy 1994). As early as 1 hour after impact, dark, shrunken neurons indicative of irreversible damage are seen in cortical layers overlying the gliding contusion that displays BBB breakdown to protein tracers. Ultrastructural studies demonstrate that early BBB dysfunction results from mechanical damage of small venules in vulnerable regions, including the external capsule. In some brain regions, focal sites of acute neuronal da mage an[1] associated with exrravasated protein, whereas neuronal damage in other regions appears to occur without overt BBB breakdown. Astrocytic swelling is observed early after injury, with increased glial fibrillary acidic protein immunoreactivity apparent at later times in areas, demonstrating histopathological damage (Diettich, Alonso, and Halley 1994; Figure 56A.1). In terms of neuroprotection, the acuteness of this damage limits the potential for therapeutic interventions directed against the early neuronal and glial response to TBI.

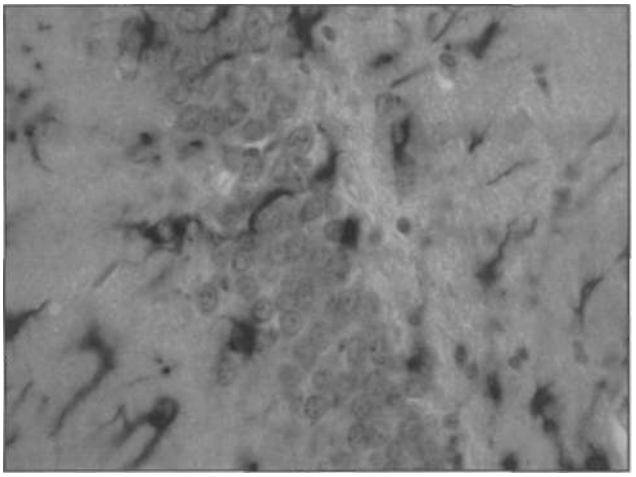

FIGURE 56A.1 Three days after fluid percussion injury, glial fibrillary acidic protein-positive astrocytes and processes are prominent in the hippocampus (x!200).

More subacute patterns of neuronal injury have been documented in various TBI models. At 3 days aftet moderate parasagittal FP brain injury, scattered necrotic neurons are present throughout the frontoparietal cerebral cortex remote from the impact site (Figure 56A.2), In addition, selective neuronal damage is seen in the CA3 and CA4 hippocampal subsectors, the dentate hilus, and lateral thalamus ipsilateral to the trauma. These patterns of selective neuronal damage are associated with a well-demarcated contusion overlying the lateral external capsule. Ultrastructural changes consistent with apoptosis have been described aftet TBI. Thctcfore delayed patterns of neuronal cell death may involve necrotic and programmed cell death processes.

Selective Neuronal Vulnerability

Damage to the hippocampus is commonly reported in autopsy studies of head-injured patients. Clinical and expetimental studies describe cognitive abnormalities thought to be associated with hippocampal dysfunction. In an acceleration model of brain injury in nonhuman primates, CAl hippocampal histopathologic^] damage was reported in the majority of animals, CA1 damage was not produced by secondary global ischemia, elevated intracranial pressure, or seizure activity. In this regard, CAl

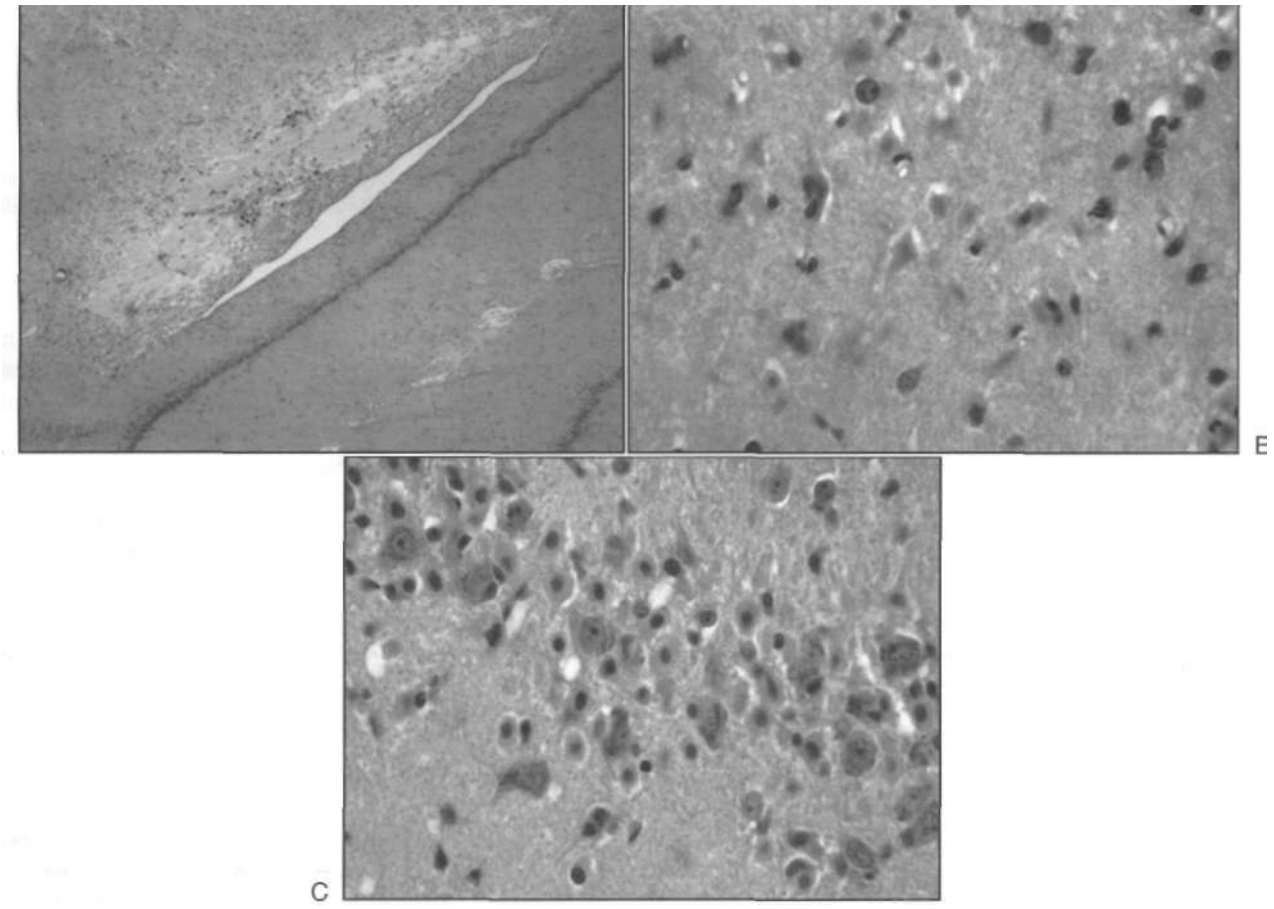

FIGURE S6A.2 Photomicrographs of rat brain 3 days after fluid percussion injury, (A) Focal contusion at gray-white interface (xl20). (B) Damaged cortical neurons overlying the contusion (xl20u). (C) Damaged and eosinophilic neurons in CA3 hippocampus (x 1200).

hippocampal damage is not routinely reported in other TBI models, including cortical contusion and moderate FP injury. However, midline FP injury followed by a delayed sublethal global ischemic insult leads to CA1 neuronal damage. It has been reported that moderate FP injury followed by a secondary hypoxic insult also results in significant CA1 damage. Also, in contrast to moderate FP injury, severe trauma causes hemodynamic reductions that reach ischemic levels and significant CA1 neuronal damage. Taken together, these findings indicate the importance of injury severity on outcome and the vulnerability of the post-traumatic brain to secondary insults. Finally, the dentate gyrus and CA3 hippocampus have also been reported to be selectively damaged in FP models, with bilateral damage to dentate hilus reported after FP injury,

Thalamic damage after brain injury is described in clinical and experimental studies. In human brain injury, the loss of inhibitory thalamic reticular neurons is proposed to underlie some forms of attention deficits. In radiographic studies of patients with TBI using magnetic resonance imaging, relationships between injury severity, lesion volume, ventricle-to-brain ratio, and thalamic volume have been teported. Patients with moderate to severe injuries have smaller thalamic volumes and greater venti ide-to-brain ratios than do patients with mild to moderate injuries. Decreased thalamic volumes suggest that subcortical brain structures may be susceptible to transneuronal degeneration after cortical damage. Focal damage to thalamic nuclei seen after long-term FP injury may result from progressive circuit degeneration after axonal damage, from neuronal cell death, or from the lack of neurotrophic delivery.

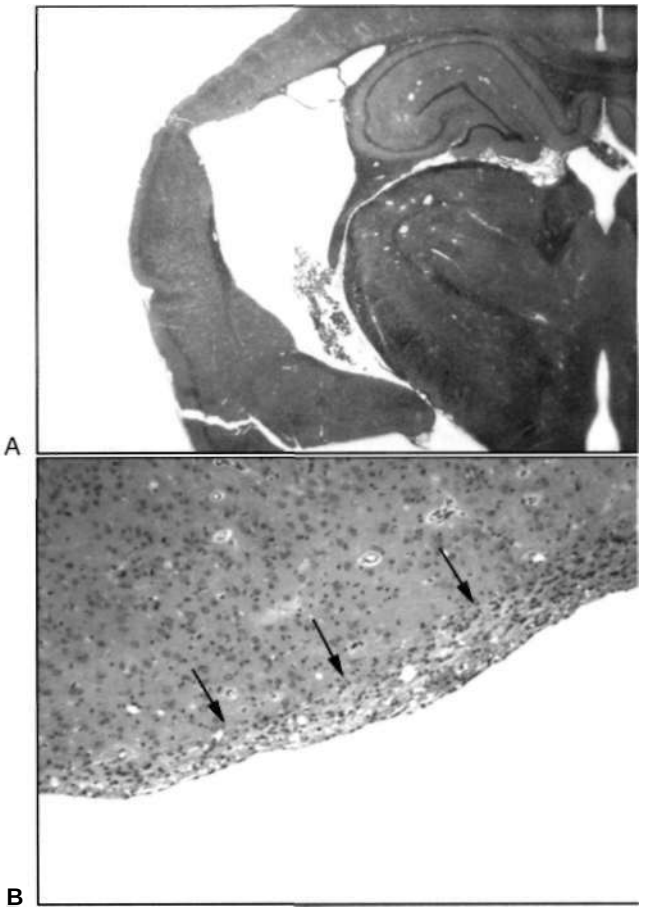

FIGURE 56A.3 Photomicrographs of rat brain 1 year after fluid-percussion injury (x30). (A) Brain shows gross atrophy with marked expansion of lateral cortex. (B) Severe loss of white matter in external capsule *{arrows,* x300).

Progressive Damage

Only recently has the progressive nature of the histopathological consequences of TBI been appteciated (Bramlett and Dietrich 2002). At *2* months after moderate parasagittal FP injury, significant atrophy of the cerebral cortex, hippocampus, and thalamus is apparent in histological sections (Figure 56A.3A). Progressive tissue loss in the cortex and hippocampus at various times up to 1 year after lateral FP injury have been reported. Similar findings have been found in a model of controlled cortical impact injury. At 3 weeks and 1 year after injury, analysis demonstrated a significant hemispheric volume loss and expansion of ipsilateral lateral ventricle. Thus atrophy of gray matter structures is associated with a significant enlargement of the lateral ventricle,

Ventricular expansion not associated with hydrocephalus or increased intracranial pressure is felt to be a sensitive indicator of structural damage and an indirect measure of white matter atrophy. Indeed, ventricular size has been correlated with memory disturbances, when patients with the highest ventricular volumes demonstrated significantly lower memory scores. Recent findings provide direct evidence of progressive white matter damage after FP brain injury (Bramlett and Dietrich 2002). At 1 yeat after TBI, severe atrophy of specific tracts including the external capsule in cerebral peduncle was documented (Figure 56A.3B). The importance of a progressive injury cascade after TBI in terms of other neurological conditions merits consideration. For example, if mild head trauma leads to a progressive reduction in neuronal reserve, would the person who sustained such trauma be more susceptible than others to neurodegenerative processes associated with aging? Indeed, some epidemiologic studies have indicated that a history of brain trauma is a risk factor for Alzheimer's disease.

Secondary and Repetitive Damage

A challenging problem faced by medical personnel responsible for the health care of amateur and professional athletes is the recognition and management of mild head injury. Returning an injured athlete to competition when the brain needs time to recover is an obvious concern. Also,

the basic understanding of the post-traumatic consequences affecting the vulnerability of the btain to secondary or repeated head injury remains unknown. This is a clinically important issue because TBI often is associated with respiratory suppression, resulting in secondary hypoxic insults (Chestnut 1995). Recently, experimental studies have documented the detrimental consequences of secondary insults after mild to moderate TBI. The effects of secondary hypoxia on histopathological and behavioral outcome were investigated. Secondary hypoxia induced immediately after moderate FP injury resulted in significantly greater cortical and hippocampal CA1 damage and sensorimotor and cognitive deficits than wete found in normoxic animals. Most recently, mild hypotension after TBI was reported to also worsen traumatic outcome. Taken together, these findings indicate the enhanced vulnerability of the post-traumatic brain to mild secondary insults.

Clinical studies indicate that patients with mild head injury may he at risk if they have a subsequent head injury (secondary impact syndrome). Recently, an animal model was developed to investigate the behaviotal and pathological changes associated with repetitive head injury. The consequences of single and repetitive injury induced 24 hours apart were assessed. Repetitive head injury led to gteater functional impairment and structural damage than was found in the single-injury group. In another study, repetitive injury in transgenic mice that expressed mutant human A/3 precursor protein produced elevated *Afi* levels and increased A/J deposition, thus linking TBI to the mechanisms of Alzheimer's disease. The known risk of developing neurodegenerative disease later in life is greater after repetitive brain trauma and makes this type of investigation extremely important.

Axonal and Dendritic Injury

In 1992, Povlishock wrote that axonal injuty exists as a spectrum involving widespread areas of the brain in experimental models of TBI. Patterns of teactive axonal change using monoclonal antibodies targeted at neurofilament subunits or ^-amyloid precursor protein have been characterized after HP brain injury and controlled cortical impact injury (Figure 56A.4; Povlishock, 1992). Within 1-2 hours of injury, reactive axonal change is most conspicuous in brainstem regions, including the pontomedullary junction. This pattern of axonal damage seen in experimental models is in contrast to the human condition, in which callosal and subcortical white mattet axonal damage predominates. In contrast, moderate parasagittal brain injury leads to widespread axonal damage in forebrain regions that represent reversible, irreversible, and delayed axonal perturbations. These findings may explain some ol the transient and delayed functional consequences of TBI.

In addition to axonal damage, studies indicate that TBI also leads to significant changes in neuronal dendrites. A common feature of damage of injured neurons is loss of microtubule-associated protein 2 (MAP2) antigenicity. MAP2 is an important microtubule cross-linking protein that is found predominantly in somatodendritic environments. Therefore changes in MAP2 may reflect damage to dendrites. Using this strategy, evidence of dendritic damage not necessarily associated with neuronal death has been obtained that may participate in some of the functional consequences of TBI.

The Importance of Gender

Recent clinical and experimental data have emphasized the importance of gender on the consequences of TBI (Stein 2001). In a study of 334 patients with TBI, female patients had a better predicted outcome at the time of discharge from an inpatient rehabilitation program. A meta-analysis of eight previous studies in which outcome was reported separately for men and women reported a worse outcome in women than in men. The impact of gender on TBI is an understudied area of clinical neurotrauma and should be emphasized in future trials.

In experimental models of TBI, gender also appears to influence traumatic outcome (Stein 2001; Bramlett and Dietrich 2001). The hemodynamic consequences of controlled cortical impact injury were reported to be less in female than in male rats. Also, contusion volume was significantly less in female than in male rats (Btamlett and Dietrich 2001). In this study, ovariectomy 10 days before TBI removed the volume differences between male and female rats. Thus intact females appear to have an endogenous neuroprotective mechanism that reduces the detrimental consequences of TBI (Stein 2001). In terms of testing neuroprotective strategies in models of TBI, gender differences must be stressed.

BASIC MECHANISMS OF INJURY

Primary Injury Mechanisms

Two major types of forces are responsible for brain injury: one localized at the impact site and a second characterized by rotational forces. Depending on the force and location of the primary impact, head trauma can produce acute damage to blood vessels and axonal projections. Contact phenomena generate superficial or contusional hemorrhages through coup and countercoup mechanisms. Direct injury is commonly superficial, and the coup-couutercoup hemorrhages may be adjacent or central.

Axonal shearing is a common lesion of the cerebral white matter, which occurs particularly in acceleration-deceleration injury. Only recently has morphological evidence of axonal shearing (primary axotomy) become available in FP models. Ultrastructural evidence demonstrates the tearing

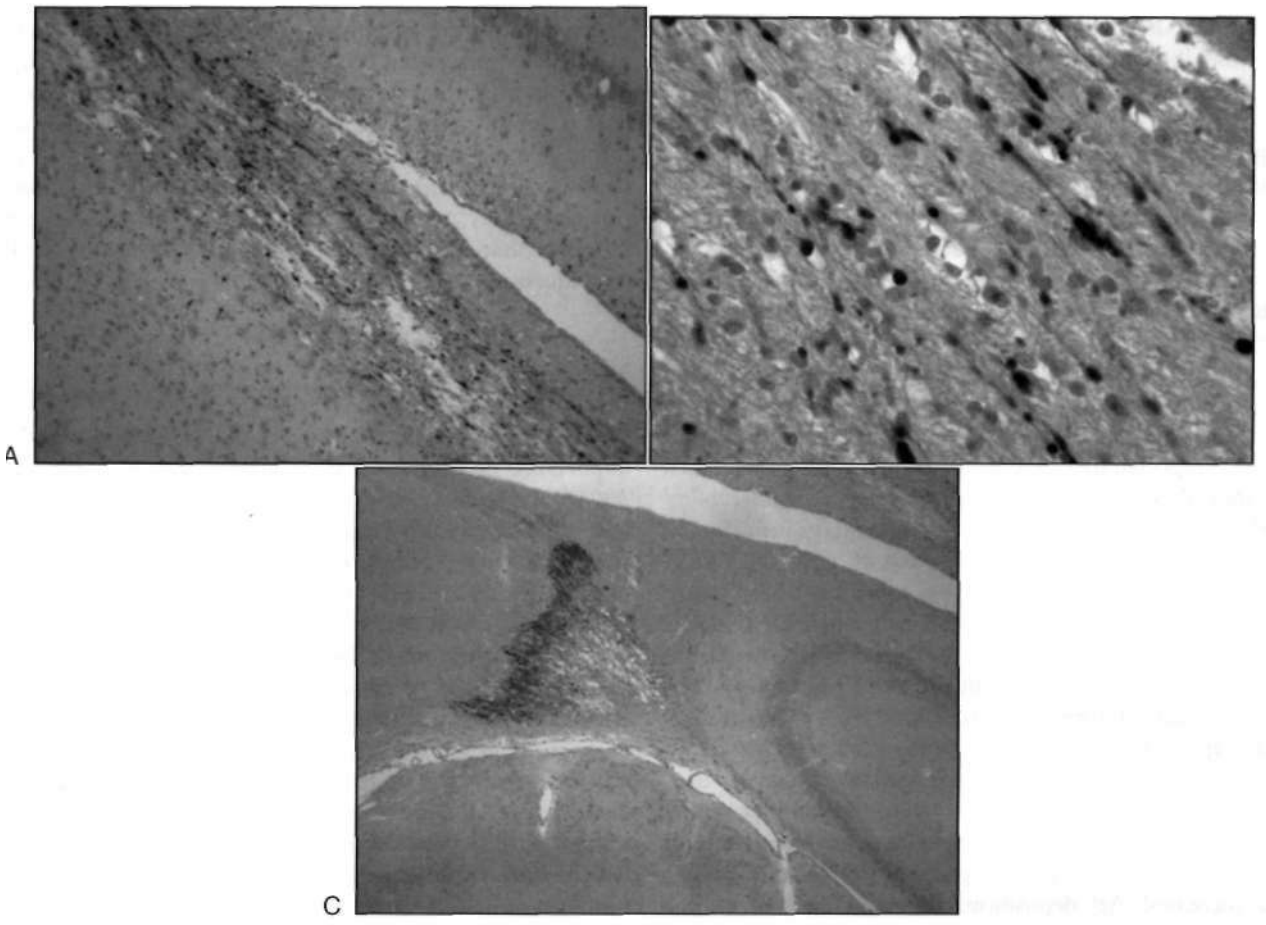

FIGURE 56A.4 /i-Amyloid precursor protein immunoreactivity after traumatic brain injury. (A) Large numbers of immnnoreactive profiles in external capsule (x 120). (B) High magnification of axonal swellings (x!200). (C) Dense reactive profiles within the fimbria of hippocampus consistent with primary axotomy (axonal shearing x 120).

or shearing of axons in nonhuman primates exposed to lateral acceleration. Pctturbations of the axolemma leading to the accumulation of cytoskeletal components and organelles or activation of intracellular mediators of injury such as calpain activation may represent secondary injury processes that can be treated.

Shearing strains may also damage blood vessels and cause petechial hemorrhages, deep intracerebral hematomas, and brain swelling. Mechanical damage to small venules resulting in focal BBB breakdown and platelet accumulation is reported immediately after FP injury (Dietrich, Alonso, and Halley 1994). Vascular damage leads to the formation of hemorrhagic contusions. Eatly vascular damage may increase neuronal vulnerability by causing post-traumatic perfusion deficits and the extravasation of potentially neurotoxic bloodbomc substances.

Secondary Injury Mechanisms

In many head-injured patients, the extent of neurological tecovery depends on the contribution of post-traumatic secondary insults (Chesnut 19951. In the clinical setting, secondary insults include hypotension, hypoxia, hyperglycemia, anemia, sepsis, and hyperthetmia. Experimental evidence indicates an increased susceptibility of the post-traumatic brain to secondary insults. For example, after midline FP brain injury, CA1 hippocampal vulnerability is enhanced with superimposed secondary ischemia. An important area of research regarding the treatment of brain injury involves the characterization of secondary injury processes, which may be targeted for intensive care management or pharmacotherapy.

A high frequency of hypoxic or ischemic brain damage occurs in patients who die as a result of nonmissile head injury. Hypoxic damage in the form of hemorrhagic infarction and diffuse neutonal necrosis is most common in arterial boundary zones between the major cerebral arteries. Hypoxic damage is also common in patients who have experienced an episode of intracranial hypertension. A significant cotrelation between hypoxic brain damage and arterial spasm in patients with nonmissile TBI has been reported. Post-traumatic hypoxia aggravates the BBB consequences of FP brain injuty.

Post-traumatic hemodynamic impairments represent another injury mechanism. Clinical and experimental investigations report moderate reductions in LCBF after TBI. After moderate parasagittal FP brain injury, widespread reductions in LCBF range from 40-80% of control. In contrast, severe FP injury leads to LCBF reductions that reach ischemic levels. Focal reductions in LCBF are associated with subarachnoid and intracerebral hemorrhage and local platelet accumulation. Reductions in LCBF result from the mechanical occlusion of cerebral vessels or the release of vasoactive substances, or possibly as a secondary consequence of reductions in neuronal activity or metabolism. Therefore injury severity is a critical factor in determining the hemodynamic and histopathological consequences of experimental TBI,

Hypotension is present in a significant number of patients with TBI. In severely injured patients, outcome is correlated with reduced mean arterial blood pressure. Hemorrhagic hypotension after FP injury results in more severe histopathological outcome than TBI alone. The increased sensitivity of the post-traumatic brain to moderate levels of hypotension may result from deficits in autorcgulation, which have been reported in patient and experimental studies. Hypotensive periods that may occur during surgical procedures and anesthesia may produce secondary insults and be hazardous to the head-injured patient.

Many patients experience fever after head injury, and clinical data indicate that hrain temperature may be higher than core or bladder temperature. Experimentally, post-traumatic brain hyperthermia induced artificially 24 hours after trauma increases mortality rate and aggravates histopathological outcome, including contusion size and axonal pathology (Dietrich et al. 1996). Thus in the clinical setting, post-traumatic hyperthermia may represent a secondary injury mechanism that might negate the beneficial effects of a therapeutic agent. Because delayed post-traumatic hyperthermia has been shown to have detrimental effects on outcome, aggressive attempts should be made to reduce brain temperature. Intravascular cooling devices may be used for temperature regulation in patients with central nervous system trauma.

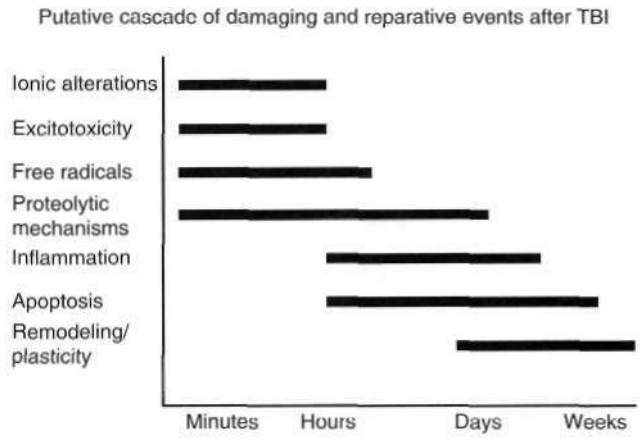

FIGURE 56A.5 *Paradigm for several time-dependent pathomechanisms and reparative events that may be targeted for therapeutic interventions (Adapted from Dirnagl, U., Iadecola, C., & Moskowitz, M. A. 1999, "Pathobiology of ischemic stroke: An integrated review," TINS, vol. 22, pp. 391-397).*

THERAPEUTIC INTERVENTIONS DIRECTED AGAINST PATHOPHYSIOLOGICAL PROCESSES

The pathophysiology of TBI has been investigated using a variety of animal models. Based on experimental data, new therapies have been initiated, some of which have been tested in the clinic. Several reviews summarize the agents that have been investigated in TBI (Mcintosh, Juhler, and Wieloch 1998). The problem of FBI involves injury pathways that arc common to other brain injuries, including cerebral ischemia. However, the pathogenesis of TBI is unique in other ways and necessitates therapeutic approaches specifically targeted at brain trauma (Figure 56A.5). The present discussion is limited to several of the major therapeutic strategics currently being assessed experimentally and clinically.

Glutamate Antagonists

Excitatory amino acid neurotransmitters have been implicated in the pathophysiology of TBI. Microdialysis techniques have documented elevated levels of extracellular amino acids, whereas N-mcthyl-u-aspartate (NMDA) receptor antagonists, including MK-801 (di?.OCilpine), provide behavioral and histopathological protection against brain trauma. The role of glutamate antagonists in treating central nervous system injury has been reviewed, and clinical stroke trials of the competitive NMDA antagonist MK-801 were withdrawn because of harmful side effects. Clinical data are still needed to determine whether NMDA receptor blockage will provide a significant benefit in clinical head trauma,

Free Radical Scavengers

The genesis of oxygen free radicals has also been implicated in the pathophysiology of TBI. Experimental FP injury increases the production of oxygen radicals, and free radical scavenger inhibitors have been reported to be protective in brain injury models. Sensitive indicators of hydroxy radical production and microdialysis have detected elevations in extracellular hydroxy radical production after FP injury. The free radical scavenger superoxide dismutase (SOD) reduces BBB opening and the genesis of

brain edema after TBI. Transgenic mice that ovcrcxprcss human copper-zinc SOD are protected against brain trauma. Clinical trials using polyethylene glycol SOD and free radical scavengers have been initiated in brain trauma, with little success.

The reason for these negative results is not known, although questions regarding brain penetration and limited therapeutic window have been discussed. In one experimental study, treatment with a potent inhibitor of lipid peroxidation and an antioxidant provided significant neuroprotection in a FP model when treatment was delayed 30 minutes but not 3 hours after TBI. Thus based on neurochemical and treatment studies, the therapeutic window for treatments that target free radical reactions and lipid peroxidation after moderate TBI seems to be short. Whether these treatments may protect against secondary insults remains to be investigated.

Neurotrophic Factors

A unique problem of brain trauma is diffuse axonal injury. Axonal injury leading to circuit disruption may not only produce immediate functional consequences but also may affect trophic signaling between neuronal populations. The addition of trophic factors after TBI may help maintain neuronal survival and promote circuit reorganization and functional recovery. Neurotrophins have been shown to be neuroprotective by in vitro and in vivo models of neuronal injury. After experimental TBI, delayed treatment with basic fibroblast growth factor significantly reduced histopathological damage and improved cognitive function. Several neurotrophic factors have also been shown to be protective when administered exogenously to animals after experimental TBI. For example, post-traumatic infusion of nerve growth factor (NGF) into the injured cortex or into the lateral ventricle was reported to improve learning and memory and to decrease apoptotic neuronal loss in septum of rats. The systemic administration of insulin-like growth factor-1 after TBI improved learning and neuromotor function. In contrast, brain-derived neurotrophic factor administration was not protective against behavioral or histopathological defects caused by TBI. In a recent publication, immortalized neural stem cells rcrrovirally transduced to produce NGF improved cognitive and neuromotor function and rescued hippocampa! CA3 neurons when transplanted into the injured brain. Therefore an important direction of future research will be to use engineered cell lines to produce neurotrophins that could synthesize and telease locally factors that enhance plasticity and circuit reorganization. If experimental studies continue to show a benefit of neuroprotection on neuronal injury and behavioral outcome in TBI models, this may be an important direction for future clinical trials in brain trauma.

Protection by Nitric Oxide-Related Species

In the nervous system, nitric oxide (NO) may serve as a neurotransmitter, a signal between cells, and an autocrine signal within a given cell. Aftet brain injury, an increase of neuronal calcium triggers constitutive NO synthase (cNOS) activity, leading to the release of NO that may enhance excitotoxicity. Studies of mutant mice deficient in neuronal (nNOS) or endothelial NOS (eNOS) activity have demonstrated that whereas nNOS exacerbates ischemic injury, eNOS protects against it.

Therapeutic strategies directed at the NO pathway have been reported in models of brain injury. Data indicate that FP injury leads to the acute activation of cNOS and that the selective inhibition of nNOS by 3-bromo-nitroindazole protects histopathologically and behaviorally. In addition, the inhibition of inducible NOS with aminoguanidine (selective iNOS inhibitor) also improved histopathological outcome. However, recent work using iNOS knockout mice has shown a beneficial role of iNOS in brain injury. Thus whereas early iNOS activity after brain trauma may contribute to secondary injury mechanisms, later or chronic activation may participate in reparative processes. These points regarding what processes should be targeted and when they should be inhibited are critical as novel strategics are developed to target NO-mediated cell injury. Additional studies using mutant mice deficient in nNOS, eNOS, or iNOS activity will be important to advance this area of investigation.

Inflammation

Inflammation is a host defense mechanism initiated by injury or infection through which blood-derived leukocytes (neutrophils, monocytes and macrophages, T cells) and soluble factors (cytokines, chemokines, complement) try to restore tissue homeostasis (Bethea and Dietrich 2002). Although evidence supports the beneficial role of inflammatory processes in acute injury, including the production of neurotrophic factors, inflammation is also thought to contribute to the tesulting neuropathology and secondary necrosis that occur after trauma. Brain trauma is associated with the production and release of proinflammatory cytokines, including tumor necrosis factor (TNF)-a, interleukin (IL)-l/3, and IL-6. The inhibition of cytokines such as IL-ljS and TNF-or has been reported to decrease lesion size and improve behavioral outcome after TBI. Also, treatment with the potent anti-inflammatory cytokine IL-10 was reported to improve outcome. However, absolute TNF-» inhibition in the form of knockout mice has yielded conflicting results regarding pathology and neurological outcome (Stahel et al. 2000). Again, these studies emphasize the diverse actions of cytokines and both the good and bad consequences of overexpression and inhibition.

Antiapoptotic Agents

Apoptosis is a mode of cell death in both physiological and pathological processes. Evidence of apoptotic cell death has also been observed after TBI. After FP injury, apoptotic cells have been identified in the ipsilateral cortex, hippocampus, and thalamus as soon as 4 hours after injury, and immunocytochemical markers for caspase-3, -8, and -9 activation have been reported (Figure 56A.6). The effects of l'T injury on the expression of the be 1-2 protein, which regulates developmental programmed cell death, have also been investigated. Evidence of apoptosis of oligodendroglia in long tracts undergoing Wallerian degeneration has been reported after SCI. Therefore demyelination of tracts after brain or spinal cord trauma may result from apoptotic death of oligodendrocytes. Importantly, indicators of apoptotic cell death have also been observed in human tissues.

Although the molecular events leading to apoptosis are not fully understood, the family of cysteine proteases (caspases) play an active role in its pathogenesis. In reference to neuroprotection, in vitro studies have demonstrated that protease inhibitors specific to caspase-3 inhibit apoptosis. Whereas some experimental data indicate that inhibition of caspasc-3 improves outcome after TBI, other studies suggest that this approach has limitations. Currently, emphasis is being placed on more upstream apoptotic processes in contrast to targeting caspase activation. Therefore more research is needed to clarify the various pathways involved in apoptotic cell death and determine which pathways may be most sensitive to therapeutic interventions. Using agents specific to apoptosis or in combination with agents that target necrosis is a potential research direction.

Therapeutic Hypothermia

Numerous studies have demonstrated that, although mild to moderate hypothermia is neuroprotective in models of TBI, mild hyperthctmia worsens outcome. After brain trauma, hypothermia has been shown to improve histopathological

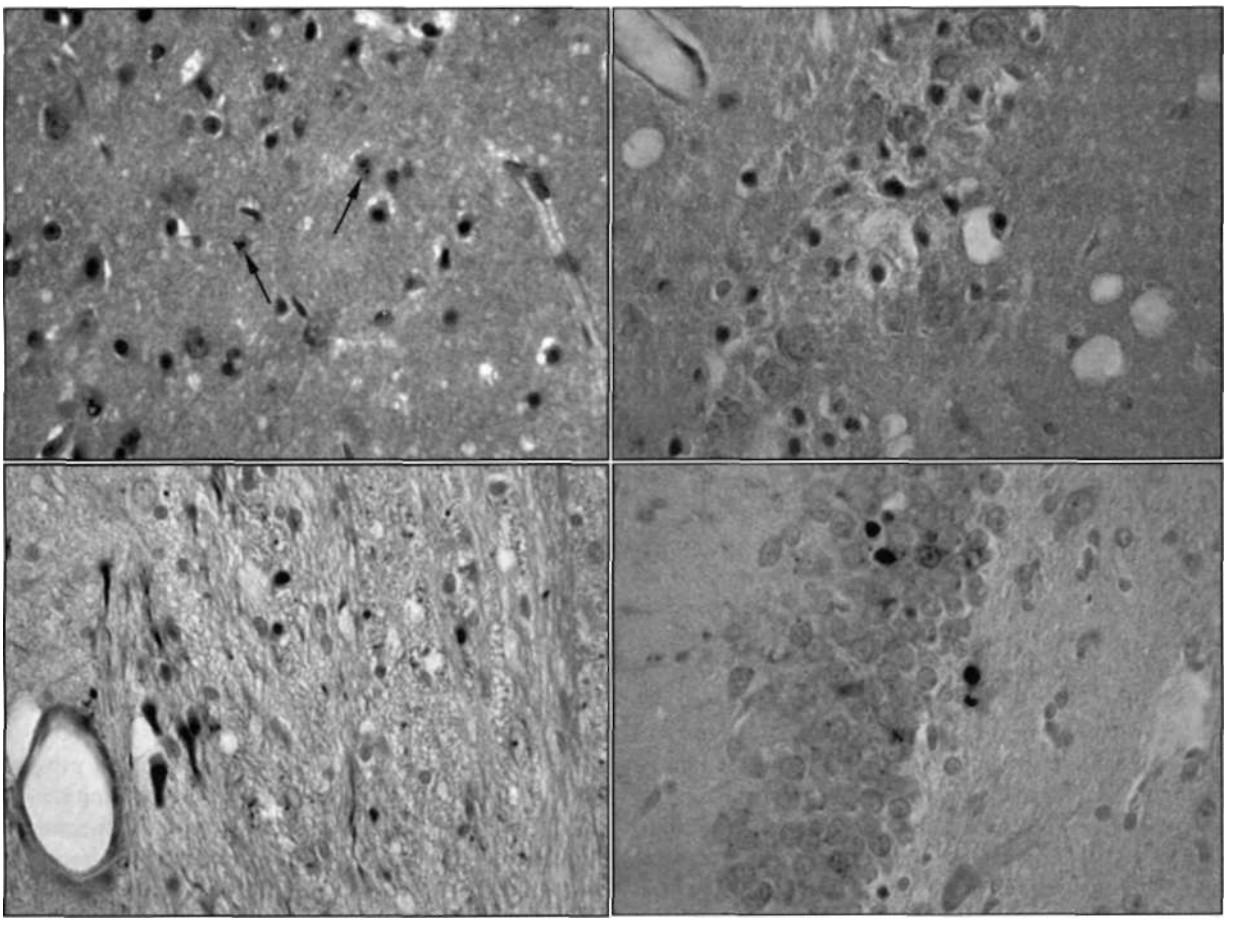

FIGURE S6A.6 Histopathological and lmniiinohistochemical evidence of apoptotic cell change 1 day after traumatic brain injury. (A) Hematoxylin and eosin-stained section showing apoptotic bodies (xl200). (B) Caspase-8 immunorcactivity (xl200), (C) Caspase-9 i mm u no reactivity in the thalamus (x!200). (D) Immurinhistochemistry of active caspasc-3 in dentate gyrus (x 1200).

and behavioral outcomes and to influence a wide range of injury processes (Dietrich et al. 1996). Microdialysis studies report that post-trauma tic hypothermia reduces the acute surge in levels of extracellular glutamatc and hydroxy free radicals after injury. Post-traumatic hypothermia protects against BBB dysfunction. In terms of long-term ourcome measures, hypothermia inhibits progressive cortical atrophy and subsequent ventricular enlargement. The ability of any therapeutic intervention to provide long-term protection is an important requirement for the advancement of any therapeutic strategy to the clinical setting,

As previously discussed, a significant number of patients with TBI sustain a secondary insult that may include hypotension, hypoxia, or hyperthermia. This fact has led to the use of complicated models to test novel neuroprotective agents before clinical trials. This point is important because experimental therapeutic strategies are commonly tested in simple models of brain injury as proof of concept (Mcintosh, Juhler, and Wieloch 1998). In this regard, post-traumatic hypothermia has been evaluated in TBI models complicated by secondary hypoxia. Taken together, these studies showed that hypothermia was protective in complicated models, but the degree of prorection depended on injury severity, duration of hypothermic period, and the rewarming procedure.

The use of moderate levels of hypothermia (>32^{C}C) also improves outcome in patient studies. Systemic hypothermia (32^{11} to 33^{C}C) begun within 6 hours of injury (Glasgow Coma Score 4-7} resulted in no cardiac or coagulopathy-related complications, a lower seizure frequency, and more patients in the good recovery to moderate disability category. In other head trauma studies, therapeutic hypothermia attenuated intracranial hypertension but did not affect the frequency of delayed intracerebral hemorrhage. Results from a recent multicenter TBI trial failed to demonstrate a protective effect of hypothermia on traumaric outcome. However, subgroup analysis showed that patients under age 45 coming into the emergency room hypothermic demonstrated an improvement with hypothermic treatment. Obviously, more experimental and clinical studies are needed to determine what factors are most important in providing protection when using hypothermic strategies. Temperature is known to affect many pathophysiological processes after TBI, and this characteristic may be advantageous because of the multifactorial nature of trauma pathomechanisms. The cooling and rewarming periods arc also important variables in determining the extent of neuroprotection. In TBI studies, prolonged periods of hypothermia (i.e., >24 hours) may therefore be necessary to protect the brain from primary and secondary injury processes. Because brain temperature can be elevated compared with bladder temperature in head-injured patients, normothcrmia or mild hypothermia should be maintained during critical postinjury periods.

RECOVERY OF FUNCTION

Environmental Enrichment

The effect of environmental enrichment (EE), which exposes animals to a complex, highly stimulatory, and social environment has been studied in a number of TBI models. Using a midline FP injury model that produced no noticeable histopathology, EE has been reported to improve cognitive function. In addition, EE has been shown to decrease overall contusion volume and improved performance in the Morris Water Maze task. The effects of EE have been suggested to be reflected in changes in dendritic arborization. Future studies combining EE with neuroprotective and reparative strategies probably will be needed to maximize improvement in outcome.

Reparative and Transplantation Strategics

Recent data indicate that after a variety of acute central nervous system injuries, there is a massive proliferation of stem or progenitor cells. Therefore the identification and origin of the fate of these cells is an area of intensive investigation. In a model of FP injury, the total number of proliferating cells as identified with 5-bromo-deoxyuridine, a marker of mitotic activity, was shown to significantly increase in areas of the subventricular zone and hippocampus. In that study, proliferating cells did not express cell markers and therefore appeared not to have begun to differentiate. Targeting this endogenous proliferative response to injury may be one way to enhance recovery following TBI.

In contrast to endogenous reparative events, the provision of new cells from exogenous sources is an alternative approach and may be necessary when neuronal loss and axonal injury are severe. Neural transplantation has been explored in TBI models (Soares et al. 1991, 1995). Fetal cortical tissue transplanted into the injury cavity improved motor function and transiently attenuated cognitive dysfunction alone and in combination with NGF infusion. Although the rccstablishmcnt of normal adult neural circuitry has not been demonstrated with fetal tissue grafts, one mechanism for improved function may be neuroprotection by release of trophic factors from the grafts (Soares et al. 1995). Recent studies have also attempted to provide cellular replacement and host-graft integration using self-renewing cell lines (Riess er al. 2002). Using immorralized neural progeniror cells derived from embryonic rat hippocampus (HiB5 cells), improved neuromotor and cognitive function and reduced hippocampal CA3 cell death after transplantation with cells transduced with the mouse NGF gene to secrete NGF have been reported. Continued study in this exciting field may establish transplantation procedures relevant to clinical strategies to promote recovery after TBI.

SUMMARY AND FUTURE DIRECTIONS

Continued experimental studies directed at investigating the pathogenesis of TBI will enhance our understanding of the neuroscicncc of brain trauma. The clarification of what injury processes dominate the injury cascade will improve our strategics directed at brain protection. The development of novel genetic mouse models of disease should also allow researchers to elucidate canse-and-effeet relationships between specific pathoinechanisms and cell death. The continued emphasis on determining how various factors, including age and gender, affect traumatic outcome should enhance the translation of experimental findings to the clinic. The relationship between early head injury and increased incidence of neurodegenerative disease is an important area for investigation as well. The determination of what genetic and environmental factors may interact to enhance the susceptibility of the post-traumatic brain to age-related disease processes is of utmost importance. Also, scientists from different laboratories need to assist in the replication of exciting data that will promote the design of successful clinical trials. Finally, the testing of combination therapies targeting multiple pathomechanisms must be encouraged. Strategies to protect vulnerable neurons, inhibit secondary injury mechanisms, and promote reparative processes must be considered in experimental studies. The continued communication between scientists involved in brain injury research and clinicians responsible for treating this patient population and designing clinical trials will advance our efforts toward these goals.

Chapter 56
Trauma of the Nervous System

B. CRANIOCEREBRAL TRAUMA

Donald W. Marion, Michael C. Sharts, and Elizabeth C. Tyler-Kabara

Traumatic brain injury (TBI) is the leading cause of morbidity and mortality in the United States for people between the ages of I and 45 years. An estimated 1.6 million people sustain a TBI each year. Approximately 270,000 must be hospitalized, of whom 52,000 die of their injuries and 80,000 are left with severe neurological disabilities. Another 760,000 are treated and released from emergency departments or clinics, and it is estimated that approximately 400,000 people with mild ot moderate TBI do not even seek medical attention (Sosin, Sniezek, and Thurman 1996). The leading causes of TBI are motor vehicle crashes (MVCs), violence, and falls. Adolescents and older adults are most at risk. Falls are the leading cause of head injury in people 65 years and older, whereas MVCs are the leading cause of head injury in those 5-64 years old. At all ages, males arc at twice the risk of TBI as females. In the United States an estimated *5.3* million people are living with a permanent Tftl-related disability, the direct and indirect costs of which are estimated to exceed $4 billion a yeat (Ktaus and McArthur 1996). TBI-related death rates have been falling in the United States, with one study documenting a 22% decline from 1979 to 1992 (Sosin, Sniezek, and Waxweiler 1995). A significant teduction in MVC-related TBI is primarily responsible. However, some large cities are seeing a rise in gunshot wounds to the head, and deaths from this cause often exceed MVC-related fatalities.

PATHOPHYSIOLOGY

Trauma to the head causes primary injuries, such as skull fractures, cerebral contusions, and hemorrhage, that are a direct physical consequence of the impact. Within hours or days of the injury, secondary injury may also occur and may be *a* major determinant of the patient's ultimate neurological outcome.

TBI is caused by extetnal forces to the head that can be categorized as contact and inettial (Graham et al. 1995). Contact fotces typically cause focal injuties such as skull ftactutes, epidural or subdural hematomas, and contusions. Inertial forces set the head into acceleration (translational ot totational) with ot without a contact fotce. These forces may cause focal or diffuse brain injuries. Inertial forces with pure translational acceleration cause focal injuries such as contracoup contusions, intracctcbral hematomas, and subdural hematomas. Inertial forces with rotational ot angulat acceleration usually cause diffuse injuries and are common with high-speed MVCs. Extetnal signs of trauma such as scalp abrasions, lacerations, and hematomas are common with blunt fotce trauma to the head, but severe TBI can also result solely from acceleration and deceleration forces (e.g., MVC) without scalp injuries.

Skull fractures result ftom an impact to the head that is usually sevete enough to cause at least a brief loss of consciousness. The most common type of skull fracture is a linear fracture, typically over the lateral convexities of the skull. Linear skull fractures usually arc noudisplaced cracks through the skull, although very severe trauma can cause a gap, or diastases, between the fracture edges. Depressed skull fractures, with fragments of the skull pushed into the cranial vault, are most common with blunt force trauma to the head caused by an object with a small surface area, such as a hammer (Figure 56B.1). Severe blunt trauma to the forehead or the occiput can cause fractures through the base

FIGURE 56B.1 A right temporal depressed skull fracture caused by an assault with a hammer. (Axial computed tomography scan, bone window.)

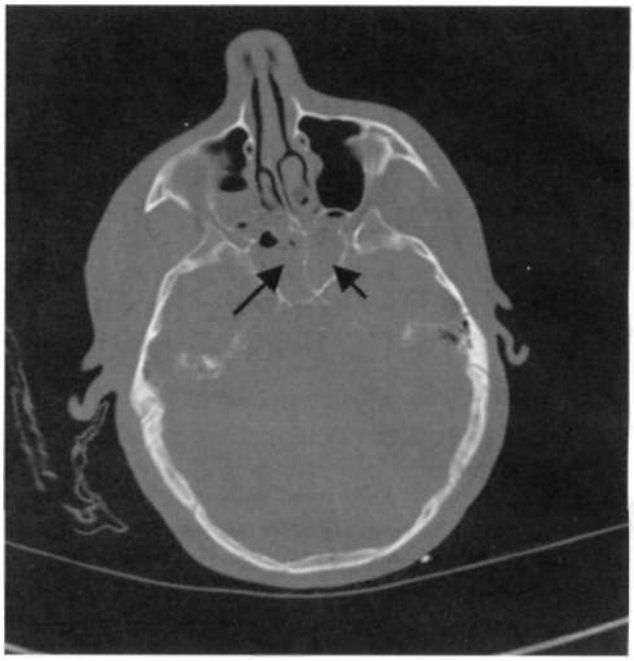

FIGURE S6B.2 Basilar skull fractures through the anterior skull base typically cause tears in the adjacent dura and cerebrospinal fluid rhiuorrhea. Computed tomography scans through the base of the skull may not show the fracture itself, but fluid in the sphenoid sinus *(arrows)* or the other paranasal sinuses is often seen. (Axial computed tomography scan, bone window.)

of the skull. Such basilar skull fractures are most common through the anterior skull base and often involve the cribriform plate, disrupting the olfactory nerves (Figure 56B.2). Posterior basilar skull fractures may extend through the petrous bone and internal auditory canal, thereby damaging the acoustic and facial nerves. The clinical significance of skull fractures is related more to the associated damage of underlying tissues or vessels than to the fracture itself. For example, linear skull fractures involving the squamous portion of the temporal bone often tear the middle meningeal artery, resulting in an epidural hematoma. Depressed skull fractures often are associated with contusions of the underlying brain tissue. If the scalp overlying the depressed skull fragment is lacerated, the depressed fragment of bone may be contaminated with bacteria. Basilar skull fractures often are associated with disruption of the dura underlying the fracture, resulting in a cerebrospinal fluid (CSF) fistulas and leakage of CSF from the nose or ear. Such fistulas are a conduit for bacterial contamination of the intracranial space from the nose, paranasal sinuses, or external auditory canal.

Typical post-traumatic intracranial lesions include hemorrhage, contusions, and diffuse brain injury, ultracrania] hem a to i n as arc classified as epidural, or hematomas that occur between the inner table of the skull and the dura matter; subdural, or hematomas that develop between the inner surface of the dura and the brain surface; and intraparencbymal, or hemorrhage that occurs in the brain substance itself. The most common intracranial hematoma is a subdural hematoma, found in 20-25% of all comatose patients with TBI {Figure 56B.3). The hematoma is thought to result from tearing of bridging veins over the surface of the cortex or from disruption of major venous sinuses or their tributaries. A subdural hematoma typically expands over most of the cerebral convexity. Spread to the contralateral hemisphere is limited b\ the Jural reflections of the falx cerebri. Because subdural hematomas often are associated with damage to the underlying brain tissue, swelling of the cerebral hemisphere also is common. In one scries, underlying contusions were observed in 67% of those with subdural hematomas. Subdural hematomas may be acute, subacute, or chronic, and each has a characteristic appearance on computed tomography (CT): Acute hematomas arc bright white, subacute lesions are isodense with brain tissue and often overlooked because of this, and chronic subdural hematomas are hypodense relative to the brain.

F.pidural hematomas arc located between the inner table of the skull and the dura and usually result from a tear of the middle meningeal artery or one of its branches caused by a skull fracture. They are less common than subdural hematomas and are found in 1-2% of all patients with TBI and 8-10% of those rendered comatose by the injury. The majority of epidural hematomas are located in the temporal or parietal regions, but they may also occur over the frontal or occipital lobes and rarely in the posterior fossa. They appear as hyperdense mass lesions on CT. Unlike that of

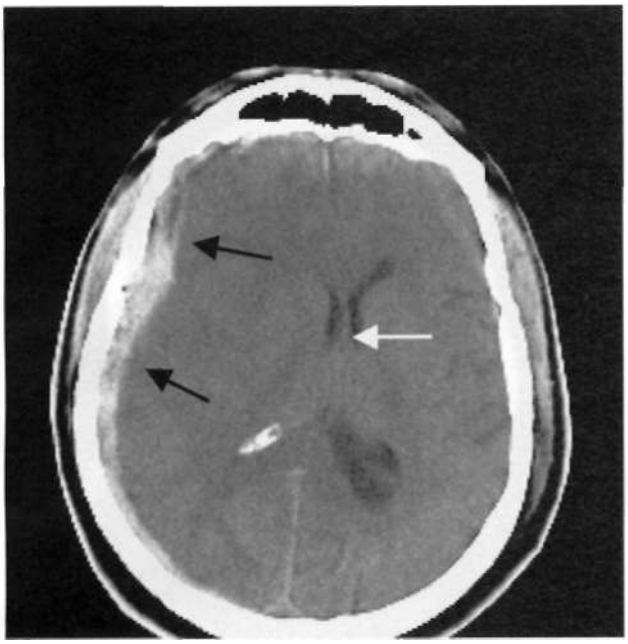

FIGURE 56B.3 An acute subdural hematoma typically spreads over the entire surface of the hemisphere *(black arrows)* and is associated with swelling of the hemisphere. As a result, shift of the midline structures away from the side of the hematoma may be greater than the thickness of the hematoma *{white arrow).* (Axial computed tomography scan.)

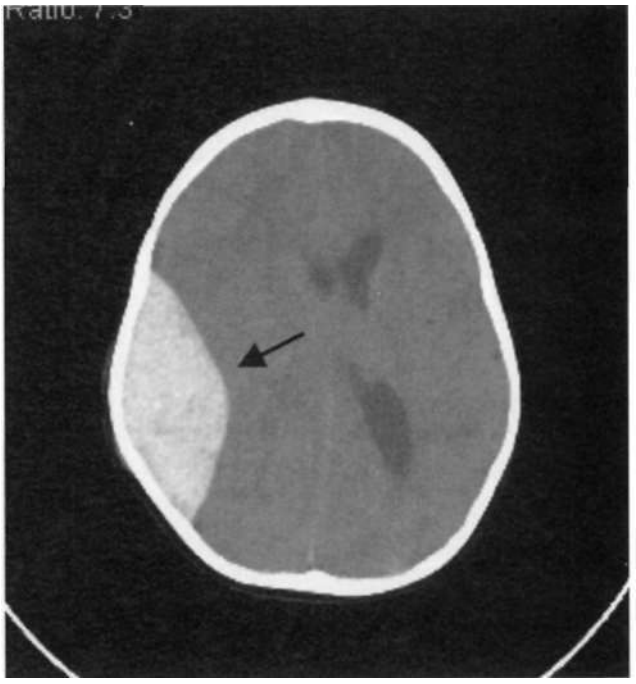

FIGURE 56B.4 Epidural hematomas have a lens-shaped appearance and smooth inner border because as they enlarge, they strip the dura away from the inner table of the skull. (Axial computed tomography scan.)

subdural hematomas, their spread is limited by the suture lines of the skull, where the dura is extremely adherent. Because there normally is no epidural space, the hematoma must sttip the dura away from the inner tahle of the skull as it enlarges, and this gives the classic biconvex or lenticular appearance (Figure 56B.4). Presumably because of the softer and more deformable skull in infants and toddlers and because of the very tight adherence of the dura to the skull in those over age 60 years, epidural hematomas are uncommon in these two age groups.

Ttaumatic subarachnoid hemorrhage (SAH) is common after severe TBI but does not produce a hematoma or mass effect (Scrvadci et al. 2002), It may be associated with a greater risk for post-traumatic vasospasm, however (Martin et al. 1992). Intraparenchymal hematomas occur after particularly severe TBI. They usually are associated with contusions of the surrounding brain tissue. Durct hemorrhage is hemorrhage into the base of the pons or midbrain thought to result from disruption of the perforating arteries at the time of uncal herniation. Brainstem hemorrhage such as this almost always results in death or vegetative survival.

Contusions are heterogeneous lesions consisting of areas of punctate hemorrhage, edema, and necrosis and are found in 20-25% of patients with severe TBI. There may be multiple contusions, often associated with other intracranial lesions. Contusions evolve over time and may he small or not apparent on the initial CT. They appear as areas of punctate hyperdensities (hemorrhages) with surrounding hypodensity (edema; Figure 56B.5A). Local neuronal damage and hemorrhage cause edema that may progress over 3-4 days. As contusions evolve they usually coalesce and appear more like intracerebral hematomas (Figure 56B.5B). Depending on size and location, they may cause significant mass effect with resultant midline shift, subfalcine herniation, or transtentorial herniation. Contusions most often occur in the inferior frontal cortex and the anterior temporal lobes. The surface of the inner table of the skull is very irregular at these locations, and shifting of the brain over the irregular skull at the time of impact causes the contusions. Direct blunt force trauma to the head also may cause a contusion in the brain tissue underlying the point of impact. If the head is in motion before impact with a rigid surface, contusions often arc found on the side of the brain opposite to the point of impact, and these contusions arc called contracoup contusions.

In high-speed MVCs where there is a severe rotational component to the injury, lacerations or punctate contusions at the interface between the gray and white matter may occur and are ofren called diffuse axonal injury (DAI; Figure 56B.6). Such punctate contusions are believed to result from the difference in density between the gray matter and white matter and the resulting difference in centripetal force associated with a rotational vector of injury. Nearly half of all severely head injured patients and a third of those who die have DAI, and this injury is a

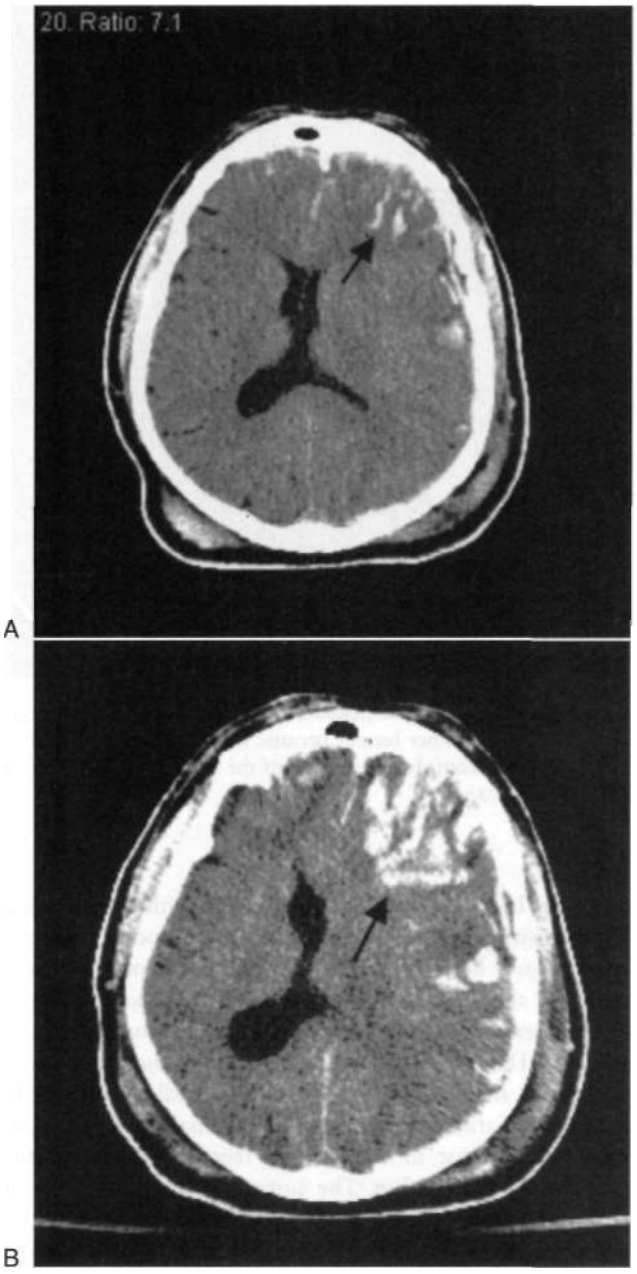

FIGURE 56B.5 Contusions most often occur in the inferior temporal and frontal *(arrow)* lobes. (A) In the first few hours after injury, they may appear only as punctate areas of hemorrhage mixed with edematous brain. But within 24-48 hours after injury hemorrhage may continue and cause significant enlargement of the contusion .mil hematoma. At its hours after injury this patieill had a sudden increase in 1CP and deterioration in the level of consciousness. (B) A repeat computed tomography scan revealed enlargement of the frontal contusion with mass effect, and the patient was taken to surgery for evacuation of the lesion. (Axial computed tomography scans.)

common cause of persistent vegetative state or prolonged coma. One study of 42 consecutive patients with TBI in a persistent vegetative state found evidence of DAI on magnetic resonance imaging in all of these patients. The

FIGURE 56B.6 Severe rotational vectors of force may cause diffuse punctate hemorrhages at the gray-white junction of the cortical mantle, as in this victim of a high-speed motor vehicle crash. (Axial computed tomography scan.)

most common locations of the lesions were the corpus callosum and the dorsolateral rostral brainstem. In the past, investigators thought that the mechanical disruption at the time of trauma was the sole cause of DAI, but recent evidence suggests that in some cases DAI may be a secondary manifestation of trauma (Povlishock and Christman 1995). They identified cases in which the histological footprints of DAI, such as fragmentation of axons and axonal swelling, do not appear until 24-48 hours after injury.

Post-traumatic intracranial lesions cause neurological deficits through direct and, in some cases, indirect mechanisms. Contusions and intraparenchymal hemorrhage destroy brain tissue •*Mtd* thereby cause neurological deficits directly related to the function of the tissue damaged. Another very important mechanism for temporary or permanent neurological dysfunction is brain herniation (Figure 56B.7), including uncal herniation. The intracranial contents are divided into compartments as a result of semirigid Jural reflections. The anterior and middle cranial fossae are separated from the posterior cranial fossa by the tentorium cerebelli. The brainstem, and specifically the miJbrain, traverses an opening in the anterior central portion of this partition (tentorial foramen). The medial portion of the temporal lobe, or uncus, lies on either side of this foramen. Because most traumatic injuries of the brain, such as hematomas or contusions, tend to occur over the lateral surfaces of the brain, and because the extreme lateral surface of the brain is the rigid skull, such lesions tend to

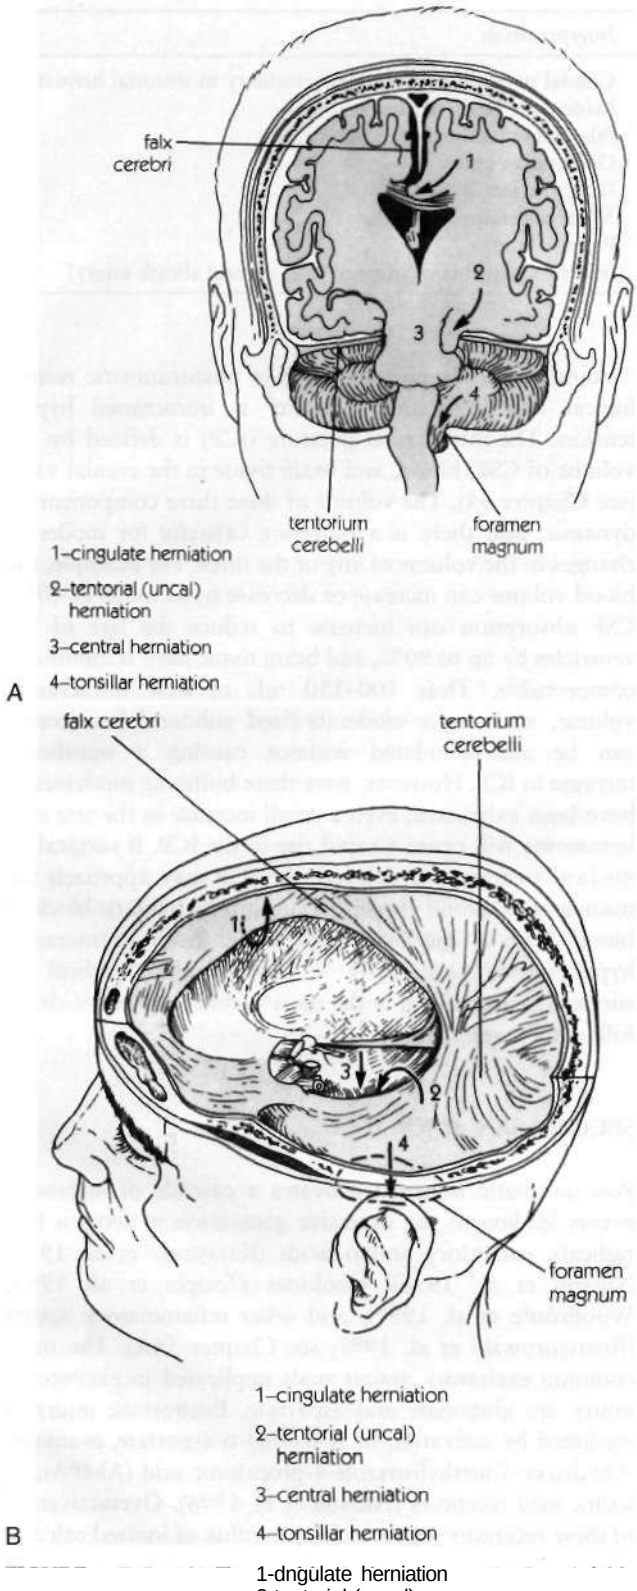

FIGURE 56B.7 (A) Types of brain herniation. (B) Dura] folds in the cranial cavity and associated herniation sites. (Reprinted with permission from Rengachary, S. S. & Duke, D. depress the brain medially. As a result, a subdural hematoma over the surface of the temporal lobe, or hemorrhagic contusion of the temporal lobe itself, tends to displace the medial portion of the temporal lobe (uncus) into the tentorial foramen, compressing the midbrain (Figure 56B.8). Neurons that are part of the reticular activating system reside in the midbrain. At the base of the midbrain are the crus cerebri, carrying pyramidal fibers from the cortex, and the third cranial nerves, which exit the midbrain through the interpeduncular cistern. Compression of the midbrain from uncal herniation causes loss of consciousness by damaging the reticular activating system, pupil dilation and loss of the light reflex by stretching the third cranial nerve and its associated parasympathetic fibers (Table 56B.1), and abnormal posturing responses in the contralateral arm and leg from damage to the pyramidal fibers in the crus cerebri.

Medial displacement of a cerebral hemisphere caused by hemispheric swelling or a subdural or epidural hematoma also can cause herniation of the cingulate gyrus under the

Tabic 56B.1: Interpretation of pupillary findings in head-injured patients

falx cerebri. This usually does not lead to permanent neurological dysfunction. However, the herniation may occlude one of the major intracranial arteries (anterior cerebral with cingulated herniation and posterior cerebral with uncal herniation), causing a secondary cerebral infarction (Figure 56B.9).

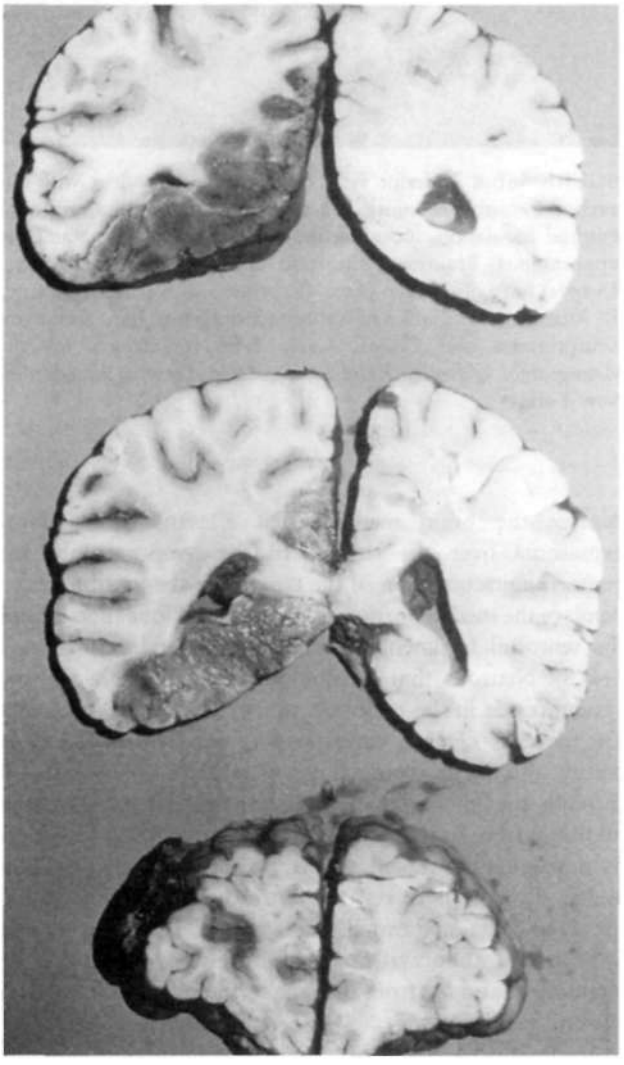

FIGURE 56B.9 Infarction of the occipital lobe as a result of tentorial herniation compressing the posterior cerebral artery.

Another very important cause of post-traumatic neurological morbidity and mortality is intracranial hypertension. The intracranial pressure (ICP) is defined by the volume of CSF, blood, and brain tissue in the cranial vault (see Chapter *65).* The volume of these three components is dynamic, and there is a buffering capacity for moderate changes in the volume of any of the three. For example, the blood volume can increase or decrease by as much as 40%, CSF absorption can increase to reduce the size of the ventricles by up to 90%, and brain tissue itself is minimally compressible. Thus 100-150 mL of new intracranial volume, such as a moderate sized subdural hematoma, can be accommodated without causing a significant increase in ICP. However, once these buffering mechanisms have been exhausted, even a small increase in the size of a hematoma will cause a rapid rise in the ICP. If surgical or medical treatment is delayed, the ICP may approach the mean arterial blood pressure, causing a hydrostatic block of blood flow to the brain and brain death. Intracranial hypertension, particularly if refractory to medical or surgical management, is the most common cause of death following severe TBI,

SFCONDARY INJURY

Post-traumatic ischemia activates a cascade of metabolic events leading to the excessive generation of oxygen free radicals, excitatory amino acids (Katayama ct al. 1990; Nilsson et al. 1996), cytokines (Taupin et al. 1993; Woodroofe et al. 1991), and other inflammatory agents (Rostworowski et al. 1997; see Chapter 56A). The most common excitatory amino acids implicated in exeitotoxic injury are glutamatc and aspartate. Fxcitotoxic injury is mediated by activation of N-methyl-D-aspartate, a-amino-3-hydroxy-5-mcthylisoazole-4-proprionic acid (AMPA), or kainic acid receptors (Nilsson et al. 1996). Overactivation of these receptors causes excessive influx of ionized calcium into the cytosol, and high levels of ionized intracellular calcium play a central role in neurodegcneration after central nervous system trauma (Fineman et al. 1993). Post-traumatic nonischemic events such as an increase in intracellular free $Ca^{'+}$, through receptor-gated or voltage-dependent ion channels, also induce the release of oxygen

free radicals from mitochondria. Excessive levels of highly reactive oxygen free radicals cause damage by lipid peroxidation of cell membranes, oxidation of intracellular proteins and nucleic acids, and activation of phospholipases A_2 and C, which hydrolyze membrane phospholipids, releasing arachidonic acid. The subsequent generation of excessive free fatty acids, leukotrienes, and thromboxane B_2 from the arachidonic acid cascade has been associated with neurodegencration and poor outcome after experi mental TBI. Inflammatory cytokines, particularly interleukin (IL)-l, IL-6, and tumor necrosis facror-«, also are produced in excess after TBI. Post-traumatic activation of microglia has been found to be an important source of these cytokines in animal models (Woodroofe et al, 1991). IL-1 and IL-6 induce an exuberant cellular inflammatory response thought to be responsible for astrogliosis, edema, and tissue destruction (Rostworowski et al. 1997; Schoettle et al. 1990).

High levels of extracellular potassium also are caused by TBI and result in an imbalance of intracellular and extracellular K^+, disruption of the Na-K^+-ATPasc cell membrane regulatory mechanisms, and subsequent eel! swelling. Clearance of excessive extracellular K^+ by astrocytes has been implicated as a cause of astrocyte swelling (Kimelberg 1995). In addition, high levels of extracellular K^+ have been implicated as the cause of widespread neuronal depolarization and spreading depression that has been observed after experimental TBI. Potassium also stimulates increased oxygen uptake in glial cells, potentially depriving adjacent neurons of oxygen. Severe TBI also causes a significant reduction in extracellular magnesium (Mg^{2+}) levels, thereby impairing normal glycolysis, cellular respiration, oxidative phosphorylation, and the biosyntheses of DNA, RNA, and protein. Because Mg^{2+} competes with $Ca^{24"}$ at voltage-gated cell membrane-associated Ca^{2+} channels, reduced levels of Mg^{2+} cause an abnormal influx of Ca^{2-r} into the cell.

PREHOSPITAL TRAUMATIC BRAIN INJURY MANAGEMENT

The acutely traumatized brain is vulnerable to further injury from systemic hypotension, cerebral hypoperfusion, hypercarbia, hypoxemia, and elevated ICP. Prevention of these physiological insults is essential for limiting secondary brain injury. Tbe initial prehospital evaluation of trauma patients should always begin with securing a patent airway and restoring normal breathing and circulation. Comatose patients usually benefit from early endotracheal intubation, but in the field this should be attempted only by experienced emergency medical providers. Securing and maintaining an airway is essential to providing optimal oxygenation and ventilation, and in patients with severe TBI early intubation has been shown ro reduce mortality (Winchell and Hoyt 1997). In patients with a Glasgow Coma Scale (GCS) score of 8 or less, those who were successfully intubated in the field had a mortality rate of 36%, compared with a mortality rate of 57% for a similar group of patients who did not have endotracheal intubation until they arrived at the trauma center. Orotracheal intubation usually is the easiest and safest method of securing an airway. Most emergency medical personnel are trained and experienced with this method of endotracheal intubation. Nasotracheal intubation is an altemarive route that may be necessary for those with severe maxillofacial trauma. It is less desirable, however, because it is a blind procedure. Irritation of the nasal passageways can cause a surge in blood pressure and ICP, and inadvertent passage of the tube into the brain is a possibility for those with severe anterior skull base fractures. A third alternative for securing the airway is the laryngeal mask airway, an easily learned and rapidly applied device that has undergone successful field trials (Sasada and Gabbott 1994). It does not protect against aspiration, however, and high airway pressures cannot be achieved with its use. A surgical airway, or cricothyroidotomy, should be considered only if all other attempts to secure an airway have failed and should be attempted only by experienced providers.

Before intubation the patient should be sedated and pharmacologically paralyzed because irritation of the oropharynx typically causes transient hypertension, tachycardia, ICP elevation, and agitation that can interfere with the procedure. Sedatives most commonly used include fentanyl, a short-acting opioid agonist that produces analgesia and sedation. The usual dosage is 3-5 pg per kilogram given intravenously 3 minutes before intubation, Etomidate is an alternative to opioids that provides adequate sedation bur is less likely to cause hypotension. Thiopental, an ultra-short-acting barbiturate, is preferred by some because its short duration of action makes it less likely to mask the patient's neurological status once he or she reaches the trauma center. However, it also is more likely than other agents to cause hypotension. Propofol has recently been introduced as a rapid onset, short-duration sedative that is very effective and unlikely to cause hypotension but is also very expensive. Neuromuscular blocking agents commonly used for endotracheal intubation include succinylcholine (1.5 mg per kilogram intravenously), which has the advantage of rapid onset, complete reliability, and a very short duration of action. This latter attribute is particularly important in the prehospital setting, where failed attempts at intubation are not uncommon. Vecuronium (0.01 mg per kilogram intravenously) is an alternative paralytic agent that has the theoretical advantage of being a nondepolarizing muscle relaxant. But because its duration of action is much longer (1-2 hours), it is less forgiving of failed attempts at intubation. Table 5 (SB. 2 si lows a recommended rapid sequence intubation pathway.

Tabic 56B.2; Recommended rapid sequence induction for the severely head-injured patient

1. Preoxygenation: 100% oxygen for 5 minutes or fout vital capacity breaths.
2. Presentment: fentanyl (3-5 ug/kg IV).
3. Wait 2-3 minutes if possible; continue preoxygenation.
4. Paralysis and sedation; succinylcholine (1.5 mg/kg IV).
5. Intubate with in-line cervical spine immobilization.
6. Positive-press LI re ventilation and consider rcparalysis with vecuronium if prolonged transport time is anticipated.

Supplemental oxygen should be provided before and immediately after intubation. Ventilatory rates of 10-12 breaths per minute for adults, 20 breaths per minute for children, and 25 breaths per minute for infants should provide adequate oxygenation. Hyperventilation should be avoided unless there is clear evidence of neurological deterioration during evaluation and transport. Aggressive hyperventilation can cause cerebral vasoconstriction, further reducing cerebral blood flow and potentially causing or worsening cerebral ischemia.

Rapid fluid resuscitation and restoration of a normal blood pressure also is critical in the prehospital setting because hypotension, and specifically a systolic blood pressure of less than 90 mm Hg, has been associated with a doubling of the mortality rate after severe TBI. The most likely cause of hypotension is hemorrhage, usually in the abdomen or chest, so hypovolemia should be assumed. Lactated Ringer's or normal saline solutions should be infused through large-bore intravenous catheters as quickly as possible until normotension is achieved. Recent preclinical studies suggest that hypertonic saline may be more effective than isotonic solutions for rapid volume resuscitation (Anderson ct al. 1997; Doyle, Davis, and Hoyt 2001), although several small clinical trials have not been convincing (Shack ford et al. 199S; Si in ma et al. 19'JSi.

All patients with a severe TBI should be treated as though they have a spinal fracture until adequate spinal evaluation proves otherwise. Those who survive long enough to reach the emergency department have a 2-6% chance of having a cervical spine fracture. Of greater concern, however, is that iatrogenic spinal cord injury during transport of the trauma patient is estimated to be the cause of up to 25% of all posttraumatic spinal cord injuries (Diliherti and I.iiidsey 1992). At the scene of the accident and after respiratory and hemodynamic stabilization, the patient should be placed in a neutral position on a flat, hard surface. If immediate endotracheal intubation is necessary, one person should provide in-line cervical spine immobilization while the second person intubates the patient. A rigid cervical spine collar should be placed as soon as possible. Next, the patient should be placed on a backboard, and the cervical spine can then be further immobilized with a buttress of foam or towels on either side of the bead. The patient should then be strapped to the board in multiple locations to prevent movement during transport.

Organization of emergency medical services and regional trauma programs has improved outcomes for trauma patients, and especially those with severe TBI. Designation as a level I or II trauma center by the American College of Surgeons Committee on Trauma or a state health department ensures that immediate neurosurgical coverage will be available when the patient arrives. Therefore every effort should be made to transport the patient with severe trauma directly to a designated trauma center. In some cases, however, the patient may need respiratory or hemodynamic stabilization .it .1 ne.irbv emergency department en route to the trauma center if an adequate airway or venous access cannot be obtained in the field.

EMERGENCY DEPARTMENT MANAGEMENT

Upon arrival at the emergency department of the trauma center the patient undergoes a thorough physical and radiological evaluation aimed at detecting all life-threatening injuries. The Advanced Trauma Life Support protocol usually is followed and provides a comprehensive routine that has proven successful in quickly identifying all major injuries (Subcommittee on Advanced Trauma Life Support of the American College of Surgeons Committee on Trauma 1993). As soon as the patient is brought into the trauma bay, emergency medical personnel provide a brief and concise review of their prehospital assessment and management, including mechanism of injury, stabilizing maneuvers, medications given, initial vital signs, GCS, and hemodynamic stability during transport. The airway is reassessed, and the need for endotracheal intubation carefully reconsidered. For those intubated in the field, proper placement of the endotracheal tube should be verified both clinically and radiographically. Once the airway is secure and adequate oxygenation is verified with the use of percutaneous oxygen saturation monitors or arterial blood gas analysis, two large-bore intravenous catheters should be inserted to provide sufficient venous access for high-volume fluid resuscitation. Isotonic saline solutions are infused to continue the volume replacement that usually was started in the field. Any life-threatening injuries such as overt hemorrhage, tension pneumothorax, or cardiac tamponade should be treated immediately upon discovery. A brief neurological examination is done and should include the GCS (Table 56B.3), pupillary size and reaction to light, and the symmetry and extent of extremity movements. The head is palpated for any fractures, lacerations, or penetrating wuunds. Lacerations are probed gently to evaluate for a depressed skull fracture or foreign body. Large lacerations should be compressed with pressure dressings or temporarily sutured to prevent further hemorrhage. Careful inspection of the head should determine the presence or absence of hemotympanum,

periorbital or mastoid ccchymosis, and CSF rhinorrhea or otorrhea.

During this primary examination there should be continuous catdiac and oxygen saturation monitoring and frequent measurements of the blood pressure. A Foley catheter should be placed to help monitor the fluid status, and an orogastric tube is inserted and connected to suction to decompress the stomach. Blood specimens are obtained and analyzed for glucose, electrolytes, complete blood count, platelets, and the prothrombin time, partial thromboplastin time, and international normalized ratio. Type and cross-match of a blood specimen should be considered and an arterial blood gas obtained. A serum and urine toxicology screen may be obtained if alcohol or substance abuse is a possibility, and a pregnancy test should be obtained for all women of childbcaring age.

Initial radiographic evaluation includes chest, pelvis, and lateral cervical spine films, which usually are obtained in the trauma bay during the primary survey. If the lateral cervical spine radiograph fails to visualize ihe lower ccr\ ical spine, a swimmer's view may be obtained, or this area can be imaged with axial CT. Once all life-threatening injuries have been identified and stabilized, all patients with suspected head injuries should undergo a CT scan of the head. Images should be obtained from the C2 vettebrae to the vertex at a minimum of 10-nini intervals. If the head CT does not reveal a surgical intracranial mass lesion, CT scans of the chest and abdomen may be obtained to detect occult hemorrhage in these cavities. However, if a surgical mass lesion is detected on the head CT scan, further imaging studies are postponed and the patient is taken directly to surgery for evacuation of the intracranial lesion. Often a diagnostic peritoneal lavage is done during the craniotomy to detect abdominal bleeding. Conversely, if hemodynamic instability necessitates that the patient be taken for emergent laparotomy or thoracotomy befotc a head CT scan can be obtained, and if intracranial injury is suspected, several diagnostic procedures can be performed in the operating room. An air ventriculogram will detect most large hematomas. With the patient in the supine position, a right coronal ventriculostomy is inserted. Preparations ate made fot an area postrema skull radiograph. fust before the radiograph is obtained, 3 ml, of air is injected into the ventticles. The air provides an outline of the ventricles, and distortion or shift of that outline suggests the ptesence and location of a hematoma. An alternative to obtaining an air ventticulogram is placement of diagnostic burr holes. This procedure is most appropriate if there are lateralizing neurological deficits, especially a unilateral fixed and dilated pupil. The initial butr hole is placed over the temporal lobe on the side ipsitateral to the dilated pupil. If no clot is derected, burr holes may then be placed over the frontal and parietal lobes. If a hematoma is encountered, the burr hole is enlarged to a craniotomy and the clot evacuated.

DEFINITIVE TREATMENT

The immediate concern in TBI is to determine the need tor craniotomy to evacuate an intracranial mass lesion such as a hematoma or contusion. In a subgroup of young patients, sutgery for decompressive craniotomy or temporal or frontal lobectomy may also be considered to treat tefractory intracranial hypertension. In addition to effectively treating elevated ICP, evacuation of post-traumatic mass lesions can prevent or reverse uncal herniation. The subsequent goal is to enhance cetebral perfusion and prevent ot limit secondary brain injury.

A reliable postres us citation GCS and assessment of pupil size and reactivity are critical for determining the severity ot the brain injury and for surgical decision making. CT scans of the head arc obtained to identify post-traumatic intracranial lesions, brain swelling, patency of the basal cisterns, and other charactetistics that will guide subsequent treatment. The need for a craniotomy is best determined by consideration of not only the CT images but also the post resuscitation GCS score and pupil status. For example, a patient with a moderate-sized subdural hematoma who has normal pupil size and reactivity and is able to follow commands might safely be treated nonoperatively. Convctscly, an elderly patient with fixed and dilated pupils and a GCS of 3 or 4 is unlikely to benefit from surgery regardless of bis or her CT findings. Thus when one is considering surgical evacuation of an acute subdural hematoma, scvetal factors must be weighed, including size and location of the hematoma, the presence and extent of

an underlying contusion or brain swelling, and the neurological examination. Deterioration of the neurological examination, particularly a decline in mental status, suggests enlargement of the hematoma, and a new CT scan should he promptly obtained. Hematomas less than 10 mm thick that cause less than 5 mm of midline shift usually can he observed, especially if they do not involve the middle cranial fossa (Servadei et al. 1998). If nonoperative management is elected in patients harboring an intracranial hematoma, they should be observed in the intensive care unit (ICU) with frequent neurological assessments. If the patient is unable to follow commands, ICP monitoring is recommended.

The classic presentation of a patient with an epidural hematoma is an initial period of unconsciousness immediately after impact to the head, followed by the so-called lucid interval in which the patient regains consciousness for a few minutes to an hour or more and then lapses into a coma. Less than a third of patients with epidural hematomas actually have a lucid interval, and most either remain conscious after the injury (smaller clots) or remain comatose.

Hematomas compressing the temporal lobes are particularly ominous and can rapidly cause uncal herniation with minimal enlargement. A lower threshold for surgical evacuation of these clots compared with that for hematomas in other locations is warranted. If the size of the clot is small enough not to necessitate evacuation, it should be observed with frequent CT scans in the first several days after injury. An increase in ICP may not always occur with enlargement of middle fossa hematomas, even those large enough to cause herniation, so ICP monitoring should not be relied upon to follow these clots.

Initial signs and symptoms of contusions vary greatly depending on the size, location, and associated lesions. Patients with small contusions may complain only of a headache and may have no symptoms. A small contusion may cause focal neurological symptoms if it is located in an eloquent area of the brain, such as the speech or motor areas. Larger contusions, particularly those involving the frontal lobes, typically cause increased ICP and coma. Patients with small or deep-seated contusions without mass effect initially can be managed nonoperatively. They should be followed closely with serial CT scans because there is a 20-30% chance that the contusion will enlarge in the ensuing 24-48 hours. Patients who are not following commands should have ICP monitoring. Like hematomas in the middle cranial fossa, contusions of the temporal lobes should be followed very closely with CT imaging. Enlargement of a temporal contusion to the point of uncal herniation can occur without a significant rise in ICP, and a low threshold for surgical evacuation of these lesions is warranted (Figure 56B.10). Unilateral fronral or temporal lobectomies usually are well toletatcd, do not cause measurable neurological deficits, and are effective in providing space for further swelling of the brain.

FIGURE 56B.10 Temporal lobe contusions *(black arrotv)* must be followed closely because even a slight enlargement can cause uncal herniation *(white arrow),* often without an increase in the intracranial pressure. (Axial computed tomography scan.)

CRITICAL CARE

In the ICU the primary goal is to prevent cerebral ischemia and thereby limit secondary brain injury. The most common potentially preventable causes of secondary injury are hypotension, hypoxia, and intracranial hypertension. It follows that optimal critical care of the patient entails comprehensive physiological monitoring to allow rapid detection and treatment of these physiological insults. Most comatose patients with TBI benefit from endotracheal intubation and mechanically controlled ventilation. Mechanical ventilation also should be considered for those with less severe TBI if they have pulmonary contusions or other causes of compromised respiration. Ventilator rates usually are set to provide an arterial PCO2 of approximately 35 mm Hg and the fraction of inspired O2 adjusted to provide an arterial P02 of 100 mm Hg.

Physiological Monitoring

The continuous monitoring of the end-tidal Pco_2 and frequent arterial blood gas analyses allow early detection of deterioration of the ventilatory status and appropriate adjustments of the ventilator. Continuous monitoring of oxygen saturation using pulse oximetry also is recommended. Continuous blood pressure monitoring is best accomplished with an indwelling arterial catheter fluid

coupled to a pressure transducer. The catheter is most commonly inserted into the radial artery and can also be used to obtain arterial blood samples for blood gas analysis. A common cause of hypotension after trauma is hypovolemia, which may result from overt hemorrhage usually detected early after injury, occult hemorrhage that may not be recognized for several hours or days, or soft tissue inflammation and swelling. Central venous pressure monitoring therefore should be considered for patients with severe TBI, especially those with significant non-central nervous system injuries. Indwelling subclavian or interna! jugular venous catheters coupled to pressure transducers are inserted for this purpose. In older adults or those with severe pulmonary contusions, pulmonary artery catheterization with a Swan-Ganz catheter may allow more accurate determinations of intravascular volume. Urine output monitoring also is essential for determining the patient's fluid status, so all of these patients should have an indwelling Foley catheter.

Continuous 1CP monitoring is essential for all patients who have a severe TBI and an abnormal CT scan of the head because 53-63% of these patients develop intracranial hypertension. Severe TBI is defined as a GCS of 3-8 and inability to follow commands. Comatose patients with TBI who arc older than 40 years and have unilateral or bilateral motor posturing or a systolic blood pressure less than 90 mm Hg also benefit from ICP monitoring even if their initial CT scan is normal. A ventricular catheter fluid coupled to an external strain gauge transducer is the gold standard against which all other ICP monitors are compared. It is not only accurate and reliable but also very inexpensive compared with newer self-contained pressure-sensing devices. Ventricular pressure monitoring also is considered more reflective of global ICP than subdural, subarachnoid, or epidural pressure measurements. Catheters placed in these extracerebral spaces arc more prone to occlusion and typically record a pressure that is lower than the global ICP because of the effects of compartmentalization. Other advantages of the ventriculostomy method of ICP monitoring are that the system can be re-zeroed after it has been inserted, something that is not possible with most of the newer self-contained devices, and CSF can be withdrawn to treat intracranial hypertension. The overall complication rate for ventricular ICP monitoring is 7.4% (infection, 6.3%; hemorrhage, 1.4%), and there is some evidence that the infection rate significantly increases for catheters that remain in place for more than 5 days.

Alternatives to the ventriculostomy technique of ICP monitoring have been developed that provide accurate measurements of global ICP, arc easier to insert, and may be associated with a lower complication rate. They include devices that contain a pressure-sensing transducer in the tip of the catheter that uses strain gauge or fiberoptic technology. These pressure sensors provide reliable ICP measurements even if they are inserted into the white matter and often arc used when it is difficult to insert a ventricular catheter because of small or collapsed ventricles. The primary disadvantage is that CSF drainage is not possible. They can be calibrated only once, before insertion, and some of the devices have been shown to have as much as 1-2 mm Hg of measurement drift per day.

The cerebral perfusion pressure (CPP) is a calculated physiological parameter that is used to describe actual cerebral perfusion and is defined as the difference between the mean arterial pressure (MAP) and the ICP. Some have suggested that maintaining a CPP above a certain threshold is more important than any particular MAP or ICP.

The adequacy of cerebral oxygenation can be assessed using brain tissue po_2 monitoring devices. These monitors provide continuous measurements of the tissue Po_2 in the small region of brain into which the device is inserted. The probes have been shown to be very sensitive to changes in the arterial P02, Pco_2, and medical interventions or physiological changes that may cause focal cerebral ischemia (Unterberg et al. 1997). Unfortunately, there are no methods for continuously monitoring global cerebral blood flow, although transcranial Doppler ultrasonography of the middle cerebral arteries can provide indirect information. Positron emission tomography and cerebral blood flow measurements with xenon, either as a radiolabeled agent or as CT contrast, can provide snapshots at different time intervals.

Treatment

Hypoxia is best avoided with the use of endotracheal intubation and mechanical ventilation. The fraction of inspired oxygen is titrated to achieve an arterial Po_2 of 100 mm Hg. Patients with severe chest injuries may develop a form of adult respiratory distress syndrome (ARDS), and positive end expiratory pressure (PEEP) is needed to maintain adequate oxygenation in these patients. Concern has been raised that the use of PEEP may increase the ICP in patients with TBI. But clinical studies find that, in the presence of ARDS, up to 15 em H_20 of PEEP can be used without measurable changes in ICP. This is probably because ARDS significantly reduces pulmonary compliance. Increased airway pressures are not transmitted to the chest cavity, so venous ourflow from the head is not restricted. Attention should also be paid to the oxygen delivery to the tissues. Maintaining an arterial Pco_2 of approximately 35 mm Hg is recommended to avoid the cerebral vasoconstriction associated with aggressive hyperventilation. Anemia must be treated aggressively, and a hematocrit of 30% or greater is recommended. Several ncurotrauma centers also are adjusting ventilatory and other rherapy to maintain a brain tissue P02 greater than 10 mm Hg, a threshold below which there may be an increased risk of tissue ischemia and worse outcomes {Kiening ct al. 1997).

Hypotension, defined as a MAP of less than 90 mm Hg, should he treated aggressively. Normovolemia should be restored by infusion of isotonic saline as needed to attain a central venous pressure of 7-12 cm H2O. Hypotonic intravenous solutions should be avoided because of the risk of worsening cerebral edema. If the patient is anemic, transfusions of packed red blood cells should also be used to restore the hematocrit to at least 30%. If hypotension persists despite adequate volume resuscitation, **a** continuous intravenous infusion of **a** vasopressor medication is recommended and the dosage titrated to elevate the MAP above 90 mm I Ig. Dopamine, Lcvophed, and norepinephrine are the preferred vasopressor agents.

Induced hypertension to elevate the CPP above 70 mm Hg is advocated by some, particularly if the ICP is elevated and difficult to treat (Rosner and Rosner 199.3). But a prospective randomized clinical trial in which a group of patients with TBI treated to maintain a CPP above 70 mm Hg was compared with a group in whom the CPP was allowed to drift to 60 mm Hg did not find any differences in 6-month clinical outcomes between the two groups (Robertson et al. 1999). Patients in the highcr-CPP group needed more vasopressor agents and had a significantly higher incidence of ARDS and other pulmonary complications than the group with the lower CPP. Others have measured brain tissue P02 in patients with TBI and found that there is typically not a fall in tissue P02 until the CPP drops below 60 mm Hg (Kiening ct al. 1997). Based on these findings, the current recommendation is to maintain a CPP above 60 mm Hg.

Intracranial hypertension is defined as sustained pressures greater than 20 mm Hg. Several clinical studies have found a significant increase in mortality and morbidity for patients with ICPs persistently above this threshold. Based on this association and the widely accepted premise that elevated ICP can compromise cerebral perfusion and cause ischemia, most believe it is important to treat intracranial hypertension aggressively. Before institution of therapy for intracranial hypertension, medical or physiological problems that can increase ICP should be considered and, if they exist, treated. They include seizures, fever, jugular venous outflow obstruction (e.g., poorly fitting cervical collars), and agitation.

Several medical and surgical options are available to lower ICP. Depending on the type of btain injury, some may be more effective than others, and each is associated with potential risks or side effects. The most commonly used treatment strategy involves a stepwise approach, with the use of the least toxic therapies first and addition of more toxic therapies only if the initial treatment is unsuccessful. Sedation and pharmacological paralysis often is an effective first treatment, particularly if the patient is agitated or posturing. We use a narcotic, such as morphine or fentanyl, for sedation and vecuronium bromide as the paralytic agent. Hypotension associated with the narcotic is avoided by ensuring normovolemia before treatment and using low dosages of the drug. The ability to obtain an accurate GCS is lost during this treatment, so the pupil examination, ICP, and CT scans must be monitored closely.

If intracranial hypertension persists after adequate sedation and paralysis, intermittent ventricular CSF drainage is used. Intermittent rather than continuous drainage allows reliable ICP monitoring. The next recommended treatment for intracranial hypertension refractory to these measures is mannitol. This osmotic diuretic lowers ICP and increases CPP by expanding the blood volume, reducing the blood viscosity, and increasing cerebral blood flow and oxygen delivery to the tissues within a few minutes of infusion. Its duration of effect averages 3-5 hours. Bolus administration of 0.25-1.0 g per kilogram every 3—4 hours as needed is recommended. Continuous mannitol infusions are more likely to lead to extravasation of the drug into brain tissue than bolus infusions, thereby causing a reverse osmotic gradient and increased edema and ICP. During mannitol administration the serum **osmolarity and sodium** should be monitored frequently and the drug discontinued if the serum sodium exceeds 160 mg/dL or the osmolarity exceeds 320 mOsm to minimize the risk of acute **tubular** necrosis and renal failure. The intravascular volume also should be monitored closely to prevent dehydration.

If the ICP remains above 20 mm Hg despite these measutes, the ventilator rate can be adjusted to reduce the $Paco_2$ to 30 mm Hg. But the use of hyperventilation in the first 24^4H hours aftet injury should be considered carefully because it will cause cerebral vasoconstriction at a time when cerebral blood flow already is critically reduced. Recent evidence also suggests that even brief periods of hyperventilation can increase extracellular lactate and glutamatc levels and thereby cause secondary brain iniury (Marion et al. 2002). Prophylactic hyperventilation in the absence of elevated ICP should always be avoided. A prospective randomized clinical trial comparing a group of patients with TBI who had prophylactic hyperventilation to a Paco2 of 25 **mm** Hg for 5 days with **a** group kept at a $Paco_2$ of 35 mm Hg found significantly worse **6-month** outcomes in the hyperventilated group (Muizelaar et al. I 991). If hyperventilation is used, monitoring of the brain tissue Po_2 or jugular venous oxygen saturation is recommended as a means of detecting cerebral ischemia that might be caused by the treatment,

If intracranial hypertension persists despite all these treatments, particularly if there is a rapid rise in ICP, or if the patient had a small contusion or hematoma on their original head CT scan, a repeat CTscan should be obtained immediately to determine whether the post-traumatic lesion has enlarged. Approximately 20-30% of contusions enlarge in the first 24-48 hours after injury. Even if the lesion has enlarged only slightly, emergent craniotomy and evacuation of the contusion or hematoma may be the best way to reduce the ICP quickly and effectively.

If the CT scan does not reveal a surgical intracranial mass lesion, the next recommended treatment for intracranial hypertension is high-dose barbiturate therapy. This medication is thought to act by reducing cerebral metabolic demand and blood flow, and preclinical studies suggest significant cerebral protective effects. Pentobarbital is the most commonly used drug for this purpose and is administered as an intravenous loading dosage of 10-15 mg per kilogram over 1-2 hours followed by a maintenance infusion of 1-2 mg per kilogram per hour. The dosage can then be increased until intracranial hypertension subsides or the MAP begins to fall. Others recommend continuous electroencephalographic monitoring and dosage increases until a burst suppression pattern is observed. The most common side effect of barbiturates is hypotension, but this can usually be avoided by ensuring a normal intravascular volume before administering the drug.

For patients with intracranial hypertension that persists despite all these measures, there are only a few remaining options, which are controversial and not embraced by all. Therapeutic moderate hypothermia has been used in several clinical trials over the last decade. The body temperature is reduced to 32-33"C as quickly as possible after injury and kept at that temperature for 24^48 hours using surface cooling techniques. Although clinical trials have not found that this treatment improves neurological outcome, they have consistently found that hypothermia significantly reduces ICP. And when its use is limited to 48 hours, hypothermia has not been shown to cause significant medical complications.

Decompressive craniectomies also are advocated by some and may include large lateral or bifrontal bone flaps with or without a generous temporal or frontal lobectomy. In one series of 29 patients with severe TBI, a subgroup that had large decompressive craniectomies was compared with a group that did not (Coplin et al. 2001). Six-month outcomes for the two groups were similar despite the craniectomy group having had a lower initial GCS and more severe radiographic injury. Importantly, the craniectomy group did not have a higher incidence of persistent vegetative state. Two other retrospective reports of patients with refractory intracranial hypertension treated with decompressive craniectomy as a last resort found good outcomes in *56-58%* (Guerra, Pick, and Gaab *1999;* Kunzc et al. 1998), and a third study suggested that decompressive temporal lobectomy improved outcomes for young patients when performed early after injury. However, others found that decompressive craniectomy did not improve ICP, CPP, or mortality {Munch et al. 2000).

Before decompressive surgery is considered, the salvageability of tin' patient should he considered carefully. Most agree that an intervention with a high probability of preventing brain death only to leave the patient in a persistent vegetative state is not a desirable intervention. Because age has such a profound impact on the likelihood of a meaningful recovery, these therapies are recommended only for those who arc less than 40 years old.

General Medical Care

Patients with TBI, particularly those who arc comatose or have significant non-central nervous system injuries, are at high risk of pneumonia, other infections, fever, malnutrition, seizures, deep venous thrombosis (DVT), pulmonary embolism, and other maladies endemic to the ICU. Most of these complications cause secondary brain injury and therefore should be diagnosed and treated rapidly. Fever is very common in the ICU and occurs in more than 90% of patients who are in the unit for 10 or more days (Kilpatrick et al. 2000}. Preclinical studies have shown that there is a logarithmic increase in neuronal cell death for every degree of brain temperature above 39 C in ischemic brain regions, and this effect is observed for 24 hours or more after injury (Baena et al. 1997). Clinical studies of patients with TBI reveal that the brain temperature often is 1-2 C higher than body temperature {Hcnkcr, Brown, and Marion 1998). Based on these findings, it is recommended that body temperarure be kept below 37°C at ail times and that infectious or other causes of fever be aggressively sought out and treated.

Comatose patients, those being treated with pharmacological paralysis, and those with pelvic and long bone fractures are at high risk for DVT and pulmonary embolism. The early use of DVT prophylaxis is recommended for this group of patients and typically includes the use of lower-extremity sequential compression devices and subcutaneous heparin or enoxaparin. The early use of minidosc heparin or low-molecular-weight heparins is safe and has not been found to cause or worsen intracranial hemorrhage after TBI (Kim et al. 2002; Norwood et al. 2002). If a pulmonary embolus occurs in the first 2-3 days after a TBI associated with intracranial contusion or hemorrhage, a vena cava filter usually is indicated. **After** the first few days, if serial CT scans verify that there is no further intracranial hemorrhage, full anticoagulation with heparin or Coumadin probably is safe. Malnutrition also is common after severe TBI when enteral feeding is poorly tolerated. The nonparalyzed patient with severe TBI typically has a 140% increase in resting metabolic expenditure (Young et al. 1985). Branched-chain amino acids from muscle protein are preferentially used for energy metabolism, potentially compromising the effectiveness of physical therapy. Nitrogen wasting also is increased, with excretion of as much as 9-12 g per day. Early enteral or parenteral feeding therefore is recommended, with the aim of providing at least 140% of the basal metabolic caloric needs each day by the third or fourth day after injury. For normal-sized adults, 2000-3000 kcal per day usually is needed. Because of the increased risk of infection with parenteral feeding, enteral administration is preferred.

Tf prolonged coma is anticipated, a surgical jejunostomy provides a convenient and well-tolerated route for tube feeding.

Post-traumatic contusions and subdural hematomas arc well-known causes of generalized seizures, so anticonvulsant prophylaxis is advocated for these and other patients with TBI. Most recommend treatment of all patients with TBI who have an abnormal CT scan with phenytoin for the first 7 days after injury. A prospective clinical trial did not find a benefit of longer prophylactic treatment (Temkin et al. 1990). A common side effect of phenytoin is fever, and this should be considered if infectious causes of fever have been excluded. The prolonged use of phenytoin also has been shown to significantly impair neuropsychological abilities after severe TBI. If seizures do occur, especially if they are prolonged, the associated cerebral hypermetabolism will cause secondary bram injury. Seizures therefore should be treated aggressively, including general anesrhesia if necessary. Patients who arc being pharmacologically paralyzed for treatment of intracranial hypertension may have seizures that are not readily apparent because they have no tonic-clonic extremity movements. Under these circumstances it is particularly important to provide anticonvulsant prophylaxis, and some even advocate continuous electroencephalographic monitoring. Clinically silent seizures should always be considered as a cause of an abrupt deterioration of cerebral oxygenation or a sudden increase in ICP, although the enlargement of an intracranial mass lesion still must be the first consideration.

PHYSICAL THERAPY AND REHABILITATION

The number of survivors of TBI is increasing with increasing successes in understanding and treating the disease and with improved injury prevention programs and technology. As a result, there is an increasing demand for high-quality, well-organized TBI rehabilitation programs. The primarv goal of these programs is to reintegrate patients with TBI back into their communities by cither restoring normal or near-normal functional capacities or teaching alternative strategies to help them function at a high level despite their disability. A multidisciplinary team of physical, occupational, and speech therapists, neuropsychologists, and social workers best accomplishes this (see Chapter 54). Ideally the team effort is coordinated by a physiatrist, or a neurologist with special training in rehabilitation. The team should be experienced in TBI rehabilitation and thoroughly understand the special needs of this group of patients. Programs that focus exclusively on TBI rehabilitation are far preferable to those that attempt to mix patients with TBI with patients suffering from stroke, neurodegenerative diseases, or tumors because the age groups affected are very different, as are the rehabilitative needs of these groups.

Rehabilitation of patients with TBI should begin in the ICU in the first few days after injury, with early consultation of the neurorehabilitation specialist and passive rangc-of-motion exercises of the extremities. Early mobilization of these patients helps prevent DVT formation, and there is evidence that early sitting of comatose patients may hasten return of consciousness. Administration of central neurostimulant medications as a supplement to physical therapy is being investigated for those with more severe injuries and minimal responsiveness (Meythaler et al. 2002). There obviously are many other critical aspects of TBI rehabilitation that are important for optimizing outcomes for these patients, but a thorough review is beyond the scope of this chapter.

PROGNOSIS

The early prediction of outcome after TBI can help guide acute and chronic care and help prepare family members for what is typically a prolonged recovery process. Just as importantly, further therapy may be determined to be futile, and expensive critical care or surgery can be reserved for those who are likely to benefit. It is obviously important that the early prediction of outcome be reliable, especially in cases in which life support withdrawal is considered. Several clinical and radiological characteristics have proven to be useful for outcome prediction, but they must be used in concert. Even with the use of these characteristics, prediction of death or vegetative survival is much more feasible than the accurate prediction of mild or no future disability and complete return to normalcy. The most powerful outcome predictors are age, initial GCS (particularly the moror component), pupil size and reaction to light, ICP, and the nature and extent of intracranial injuries. Age is perhaps the most important factor limiting good outcomes after TBI. In the Traumatic Coma Data Bank (TCDB) study of more than a thousand patients with severe TBI, the likelihood of death, persistent vegetative state, or severe disability was 92% for those older than 60 years, 86% for those older than 56, and 50% for younger patients. The older patients had a higher incidence of traumatic intracranial mass lesions, midline shift, and SAH, and the presence of these brain injuries was strongly correlated with poor outcomes. Subsequent studies confirm that the likelihood of a good recovery for patients over age 60 who present with a GCS score of 8 or less is very low.

The second most important predictor of outcome is the initial postresuscitation GCS score. Among the 746 patients with severe closed head injuries in the Traumaric Coma Data Bank study, good outcomes were observed in only 4.1% of those with an initial GCS of 3, 6.3% if their initial GCS was 4, and 12.2% if their initial GCS was 5. Again, subsequent clinical studies confirm a strong direct correlation between the initial GCS and likelihood of a good

outcome. The presence of unilateral or bilateral dilated pupils unrcactive to light also is important for outcome prediction, usually because it reflects uncal herniation and significant compression and damage of the brainstem. In several large clinical series, patients with bilaterally fixed and dilated pupils had a greater rlian 4JO"•:> likelihood of death or vegetative survival. Intracranial hypertension refractory to medical management is associated with a 43% mortality rate and 0% chance of a functional outcome.

The effect of the type and size of post-traumatic intracranial lesions on outcome has been analyzed in terms of both the specific lesions and CT-defined characteristics of the mass effect of these lesions. Subdural hematomas are associated with the worst prognosis, and in one study only 26% of patients with these clots had a functional recovery. Prognosis for those with subdural hematomas is related to the time it takes to evacuate the clot, however, and Seelig et al. observed a lower mortality in comatose patients with TBI who had operative decompression within 2 hours of injury compared with those who had surgery 6 or more hours after their injury (30% and 90%, respectively). The mortality for patients with epidural hematomas is much lower and usually results from *a* delay in the diagnosis and treatment of these lesions. The reason for the much better prognosis in those with an epidural hematoma compared with those with a subdural hematoma is that epidural hematomas usually are not associated with underlying cerebral contusions or swelling, whereas subdural hematomas often are. If left untreated, however, epidural hematomas can cause uncal herniation and death. One study found that the mortality rate increased from 17% to 65% if it took 2 or more hours to evacuate an epidural hematoma after onset of coma. Traumatic SAH also has been associated with 50% higher mortality than in patients with TBI who did not have SAH (Greene et al. 1996; Servadei et al. 2002). But the link between traumatic SAH and worse outcomes is controversial, and many believe that traumatic SAH is simply an indication of a more severe TBI and not directly responsible for outcomes.

Marshall et a), developed a CT-bascd classification scheme emphasizing the mass effect caused by post-traumatic intracranial lesions that has proven useful for outcome prediction when applied to the patients in the Traumatic Coma Data Bank (Marshall et al. 1991; Tables 56B.4 and 56B.5). As might be expected, those with large intracranial mass lesions and uncal herniation were found to have the worst outcomes. Based on these studies, one can say with certainty that an 80-ycar-old patient who presents with bilaterally fixed and dilated pupils, a CCS score of 3-4, and a large subdural hematoma will not have a functional outcome regardless of treatment. However, young patients with a higher GCS have a much better prognosis, and aggressive surgical and medical management usually is warranted.

Tabic 56B.4: Computed tomography (CT) classification of traumatic brain injury

Category	*Definition*
Diffuse injury I (no visible pathology)	No visible intracranial pathology seen on CT
Diffuse injury II	Cisterns are present with midline shift 0-5 mm; no high-density lesion >25 cc
Diffuse injury III (swelling)	Cisterns compressed or absent with midline shift 0-5 mm; no high-density lesion >25 cc
Diffuse injury IV (shift)	Midline shift >5 mm; no high-densiry lesion >25 cc
Evacuated mass lesion	Any lesion surgically evacuated
Nonevacuated mass lesion	High-density lesion >25 cc; not surgically evacuated

PENETRATING HEAD TRAUMA

The most common cause of penetrating head injury is gunshot wounds. While the incidence of TBI caused by MVCs appears to be declining, probably as a result of increased use of passive restraint systems, the incidence of gunshot wounds to the head is increasing. From 1984 to 1992 the TBI death rate from MVCs declined by 25%, but the fire arm-re I a ted death rate increased by 13% (Sosin, Sme/ek, and Waxwcilcr 1995). In fact, in 1990 the number of firearm-re I a ted deaths surpassed MVCs as the single largest cause of death related to TBI.

Gunshot wounds to the head usually cause massive brain tissue destruction, severe brain swelling, and death. The wounding potential of a bullet depends primarily on its velocity at impact and its mass, although the shape of the

bullet and its lateral movements at impact also play a role. The relationship of bullet mass and velocity to the energy imparted to the head is described by the equation KE = j MV , where KE = kinetic energy, M = mass of the bullet, and V —impact velocity of the bullet. According to this equation the impact velocity is by far the most important determinant of the wounding potential of the bullet. It explains why high-velocity rifle wounds to the head are uniformly fatal, whereas low-velocity open-chambered handgun wounds often arc not. Once the bullet enters the skull it creates a variety of pressure waves in the brain, some of which can cause tissue pressures of nearly 100 atm, and these pressure waves produce more tissue injury. In addition to forward velocity, lateral motion of the bullet before and after impact also contributes to the severity of tissue destruction. Such motion is described as yaw, or the angle between the path of flight of the bullet and its long axis and precession and nutation, which arc circular rotations of the bullet around the center of its mass. These movements increase the bullet's relative surface area at the point of impact and allow it to pass more of its KE to the surrounding tissue. They increase the size of the entrance wound and cause greater cavitational injury. Bullets often fragment after impact with the skull and fracture a portion of tin- skull into multiple fragments. Both the bullet and bone fragments then become numerous secondary missiles that cause further tissue damage.

Low-velocity missile wounds, such as those caused by knives, ice picks, or arrows, do not cause the massive brain injuries seen with bullets, as might be predicted by the KE equation. Typically the only tissue damaged is that which lies in the immediate path of the missile, and complete neurological recovery after surgical extraction of the missile is not uncommon. Rarely, the missile damages a major intracranial artery or venous sinus, and these vascular injuries can result in large intracranial hematomas. Vascular injuries should always be considered in high- or low-velocity missile injuries to the head, especially those located near or in the base of the skull or the sylvian fissures.

The initial assessment and resuscitation of patients with penetrating head injuries is the same as for those with closed head injuries and is described in derail earlier in this chapter. Prompt and aggressive cardiopulmonary resuscitation is critical. Knives or other missiles protruding from the head should never be removed in the field or emergency department because they may be tamponading a damaged intracranial vessel, and removal could lead to intracranial hemorrhage. If there is a gunshot wound to the head, the neck, chest, and abdomen should be inspected carefully to ensure that there are no other gunshot wounds because wounds to the heart or great vessels in the chest or abdomen may be even more life threatening. A posrrcsuscitation GCS should always be obtained early after injury because it will guide future therapeutic decision making, A CT scan of the head defines the intracranial path of the missile and related skull and tissue damage (Figure 56B.11), but more importantly it identifies any large intracranial hematomas or contusions that, in some cases at least, may significantly contribute to outcome and should be evacuated rapidly. Cerebral angiography should be obtained if the missile trajectory is in or near the skull base or sylvian fissures, assuming the patient is deemed salvageable.

Most patients who are not thought to have lethal brain injuries need at least limited surgical management for their penetrating head injuries. Large intracranial hematomas should be evacuated quickly. Those with low-velocity

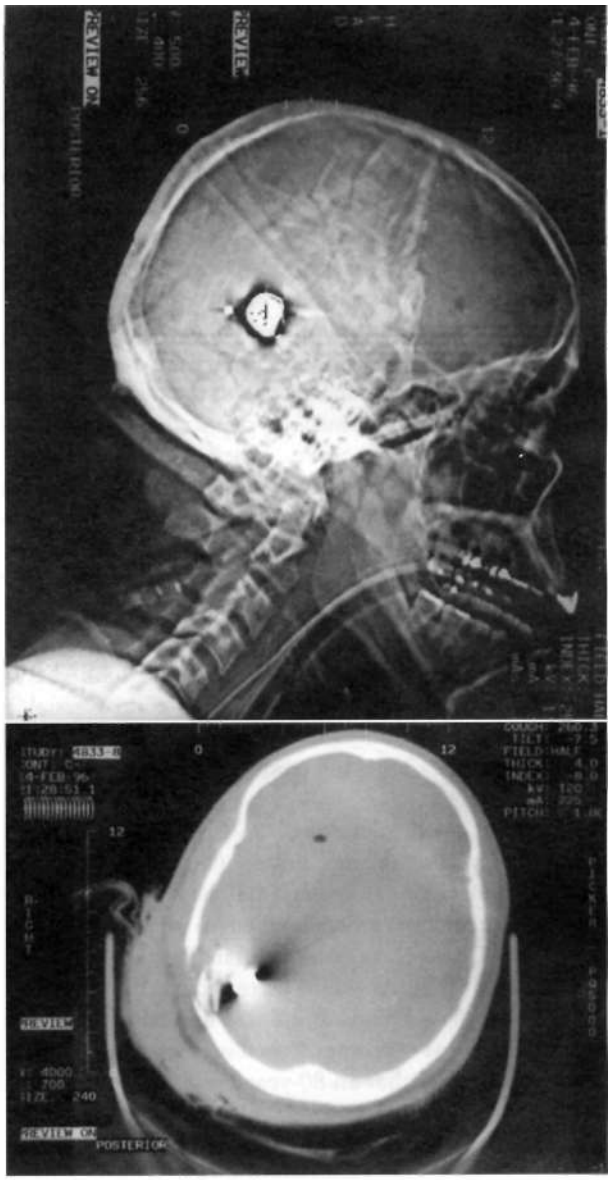

FIGURE 56B.11 (A) Scout view of bullet penetrating right parietal skull. (B) Axial computed tomographic view of same bullet.

missile wounds in which the object is still protruding from the head also should undergo a formal craniotomy. At surgery a segment of skull containing the missile, large enough to allow intracerebral exploration, is removed. The surgeon is then prepared to search for and immediately repair or occlude vascular injuries that may have been caused by the missile. Patients with gunshot wounds to the head should undergo a limited debridement of the scalp and skull wound. Scalp, bone, and bullet fragments penetrating the brain should bo removed only it rhey lie near the surface. Easily accessible necrotic brain is debrided, and meticulous hemostasis is achieved. Dura! closure is important because it reduces the risk of CSF leak and infection hut usually necessitates the use of a pericranial graft. The use of artificial dura! substitutes or allografts is not recommended because of the risk of infection.

Subsequent medical management of penetrating injuries is as described earlier in this chapter for patients with closed injuries. In addition, prophylactic antibiotics should be administered for at least 14 days because the missile usually carries skin and hair into the brain. By definition, all these patients have disruption and contusion of btain tissue and therefore should be treated with anticonvulsants.

The catly prediction of outcome and determination of salvageability are far less ambiguous for patients with penetrating injuries than for those with closed head injuries. The majority of those with gunshot wounds to the head die before or shortly after admission to the hospital. In one sctics of 314 patients with civilian craniocerebral gunshot wounds, the mortality rate was 92%, with 73% of that group pronounced dead at the scene of the injury and 12% dying within 3 hours of injury (Siccardi et al. 1991). The mortality tare among the 151 patients with gunshot wounds to the head that were entered into the Traumatic Coma Data Bank was 88%. No patient with an initial GCS of 8 or less achieved a normal neurological outcome, and only three recovered to the level of moderate disability, suggesting that the initial GCS score is an even more powerful predictor of outcome for these patients than it is fot those with closed TBI. In a meta-analysis of tecent clinical reports of civilian gunshot wounds to the head, only 5 of 490 patients with an initial GCS of 3-5 had favorable outcomes. The mortality rate was 51-87% for patients with GCS score of 8 or less and an unfavorable outcome rate of 61-94%. However, those who had an initial GCS score of 13-15 all survived and had a favorable outcome (Glasgow Outcome Scale of 4 or 5; Table 56B.6).

The extent of intracranial injury caused by the missile, as determined by CT scans, also has prognostic significance. CT findings of hypctdense lesions grcatct than 15 mL in volume, a midline shift of greater than 3 mm, compressed or absent basal cisterns, SAH, and intraventricular hemorrhage, as well as a bullet trajectory that traverses both hemisphctcs, the basal ganglia, or the posterior fossa, all are associated with mortality rates ranging from 80-90%. Additional clinical signs associated with death or poor outcome include fixed and dilated pupils, intracranial hypertension, and hypotension. Also, death is more likely if the gunshot wound is self-inflicted than if it is not.

MILD AND MODERATE BRAIN INJURY

Patients with a mild TBI have an initial GCS score of 14-15, and those with a modetate injury have a GCS score of 9-13. These injuries, often called concussions, typically involve a brief period of loss of consciousness at the time of impact to the head and some degtee of retrograde or post-traumatic amnesia. However, at the time of medical evaluation all of these patients are able to follow commands. Most patients with mild or moderate TBI do not have the complex intracranial pathology associated with severe TBI and thetefore have a very low likelihood of dying from their injury. However, the cognitive and neuropsychological injuries they may sustain ate magnified by the fact that of the estimated 220 victims of TBI per 100,000 population per year in the United States, 90%, or approximately 450,000, have mild or moderate injuries (Kraus and McArthur 1996). Although the mortality fate for those with mild injuries is nearly zero and for those with moderate injuries is approximately 4%, as many as 10% of those with mild injuties and 66% of those with modetate TBI have prolonged or permanent disabilities such that they ate unable to tetutn to work ot school.

Rotational acceleration and deceleration are common causes of these injuries, particularly those that cause loss of consciousness. However, the impact usually is not

Tabic 56B.6: Glasgow outcome scale

Unfavorable outcomes			*Favorable outcomes*	
1	*2*	*3*	*4*	*S*
Death Loss of life due to head injury	Persistent vegetative state Unresponsive, + steep cycles, + eye opening	Severe disability Conscious but disabled, dependent for daily care	Moderate disability Disabled but independent, able to care for self	Good recovery Resumes normal lite. minor residual deficits

severe enough to cause intracranial hematomas, cerebral contusions, skull fractures, or brain swelling. A small amount of traumatic SAH may be seen, usually in the sulci over the frontal ot temporal lobes. Most often, however, the CT scans are normal. Abnormal magnetic resonance imaging findings have been reported in as many as 30% of these patients, with diffuse hyperdense lesions on T2-weighted images the most common findings. These lesions are thought to represent focal or punctate contusions. Abnormal activation patterns often are identified with functional magnetic tcsonance imaging studies and are most common when there has been loss of consciousness or when the patient is symptomatic at the time of study.

The level of medical evaluation and management appropriate for patients with mild ot moderate injuries depends on several factors. Medical personnel should carefully evaluate any patient who lost consciousness at the time of impact ot has several minutes or more of retrograde or antegrade amnesia. Those with persistent headaches, confusion, dizziness or diplopia, or persistent weakness or numbness also should undergo a thorough medical assessment. Most of these patients benefit from a fotmal evaluation in the emergency department. If the patient is found to be n euro logically normal and asympto-matic after 1 hour or more of observation and serial evaluations, he or she usually can be safely discharged with careful instructions to return immediately if symptoms or signs of TBI develop. Ideally, the instructions are given both to the patient and a family member. Those with persistent symptoms or neurological deficits should have a CT scan of the head and be admitted to the hospital for observation. This is particularly important for those with a GCS score of 13 or less because the risk of an intracranial hematoma or contusion large enough to necessitate emergent craniotomy incteases as the GCS decreases. Of those with an initial GCS score of 9-13, as many as 40% have abnormal CT scans, and 8% need neurosurgical intervention (Stein and Ross 1992).

Athletes, particularly those involved in contact sporrs such as boxing, football, soccer, wrestling, and field hockey, are at high risk of mild and moderate TBI. In one recent report the incidence of concussion was estimated at 40,000 per year among high school football players (Powell and Bnrber-P'oss 1999). Multiple concussions, especially if they are sustained in a short period, are much more likely to cause prolonged or permanent neurological disability than a single concussion, and athletes also are at greater risk for multiple concussions. Second impact syndrome is a rare but potentially lethal problem and has been implicated as the cause of sudden death in several high school football players (Saunders and Harbaugh 1984). Because of these disabling and potentially life-threatening consequences of sports-re I a ted concussion, coaches and athletic trainers must carefully consider the advisability of return to play or retirement from athletic competition for each athlete immediately after a concussion. Several groups have devised concussion grading scales to be used to evaluate the severity of a concussion and have used these scales to develop guidelines for determining when an athlete can safely return to play. The most widely adopted scales are those developed by Jim Kelly at the University of Colotado (Colorado Guidelines; Kelly et al. 1991), Robert Cantu (Cantu Guidelines; Cantu 1998), and the American Academy of Neurology (AAN Guidelines; Goodman and Gactz 2002; Tables 56B.7 and 56B.8). In addition, most authorities recommend that the athlete be retired from play for at least one season if he or she sustains three or more grade I or II concussions during a season or two grade 111 concussions. Many athletic organizations at the high school, college, and professional levels also have adopted neuropsychological testing as a means of objectively evaluating the cognitive and neuropsychological conse-quences of each concussion (Maroon et al. 2002). When compared with preseason scores, such tests can provide a powerful tool for use in determining who should return to play and who should retire from the sport.

A common sequela of mild or moderate TBI is postconcussive syndrome, a constellation of symptoms that can be very disabling weeks or even months after the injury. The most common symptoms are headache, irritability, dizziness, tinnitus, lethargy, and sleep distur-bances (Ingebrigtsen et al. 1998). Approximately 30% of

Table 56R.7: Grading scales for concussion

	Grade of concussion		
Name of scale	*1*	*11*	***in***
Colorado (Kelly et al. 1991)	Confusion, no LOC, PTA <30 min	IOC o min, confusion, PTA >30 min	LOC >*S* min, PTA >24 hr
Cantu (199S)	PTA <30 min, no LOC	LOC <5 min, PTA 30 min-24 fir	LOC >5 min, PTA >24 hr
American Academy of Neurology (Goodman and Gaetz 2002)	Transient confusion, symptoms <15 min, no LOC	No LOC, transient confusion, symptoms >15 min	Any LOC

LOC = loss of consciousness; PTA = post-trauma tic amnesia.

Tabic 56B.8: Recommendations for return to play

Grade of concussion	*Colorado guidelines (Kelly et al. 1991)*	*Cantu guidelines (Cantu 1998)*	*American Academy of Neurology Guidelines (Goodman and Gaetz 2002)*
I	Return after 20 mm if norms I examination	Return the same day if normal at rest and exertion and after 7 days if symptomatic	Return the same day if normal at rest and exertion
II	Rmini alter 7 days if asymptomatic	Return after 2 wk if asymptomatic at rest and exertion for 7 days	Return after 7 days if asymptomatic
III	Evaluation by neurologist or neurosurgeon, return .liter *2* wk it asymptomatic and cleared by specialist	Return after 1 month if asymptomatic at rest and exertion for 7 days	Evaluation by neurologist or neurosurgeon; return after 2 wk if neurologieally cleared

patients with mild or moderate injuries have one or more of these symptoms 1 week after their injury, but they usually subside within 3 months (Levin et al. 1992). Only about 7% of patients still report residual symptoms after I year, and the most common is persistent headache. Postconcussive syndrome is best treated by primary care physicians or neuropsychologists, who thoroughly understand the syndrome. Cognitive testing is recommended for those who have symproms that last more than a few weeks because symptoms such as frustration and irritability often are linked to a cognitive inability to resume normal daily activities. If specific deficits are identified, cognitive rehabilitation is recommended. Persistent headaches, dizziness, and tinnitus are treated symptomatically after a head CT establishes that there are no intracranial lesions. Post-traumatic disturbances of the ossicles of the inner car semicircular canals can cause severe positional vertigo, and patients with vertigo or tinnitus often arc referred for evaluation by an otolaryngologist. Factors associated with an adverse long-term outcome after concussion include old age (Katz and Alexander 1994), long duration of post-traumatic amnesia (Lishman 1968), and a reduced premorbid intellectual capacity.

Chapter 56
Trauma of the Nervous System

C. SPINAL CORD TRAUMA

Paul Santiago and Richard G. Fessler

Spinal cord injury (SCI), both in the acute and the delayed setting, is one of the most common clinical entities encountered by the neurologist and neurosurgeon. SCI often results in permanent neurological deficit and, depending on the level of injury, may leave the patient severely disabled. Delayed ot missed diagnosis, poot initial management, comorbidity, and age can significantly affect outcome. Early diagnosis, early stabilization of spinal fractures, aggressive management of comorbid disease, and multidisciplinary rehabilitation have increased sutvival rates and quality of life for these patients. Ttiage, management, and prognostication depend on a thorough understanding of the mechanism of injury, clinical examination, and diagnostic studies.

EPIDEMIOLOGY

Approximately 11,000 new cases of SCI are reported yearly in the United States (approximately 40 cases per million people). The incidence ranges from 11.5 to 53.4 cases per million people in developed countries across the world. These figures do not include patients who die at the time of injuty. About 1 in 40 patients admitted to a trauma centet has an SCI (Kraus et al. 1975; Kraus 1978; Fine et al. 1979; Woodruff and Baron 1994). SCI is also commonly associated with spinal injury. However, the majority of injuries to the spinal column occur without associated neurological deficit. Approximately 25% of patients with SCI have an associated head injury (Tator et a!. 1993), and 50% of patients with head injuries have an associated SCI, making it important that patients with SCI be treated in polytrauma units. Males make up approximately 85% of patients with SCI, and nearly 70% of patients with SCI are under the age of 40 (Table 56C.1; Tator et al. 1993). For patients sutviving to reach the hospital, reported mortality ranges from 4,4-16.7% (Tator etal. 1993). The estimated cost of care for patients with SCI in 1990 was estimated to be $4 billion (Tatot et al. 1993).

Roughly 55% of SCIs occur in the cervical region, with the remainder being evenly distributed in the thoracic, lumbar, and sacral regions. Thoracic spine injuries have been shown ro have a higher rare of complete SCI than injuries of the cervical and thoracolumbar spine. Recovery

Table 56C.1: Demographics of acute spinal cord injury

Source: Modified from Tator, C. H., Duncan, E. G,, Edmonds, V. E., et al. 1993, "Changes in the epidemiology of acute spinal cord injury from 1947 to 1981," *Surg Neuro!,* vol. 40, pp. 207-215.

from complete injuries is mote likely in cervical spine injuries and poorest in thoracolumbar injuries. In all cases, the degree of permanent impairment directly correlates with extent of injury at admission.

The causes of SCI injury vary greatly between countries and even between age gtoups in a particular country. In developed countries traffic accidents and high-risk sports (e.g., rock climbing, surfing, and diving) have replaced work-related accidents as the leading cause of SCI. For example, diving results in approximately 1000 SCIs per year in the United States, with a 95% rate of quadriplcgia. Of note, alcohol has been implicated as a factor in as many as 25% of SCIs in the United States (Tatot et al. 1993). Increased awareness of the risk of SCI has significantly decreased the frequency of SCI at the workplace. Regional differences exist, however; SCI is particularly common in regions where high-risk occupations such as mining and logging are practiced. As the spine ages, it becomes more brittle and calcified, thereby increasing the chance that a fall will cause spinal fracture and SCI. Falls are the number-one cause of SCI among older adults. Violence, particularly gun-related violence, has become a much more common cause of SCI in the last two decades. Some authots report violence as the most common cause of SCI in certain parts of the United States (Sutherland 1993).

Iatrogenic SCI should be noted as a significant but often unrecognized cause of SCI. It is estimated that approximately 15% of patients with SCI worsen neurologically during the period immediately after admission to the hospital. A portion of these deteriorations may result from missed or poorly managed spinal injuries. Every patient possibly at risk for SCI should be treated as having an unstable spine injury until proven otherwise. In a patient with altered mental status this may not be easy in the acute phase. Workup should include a detailed physical examination and dynamic testing to rule out ligamentous injury, when indicated.

GRADING OF SPINAL CORD INJURY

Initial management of the patient with SCI includes not only a thorough neurological examination but also an accurate description of this examination in a standardized fashion. The currently adopted standard in the United States and most developed countries is the American Spinal Injury Association/International Medical Society of Pataplegia (ASIA/IMSOP) scale (Table 56C.2) in conjunction with the Medical Rcscatch Council muscle grading system (Table 56C.3; 1986). Several points should be made. These are not continuous scales, and there is a significant functional jump between grades. Secondly, muscle strength should be assessed on full range of motion across the affected joint, F'xaminers tend to grade patients on strength through partial range of motion, which results in some patients being given a motor scote that is too high. This i> a common source of confusion. Finally, the "+" and "-" subjective qualifiers are applied only to grade 4. The standard is to test 10 myotomes and 28 dermatomes bilaterally (Figure 56C.1). It is unfortunate that testing of the sacral dermatomes and myotomes (sensation at the anal mucocutaneous junction, deep anal sensation, and voluntary contraction of the anal sphincter) often is left to the most junior member of the team. Preservation of the sacral roots, or sacral sparing, has been associated with better outcome. The presence of sacral sparing has also been used as an indication fot emergent spinal decompression. The indication for emergent surgical decompression of incomplete traumatic SCI remains highly controversial.

Table 56C.2: ASIA/IMSOP impairment scale

Grade A	Complete	No motor or sensory function is preserved in the sacral segments S4-S5.
Grade B	Incomplete	Sensory but not motor function is preserved below the neurological level and extends through the sacral segments S4—S5.
Grade C	Incomplete	Motor function is preserved below the neurological level, and the majority of key muscles below the neurological level have a muscle grade <3.
Grade D	Incomplete	Motor function is preserved below the neurological level, and the majority of key muscles below the neurological level have a muscle grade >3.
Grade H	Normal	Minor and sensory functions are normal,

The term *spina! cord level* is used to establish the functional level of injury in patients with SCI, The stricrcst definition of SCI level is based on the ASIA/IMSOP scales, in which sensory and motor levels are reported for both sides of the body, along with zones of partial preservation. The spinal cord level is defined as the caudalmost segment of the spinal cord demonstrating normal function. In practice, it is more common to report the level at which normal motor and sensory function exist on both sides of the body or to report rhc level at which motor function is graded at 3/5 or better. Ffficient communication requires that all parties use the same system. Because the spinal cord is shorter than the spinal column, there is often a significant disparity between the spinal cord and skeletal levels of injury.

Complete SCIs are injuries that meet the criteria for the ASIA/IMSOP scale grade A injury. Because there is often a zone of partial preservation below the lowest level considered normal, the definition includes patients with complete absence of normal motor and sensory function starting four levels below the caudalmost normal level. Incomplete injuries make up grades B, C, and D.

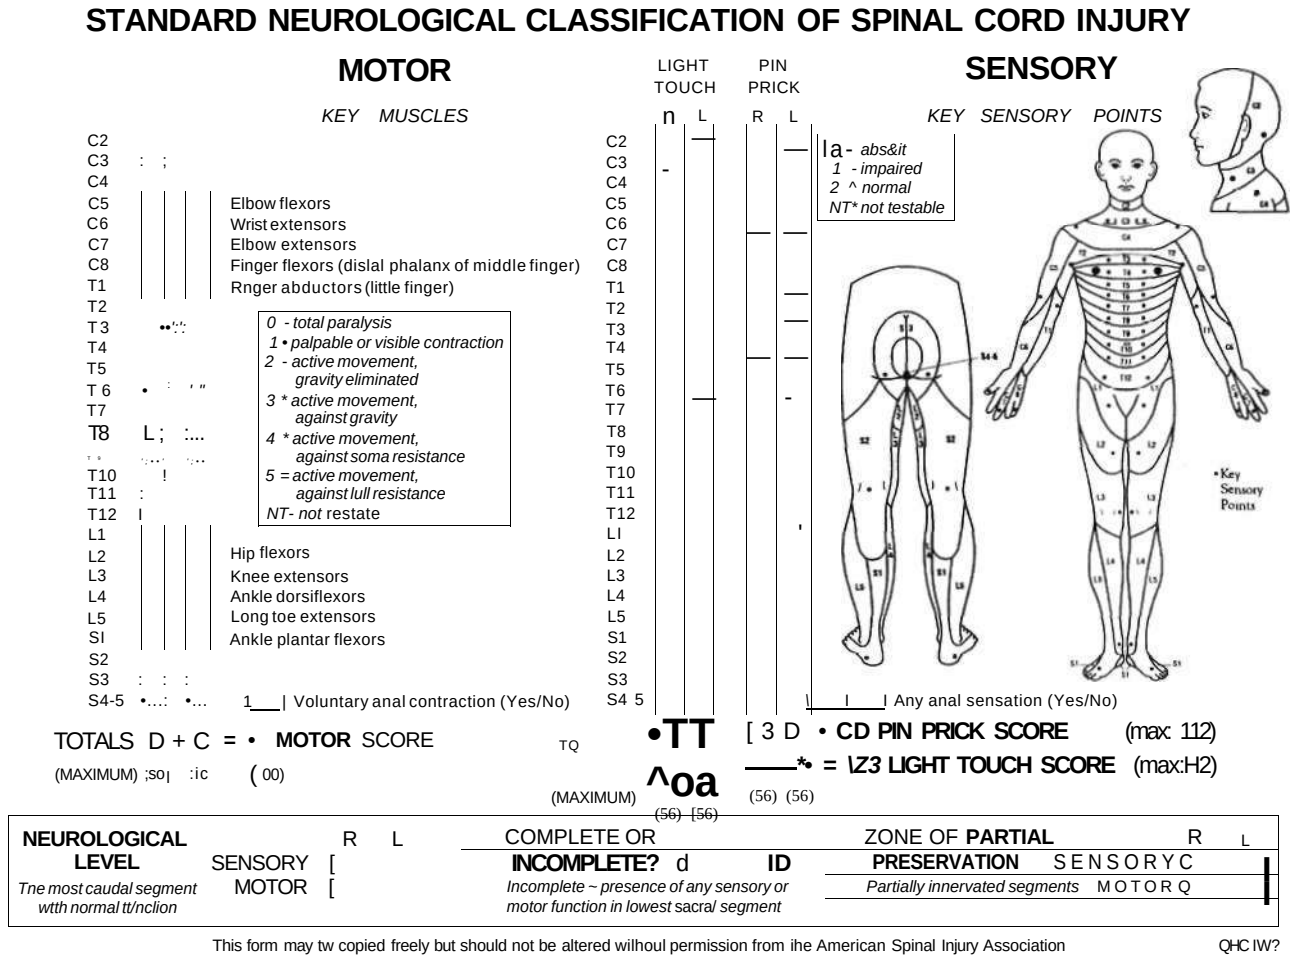

FIGURE 56C1 Template summarizing the spinal examination suggested by the American Spinal Injury Association (ASIA) and the International Medical Society of Paraplegia (IMSOP). This diagram contains the principal information about motor, sensory, and sphincter function necessary for accurate classification and scoring of acute spinal cord injuries. The 10 key muscles to be rested for the motor examination are shown on the left, along with the Medical Research Council grading system. The 28 dermatomes to be tested on each side for the sensory examination are shown on the right. The system for recording the neurological level, the completeness of the injury, and the zone of partial preservation (in complete injuries) is shown at the bottom. (Reprinted with permission.)

SPECTRUM OF DISEASE

SCI represents a spectrum of disease, not all of which is permanent. At one end of the spectrum are disorders such as "stingers" and transient paraplegia, most often encountered in young athletes, which represent self-limited injury to the spinal cord and nerve roots. In the middle of this spectrum are disorders such as the progressive myelopathy associated with severe cervical spinal stenosis and chronic progressive conditions with an insidious onset whose course can be arrested. At the other end of the spectrum are the disorders associated with immediate irreversible paralysis such as spinal cord transection and vascular injury. An understanding of the underlying pathophysiology of each condition is needed for a diagnosis and determination of the timing and course of treatment. Clearly, the evaluation and treatment of an otherwise healthy 18-year-old football player who presents with weak arms and legs after a tackle is different than that of a 78-yeat-old ex-miner who presents with the progressive lower extremity weakness. In the former case workup may reveal an acutely herniated disc compressing the spinal cord, an indication for emergent surgical decompression, with the hope of retutn of function. In the latter case, the presence of severe cervical stenosis, a chronic process, does not necessitate emergent intctvention. Rathet, a thorough discussion of the risks and benefits of surgical intervention is indicated. Surgical intervention in this case most often is aimed at preventing futthet loss of function rather than at improvement and carries a small risk of detetioration in level of function.

SCI is most often seen in the setting of pte-existing injury, even in young adults (Table 56C.4). The most common disorder associated with SCI is cervical spondylosis; studies have documented a prevalence of 10% cervical spondylosis among patients with SCI (Tator et al. 1993). Many of these disorders alter the biomechanics of the spinal column, affecting its ability to beat physiological and unphysiological loads, resulting in SCI when otherwise an SCI might not normally occur. For example, a 20-year-old tripping on the edge of a carpet and striking his forehead most often results in a btuise and some embatrassmenr. A normal spine is able to protect the underlying cervical cord during unphysiological hypcrcxtension of the cervical spine, dispersing the translated forces and cushioning the spinal cord with cctebtospinal fluid (CSF). This is very different from the case of a 20-year-old with Down syndrome and a congenital abnormality of occipital-cctvical junction. In this case, even a minor extension injury may result in a severe SCI because of the associated ligamentous laxity and cctvical stenosis.

Table 56C.4 Most common causes of acute and chronic spinal cord injury in clinical practice

- Trauma

SCI in the setting of multisystem trauma deserves special mention. Only 20% of patients with SCI have isolated SCI, and approximately 20% of patients with SCI have other significant injuries, including ttaumatic brain injury, hemothotax or pneumothorax, extremity fractures, and intra-abdominal injury. These concomitant injuries present a numbct of short- and long-term management challenges. In genera], patients with isolated SCI have a better outcome than those with multiple injutics.

The so-called polytrauma patient often presents to the emergency room sedated, if not intubated and chemically paralyzed. In this setting it is nearly impossible to initially assess and determine a change in neurological function. SCI itself can tesult in hypotension and hypoxia through inrerruption of the autonomic nervous system and paralysis of the respiratory muscles, respectively. Undet sedation and chemical patalysis, the natural splinting mechanism provided by muscular spasm may not be present, and poor management in the field can result in the conversion of a spinal injury into an SCI or a partial SCI into a complete one. Patients needing intubation may have unstable cervical spmc fractures, adding SCI to the risks associated with emergent intubation. Additionally, polytrauma patients can present with hypotension caused by ongoing hemorrhage, decreasing the perfusion pressure to a potentially swollen, injured spinal cord. As with brain injury, prolonged hypoperfusion and hypoxia may be harbingers of poor outcome (Sentet and Venes 1979; Dolan and Tator 1982; Tator 1992, 1996; King, Gupta, and Narayan 2000). The systemic inflammatoty response syndrome associated with polytrauma can make it difficult to maintain tissue pctfusion, and injury to the lung parenchyma and adult respiratory distress syndrome can make it difficult to maintain tissue oxygenation. To further complicate matters, many polytrauma patients with spinal ftactutcs and SCI are unable to withstand the stress of general anesthesia and surgery in the acute setting. This results in the need to delay surgery and mobilization. For this reason, treatment of patients with SCI and polytrauma often entails constant interaction between subspecialties.

The examining physician should also keep in mind that just as polytrauma can have a negative impact on the management of SCI, the reverse is also true. Given that only 20% of patients with SCI present with isolated SCI, the clinician must be vigilant for the presence ot comorbidity,

Hypotension may be the result of occult hemorrhage, cardiac tamponade, or pneumothorax. Hypoventilation may be caused by hemothorax or pneumothorax, chest wall injury, or abdominal distension (abdominal compartment syndrome). These symptoms may be masked by the autonomic collapse and decreased tidal volumes associated with cervical SCI. Cervical and thoracic SCI can result in absence of sensation below the level of injury, delaying the diagnosis of intra-abdominal, pelvic, and extremity injuries, which would otherwise be severely painful. Special care should also be taken in the case of older adults, in whom low-energy collisions, such as falls from standing or **bed,** can produce significant injury. These low-impact events can result in bony fractures and bleeding, particularly in patients receiving anticoagulation therapy. Just as all polytrauma patients should be treated as if they had SCI until proven otherwise, all patients with traumatic SCI should be treated as if they had polytrauma until adequate screening is performed.

MECHANISMS OF TRAUMATIC INJURY

A detailed discussion of individual spinal fractures and dislocations is beyond the scope of this chapter. However, it is important to recognize that different fracture patterns carry different prognoses with respect to SCI.

There is a dramatic difference in the cross-sectional area of the spinal canal occupied by the spinal cord and the subarachnoid space (space available for the cord [SAC|) depending on the region of the spine in question. In the normal state, at the level of the foramen magnum and atlantoaxial unit (C'l/2), the subarachnoid space is large relative to the cross-sectional area of the spinal cord. Therefore most fractures of the occipital condyles, CI, and C2 do not result in SCI. The exception occurs in the case of atlantoaxial dissociation/dislocation (AOD), a predominantly ligamentous injury in which axial traction is applied to the spinal cord. Death is often the result of AOD, but in mild cases bulbar symptoms and patchy long tract findings can occur. The diagnosis often requires magnetic resonance imaging (MRI); surgical intervention is indicated,

In the lower cervical canal, the SAC decreases. Consequently, anterior dislocations and fracture dislocations result in decreased SAC and are more likely to be associated with SCI. Injuries such as laminar fractures (which can actually increase the SAC) and spinous process fractures usually are not associated with SCI. As the SAC reaches a minimum in the thoracic spine, thoracic dislocation and fracture dislocations carry a high risk of SCI.

As the spinal column transitions from the thoracic to the lumbar region, the spinal canal enlarges. At the level of the conus (usually at Ll/2) and lumbosacral enlargement of the spinal cord, a spectrum of injuries can occur, ranging from a ncurologically complete SCI to an isolated sacral root injury. The cauda equina is made up of nerve roots and has a smaller cross-sectional area in a wider spinal canal and therefore is more resistant to injury. It also has a greater potential for recovery after injury than the spinal cord. It is not uncommon to see burst fractures and fracture dislocations in the lumbar spine with greater than 75% canal compromise without associated neurological deficit.

COMPLETE VERSUS INCOMPLETE INJURY

Approximately two thirds of patients currently admitted with acute SCI have incomplete injuries, a significant change from the 1960s, when the majority of patients presented to tertiary care centers with complete injuries. This change has been attributed to a number of factors, including improved recognition and management of SCI in the field, improved treatment at referring hospitals, earlier referral to tertiary care centers, increased automobile and workplace safety, and better recognition of the difference in prognosis between complete and incomplete injuries.

Approximately 1-2% of patients with reportedly complete SCI can become ambulatory. This figure is controversial, with opponents arguing that these patients were wrongly diagnosed and should have been classified as having incomplete injuries. The difficulties associated with the initial diagnosis of SCI are reviewed earlier in this chapter. Alcohol, recreational drugs, sedatives, paralytics, lack of cooperation, and traumatic brain injury can make initial examination difficult. Proponents of the 1-2% recovery rate cite evidence of intact residual nerve fibers on electrophysiological testing of patients with clinically complete lesions ("dis-complete" syndrome; Dimitrijevic, Hsu, and McKay 1992). Given this, some argue for aggressive treatment of all patients with SCI, regardless of whether they are complete or incomplete on initial presentation.

SPINAL SHOCK

Spinal shock is the clinical syndrome often seen in major SCI to the cervical and upper thoracic spinal, characterized by complete loss of somatic motor, somatic sensory, and sympathetic autonomic function. The more severe and higher the SCI, the greater the duration and severity of the spinal shock. Typically, patients suffer from flaccid paralysis, loss of cutaneous and deep tendon reflexes, and anesthesia to all sensory modalities below the level of the inJury. Autonomic dysfunction is characterized by systemic hypotension, cutaneous hyperemia, and bradycardia caused by unopposed vagal tone. The exact mechanism of spinal shock remains unclear. Some propose a vascular event whereby some form of trauma induces hypoperfusion of the spinal cord. Another theory implicates abnormal neurotransmitter effects on impulse conduction.

The major difficulty in clinical practice occurs in the first few hours after SCI, when there is an admixture of the

Tabic 56C.5: Similarities and differences between neurogenic and hypovolemic shock

Neurogenic shock	*Hypovolemic shock*
Hypotension	Hypotension
Bradycardia	Tachycardia
Areflexia	Normal reflexes
Responsive to pressors	Responsive to volume replacement

temporary effects of spinal shock with the pathological, more permanent effects of the SCI. Another problem is the variable duration of spinal shock. In general, the loss of power and sensation that results from spinal shock resolves within I hour after injury. Therefore any weakness or numbness remaining after this time arc likely to indicate physical cord injury rather than spinal shock. The loss of reflexes and autonomic tone may last days to months, depending on the spinal level and severity of the initial injury.

By the time the average patient is evaluated in the field and transferred to a medical center, more than an hour has passed. Spinal shock generally is associated with severe SCI. The exception is the transient quadriplegia seen in athletes playing high-impact sports; in these cases the motor and sensory changes generally show improvement within minutes of symptom onset. If the signs of spinal shock are present, a diagnosis of severe SCI should be assumed and confirmed by diagnostic testing. The rapid changes that can occut within the first 24 hours of an SO underscore the need for frequent and systematic documentation of the neurological examination during that time. These changes also suggest that final prognostication should be delayed until the neurological deficit plateaus.

The clinician should not confuse the signs of spinal shock with those of hypovolemic shock (Table 56C.5). Hypovolemia-induced shock results in hypotension and tachycardia in an attempt to maintain cardiac output, and patients respond to volume repletion. In spinal shock the intravascular volume is normal, but the volume of the intravascular space is increased by loss of vascular tone. Although the heart could partially compensate for this by increasing cardiac output, the presence of unopposed vagotonia inhibits the normal physiological response of tachycardia. As a result, patients with spinal shock respond to sympathomimetic agents (e.g., phenylephrine) better than to volume replacement.

SPINAL CORD INJURY SYNDROMES

Knowledge of the functional organization of the tracts and nuclei that make up the spinal cord is crucial to understanding the effect of SCI at any given level. For several of the described SCI syndromes, however, the anatomical basis of the consequent deficits is poorly understood and the subject of much controversy. Table 56C.6 lists the commonly accepted SCI syndromes. A discussion of their anatomical basis and prognoses follows.

Cervicomedullary Syndrome

This SCI syndrome includes injuries that extend from the medulla to the mid-cervical cord, although injury may extend as far rostral as the pons and as far caudal as the lower cervical cord. The term *bulbar-cervical dissociation pattern* has also been used to describe these injuries. The neurological signs depend on the severity and level of injury. Respiratory arrest, loss of sensation in the C1-C4 dermatomes, quadriplegia, and hypotension damage to the spinal tract of CN V may result in facial numbness with an onionskin or Dejerine pattern of greater involvement posteriorly and perioral sparing or in sensory loss mainly in the brow area, depending on the details of the SCI. In the most extreme cases death can result. Proposed mechanisms of injury include direct stretch injuries (as in cases of atlanto-occipital dissociation), injury to the vertebral arteries, compression of the cord by a ruptured disc or vertebral burst fracture, and displacement of the odontoid peg.

The examination finding of an upper cervical sensory level in combination with facial numbness should lead to the conclusion that the lesion lies at the cervicomedullary junction. The spinal tract of CN V is organized in an onionskin pattern, with the fibers for perioral sensation crossing at the most rostral end of the tract and periauricular sensation at the most caudal end of the tract. Injury to the lower medulla and upper cervical spine results in injury to the most caudal fibers in the spinal tract of CN V, sparing the rostrally placed fibers subserving perioral sensation.

bell's cruciate paralysis should be included in any discussion of SCI at the cervicomedullary junction. This syndrome includes not only signs of the cervicomedullary syndrome but also quadriparesis characterized by arm greater than leg weakness. In the past, this pattern of injury was attributed to compression of the decussating pyramidal tracts in the ventrolateral aspect of the spinal cord at the level of the anterior rim of the foramen magnum and odontoid peg. The motor fibers to the upper extremities were postulated to decussate rostral and ventral to the

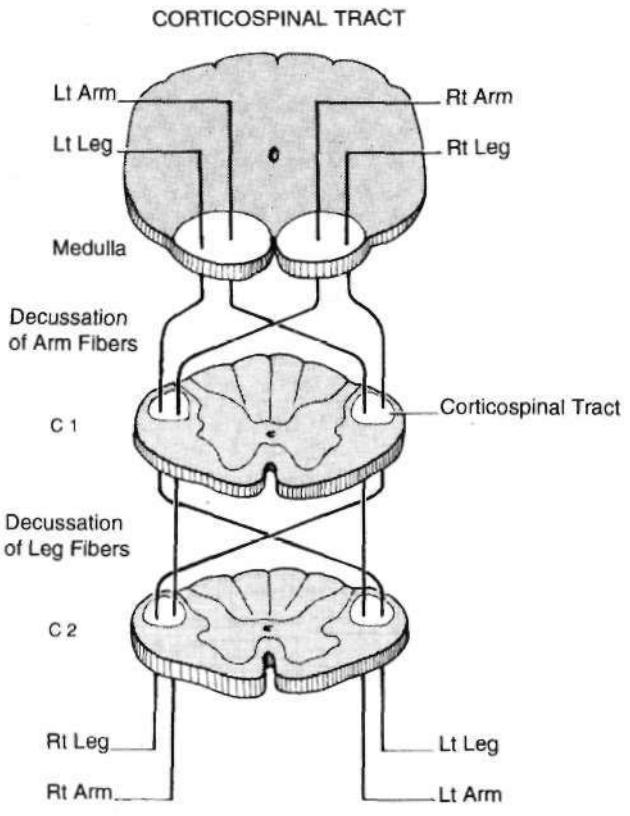

FIGURE 56C.2 The decussation of the axons in the corticospinal tracts. The upper, middle, and lower cross-sections show the medulla, the spinal cord at CI, and the spinal cord at C2, respectively. The axons subserving arm function cross the midline between the medulla and CI, whereas those subserving leg function cross between CI and C2. As noted in the text, recent evidence does not support the lamination concept in the corticospinal tract. (Reprinted with permission from Tator, C. H. 1994, "Classification of spinal cord injury based on neurological presentation," in *Neurotrauma,* eds R.J. Narayan, J. E. Wilberger Jr, & J. T. Povlishock, McGraw-Hill, New York, pp. 1059-1073.)

lower extremity fibers and to descend through the spinal cord in the medial aspect of the lateral corticospinal tracts. The upper-extremity fibers were believed to decussate between the foramen magnum and CI, whereas **the** lower-extremity fibers decussate more caudally between CI and C2. Consequently, the mote ventrally placed upper-extremity fibets would be more susceptible to injury at the level of the foramen magnum than the lower-extremity fibers. (Figure 56C.2 and Figure 56C.3) This anatomy of the injury remains controvetsial. No evidence has been found to support the theory that arm and leg fibers decussate at diffetent levels of the spinal cord. Indeed, there is evidence that the atm and leg fibers are intermingled at the **level of the decussation (Levi,** Tator, and Bunge 1996). Research in nonhuman primates suggests that only upper-extremity fibers may travel in the unctossed ventral corticospinal tracts and that injury of these venttally located ttacts at the level of the foramen magnum may

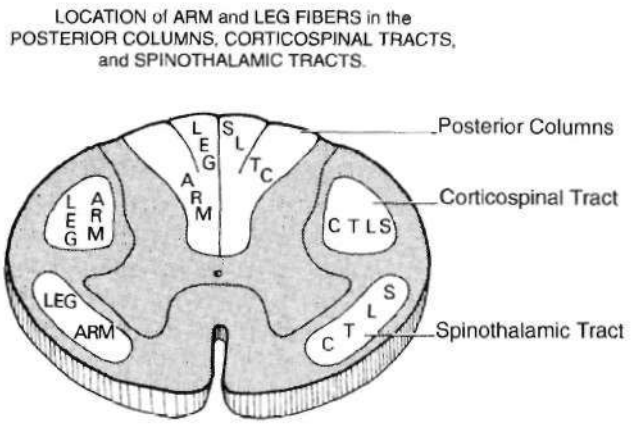

FIGURE 56C.3 Topographic distribution in the posterior columns, corticospinal tract, and spinothalamic tract. The locations of the axons subserving arm and leg function are shown in the three tracrs. Similarly, the locations of the axons subserving sacral (S), lumbar (L), thoracic (T), and cervical (C) function in the three tracrs are indicated. (Reprinted with permission from Tator, C. H. 1994, "Classification of spinal cord injury based on neurological presentation," in *Ncurotrauma,* eds R. J. Narayan, J. E. Wilberger Jr, & J. T. Povlishock, McGraw-Hill, New York, pp. 1059-1073.)

explain the ptefctential arm weakness seen in this syndrome. The prognosis for recovery usually is good.

Acute Central Cord Syndrome

Originally described by Schneider (1954), this SCI syndrome is characterized by arm greater than leg weakness, patchy sensory loss, dysesthesias, and areflexia. The injury is generally in the midcervical to lower cervical spine. Differentiating between an acute central cord syndrome and cruciate paralysis on clinical examination alone can be difficult. Computed tomography (CT) and MRI scanning have largely eliminated this difficulty, although the presence of cranial nerve abnormalities usually rules out an isolated central cord syndrome (Table 56C.7). The syndrome is commonly seen in cervical injuries in older adults with cervical spondylosis. The classic presentation is of an older adult with bruising of the forehead and quadriparesis caused by a fall forward, causing hyperextension of the neck. Schneider and colleagues hypothesised that during hypercxtension the cervical spinal cord in these patients is trapped anteriorly by an ostcophyric bar and posteriorly by hypertrophied ligamentum flavum, resulting in central hemaromyelia and necrosis with surrounding edema (Figure 56C.4). His theory was based on the premise that the corticospinal tracts are arranged in a topographic manner, such that the medial fibers subserving arm function are more medially placed than the fibers subserving leg function. As a tesult, in an injury to the central cord, the leg fibers would be injured less than the more centtally placed arm fibers. The anterior hotn cells would

Source: Reprinted with permission from Tator, C. H., Duncan, E. G., Edmonds, V. E., et al. 1993, "Changes in epidemiology of acute spinal cord injury from 1947 to 1981," *Surg Neurol,* vol. 4, pp. 207-215.

also be damaged, resulting in a lower motor neuron (LMN) type of injury. In cases of central cord syndrome without spondylosis or obvious mechanical compression, Schneider later hypothesized that a vascular event involving the central aspect of the spina! cord could result in a similar injury. The anterior spinal, vertebral, and medullary arteries supply the ventral third of the spinal cord. During trauma these arteries can be stretched or transiently-occluded, resulting in ischemic injury to the spinal cord. The dorsal and lateral aspects of the spinal cord are less prone to ischemic injury because the pial mesh, supplied by both the anterior and posterior spinal arteries, serves them.

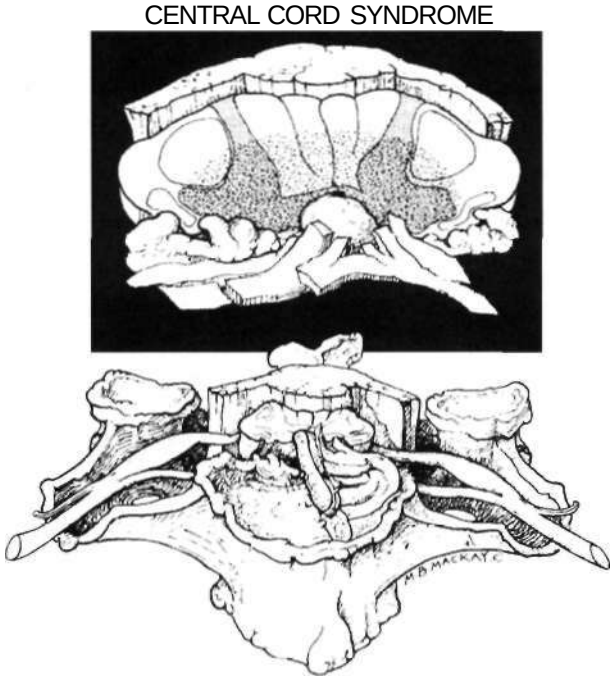

FIGURE 56C.4 Central cord syndrome. The drawing depicts a case of cervical spondylosis with osteoarthritis of the cervical spine, including anterior and posterior osteophytes and hypertrophy of the ligamentum flavum. Superimposed is an acute hyperextension injury that has caused rupture of the intervertebral disc and infolding of the ligamentum flavum. The spinal cord is ciimpressed anteriorly and posteriorly. The central portion of the cord *{rough stippling)* sustained the greatest damage. The damaged area includes the medial segments of the corticospinal tracts presumed to subserve arm function. (Reprinted with permission from Tator, C. H, 1994, "Classification of spinal cord injury based on neurological presentarion," in *Neurotrauma,* eds R. J. Narayan, J. E. Wilberge Jr, & J. T. Povlishock, McGraw-Hill, New York, pp. 1059-1073.)

Schneider's theory remains controversial. Anatomical studies have demonstrated the arm and leg fibers in the corticospinal tracts to be intermingled, as in the pyramidal decussation. More recent work using MRI and limited autopsy data has demonstrated a pattern of injury very different from that proposed by Schneider (Quencer et al. 1992). Both autopsy and MRI failed to demonstrate central cord necrosis or hematomyelia. Rather, the injury appeared to involve predominantly the white matter tracts, with evidence of edema and demyclination of large axons including but not limited to the corticospinal tracts, with little evidence of injury to the central gray matter. In fact, injury appeared to be concentrated along the posterolateral aspect of the cord. A unifying hypothesis explaining the pattern of injury in patients with an acute central cord syndrome docs not currently exist.

Prognosis for patients with acute central cord syndrome is fair. Recovery is rarely complete and depends on the pattern of injury. Patients with evidence of hematomyelia ot cord disruption on MRI have the worst prognosis. Recovery favors the lower extremities over the upper extremities. The upper extremities often are left severely weak and clumsy secondary to severe proprioceptive loss. Overall, 50% of patients with acute central cord syndrome and no evidence of hematomyelia will recover enough lower-extremity function to walk independently. There is no clear evidence that early surgical intervention improves outcome, but prospective, randomized trials are under way. If there is no evidence of bony or gross ligamentous instability, some surgeons place patients in cervical traction for 48-72 hours after injury. Thereafter, the patients are taken out of traction, and further imaging is obtained to

rule out occult instability. Many surgeons currently favor delayed surgery, waiting for the patients to reach the plateau phase of recovery, which usually occurs 6-12 weeks arret injury. Conservative treatment before surgical intervention generally includes the use of a hard cervical collar because it is believed that the swollen cord is more prone to injury from micromotion of the spine at the level of injury. Surgery is then offered to patients with significant spinal cord compression. For patients not considered surgical candidates, the cervical collar usually is discontinued after 12 weeks. Patients who present with gross instability usually are placed in traction and operated on within 48 hours. Emergent surgery is reserved for patients with abnormal alignment of the spinal column refractory to cervical traction and patients with acute disc herniation. The use of corticosteroids in SCI is highly controversial, although many centers favor the use of methylprcdnisolone within the first 8 hours after injury.

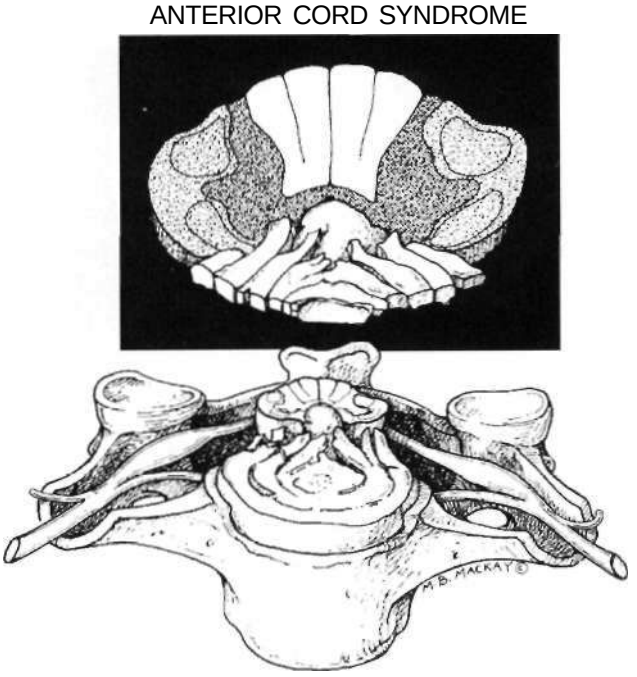

FIGURE 56C.5 Anterior cord syndrome. A large disc herniation is shown compressing the anterior aspect of the cord and resulting in damage *(rough stippling)* to the anterior and lateral white matter tracts and to the gray matter. The posterior columns remain intact. (Reprinted with permission from Tator, C. H. 1994, "Classification of spinal cord injury based on neurological presentation," in *Nettrotrauma,* eds R. J. Narayan, J. E. Wilberger Jr, J. T. Povlishock, McGraw-Hill, New York, pp. 1059-1073.)

Anterior Cord Syndrome

Acute anterior cord syndrome, also originally described by Schneider, is characterized by complete paralysis below and hypalgesia at the level of injury, with preservation of posterior column sensory modalities at and below the lesion. This syndrome may be associated with an anterior spinal artery occlusion or trauma. Typical injuries include large disc herniations and burst fractures with retropulscd bone fragments (Figure 56C.5). Acute surgical intervention usually is performed. Corticosteroid use is controvetsial. Prognosis for recovery of motor function is poor (10-20% recover functional motor control of the limbs), but some return of pain and temperature sensation can be expected.

Posterior Cord Syndrome

Acute posterior cord syndrome may not occur. It has been described as resulting from destruction of the posterior aspect of the cord, sparing the vcntrally placed spinothalamic tracts (Figure 56C.6). Patients with this syndrome can be expected to suffer complete paraplegia wirh loss of proprioception and vibration sense. Pain and temperature sensation and light touch are preserved.

Brown-Sequard Syndrome

A true Brown-Sequard syndrome, in which the patient suffers ipsilateral loss of motor control and posterior column function below the level of injury and contralatetal loss of pain and temperature sensation, usually one to two dermatomes below the level of proprioceptive loss (injury to fibers crossing the midline to join the ascending spinothalamic tract), is rare (Figure 56C.7). This pattern of sensory loss is often called dissociated, that is, with posterior column and spinothalamic tract loss being on opposite sides of the body. Loss of sphincteric function is variable and has a good prognosis for recovery. The mechanism of injury involves damage to one lateral half of the spinal cord, most commonly in the cervical cotd. Partial syndromes and combinations with other SCI syndromes ate common. Evolution from a bilateral complete injury to a Brown-Sequard syndrome has also been described. The causes of this injury are legion. Penetrating ttauma, spinal fracture, spinal dislocation, disc herniation, vasculitis, and radiation-induced injuty are common. The prognosis for recovery is good, with 90% of patients regaining the ability to walk independently.

Conus Mcdullaris Syndrome

Acute conus medullaris syndrome accounts for approximately 25% of all SCIs, These injuries can result in a range of lower-extremity dysfunction, usually with flaccid lower-extremity paralysis and loss of bladder and anal sphincter function. Sensory loss is variable. The anatomical basis of this injury pattern lies in the telationship between the conus

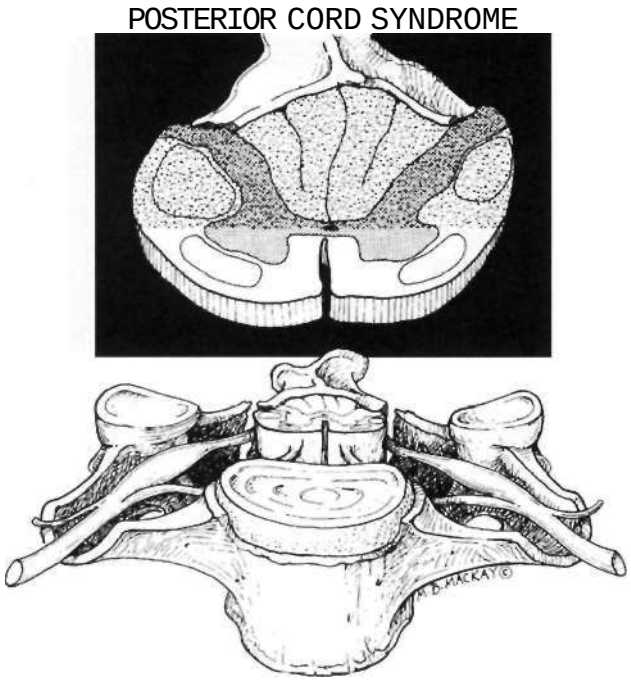

FIGURE 56C.6 Posterior cord syndrome. A laminar fracture is depicted with anterior displacement of the fractured bone and compression of the posterior aspect of the spinal cord. The damaged area of the cord *{rough stipphng)* includes the posterior columns and the posterior half of the lateral columns along with the corticospinal tracts. Povlishock, McGraw-Hill, New York, pp. 1059-1073.)

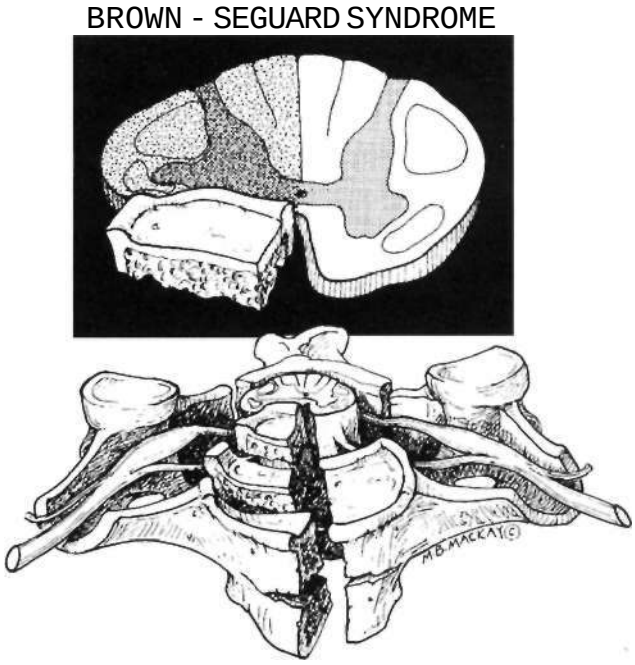

FIGURE 56C.7 Brown-Scquard syndrome. A burst fracture is depicted with posterior displacement of bone fragments and disc, resulting in unilateral compression and damage *(rough Stippling)* to one half of the spinal cord. (Reprinted with permission from Tator, C. H. 1994, "Classification of spinal cord injury hased on neurological presentation," in *Neurotrauma,* eds R. [. Narayan, J. E. Wilbcrgcr Jr, & J. T. Povlishock, McGraw-Hill, New York, pp. 1059-1073.)

medullaris and the thoracolumbar junction. In most patients, the conus lies directly opposite the vertebral bodies of T12 and LI, with the tip of conus not extending past the Ll/2 disc space, Biomechanically, this is a region of high stress, with the spinal column transitioning from the rigid thoracic spine to the more mobile lumbar spine. As a result, flexion-distraction and hurst fractures are common in this region (Figure 56C.8). These injuries produce a combination of upper and lower motor neuron deficits, including muscle atrophy, weakness, spasticity, and the development of a neurogenic bladder. Sensory abnormalities may vary. Recovery is variable. The use of corticosteroids remains controversial.

Cauda Equina Syndrome

The cauda equina normally begins at the level of the Ll/2 disc space, distal to the conus medullaris. This bundle of nerves is composed of the lumbar, sacral, and coccygeal nerve roots from L2 to CO. Injury to the cauda equina obviously is not a true SCI, but nevertheless the cauda equina syndrome is generally considered in the context of SCI. Partial and complete cauda equina syndromes are common. Rapid diagnosis and surgical intervention may improve outcome. The cauda equina is more resistant to injury than is die spinal cord. Typically, patients present with weak or flaccid lower extremities with at least partially preserved sensation. Knee and ankle jerks are absent. Sensory loss usually is asymmetrical and can be radicular, as opposed to the sensory impairments seen in the conus medullaris syndrome, which are more symmetrical. So-called saddle anesthesia is the most common sensory deficit. Saddle anesthesia denotes loss of sensation around the anus, genitals, perineum, buttocks, and posterior-superior thighs. Loss of bowel, bladder, and sexual function is also common. Urinary retention is the most common feature of a cauda equina syndrome; in the absence of urinary retention there is only a 1 in 1000 chance of having a cauda equina syndrome (OT.aoire, Crockard, and Thomas 1981; Kostuik et al. 1986). The cauda equina syndrome can be complete, albeit rarely. Sensory axons are much more resistant to injury than motor axons. The detailed signs depend on the level of the injury. A large, centrally herniated disc at L5/S1 can result in bladder and anal sphincteric dysfunction with associated perianal numbness and little or no other motor or sensory

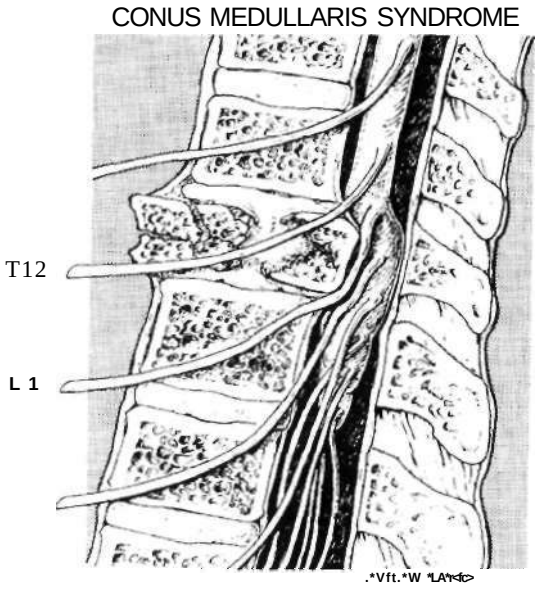

FIGURE 56C.8 Conus medullars syndrome. A burst fracture of T12 is depicted with posterior dislocation of bone fragments from the vertebral body into the spinal canal, resulting in compression of the conns medullars. Almost all the lumbar cord segments arc opposite the TI2 vertebral body, so a severe compression injury at this level could affect all the lumbar and sacral segments of the cord. (Reprinted with permission from Tator, C. H. 1994, "Classification of spinal cord injury based on neurological presentation," in *Neuroirauma,* eds R. J, Narayan, J. R. Wilberger Jr, &). T. Povlishock, McGraw-Hill, New York, pp. 1059-1073.)

dysfunction. Pain in cases of cauda equina syndrome can vary from absent to quite severe. In cases of severe pain, the pain is often asymmetrical and can be radicular.

The most common cause of a cauda equina syndrome is a large, acutely herniated disc (Figure 56C.9). However, absolute disc si?.e does not determine the extent of the cauda equina syndrome because it is possible for patients with underlying lumbar canal stenosis to present with a cauda equina syndrome from a moderately sized disc. Other causes include epidural compression from bony collapse, epidural tumor spread, epidural hematoma, and carcinomatous meningitis.

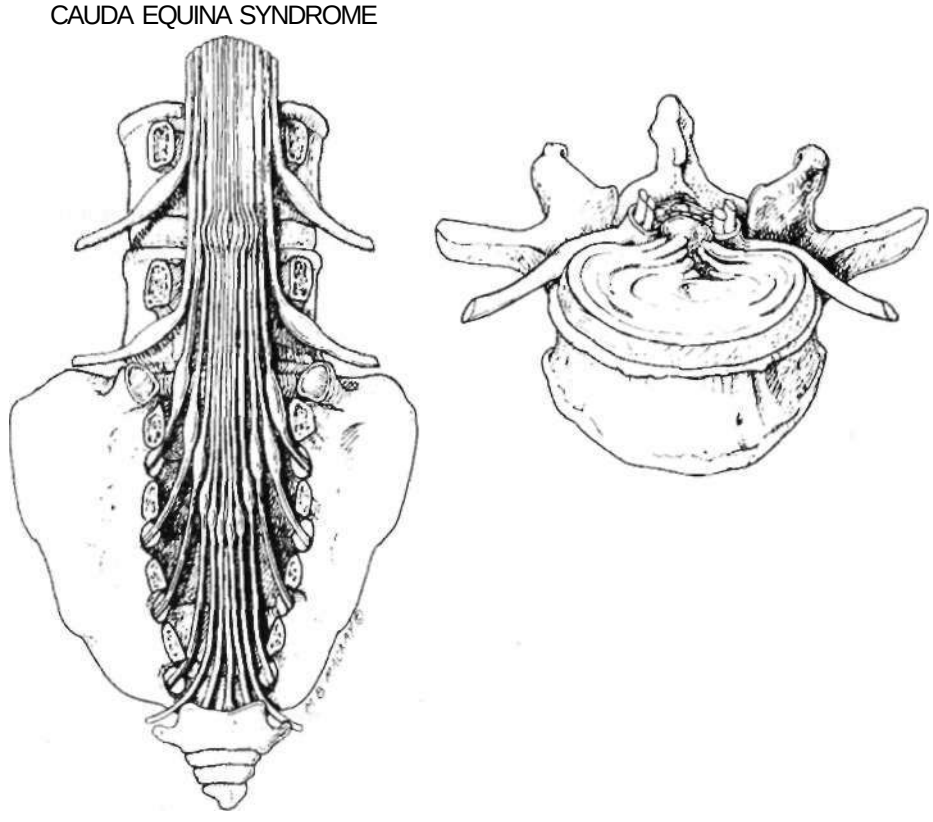

FIGURE 56C.9 Cauda equina syndrome. The drawing shows an acute central disc herniation of L4-L5 with major compression of the central aspect of the cauda equina. The medially placed sacral roots from S2 downward sustain the maximal compression, whereas tin- moiv laterally located L5 and SI roots are completely or partially spared. (Reprinted with permission from Tator, C. H. 1994, "Classification of spinal cord injury based on neurological presentation," in *Neurotrauma,* eds R. j. Narayan, J. E, Wilberger Jr, & J. T. Povlishock, McGraw-Hill, New York, pp. 1059-1073.)

Initial management should include a through neurological examination, including assessment of perineal sensation, anal sphincter function, and urinary retention. Urinary retention is easily assessed by measurement of the pnstvoid residua! (PVR). A PVR greater than 150 mL in adults indicates bladder dysfunction and may be caused by injury to the sacral roots. However, a large PVR may result from pharmacological blockade by anticholinergics or opiates. Therefore in a case of suspected cauda equina injury, a large PVR is a particularly sensitive but not specific indicator of injury. Imaging should include plain radiographs of the lumbar region and MRI of the thoracic and lumbar spine. In the absence of an MRI scan, a myelogram is indicated because a contrast-enhanced CT is much less sensitive. Care should be taken to ensure that the imaging includes the conus and at least screens the thoracic spine if no injury is evident below Tl2. Corticosteroids have not proven useful in most settings, although in some cases of carcinomatous meningitis, symptoms have improved with corticosteroids.

Outcome is variable but generally good compared with those of other incomplete SCIs. The earlier the decompression with emergent intervention, the better the prognosis. Motor and sensory changes have been known to improve dramatically. However, patients presenting with loss of perineal sensation and bowel or bladder difficulties often show little improvement in these symptoms.

Transient Spinal Cord Injury Syndromes

Transient SCI syndromes include a variety of conditions that have in common significant loss of neurological function with rapid return to normal function. These syndromes arc most commonly seen in young athletes.

The burning hand syndrome is characterized by transient paresthesias and dysesthesias in the upper extremities, often most severe in the hands. The symptoms usually are bilateral and symmetrical. This syndrome is often confused with "stingers," which are usually unilateral and felt to be secondary to unilateral nerve root or brachial plexus traction injury. The exact mechanism of injury is unclear, although some form of mild SCI secondary to cervical hyperextension has been suggested. These injuries tend to occur most often in patients with cervical spondylosis and congenital spinal stenosis. Though transient, these symptoms should raise concern, and for an athlete with repetitive episodes of burning hands, investigation should include cervical spine radiographs {including odontoid and flexion and extension views) and MRI of the cervical spine (including short TI inversion recovery sequences to help rule out ligamentous injury). In the acute setting, flexion and extension views should be obtained only after standard anteroposterior and lateral views do not demonstrate any significant injury. If the patient is in severe pain, we advise use of a cervical collar and delay of flexion and extension studies until they can be tolerated by the patient. In any case, the studies should be aborted if the patient develops worsening pain or neurological changes during the maneuver. CT scanning can be used to further define bony anatomy if any abnormality is detected on radiographs or MRI.

Transient quadriplegia or spinal cord concussion is also a transient SCI commonly seen in athletes. Unlike in the burning hand syndrome, which is limited to the upper extremities, patients present with loss of motot and sensory function in all four limbs. Most patients recover within minutes, all within hours, and those who do not do so have a more serious SCI. The exact mechanism of the transient syndrome is unclear, but it probably is caused by distortion of the nerve fibers of the spinal cord, which is of sufficient degree to produce conduction block but not to cause axonal degeneration (neurapraxia). Again, hyperextension injury in the setting of cervical stenosis or spondylosis has been implicated as the biomechanical mechanism of injury. Workup is as described for burning hand syndrome except that one episode is considered enough to warrant workup. If a cervical abnormality is found, a discussion should ensue regarding the risk of continuing contact sports. If no abnormality is present on plain film or MRI, other causes of quadriplegia should be considered, including head injury. A screening CT scan or MRI of the head should he obtained if there is any suspicion of a head injury. Although no hard data exist, there are rough guidelines for return to play after these transient syndromes (Torg 1987; Torg et al. 1997; Boockvar, Durham, and Sun 2001). Referral to a neurosurgeon or orthopedic surgeon specializing in spinal disorders is generally recommended.

Spinal Cord Injury Without Radiographic Abnormality and Spinal Cord Injury Without Radiological Evidence of Trauma

SCI without radiographic abnormality (SCIWORA) is most commonly seen in children, whereas SCI without radiological evidence of trauma (SCPWORET) is most commonly described in adults. The distinction between the two syndromes is subtle, and both syndromes may eventually cease to exist as the sensitivity of MRI continues to improve. Classically, radiographic evidence includes only plain films and CT. SCIWORA presents as a mild to moderate SCI with no evidence of bony injury. However, cases of complete SCI have also been reported. The laxity of the ligaments and paraspinous musculature has been implicated as an etiological factor in SCIWORA. Patients with SCIWORET have abnormal imaging of their spine on presentation but no evidence of trauma. Abnormalities such as cervical spondylosis, Klippel-Feil syndrome, and congenital spinal stenosis often are detected without evidence

of fracture or malalignment. In truth, many of these injuries may represent missed diagnoses. A hairline fracture, disc disruption, or epidural hematoma in the case of a patient with ankylosing spondylitis may be difficult to assess on plain film or CT.

An extremely rare cause of SCIWORA or SCIWORET is nucleus pulposus embolism. In this syndrome, trauma results in herniation of disc material into the venous channels in the adjacent vertebral body. This in turn may cause impairment of venous drainage of the spinal cord at that level. Spinal cord infarction may occur. CT and plain film may reveal a fracture of the vertebral endplatc but otherwise no bony abnormality to explain the extent of injury. This is believed to be an extremely rare cause of SCI and should remain a diagnosis of exclusion. Other causes of venous congestion and spinal cord infarction such as transverse myelitis and AV fistula should be considered before nucleus pulposus embolism is diagnosed.

Post-traumatic acute SCI without direct trauma to the spine is a nebulous syndrome that includes SCI caused by injuries to sites other than the spine and spinal cord. Penetrating trauma to the chest and abdomen can result in direct injury to the radicular feeding arteries of the spinal cord and cause hypotension and shock, resulting in a spinal cord infarct. Patients with severe atherosclerosis can undergo plaque embolism with a similar result. Unlike in SCIWORA or SCIWORET, the cause of injury is clear, although there is no evidence of SCI on plain film or CT.

Penetrating Spinal Cord Injury

The two most common penetrating injuries to the spine and spinal cord are missile injuries (particularly gunshot wounds) and stab wounds. Several general principles can be gathered from the management of gunshot wounds and stab wounds; these can later be extrapolated in to cover other clinical scenarios.

High-velocity missile injuries to the spine (e.g., 9 mm and fully jacketed rifle rounds) usually result in biomechanically stable injuries. This is not to imply that they are benign, however. Injury can be threefold. First, foreign material can be carried into the spine and spinal cord by the missile. This can include soil, plant matter, skin, blood, muscle, bone, and bowel contents depending on the missile trajectory, Such foreign material can result in osteomyelitis, epidural abscess, and meningitis, which may be chemical or infectious. Intestinal injury can lead to severe infection in the presence of a CSF leak, and fistulas between the extradural and intradural space have been reported. Second, a high-velocity missile can result in direct injury to the cord and surrounding tissues, usually leading to either complete or partial transection of the cord or possibly spinal compression by an epidural or subdural hematoma. Last, high-velocity missiles can cause a "blast effect" on the tissues surrounding the path of the missile. As a missile passes through an object, there is a transfer of energy from the missile to the surrounding tissue. Depending on the tissue and the velocity and nature of the missile, this energy can be dissipated over a large area. Fluid-filled structures tend to spread rhis energy over larger distances. As a result, a bullet passing from anterior to posterior and lodged in the T12 disc space can result in a complete injury to the conus without actually touching the conus. Diffuse hemorrhage in the white and gray matter can be identified on autopsy.

In the presence of bowel injury, antibiotic therapy is recommended. Persistent CSF leak may necessitate local debridement and repair. As noted earlier, the development of a CSF fistula can be a serious complication. In the absence of bowel injury and CSF leak, the use of antibiotics remains controversial because osteomyelitis and intradural infection arc quite rare. Corticosteroid use is contraindicated, given the concern for the possibility of infection.

Stab wounds to the spine rarely result in complete SCI. The spinal anatomy usually drives the offending blade to one side of the spinal cord or the other. This can result in the Brown-Sequard syndrome or a variant thereof, Dural laceration and CSF leak, epidural hematoma, nerve root injury, and brachial plexus injury have also been described. In acute stab wounds of the spine and spinal cord, the examiner should consider the presence of concomitant injury to the surrounding tissues.

Initial management of penetrating injuries to the spine and spinal cord should include plain films and CT, A screening CT of the area surrounding the site of injury should be performed to rule out occult injury to other structures in these regions. MRI scanning is generally of little use because of artifact from retained metal fragments. CT myelography may be substituted and indeed is preferred for evaluation of a CSF leak or nerve root injury. Foreign bodies should be left in situ until the patient is evaluated by the appropriate surgical specialists because significant hemorrhage from a previously tampo-naded vessel is theoretically possible upon removal of an imbedded foreign body. Antibiotic treatment is indicated, particularly in the setting of a CSF leak. Corticosteroids are contraindicated for the reasons described earlier. Persistent CSF leak may necessitate surgical exploration or lumbar drainage. Incomplete SCI in the setting of an intradural foreign body is generally considered an indication for surgical intervention. Depressed bone fragments may also necessitate surgical debridement. Recovery is generally good, in keeping with the incomplete nature of these injuries.

Delayed effects have been noted with penetrating as well as nonpenetrating SCI. As discussed later in this chapter, migration of bullet fragments, inflammatory responses to retained foreign bodies, and toxicity from metals such as copper and lead must be considered.

Delayed Post-Traumatic Spinal Cord Syndromes

Several SCI syndromes develop in the late stages (months to years after SCI). The most common of these is syringomyelia. These lesions typically result from the cystic degeneration of the injured spinal cord, particularly in cases of hemorrhagic necrosis and spinal cord infarct. The cysts spread rostrally and caudally, often involving the central region of the spinal cord. The abnormality may consist of a single cyst or multiple adjacent loculated cysts. The cysts may or may not communicate with the subarachnoid space and may be filled with protcinaccous fluid. Arachnoiditis is often seen in conjunction with post-traumatic syringomyelia, although the conditions may occur independently. The extent of injury correlates with development of both disorders: The more severe the injury, the more likely syringomyelia and arachnoiditis are to develop. Approximately 3% of patients with SCI develop syringomyelia. The most widely held theory relates to altered CSF flow whereby arachnoiditis leads to a blockage in the normal CSF flow pattern, resulting in accumulation of CSF in the central canal and surrounding gray matter. The CSF may he under absolutely increased pressure or may transmit venous, arterial, respiratory, or postural pressure effects. Symptoms include both motor and sensory abnormalities. Motor abnormalities include ascending [,MN abnormalities above and descending upper motor neuron (UMN) abnormalities below the level of injury in an incomplete injury. Sensory abnormalities involve the spinothalamic tracts as they cross in the region of central cord. Sensory abnormaliries may also include progressive chronic pain syndromes with causalgia-like symptoms. Bowel and bladder function may also deteriorate. However, asymptomatic syringomyelia is not uncommon, and the demonstration of progression is important in assessing its relevance. Therefore follow-up observation is often warranted. Baseline studies should include an MR1 scan of the complete neuroaxis. This will establish the anatomy of the syrinx and serve as a basis for later comparison. Special attention should be given to examination of the craniocervical junction to rule out a Chiari malformation and the need for posterior fossa decompression. Also, untreated hydrocephalus may contribute both to a Chiari malformation and syringomyelia. Further tests may include a cine-MRI to evaluate CSF flow patterns and myelography with immediate and delayed scanning to determine whether communication exists with the subarachnoid space. Some specialists obtain baseline and serial electromyography and spinal somatosensory evoked potential studies as objective measure of disease progression. Despite the array of potentially invasive and expensive diagnostic tests available, patient complaints remain the most sensitive measure of disease progression. Loss of any neurological function can be devastating to a patient with an SCI and can translate into significant loss of independence. Nonsurgical treatment is limited to observation and palliative care. Disease progression often occurs in a steplike fashion with long intervening plateau periods. A number of surgical approaches have been developed to treat this disorder, with mixed results. At best, symptoms show only temporary improvement; often there is only arrest of disease progression. Surgical approaches include dural augmentation and lysis of subarachnoid adhesions, cyst fenestration, and shunting. Multiple approaches have been used in the shunting of syrinxes, including syringo-subarachnoid, syringopleural, and syringoperitoneal shunt. Failure rates can be as high as 50% in the first 2 years. Low flow through the system has been implicated as the cause of shunt failure. Revision can be attempted, hut failure rates tend to increase with time. The overall prognosis for patients with progressive syringomyelia is poor.

Post-traumatic microcystic myelomalacia is another delayed syndrome encountered in patients with SCI. Symptoms can be similar to those of post-traumatic syringomyelia. MRI and direct observation reveal microcystic degeneration of the spinal cord. These observations have led to the name of *marshy cord syndrome.* Detailed pathological studies of the syndrome have yet to be performed. The disorder is not well characterized, and treatment options are limited. The prognosis is similar to that of syringomyelia.

Arachnoiditis has already been mentioned. As an independent finding, it is a rare complication of SCI. Although there is a loose correlation between severity of injury and the potential to develop arachnoiditis, many patients with severe SCI never develop the disorder, and patients with less severe insults (intraoperative durotomy during surgical decompression) may go on to suffer from arachnoiditis. Symptoms usually are progressive, and abnormalities generally spread to include previously unaffected areas. Abnormal connective tissue bands between the arachnoid and pia mater, arachnoid and spinal cord parenchyma, and nerve roots of the cauda equina lead to progressive strangulation of the normal spinal cord or nerve roots. Cases of tethered cord syndrome, similar to spinal dysraphism, have been described. Uutethering operations have had limited success. Patients generally describe progressive loss of neurological function. MRI scanning and myelography, in particular, best demonstrate the abnormality. There is currently no treatment, and the prognosis is poor, alrhough the severity of symptoms and degree of disease progression are highly variable.

A variety of pain syndromes have been described in the immediate period after SCI. Only 25% of patients go on to develop a chronic pain syndrome, mostly of the neuropathic type. Treatment consists of opiate and nonopiate medications, including tricyclic and selective serotonin reuptake inhibitors, antidepressants, and antiepileptic drugs. The mechanism or action of the antidepressants and antiepileptic drugs is considered in Chapter 50. Opiates can be delivered systemically or intrathecally. Intrathecal

delivery is accomplished by the use of an indwelling pump refilled at regular intervals.

MANAGEMENT OF ACUTE SPINAL CORD INJURY

The improvement in outcome for patients with acute SCI has resulted from better management both in the field and upon arrival at the hospital. Management in the field should include the assumption that all trauma patients suffer from spinal injuries and SCI until proven otherwise. Initial hospital management should also include the assumption that every patient has multiple systemic injuries until proven otherwise. Treatment of patients with acute spinal cord damage who have no history of injury poses more of a difficulty. In general, acute loss of any type of neurological function should be treated as a medical emergency. Rapid diagnosis and intervention may prevent further loss of function and lead to improvement. For the patient with a potential SCI, a detailed physical and neurological examination is mandatory. The decision to obtain imaging studies of the spine depends on the patient's history and physical examination findings. All patients with an altered mental status should undergo a complete diagnostic workup.

Management in the Field

All trauma patients should be treated as potentially unstable until proven otherwise. Initial management should include assessment of the airway, breathing, and circulation (ABCs). For patients with cervical spinal injuries, injury to the prevertebral soft tissues, hematoma, or edema of the retropharynx can lead to airway obstruction despite neurological ly intact muscles of respiration. The ability to speak is a rough indicator of adequate air movement through the airway. In the comatose patient, cyanosis, stridorous breath sounds, flaring of the nostrils, and tracheal deviation may all be signs of a compromised airway. Foreign bodies and vomitus are common causes of upper airway obstruction and can be readily cleared. Altered mental status may also result in dysfunction of the soft tissues of the upper airway, leading to obstruction. This often can be treated with the use of an oral or nasal airway. In cases of severe injury to the airway or airway edema, a field tracheostomy or cricothyroidectomy may be necessary. Despite an unobstructed airway, a high SCI or altered menial status secondary to traumatic brain injur) or intoxication may lead to impaired respiration. Lack of breath sounds may be caused by a pneumothorax and necessitate placement of a flutter valve in the field. Observation often reveals paradoxical breathing (abdominal breathing), shortness of breath, cyanosis, and a progressive decline in mental status. Such a patient may need endotracheal or nasotracheal intubation. Although maintaining normal tissue oxygenation is paramount in **the** treatment of trauma patients, there is a risk associated with manipulation of the cervical spine for intubation in patients with undiagnosed cervical spine injuries. The indications for nasotracheal and endotracheal intubation in trauma patients remain unclear. Good judgment and technique should be exercised at all times. Systemic blood pressure and heart rate should be assessed and an intravenous line placed as soon as possible. Patients with acute SCI may **not** respond to standard volume resuscitation; care should be taken to assess for spinal shock and autonomic dysfunction. In the case of bradycardia and hypotension unresponsive to fluid replacement, the use of vasopressors is indicated.

Once the ABCs have been addressed, extrication and mobilization should be considered. The patient's neck should be placed in a rigid cervical collar. If an adequate collar is unavailable, a rolled towel and tape can be used to secure the neck. Care should be taken to avoid airway obstruction. The patient's spine should be kept in as close to neutral alignment as possible. Once the patient has been extricated, a rigid backboard slum Id be used for i ran spurt. The head can be raped to the backboard or secured with sandbags for further stability. The possibility of hemodynamic instability, secondary to ongoing bleeding not identified before mobilization, or autonomic dysfunction should be noted. Intravenous fluids and pressors should be immediately available.

There are a few exceptions in the treatment of patients with traumatic SCI, as described earlier. In the very young patient care should be taken to avoid placing a collar or towel that may result in axial distraction (2002). If a properly fitting cervical collar is unavailable, sandbags or rolled towels and tape may suffice. Older adults with kyphotic deformities should not be forced into an anatomically neutral position, particularly those with ankylosing spondylitis. In this case, forcing the spine into neutral alignment may cause subluxation of the spine at the level of a fracture, leading to further neurological impairment. Immobilization of the spine rather than restoration of alignment should be stressed. Finally, rhe patient may be a danger to himself or herself. Patients who are agitated and uncooperative because of stress, head injury, or intoxication may need to be sedated or chemically paralyzed as well as intubated. This should be considered a measure of last resort in the field because once a patient is intubated, sedated, and chemically paralyzed, the opportunity for serial neurological examination is lost.

Initial Hospital Assessment

If the goal on transfer is stability, then the goal on arrival to the hospital is rapid diagnosis. Timely delivery of acute care can prevent complications, which can last a lifetime or be fatal. In most settings, a multidisciplinary trauma team is

needed. However, not all hospitals have access to the services available to a major trauma center. Often, patients are transferred to a local community hospital for initial screening and then possible transfer to a major trauma center, Despite the difference in resources, the initial evaluation at an outside hospital is critical to patient outcome.

Initial evaluation should consist of recapitulation of the ABCs. Further swelling of the airway, vomiting, or teeth dislodged during intubation may lead to airway obstruction not present in the field. Chest radiographs may reveal poor tube placement in the field. A delayed or intubation-related pneumothorax may necessitate placement of a chest tube. Placement of flutter valves in the field also necessitates placement of chest tubes in the hospital. Ongoing hypotension may necessitate the placement of central venous and arterial lines to monitor fluid resuscitation. Further discussion of initial trauma management is beyond the scope of this chapter. However, it must be stressed that all clinicians treating a patient with acute trauma should be aware of concomitant injury, and efficient dialogue between managing specialties is critical to good patient outcome.

Once the patient has cleared the ABCs, the detailed examination, or "D," follows. This should include a derailed neurological examination in all patients, which with practice can be performed in minutes. For the patient with a potential or actual spinal cord lesion, this must include assessment of cranial nerve, sensory, and motor function. Cranial nerve dysfunction may be a sign of brain injury or, in the presence of lower cranial nerve dysfunction, of a craniocervical junction abnormality. Because many health care decisions arc based on this early neurological examination and on serial neurological examinations, a standard approach is mandatory. The accepted standard is the AS1A/IMSOP scale, discussed earlier in this chapter. The presence of priapism should also be noted because its presence indicates SCI. The presence or absence of a bulbocavernosus reflex is of controversial utility because as many as 15% of normal patients have an absent reflex (Blaivas, Zayed, and Labib 1984),

The physical examination should also include examination of the patient's neck, abdomen, and back. Obvious deformities should be noted, Examination of the abdomen may reveal ecchymoses and rigidity, indicative of an intra-abdominal injury. The so-called scatbclt sign, a bruise in the distribution of a lap belt, should alert the examiner to the possibility of a flexion-distraction injury of the spine. Examination of the back may reveal bruising and a step-off, further evidence of ligamentous or bony injury. Although a thorough examination of the neck and back is a part of the complete examination of the trauma patient, care should be taken to minimize the number of times a patient is moved. For the patient with an unstable spinal injury, every move can increase the extent of SCI. If a patient must be rolled, the appropriate technique should be used. At least four people are needed. One person maintains the head in neutral alignment in relation to the body and applies gentle traction (in cases of suspected AOD, traction should be avoided), while two others roll the trunk. Those rolling the patient should cross arms in the middle in case one person loses his or her grip. The fourth person is then free to examine the back. Am dehns and clothing should be moved from beneath the patient. After a thorough examination the patient is gently rolled back into place.

In most instances, patients with presumed acute SCI will arrive at the hospital on a rigid backboard. These backboards allow safe and efficient patient transfer during transport and initial workup at the hospital. Backboards are uncomfortable to lie on for prolonged periods of time. Apart from discomfort, there is the risk of developing a decubitus ulcer, which may cause lifelong complications. Most centers try to limit the use of backboards to less than 2 hours.

It is often difficult to determine the level of bony injury from the neurological examination, given the anatomical differences between spinal cord level and spinal level. However, the standard is to report the cord level. In addition, head injury, sedation, peripheral nerve injury, and intoxication can cloud the initial assessment. This underscores the need for serial neurological examinations. Any condition that might affect the accuracy of the neurological examinations should be noted.

Radiographic Evaluation

Plain radiographs remain the standard in the initial evaluation of any patient with a possible SCI. A screening latetal cervical spine film is part of the immediate trauma workup. Knowledge of a significant cervical subluxation or AOD will affect the course of initial workup and prioritization of consultations. Once a patient has been evaluated and stabilized, further imaging workup should be obtained.

Radiographic and clinical clearance of the cervical spine is needed before a cervical collar can be removed. Many trauma centers require a full set of cervical spine films (anteroposterior, lateral, and open mouth odontoid views) on all trauma patients. The lateral view must include the top of the Tl vertebral body. If the Tl vertebral body is poorly visualized, a Swimmer's view should be obtained. If this is not possible, a CT scan thtough this level shun hi be obtained. Oblique films are useful for examination of the facets and neural foramina but are not considered standard. As access to helical CT scanning increases, so will the substitution of a screening spiral CT of the cervical spine for plain films. Screening helical CT of the cervical spine has been demonstrated to have at least the same sensitivity and specificity of plain films (Blackmorc ct al. 1999; Blackmore, Mann, and Wilson 2000; Hanson et al. 2000). To substitute for plain films the study must include coronal and sagittal reconstructions. Because many trauma patients

now undergo screening CT scans of the abdomen, pelvis, and head, a screening CT scan of the cervical spine adds only a few minutes to the time spent in the scanner, as opposed to 20-30 minutes to obtain plain films. Should physical examination of the neck reveal any sites of midline point tenderness, the recommendation is for fine cut CT studies (3 mm) through the appropriate levels. Any abnormality detected on plain film or screening CT scan should also be followed up with a fine cut study.

Recent recommendations by the American Association of Neurological Surgeons and the Congress of Neurological Surgeons Joint Section on Disorders of the Spine and Peripheral Nerves dispute the need for cervical spine films in .ill trauma patients (Tabic 56C.8). Patients who meet all the criteria to he deemed asymptomatic can have their cervical spines cleared solely on the basis of history and physical examination. This decreases the number of radiological examinations performed and reduces the use of health care resources (2002).

In a patient with a normal neurological examination and no evidence of bony injury or malalignment on radiograph or CT scanning, a cervical collar can be removed if the following criteria are met. The patient must be fully conscious and able to complain of pain on palpation of posterior cervical spine and paraspinous musculature. If a patient is fully conscious and pain-free, the cervical collar may be removed. Strain and spasm of the cervical paraspinous musculature is a common post-traumatic disorder and is commonly called whiplash, a poorly characterized and poorly understood syndrome whose discussion is beyond the scope of this chapter. Significant pain in the absence of bony injury may also indicate a ligamentous injury. Ligamentous injuries heal poorly and are normally an indication for surgical stabilization. "Clearance" of the cervical spine in a patient with neck pain can be handled in one of several ways. If the pain is severe and the patient is unable to move his or her neck, the cervical collar should be replaced. The patient may then return for evaluation after the pain has subsided (usually 7-10 days). Lateral, anteroposterior, open mouth odontoid, flexion, and extension views of the cervical spine are then obtained without a cervical collar. Many centers require the presence of a physician during these studies. The patient should be instructed to flex and extend the neck slowly and to stop if pain, weakness, or sensory abnormality develops. If abnormal movement is not detected and the patient's pain has improved, the cervical collar can be removed and the patient referred to physical therapy. Persistent, severe pain usually is considered an indication for MRI. Flexion and extension studies may also be obtained in the acute setting if full range of motion is not hindered by pain. Many centers delay obtaining dynamic-radiographs because a physician may nor be available to accompany patients to radiology in a busy emergency room. Patients with altered mental status should remain in cervical collars until they can comply with physical examination. Patients unable to comply with examination for a prolonged period of time {weeks to months) may undergo an MRI, upright films, and passive flexion and extension studies under fluoroscopy to clear the cetvical spine. Protocols vary from center to center.

Tabic 56C.8: Criteria for classification of an asymptomatic trauma patient with respect to cervical spine injury

Neurologically normal: Patients must have a Glasgow Coma Scale score of 15 and must not have any of the following: disorientation to person, place, or time; inability to remember three objects at 5 minutes; delayed or inappropriate response to external stimuli; or any focal motor or sensory deficit.

Not intoxicated: Patients should be considered intoxicated if they have: a recent history of intoxication or intoxicating ingestion; evidence of intoxication on clinical examination; or laboratory evidence of the presence of drugs that alter the level of alertness, including blood alcohol levels higher than 0.08 mg/dL.

No *neck pain or midline tenderness:* Midline tenderness is present if the patient complains of pain on palpation of the posterior midline neck from the nuchal ridge to the first thoracic vertebra.

No *associated injury that is distracting to the patient:* Significant distracting injuries have been defined as long bone fractures; visceral injuries necessitating surgical consultation; large lacerations, degloving, or crush injuries; large burns; and any other injury that might impair the patient's ability to participate in a general physical, mental, and neurological examination.

Source: Adapted from Hoffman, J. R., Mower, W. R., Wolfson, A. B., et al. 2000, "Validity of a set of clinical criteria to rule out injury to the cervical spine in patients with blunt trauma," N *Engl j Med,* 343, p. 9499.

The standard for imaging of the thoracolumbar spine in trauma patients is less rigid. In the absence of point tenderness or other localizing sign (e.g., bruising or step-off), screening films are not mandatory. Complaints of significant pain referable to the spine should be addressed with imaging studies. Despite negative plain films, a screening MRI scan of the thoracolumbar spine may demonstrate an occult fracture, which can be followed up with a fine cut CT scan. Patients with a significant injury mechanism (high-speed motor vehicle accident or fall from a significant height), patients with an altered mental status, or patients with a spine fracture or detectable ligamentous injury anywhere in the spine should have their complete spine surveyed (there is a 10-15% incidence of a concomitant fracture).

Conventional Tomography

In most instances, conventional tomography has been replaced by CT scanning. The large doses of radiation, the time of image acquisition, and the need for the decubitus position have led to its decline. However, conventional tomography remains the most sensitive way to study horizontally oriented vertebral fractures, particularly those involving the odontoid.

Computed Tomography

CT is the most useful imaging modality available for managing acute SCI. CT scans ate cheap, rapid, and easy to transfer electronically. CT is most sensitive in defining vcrtcbtal bony alignment, fracture pattern, and bony encroachment on the spinal canal. It is also useful in the diagnosis of acute epidural and subdural hematomas. CT allows not only detailed study in the axial plane but also study in the coronal and sagittal planes. Despite these advantages, CT has some significant limitations. In most circumstances, a patient must be transported to the CT scanner. Access to the patient may be limited during image acquisition, making CT scanning unsuitable for unstable patients. Plain radiographs of acceptable quality often can be obtained at the bedside in these patients. CT also does not adequately demonstrate soft tissue anatomy, making it difficult to identify spinal cord, ligamentous, and disc injuries.

CT remains more expensive than plain films. Combined use of plain films and CT is often the most effective use of resources. CT can be used to screen regions such as the cervicothoracic junction and thoracic spine, which can otherwise be difficult to study on plain films. In addition, vertically oriented fractures are best visualized on CT. Therefore in patients with persistent pain and symptoms localized to a particular spinal segment, CT scan of the suspected segment and adjacent segments can be an efficient confirmatory test.

Myelography

In the MR I era, myelography is seldom used in the setting of acute trauma. Despite the added resolution gained from postmyelography CT, the indications for its use are limited. Myelography can often be attempted as a substitute for MR1 when MRI is not possible, and when spinal canal compromise is in question. For example, CT myelography can be used as a substitute for MRI in the diagnosis of a traumatic disc herniation. Additionally, myelography remains the gold standard in evaluating nerve root avulsion {contrast leakage into the surrounding soft tissues can be readily identified).

Magnetic Resonance Imaging

Of the imaging modalities used in the diagnosis and management of SCI, MRI is the only modality capable of consistent and detailed imaging of the spinal cord parenchyma, spinal ligaments and discs, and paraspinal soft tissues. As opposed to myelography, which it has supplanted as the imaging modality of choice in SCI, MRI is noninvasive and can produce higher-quality images in a shorter period of time. MRI can also be useful in detecting occult boil)- injury b\ detecting changes in the bone marrow and soft tissues adjacent to a bony injury. Despite the greater sensitivity of MRI over CT in detecting injury, MRI does not provide adequate anatomical detail of bony structures. There are also several other drawbacks to MRI. MRI is expensive, and a radiologist often is needed to perform and interpret the study. Patients must be left deep in the bore of a large magnet for extended periods of time, precluding its use in unstable patients. Intubated patients must be switched to special ventilators, which often cannot provide complex ventilatory support. Patients must remain still during imaging, necessitating deep sedation or chemical paralysis in noncompliant patients.

Patients must be immobilized before MRI scanning. The commonly used cervical collars are all MRI compatible. Care should be taken to ensure that halos and tongs are MRI compatible (most new traction and halo devices are made of graphite for this reason). Patients with acute penetrating injuries often cannot be scanned because of the artifact from retained metallic fragments and the risk of migration of these fragments in the magnetic field.

Several different MRI sequences are useful in the diagnosis of spinal injury and SCI. Images can be acquired in the axial, sagittal, and coronal planes. Axial images provide detailed information about the cord parenchyma, particularly in latcralizing injury and determining the patency of the subarachnoid space. Sagittal imaging provides information regarding the rostral-can da I extent of injury, spina! alignment, and integrity of longitudinally oriented structures, such as the anterior and posterior longitudinal ligaments. Coronal imaging can be useful in patients with traumatic scoliosis and in studying the integrity of the nerve roots and brachial plexus. Images usually are acquired in 3- to 4-mm-thick slices. T1-weighted imaging provides the greatest anatomical detail and can serve as a reference for comparison with other sequences. T2-weighted imaging is the most sensitive for tissue edema and is often used to assess the extent of cord injury. However, edema often spreads several levels above and below the level of injury, making identification of the exact level of injury difficult on T2-weighted imaging. The extent of injury on acute T2-weighted imaging is not a good indicator of extent of injury in the long term. The presence of hematoma appears to be a much more sensitive predictor of long-term disability. The appearance of hematoma on MRI is very dependent on the interval between injury and imaging. The relative ratios of water, hemoglobin, and hemoglobin breakdown products in a clot at a given time determine its appearance on a particular imaging sequence. Hyperacute clots (up to 2 hours after injury) appear isointense with gray matter on Tl-weighted imaging and (because of their large quantities of protein-neb water) hyperintense on T2-weighted imaging. Acute hemorrhages (a few hours to days after injury) appear isointense on T1- and profoundly hypointense on T2-weighted imaging, in part because of the conversion of oxyhemoglobin to deoxyhemoglobin. Hemorrhages between a few days and

months after injury arc called subacute. ID the early subacute phase, methcmoglobin is contained in intact red blood cells, and hematomas appear bright on Tl- but hypointense on T2-weighted imaging. Late subacute hemorrhages contain a significant amount of extracellular methemoglobin, which appears hypcrintense on Tl- and T2-weighted imaging. In the chronic stage {more than a few months), hemorrhages appear hypcrintense on bothTl- and T2-weighted imaging, with a rim of hypointensity on T2-weighted imaging caused by hemosiderin deposition. Over the years hemosiderin can be cleared by tissue macrophages, but residual hemosiderin in glial cells results in an isointense signal on Tl- and hypointense signal on T2-wcighted imaging. These patterns are summarized in Table 56C.9.

MRI is also very sensitive for detecting injury in the marrow cavities and soft tissues of the spine. Vertebral body fractures result in edema of the marrow spaces, causing them to appear bright on 'I'2-weightcd imaging, Intervertebral disc disruption or herniation has been detected in as many as 54% of traumatic SCIs and appears as a bright signal on T2-weighted imaging (Flanders et al. 1992). If demonstrated, intervertebral disc herniation can be an indication for emergent surgical intervention. Shott Tl inversion tecovery sequences are helpful in the diagnosis of ligamentous injury. Again, depending on the level, significant ligamentous injury may be an indication for surgical stabilization. MRI is also the imaging modality of choice for serial examination of post-traumatic syringo-myelia and hydromyelia. Given the hyperemia associated with acute tiauma, gadolinium enhancement has not been demonstrated to add significantly to the management of acute SCI. However, gadolinium enhancement is quite useful in the workup of patients with SCI caused by malignancy and infection.

TREATMENT OF SPINAL CORD INJURY

The initial management of patients with acute SCI has already been discussed. Until a patient's spine has been declared stable, eithet by tilling out of a spinal injury or by surgical stabilization, care should be taken to maintain the spine in as neutral :i position as possible. Tins may necessitate the use of a cervical collar, traction tongs, or halo.

Cervical collars are cheap and readily available. They should be rigid, and care should be taken to ensure that they fit properly. Poorly fitting cervical collars can cause a decubitus ulcer, which can last a lifetime. Two general types of cervical collar are available: the disposable plastic collars used by emergency professionals in the field and the long-term composite collars used in the hospital, made of foam, cloth, and plastic. Both offer the same mechanical stability, but the disposable type is uncomfortable and can lead to the development of skin breakdown. The soft foam collars available over the counter provide no significant mechanical stability and are contra indicated fot use in patients with spinal injuries.

If a patient ptesents with a malaligned cervical spine fracture or SCI, the use of tong traction is indicated. Early reduction of a malaligned spinal injuty can result in significant pain reduction and return of neurological function (Evans 1961; Brunette and Rockswold 1987; Harrington, Likavec, and Smith 1991; Olerud and Jonsson 1991; Hadley et al. 1992; Lee, MacLean, and Newton 1994; Grant et al. 1999). Significant imptovement in function has been noted in the literature when reduction has been performed within 2 hours of arrival at a major medical center. Data from as late as 8 hours aftet injuty have also demonstrated a significant benefit to alignment restoration. Most advocate reduction aftet diagnosis of the malalignment on CT scan or plain film. The utility of prereduction MRI remains controversial because disc herniation is commonly seen. The bone windows of a head CT scan or at least plain films of the skull should be tevicwed before the tongs arc applied. A temporal or parietal skull fracture may necessitate the use of a halo ring. Radiographic facilities slum Id be immediately available, or if manual reduction is to be performed, the procedure is best performed under fluoroscopy. A conscious patient is ideal because he or she can report any change in neurological function immediately, but this may not be possible in a severely injured or noncompliant patient. Bilaterally, points two fingerbreadths above the pinna and in line with external auditoty meatus are marked and the

area around the sires prepared with antibiotic solution. Shaving usually is not necessary. A line through these points defines the neutral plane of the head and neck. The traction ring should be inspected before use. The ring should be large enough to allow fur swelling of the sculp but small enough to allow for tightening of the pins. Although older stainless steel models may be available for use in the operating room, trauma patients should be placed in an MRI-compatible apparatus. The "S" hook to which the traction cord will be tied should be placed on the tongs before application. Two screws are used. One screw is a set-screw, and the other has a built-in tension pin. Local anesthetic is injected into the pin sites several minutes before application. If reduction of a spinal injury is to be attempted, sedation and intravenous analgesia can be administered. Diazepine can be quite useful as a muscle relaxant, reducing the amount of weight necessary for reduction. Once the patient is ready, both screws are tightened simultaneously until the tension pin protrudes by 1 mm (approximately 30 lb of pressure). The pins should find purchase in the outer cortex of the skull (>150 lb of pressure at the pin sites is needed to penetrate the inner cortex of a normal skull).

After application of the traction apparatus, baseline radiographs should be obtained with no weight attached. In patienrs with SCI and normal alignment, 10-15 lb of traction can be applied. The purpose of traction in these patients is to maintain alignment and to remind caregivers of the presence of an SCI. In patients needing reduction, weight can be applied in 5- to 10-lb increments; the weight should be applied and a new radiograph obtained 5 minutes after application of the weight. This allows for fatigue of injured cervical soft tissues, which may prevent reduction. The amount of weight needed is controversial. Classically 3-5 lb per vertebral body level has been advocated (and 30 lb for a C5/C6 fracture or dislocation). However, in a large or muscular person this may prove inadequate. There is no established maximum weight. The safest technique is to monitor for distraction of the spinal column. Significant distraction at any disc level should prompt reduction in the amount of weight applied. If the malalignment has not been reduced, open reduction or manipulation of the spine must be considered. There are several practical concerns. The pins should be checked routinely to ensure that they maintain the desired amount of tension. Loose pins can pull out and result in significant injury to the scalp. As the amount of weight used increases, the patient may start to slide in the direction of the weight, necessitating the use of restraints. MRI-compatible screws do not have the same pull-out strength as stainless steel screws. If the applied weight exceeds 70 lb, an MRI-compatible halo ring should be considered. A greater amount of weight can be used, with four rather than two screws securing the halo to the skull. Once the malalignment has been reduced, the weight should he dropped to 15-20 lb. An immediate and then routine radiographs should be obtained to confirm that alignment is maintained. The tension pin should be examined daily. Inability to maintain alignment and an incomplete SCI level are indications for immediate surgical intervention (after emergent MRI).

Patients with suspected AOD can be placed emergently into a halo vest. Additionally, a halo vest can be used to immobilize the cervical spine when continuous traction is not feasible (e.g., long-distance transport to a tertiary care center). A health care provider with the appropriate training should apply the halo ring and vest.

Patients with grossly malaligncd spinal fractures of the thoracic and lumbar region are rare. Closed reduction of these fractures is not recommended; because the great vessels are closely associated with the thoracic and lumbar spine, there is a significant risk of injury to these structures with closed reduction. Threatened breakdown of the skin over a fracture is an indication for emergent open reduction and internal stabilization. Nonsurgical thoracolumbar spine fractures can be treated in a variety of orthoses, depending on the type of injury. A detailed discussion of the available bracing options is beyond the scope of this chapter.

In some patients, application of an orthosis, halo ring, or halo vest is the definitive means of spinal stabilization. These patients can then be mobilized within the constraints of their associated injuries. Patients in traction or awaiting surgical stabilization should be maintained under full spinal precautions. A rotating airbed is recommended to decrease the likelihood of decubitus ulcer formation. Early surgical stabilization is recommended. Indications for emergenl surgical intervention can be controversial and will be discussed separately. When possible, stabilization should he performed within 48 hours of injury. Acute trauma patients are at risk for the development of pneumonia, sepsis, deep vein thrombosis (DVT), pulmonary embolism, and skin breakdown. All can be exacerbated by the need for strict immobilization. The development of these morbidities can further delay surgery.

A comparison can be drawn between the injured spinal cord and brain injured by an ischemic stroke. A widely accepted stroke model describes an area of partially injured brain adjacent to the frank infarct. This endangered brain is called the ischemic penumbra. This area can survive if the necessary metabolic substrates are available. For this reason, care is taken to prevent hypoxia and anemia in patients with acute stroke. Similarly, patients with acute spinal injury should remain well ventilated with a Po^ and Pco_2 in the normal range. Furthermore, data exist to support maintaining the hematocrit above 30% and maintaining mean arterial pressure above 90 mm Hg in the acute period (2002). Although some authors advocate acute laminectomy in SCI to improve spinal cord perfusion pressure, the data do not support this argument.

The most important medical intervention that can be performed on the patient with an SCI is the prevention of

further injury. This can be accomplished with vigilance and adherence to spinal protocols.

Pharmacological Intervention

At least four pharmacological agents have undergone randomized controlled trials to determine their efficacy in improving outcome in patients with acute SCI. Two of these agents, methylprednisolone and tirilazad, arc corticosteroids. Naloxone is an opiate agonist that has shown some effect in patients with SCI. GM| ganglioside is a complex sugar that is a normal cell membrane component, Analysis of the data from multiple trials involving these drugs has failed to show consistent or clinically significant results. Nevertheless, the use of methylprednisolone in patients with SCI remains widespread, despite the fact that recent guidelines published by the American Association of Neurological Surgeons and the Congress of Neurological Surgeons Joint Section on Disorders of the Spine and Peripheral Nerves does not advocate using any of these drugs to treat SCI (2002).

A number of animal models of acute SCI support the testing of corticosteroids in human SCI- The mechanism of action of corticosteroids remains unknown, but it is postulated to involve membrane stabilization, reduction of vasogenic edema, alteration of electrolyte concentration at the injury site, and inhibition of endorphin release. Tirilazad, in particular, has been postulated to act as potent free radical scavenger at the injury site. The National Acute SCI Study (NASC1S I), initiated in 1979 and reported in 1984, was the first attempt at a large, randomized, controlled trial of methylprednisolone in acute SCI (Bracken et al. 1984). The study design had significant flaws, including the dosage used. Based on animal data, the drug dosage used was too small to expect any effect (1000 mg bolus and 100 mg daily compared with 1000 mg bolus and 1000 mg daily for 10 days, no control). As a result, NASCIS II was initiated in 198.5 and repotted in 1990 (Bracken et al. 1990). Inclusion criteria were essentially the same for NASCIS I and II; no attempt was made to exclude injuries to the cauda equina or to exclude patients with normal motor examinations. Penetrating SCIs were excluded. In NASCIS II, patients were randomized to one of three groups within 12 hours of injury: methylprednisolone 30 mg/kg bolus, followed by 5.4 mg/kg per hour for 23 hours; naloxone 5.4 mg/kg bolus, followed by 4.0 mg/kg per hour for 23 hours; or placebo. Of the 487 patients (roughly evenly divided between the three groups), 62 of 162 receiving methylprednisolone demonstrated an improvement in sensory scores at 6 months and motot scores at 6 and 12 months. Furthermore, restratification of the data demonstrated that all 62 patients had received methylprednisolone within 8 hours of injury. Side effects were limited to wound healing problems and gastrointestinal bleeding. A numbet of significant criticisms have been raised. Many deal with the complex statistical analysis applied to the small responder group, without interpretation of this data in the context of the entire study-population. For example, the group of patients who received methylprednisolone 8 hours after injury had the same outcome as those who received placebo 8 hours after injury. No attempt was made to standardize other aspects of the medical and surgical management. Review of these aspects of care demonstrated a significant difference between treatment centcts. Finally, both NASCIS I and II lacked a functional outcome measure to determine whether the improvements in motor scores noted were of any clinical significance.

NASCIS III results were reported in 1997 (Bracken, Shepard et al. 1997), Patients were divided into three groups: methylprednisolone for a total of 24 hours, methylprednisolone for a total of 48 hours, and tirilazad for a total of 48 hours. All patients were treated within 8 hours of injury. There was no placebo group, and functional outcome was measured. The 499 patients were nearly evenly distributed between the three groups. Follow-up was performed at 6, 24, and 52 weeks. Analysis of the data suggested that improved motor scores were detected in patients who received 48 hours of methylprednisolone 3-8 hours after injury. No difference in motor score improvement was noted in any group treated within 3 hours of injury. Functional outcome was identical in all three groups, regardless of the timing of drug administration. Based on these data, the designers of NASCIS III recommended the administration of methylprednisolone for 48 hours when patients present 3-8 hours after injury. Like the previous two studies, NASCIS III has been plagued by criticism. Criticism stemmed from the arbitrary nature of the time cutoffs for treatment (<3 versus 3-8 hours after injury), the method used to score motor improvement, and the lack of significant clinical improvement in any group. Although not clinically significant, there is a suggestion of increased rates of pneumonia, sepsis, and death due to respiratory complications among patients who received 48 hours of methylprednisolone treatment.

GMi ganglioside is a complex carbohydrate and is a normal constituent of the neuronal cell membrane. GM_L ganglioside has been implicated in cell growth, development, and repair. Two North American multicenter clinical trials have failed to demonstrate a convincing benefit in patients with acute SCI (Geisler, Dorsey, and Coleman 1991a, 1991b; Gerhart ct al. 1995; Geisler et al. 2001). The data suggest that patients treated with GM| ganglioside may improve faster than controls, but long-term outcome has not been significantly different from that of control groups. For those wishing to administer GM| ganglioside despite the lack of proven clinical efficacy, the accepted protocol is methylprednisolone per the NASCIS II protocol within 8 hours of injury, followed immediately by a loading dose of GM| ganglioside 300 mg and a maintenance dosage of 100 mg per day for 56 days.

No significant randomized clinical trials have been carried out on the use of tirilazad and naloxone apart from their inclusion in the NASCIS studies. There currently is no recommendation regarding their use in acute SCI.

The use of methyl prednisolone and GM, ganglioside in acute SCI treatment remains one of the most controversial topics in the field of spinal cord disorders. Although the data do not suggest efficacy on the part of either agent, great benefit has been derived from these studies. With each phase of the NASCIS studies, the experimental design has become more rigorous and detailed. Only when clinical research is subjected to the same scientific standards as bench research will any significant strides in outcome research be made. Perhaps it is the lack of a medical or surgical treatment with any significant effect on acute SCI that drives clinicians to continue the use of methylpredm-soloue and (IM] ganglioside. Unfortunately, their use is not without risk.

Surgical Intervention

There tire two goals in the surgical management of patients with acute SCI: decompression of the neural elements and spinal stabilization. The timing of acute decompression is a controversial topic and can be influenced by the location of injury. Progressive neurological deterioration in the setting of ongoing compression is the most common justification for acute intervention. Interventions in patients with a fixed incomplete injury and ongoing neurological compression are more controversial. The controversy is likely to continue until the results of well-designed, randomized, controlled trials become available.

The classic teaching in the management of acute central cord syndrome is to avoid acute intervention whenever possible. In fact, in the absence of ongoing compression and neurological deterioration, acute intervention in cervical SCIs is generally accepted to be contra indicated. In the setting of cervical spondylosis, the practice of delayed surgery is based on the experience of Schneider in the 1950s (Schneider 1954). One must keep in mind that Schneider performed his procedures without the benefit of an operating microscope or detailed preoperative imaging. His approach to the cervical disc was from the posterior and involved sectioning of the dentate ligaments and mobilization of the injured spinal cord. However, the literature is rife with examples of miraculous improvement in the setting of acute decompression. Similarly, the 1992 study of thoracolumbar burst fractures by the Scoliosis Research Society reported a 25% complication rate for acute surgery compared with a 3% complication rate for nonoperative management (Gerr/bem 1992). Willi wound healing and instrumentation and graft complications considered, neurological deterioration caused by surgical intervention occurred in 0.6% of patients. Randomized controlled trials comparing early and late surgery are woefully absent in the literature. In one of the few studies available, no significant difference in length of stay or outcome was detected in patients undergoing early and late surgery for cervical SCIs (Vaccaro et al. 1997). In the absence of class I data, other retrospective reports in the literature suggest that early surgical intervention speeds recovery but may not have an effect on long-term outcome.

Traumatic injuries resulting in complete SCI are generally managed on a nonemergent basis with the following exceptions. Closed reduction of malaligned cervical spine injuries should be attempted cmcrgently. Evidence of a herniated disc, bony compression of the spinal cord, or inability to reduce a dislocation should be considered a surgical emergency. However, patients who present more than 24 hours after injury are unlikely to experience any improvement in neurological function. Elective stabilization of unstable injuries soon after injury (within 1 week) allows early mobilization. This may prevent some of the early complications of SCI: pneumonia, decubitus ulcer formarion, and DVT. Class I data in support of these recommendations are currently unavailable.

Acute surgery for incomplete traumatic lesions involving the thoracic spinal cord, conus, and cauda equina is controversial. There are few data to support acute intervention in these patients. Early decompression may shorten the recovery period but docs not appear to improve the extent of recovery. Many centers favor urgent decompression, that is, surgery within 72 hours of injury. This approach has the advantage of allowing the procedure to occur on an elective basis, allowing adequate workup and observation. Although some studies suggest that operative management of these injuries has a higher complication rate than nonoperative management, a closer look at the data reveals that the complications rarely involve injury to the cord. Rather, complications tend to be related to positioning, blood loss, and exacerbation of other injuries (e.g., pulmonary complications).

A detailed discussion of the surgical approaches, instrumentation, and nonoperative treatment strategies is beyond the scope of this chapter.

ACUTE **SPINAL CORD** INJURY SECONDARY TO INFECTION, HEMATOMAS, AND MALIGNANCY

The majority of patients who present with vertebral osteomyelitis, discitis, and epidural or paraspinal abscesses can be managed nonopcrativcly. A variety of surgical and nonsurgical options arc available tor treatment. Indications for surgery include signs of instability, progressive bony destruction despite appropriate therapy, and neurological dysfunction. Acute vertebral body collapse or large epidural collections can lead to compression of the neural elements. Acute loss of neurological function is a surgical emergency. Epidural collections can be drained without bony debridement if the surrounding bone is intact.

Collapsed or unstable vertebrae necessitate extensive debridement and fusion or instrumentation procedures.

In the absence of neurological symptoms and signs, patients with traumatic or spontaneous spinal epidural hematomas can be treated conservatively. Patients with spontaneous hematomas should be evaluated for clotting deficiencies and the underlying problem treated with blood products or factor replacement. Patients with progressive neurological deterioration should be referred emergently for surgical decompression.

Patients with metastatic or primary malignancies of the spine almost always need multidisciplinary treatment. Neurologists, neurosurgeons, and oncologists often find themselves crowded around the same patient. Patients presenting only with pain often can be treated conservatively and scheduled for elective surgery. Patients presenting with sensory changes and radiculopathy can be treated with radiation or chemotherapy and surgery on a semielective basis. High-dose corticosteroids and radiation therapy in many cases can control disease without surgery.

Acute or progressive loss of motor, bowel, or bladder function is a surgical emergency. Patients who present with paraplegia secondary to spinal cord compression (SCC) from malignancy usually have a life expectancy of months. Furthermore, patients with spinal cord compression can progress rapidly from symptoms of back pain to paraparesis and ultimately paraplegia. Patients presenting with paraplegia rarely become fully ambulatory after treatment. Pain is the most common presenting symptom of SCC. Therefore any patient with cancer and back pain has presumed SCC until proven otherwise. MRI is the imaging modality of choice. The entire spinal column should be screened. Plain films and CT should be performed as indicated. High-dose corticosteroid therapy should be initiated immediately. The dosage and type of corticosteroid administered has not been standardized (Cantu 1968; Posner, Howieson, andCvitkovic 1977;Delattreetal, 1989). Dcxamethasone dosages as high as a 100 mg inttavenous bolus followed by 24 mg intravenously every *6* hours for 3 days have been recommended. Corticosteroids often result in neurological improvement within 12 hours. The exact mechanism of action is unclear but may be related to decreasing edema in the injured spinal cord and an oncolytic effect {i.e., reduction in tumor volume). During this interval patients can undergo radiation or surgical therapy. After 3 days the corticosteroids should be weaned back to 4 mg intravenously or orally every 6 hours. High-dose corticosteroid administration is not without risk of complication. Known complications include gastrointestinal perforation and bleeding, infection, and poor wound healing. Patients who have not undergone some form of radiation or surgery in the 3-day treatment period are at risk of developing rebound edema and worsening of their symptoms. Patients presenting more than 48 hours after loss of function usually do not improve and can be treated on a semielective basis as indicated. Surgical techniques for tumor resection and stabilization have evolved over the past 20 years. If a patient's systemic tumor burden is under control, surgical intervention can improve pain control and maintain independence. Survival time plays a role only with respect to the length of postoperative rehabilitation necessary. Obviously, patients whose life expectancy does not extend beyond the anticipated postopetative recovery period arc not surgical candidates. Decision making therefore entails interaction not only between the surgeon and patient but also with oncologist treating the underlying disorder.

SPINAL CORD INJURY AND BLADDER FUNCTION

Complications from loss of normal bladder function arc the second leading cause of death among patients with SCI (Frankel et al. 1998). An improperly functioning bladder not only may cause social embarrassment and poor hygiene but also may lead to local infection, sepsis, hydronephrosis, renal and bladder calculi, vesiculourethral reflux, renal failure, and infertility (Benevento and Sipski 2002; Siroky 2002).

Normal bladder function depends on the coordination of inputs between the cerebral cortex, hypothalamus, brainstem, and spinal cord and their influence on the sympathetic, parasympathetic, and somatic nervous systems (see Chapter 42). The pontine micturition center (Barrington nucleus) directly excites motoneurons in the bladder while inhibiting contraction of the internal urethral sphincter. Nuclei in the periaqueductal gray receive input concerning bladder filling. The preoptic area of the hypothalamus may be involved in the initiation of micturition, whereas the cingulum and premotor area appear to inhibit micturition. Within the bladder wall is the detrusor muscle, a layer of smooth muscle responsible for bladder contraction. Contraction of the detrusor muscle is under control of the parasympathetic nervous system. Parasympathetic input is catried by the pelvic nerves and originates from nuclei in sacral spinal cord segments S2-S4. Sympathetic tone leads to bladder relaxation (/}-adrenergic reccptot) and contraction of the smooth muscle that makes up the internal urethral sphincter (a-adrenergic receptor). This input is carried by the hypogastric nerves and originates from spinal cord levels T11-L2. Finally, somatic efferents control contraction of the striated muscle that comprises the external urethral sphincter. These efferents originate in spinal cord segments S1-S4 (Onuf nucleus) and run in the pudendal nerves.

Normal micturition control is thought to begin with afferent signals from stretch receptors in the bladder wall traveling to the periaqueductal gray. These inputs then project to the hemispheres, where the urge to void is initiated. The cingulum and premotor areas then help to suppress this urge until it is convenient and socially appropriate to initiate micturition by causing increased

tone in the striated muscles that make up the external urethral sphincter (the guarding reflex). When appropriate, the nuclei in the pteoptic area of the hypothalamus initiate contraction of the bladder wall and relaxation of the smooth and striated muscle sphincters. The Barrington nucleus in the dorsomedial pontine tegmentum is believed to coordinate this activity.

Bladder injuries can be divided into two types: disorders of storage and disorders of emptying. Failure to properly store unne can be caused by a hyper-reflexic bladder. The high filling pressures that result from poor bladder compliance can then lead to failure of the bladder sphincters and incontinence. An areflexic bladder neck can also cause storage failure. In this case, there is no obstruction to urine flow. Failure of emptying can be caused by either a flaccid, hypotonic bladder or a hyperactive sphincter causing resistance to urine flow.

In general, the location of SCI dictates the type of bladder dysfunction observed. The action of the cortical, hypothalamic, and pontine micturition centers is to inhibit bladder contraction and coordinate bladder relaxation. Cervical, thoracic, and high lumbar cord injuries result in loss of this inhibitory reflex. In the acute period after an SCI, however, a period of spinal shock exists that may persist for several months. This results in a hypotonic, areflexic bladder. As spinal shock fades, the sacral segmental spinal bladder reflex becomes evident. Capsaicin-sensitive, unmyelinated C-fiber afferents determine bladder tone. The bladder becomes hyperactive and can develop high filling pressures. This contraction may or may not be associated with sphincter relaxation, which is the normal physiological sequela ot bladder contraction. This condition is called detrusor-sphincter dyssyncrgia, and in males it can lead to significant bladder obstruction (for unclear reasons it does not cause as significant a degree of obstruction in females). Up to 85% of patients with a lesion above the sacral cord suffer from this disorder. Although these patients may suffer from incontinence, the abnormal sphincter function leads to obstruction in the setting of high bladder pressures. Therefore these patients are at greatest risk of vesicourethral reflux and its sequelae. Patients with sacral cord or cauda equina lesions may suffer an LMN type of bladder impairment. In this case the bladder has little or no tone and the sphincters are incompetent, leading to incontinence, Both patterns of bladder dysfunction can range in severity that correlates with the severity of the underlying spinal cord or cauda equina injury. Additionally, one type of injury may over time develop into the other, and some patients may suffer from a mixed picture. Urodynamic testing is the screening tool of choice and can help determine the type of dysfunction present {see Chapter 42).

In the setting of acute SCI, the goal of bladder management should be to prevent the development of a dilated atonic bladder. Overstretching of the bladder may cause irreparable damage to any remaining bladder wall function. Prevention is best accomplished with the use of intermittent catheterization. Although patients with complete cord injuries have no sensation of bladder fullness, an over distended bladder can lead to episodes of autonomic dysreflexia, a potentially life-threatening condition caused by hypertension and bradycardia. Use of a long-term indwelling urethral catheter has been demonstrated to carry as high as 6.5 times the rate of urinary tract infection as the use of condom catheters and intermittent catheterization (Esclarin De Ruz, Garcia Leoni, and Herruzo Cabrera 2000). It is a generally accepted principle that the use of intermittent catheterization is superior to the use of both condom and indwelling catheterization. It should be noted that the rate of infection between condom and intermittent catheterization is approximately equal and that the rate of serious infection (e.g., pyelonephritis, urosepsis, and epididymitis) is identical for all three techniques of bladder drainage. Interestingly, some studies have suggested that assisted catheterization may carry a higher risk of infection than sclf-catheterination (Bakke and Vollset 1993). There is some evidence to support the concept that infections with normal perineal flora are the most common forms of infections and that with time the genitourinary tract may become resistant to infection with these organisms. Assisted catheterization may challenge the patient's immune system to an array of new pathogens to which the patient cannot develop immunity. Therefore patients with high cervical quadriplcgia may benefit more from the use of an indwelling catheter than assisted intermittent sel^catheterization, As in bowel care, adherence to a set regimen and good technique is the best way to reduce infection, regardless of the method of bladder drainage.

The chronic management of bladder dysfunction is beyond the scope of this chapter. The clinician has at his or her disposal a number of pharmacological, prosthetic, and surgical options. Studies are also under way in the use of inert bacterial strains to colonize the genitourinary tract and suppress the growth of other bacterial strains (Hull et al, 2000). The choice of treatment depends not only on the type of injury but also on the patient, comorbid disease, drug regimen, caregivers, socioeconomic setting, and desire for sexual function.

SPINAL CORD INJURY AND BOWEL FUNCTION

Bowel dysfunction in SCI can lead not only to the inconvenience and embarrassment of fecal incontinence but also to ileus, gastric ulcers, gastroesophageal reflux disease, discomfort, anorexia, diverticular disease, hemorrhoids, impaction, constipation, and autonomic dysreflexia (Benevento and Sipski 2002). Initiation of a strict bowel program can help prevent or minimize the effect of these complications.

Physiologically, the colon can be regarded as a tube of smooth muscle bounded by the ileocecal valve proximally

and the anal sphincter distally. Puborcctalis forms a sling of muscle around the rectum. Contraction of the puborcctalis muscle results in elevation of the rectum and formation of a more acute angle between the rectum and anus. This impedes the flow of liquid and feces through the rectum to the anus. The anal sphincter is made up of two regions: the internal anal sphincter (IAS) and the external anal sphincter (EAS). The IAS is made up of a band of continuous smooth muscle at the rectum end of the colon. The EAS is made up of a circumferential band of striated muscle continuous with the pelvic floor just proximal to the anus.

Continence is maintained by the resting tone of the IAS. A centrally mediated reflex causes the EAS and puborcctalis to contract during a Valsalva maneuver and coughing, helping to maintain continence. Colonic movement is mediated by a number of inputs. The gastrointestinal tract contains an intrinsic nervous system, which includes a plexus of nerves (Auerbach's plexus) situated between the layers of muscle forming the walls of the colon. The intrinsic plexus promotes peristaltic movement of luminal contents toward the tectum. The autonomic and somatic nctvous systems modulate the activity of the colon. Last, local chemical and tactile stimuli can modulate colonic motor activity and emptying. The sympathetic input to the colon is carried by the superior and inferior mesenteric nerves (spinal cord levels T9-T12) and hypogastric nerves (T12-L2). The vagus nerve carries parasympathetic input from the esophagus to the splenic flexure. The pelvic nerves (S2-S4) carry parasympathetic fibers to the descending colon and rectum. Somatic input to the rectum and pelvic floor travels in the pudendal nerves (S2-S4).

Peristaltic movement of the large intestine is primarily autonomous, with some spinal cord influence. Peristaltic waves push luminal contents both toward and away from the ileocecal valve in the ascending colon, but movement in the descending colon is primarily toward the anus. Gap junctions between smooth muscle cells in the wall of the colon help coordinate contraction. Breakdown products in the lumen of the colon help stimulate or inhibit contraction. Stretch of the smooth muscle wail results in a reflex involving Auerbaeh's plexus: The smooth muscle proximal to the area of luminal distension contracts while the region distal to the area of distension relaxes. In this fashion the bolus in the lumen is propelled forward in the descending colon. The vagus nerve and sacral parasympathetics stimulate colonic motility. The gastrocolic reflex increases colonic motility after a fatty or proteinaceous meal. The exact mechanism is unclear but may also involve the sacral parasympathetics.

The IAS and EAS are normally active in conjunction with the puborectalis muscle in maintaining an acute anal-rectal angle. This acts to maintain continence. The IAS normally maintains continence of gas and fluids, whereas the EAS maintains continence of solids. As the rectum fills and distends with stool, the IAS relaxes, and the tone of EAS increases. The sensation of the need to defecate is also relayed to the cerebral cortex. Voluntary contraction of the IAS helps to maintain continence until it is convenient and appropriate to initiate defecation. There is also reflexive contraction of the EAS and the puborectalis muscle during Valsalva and coughing. Voluntary relaxation of the puborectalis and the EAS results in involuntary movement of stool into the rectum. As stool fills the rectum, the anal rectal angle becomes less acute, making the passage of stool easier. Valsalva and increased peristalsis lead to further evacuation of stool.

Despite the presence of the autonomous enteric nervous system, SCI can have a profound impact on bowel function. Bowel dysfunction can be divided into two types: UMN and LMN dysfunction. In UMN dysfunction, a lesion exists in the spinal cord above the level of the conus medullaris. This results in a hyper-rcflcxic bowel, with increased colonic wall and anal tone. The connections between the sacral spinal cord segments and the colon remain intact, This results in reflex coordination and stool movement. Voluntary inhibition of the EAS is lost, and the anal sphincter remains tightly closed. This results in constipation and fecal retention. Involuntary emptying of the rectum can occur as stool builds up in the rectal vault. An LMN pattern exists when injury occurs at the level of the conus or cauda equina. Disruption of the parasympathetic outflow to the colon occurs. The result is in an areflexic colon. In this case peristalsis depends only on the myenteric plexus. Because of the slow transit time, stool tends to be rounder and drier. The nerves to the EAS and puborectalis muscles are also disrupted, resulting in loss of sphincter tone and a reduction in the anal rectal angle. This injury leads to constipation with frequent episodes of incontinence.

Patients with SCI have varying amounts of sensation with respect to defecation. Even in patients with a complete SCI there may still be a feeling of discomfort associated with a large amount of stool in the colon, as well as episodes of autonomic dysreflexia. In the acute setting, SCI can be associated with decreased motility throughout the gastrointestinal tract (ileus). Patients may need a nasogastric tube because gastric emptying may be significantly delayed. This decreased motility can result in abdominal distension to the extent that diaphragmatic excursion is inhibited, often further compromising respiratory function. Initiation of a bowel program early in the hospital course can prevent problems in the subacute period and shorten overall hospital stay.

Approximately 37% of patients with SCI need some form of assistance with bowel care. A detailed discussion of bowel management in chronic SCI is beyond the scope of this chapter. However, several key points can be summarized (Bryant 2000). Strict adherence to a bowel regimen is critical to success. Involvement of the patient, family, and caregivers is crucial. The seated position allows easier passage of stool because of the anatomical relationship between the puborectalis muscle and the rectum. The type of program used must take into account the type of injury

present (UMN or LMN). Patients with a UMN pattern of bowel dysfunction can benefit from stimulation of the anal sphincter and triggering of the normal sacral spinal cord reflexes. Stretching of the anal sphincter can result in autonomic dysreflexia in some patients, and caregivers should be prepared for this in high-risk patients. The goal of dietary and pharmacological management should he the formation of soft, well-formed stools that can be passed easily after digital stimulation. Patients with an LMN problem may need intermittent manual disimpaction to prevent incontinence. The goal of therapy is the formation of firm, well-formed stool that can be stored and easily removed manually. Dietary and pharmacological manipulation of bowel function is multifaceted. Patients often are given a warm beverage 30 minutes before the start of a bowel program to help stimulate the gastrocolic reflex, which can be partially preserved even in complete spinal cord lesions. Dietary control includes the inclusion of high-fiber foods and psyllium to give stools bulk and increase transit time. Pharmacological intervention can include stool softeners such docusate sodium, which emulsifies fat in the gastrointestinal tract. Senna tablets stimulate Aucrbach's plexus, increasing peristalsis. Bisacody) and similar suppositories act as mucosal irritants and can help stimulate colonic motility. Finally, gentle soapsud enemas can help to soften hard, impacted stool. Bowel care and hygiene can be intensely private matters. Care must be taken to protect a patient's privacy and dignity as much as possible. Surgical intervention can take the form of a colostomy or ileostomy in patients unable or unwilling to perform adequate bowel care.

SEXUAL DYSFUNCTION, SEXUALITY, AND **FERTILITY IN SPINAL** CORD **INJURY**

Sexual function and sexuality are complicated issues in the patient with SCI (see Chapter 42). Although the mechanics of sexual function may be partially preserved in patients with complete and incomplete SCI, libido often is adversely affected. Decreased libido probably is secondary to concerns regarding body image, poor sexual performance, and possibly concerns regarding continence during sexual activity. Pharmacological and prosthetic advancements have had a significant impact on the sex lives of patients with SCI, in addition to the strides made in counseling and support groups. A detailed review of the topic is beyond the scope of this chapter, but several key points deserve comment. Among these is the point that men and women demonstrate profound differences in the effect of SCI on sexual and reproductive function (Benevcnto and Sipski 2002).

One model of sexual function divides the sexual response into four phases: arousal, plateau, orgasm, and resolution (Masters and Johnson 1966}. Ejaculation normally is a component of the orgasm phase. Erection occurs during the arousal phase and can be stimulated in one of two ways. Direct stimulation of the penis and perineum results in an erection mediated by a spinal sacral parasympathetic reflex. An erection can also be stimulated psychogenic^lly. In this case erotic thoughts and nontactile stimuli result in erection. Nerve fibers in the hypogastric plexus (T11-L2) and sacral parasympathetics both play a role in tins type of erection. Therefore men with complete SCIs above Tl 1 lose the ability to have psychogenic erections but maintain the ability to have a reflex erection secondary to perineal stimulation. Men with incomplete injures above Til may retain the ability to develop an erection in response to psychogenic stimuli and retain reflexive erections. Men with complete injuries below spinal cord level L2 and those with cauda equina (LMN) injury often maintain the ability to develop psychogenic erections but lose reflexive erections. Incomplete LMN injuries result in a spectrum of erectile dysfunction, from nearly normal reflexive and psychogenic erection to complete impotence.

However, erection is only a single event in one phase of a four-phase process. During orgasm, involuntary smooth muscle contractions normally result in ejaculation of semen and the sensation of pleasure. The connections that trigger these sensations are unclear and may be carried via the autonomic nervous system. Data regarding orgasm and patients with SCI have been collected only through the use of questionnaires. No attempt has been made to standardize responses. However, several studies have demonstrated similar results (Bors and Comarr I960; Phelps et al. 1983; Alexander, Sipski, and Findley 1993). Approximately 45% of men with SCI reported achieving orgasm through coitus or masturbation. In one study 38% of patients with complete SCI reported achieving orgasm. Ejaculation involves the coordination of sympathetic, parasympathetic, and somatic nervous systems. Injury to any of these systems can result in difficulty with normal ejaculation. Retrograde ejaculation results in the delivery of semen into the bladder rather than out the penile meatus, thereby hindering fertility. Studies report that 4".. of patients with complete and 32% of patients with incomplete UMN lesions retain the ability to ejaculate (Bors and Comarr 1960). Eighteen percent of patients with complete and 70% with incomplete LMN lesions are reported to ejaculate normally.

The sexual response in women has been better studied in the laboratory than in men, albeit later (Sipski, Alexander, and Rosen 1995a, 1995b, 1997, 200 I; Sipski, Rosen, and Alexander 1996; Whipple, Cerdes, and Komisaruk 1996). The female sexual response can be divided into the same four phases as the male sexual response. Arousal can be measured by detection of clitoral engorgement and vaginal lubrication. As in men, arousal can be either reflexic or psychogenic. UMN lesions above the T11-12 spinal cord level appear to prevent psychogenic arousal while preserving reflexic arousal. Similarly, LMN lesions appear to prevent reflexic arousal but do not disturb psychogenic arousal. In one study, only 52% of women with SCI were able to stimulate themselves to orgasm (Sipski, Alexander,

and Rosen 1995). Women with complete LMN injures are the least likely to achieve orgasm, and women with SCI in general take longer to reach orgasm than women without SCI. The sensation of orgasm appears to be identical between injured and control patients. Finally, no episodes of autonomic dysreflexia were noted among women with SCI who are able to achieve orgasm. Orgasm in women also appears to involve an autonomic sacral reflex.

Treatment of sexual dysfunction has been limited to the treatment of erectile dysfunction (ED) in men. Although many men with SCI can develop erections, they often complain that they are unable to maintain erection and that their erections are not firm enough to allow intercourse. Prostheses, vacuum pumps, rings, and penile injections have all been successful in managing ED. The type of method used depends on the patient's comfort and type of dysfunction. Orally active vasoactive drugs such as sildenafil have had n dramatic effect on the treatment ot ED. Studies have demonstrated it to be safe in men with SCI. Little research has been undertaken to improve the female sexual response after SCI. Studies have suggested some benefit of sildenafil in the treatment of female sexual dysfunction (Sipski et al. 2000), but the benefit is not as dramatic as that observed in men.

Men with SCI injury have a number of obstacles to overcome with respect to fertility. First, SCI can have a dramatic effect on the ability to ejaculate. Furthermore, sperm from patients with SCI have impaired motility, and semen from the same patients may not provide the same substrate for conception when compared with controls (Bracket! et al. 1996), although the connection between SCI and poor sperm or semen quality had yet to be made at the time of study. Recurrent urinary tract infections and renal complications of SCI may also lead to infertility. Improved methods of harvesting sperm and semen have led to dramatic improvements in the ability of men with SCI to father children. SCI may not decrease fertility in females. However, pregnancy rates among women with SCI are lower than among age-matched controls. Whether this represents a physiological derangement or the decision of women with SCI not to have children remains to be determined.

AUTONOMIC DYSREFLEXIA

Distension of the bladder or bowel in patients with SCI may lead to episodes ol autonomic dysreflexia, a potentially life-threatening situation. Seen in patients with SCI at the midthoracic level or above, the syndrome may also be triggered by other noxious stimuli, including decubiti, nephrolithiasis, genitourinary infection, surgical procedures under local anesthesia, and biliary disease. The syndrome presents as chills, diaphoresis, piloerection, hypertension, reflex bradycardia, pupillary dilatation, headache, and pallor (Head and Riddock 1917; Kcndrick et al. 1953). Death can result from cardiac arrest caused by profound vagal overactivity. Symptoms can occur even years after SCI. The Threshold for the development of symptoms appears to decrease with successive episodes. Treatment should be directed at eliminating the noxious stimulus (e.g., bladder or bowel decompression). Antihypertensive agents or vagolytics (e.g., atropine) may be necessary in severe cases.

DEEP VEIN THROMBOSIS **AND** THROMBOEMBOLISM IN SPINAL CORD INJURY

There is little consensus in the literature and in clinical practice regarding the prevention of DVT and thromboembolism in patients with SCI (2002). The incidence of thromboembolic events in untreated or inadequately treated patients with SCI ranges from 7% to 100% (Perkash, Prakash, and Perkash 1978; Frlsbie and Sasahara 1981; Myllynen et al. 1985; Tator et al. 1987; Green et al. 1988; Merli et al. 1988; Waring and Karunas 1991; Kulkarni et al. 1992; Burns et al. 1993; Gunduz et al. 1993; Lamb et al. 1993; Geerts et al. 1994; Powell, Kirshblum, and O'Connor 1999). The complications of a thromboembolic event are significant, including cardiopulmonary arrest and death. Prophylactic therapy has included the use of rotating beds, pneumatic sleeves, low-dose unfractionatcd heparin, adjusted-dose un fractionated heparin, low-molecular-weight heparin, warfarin, electrical stimulation, aggressive physical therapy, and pcrcutaneously placed inferior vena cava (1VC) filters. In general, some form of prophylactic therapy appears to be superior to no therapy. Some therapies stand out, however, either because of ease of administration or increased efficacy in a particular situation. Rotating beds are commonly used during the acute phase of SCI before spinal stabilization. Patients benefit from the increased venous return and decreased pressure sore formation associated with frequent turning without the risk of injury to an unstable spine. Rotating beds arc not comfortable and arc poorly tolerated by conscious patients over the long term. Similarly, pneumatic compression sleeves are convenient in an immobile patient but impractical in a patient who is not confined to bed (e.g., a patient actively participating in spinal cord rehabilitation). The increased risk of bleeding associated with higher-dose anticoagulation regimens can outweigh the benefits of their use, particularly in patients with a ptevious history of bleeding or those who are prone to falls. IVC filter placement is associated with rare and even fatal complications. Filters can be placed in the acute period without concomitant anticoagulation in patients at high risk for bleeding or with short life expectancies. However, current recommendations include the need for lifelong anticoagulation (Becker, Philbrick, and Selby 1992). The cumulative lifetime risk of a major bleeding complication in a youne, person with an IVC filter ean he

quite high and calls into question the safety of IVC filter placement in younger patients. Finally, all studies investigating the efficacy of IVC filters have compared them with historical controls. No studies comparing the efficacy of IVC filter placement with current prophylactic regimens have been reported in the literature. Length of prophylactic therapy is also a subject of debate. A recent review of the literature demonstrates the reported risk of a thromboembolic event to be highest during the first 2-3 months after injury (2002). The risk declines significantly over time but never approaches that of controls. In fact, one study demonstrated the risk of dying from a pulmonary embolism to remain 20 times higher at *6* months for patients with a history of SCI than for control patients (DeVivo et al. 1989). The incidence has been reported to fall between 0.5% and 1% after 1 year (McKinley et al. 1999). Additionally, the risk of DVT decreases dramatically in patients with significant lower extremity motor function, and given the evidence in the medical literature, cessation of therapy earlier is warranted once such patients are mobile (Myllynen et al. 1985; 1997).

No studies have demonstrated a decreased risk of thromboembolic event in patients undergoing serial screening for DVT. In patients clinically suspected of having a DVT, venography remains the diagnostic gold standard. The invasive nature and cost of the procedure preclude its use as a screening tool. Fibrin degradation product (D-dimer) measurement, Doppler ultrasound, and venous occlusion plethysmography (VOP) have all been used in the diagnosis of DVT. Although the measurement of D-dimers has a high negative predictive value, the positive predictive value of this study has been documented to he 13% (Roussi et al. 1999). Doppler ultrasound and VOP demonstrate high positive and negative predictive values (Chu et al. 1985). Compared with venography, they are both cheap and readily available. Clinically significant pulmonary embolisms have been reported in the absence of a documented DVT. As a result, clinical suspicion of a pulmonary embolism should not be set aside after negative Doppler studies, VOP, or venography. Confirmatory tests for pulmonary embolism include ventilation/perfusion scanning and spiral chest CT. Ventilation/perfusion scanning is sensitive but not specific and may not be possible in patients with concomitant pulmonary disease. Spiral CT scanning is sensitive and specific, but some clinicians question the clinical significance of lesions detected by spiral CT. Clinical judgment should guide the decision to treat a radiographically documented pulmonary embolism.

Review of the existing data has led the American Association of Neurological Surgeons and the Congress of Neurological Surgeons Joint Section on the Disorders of the Spine and Peripheral Nerves to make the following recommendations. The prophylactic treatment of thromboembolism in patients with severe motor deficits caused by SCI is recommended. The use of low-molecular-weight heparin, rotating beds, pneumatic sleeves, adjusted-dose heparin, or combination therapy is recommended. Neither low-dose heparin nor oral anticoagulation monotherapy appears to be an effective treatment strategy. IVC filters are recommended only for patients who do not respond to anticoagulation or are not candidates for anticoagulation or mechanical devices. More research is needed to compare the efficacy of IVC filters and modern treatment paradigms. Surveillance scanning for DVT does not appear to reduce the rate of thromboembolism.

REHABILITATION AND LONG-TERM CARE

The impact of physiatry on the survival and quality of life of patients with SCI cannot be overemphasized. A detailed discussion on this topic can be found in Chapter 54,

Chapter 56
Trauma of the Nervous System

D. PERIPHERAL NERVE TRAUMA

Brian Murray

Traumatic injury to the peripheral nervous system (PNS) is a common and under-recognized source of physical disability. Interest in PNS trauma has been recorded repeatedly through the centuries. Leonardo da Vinci made several detailed anatomical drawings of the brachial plexus, believing that this complex of nerves existed to ensure continued function of the upper extremity should one of its elements be severed (e.g., by a sword thrust). "Weir Mitchell and colleagues wrote the first systematic study of nerve injuries during the American Civil War, titled "Gunshot Wounds and Other Injuries of Nerves." By 1885, Duchcnnc, Erb, and Klumpkc had all made their landmark descriptions of various upper and lower trunk brachial plexus injuries. World Wars I and II generated further interest in peripheral nerve trauma, culminating in **both** the classification systems that arc still in use today and the development of microsurgical techniques in nerve repair.

There are many ways in which peripheral nerves may be lacerated, compressed, crushed, or stretched. In the modem world, most such injuries arise from motor vehicle accidents, but they are also distressingly common in sports, in the operaring room, from drug injections, and from gunshot wounds (both civilian and military). Also, nerves may be injured by exposure to extreme physical conditions such as freezing, electrical current, and radiation. Overall, up to 5% of all patients admitted to level I trauma centers have a peripheral nerve, nerve root, or plexus injury (Noble et al. 1998). Upper extremity nerve and plexus injuries arc more common than lower extremity injuries, with the radial, ulnar, and median nerves being most often affected. In the lower limb, the sciatic nerve and peroneal nerves are most often affected.

In this chapter, we discuss the relevant anatomy of the PNS to better understand the classification of peripheral nerve trauma and how elements of the PNS degenerate and regenerate in response to injury. Although both cranial and autonomic nerves are also part of the PNS, they are not covered in detail in this chapter; rather, the focus is on the spinal sensorimotor system that extends between nerve roots and target organs in the trunk and extremities. The most common mechanisms causing nerve trauma, their clinical evaluation, and the current techniques used in nerve repair are discussed, followed by an introduction to some of the fututc developments that may soon revolutionize the management of nerve injuries.

ANATOMY OF THE SPINAL NERVES OF **THE** PERIPHERAL NERVOUS SYSTEM

The PNS is composed of the neural elements, along with their support tissues, that extend between the central nervous system (CNS, in this case the spina! cotd) and their target organs. Thus the peripheral motor system (somatic efferents) extends in a segmental pattern from anterior horn cells lying in the anterior gray matter of

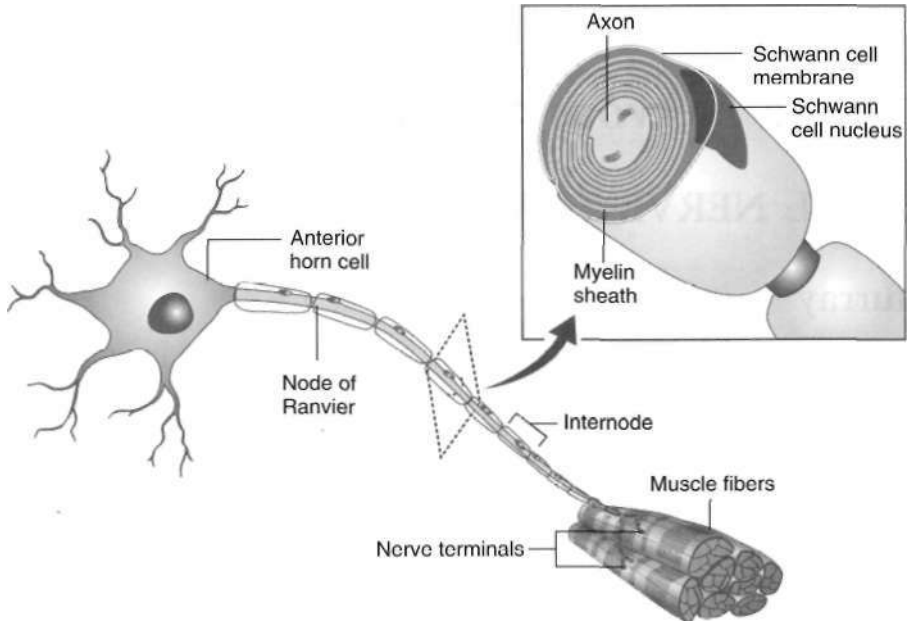

FIGURE 56D.1 The motor nerve cell body lies within the anterior horn of the spinal cord. A single axon extends from the anterior horn cell to its target muscle, making contact at the neuromuscular junction. Local support cells, called Schwann cells, generate a myelin sheath that is laid down at regular intervals around the axon; each interval is called an internode, and the intervening gap is called the node of Ranvier.

the spinal cord to muscles in the limbs and trunk (Figure 56D.1). Fibers of the peripheral sensory system (somatic afferents) extend from specialized sensory organs in skin, muscle, and viscera to their cell bodies lying in the dorsal root ganglia just outside the intervertebral foramina of the spinal column. Spinal nerves are formed when anterior (motor) and posterior (sensory) roots combine, After a brief intraforaminal course, posterior branches (posterior rami) extend backward to supply paravertebral muscles, whereas anterior branches (rami) extend forward to supply the trunk and also give rise to the roots of the plexuses (Figute 56D.2).

Some peripheral nerves, such as the anterior Interosseous nerve, are almost entirely composed of motot fibers,

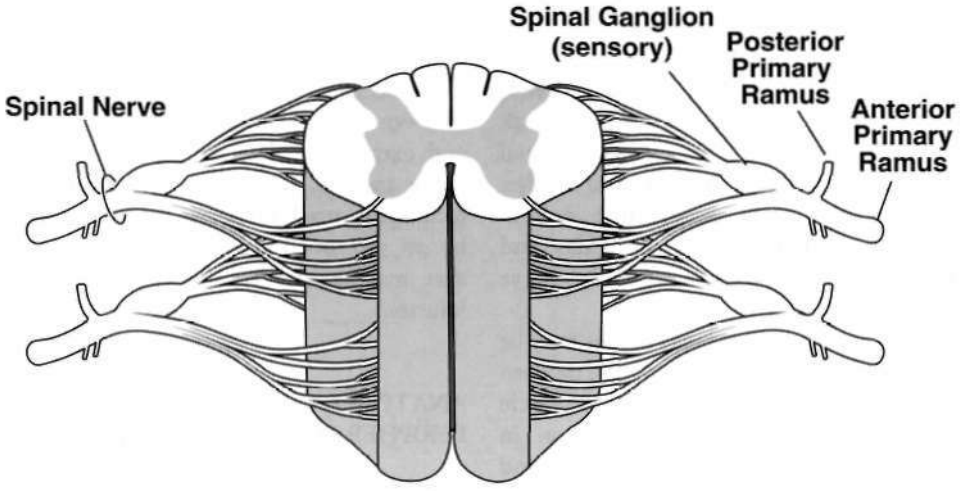

FIGURE 56D.2 Spinal nerves originate in segmental fashion as rootlets from the substance of the spinal cord. The anterior (efferent, motor) rootlets are derived from motor neurons in the anterior lion) ot the spinal cord. Afferent fibers from the periphery reach their cell body in the spinal ganglion in the intervertebral foramen, from which fibers extend as rootlets to the posterior horn of the spinal cord. Afferent and efferent fibers come together just distal to the dorsal root ganglion to form the spinal nerve. The spinal nerve divides into posterior and anterior primary rami; the anterior primary rami constitute the roots of the plexi,

whereas others, such as the sural nerve, arc purely sensory, Most spinal nerves, such as the sciatic nerve, are mixed (i.e., they contain both sensory and motor fibers). It should be remembered that motor nerves also contain small-diamctcr fusimotor fibers that supply the intrafusal muscle fibers. Furthermore, motor nerves are not pure motor nerves in the strictest sense; they also contain large-caliber afferent sensory fibers arising from the muscle spindles.

The core element of any nerve fiber is the axon, a thin tube of membrane-bound axoplasm that extends from the nerve cell body to the target otgan. This axon contains numerous mitochondria, along with a complex of cytoskeletal components such as mictotubules and neurofilaments. Through ionic current shifts mediated by a complex array of membrane ion channels, the axolemma is able to propagate an action potential along its length. The axon is invested in a layer of lipid-rich myelin that is made by a specialized I'NS support cell, the Schwann cell, the outer membrane and basal lamina of which are called the neurilemma.

Peripheral nerve axons may be classified as being unmyelinated or myelinated. The former are multiply arranged in and partially ensheathed by invaginations of the Schwann cell membrane, whereas the latter are enveloped in concentric lamellae of myelin to form a sheath {see Figure 56D.1). The latter serves a vital role in nerve impulse transmission, acting as an electrical insulator that significantly speeds up the conduction of an action potential along the entire length of the axon. The myelin sheath is not a continuous structure but is laid down in tubular segments called internodes, each derived from one Schwann cell, of varying lengths depending on the diameter of the axon. The small gap of naked axolemma between the myelin sheaths is called the node of Ranvier. This has a complex structure and is partly covered by finger-like processes of the adjacent Schwann cells and by basal lamina. The node is the site where ion flow takes place to maintain the action potential. In a process called saltatory conduction, these action potentials leap from node to node rather than travel in a continuous conduction process along the entire length of the axolemma. In this way, a myelinated large-caliber axon may conduct electrical impulses at up to 80 m pet second, whereas a small unmyelinated axon may conduct as slowly as 0.5 m per second.

It is important to be familiar with the various connective tissue components in a peripheral nerve trunk; they provide structure, tensile strength, and elasticity. The connective tissue elements of the nerve and the specialized perineurium provide the anatomical elements of the blood-nctvc barrier that maintains an immunologically privileged nerve microenvironment. After more severe grades of injury, the success or failure of nerve regeneration depends on the nature and degree of injury to connective tissue.

A thin layer of collagenous connective tissue called the endoneurium surrounds individual nerve fibers. This endoneurium is continuous with the subarachnoid space proximally. In the nerve trunk, endoneurium-encascd, myelinated and unmyelinated nerve fibers are arranged into bundles called fascicles. These fascicles, which vary greatly in size and number, are often artanged in an intertwining pattern (sometimes called Sunderland's plexus) in the more proximal portion of the nerve trunk but are arrayed m a more parallel pattern m the distal parts of the nerve. Each fascicle is invested in a layer of tough, specialized cells that have a basal lamina and that constitute part of the biood-nerve barrier, called the perineurium. A typical nerve trunk consists of a variable number of fascicles separated by interfascicular epineurium and surrounded by a tough layer of extrafascicular epineurium, which is in continuity with the dura mater proximally. Finally, the epineurium of the nerve trunk melds into surrounding structures via a loose layer of protective ateolar tissue called the mesoneurium. The latter structure is roughly equivalent to the adventitia of blood vessels and allows the nerve some degree of passive movement in the transverse and, most importantly, the longitudinal planes.

The arterial and venous blood supply of a peripheral nerve is segmental and enters the nerve proper at various sites along the length of the nerve via the mesoneurium. Longitudinally arranged arterioles travel along the interfascicular epineurium before they branch off to pierce the perineurium. It is the multilayered perineurium and the endoneurial capillary wall that form the blood-nerve barrier. The endoneurial capillaries have a larger diameter than typical capillaries in other organs and resemble end arterioles.

CLASSIFICATION OF NERVE TRAUMA

Based on observations made in wartime Britain in the 1940s, Seddon devised a thtee-tiered classification system for nerve trauma (Seddon 1942; Table 56D.1). In this system, the mildest form of injury is caused by a transient focal block in conduction along the nerve fiber caused by injury that is confined to the myelin and spares the axon. He called this neurapraxia, derived from the Greek word for *nonaction.* This type of injury has an excellent prognosis for complete recovery and is rarely clinically evident after *6* weeks; indeed, many patients return to normal within hours. A good clinical example of neurapraxia is Saturday night palsy, a wrist drop caused by compression of the radial nerve at the spiral groove of the humctus that classically involves the intoxicated person who goes to sleep with an arm hanging over the back of a chair. Seddon's second grade of injury, axonotmesis ("a cutting of the axon"), is an injury nor only to myelin but also to the axon itself so that "the sheath and the more intimate supporting structures of the nerve have not been completely divided, which means that the nerve as a mass of tissue is still in continuity" (Seddon 1942, p. 237). Axonotmesis is common in crush injuries and displaced bone fractures, and complete recovery is less likely than

Table 56D.1: Classifications of nerve trauma

Injured tissues	*Seddon*	*Sunderland*	*Modification (MacKinnon)*	*Modification (Millesi)*
Myelin	Neurapraxia	Grade 1	Grade I	Suffix A = epineurial fibrosis (e.g., IA, IIA)
Myelin, axon	Axonotmesis	Grade II	Grade II	Suffix B = interfascicular epineurial fibrosis (e.g., IB, IIB)
Myelin, axon, endoneurium		Grade III	Grade III	Sulfix C — endoneural scarring (e.g., II1C)
Myelin, axon, endoneurium, perineurium		Grade IV	Grade IV	
Myelin, axon, endoneurium, perineurium, epineurium	Neurotmesis	Grade V	Grade V	
Combination			Grade VI	

with neurapraxia. It triggers the process of wallerian degeneration and regeneration, the success of which depends in part on the preservation of connective tissues such as endoneurium and perineurium. Seddon's most severe type of injury is called neurotmesis ("a cutting of the nerve"), which entails damage to myelin, axon, and connective tissue. Seddon used this term to describe complete nerve transection in which "the injury produces a lesion which is in every sense complete" (Seddon 1942, p. 237). This is common after laceration injuries and has the worst prognosis for clinical recovery, ofren necessitating surgical intervention.

A second classification system for nerve trauma was devised by Sunderland to include additional information regarding the degree of injury to connective tissue. This system is divided into five grades, of which grades I and II are identical to Seddon's neurapraxia and axonotmesis, respectively. However, Sunderland subdivides Seddon's neurotmesis into three further levels of injury. Grade III entails injury to myelin, axon, and endoneurium, with sparing of the perineurium and cpineurium. Grade IV describes an injury to all nerve trunk elements except the epineurium, and grade V entails complete transection of all neural and connective tissue elements of the nerve trunk.

Modifications to these two systems have been devised, largely with the surgeon in mind. A further grade (grade VI) has been proposed to highlight the fact that in some injuries there may be a combination of Sunderland grades (e.g., some areas may be grade III and others grade IV) affecting different fascicles within a segment of nerve. Furthermore, a subclassification system has been devised to account for the degree of scarring present in the injury site. This is of vital importance to the surgeon in determining the likelihood of recovery from an injury; excessive scarring (fibrosis) may significantly impede axon.il regeneration. I his system may be used in conjunction with the Sunderland system. The suffix *A* refers to fibrosis that is located mainly in the epifascicular epineurium, so that, for example, IA injury implies that a conduction block has occurred (ncurapraxia, Sunderland grade I) together with epifascicular scarring, and IIA implies an axonotmesis lesion with epifascicular epineurial scarring. The suffix *B* refers to interfascicular epineurial fibrosis so that, for example, a IIB injury implies axonotmesis (Sunderland grade II) with interfascicular epineurial fibrosis; type C fibrosis occurs in the endoneural space and may occur with Sunderland grade III injuries (see Table 56D.1).

PERIPHERAL NERVE DEGENERATION AND REGENERATION

Large myelinated axons are the most vulnerable to traumatic injury. These axons predominate in motor nerves that supply extrafusal muscle fibers and sensory fibers subserving appreciation of vibration, position, and light touch. There arc three main ways in which peripheral nerve fibers may respond to injury: segmental demyelination, wallerian degeneration, and axonal degeneration. The first two of these processes are relevant to traumatic nerve injury and arc discussed in more detail in this chapter, whereas the latter is more characteristically seen in metabolic and toxic nerve disorders such as diabetes mellitus and renal failure, which arc discussed elsewhere (see Chapter 82).

Segmental Demyclination

Segmental demyclination typically occurs with nerve trauma at a focal segment of nerve that is subjected to a significant compressive force. The nerve segments that lie proximal and distal to the site of injury are not affected and function normally. Distortion of the myelin sheath may cause degeneration of one or several intcrnodes, which leak current and thus affect the ability of the sheath to act as an electrical insulator. If the myelin is only slightly damaged, there may be simply a widening of the node of Ranvier that causes a slowing of conduction velocity across the nerve segment. Such focal demyclination of axons within a nerve fascicle may affect some but not all

fibers, resulting in asynchronous conduction across the affected nerve segment. In this case, impulses eventually reach their destination after a delay, but the slowing may affect certain nerve functions that rely on highly synchronous firing, such as deep tendon reflexes and vibration sensation.

More severe degrees of compression may involve most, or indeed all, myelinated nerve fibers at the injury site and several internodes. In this situation there is blockade of conduction across that segment, which causes weakness or sensory disturbance. Ultrastructural studies of nerve segments that have been subjected to tourniquet compression reveal that the nodes of Ranvier are heavily distorted. Furthermore, the regions of myelin located at the edge of the tourniquet are deformed to a greater degree than the segment lying directly beneath the tourniquet. The tourniquet causes the underlying axon and myelin to telescope into a neighboring segment, which greatly distorts the paranodal segment of myelin to cause conduction slowing and, later, actual segmental demyelination and conduction block. Once a segment of myelin has been lost in this way, the Schwann cell divides and initiates remyclination. Conduction is re-established within a few weeks, but the new myelin sheath usually is thinner and has several internodes for each original internode.

Wallerian Degeneration and Regeneration

Interruption of axonal continuity triggers a carefully-orchestrated process called Wallerian degeneration that involves the axon, its cell body, its cellular connections, and surrounding connective tissues (Figure 56D.3).

Changes in the Distal Segment

After axotomy, the first changes that occur are in the axon distal to the site of injury. The initiating event for this

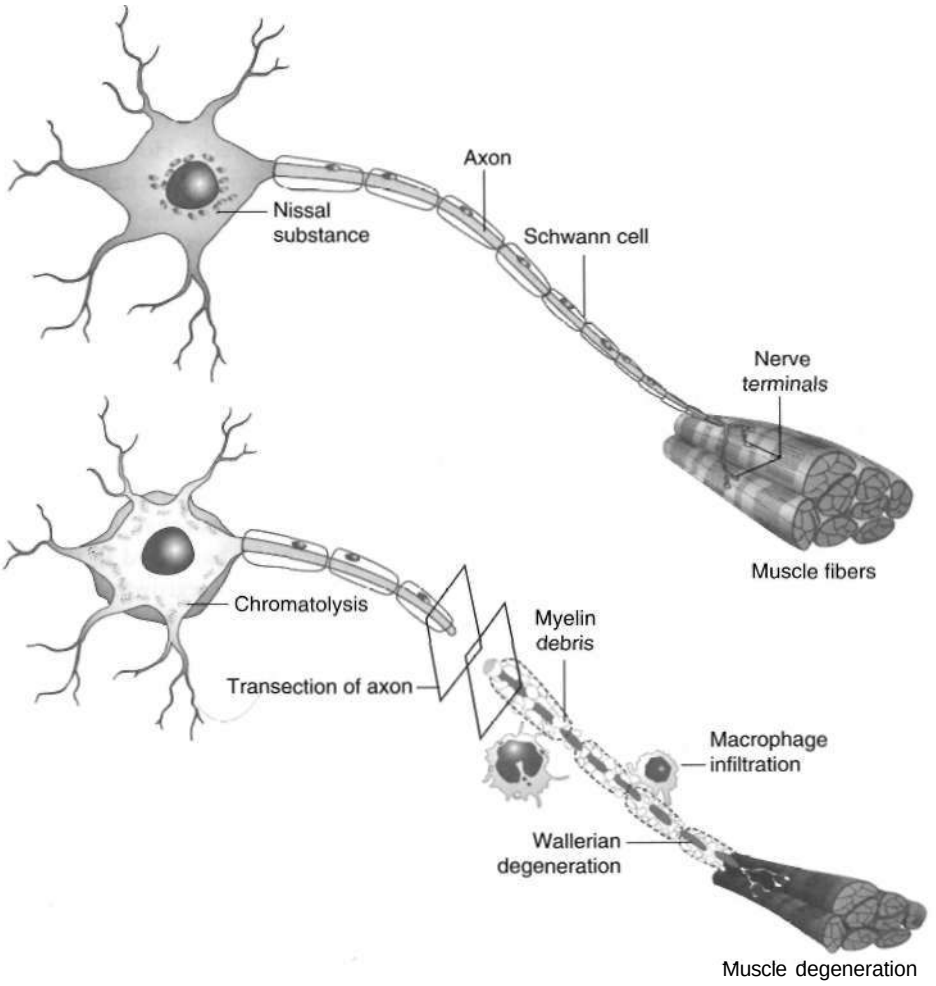

FIGURE S6D.3 Wallerian degeneration. After axotomy, the axon and myelin sheath distal to the transection begin to degenerate. Within a few days, macrophages are recruited into the injury site and digest the debris. Changes also occur proximal to the site of injury. A degree of wallerian degeneration takes place up to the first encountered node of Ranvier, and the cell body undergoes chroma to lysis, winch represents a switch in function of the cell body from axon maintenance to axon regeneration. If regeneration does not take place, the target tissue is not re innervated, and degeneration of the target organ eventually occurs,

process has yet to be defined, hut recent research supports an active father that passive process (i.e., degeneration does not occur simply because the axon cannot receive trophic support from the cell body). Many of the degenerative processes that take place share features with apoptosis. One of the key mechanisms mediating axon degeneration is an increase in the activity of calcium-activated proteinases (calpains). The axon immediately distal to the injury site leaks axoplasm, becomes swollen with organelles, and the plasma membrane develops blebs. By the third day, the nxophsm abruptly undergoes granular disintegration. which rapidly progresses distally.

Contact between the axon and its myelin sheath is compromised, so that within hours of the injury, the Schwann cell separates itself from the myelin sheath. The latter retracts from the node of Ranvicr before undergoing digestion by locally produced lipases and proteases. By day 3, myelin ovoids form in the distal segment. Mitogenic substances released after axotomy, such as glial growth factors and neuregulins, trigger a switch in Schwann cell gene expression so that it ceases production of myelin (which inhibits regeneration). Instead, the Schwann cells enter a proliferative phase, during which they dedifferentiate and upregulate the expression of adhesion molecules and neurotrophins that are necessary for the regenerative phase soon to follow. These denervated Schwann cells form cords aligned along the original basal laminal tubes of the myelinated axons in structures called bands of Bungner that form a pathway along which new axons are destined to grow. They also migrate from the proximal stump across any discontinuity in the basal laminal tubes to assist in guiding axon regrowth.

By day 3, lipases and proteinases, initially produced by the Schwann cell and later by activated macrophages, begin to digest myelin. There is activation of cells of the monocyte-macro phage system within the endoneurium. Additional macrophages are recruited from the circulation into the milieu of the distal degenerating nerve. The likely trigger to this process is the production of chemokines and inrerleukin-10 from local tissues. Myelin debris accumulates in the distal nerve and is slowly removed by phagocytosis.

Changes Proximal to the Site of Injury

A limited degree of axonal breakdown occurs proximal to the injury site, usually up to the level of the first encountered node of Ranvier. Very proximal injury may lead to apoptosis of the cell body itself, but the more common consequence of axotomy is for the cell body to go through a series of dramatic structural changes that set the stage for the upcoming regenerative phase. The trigger for this response has yet to he defined but appears to be related to retrograde transport of injury signals, including nerve growth factor, from the proximal stump together with increased local levels of the Schwann cell injury factor, ciliary neurotrophic factor. The cell body reaction is known as central chromatolysis ("loss of color"), wherein it swells with new proteins that force the nucleus into an eccentric position, and ribosomes become dispersed rather than clumped into Nissl bodies (and therefore can no longer be identified when stained with cationic dyes). One of the earliest axotomy-induced molecular events in the cell body is increased nuclear expression of transcription factors, such as c-Jun, that change the pattern of gene expression from that of axon maintenance to that of protein synthesis. The full complement of proteins generated in this process has yet to be determined. However, certain substances have already been identified with putative roles in the stimulation and regulation of nerve regrowth, including GAP-43 (growth-associated protein of 43 kDa), alpha tubulin, dynein, kinesin, SPRR1A, TOAD-64, ninjunn, and Reg-2.

Studies of axotomized facial nerve show that microglial cells in the CNS migrate to and proliferate around chromatolytic motor neurons. Synaptic connections between the motor neuron and other CNS neurons are lost and displaced by foot processes from local glial cells. This process is known as synaptic stripping.

The entire process of wallerian degeneration takes approximately 1 week. However, the distal segment of axon remains electrically excitable for the first *3-5* days of this process. Usually by the eighth day, the distal (and a small part of the proximal) axon has been completely digested, debris has been cleared from the site, bands of Bungner are in place, and the process of regeneration begins.

Regeneration

The PNS has a significantly greater regenerative capacity than the mature CNS. This results from a multitude of both neuronal and non-ncuronal factors. Furthermore, CNS axons appear to be hampered in their regenerative efforts by inhibitors of axon regrowth, such as Nogo-66 protein, which is expressed on the surface of CNS oligodendrocytes, and chondroitin sulfate proteoglycans, which are present in CNS scar tissue.

Regeneration is a slow process; axonal sprouts grow from the proximal to the distal stump at a rate of 1-2 mm per day (or 1 inch per month). Thousands of these nascent axon sprouts appear at the proximal nerve stump. The tip of the axon sprout is called the growth cone and is a highly motile structure, packed with mitochondria and cytoskcletal components, that emerges just proximal to the severed axon tip in response to regulated shifts in calcium concentrations in the local microenvironment. Under guidance from trophic factors, chemokines, and cell adhesion proteins produced by local tissues, the growth cone navigates through the bands of Bungner to make contact with the distal target organs (Figure 56D.4). These signals induce rapid alterations in the shape and

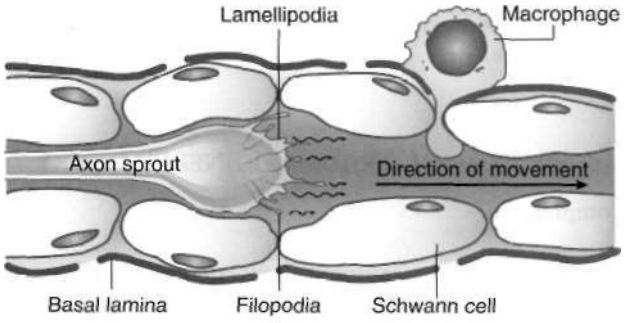

FIGURE 56D.4 Schematic diagram of axonal regeneration. The axon sprout grows out from the proximal stump and proceeds toward the degenerated distal axon stump via the bands of Bungner (formed by proliferating Schwann cells and bounded by the intact basal lamina). Macrophages migrate through the basal lamina into the injury site to phagocytose myelin ovoids and axoual debris. This clears the way for the axon sprout to progress distally. The motile tip of the axon sprout is called the growrh cone, which bears receptor-rich lamellipodia (sheetlike) and filopodia (finger-like). These structures are guided through the bands of Bungner to their target by multiple signals in the microenvironment.

conformation of the internal cytoskeleton, which lead to the extension of finger-like filopodia and sheetlike lamellipodia. Once adequate connections have been established, Schwann cells generate a fresh myelin sheath, which is thinner and has universally short internodes compared with the original sheath. The final stage in regeneration is the development of mature contacts with the target organs, be they motor endplates or sensory receptors.

At the molecular level, several mechanisms regulate and mediate peripheral nerve regeneration, which are summarized here:

- The Schwann cells and surrounding basal lamina that make up the bands of Bungner arc critically important in nerve regeneration. Once an axon has been severed, Schwann cells upregulatc expression of several adhesion factors including cadherins, immunoglobulin superfamily factors, and laminin, which promote the migration of axon sprouts from the proximal stump. In addition, special cytokines called neurotrophic factors are produced by the Schwann cells, including nerve growth factor (NGF), brain-derived neurotrophic factor, insulin-like neurotrophic factor, and ciliary neurotrophic factor. These nerve "fertilizers" promote the growth of axon sprouts.
- Neurotrophic factors such as brain-derived neurotrophic factor, adhesion molecules such as nmjurin, and cytokines and chemotaxins such as osteopontin are present in the tegion of the distal Stump to guide the advancing growth cone of axon sprouts in the correct tissue plane. Other locally produced substances such as nitric oxide and fibrin are also important in the regulation of axonal regeneration and cemyelination.
- It is important that axon sprouts do not stray off the correct path as they migrate from the proximal to the distal stump. In addition to the aforementioned positive chemical signals, inhibitory molecules, such as the semaphorins and nctrins, are produced by the Schwann cell and surrounding tissues to prevent misdirected growth of axon sprouts.
- The basal laminae of target muscle membranes release chemoattractant substances so that new motor axons make contact at the precise points where previous synapses were present. Recent research shows that non-neural elements, probably Schwann cells, are viral in guiding these terminal motor axons to such precise points on the target muscle (Nguyen, Sanes, and Lichtman 2002). Furthermore, Schwann cells at these motor terminals can extend processes to adjacent motor endplates, which increase the degree of muscle fiber innervation. It is important to note that prolonged denervation leads to irreversible degeneration of intramuscular nerve sheaths.

A number of factors dictate the success or failure of nerve regeneration. First and foremost is the nature of the injury itself. A clean transection of a nerve from a scalpel blade creates a small, debris-free, well-perfused gap. Conversely, a crush injury may not only cause extensive damage to surrounding connective tissues and blood vessels but also create an extensive gap between the healthy nerve stumps. In the latter situation, there is often a delay in initiating axonal sprouting as the proximal stump undergoes retrograde degeneration for about 1 cm (a process that can take up to 1 week). Complications are common in such injuries (usually Sunderland grade III and above), not the least of which is the formation of a neuroma. The latter is a multicompartmentalized mass of axon sprouts, fibrotic tissue, Schwann and perineuria! cells, and capillaries caused by disorganized regrowth across a ragged injury site. Neuroma in continuity is unable to satisfactorily conduct electrical impulses to or from the cell body but, when directly stimulated, can discharge spontaneously, causing significant local pain.

Regeneration is rarely 100% efficient. Even in the best functional outcomes, patients often note subtle residual deficits such as loss of dexterity or vague sensory disturbances. There are several plausible reasons why this might be so. Synaptic stripping has reduced the number of neural connections making contact with the cell body, and regenerated myelin sheaths are thinner and more variable in length than previously. New motor axons destined for muscle may inadvertently make their way into sensory-tracts in the distal stump. Motor fibers may fail to reinnervate all the dencrvated muscle fibers and may even reinnervate the wrong muscle entirely. This is known

as aberrant regeneration and produces the clinical sign called synkinesis. For example, after facial nerve injury, there may be aberrant reinnervation of the orbicularis oculi muscle by fibers intended for the orbicularis oris muscle, thus causing involuntary eye closure during voluntary oral movements. Facial nerve visceromotor fibers intended for the salivary glands may instead make their way to the lacrimal gland, thus causing the production of tears during meals.

The premorbid health of the patient is another crucial factor; patients with metabolic disease may not enjoy the same amount of successful regeneration as their healthier counterparts. Recent molecular research shows that certain immediate early genes are not activated adequately after injury in diabetic patients, so vital trophic factors are not produced quickly enough at the injury site to enable maximum nerve axon sprouting. In addition, impaired axonal regeneration in injured diabetic nerve may be related to altered expression of cytoskeletal components, including tubulin and neurofilament proteins, together with either failure or delay in re-establishing an adequate microcirculation,

After 24-36 months, a target muscle will be completely replaced by fibrotic tissue, so functional reinnervation is no longer possible. The rate at which this occurs varies from muscle to muscle; it appears to be prolonged in many of the larger muscles of the body, including the quadriceps, triceps, and biceps. Sensory organs are hardier than motor units and may be intact for up to 7 years after loss of contact with the cell body. Thus even late sensory reinnervation may be able to restore useful protective function to a limb. Neurophysiological, neuropsychological, and functional neuroimaging studies have identified a reorganization of the central motor and sensory pathways in the aftermath of peripheral nerve injury or repair,

Chronic denervation leads to extensive reorganization of representational maps in the sensory cortex, perhaps through redistribution of afferents from adjacent cortical regions. This may involve growth of new collateral sprouts and synapses or the recruitment of neural inputs that were dormant before the injury. There appears to be an age-related deterioration in sensory relearning after peripheral nerve injury: After repair of peripheral nerve lesions in the hand, cortical sensory relearning peaks in children under age 10. Traumatic injury of peripheral motor fibers induces an enlargement of the motor cortex output area. After a nerve transfer surgical procedure, there is a shift in the activity of the motor cortex representing the axon donor (e.g., the intercostal region) to that of the axon recipient (e.g., the elbow region). This plasticity is not limited to cortical structures; there appears to be a limited degree of reorganization within subcortical structures, such as the sensory relay stations in the dorsal columns and thalamus. Indeed, some peripheral nerve injuries may be followed by movement disorders in the affected limb, such as dystonia, choreoathetosis, and tremor, although this remains the subject of debate.

MECHANISMS OF TRAUMATIC NERVE INJURY

Compression

Compressive nerve injuries most commonly affect the nerves that cross over bony protuberances at exposed positions, such as the ulnar nerve at the elbow and the common peroneal nerve at the fibular head (Table 56D.2). Large-caliber myelinated nerve fibers are most susceptible to compression. More often than not compression neuropathies occur in patients who have been sedated or unconscious in a single position for an extended period of time. The classic example is the aforementioned Saturday night palsy, in which the patient characteristically awakens with a wrist and finger drop. Because the primary underlying pathophysiology is that of demyelinating conduction block, there is generally an excellent recovery in the following days to weeks. If a functional deficit remains after an 8-week period, however, it is likely that compression was severe enough to cause an additional element of axon loss. A similar problem can be recognized in the postoperative setting. For example, a patient may awaken from general anesthesia with complete upper limb paralysis caused by compression and stretch of brachial plexus elements between the clavicle and first rib while the arm is extended and hyperabducted intraoperatively. The deficit characteristically reduces to a pure upper trunk distribution in the first 1-2 days and in 2-3 months has fully resolved. Electrophysiological examination may reveal a combination of upper trunk demyelinating conduction block and a lesser component of axon loss. Anesthesiologists take care to protect potentially compressible nerves in patients who are undergoing general anesthesia.

Stretch

Peripheral nerves are vulnerable to serious injury from excessive stretch or traction. As the stretching force increases, the clastic properties of the nerve are overcome and a rupture occurs involving myelin, axon, and connective tissue. In addition, it has heen shown in an in vivo rat sciatic model that an 8% elongation of a nerve increases mtrancurial pressure to the point that blood flow is reduced about 50% (Clark et al. 1992).

An important example of a closed traction or stretch injury is Erb-Duchenne palsy caused by difficult delivery of an infant with consequent excessive traction forces applied to the child's C5-C6 roots and fibers of the upper trunk of the brachial plexus. Significant axonal injury characteristically occurs, which may leave the child with permanent

Table 56D.2: Examples of predominantly compressive nerve injuries

Nerve and site of injury	*Clinical picture*	*Pathophysiology*
Radial nerve at spiral groove of humerus; compression	Saturday night palsy; wrist and finger drop with sparing of triceps function	Demyelinating conduction block Generally recovers over 6-8 wk
Common peroneal nerve at fibular head; compression	Acute footdrop: weakness of ankle dorsiflexion, foot evcrsion, great toe extension; sensory loss on dorsum of ankle and foot	Demyelinating conduction block Generally recovers over 6-8 wk
Upper trunk of brachial plexus between clavicle and first rib; compression or traction	Classic postoperative brachial plexopathy Paralysis of shoulder abduction and elevation Paresthesias into lateral forearm	Predominantly demyelinating conduction block; lesser component of axon loss Usually recovers over 3 mo; can be delayed recovery up to 1 yr
Infraclavicular brachial plexus by pseudoaneurysm or hematoma secondary to transaxillary arteriography; compression	Median neuropathy Combined median and ulnar neuropathy Combined median, ulnar, axillary, and musculocutaneous neuropathies	Predominantly demyelinating conduction block if decompressed within first few hours Axon loss if not repaired
Ulnar nerve at olecranon groove or in cubital tunnel; compression	Paresthesias, pain in medial hand, and weakness of intrinsic hand muscles	Varies between demyelinating conduction block and axon loss; combined conduction block and axon loss

paralysis of upper arm flexors and forearm supinators; the arm is held in the waiter's tip position.

Particularly severe stretch ptoduced by distraction of the neck from the shoulder may cause an avulsion injury of the intraspinal rootlets from the spinal cord. Avulsion injuries most often occur in motor vehicle and motorcycle accidents and generally affect cervical root and brachial plexus fibers rather than components of the lumbosacral plexus or roots. The prognosis is poor; avulsed preganglionic sensory fibers fail to make contact with the spinal cord, and the distance between the site of motor nerve root injury and **the** target musculature is too long for effective regeneration. Furthermore, patients may suffer a severe pain syndrome that is notoriously difficult to treat. A vivid description of this deafferentation pain was by a physician who suffered a brachial plexus avulsion injury himself, having been struck by a window cleaner who had fallen from the fourth floot of a building as he was passing: "The pain is continuous; it does not stop cither day or night. It is either burning or compressing (like a vise) or dragging (a sense of weight) in character, or a combination of all these at the same time" (Murray and Wilbourn 2002, p. 1187).

Laceration

A laceration implies that a nerve has been partially or completely severed by a sharp object. Knife wounds are a common source ol such injuries, but they also can be caused by scalpel blades, broken glass, metal shards, chainsaw blades, wood splinters, and even animal bites. In general, the sharper the blade, the neater the injury and the shorter the distance between proximal and distal nerve stumps, and hence a greater likelihood of a satisfactory functional recovery. An example is the inadvertent transection of branches of the spinal accessory nerve during surgical removal of a mass in the posterior triangle of the neck.

Crush

A crush injury may arise from a sudden, significant force applied to the nerve by a blunt object such as a surgical clamp, lead pipe, baseball bat, or motor vehicle component. Mild degrees of crush may cause a predominantly demyelinating conduction block injury, but axon loss usually is prominent in most cases. Experimental work on animal nerves using smooth-tipped forceps have shown that axon and myelin debris is displaced longitudinally by the crush force, whereas the Schwann cell and its membranes remain intact. After removal of the crush force, axon and myelin tissues flow back into the crush site. Wallerian degeneration and regeneration may be satisfactory if the distance between the proximal and distal healthy matgins is not too great. The nerve remains in continuity, but neuroma formation is common at lengthy injury sites.

Gunshot Injuries

It is important to distinguish between low-velocity and high-velocity gunshot injuries. Low-velocity weapons are more often used in the civilian setting, and their missiles typically cause laceration, compression, and stretch injuries to localized segments of nerve and tissue. High-velocity weapons are used in both the military and civilian settings.

Missiles fired from such weapons are surrounded by a high-pressure zone, the explosive force of which causes extensive damage to both local and distant nerves, together with other tissues such as muscle, bone, organs, and blood vessels. As a consequence, all grades of nerve injury may occur concurrently in and around the wound site. Although neurotmesis lesions may be clearly apparent upon first inspection of the wound, one must consider the very real likelihood of additional areas of neurapraxia and axonotmesis. Therefore it is vital that these patients be serially followed clinically and by electrophysiological studies after the injury.

Radiation

One of the most common radiation-induced nerve injuries is to the infraclavicular brachial plexus during radiotherapy of the axillary chain of lymph nodes for breast cancer, There is a delay in the onset of 6 months to 4 years after therapy, and it most commonly starts with paresthesias in the index or middle finger, followed by weakness in muscles derived mainly from the lateral cord. Progression over time is the rule, so that the involved limb may eventually flail. This form of plexopathy is characterized by the initial development of demyelinating conduction blocks, which actually portend a poor prognosis and thus differ considerably from the neurapraxias associated with acute compression injuries (Wilbourn 1998).

Cold Injury

Peripheral nerves are especially prone to damage from excessively cold temperatures. Frostbite may affect a nerve that has been exposed to ambient temperatures her ween —2.5"C and +10°C for several hours. In the initial stages, the underlying pathophysiology is primarily that of demyelinating conduction block, but continued exposure to low ambient temperatures causes increasingly severe degrees of axon injury. The endoneurium becomes particularly edematous, which raises intraneural pressure to the point at which blood flow is compromised, further compounding the injury. Freezing temperatures cause necrosis of all exposed tissues.

Electrical Injury

Both the CNS and PNS are excellent conductors of electricity. Although this is of obvious physiological importance, it predisposes people to severe neurological injury if injured by an electrical current at home, in the workplace, or by lightning strike. Overall, the severity of an electrical injury is most dependent on voltage. High voltages (>1000 V) may cause frank necrosis of all tissues, including nerve, with subsequent loss of the limb or part thereof. Low voltages (<1000 V) portend a better prognosis and may or may not be associated with cutaneous burns. Most peripheral nerve injuries occur in association with third- and or fourth-degree electrical burns and include mononeuropathies, polyneuropathies, and plexopathics, which may be either early or delayed and often bilateral, depending on entry and exir point locations. The median and ulnar nerves are most commonly affected. Indeed, symptoms and signs may be similar to those of focal compression neuropathies, occurring at sites of minimal limb cross-sectional area where nerves cross over bony protuberances, joule's law predicts ihai maximal heal production should occur at such sites, and it has recently been proposed that perineuria! fibrosis may occur at these sites, giving rise to neuropathies that may be relieved by surgical decompression.

Injection Injury

One of the most severe forms of peripheral nerve injury is that caused by injection of a drug (prescribed or illicit) or toxin. Unfortunately, these injuries are common and are a direct effect of needle insertion into the nerve or, more often, of the drug itself (or its associated buffer and solvent). The presence of a toxic drug around a nerve may stimulate an intense inflammatory reaction, which may cause extensive degrees of epineurial scarring and distortion of the architecture of the nerve trunk. In general, an intact blood-nerve barrier (i.e., an intact perineurial-endoneurial border) will prevent diffusion of drug or toxin into the nerve fibers themselves. However, direct injection of drug into nerve may cause severe endoneural fibrosis with neural ischemia and axon loss. The degree of injury and the pattern observed (diffuse versus focal) vary from drug to drug. The radial and sciatic nerves are the most commonly affected, but injection injuries have also been described in the median, femoral, and ulnar nerves. The first symptoms often are immediate pain, paresthesias, and paralysis, but in some patients the onset apparently is delayed. Patients who do not show signs of recovery within 5 months or who have persistent pain need surgical intervention.

EVALUATION OF NERVE TRAUMA

Clinical and Electrodiagnostic Examination

The assessment of any traumaric nerve injury begins with a careful bedside history and clinical examination and is preferably carried out by those with particular expertise in the area. There are certain key elements to record in the history; the most important is the time interval that has elapsed between the injury and presentation. For example, if

4 years have elapsed from the time of injury, it is very unlikely that any significant motor recovery will take place despite surgical intervention because of extensive degeneration of muscle fibers. The mechanism of the injury is also important; intraoperative transection of a nerve by a scalpel is likely to portend a better prognosis than a laceration by a chainsaw. Elderly patients and those with metabolic disorders such as diabetes and renal failure are less likely to enjoy a good functional outcome after nerve injury.

A detailed knowledge of peripheral neuroanatomy is needed to appreciate the nature, extent, and likely consequences of a nerve injury. During examination one should also focus on whether the wound is open or closed, whether other tissues are involved, whether wound contamination or infection is present, and whether the vascular supply of the region might he compromised. An estimation of the distance between the injury and its target organ (e.g., muscle) is also of prime importance. For example, if the target organ is 3 inches from the injury site on the nerve, there is a reasonable likelihood of a good outcome over the next 3 months. The reverse is true of nerve injures that occur at a great distance from the target muscle; a lower trunk brachial plexus injury may be 16 inches or more from target intrinsic hand muscles. Tinel's sign, a tingling induced by mechanical distortion of the distal terminus of a regenerating axon (elicited by tapping the nerve with a finger or tendon hammer), is a useful bedside test that may help discern the site and rate of nerve regrowth after nerve injury or nerve repair.

Additional investigations are important in defining any nerve injury. (. hie I among these is the eleetrodia gnostic examination (EDX), which consists of nerve conduction studies (NCSs) and needle electrode examination (NEE; sec-Chapter 37B). The two main components of the NCS are assessment of sensory nerve action potentials (SNAPs) and compound muscle action potentials (CMAPs}, although late responses, including F waves and the H reflex, also provide useful information, particularly about the proximal portions of nerves. The EDX provides information about the site of the injury, its underlying pathophysiology, and the rate of recovery.

The timing of this complex test is vital and is of both practical and prognostic importance. If it is performed too soon after the injury, there may not have been sufficient time for EDX signs of axon loss to develop, and the physician cannot judge whether a nerve lesion is caused primarily by demyelinating conduction block or axon loss. In the case of a severe axon loss injury, CMAPs and SNAPs are entirely normal for the first 2 days despite the presence of an obvious clinical deficit and an inability of the patient to voluntarily recruit motor units during NEE. By day 3, however, wallerian degeneration should cause some loss of the distal CMAP amplitude, and by day 9 the CMAP may have further diminished ot even disappeared. By days 11-12 the SNAP amplitude also is diminished (the reason for the earlier loss of CMAP amplitude relates to the early failure of neuromuscular junction transmission). Finally, after a few weeks, there should be clear evidence of active denervation in the form of fibrillation potentials and positive sharp waves during NEE.

If the lesion is caused by conduction block, one should detect a significantly (e.g., >50%) lower proximal as compared with distal CMAP amplitude, with abnormal neurogenic motor unit action potentials or even their complete absence. The distal CMAP amplitude (if stimulating and recording beyond the site of conduction block) should be within normal limits in cases of conduction block. There may be a limited amount of axon loss if injury has occurred to some axons at the site of the conduction block. Therefore there may be some positive sharp waves or fibrillation potentials on NEE. It is important to remember that many nerve injuries involve components of both conduction block and axon loss (Wilbourn 1998).

There is no way to clearly differentiate a predominantly demyelinating conduction block process from an axon loss lesion on the basis of clinical symptoms or signs or of an EDX performed within 7 days of the injury.

An avulsion injury that involves both anterior and posterior preganglionic segments ma) produce a characteristic EDX pattern; there will be loss of CMAP amplitudes but preservation of SNAP amplitudes. This is because the lesion affects the dorsal root proximal to the ganglion that lies outside the spinal canal in the intervertebral foramen.

Repeat examination should always be performed to assess for electrophysiological recovery or worsening. One must assess for recovery of SNAP and CMAP amplitudes; during regeneration, the SNAP amplitude characteristically recovers before the motor amplitude. Furthermore, one may appreciate some degree of normalization of motor unit recruitment and morphology. One particularly important NEE feature is the appearance of low-amplitude, polyphasic unstable nascent motor unit potentials, which is important EDX evidence of early motor unit reinnervation.

Somatosensory evoked potentials (SSEPs) resulting from distal stimulation of the injured nerve may also be useful in evaluating peripheral nerve trauma, giving information about the integrity of posterior sensory tracts in the spinal cord and therefore useful in evaluating suspected posterior nerve root avulsion. However, the presence of an intact SSEP does not reliably indicate satisfactory nerve root function. SSEPs are so sensitive that they may yield positive waveforms in the presence of only a few hundred intact nerve root axons (Kline 2000). Furthermore, they do not provide enough localizing information to be of great assistance in postganglionic peripheral nerve injuries and do not provide information about injury to anterior (motor) rootlets in the spinal canal. Intraoperative SSEPs have been shown not to decrease the incidence of iatrogenic sciatic neuropathies during surgical repair ot acetabular fractures.

Neuroradiology Assessment

Even the most careful clinical and EDX examinations may be limited in certain situations. A very proximal injury to the sciatic nerve or brachial plexus may be inaccessible to a proximal motor stimulation point, thus pteventing assessment of proximal conduction. It may be difficult to accurately localize axon loss lesions either clinically or by EDX in certain sections of a peripheral nerve; for example, the ulnar nerve lacks any motor branch above the elbow. Furthetmore, in the earliest stages of closed-wound nerve trauma, it is not possible to differentiate a nerve transection from a lesion that remains in continuity. Radiological techniques have always had a part to play in nerve trauma evaluation, in cases of multiple trauma, plain films of the skull base, spine, and long bones may disclose fractures at sites that may compromise local nerve structures. Computed tomography myelogtaphy often is used to diagnose nerve root avulsions; conttast may be seen passing through the torn meningeal sheaths of avulsed nerve roots (pseudomeningoceles). Magnetic resonance imaging (MRI) of the spinal cotd has replaced computed tomography myelography as the first-line investigation in cases of suspected nerve root avulsion.

The most exciting advances have been in the emerging field of MRI neurography, which is based on the longitudinally orientated water diffusion properties of nerve as opposed to surrounding tissues. Diffusion images of nerve require high-field-strength MRI scanners, but one may also obtain detailed images using 1.5-Tesla scanners in conjunction with phased atray coils. For example, signal hypcrintensity can be seen on T2-weighted and short time inversion tecovery images of traumatized netve segments; abnormal high signal is seen both at and **distal** to the injury site. This MRI modality can diffetentiate between axonotmesis and neutotmesis lesions and also detect neutoma formation at nerve repair sites; using specialized phased array coils, one may even be able to identify which fascicles in a nerve trunk are injured and which are spared. These signal changes may be ttansient in cases of mild nerve injury or may be prolonged (up to many years) in severe preganglionic brachial plexus avulsion injuries. Early (within 1 week) signal hyperintensity may also be seen in denervated muscle on T2-weightcd and shott time inversion recovery (STIR) images, which will persist if nerve discontinuity picvents reinnervation (Figure 56D.5}.

MRI neurography is still a developing field, As the technique is perfected and experience grows, it will become a standard part of the evaluation of nerve injury,

SURGICAL REPAIR OF NERVE TRAUMA

The necessity for peripheral nerve surgery depends on several key factors, including the nature of the injury, the site of the injury, and the likelihood of satisfactory functional recovery. Surgical intervention is not indicated in an obvious case of neurapraxia because it is likely that the patient will enjoy an excellent outcome. However, one cannot be certain in cases of axonotmesis, which account for approximately 70% of all setious nerve injuries. Although connective tissue elements are intact and therefore the lesion is in continuity, a neuroma may develop that bars the progress of axonal sprouts from the proximal to the distal stump. One may suspect such a problem in a patient who docs not make a clinical recovery at the expected rate or in the patient who complains of significant spontaneous pain at the site of the injury. It is important for the surgeon to be aware that neuromas often are invisible to the naked eye and impalpable during wound exploration.

A specialized intraoperative technique called nerve action potential (NAP) recording has been developed to enable the surgeon to locate abnormal sites of nerve conduction caused by axon loss or neurapraxia and to define the healthy margins of the nerve. This technique entails placing stimulating and recording electtodes directly onto the nerve surface proximal and distal to an obvious or suspected site of nerve trauma that has remained in continuity. If the netve is healthy, the segment will transmit a normal NAP between the stimulation point and the recording point. NAP recordings provide evidence of regeneration within 8 weeks of a focal in-continuity lesion; the presence of a reasonable NAP in the distal segment indicates the ptesenee of 3000-5000 moderate-diameter myelinated axons at the recording site (Spinner and Kline 2000). Conversely, a neuroma or severely scarred intraneural site may fail to transmit an impulse and will manifest as a dropout in NAP waveform at the recording point. Absence of a NAP 6 weeks or more after the injury generally indicates a Sunderland grade IV lesion and is an indication for surgical repair of the injury.

Neurotmesis lesions do not regenerate spontaneously and necessitate some form of surgical intervention, the extent and timing of which depend on the severity of the injury. If the wound is open, it may be easy to inspect the site and make an immediate decision about the need for repair. For example, a nerve transection caused by a sharp blade in a clean wound may be repaired within 72 hours by direct end-to-end anastomosis (primary repair). A rapidly worsening neurological deficit in a closed wound may indicate the need for early intervention; one must also considet vascular lesions such as pscudoancurysms, expanding hematomas, or arteriovenous fistulas that may damage the netve in the wound site. Furthermore, the incteased interstitial pressures characteristic of compartment syndrome may cause a rapidly worsening neurological deficit necessitating emergency fasciotomy.

On the other hand, a blunt nerve laceration with a ragged epineurium (e.g., from a propeller blade) should be formally repaired at a later stage when it is easier to judge

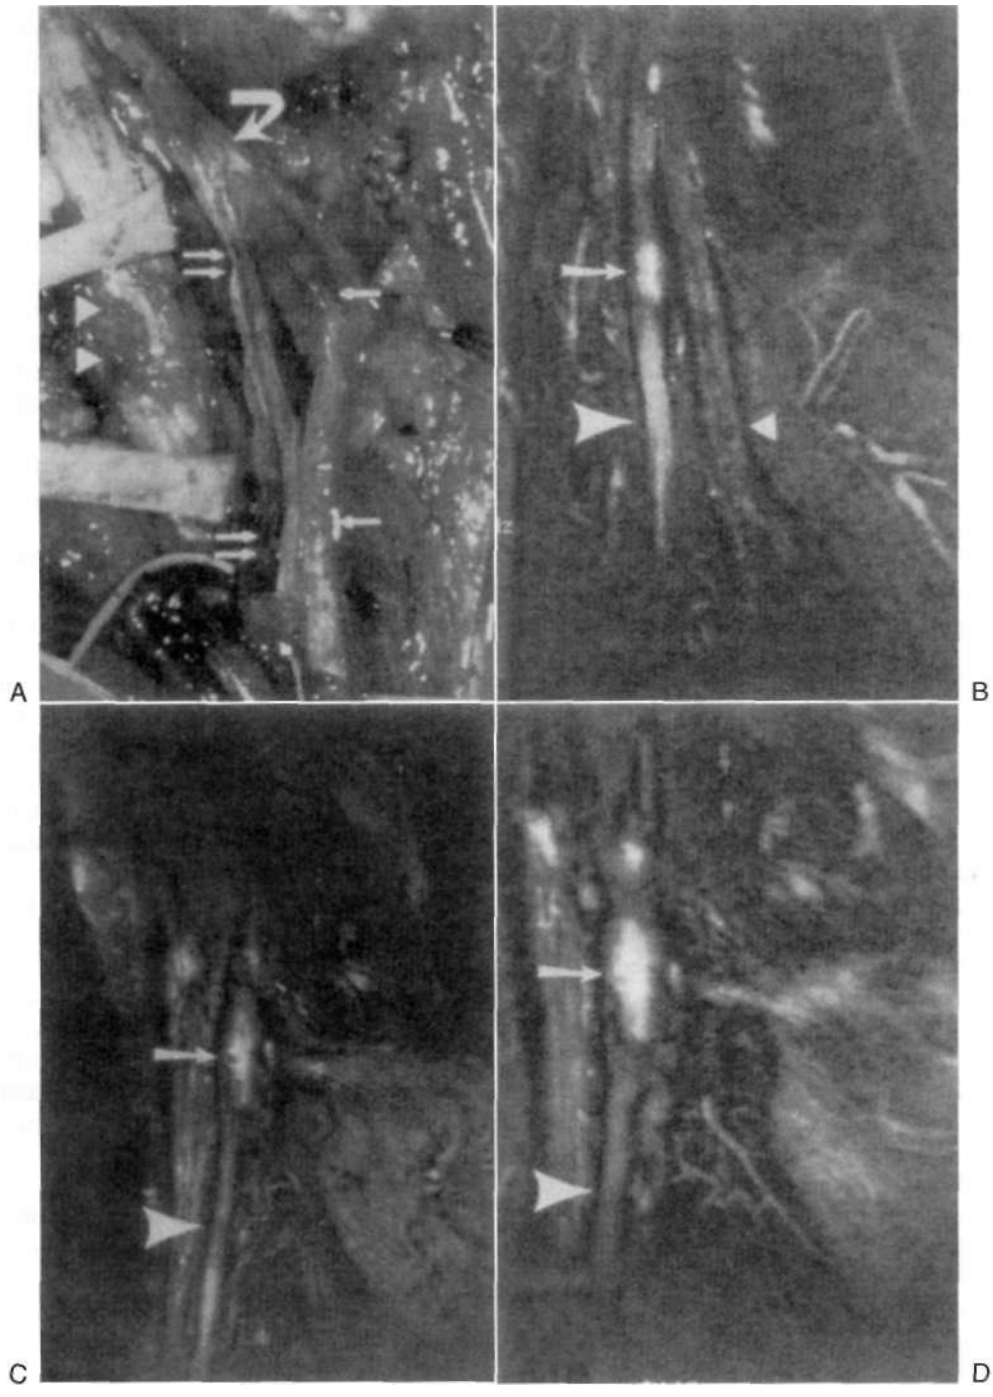

FIGURE 56D.5 MRl in nerve injury. (A) A scarred suture repair site after a laceration injury to the peroneal nerve was repaired using two sural nerve grafts *(double white arrows).* (B) High signal (T2-weighted) both at *[small arrow)* and distal to *(large arrowhead)* the scarred suture repair site 6 months after the original injury and suture repair but before the graft repair. (C) incomplete resolution of high signal seen several months after graft repair. Patient showing signs of clinical improvement. (D) 16 months later, the patient has made significant recovery. Almost complete resolution of high signal from the distal nerve segment *(large arrowhead).* High signal remains at the graft repair site *(arrow).* (Reproduced with permission from Grant, G. A., Britz, G. W., Goodkin, R., et a I. 2002, "The utility of magnetic resonance imaging in evaluating peripheral nerve disorders," *Muscle Nerve,* vol. 25, no. 3, pp. 314-331, Figure 10, p. 327. Wiley Periodicals, Inc., 2002.)

the true extent of the injury. For example, there may be a long segment of in-continuity injury proximal and distal to the transection or other areas of compression or axonotmesis at distant sites. One must also account for injury to vascular structures, bone, and soft tissues in the wound site. In such situations, it is prudent to delay formal nerve repair for at least 2 weeks. At the initial surgical debridement of the wound, the surgeon tacks the proximal and distal nerve stumps to local healthy fascial and muscular tissue and later reinspects the wound at a time when wallerian degeneration has occutred, the stumps have retracted, and easily detectable neuromas have formed. This is called a delayed primary repair.

Most nerve injuries occur in closed wounds and thetefore are more difficult to judge. One must pay close attention to clinical or EDX signs of recovery during serial evaluation; one should follow the patient for 2-3 months in the case of a suspected focal lesion and 4-5 months for a suspected lengthy lesion. Failure to progtess usually indicates a mote severe injury that warrants surgical inspection (Spinner and Kline 2000). In general, surgical repair of nerve trauma is needed for most grade IV and all grade V injuries.

Surgical Procedures

Great advances in peripheral nerve surgery have been made since the introduction and refinement of microsurgical techniques in the last half century. A detailed account of peripheral nerve surgery is beyond the scope of this chapter, but the basic techniques that are currently used in most specialized centers are outlined in the following sections.

Neurolysis (External and Internal)

The presence of scar tissue either around or within the nerve can significantly impede regeneration. Therefore one of the most important ptocedures is debridement of the wound, isolation of the nerve injury site, and mobilization of vascular and connective tissues above and below the nerve injury. This external neurolysis frees the nerve from surrounding scar tissue and may be sufficient to manage in-continuity lesions with recordable NAPs. Incomplete lesions may include scat tissue that involves the cpifascicular epineurium or the interfascicular epineurium. Internal neurolysis entails surgically freeing the nerve trunk or fascicles from such scar tissues using the surgical microscope. If the epifascicular epineurium is the only site of scat formation, a longitudinal incision called an epineurotomy may be sufficient. However, interfascicular scars may necessitate more intricate separation of involved from uninvolved nerve fascicles. The latter procedure usually is performed as part of the preparation for nerve graft repairs during which NAPs are used to identify damaged nerve fascicles. Review of outcomes after neurolysis of in-continuity radial and median nerve injuries at a major nerve trauma center showed good motor functional recovery in 98% and *95%* of cases, respectively,

Primary Neurorrhaphy

Primary repair (primary neurorrhaphy) of a neurotmesis lesion involves the direct suturing of the proximal to the distal stump and is the procedure of choice. If the parent nerve trunk contains few fascicles that are easy to align, an epineurial repair often is the preferred option. Consequently, this kind of repair usually is carried out on the distal segments of smaller nerves in the distal upper and lower extremity (e.g., digital nerves). Sutures are placed through the epineurium of the proximal and distal stumps, which ate then tightened into approximation without causing undue tension on the newly repaired nerve. Local landmarks, such as the orientation of blood vessels, are used to ensure the correct alignment of the nerve endings.

As mentioned previously, the proximal portions of larger nerves may have a complex intetlaced fascicular pattern (Sunderland's plexus), making it difficult to align transected whole nerve endings. If one were to carry out a whole nerve coaption and fail to pay attention to the fascicular pattern, a predominantly motor fascicle in the proximal stump could come into contact with a predominantly sensory fascicle in the distal stump, which would result in an unsatisfactoty functional outcome. In fascicular repair, the preferred technique in such proximal extremity nerve injuries, the surgeon coapts the proximal and distal ends of individual fascicles rather than the entire nerve trunk. Sutures are placed through the fascicular perineurium (Figure 56D.6). Histochemical staining of stumps, local landmark orientation, and intraoperative NAPs help the surgeon to choose the correct fascicular stumps.

Overall, good functional outcome is seen in about 70% of primary neurorrhaphies, but results vary. In one major nerve trauma center, good functional outcome was observed in 91% of radial and 86% of median nerve injuries repaired by primary neurorrhaphy.

Nerve Grafts

If there is a significant gap between the proximal and distal stump, as in a sevete neurotmesis lesion from a high-velocity gunshot, it may not be possible to perform primary neurorrhaphy because excessive tension will be placed on the nerve. This will increase intraneural pressure to the point at which blood flow is compromised. Excessive stretch leads to scat formation, especially when there is passive stretch across bony protuberances and joints. In Mich situations, nerve grafting is the preferred choice. This entails suturing a piece ot nerve harvested from elsewhere between the proximal and distal stumps of the injured nerve. In most centers, an autologous nerve graft is used

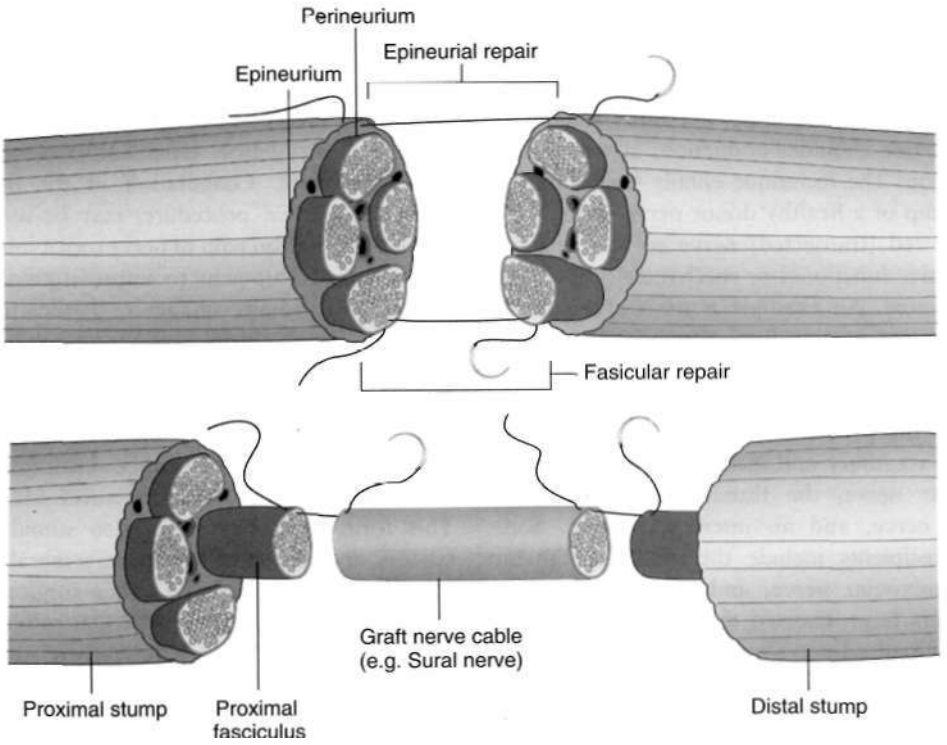

FIGURE 56D.6 Basic techniques in surgical repair. Schematic diagram illustrating the basic concepts of epineurial, fascicular, and graft repair. Direct end-to-end neurorrhaphy of small distal nerves usually is carried out using an epineurial repair approach *(top),* which entails placing sutures through the epifascicular cpincurium and bringing the nerve stumps into approximation. Fascicular repair *(top)* is preferred for more proximal nerves that have a more complex interlaced fascicular pattern. Stumps are approximated using sutures that have been placed through the perineurium. Graft repairs *{bottom)* are performed when direct end-to-end neurorrhaphy would cause excessive tension on the repair site. The graft material is harvesred from a nonessential sensory nerve (e.g., the sural nerve), which is then sutured between fascicles.

(i.e., a healthy segment of nerve is removed from the patient's body and sutured between the stumps at the trauma site; Millesi 1998). In general, these grafts are sutured via a fascicular rather than an epineurial approach (see Figure 56D.6). Common donor nerves are those that are nonessential and largely sensory in function such as the sural nerve, lateral antebrachial cutaneous nerve, and lateral tumoral cutaneous nerve. It is important to counsel the patient that once such a nerve is sacrificed, there will be an area of permanent sensory loss in the sensory distribution of the donor nerve.

The success rate of nerve grafting varies, but a satisfactory functional outcome occurs in about 50% of cases. Results vary depending on the experience and skill of the nerve trauma team and the particular nerve involved. For example, good functional recovery of motor function was observed in 68-75% of median and 80% of radial nerve injuries that were repaired by nerve grafting at one major nerve trauma center. Retrospective review of functional outcomes after repair of sciatic nerve injuries at the same center reported good outcomes after repair of tibial but not peroneal *(<3>6%)* division injuries. A number of factors influence whether successful functional regeneration takes place after graft repair, such as the distance between the proximal and distal stump and the type of nerve graft or conduit used. However, a recent primate study showed that the single most important prognostic factor is the time interval between the nerve injury and reinnervation of the target motor or sensory organ. The authors of this study postulate that there may be a time-dependent degeneration of Schwann cells in the bands of Biingner together with fragmentation of the basal lamina in the distal nerve. In addition, the neuron proximal to the injury site may also lose some of its ability to support axon regeneration. They suggest that, at least in nonhuman primates, the optimum time to successful reinnervation of the target organ using nerve grafts occurs within 100 days of sustaining the nerve lesion (Krarup, Archibald, and Madison 2002).

In general, a better outcome is seen in younger, healthier patients. Regeneration is better across shorter nerve grafts. Pure motor and pure sensory nerves recover more satisfactotily than mixed nerves.

Nerve Transfers

Avulsion injuries create a special problem in nerve repair because there is often no proximal stump with which an anastomosis may be made to a distal stump or an

intervening nerve graft. A specialized nerve transfer technique, also called neurotization, has been developed to improve the outcome of these functionally debilitating injuries. Neurotizations in the upper extremity usually are performed to provide shoulder abduction, elbow flexion, and hand sensation. The technique entails the transfer of the prn\im;i] stump of .1 healthy donor nerve to the distal stump of an injured (transected) nerve so that a target muscle of particular functional or mechanical importance becomes reinnervated. An example is the transfer of the spinal accessory nerve to the distal stump of the injured musculocutaneous nerve in a case of proximal upper extremity nerve root avulsion; the patient gains useful elhow flexion in the process. Other axon donor nerves depend on the exact injury and include the phrenic nerve, the suprascapular nerve, the thoracodorsal nerve, the medial pectoral nerve, and an intercostal nerve. Some common axon recipients include the musculocutaneous nerve, the suprascapular nerve, and the axillary nerve. Certain researchers have assessed the feasibility of direct reimplantation of avulsed nerve roots back into the spinal cord, with mixed results. Although some patients regain useful function of proximal limb muscles, more distal hand muscles are not successfully reinnervated, and there is a risk of causing operative injury to spinothalamic tracts within the spinal curd.

A similar problem also arises when the very terminal segments of a nerve have lost contact with the target organ, thus failing to leave a distal stump for reanastomosis. Although it is performed in highly specialized centers, a technique has been developed in which the distal nerve stump is split into fascicles, which are then implanted directly into the endplate region of the target muscle belly. One may even transfer an entire muscle together with its blood and nerve supply to the site of a functionally more important muscle that is nonfunctioning through prior injury. For example, a chronically denervated and degenerated biceps muscle in the upper extremity may be replaced by a neurotized and vascularized gracilis muscle that has been harvested from the lower extremity.

OTHER ASPECTS **OF NERVE INJURY MANAGEMENT**

Patients often complain of pain in the distribution of an affected nerve, which may be deep-seated, burning, stabbing, or ice cold in nature. Such pain may be caused by persistent distortion, compression, or ischemia of the nerve and may also represent a subtype of complex regional pain syndrome (type I or II) or post-traumatic neuralgia or in others may be psychological in origin. Some patients also complain of pain for secondary gain, which may or may not be apparent in the history. For many patients it is the most significant symptom of their injury and affects all aspects of daily living. The most severe pain syndrome is seen after avulsion of preganglionic posterior nerve roots and is very difficult to treat. A number of pharmacological and surgical procedures may assist these patients. Some of the mote commonly prescribed agents include amitriptyline, **carba-**mazepine, mexiletinc, gabapentin, clonazepam, opioids, and topiramate. Coagulation of the dorsal root entry zones (the DREZ procedure) may be useful in managing the deafferentation pain of nerve root avulsion. Novel drugs are under development to improve pain, including modulators of sodium channels, modulators of nicotinic acetylcholine receptors, and N-type voltage-sensitive calcium channel blockers. Physical and occupational therapy are integral parts of nerve injury management for **both** surgical and nonsurgical patients. It is imperative that range of motion exercises be instituted early after an injury to prevent joint contractures and muscle wasting, This form of therapy may also stimulate and enhance sensory and motor relearning in cerebral cortex. **It** is **best** to allow a brief interlude after a surgical nerve repair to allow wound healing and revascularization before performing full physical therapy, but passive movements may be instituted early. A range of specialized assist devices and splints are available to ensure adequate functional positioning of a weak limb. It is preferable to custom fit these lightweight devices so that agonist muscles are not overstretched and antagonists arc not excessively shortened.

FUTURE DIRECTIONS

Although the gold standard in nerve gap management is the autologous nerve graft, there are some disadvantages to its use. As already mentioned, the technique requires that a perfectly functioning nerve from elsewhere be sacrificed to repair the injured nerve. This may present a significant problem if multiple nerve trauma occurs or the gap between stumps is very great. Furthermore, nerve regeneration across the graft may not be as effective as across a direct end-to-end repair; the regenerating axon must make its way across two suture lines and the intervening graft tissue before making contact with the distal stump. The intrafascicular pattern may be very different between the nerve and graft stumps, and although the graft is from the same patient, it may not produce as much tropic and trophic support as local nerve tissue. The more suture lines present, the greater the chance of in situ neuroma formation, and in cases of severe multiple trauma there is the possibility of an inadequately vascularized graft bed. One approach may be to use human cadaveric nerve grafts (allografts) rather than autologous nerve grafts, which would obviate the sacrifice of perfectly healthy nerves from the patient to treat a damaged nerve and would also provide a more plentiful supply in the event that multiple grafts are needed. However, this foreign material triggers graft rejection, which necessitates the administration of potent immunosuppressive therapy.

For these reasons, there have been moves to develop alternative conduits to bridge the gap between separated nerve stumps. Much of this research has been carried out in animal models using many absorbable and nonabsorbable synthetic, semisynthetic, and biological devices, including collagen, epincurium, mesothelium, muscle, vein, glycolide trimethylene carbonate, silicone, poly-3-hydroxybutyrate, and poly-L-lactic acid. Although the results have been variable, most such devices have not been quite as effective as autologous grafts; nevertheless, they hold promise for the future. A recenr randomized prospective trial in humans showed favorable results using polyglycolic acid conduits for repair of digital nerves. Superior functional sensory outcome was observed when conduits were used to repair gaps of 4 mm or less compared with primary neurorrhaphy, and superior results occurred when conduits were used to repair gaps of 8 mm or more compared with autologous nerve grafts.

A number of ingenious modifications have been used to improve the effectiveness of conduits, the most widely reported of which is to seed the lumen of the entubulation device with a monolayer or scaffold of Schwann cells. Research in cell cultures and animals indicates that these seeded grafts may approach autologous graft levels in their ability to support nerve regeneration.

Another experimental approach is to seed synthetic conduits not with whole cells but with molecules, such as neurotrophic factors, that are known to promote regrowth of axons. For example, nerve growth factor has been studied extensively in the treatment of peripheral neuropathy. It is selectively trophic for small-caliber, unmyelinated sensory and autonomic (sympathetic) nerve fibers, and reduced levels may play a significant part in the pathogenesis of small fiber sensory neuropathy. Several trials have already been undertaken to assess the potential effect of subcutaneous recombinant human nerve growth factor in the management of diabetic and HIV-rclated small fiber polyneuropathies, but despite promising early results a placebo-controlled phase III trial did not show any clear benefit in the treatment of diabetic neuropathy. However, when one considers this in the context of nerve trauma repair, the delivery of neurotrophic factors via a local matrix bypasses many of the problems of systemic administration and also ensures a steady local concentration of agent along the course of the conduit. There is additional early evidence that vascularizing synthetic conduits containing vascular endothelial growth factor may also improve target organ reinnervation.

As further inroads arc made into the understanding of the molecular basis of nerve injury and regeneration, it is likely that other novel drug treatments will be evaluated in human trials to maximize functional recovery in both surgical and nonsurgical settings. Such agents may include modulators of cell signaling, cell adhesion, or inflammation and immunosuppressant drugs such as cyclosporine and rapamycin that also promote axon regeneration. Non-pharmacological strategies may also be of benefit. For example, it has been shown in an animal model of nerve injury that it may be possible to rescue muscles from denervation-induccd degeneration by transplanting embryonic anterior spinal cord cells into peripheral nerve. Furthermore, there is some evidence that continuous electrical stimulation using an implantable device may improve functional outcome after nerve injury. A gene therapy approach may be used to deliver neurotrophic and other substances to target tissue, bypassing the problems encountered by systemic administration, such as low bioavailability, short half-life, and frequent side effects caused by high dosage needs. Several groups have reported beneficial effects in animal models of nerve root avulsion using viral vectors to deliver the coding sequences of adhesion molecules, antiapoptotic proteins, and neurotrophic factors to both glial and neuronal cells in the dorsal and ventral horns of the spinal cord. Other advances undoubtedly will include detailed studies on brain plasticity after nerve injury and how this might be enhanced by various stimulation techniques to improve functional outcome. Magnetoencephalography is an exciting new technique that may prove invaluable in the finely detailed mapping of cortical responses to peripheral nerve injury.

Chapter 57
Vascular Diseases of the Nervous System

A. ISCHEMIC CEREBROVASCULAR DISEASE

Jose Biller and Betsy B. Love

EPIDEMIOLOGY AND RISK FACTORS

Every year, at least 750,000 Americans experience a new or recurrent stroke. Despite gradual declines in overall stroke death rates in many industrialized countries, stroke remains the third leading cause of death, with 160,000 stroke-related fatalities annually in the United States. Stroke is also the leading cause of disability in adults. Of the hundreds of thousands of stroke survivors each year, approximately 30% require assistance with activities of daily living, 20% require assistance with ambulation, and 16% require institutional care. The human and financial costs of stroke are immense, and its estimated annual economic impact on our society, both directly in health care and indirectly in lost income, is approximately $41 billion.

Steep decreases in stroke incidence and mortality have occurred in industrialized nations in recent years. The reduction in stroke mortality in the United States has been attributed to a declining stroke incidence, with suggestive evidence favoring a trend in declining stroke severity. Despite these trends in developed countries, stroke mortality and incidence are still high in many other countries. Socioeconomic factors, dietary and lifestyle behaviors, different patterns of risk factors, and environmental conditions may explain the different incidences of stroke observed in different parts of the world.

A number of factors that may be classified as modifiable and unmodifiablc increase the risk of ischemic stroke (Table 57A.1). Risk factors for stroke include older age, male gender, black ethnicity, low socioeconomic status, family history, arterial hypertension, diabetes mellitus, dyslipidemia, heart disease, cigarette smoking, excessive alcohol intake, and **body** mass index. Clinicians cannot assume that these risk factors express themselves exclusively by accelerating atherosclerosis. There are also considerable data implicating hemostatic and microcirculatory disorders in stroke as well as circadian and environmental factors.

The incidence of stroke increases dramatically with advancing age, and increasing age is the most powerful risk factor for stroke. The incidence of stroke doubles each decade past *55* years of age. Half of all srrokes occur in people older than 70 to 75 years. Men develop ischemic strokes at higher rates than women up to the age of 75 years. With an estimated 20% of the population being older than age *65,* and with greater than 10 million octogenarians, and an increasing life expectancy in the United States, it is predicted that in the near future, the incidence of stroke will reach 1 million per year. The rate of cerebral infarction is higher in blacks than in whites; this could be partially explained by the higher prevalence of diabetes and arterial hypertension experienced by blacks.

Table 57A.1: Risk factors for ischemic stroke

Nonmodifiable	*Modifiable*
Age	Arterial hypertension
Gender	i'r.siiMrnl ischemic ;imicks
Race/ethnicity	Prior stroke
Family history	Asymptomatic carotid hruit/sluisusis
Genetics	Cardiac disease
	Aortic arch atheromatosis
	Diabetes mellitus
	Dyslipidemia
	Cigarette smoking
	Alcohol consumption
	Increased fibrinogen
	Elevated homocyst(e)ine
	Low serum folate
	Elevated anticardiolipin antibodies
	Oral contraceptive use
	Obesity

Blacks also have higher rates of intracranial atherosclerotic occlusive disease, compared with whites (Sacco et al. 1995). **The** stroke incidence and case fatality rates are also markedly different among the major ethnic groups in Auckland, New Zealand. Maori and Pacific Islands people have a higher mortality within 28 days of stroke when compared with Europeans, especially men (Bonita ct al. 1997}.

Heredity seems to play a minor role in the pathogenesis of cerebral infarction. However, an increased risk is seen with a family history of stroke among first-degree relatives. There are also a number of genetic causes of stroke. Some inherited diseases, such as the hereditary dyslipoprotein-emias, predispose to accelerated atherosclerosis. A number of inherited diseases ate associated **with non**atherosclerotic vasculopathies, including Ehlcrs-Danlos (especially type IV) syndrome, Marfan's syndrome, Rendu-Osler-Weber disease, and Sturgc-Wcbcr syndrome. Familial atrial myxomas, hereditary cardiomyopathies, and hereditary cardiac conduction disorders are examples of inherited cardiac disorders that predispose to stroke. Deficiencies of protein C and S or antithrombin (AT) **III** are examples of inherited hematological abnormalities that can cause stroke. Finally, rare inherited metabolic disorders that can cause stroke include mitochondrial encephalopathy, /actic acidosis, and stroke-like episodes (MELAS), Fabry's disease, and homocysrinuria. Controversial evidence shows that the presence of the apolipoprotein K2 allele in elderly individuals and deletion of the gene for the angiotensin-converting enzyme may increase the risk of stroke (Slooter et al. 1997).

At least 25% of the adult population has arterial hypertension, defined as systolic blood pressure (SBP) greater than 140 mm Hg, or diastolic blood pressure (DBP) greater than 90 mm Hg. High notmal blood pressure is defined as SBP between 130-139 mm Hg or DBP between 85-89 mm Hg; normal blood press Lire as SBP less than 130 mm Hg and DBP less than 85 mm Hg, and optimal blood pressure as SBP less than 120 mm Hg, and DBP less than 80 mm Hg (National Institutes of Health |NIH| 1997), Arterial hypertension predisposes to ischemic stroke by aggravating atherosclerosis and accelerating heart disease, increasing the relative risk of stroke three- to fourfold. The risk is greater for patients with isolated systolic hypertension and elevated pulse pressure. Arterial hypertension is also the most important modifiable risk factor for stroke and the most powerful risk factor for all forms of vascular dementia. Lowering blood pressure in stroke survivors helps prevent recurrent stroke and is more important than the specific hypotensive agent used. Blood pressure treatment, resulting in a reduction in SBP of 10-12 mm Hg and *5-6* mm Hg diastolic, is associated with a 38% reduction in stroke incidence (MacMahon et al. 1996). Treatment of isolated systolic hypertension in the elderly is also effective in reducing stroke risk. The Systolic Hypertension in the Elderly Program showed a 36% reduction in nonfatal plus fatal stroke over 5 years in the age 60 and older group when isolated systolic hypertension was treated. Treating systolic hypertension also slows the progression of carotid artery stenosis. The PROGRESS Trial evaluated the effects of perindopril and indapamide on the risk of stroke in patients with histories of stroke or transient ischemic attack (TIA). Regardless of blood pressure at entry, patients clearly benefitted from treatment (PROGRESS Collaborative Group 2001).

Six million Americans have diabetes mellitus, and there are at least 5 million more people in which it is undiagnosed. Diabetes mellitus increases the risk of ischemic cerebrovascular disease two- to fourfold compared with the risk in people without diabetes. In addition, diabetes mellitus increases morbidity and mortality after stroke. Macrovascular disease is the leading cause of death among patients with diabetes mellitus. The mechanisms of stroke secondary to diabetes may be caused by cerebrovascular atherosclerosis, cardiac embolism, or rheological abnormalities. The excess stroke risk is independent of age or blood pressure status. Diabetes associated with arterial hypertension adds significantly to stroke risk. There is a fourfold increase in the relative risk of cardiovascular event among patients with diabetes and hypertension than among those without the two conditions (Hypertension in Diabetes Study [HDS] 1993). Diabetic persons with retinopathy and autonomic neuropathy appear to be a group at particularly high risk for ischemic stroke. High insulin levels increase the risk for atherosclerosis and may represent a pathogenetic factor in cerebral small vessel disease. However, presently no evidence exists that tighter diabetic control or normal HbA_u. levels over time decrease the risk of stroke or stroke recurrence.

High total cholesterol and high low-density lipoprotein (LDL) concentration are correlated with atherosclerosis. Although overwhelming evidence relates low levels of

high-density lipoprotein (HDL) cholesterol with coronary heart disease, the association with cerebrovascular disease is less clear. Some studies have shown a positive relationship between serum cholesterol levels and death resulting from nonhemorrhagic stroke. The relationship has not been consistent, however, possibly because different risks are associated with different lipoprotein subtypes. Lipid-modifying therapy with 3-hydroxy 3-methylglutaryl coenzyme A reductase inhibitors (statins) have definitively established that reduction of LDL cholesterol reduces cardiovascular risk. Statins appear likely to benefit stroke survivors as well. The frequency of hemorrhagic strokes is not increased by the use of statins. Lipid-lowcring agents may slow progression of atherosclerotic plaque growth and may possibly cause a regression in plaque formation.

The Scandinavian Simvastatin Survival Study (4S) (Scandinavian Simvastatin Survival Study Group 1999} investigated cholesterol lowering in persons with coronary heart disease and hypercholesterolemia and reported a highly significant relative reduction in the total mortality rate, major coronary events, and number of cardiac revascularization procedures. Post hoc analysis also showed a 28% reduction in fatal or nonfatal stroke and TIAs (Pedersen et al. 1998).

The Long-Term Intervention with Pravastatin in Ischaemic Disease (LIPID) Study investigated cholesterol lowering with pravastatin in patients with a previous myocardial infarction or unstable angina who had cholesterol levels between 155 and 271 mg/dL, and reported a remarkable reduction in myocardial infarction, cardiac tevascularizations, and cardiovascular deaths, as well as a 20% reduction in the risk of stroke (The Long-Term Intervention with Pravastatin in Ischaemic Disease [LIPID] Study Group 1998).

An estimated 1 to 2 million Americans have chronic nonvalvular atrial fibrillation (NVAF), a condition that is associated with an overall risk of stroke of approximately five to sixfold, and a mortality of approximately twice that of age- and sex-matched individuals without atrial fibrillation. The prevalence of atrial fibrillation increases with advancing age and is 0.5% for patients aged 50 to 59 years and 8.8% for those aged 80 to 89 years (Wolf et al. 1991). Approximately 70% of individuals with atrial fibrillation are between 65 and 85 years of age. NVAF is associated with a substantial risk of stroke. Heart failure, arterial hypertension, diabetes, prior stroke or TIA, and age older than 75 years increase the risk of embolism in patients with NVAF. High-risk patients have a 5-7% yearly risk of thromboembolism. The use of warfarin therapy with the international normalized ratio (INR) adjusted to between 2.0 to 3.0 decreases the relative risk of stroke in patients with NVAF by approximately two thirds. Left atrial enlargement increases the risk of stroke in men. Likewise, left ventricular hypertrophy as demonstrated by electrocardiography (KCG) in men with pre-existing ischemic heart disease is a major risk factor for stroke.

Smoking is the leading cause of preventable death in the United States. Cigarette smoking is a major risk factor for coronary artery disease, stroke, and peripheral arterial disease. Cigarette smoking is an independent risk factor for ischemic stroke in men and women of all ages, and a leading risk factor of carotid atherosclerosis in men. The risk of stroke in smokers is two to three times greater than in nonsmokers. The mechanisms of enhanced atherogenesis promoted by cigarette smoking are incompletely understood, but include reduced capacity of the blood to deliver oxygen, cardiac arrhythmias, and triggering of arterial thrombosis and arterial spasm. More than 5 years may be required before a reduction in stroke risk is observed aftet cessation of smoking. Switching to pipe or cigar smoking is of no benefit. Nicotine replacement therapy and bupropion are efficacious smoking cessation treatments.

There is a J-shaped association between alcohol consumption and ischemic stroke; light to moderate use (up to two drinks a day) evenly distributed throughout the week offers a reduced risk, whereas heavy drinking is associated with an increased risk of total stroke. Heavy drinking may precipitate cardiogenic brain embolism. Alcohol consumption increases the risk of hemorrhagic stroke; alcohol-induced hypertension predisposes to spontaneous intracranial hemorrhage. Furthermore, active drinkers have a higher frequency of obstructive apneas and more severe hypoxemia. Conversely, moderate alcohol consumption may reduce the risk of ischemic stroke and may elevate HDL concentration.

The prevalence of obesity (body mass index of 30 or higher) has increased nationwide. More than 61% of adult Americans are overweight, and 27% are obese. Obesity, particularly abdominal or truncal, is an important risk factor for cardiovascular disease in men and women of all ages. There is some evidence that physical activity can teduce the risk of stroke. Regular exercise lowers blood pressure, decreases insulin resistance, increases HDL cholesterol, and is associated with lower cardiovascular morbidity and mortality. Habitual snoring increases the risk of stroke and adversely affects outcome of patients admitted to the hospital with stroke. Mounting evidence also suggests that inflammation, impaired fibrinolysis, and increased thrombotic potential are important nontraditional cardiovascular risk factors.

Atherosclerotic lesions of the carotid bifurcation are a common cause of stroke. Asymptomatic carotid disease carries a greater risk of vascular death from coronary artery disease than from stroke. Persons with an asymptomatic carotid bruit have an estimated annual risk of stroke of 1.5% at 1 year and 7.5% at 5 years. Asymptomatic carotid artery stenosis less than 75% carries a stroke risk of 1.3% annually; with stenosis greater than 75%, the combined TIA and stroke rate is 10.5% per year, with most events occurring ipsilatcral to the stenosed carotid artery. Plaque composition may be an important factor in the pathophysiology of carotid artery disease. Plaque structure rather

than degree of carotid artery stenosis may be a critical factor in determining stroke risk. Ultrasonographic carotid artery plaque morphology may identify a subgroup of patients at high risk of stroke. Ulcerated, echoluccnt, and heterogeneous plaques with a soft core represent unstable plaques at high risk for producing arterioarterial embolism.

Patients who suffer TIAs are at greater risk than normal controls for stroke or death from vascular causes. The risk of stroke is approximately three times higher. Symptomatic carotid artery stenosis greater than 70% carries an annual risk of stroke of approximately 15%. Approximately 10-15% of those experiencing a stroke have TIAs before theit stroke. Patients with hemispheric TIAs arc at greater risk of ipsilatctal stroke than patients with tetinal TIAs. Patients with a first stroke arc at greater risk of recurrent stroke, especially, but not exclusively, early aftet the first stroke. Those who suffer a recurrent stroke have a higher mortality than patients with first stroke. If the recurrence is contralateral to the first stroke, prognosis for functional recovery is poor. The risk of stroke recurrence is increased also by the presence of underlying dementia.

The aorta is the most frequent site of atherosclerosis. Protruding atheroma may be the cause of otherwise unexplained TIAs ot strokes. Aortic arch atheromatosis detected by transesophageal echocardiography is an independent risk factor for cerebral ischemia; the association is particularly strong with mobile and thick atherosclerotic plaques measuring greater than or equal to 4 mm in thickness (The French Study of Aortic Plaques in Stroke Group 1996).

Hemostatic factors may be important in assessing the risk of cerebrovascular disease. Elevated hematocrit, hemoglobin concentration, and increased blood viscosity may be indicators of risk for ischemic stroke. Elevation of plasma fibrinogen is an independent risk factor for the development of cerebral infarction. An elevated plasma fibrinogen level may reflect progression of atherogenesis. Plasminogen activator inhibitor-! excess and factor VII are independent risk factors for coronary heart disease. Compared with while Americans, black Americans have higher mean levels of fibrinogen, factor VIII, von Willebrand's factor, and AT, and lower mean levels of protein C. Fibrinogen levels are closely correlated with other stroke risk factors such as cigarette smoking, arterial hypertension, diabetes, obesity, hematocrit levels, and spontaneous echocardiographic contrast. Antiphospholipid (aPL) antibodies are a marker for an increased risk of thrombosis, including TIAs and stroke, particularly in those younger than 50 years of age. The factor V Leiden mutation is associated with deep venous thrombosis in otherwise healthy individuals with additional prothtombotic risk factors. An overall association of the factor V Leiden mutation and arterial thrombosis has not been found. Elevated von Willebrand's factor is a risk factor for myocardial infarction and ischemic stroke. Elevated levels of fasting total homocysteine (normal 5-15 mmol/L), a sulfhydryl-containing amino acid, have been associated with an increased risk of stroke and thrombotic events in case-controlled studies. Metabolism of homocysteine requires vitamin B_6 (pyridoxine), vitamin Bi_2 (cobalamine), folate, and betaine. Plasma homocysteine concentrations may be reduced by folic acid alone or in combination with vitamin B_6 and vitamin $B|_2$. Conversely, serum folate concentrations less than or equal to 9.2 nmol/liter have been associated with elevated plasma levels of homocysteine, and a decreased folate concentration alone may be a risk factor for ischemic stroke, particularly among blacks (Giles et al. 1995).

Stroke is uncommon among women of childbearing age. The relative risk of stroke is increased among users of high-dose estrogen oral contraceptives, particularly with coexistent arterial hypertension, cigarette smoking, and increasing age. New agents containing lower doses of estrogen and progestogen have reduced the frequency of oral contraceptive-related cerebral infarction. Two recent postmenopausal hormone replacement studies with equine estrogen (Premarin) showed no benefit in reducing the incidence of stroke in a cohort of women with coronary heart disease (Hulley et al. 1998; Herrington et al. 2000). In addition, the Women's Health Initiative, a prospective randomized trial of estrogen therapy in healthy postmenopausal women, was halted prematurely because the risks outweighed the benefits. Absolute excess risks per 10,000 person-years attributable to estrogen plus progestin were sevenfold for coronary heart disease events, eightfold for strokes, eightfold for pulmonary thromboembolisms, and eightfold for invasive cancers, whereas absolute risk reductions per 10,000 person-years were sixfold for colorectal cancers and fivefold for hip fractures (Writing Group for the Women's Health Initiative Investigators. 2002). The risk of thrombosis associated with pregnancy is high in the postpartum period. The risk of cerebral infarction is increased in the 6 weeks after delivery but not during pregnancy.

A diurnal and seasonal variation of ischemic events occurs. Orcadian changes in physical activity, catecholamine levels, blood pressure, blood viscosity, platelet aggregability, blood coagulability, and fibrinolytic activity may explain the circadian variations in onset of myocardial and cerebral infarction. Although an early morning peak occurs for all subtypes of stroke, most clinical trials on the use of platelet antiaggregants or other antithrombotic agents do not take these circadian variations into account. Rhythmometric analyses support the notion that stroke is a chrono-risk disease, in which cold temperatures also represent a risk factor. A history of recent infection, particularly of bacterial origin and within 1 week of the event, is also a risk factor for ischemic stroke in patients of all ages. A number of recent reports suggest that *Chlamydia pneumoniae,* a causative organism of respiratory infections, has a role in carotid and coronary atherosclerosis. Some studies have also identified an association with chronic

infections with *Helicobacter pylori* and cytomegalovirus (Ross 1999;Bittner 1998).

PATHOPHYSIOLOGY OF CEREBRAL **ISCHEMIA**

Except for the lack of an external elastica lamina in the intracranial arteries, the morphological structure of the cerebral vessels is similar to those in other vascular beds. The arterial wall consists of three layers: the outer layer, or adventitia; the middle layer, or media; and the inner layer, or intima. The intima is a smooth monolayer of endothelial cells providing a nonthrombotic surface for blood flow. One of the major functions of the endothelium is active inhibition of coagulation and thrombosis.

The brain microcirculation comprises the smallest components of the vascular system, including arterioles, capillaries, and venules. The arterioles are composed primarily of smooth muscle cells around the endothclial-lincd lumen, and are the major sites of resistance to blood flow in the arterial tree. The capillary wall consists of a thin monolayer of endothelial cells. Nutrients and metabolites diffuse across the capillary bed. The venules are composed of endothelium and a fragile smooth muscle wall and function as collecting tubules. The cerebral microcirculation distributes blood to its target organ by regulating blood flow and distributing oxygen and glucose to the brain while removing by-products of metabolism.

A cascade of complex biochemical events occurs seconds to minutes after cerebral ischemia. Cerebral ischemia is caused by reduced blood supply to the microcirculation. Ischemia causes impairment of brain energy metabolism, loss of aerobic glycolysis, intracellular accumulation of sodium and calcium ions, release of excitotoxic neurotransmitters, elevation of lactate levels with local acidosis, free radical production, cell swelling, overactivation of lipases and proteases, and cell death. Many neurons undergo apoptosis after focal brain ischemia (Choi 1996). Ischemic brain injury is exacerbated by leukocyte infiltration and development of brain edema. Exciting new treatments for stroke target these biochemical changes.

Complete interruption of cerebral blood flow causes suppression of the electrical activity within 12-15 seconds, inhibition of synaptic excitability of cortical neurons after 2-4 minutes, and inhibition of electrical excitability after 4-6 minutes. Normal cerebral blood flow at rest in the normal adult brain is approximately 50-55 mL/100 g per mmute, and the cerebral metabolic rate of oxygen is 165 mmol/100 g per minute. There are certain ischemic flow thresholds in experimental focal brain ischemia. When blood flow-decreases to 18 mL/100 g per minute, the brain reaches a threshold for electrical failure. Although these neurons are not functioning normally, they do have the potential for recovery. The second level, known as the *threshold of membrane failure,* occurs when blood flow decreases to 8 mIV100 g per minute. Cell death can result. These thresholds mark the upper and lower blood flow limits of the ischemic penumbra. The ischemic penumbra, or area of misery perfusion, is the area of the ischemic brain between these two flow thresholds in which there are some neurons that are functionally silent but structurally intact and potentially salvageable.

PATHOLOGY OF **ISCHEMIC STROKE**

The pathological characteristics of ischemic stroke depend on the mechanism of stroke, the size of the obstructed artery, and the availability of collateral blood flow. There may be advanced changes of atherosclerosis visible within arteries. The surface of the brain in the area of infarction appears pale. With ischemia caused by hypotension or hemodynamic changes, the arterial border (or watershed) zones may be involved. A wedge-shaped area of infarction in the center of an arterial territory may result if there is occlusion of a main artery in the presence of collateral blood flow. In the absence of collateral blood flow, the entire territory supplied by an artery may be infarcted. With occlusion of a major artery, such as the internal carotid artery, there may be a multilobar infarction with surrounding edema. There may be evidence of flattening of the gyri and obliteration of the sulci caused by cerebral edema. A lacunar infarction, with a size of *1.5* cm or less, in subcortical areas or in the brainstem may be barely visible in the macroscopic analysis of the cut brain. Emboli to the brain tend to lodge at the junction between the **cerebral** cortex and the white matter. Early reperfusion of the infarct may occur when the clot lyses, leading to hemorrhagic transformation,

The microscopic changes after cerebral infarction are well documented. The observed changes depend on the age of the infarction. The changes do not occur immediately and may be delayed up to 6 hours after the infarction. There is neuronal swelling initially, which is followed by shrinkage, hyperchromasia, and pyknosis. Chromatolysis appears and the nuclei become eccentric. Swelling and fragmentation of the astrocytes and endothelial swelling occur. Neutrophils infiltrate appear as early as 4 hours after the ischemia and become abundant by 36 hours. Within 48 bouts, the microglia proliferate and ingest the products of myelin breakdown and form foamy macrophages. Later, there is neovascularity with proliferation of capillaries and increased prominence of the existing capillaries. The elements in the area of necrosis are gradually reabsorbed and a cavity, consisting of glial and fibrovascalar elements, forms. In a large infarction, there are three distinct zones: an inner area of coagulativc necrosis; a middle zone of vacuolated neuropil, leukocytic infiltrates, swollen axons, and thickened capillaries; and an outer marginal zone of hyperplastic astrocytes and variable changes in nuclear staining.

CLINICAL SYNDROMES OF CEREBRAL ISCHEMIA

A number of syndromes result from ischemia involving the central nervous system (Brazis et al. 2001).

Transient Ischemic Attacks

Approximately 80% of ischemic strokes occur in the carorid (or anterior) circulation, and 20% occur in the vertebrobasilar (or posterior) circulation. A TIA is a prognostic indicator of stroke, with one third of untreated TIA patients having a stroke within 5 years. The interval from the last TIA is an important predictor of stroke risk; of all patients who subsequently experience stroke, 21% do so within 1 month and 51% do so within 1 year of the last TIA. Cardiac events are the principal cause of death in patients who have had a TIA. The 5-6% annual mortality after TIA is mainly caused by myocardial infarction, similar to the 4% annual cardiac mortality in patients with stable angina pectoris.

A TIA is a temporary, focal, and "nonmarching" neurological deficit of sudden onset; related to ischemia of the brain, retina, or cochlea; and lasting less than 24 hours. Yet most TIAs last only 5-20 minutes. Episodes that last longer than 1 hour are usually caused by small infarctions. The onset of symptoms is sudden, reaching maximum intensity almost immediately. To qualify as a TIA, the episode should be followed by complete recovery. TIAs involving the carotid circulation should be distinguished from those involving the vertebrobasilar circulation. Headache is a frequent symptom in patients with TIAs. The following symptoms are considered typical of TIAs in the carotid circulation: ipsilateral amaurosis fugax, contralateral sensory or motor dysfunction limited to one side of the body, aphasia, contralateral homonymous hemianopia, or any combination thereof. The following symptoms represent typical TIAs in the vertebrobasilar system: bilateral or shifting motor or sensory dysfunction, complete or partial loss of vision in the homonymous fields of both eyes, or any combination of these symptoms. Perioral numbness also occurs. Isolated diplopia, vertigo, dysarthria, and dysphagia should not be considered as being caused by a TIA, unless they occur in combination with one another, or with any of the othet symptoms just listed (Table 57A.2).

Table S7A.2: Recognition of carotid and vertebrobasilar transient ischemic attacks

Symptoms suggestive of carotid transient ischemic attacks
Transient ipsilateral monocular blindness (amaurosis fugax)
Contralateral body weakness or clumsiness
Contralateral body sensory loss or paresthesias
Aphasia with dominant hemisphere involvement
Various degrees of contralateral homonymous visual field defects
Dysarthria (not in isolation)
Symptoms suggestive of vertebrobasilar transient ischemic attacks
Usually bilateral weakness or clumsiness, but may he unilateral or shifting
Bilateral, shitting, or crossed (ipsilateral face and con era lateral body) sensory loss or paresthesias
Bilateral or contralateral homonymous visual field defects or binocular vision loss
Two or more of the following symptoms: vertigo, diplopia, dysphagia, dysarthria, and ataxia
Symptoms not acceptable as evidence of transient ischemic attack
Syncope, dizziness, confusion, urinary or fecal incontinence, and generalized weakness
Isolated occurrence of vertigo, diplopia, dysphagia, ataxia, tinnitus, amnesia, drop attacks, or dysarthria

Occlusive disease in the subclavian arteries or the innominate artery can give rise to extracranial steal syndromes. The most well-defined syndrome is rhe subclavian steal syndrome. In this syndrome, reversal of flow in the vertebral artery is caused by a high-grade subclavian artery stenosis or occlusion proximal to the origin of the vertebral artety from the aortic arch or innominate artery, with resultant symptoms of brainstem ischemia, usually precipitated by actively exercising the ipsilateral arm. The left side is involved most frequently. With innominate artery occlusion, the origin of the right carotid is also subject to the consequences of reduced pressure. The subclavian steal syndrome can be suspected by the presence of a reduced or delayed radial pulse and diminished blood pressure in the affected arm relative to the contralateral arm. A subclavian steal may he symptomatic or asymptomatic. Many patients have angiographic evidence of reversed vertebral blood flow without ischemic symptoms. Transcranial Dopplcr sonography may detect transient retrograde basilar blood flow. Retrograde vertebral artery flow is a benign entity. Brainstem infarction is an uncommon complication of the subclavian steal syndrome.

Transient global amnesia {TGA) is characterized by a reversible anregrade and retrograde memory loss, except for a total amnesia of events that occur during the attacks, and inability to learn newly acquired information. During the attacks, patients remain alert without motor or sensory impairments and often ask the same questions repeatedly. Patients are able to retain personal identity and carry on complex activities. TGA most commonly affects patients in their 50s and older. Men are affected more commonly than women. The attacks begin abruptly and without warning. A typical attack lasts several hours (mean, 3-6 hours) but seldom longer than 12 hours. Onset of TGA may follow physical exertion, sudden exposure to cold or heat, or sexual intercourse. Although a large number of conditions have been associated with transient episodes of amnesia, in most instances TGA is of primary or unknown cause. TGA has been documented in association with epilepsy, migraine, intracranial tumors, overdose of diazepam, cardiac arrhythmias secondary to digitalis intoxication, and as a complication of cerebral and coronary angiography. Many reports

have suggested a vascular causal factor for this heterogeneous syndrome. Bilateral hippocampal and parahippocampal complex ischemia, possibly of migrainous origin, in the distribution of the posterior cerebral arteries is a potential mechanism. Acute confusional migraine in children and TGA have a number of similar features. Others have suggested an epileptic causal factor for a minority of patients. Transient amnesias have been divided into pure TGA, probable epileptic amnesia, and probable transient ischemic amnesia. In contrast to patients with TIAs, the prognosis of persons with pure TGA is benign, with no apparent increased risk for vascular endpoints. Recurrences are uncommon. Extensive evaluations are not required. Treatment with platelet antiaggregants is not indicated in most patients unless there is a suspicion for transient ischemic amnesia. The use of prophylactic calcium-channel blockers may be justified in patients with a potential migtainous causal factor.

Drop attacks are charactetized by the sudden loss of muscle tone and strength. The attacks cause the patients to unexpectedly fall to the ground. Consciousness is preserved. Most attacks occut while standing or walking and often follow head or neck motion. Drop attacks have been considetcd a symptom of vertebrobasilar ischemia, but many of these patients have other coexistent disotdcts that could otherwise explain their symptoms. In rare instances, drop attacks may indeed be caused by ischemia of the corticospinal tract or reticular formation. However, isolated drop attacks are seldom a manifestation of vertebrobasilar occlusive disease. In most instances these attacks ate secondaty to akinetic seizures, high cervical spine or foramen magnum lesions, postural hypotension, Tumarkin's otolithic ctises (in Meniere's disease), or near syncope.

TIAs may result from atherothromboembolism that originates from ulcerated extracranial arteries, emboli of cardiac origin, occlusion of small penetrating arteries that arise from the large surface arteties of the circle of Willis, altered local blood flow (perfusion failure) caused by severe arterial stenosis, nonatherosclerotic vasculopathies, or hypercoagulable states. Pteceding TIAs occur in large numbers of patients with brain infarction. In published series of cases of stroke, TIAs occurred before 25-50% of a the ro thrombotic infarcts, in 11-30% of cardiocmbolic infarcts, and in 11-14% of lacunar infarcts. Lacunar TIAs in general share the same pathogenetic mechanisms of lacunar infarcts and are associated with a substantially better prognosis than are nonlacunar TIAs.

Crescendo episodes of cerebral ischemia that increase in frequency, severity, or duration may be most threatening. A small subset of ctcsccndo TIAs is the capsular warning syndrome, characterized by restricted stereotyped, repeated episodes of capsular ischemia, causing contralateral symptoms involving face, arm, and leg. When capsular infarction develops, it is usually a lacunar-type stroke and involves a single penetrating vessel. Occasionally, striatocapsular or anrcrior-choroidal artery territory infarction occurs. Typically, these patients are refractoty to conventional forms of therapy (Donnan et al. 1993).

Rational treatment of patients with TIAs depends on a careful history and derailed physical examination. The neurovascular examination may disclose a well-localized bruit in the mid- or upper-cervical area. Bruits arise when normal laminar blood flow is disturbed. However, the presence of a cervical bruit does not necessatily indicate undeilying carotid atherosclerosis. Correlation with angiography or ultrasound studies show only 60% agreement with cervical auscultation in predicting the presence of arterial stenosis. Radiated cardiac murmurs, hyperdynamic states, nonathetosclerotic carotid arterial lesions, and venous hums can produce cervical murmurs. The absence of a bruit has little diagnostic value; the bruit may disappear when the stenosis is advanced. Convetsely, a cervical bruit may be heard contralateral to an internal carotid artery occlusion.

Different types of microemboli (e.g., cholesterol crystals, platelet fibrin, calcium, and so forth) can be seen in the retinal arterioles during or between attacks of transient monocular visual loss. Engorgement of conjunctival and episcleral vessels, conical edema and rubeosis irides, and anterior chamber cells flare arc indicative of an underlying ischemic oculopathy. Asymmetrical hypertensive retinal changes noted on funduscopy ate suggestive of a high-gtade carotid artery stenosis or occlusion on the side of the less severely involved retina. Venous stasis retinopathy may occut with high-grade carotid stenosis or occlusion and is characterized by diminished or absent venous pulsations, dilatated and tortuous retinal veins, peripheral microaneurysms, and blossom-shaped hemorrhages in the mid-peripheral retina. Corneal arcus senilis may be less obvious or absent on the side of low perfusion.

Many conditions can tesemblc a TIA. Space-occupying lesions; subdural, intracerebral, or subarachnoid hemorrhage; seizures; hypoglycemia; migraine; syncope; and labyrinthine disorders are among the divctse conditions in the differential diagnosis when TIA is considered. Symptoms of a transient neurological dysfunction that resolve incompletely should lead the physician to question the diagnosis of TIA. Similarly, a migration or march of symptoms from one part of the body to another is rare during a TIA and more indicative of a focal seizure or migraine. Fortification phenomena or scintillating bright visual symptoms are suggestive of migraine. In rare instances, involuntary limb shaking movements can occur, but, in general, involuntary movements reflect convulsive activity rather than a TIA.

Carotid Artery System Syndromes

Amaurosis fugax may he described as a sudden onset of a fog, haze, scum, curtain, shade, blur, cloud, or mist. A curtain or shade pattern with the loss of vision moving

superiorly to interiorly is described only in 15-20% of patients. Less commonly, a concentric vision loss, presumed to be caused by marginal perfusion, can diminish blood flow to the retina. The vision loss is sudden, often brief, and painless. The duration of vision loss is usually 1-5 minutes and rarely lasts more than .30 minutes. After an episode of amaurosis fugax, the vision is usually fully restored, although some patients may have permanent vision loss caused by a retinal infarction (see Chapters 14 and 15).

The sole feature that distinguishes the middle cerebral artery (MCA) syndrome from the carotid artery syndrome is amaurosis fugax. An MCA infarction is one of the most common manifestations of cerebrovascular disease. The clinical picture with an MCA infarction is varied and depends on whether the site of the occlusion is in the stem, superior division, inferior division, or lenticulostriate branches, and whether there is good collateral blood flow.

When the stem of the MCA is occluded, there is usually a large infarction with contralateral hemiplegia, conjugate eye deviation toward the side of the infarct, hemianesthesia, and homonymous hemianopia. Associated global aphasia occurs if the dominant hemisphere is involved and hemineglect with nondominant hemispheric lesions. The difference between an upper division MCA infarction and an MCA stem lesion is that the hemiparesis usually affects the face and arm more than the leg with upper division infarction. A Broca-type aphasia is more common in upper division infarcts because of the preferential involvement of the anterior branches of the upper division in occlusions. With lower division MCA syndromes, a Wernicke-type aphasia is seen with dominant hemisphere infarction and behavioral disturbances are seen with nondominant infarction. A homonymous hemianopia may be present. A lenticulostriate branch occlusion may cause a lacunar infarction with involvement of the inrernal capsule producing a syndrome of pure motor hemiparesis. These syndromes are variable and depend on the presence of collaterals or whether brain edema is present.

Alexia with agraphia may occur with left-sided angular gyrus involvement. Gerstmann's syndrome, which consists of finger agnosia, acalculia, right-left disorientation, and agraphia, may be seen with dominant hemisphere parietal lesions. The aphasias with dominant hemispheric infarctions may be of the Broca, Wernicke, conduction, transcortical, or global type, depending on the site and extent of involvement. Anosognosia, the denial of hemiparesis, most commonly is associated with right hemispheric strokes. Nondominant infarction may cause hemi-inattention, tactile extinction, visual extinction, anosognosia, anosodiaphoria, apraxia, impaired prosody, and rarely acute confusion and agitated delirium. A contralateral homonymous hemianopia or contralateral inferior quadrantanopia can occur with infarctions in cither hemisphere.

Anterior cerebral artery (ACA) territory infarctions are uncommon (Figure 57A.1). They occur in patients with vasospasm after subarachnoid hemorrhage caused by ACA or anterior communicating artery aneurysm. Excluding these causes, the percentage of acute cerebral infarcts that are in the ACA territory is less than 3%. The characteristics of ACA infarction vary according to the site of involvement and the extent of collateral blood flow. Contralateral weakness involving primarily the lower extremity, and to a lesser extent, the arm, is characteristic of infarction in the territory of the hemispheric branches of the ACA. Other characteristics include abulia, akinetic mutism (with bilateral mesiofronral damage), impaired memory or emotional disturbances, transcortical motor aphasia (with dominant hemispheric lesions), deviation of the head and eyes toward the lesion, paratonia (gegenhaltcn), discriminative and proprioceptive sensory loss (primarily in the lower extremity), and sphincter incontinence. An anterior disconnection syndrome with left arm apraxia caused by involvement of the anterior corpus callosum can be seen. Pericallosal branch involvement can cause apraxia, agraphia, and tactile anomia of the left hand. Infarction of the basal branches of the ACA can cause memory disorders, anxiety, and agitation. Infarction in the territory of the medial lenticulostriate artery (artery of Heubner) causes more pronounced weakness of the face and arm without sensory loss caused by this artery's supply of portions of the anterior limb of the internal capsule.

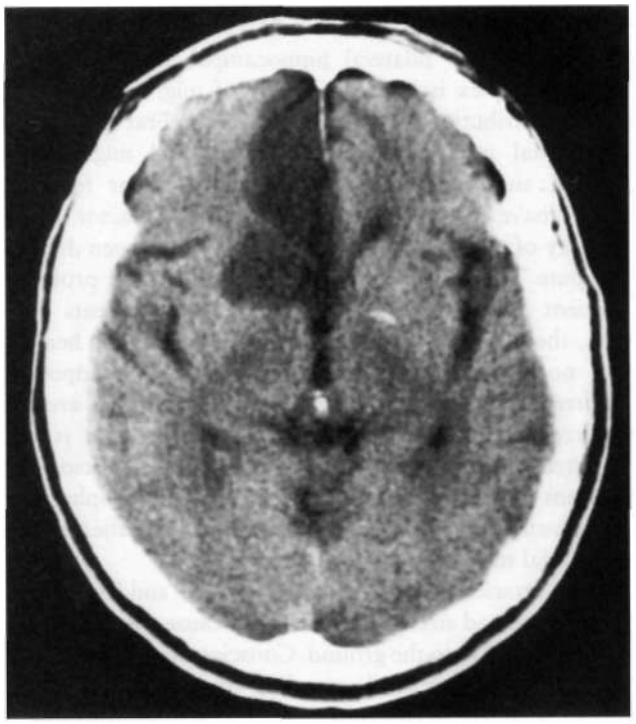

FIGURE *57* A.I N on enhanced axial computed tomographic scan of a 63-year-old man with left-sided weakness and abulia demonstrates a right anterior cerebral artery (ACA) territory infarction. More superior images showed the entire ACA distribution was in famed.

The anterior choroidal artery syndrome is often characterized by hemiparesis caused by involvement of the

posterior limb of the internal capsule, hemisensory loss caused by involvement of the posterolateral nucleus of the thalamus or thalamocortical fibers, and hemianopia secondary to involvement of the lateral geniculate body or the gcniculocalcarine tract. The visual field defect with anterior choroidal artery syndrome infarcts is characterized by a homonymous defect in the superior and inferior visual fields that spares the horizontal meridian. In a small number of patients left spatial hemineglcct with right hemispheric infarctions and a mild language disorder with left hemispheric infarctions may occur. With bilateral infarctions in the anterior choroidal artery syndrome territory, there can be pseudobulbar mutism, and a variety of other features including facial diplegia, hemisensory loss, lethargy, neglect, and affect changes.

LACUNAR SYNDROMES

Ischemic strokes resulting from small vessel or penetrating artery disease (lacunes) have unique clinical, radiological, and pathological features. Lacunar infarcts are small ischemic infarctions in the deep regions of the brain or brainstem that range in diameter from 0.5-15.0 mm. These infarctions result from occlusion of the penetrating arteries, chiefly the anterior choroidal, middle cerebral, posterior cerebral, and basilar arteries. Lacunar infarcts could also be the result of occlusion of penetrating arteries by atherosclerosis of the parent artery or microembolism. Lacunes may be single or multiple, symptomatic or asymptomatic. At least 20 lacunar syndromes have been described. Lacunar syndromes are highly predictive of lacunar infarcts, with a positive predictive value of approximately 84% to 90% (Can et al. 1997). The five best recognized syndromes are (1) pure motor hemiparesis, (2) pure sensory stroke, (3) sensory-motor stroke, (4) homolateral ataxia and crural paresis (ataxic hemiparesis), and (5) dysarthria-clumsy hand syndrome. Multiple lacunes may be associated with acquired cognitive decline. Headaches arc uncommon in patients with lacunar infarcts.

Pure motor hemiparesis is often caused by an internal capsule, basis pontis, or corona radiata lacune and is characterized by a contralateral hemiparesis or hemiplegia involving the face, arm, and to a lesser extent, the leg, accompanied by mild dysarthria, particularly at onset of stroke. There should be no aphasia, apraxia, or agnosia, and there are no sensory, visual, or other higher cortical disturbances. Pure sensory stroke is often caused by a lacuna involving the ventroposterolateral nucleus of the thalamus. It is characterized by paresthesias, numbness, and a unilateral hemisensory deficit involving the face, arm, trunk, and leg. Sensory-motor stroke is often caused by a lacuna involving the internal capsule and thalamus or posterior limb of the internal capsule; large striatocapsular infarcts also can cause a similar syndrome. It is characterized by a contralateral unilateral motor deficit with a superimposed hemisensory deficit. Homolateral ataxia and crural paresis are often caused by a lacuna either in the contralateral posterior limb of the internal capsule or the contralateral basis pontis. It is characterized by weakness, predominantly in the lower extremity, and ipsilateral incoordination of the arm and leg. Dysarthrla-clumsy hand syndrome is often caused by a lacuna involving the deep areas of the basis pontis and is characterized by supranuclear facial weakness, dysarthria, dysphagia, loss of fine motor control of the hand, and Rabinski's sign.

Vertebrobasilar System Syndromes

The areas of the cerebellum supplied by the posterior inferior cerebellar artery (PICA) are variable. There are several different patterns of PICA territory cerebellar infarctions. If the medial branch territory is affected, involving the vermis and vestibulocerebellum, the clinical findings include prominent vertigo, ataxia, and nystagmus. If the lateral cerebellar hemisphere is involved, patients can have vertigo, gait ataxia, limb dysmetria and ataxia, nausea, vomiting, conjugate or dysconjugate gaze palsies, miosis, and dysarthria. If the infarction is large, altered consciousness or confusion may occur. Hydrocephalus or herniation may develop. Although a PICA occlusion can be the cause of Wallenberg's (lateral medullary) syndrome, this syndrome is more often caused by an intracranial vertebral artery occlusion.

The anterior inferior cerebellar artery (AICA) syndrome causes a ventral cerebellar infarction. The signs and symptoms include vertigo, nausea, vomiting, and nystagmus caused by involvement of the vestibular nuclei. There may be ipsilateral facial hypalgesia and thermoanesthesia and corneal hypesthesia because of involvement of the trigeminal spinal nucleus and tract. Ipsilateral deafness and facial paralysis occurs because of involvement of the lateral pontomedullary tegmentum. An ipsilateral Horner's syndrome is present because of compromise of the descending oculosympathetic fibers. Contralateral trunk and extremity hypalgesia occurs and thermoanesthesia caused by involvement of the lateral spinothalamic tract. Finally, ipsilateral ataxia and asynergia is caused by involvement of the cerebellar peduncle and cerebellum.

Infarction in the territory of the superior cerebellar artery (SCA) produces a dorsal cerebellar syndrome (Hgure 57A.2). Vertigo may be present, although it is less common with SCA infarcts than with the other cerebellar syndromes. Nystagmus is caused by involvement of the medial longitudinal fasciculus and the cerebellar pathways. An ipsilateral Horner's syndrome is caused by involvement of the descending sympathetic tract. Ipsilateral ataxia and asynergia and gait ataxia are caused by involvement of the superior cerebellar peduncle, brachium pontis, superior cerebellar hemisphere, and dentate nucleus. There is an intention tremor caused by involvement of the dentate

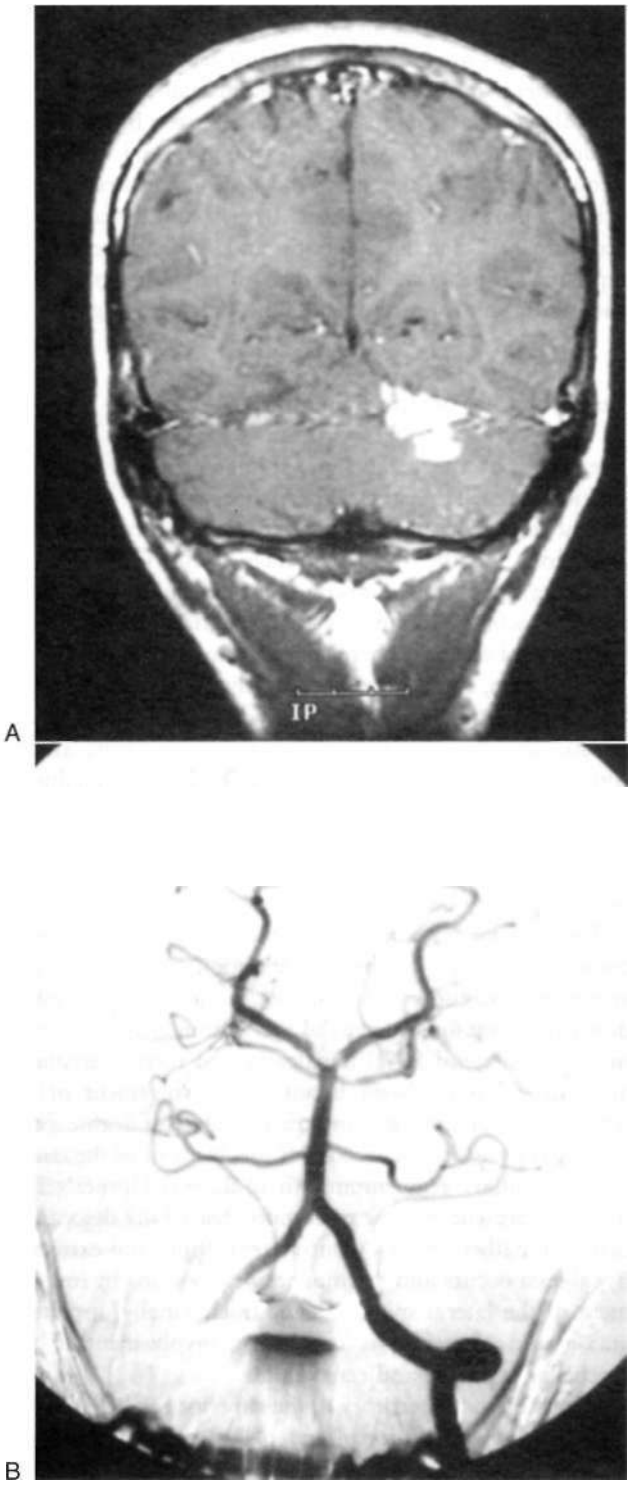

FIGURE 57A.2 A 15-year-old boy had vomiting, tinnitus, and unsteadiness. (A) Tl coronal postgadolinium magnetic resonance imaging shows enhancing lesions in the superior aspect of the left cerebellar hemisphere consistent with superior cerebellar artery infarct. (B) Anteroposterior view left vertebral artery injection shows a filling defect of the basilar apex also involving the proximal left superior cerebellar artery consistent with thromboembolus,

nucleus and superior cerebellar peduncle. Choreiform dyskinesias may be present ipsilarerally. Contra laterally, there is hearing loss caused by lateral lemniscus disruption and trunk and extremity hypalgesia and thermoanesthesia caused by spinothalamic tract involvement,

Weber's syndrome is caused by infarction in the distribution of the penetrating branches of the posterior cerebral artery (PCA) affecting the cerebral peduncle, especially medially, with damage to the fascicle of cranial nerve III and the pyramidal fibers. The resultant clinical findings are contralateral hemiplegia of the face, arm, and leg caused by corticospinal and corticobulbar tract involvement and ipsilateral oculomotor paresis, including a dilated pupil. A slight variation of this syndrome is the midbrain syndrome of Foville in which the supranuclear fibers for horizontal gaze are interrupted in the medial peduncle, causing a conjugate gaze palsy to the opposite side. Bcncdikt's syndrome is caused by a lesion affecting the mesencephalic tegmentum in its ventral portion, with involvement of the red nucleus, brachium conjunctivum, and fascicle of cranial nerve III. This syndrome is caused by infarction in the distribution of the penetrating branches of the PCA to the midbrain. The clinical ma infestations are ipsilateral oculomotor paresis, usually with pupillary dilation and contralateral involuntary movements, including intention tremor, hemiathcrosis, or hemichorca. Claude's syndrome is caused by lesions that are more dorsally placed in the midbrain tegmentum than with Benedikt's syndrome. There is injury to the dorsal red nucleus, which results in more prominent cerebellar signs without the involuntary movements. Oculomotor paresis occurs (see Table 76.1 for variations of these syndromes). Nothnagel's syndrome is characterized by an ipsilateral oculomotor palsy with contralateral cerebellar ataxia. Infarctions in the distribution of the penetrating branches of the PCA to the midbrain is the cause of this syndrome. Pannaud's syndrome can result from infarctions in the midbrain territory of the PCA penetrating branches. This syndrome is characterized by supranuclear paralysis of eye elevation, defective convergence, convergence-retraction nystagmus, light-near dissociation, lid retraction, and skew deviation (see Chapter 22).

Top of the basilar syndrome (sec Chapter 22) is caused by infarction of the midbrain, thalamus, and portions of the temporal and occipital lobes. It is caused by occlusive vascular disease, often embolic in nature, of the rostral basilar artery. The following signs may occur: Behavioral abnormalities include somnolence, peduncular hallucinosis, memory disturbances, or agitated delirium.

Ocular findings include unilateral or bilateral paralysis of upward or downward gaze; impaired convergence; pseudoabducens palsy; convergence-retraction nystagmus; abnormalities of abduction; Collier's sign, which consists of elevation and retraction of the upper eyelids; skew deviation; and oscillatory eye movements. Visual defects that may be present include hemianopia, cortical blindness, and Balint's syndrome.

Pupillary abnormalities are variable, and may be either large or small, reactive, or fixed. Motor deficits may also occur.

Although there are many named pontine syndromes, the most beneficial categorization is based on neuroanaromical divisions. Locked-in syndrome is the result of bilateral ventral pontine lesions that produce quadriplegia, aphonia, and impairment of the horizontal eye movements in some patients. Wakefulness and normal sleep-wake cycles are maintained because of sparing of the reticular formation, The patient can move his or her eyes vertically and can blink because the supranuclear ocular motor pathways lie more dorsally. In some patients with symptomatic basilar artery occlusive disease, there may be a herald hemiparesis that suggests a hemispheric lesion (Fisher 1988). However, within a few hours, there is progression to bilateral hemiplegia and cranial nerve findings associated with the locked-in syndrome. Pure motor hemiparesis and ataxia-hemiparesis caused by pontine lesions are discussed with the lacunar syndromes.

Occlusion of the AICA can lead to the lateral inferior pontine syndrome. Findings with this syndrome include ipsilateral facial paralysis, impaired facial sensation, paralysis of conjugate gaze to the side of the lesion, deafness, tinnitus, and ataxia. Contralateral to the lesion, there is hemibody impairment to pain and temperature, which in some instances includes the face. There may be horizontal and vertical nystagmus and oscillopsia. The medial inferior pontine syndrome is caused by occlusion of a paramedian branch of the basilar artery. With this syndrome, there is ipsilateral paralysis of conjugate gaze to the side of the lesion, abducens palsy, nystagmus, and ataxia. Contralateral to the lesion, there is hemibody impairment of tactile and proprioceptive sensation and paralysis of the face, arm, and leg. An occlusion of the AICA may lead to the total unilateral inferior pontine syndrome, a combination of the symptoms and signs seen with the lateral and medial pontine syndromes.

The lateral pontomedullary syndrome can occur with occlusion of the vertebral artery. The manifestations are a combination of the medial and lateral inferior pontine syndromes. Occlusion of the paramedian branch of the midbasilar artery can lead to ipsilateral impaired sensory and motor function of the trigeminal nerve with limb ataxia, characteristics of the lateral midpontine syndrome. Ischemia of the medial midpontine region is caused by occlusion of the paramedian branch of the midbasilar artery and can lead to ipsilateral limb ataxia. Contralateral to the lesion, eye deviation and paralysis of the face, arm, and leg occur. Although there are predominant motor symptoms, variable impaired touch and proprioception may occur. The lateral superior pontine syndrome may occur with occlusion of the SCA and produces a characteristic syndrome of ipsilateral Horner's syndrome, horizontal nystagmus, paresis of conjugate gaze, occasional deafness, and severe ataxia of the limbs and gait. Contralateral to the lesion, there is hemibody impairment to pain and temperature, skew deviation, and impaired tactile, vibratory, and proprioceptive sensation in the leg greater than in the arm.

The lateral medullary syndrome (Wallenberg's syndrome) is most often caused by occlusion of the intracranial segment of the vertebral artery (Figure 57A.3). Less commonly, it is caused by occlusion of PICA, This syndrome produces an ipsilateral Horner's syndrome; loss of pain and temperature sensation in the face; weakness of the palate, pharynx, and vocal cords; and cerebellar ataxia. Contralateral to the lesion, there is hemibody loss of pain and temperature sensation. The medial medullary (Dejerine) syndrome is less common and may be caused by occlusion of the distal vertebral artery, a branch of the vertebral artery, or the lower basilar artery. Vertebral artery dissection, dolichoectasia of the vertebrobasilar system, or embolism are less common causes of the medial medullary syndrome. The findings with this Syndrome include an ipsilateral lower motor neuron paralysis of the tongue and contralateral paralysis of the arm and leg. The face is often spared. In addition, there is contralateral hemibody loss of tactile, vibratory, and position sense. Occlusion of the intracranial vertebral artery can lead to a total unilateral medullary syndrome (of Babinski-Nageotte), a combination of medial and lateral medullary syndromes.

FIGURE 57A.3 A 74-year-old man had sudden onset of vertigo, vomiting, and gait unsteadiness. T2-weighted axial magnetic resonance imaging of the brain demonstrates an infarct in the posterolateral side of the medulla and a small cerebellar infarct in the distribution of the left posterior inferior cerebellar artery. There is poor flow void seen in the left vertebral artery.

The manifestations with PCA territory infarctions are variable, depending on the site of the occlusion and the availability of collateral blood flow. Occlusion of the precommunal PI segment causes midbrain, thalamic, and hemispheric infarction. Occlusion of the PCA in the proximal ambient segment before branching in the thalamogeniculate pedicle causes lateral thalamic and hemispheral symptoms. Occlusions also may affect a single PCA branch, primarily rhc calcarine artery, or cause a large hemispheric infarction of the PCA territory. Unilateral infarctions in the distribution of the hemispheral branches of the PCA may produce a contralateral homonymous hemianopia caused by infarction of the striate cortex, the optic radiations, or the lateral geniculate body. There is partial or complete macular sparing if the infarction does not reach the occipital pole. The visual field defect may be limited to a quadrantanopia. A superior quadrantanopia is caused by infarction of the striate cortex inferior to the calcarine fissure or the inferior optic radiations in the ternporo-occipital lobes. An inferior quadrantanopia is the result of an infarction of the striate cortex superior to the calcarine fissure or the superior optic radiations in the parieto-occipital lobes.

More complex visual changes may occur, including formed or unformed visual hallucinations, visual ami color agnosias, or prosopagnosia. Finally, some alteration of sensation with PCA hemispheral infarctions occurs, including paresthesias or altered position, pain, and temperature sensations. Infarction in the distribution of the callosal branches of the PCA involving the left occipital region and the splenium of the corpus callosum produces alexia without agraphia (Figure 57A.4). In this syndrome, patients can write, speak, and spell normally, but are unable to read words and sentences. The ability to name letters and numbers may be intact, but there can be inability to name colors, objects, and photographs. Right hemispheric PCA territory infarctions may cause contralateral visual field neglect. Amnesia may be present with PCA infarctions that involve the left medial temporal lobe or when there are bilateral mesiotemporal infarctions. In addition, an agitated delirium may occur with unilateral or bilateral penetrating mesiotemporal infarctions. Large infarctions of the left posterior temporal artery territory may produce an anomic or transcortical sensory aphasia.

Infarctions in the distribution of the penetrating branches of the PCA to the thalamus can cause aphasia if the left pulvinar is involved, akinetic mutism, global amnesia, and the Dejerine-Roussy syndrome. In the latter syndrome, the patient has contralateral sensory loss to all modalities, severe dysesthesias on the involved side (thalamic pain), vasomotor disturbances, transient contralateral hemiparesis, and chorcoathetoid or ballistic movements. A number of syndromes that can result from infarctions in the distribution of the penetrating branches of the PCA to the midbrain were previously discussed with the midbrain syndromes.

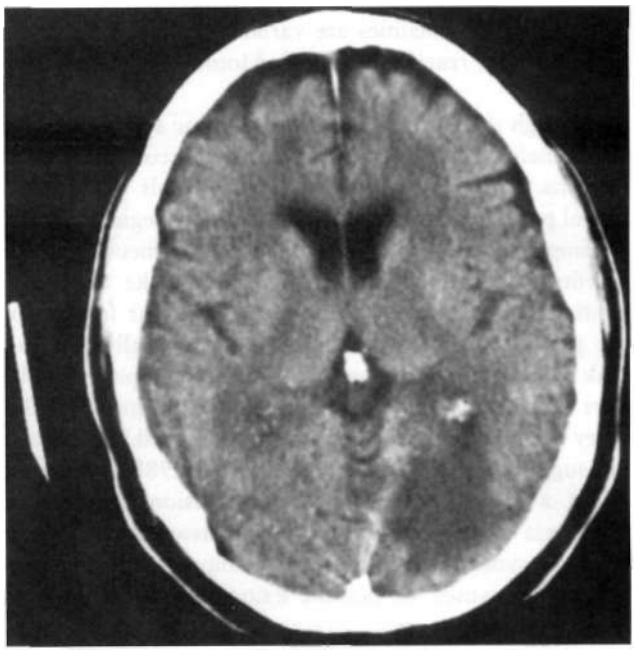

FIGURE 57A.4 A 77-year-old man had alexia without agraphia, right homonymous hemianopia, and antegrade amnesia. Nonenhanced axial cranial computed tomography demonstrates an area of decreased parenchymal attenuation in the left occipito-parii-ral region.

Bilateral infarctions in the distribution of the hemispheric branches of the PCAs may cause bilateral homonymous hemianopias. Bilateral occipital or occipitoparietal infarctions can cause cortical blindness, often with denial or unawareness of blindness (Anton's syndrome). Another syndrome, Balint's syndrome, seen with bilateral occipital or parieto-occipital infarctions, consists of optic ataxia, psychic paralysis of fixation with inability to look to the peripheral field and disturbance of visual attention, and simu I tan agnosia.

Syndromes of Thalamic Infarction

The main thalamic blood supply comes from the posterior communicating arteries and the perimesencephalic segment of the PCA. Thalamic infarctions typically involve one of four major vascular regions: posterolateral, anterior, paramedian, and dorsal. Posterolateral thalamic infarctions result from occlusion of the thalamogeniculate branches arising from the P2 segment of the PCA. Three common clinical syndromes may occur: pure sensory stroke, sensorimotor stroke, and the thalamic syndrome of Dcjcrine-Roussy. Anterior thalamic infarction results from occlusion of the polar or tuberothalamic artery. The main clinical manifesrations consist of neuropsychological disturbances, emotional-facial paresis, occasional hemiparcsis, and visual field deficits. Left-sided infarcts are associated with dysphasia, whereas neglect is seen primarily in patients

with right-sided lesions. Paramedian thalamic infarctions result from occlusion of the paramedian, thalamic, and subthalamic arteries. The main clinical manifestations include the classic triad of decreased level of consciousness, memory loss, and vertical gaze abnormalities. Dorsal thalamic infarctions result from occlusion of the posterior choroidal arteries. These infarctions are characterized by the presence of homonymous quadrantanopia or horizontal sectoranopias. Involvement of the pulvinar may account for thalamic aphasia.

Watershed Ischemic Syndromes

Watershed infarcts occur in the border zone between adjacent arterial perfusion beds. During or after cardiac surgery or after an episode of sustained and severe arterial hypotension after cardiac arrest, prolonged hypoxemia, or bilateral severe carotid artery disease, ischemia may occur in the watershed areas between the major circulations. Watershed infarctions also may be unilateral when there is some degree of hemodynamic failure in patients with underlying severe arterial stenosis or occlusion. Watershed infarcts also may be caused by microembolism or hyperviscosity states.

Ischemia in the border zone or junctional territory of the ACA, MCA, and PCA may result in bilateral parieto-occipital infarcts. There can be a variety of visual manifestations, including bilateral lower altitudinal field defects, optic ataxia, cortical blindness, and difficulty in judging size, distance, and movement. Ischemia between the territories of the ACA and MCA bilaterally may result in bibrachial cortical sensorimotor impairment (man-in-a-barrel), and impaired saccadic eye movements caused by compromise of the frontal eye fields. Ischemia on the border zone regions between the MCA and PCA may cause bilateral parietotemporal infarctions. Initially there is cortical blindness that may improve, but defects such as dyslexia, dyscalculia, dysgraphia, and memory defects for verbal and nonverbal material may persist.

Watershed infarcrs are also recognized between the territorial supply of the PICA, AICA, and SCA. Watershed infarctions may also involve the internal watershed region in the centrum semiovalc adjacent to, and slightly above, the body of the lateral ventricles.

DIAGNOSIS AND TREATMENT OF THREATENED ISCHEMIC STROKE

An ischemic stroke develops when there is interrupted cerebral blood flow to an area of the brain. Ischemic strokes account for approximately 80-85% of all strokes. Ischemic strokes may result from (1) large artery atheroscleroric disease resulting in stenosis or occlusion, (2) small vessel or penetrating artery disease (lacunes), (3) cardiogenic or artery-to-artery embolism, (4) nonatheioselerotic vasculopathies, (5) hypcrcoagulablc disorders, and *(6)* infarcts of undetermined causes. However, a rigid classification of ischemic stroke subtypes is difficult to establish because of the frequent occurrence of mixed syndromes.

LARGE ARTERY ATHEROTHROMBOTIC INFARCTIONS

Large artery atherothrombotic infarctions almost always occur in patients who already have significant risk factors for cerebrovascular atherosclerosis (see Table 57A.1). A tli ero thrombosis is multifactorial, comorbidities frequently overlap, and risk factors are often additive. For example, arterial hypertension is often associated with hyperlipidemia, hyperglycemia, elevated fibrinogen levels, excessive weight, and left ventricular hypertrophy on ECG. A resting ankle-brachial index less than 0.90 is indicative of generalized atherosclerosis (Zheng et al. 1997). Persons with a stroke are at high risk for development of other vascular complications. After a stroke, rhere is a 25% chance of a fatal thrombotic event in 3 years. Many of these deaths are caused by myocardial infarction. The mechanisms of large artery atherothrombotic infarction often reflect plaque complication; ulceration with artery-to-artery embolization (Figure 57A.5), or thrombosis in rhc setting of pre-existing arterial stenosis. Arteriogenic embolism is a common mechanism of cerebral ischemia. Embolism from ulcerated carotid artery atherosclerotic plaques is a common cause of cerebral infarction. In situ thrombosis occurs in the proximal carotid, distal vertebral artery, and lower or middle basilar artery (Figures 57A.6A and 57A.6B). Atherosclerotic involvement of the intracranial portion of the vertebrobasilar system frequently occurs in tandem and is the common pathological mechanism associated with the syndrome of vertebrobasilar territory infarction; this may arise in association with hypercoagulable states. Hypoperfusion secondary to hemodynamic alterations also may trigger these events. Whether the pathogenesis of stroke caused by intracranial arterial stenosis is different from that caused by extracranial aire rial disease is unsettled.

In patients with risk factors for atherosclerosis, the cholesterol-rich minimally raised fatty streak may progress to a fibrous plaque rhat can evolve into a complicated plaque with intraplaque hemorrhage, extensive necrosis, calcification, and subsequent thrombosis (Figure 57A.7). The infiltrarion of the fibrous cap by foam cells may contribute to the rupture of the atherosclerotic carotid artery plaque. Atherosclerosis is often segmental and asymmetrical, and earlier lesions tend to occur in areas of low shear stress, such as the outer aspect of the carotid artery bulb. Atherosclerosis primarily affects the larger extracranial and intracranial vessels, particularly the carotid siphon, MCA stem, origin of the vertebral arteries

FIGURE 57A..S Right common carotid angiogram shows 17% right internal carotid artery stenosis (North American Symptomatic Carotid Endarectomy Trial criteria) just superior to a large carotid ulceration. (Courtesy Vincent Mathews, MD.)

(Vi), intracranial segment of the vertebral arteries (V_4), and basilar artery. The distribution of cerebral atherosclerosis is different in certain ethnic groups. Stenosis of **major** intracranial arteries is more prevalent among blacks and **Asians** than in **whites.**

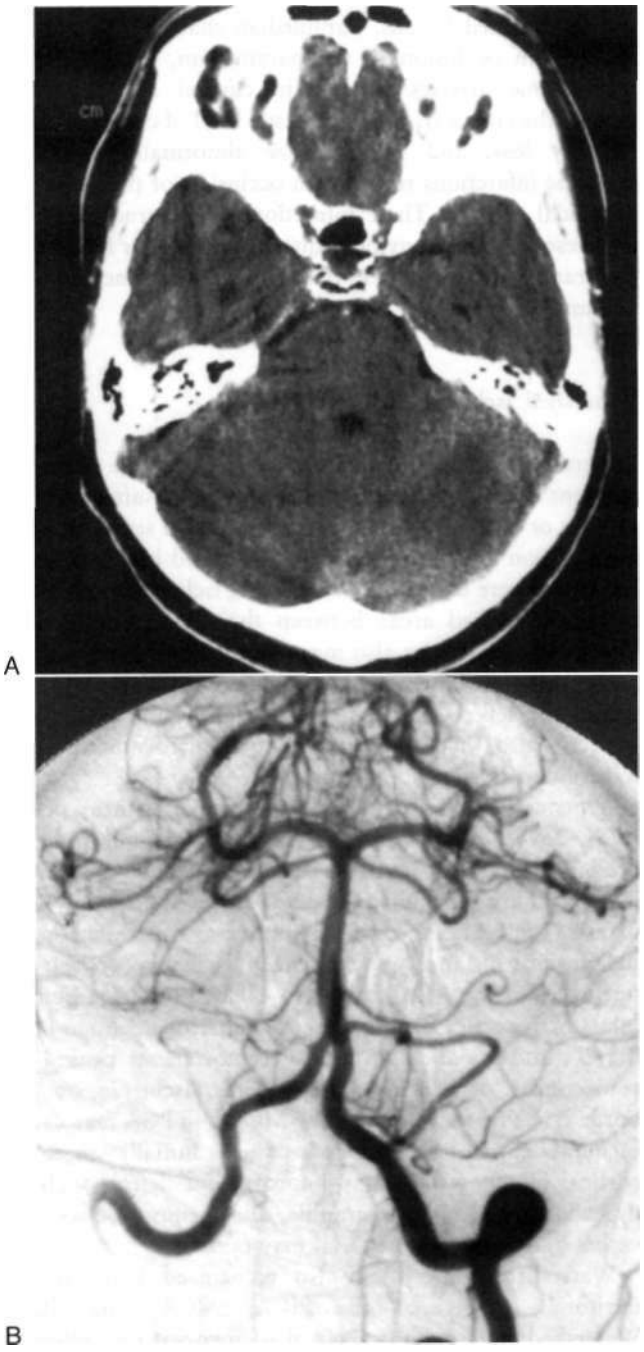

FIGURE 57A.6 (A) Nonenhanced axial computed tomographic scan shows bilateral cerebellar and pontine infarcts. (B) Anteroposterior view of vertebrobasilar angiogram shows a large filling defect on the basilar artery, consistent with partial thrombosis. (Courtesy Vincent Mathews, MD.)

SMALL VESSEL OR PENETRATING ARTERY DISEASE

Lacunes usually occur in patients with long-standing arterial hypertension, current cigarette smoking, and diabetes mellitus. The most frequent sites of involvement are the putamen, basis pontis, thalamus, posterior limb of the internal capsule, and caudate nucleus. Multiple lacuna are associated strongly with arterial hypertension and diabetes mellitus. Available evidence suggests that structural **changes** of **the cerebral** vasculature caused by arterial hypertension are characterized by fibrinoid angiopathy, lipohyalinosis, and microaneurysm formation. Accelerated hypertensive arteriolar damage of the small penetrating arteries is operative in a large number of patients with lacunar infarction. Microatheroma of **the** ostium of a penetrating artery, embolism, or changes in hemorrheology

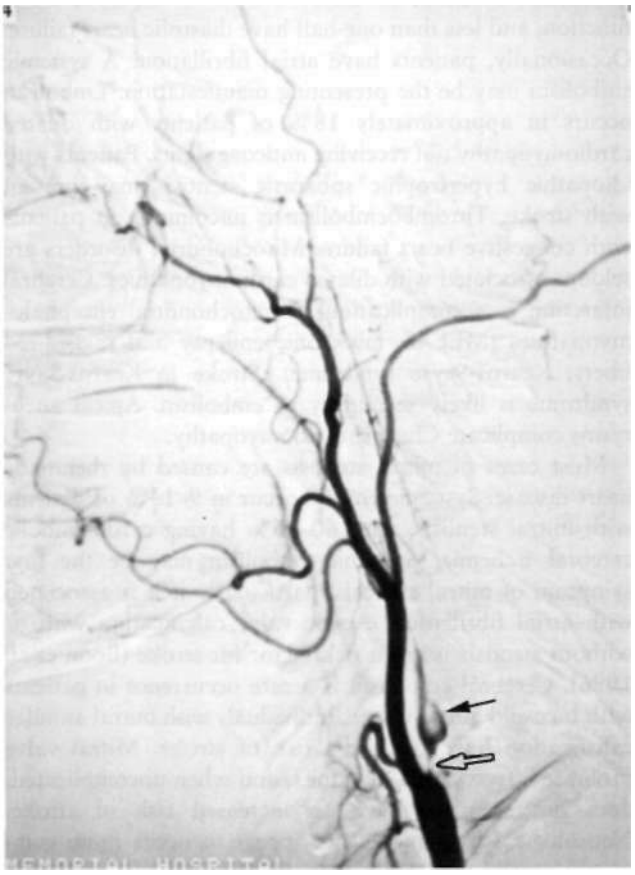

FIGURE 57A.7 Left carotid angiogram (lateral view) shows severe stenosis *[open arrow)* of origin of tlic left internal carotid artery with an intraluminal thrombus *[arrow).* **The artery was occluded in other images. (Courtesy Vincent Mathews, MD.)**

are pathophysiological^ operative in the remainder of cases. However, rhe mere association of a lacunar syndrome in a patient with arterial hypertension and diabetes is not sufficient for a diagnosis of a lacunar infarct, and other causes of ischemic stroke must be excluded, Large striatocapsular infarctions should be distinguished from lacunar infarcts, because they frequently have potential cardioembolic sources or coexistent severe carotid or MCA stenosis and often present with signs and symptoms of cortical dysfunction (Nicolai et al. 1996). Control of hypertension, prevention of microangiopathy, a better understanding of the ideal hemodynamic profile, and judicious use of platelet antiaggregants are essential in the management of patients with lacunar infarcts.

CARDIOGENIC EMBOLISM

Cerebrovascular events are a serious complication of a diverse group of cardiac disorders. Cardioembolic strokes are associated with substantial morbidity and mortality. Embolism of cardiac origin accounts for approximately 15-20% of all ischemic strokes. Cardiac emboli may be composed of platelet, fibrin, platelet-fibrin, calcium, microorganisms, or neoplastic fragments. The most common substrate for cerebral embolism in older individuals is atrial fibrillation, accounting for two thirds of emboli of cardiac origin. Other cardiac conditions with high embolic potential include acute myocardial infarction, infective endocarditis, rheumatic mitral stenosis, mechanical prosthetic heart valves, dilated cardiomyopathy, and cardiac tumors. Low or uncertain embolic risk disorders include mitral valve prolapse, mitral annulus calcification, aortic valve calcification, calcific aortic stenosis, remote myocardial infarction, left ventricular aneurysm, hypertrophic cardiomyopathy, patent foramen ovale (PFO), atrial septal aneurysm (ASA), atrial flutter, valvular strands, and Chiari network,

Congenital heart disease is probably the most common cardiac disorder causing ischemic stroke in children. Children with congenital heart disease and a low hemoglobin concentration are at special risk for arterial strokes; those with a high hematocrit are more likely to experience cerebral venous thrombosis (Perloff 1998). Emboli from cardiac sources may be silent or cause severe neurological deficit or death. Although most types of heart disease may produce cerebral embolism, certain cardiac disorders are more likely to be associated with emboli (Table 57A.3). Cardioembolic cerebral infarcts arc often large, multiple, bilateral, and wedge shaped. Sudden, unheralded, focal neurological deficits worse at onset are often presenting manifestations. Any vascular territory may be affected. Ischemic strokes with a potential cardiac source are more often associated with Wernicke's aphasia, homonymous hemianopia without hemiparesis or hemisensory disturbances, and ideomotor apraxia. Other features suggestive of a potential cardiac source of embolism include posterior division of the MCA, ACA, or cerebellar compromise; involvement of multiple vascular territories; or a hemorrhagic component of the infarction. Reliable clinical determination of a cardioembolic source of stroke may be hampered by a variety of problems. Identification of a potential embolic cardiac source is not by itself sufficient to diagnose a brain infarct as cardioembolic because (1) many cardiac problems may coexist with cerebrovascular atherosclerosis, {2) cardiac arrhythmias may occur after arrhythmogenic lesions such as parietoinsular and brainstem infarcts, (3) computed tomographic (CT) scan differentiation between cardioembolic and atherosclerotic causes of cerebral infarction is not always reliable, and (4) cardiac changes derected by echocardiography are prevalent in control populations.

An embolic stroke occurs in approximately 1% of hospitalized patients with acute myocardial infarction. Left ventricular thrombi are commonly associated with recent anterior wall transmural myocardial infarction. Echocardiography studies have demonstrated that approximately one third to one half of acute anterior myocardial infarctions, but less than 4% of acute inferior myocardial

Table 57A.J: Sources of cardioembolism

Acute myocardial infarction
Left ventricular aneurysm
Dilatated cardiomyopathy
Cardiac arrhythmias
Atrial fibrillation
Sick sinus syndrome
Valvular heart disease
Rheumatic mitral valve disease
Calcific aortic stenosis

Mitral valve prolapse
Infective endocarditis
Nonbacterial thrombotic endocarditis
Prosthetic heart valves
Filamentous strands of the mitral valve
Giant Lambl's excrescences
Aneurysms of the sinus of Valsalva
Intracardiac tumors (atrial myxoma, rhabdomyoma, papillary fibroelastoma)
Intracardiac defects with paradoxical embolism
Patent foramen ovale
Atrial septal aneurysm
Atrial septal defect
Cyanotic Congenital heart disease
Eontan procedure or its modifications (cavopulmonary anastomosis)
Mitochondrial encephalomyopathics (mitochondrial encephalopathy, lactic acidosis, and strokelike episodes; myoclonic epilepsy and ragged-red fibers; Kearns-Sayre syndrome)
Coronary artery bypass grafting
VVI pacing
Heart transplantation
Artificial hearts
Cardioversion for atrial fibrillation
Balloon angioplasty
Ventricular support devices
Extracorporeal membrane oxygenator

infarctions, develop left ventricular thrombi. Almost all episodes of embolism occur within 3 months following acute myocardial infarction, with 85% of emboli developing in the first 4 weeks. A decreased ejection fraction is an independent predictor of an increased risk of stroke following myocardial infarction (Loll ct al. 1997). Patients with acute myocardial infarction who receive thrombolytic therapy have a small risk of stroke. A direct comparison of tissue plasminogen activator (tPA) and streptokinase (SK) shows an excess of strokes with tPA. Myocardial infarction is rare in young adults. Although the prevalence of left ventricular thrombi in individuals with left ventricular aneurysms is high, the frequency of systemic embolism is low. Dilated or congestive cardiomyopathy may result from arterial hypertension or a variety of inflammatory, infectious, immune, metabolic, toxic, and neuromuscular disorders. The global impairment of ventricular performance predisposes to stasis and thrombus formation. Patients commonly have signs of impaired left ventricular systolic function, and less than one hall haw-diastolic heart failure. Occasionally, patients have atrial fibrillation. A systemic embolism may be the presenting manifestation. Embolism occurs in approximately 18% of patients with dilated cardiomyopathy not receiving anticoagulants. Patients with idiopathic hypertrophic subaortic stenosis may present with stroke. Thromboembolism is uncommon in patients with congestive heart failure. Mitochondrial disorders are seldom associated with dilated cardiomyopathies. Cerebral infarction is a complication of mitochondrial enccphalomyopathies (MELAS; myoclonic epilepsy and ragged-red fibers; Kearns-Sayre syndrome). Stroke in Kearns-Sayre syndrome is likely secondary to embolism. Apical aneurysms complicate Chagas' cardiomyopathy.

Most cases of mitral stenosis are caused by rheumatic heart disease. Systemic emboli occur in 9-14% of patients with mitral stenosis, with 60-75% having cardioembolic cerebral ischemia. Systemic embolism may be the first symptom of mitral stenosis, particularly if it is associated with atrial fibrillation. Aortic valve calcification with or without stenosis is not a risk factor for stroke (Boon et al. 1996). Cerebral embolism is a rare occurrence in patients with bicuspid aortic valves. Individuals with mitral annular calcification have twice the risk of stroke. Mitral valve prolapse affects 3^4% of adults, and when uncomplicated, does not seem to have an increased risk of stroke. Neurological ischemic events appear to occur more commonly among men older than 50 years with auscultatory findings of a systolic murmur and thick mitral valve leaflets on echocardiography. Thromboembolic phenomena complicating infective endocarditis may be systemic (left-sided endocarditis) or pulmonan (right-sided endocarditis). Vegetations are detected by transthoracic echocardiography in 54-87% of patients with infective endocarditis and are associated with an increased risk of embolism (Eishi et al. 1995). Systemic emboli may occur in nearly one half of patients with nonbacterial thrombotic endocarditis, a condition characterized by the presence of multiple, small, sterile thrombotic vegetations most frequently involving the mitral and aortic valves. The risk of thromboembolism is higher with mechanical prosthetic heart valves than with biological prosthetic heart valves. Thromboemboli are more common with prosthetic heart valves in the mitral position than with prosthetic heart valves in the aortic position. The rate of systemic embolism in patients with mechanical heart valves receiving anticoagulant therapy is 4% per year in the mitral position, and 2% per year in the aortic position. Filamentous strands attached to the mitral valve appear to represent a risk for cerebral embolism, particularly in young patients, but the risk of recurrent cerebral ischemia is incompletely understood. The association of giant Lambl's excrescences or aneurysms of the sinus of Valsalva and cerebral embolism is low.

Atrial fibrillation is the most common arrhythmia requiring hospitalization in the United States. The incidence of thromboembolism in patients with atrial fibrillation is

4-7.5% per year (Atrial Fibrillation Investigators 1994). Patients with NVAF, the leading source of cardioembolic infarctions in older adults, have a five- to sixfold increase in stroke incidence, with a cumulative risk of 35% over a lifetime. Patients with rheumatic atrial fibrillation have a 17-fold increase in stroke incidence. However, individuals younger than 65 years with lone atrial fibrillation have a low embolic potential. Stroke patients with atrial fibrillation are also at high risk of death during the acute phase of stroke and during the subsequent year after stroke. A dramatic increase in the rate of atrial fibrillation occurs with age, from 0.2 cases per 1000 patients aged 30-39 years to 39 cases per 1000 patients aged 80-89 years. The proportion of strokes caused by atrial fibrillation also steadily increases, from 6.7% of all strokes in patients aged 50-59 to 36.2% in those aged 80-89. The risk of embolism is increased among patients with atrial fibrillation and hyperthyroidism, who also have an increased sensitivity to warfarin,

Cerebral and systemic embolism may occur also in the setting of the sick sinus syndrome. Patients at greatest risk for embolization have bradytachyarrhythmias; left atrial spontaneous echocardiography contrast and decreased atrial ejection force increase stroke risk (Mattioli et al. 1997). Patients with sick sinus syndrome may experience cerebral ischemia or systemic embolism, even after pacemaker insertion. VVf pacing is associated with a higher risk of embolic complications than atrial or dual-chamber pacing. The risk of thromboembolism is also higher among patients in chronic atrial flutter (Wood et al. 1997; Seidl et al. 1998).

Atrial myxomas are rare cardiac tumors complicated by postural syncope and systemic and embolic manifestations. Embolic complications are a presenting symptom in one third of patients with atrial myxoma. Recurrent emboli before surgery are common. Peripheral and multiple cerebral arterial aneurysms also have been diagnosed years following the initial embolic manifestations from atrial myxoma. Treatment of atrial myxomas consists of prompt surgical resection of the cardiac mass. Cardiac rhabdomyomas are associated closely with tuberous sclerosis; systemic embolism is unusual. Mitral valve papillary fibroe la stoma, an uncommon valvular tumor, is complicated rarely by stroke.

A paradoxical embolism caused by a right-to-left shunt through a PFO or ASA can be responsible for stroke and other ischemic cerebral events. A PFO is present in 35% of subjects between the ages of 1 and 29 years, in 25% of people between ages 30 and 79, and in 20% between ages 80 and *99* years. A PFO provides opportunity for right-to-left shunting during transient increases in the right atrial pressure. PFO is more common in patients with stroke than in matched controls. Patients with no identifiable cause for ischemic stroke and PFO usually have a larger PFO with more extensive right-to-left shunting than patients with stroke of determined cause. Platelet antiaggregants, oral anticoagulants, transcathctcr closure of the PFO, or surgical closure of the PFO have been recommended. A recent study found no difference in the time to primary endpoints between aspirin and warfarin (mean INR = 2.04) (Homma et al. 2002). ASA also might be a source of cerebral emboli. The coexistence of PFO and ASA increases the risk of embolic stroke. PFO and ASA have been associated also with mitral valve prolapse. Strokes are often severe but recurrences are uncommon. Pulmonary arteriovenous malformations occur in 15-20% of patients with Rcndu-Oslcr-Weber syndrome and can be the source of paradoxical embolism causing cerebral ischemia.

Spontaneous echocardiographic contrast is associated with elevated fibrinogen levels and plasma viscosity and is a potential risk factor for cardioembolic stroke. Spontaneous cchocardiographical contrast is highly associated with previous stroke or peripheral embolism in patients with atrial fibrillation or mitral stenosis and increased left atrial size. The risk of cerebrovascular events is increased in adults with cyanotic congenital heart disease in the presence of arterial hypertension, atrial fibrillation, history of phlebotomy, and particularly with microcytosis (Perloff etal. 1993).

The preponderance of posterior circulation ischemia following cardiac catheterization is unexplained. Stroke occurs after coronary artery bypass grafting with a frequency ranging between 1% and 5% (Figure 57A.8). Two thirds of strokes occur by the second postoperative day, and predominantly involve the cerebral hemispheres; brainstem/cerebellar infarcts and lacunar strokes are less common. The cause of postoperative stroke is multifactorial; hypoperfusion, ventricular thrombus, and emboli are probable causal factors, although embolic causes are the most likely mechanisms. Clamp manipulation during coronary artery bypass surgery also may favor the release of aortic atheromatous debris. Epiaortic ultrasound studies demonstrate an increased stroke rate associated with an increased severity of aortic atherosclerosis. Strokes rarely relate to carotid artery stenosis. Carotid artery occlusion, but not carotid artery stenosis, increases the risk for stroke following coronary artery bypass grafting (Micklcborough et al. 1996). Thromboembolic phenomena can complicate cardiac surgery using cardiopulmonary bypass with deep hypothermia and cardiac arrest. Stroke is a potential complication of cardioversion for atrial fibrillation. Cerebral embolism may also complicate valvuloplasty; the risk is greater for aortic rather than mitral valvuloplasty. Strokes may follow heart transplantation, the use of ventricular support systems and artificial hearts, and the use of the extracorporeal membrane oxygenator. Stroke following inadvertently placed left-sided heart pacemaker leads is an unusual complication. Ischemic myelopathy is a rare complication of intra-aortic balloon pump. Aortic dissection or hematoma may lead to an occlusion of a major radicular branch or local occlusion of the artery of Adainkiewicz (see Chapter 57F),

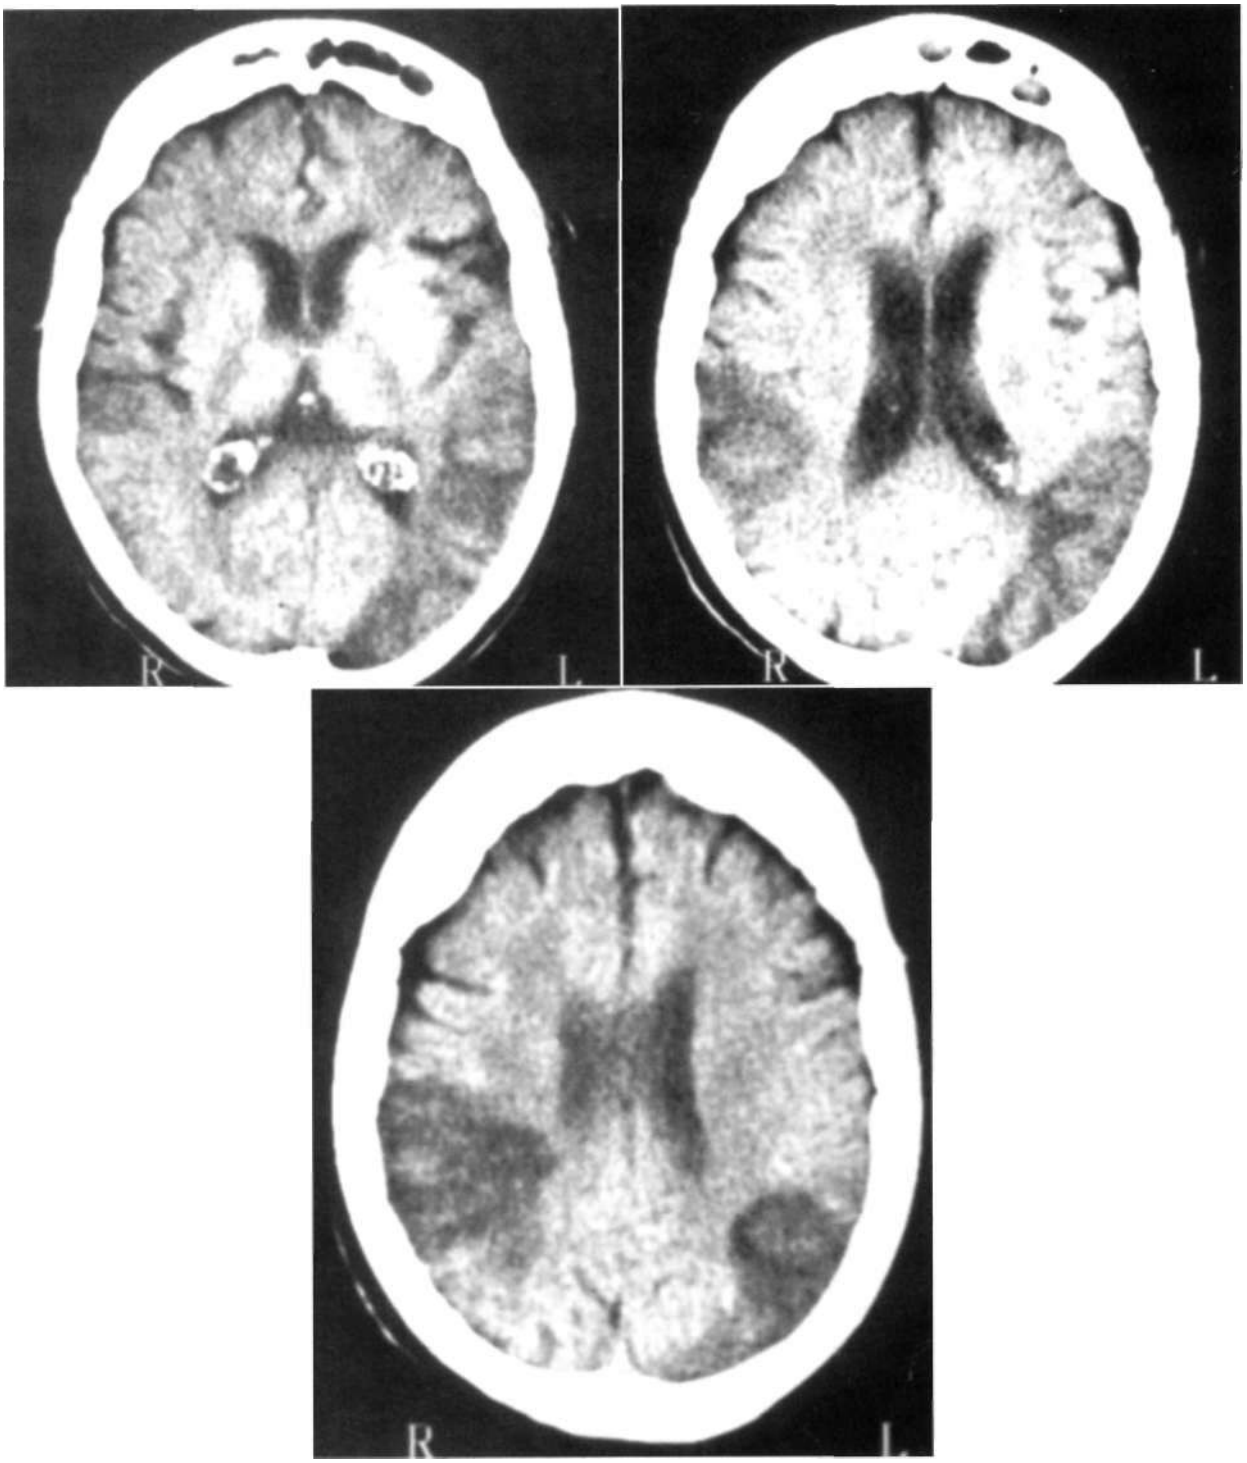

FIGURE 57A.8 An 80-year-old woman remained unresponsive with left-sided hemiplegia and right-sided hemiparesis after coronary-artery bypass grafting and aortic valve replacement. Noncnhanccd axial computed tomography demonstrates large left temporo-paricto-occipital and right frontoparietal infarctions.

NONATHEROSCLEROTIC VASCULOPATHIES

Although the majority of arterial disorders leading to stroke is caused by atherosclerosis, several nonathcrosclerotic vasculopathies can be responsible for a minority of ischemic strokes. These vasculopathies include ccrvicocephalic arterial dissections, traumatic cerebrovascular disease, radiarion vasciiloparhy, moyamoya, fibromuscular dysplasia (FMD), and cerebral vasculitis (Tables 57A.4 and 57A.5}. Together, these uncommon conditions represent 5% of all

Table 57A.4: Selected nonathcrosclerotic vasculopathies

Vasculitis
Migrainous infarction

ischemic strokes. They are relatively more common in children and young adults.

Cervicocephalic arterial dissections are one of the most frequent n on atherosclerotic vasculopathies causing ischemic stroke in young adults. A dissection is produced by subincimal penetration of blood in a cc r vie ocep ha lie- vessel with subsequent longitudinal extension of the intramural hematoma between its layers. Most dissections involve the extracranial segment of the internal carotid artery or extracranial vertebral arteries. Intracranial carotid and vertebrobasilar dissections are less common; intracra- nial dissections are usually subintimal, and may follow trivial trauma, closed head trauma, basilar skull fractute, or penetrating injuries. The recurrence rate of extracranial cervicocephalic arterial dissections is approximately 1% per year. The risk of recurrent dissections is increased in younger patients and in patients with family history of arterial dissections.

Tabic S7A.5: Classification of cerebral vasculitides

Infectious vasculitis
Bacterial, fungal, parasitic
Spirochetal (syphilis, Lyme disease)
Viral, rickettsial, mycobacterial
Cysticercosis, free-living amebae
Necrotizing vasculitides
Classic polyarteritis nodosa
Wegener's granulomatosis
Allergic angiitis and granulomatosis (Churg-Strauss)
Necrotizing systemic vasculitis-overlap syndrome
Lymphomatoid granulomatosis
Vasculitis associated with collagen vascular disease
Systemic lupus erythematosus
Rheumatoid arthritis
Scleroderma
Sjogren's syndrome
Vasculitis associated with other systemic diseases
Behcet's disease
Ulcerative colitis
Sarcoidosis
Relapsing polychondritis
Kohlmeier-Degos disease (malignant atrophic papulosis)
Giant cell artcritides
Takayasu's arteritis
Temporal (cranial) arteritis
Hypersensitivity vasculitides
Henoch-Schonlein's purpura
Drug-induced vasculitides
Chemical vasculitides
Essential mixed cryoglobulinemia
Miscellaneous
Vasculitis associated with neoplasia
Vasculitis associated with radiation
Cogan's syndrome
Der m a to my o s i ti s polymyositis
X-linked lymphoproliferative syndrome
Thromboangiitis obliterans
Kawasaki's syndrome
Primary central nervous system vasculitis

Cervicocephalic artetial dissections have been reported after blunt or penetrating trauma and also are associated with FMD, Marfan's syndrome, Ehlers-Danlos syndrome type IV, pseudoxanthoma elasticum, coarctation of the aorta, Menkes' disease, or [-antitrypsin deficiency, cystic medial degeneration, reticular fiber deficiency, accumula- tion of mucopolysaccharides, osteogenesis imperfecta, adult polycystic kidney disease, elevated arterial elastase content (Thai et al. 1997), lentiginosis, atherosclerosis, extreme vessel tortuosity, moyamoya syndrome, homocystinuria, pharyngeal infections, sympathomimetic drug abuse, and luetic arteritis. Not infrequently, cervicocephalic arterial dissections occur spontaneously.

Dissection of the cervicocephalic vessels may cause transient retinal, hemispheric, or posterior fossa ischemia, Horner's syndrome, hemicranial pain, cranial nerve palsies, cerebral infarction, or subarachnoid hemorrhage. Ischemic symptoms result from arterial occlusion or secondary embolization. In addition to a postganglionic Horner, neuro-ophthalmological manifestations of internal carotid artery dissections may also include central retinal artery occlusion, ophthalmic artery occlusion, ischemic optic neuropathy, homonymous hernia no pia, and ocular motor nerve palsies (cranial nerve ICN] III, IV, and VI). In addition to a first-order neuron Horner syndrome, other ncuro-ophthalmological manifestations of vertebrobasilar dissections include diplopia, nystagmus, oscillopsia, ocular misalignment, skew deviation, ocular motor nerve palsies (CN III, IV, and VI), lateral gaze palsy, internuclear ophthalmoplegia, and homonymous visual field defects.

Cervicocephalic arterial dissections should be considered in the differential diagnosis of ischemic stroke in any young adult, particularly when traditional risk factors are absent. Diagnosis is based on artcriographical findings, although high-resolution magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA), computed tomog- raphy angiography, and extracranial and transcranial Doppler ultrasound are rapidly replacing contrast angiog- raphy for the diagnosis of cervicocephalic arterial dissec- tions, particularly in cases of carotid artery involvement (Figure 57A.9).

Arteriographical features include the presence of a pearl and string sign; double-lumen sign; short, smooth, tapered

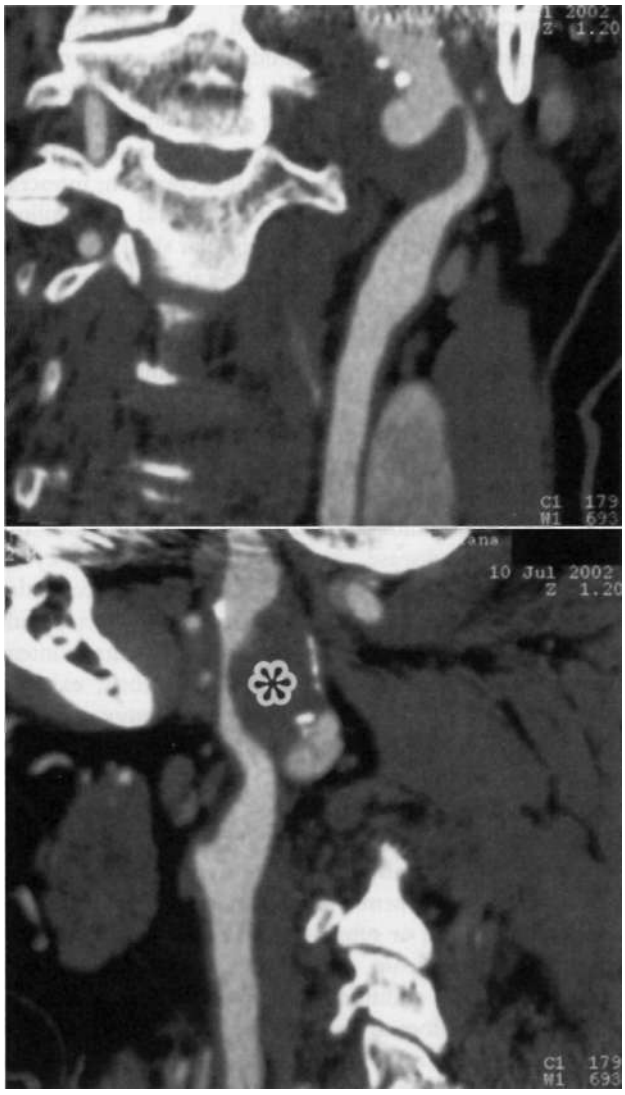

FIGURE 57A.9 Following the intravenous administration of iodinated contrast, spiral CT images were obtained using 1.3 mm collimation and 0.5 mm image reconstruction intervals. A pseudoaneurysm of the left internal carotid artery is noted. This pseudoaneurysm measures 1.9 x 2.9 cm in greatest axial dimensions. There is calcification in the wall of the aneutysm. There is extensive mural thrombus such that the aneurysm lumen containing contrast measures 12.5 x 10.7 mm (*). The internal carotid artery is severely narrowed just proximal to its entry site into the aneutysm.

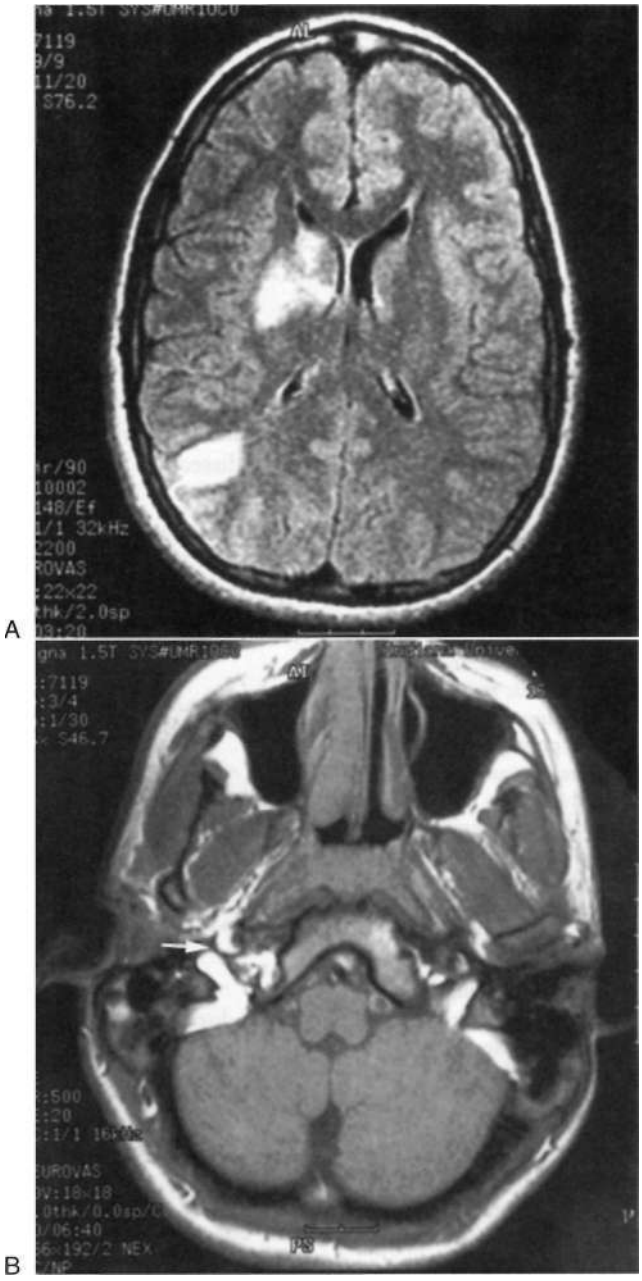

FIGURE 57A.10 A 16-ycar-old boy collapsed to the ground after experiencing right eye pain and left-sided weakness. (A) Axial T2-weighted magnetic resonance imaging of the brain shows ischemic areas in the right basal ganglia and right posterior parietal region, (B) associated with a crescent sign *(arrow)* of high signal consistent with intraluminal blood products on the right internal carotid artery suggestive of a dissection.

occlusion; or pseudoaneurysm formation. MRI demonstrates the intramural hematoma and the false lumen of the dissected artery (Figure 57A.10), Ultrasound studies can be helpful in monitoring their course.

Therapeutic interventions have included immediate anticoagulation with heparin followed by a 3- to 6-month course of warfarin; platelet atitiaggregants; or surgical correction for selected individuals with pseudoaneurysms or those who fail to respond to medical therapy. Although anticoagulants are often empirically recommended, their value in patients with extracranial cervicoccphalic arterial dissections has not been firmly established. Anticoagulation should be withheld in patients with intracranial dissections (particularly involving the vertebrobasilar circulation) because of the risk of subarachnoid hemorrhage.

Trauma is a leading cause of cerebrovascular mortality in the United States. Blunt or penetrating traumatic cerebrovascular disease may result in cervicocephalic arterial

dissection, arterial thrombosis, arterial rupture, pscudo-aneurysm formation, or development of an arteriovenous fistula. Internal carotid artery thrombosis also may follow maxillary and mandibular angle fractures. Carotid artery trauma may cause hematoma formation of the lateral neck, retinal or hemispheric ischemia, and a Horner's syndrome. Neurological deficits may be mild or devastating. Comatose patients with carotid arterial injuries with a Glasgow Coma Scale score of 8 or less do poorly regardless of management (see Chapter 5, Table 5.4). Missing the diagnosis may lead to devastating results. A thorough evaluation of the airway, oropharynx, and esophagus is needed. Arteriography is indicated in most instances, and surgical repair may be needed.

Injury to the endothelial cells by high-intensity radiation may cause accelerated atherosclerotic changes, particularly in the presence of hyperlipidemia. These changes may occur months to years after completion of radiation therapy. Radiation vasculopathy correlates with radiation dose and age at time of radiation therapy. Lesions develop in locations that are unusual for atherosclerosis and may involve the extracranial or intracranial vessels. Patients who receive therapeutic radiation therapy for lymphoma, Hodgkin's disease, or thyroid carcinoma are at risk for involvement of the extracranial circulation. Follow-up ultrasound carotid and MRI studies are recommended in these patients. Radiation therapy also may cause an occlusive vasculopathy of small and large intracranial arteries following irradiation of craniopharyngiomas, germinomas, pituitary tumors, or other intracranial neoplasms. Intracranial arterial stenosis also may follow stereotactic radiosurgery.

Moyamoya is a chronic progressive non-atherosclerotic, non-inflammatory, non-amyloid occlusive intracranial vasculopathy of unknown cause. Pathologically, there is fibrocellular intimal thickening and smooth muscle cell proliferation and increased elastin accumulation resulting in stenosis of the suprasellar intracranial internal carotid arteries. There is also thinning of the media, and a tortuous and often multilayered internal elastic lamina. Thrombotic lesions may be seen in major cerebral arteries. There are also numerous, perforating and anastomotic branches around the circle of Willis. Intracranial aneurysms may be seen at the circle of Willis or in the peripheral vessels (Yamamoto et al. 1997). Cases have been associated with neonatal anoxia, trauma, basilar meningitis, tuberculous meningitis, leptospirosis, cranial radiation therapy for optic pathway gliomas, neurofibromatosis type-1, tuberous sclerosis, encephalotrigeminal angiomatosis (Sturge-Weber syndrome), phakomatosis pigmentovascularis type Illb, brain tumors, FMD, polyarteritis nodosa, Marfan's syndrome, Turner's syndrome, pseudoxanthoma clasticum, hypomelanosis of Ito, Williams' syndrome, cerebral dissecting and saccular aneurysms, sickle cell disease, *0*-thalassemia, Fanconi's anemia, hereditary spherocytosis, lupus anticoagulant, Sneddon's syndrome, homocystinuria, oral contraceptives, factor XII deficiency, type I glycogenosis, reduced form of nicotinamide-adenine dinuclcotide phosphate-coenzyme Q reductase deficiency, renal artery stenosis, Down's syndrome, Apert's syndrome, Graves' disease, coarctation of the aorta, Alagille syndrome, hyperphosphatasia, Schimke's immunosseous dysplasia, primary oxalosis, pulmonary sarcoidosis, and Hirschprung's disease.

Moyamoya disease may cause TIAs, including hemodynamic paraparetic TIAs secondary to watershed paracentral lobule ischemia, headaches, seizures, movement disorders (chorea, hemidystonia, hemichorcoathetosis), mental deterioration, cerebral infarction, or intracranial hemorrhage. TIAs are often precipitated by crying, blowing, or hyperventilation.

Moyamoya disease has a bimodal age distribution with peaks in the first and fourth decades of life. Childhood moyamoya is characterized by ischemic manifestations, whereas adult moyamoya disease presents with hemorrhagic manifestations. Moyamoya affects children, adolescents, and young adults most frequently. Diagnosis is based on a distinct arteriographical appearance as described by Suzuki's six angiographic stages: (1) stenosis of the carotid fork, (2) initial appearance of moyamoya vessels at the base of the brain, (3) inrensification of moyamoya vessels, (4) minimization of moyamoya vessels, (5) reduction of moyamoya vessels, and (6) disappearance of moyamoya vessels (collaterals only from external carotid arteries) (Figure .S7A.11). Moyamoya is characterized by progressive, bilateral stenosis of the distal internal carotid arteries

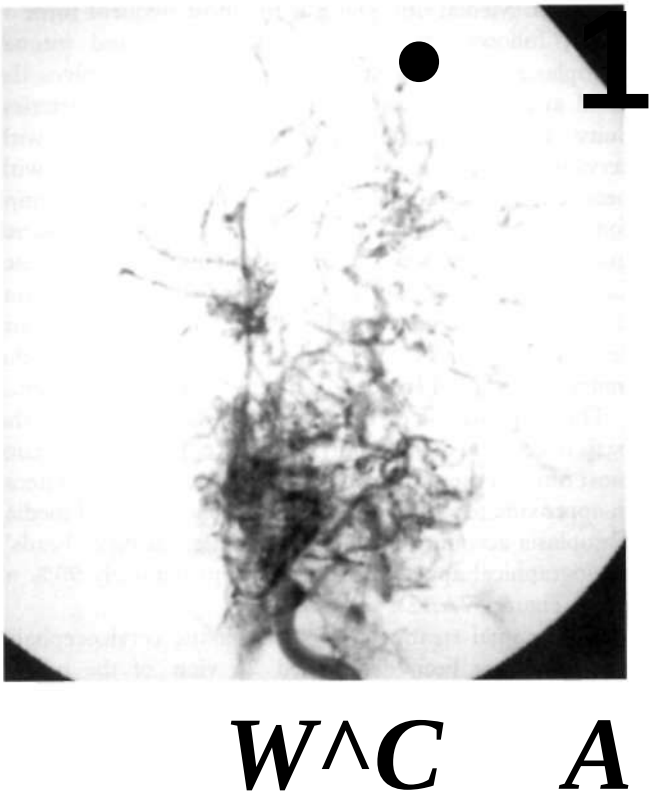

FIGURE 57A.11 Left carotid angiogram (anteroposterior view) shows occlusion of the supraclinoid internal carotid artery and innumerable moyamoya vessels. (Courtesy Vincent Mathews, MD.)

extending to the proximal ACA and MCA, often with involvement of the circle of Willis and development of an extensive collatetal {parenchymal, leptomeningeal, and transdural) network at the base of the brain like a cloud or puff of smoke (moyamoya). Intracranial aneurysms, particularly located in the posterior circulation, may be present.

The optimal treatment of ischemic moyamoya has not been determined. Platelet antiaggregants, vasodilators, calcium-channel blockers, and corticosteroids have been used with variable results. Anticoagulants are not useful. Good results have been reported with superficial temporal artery to MCA anastomosis and other indirect or combined surgical revascularization procedures. No clear superior therapy to ptevent rebleeding has been shown in the hemorrhagic type of moyamoya disease.

FMD is a segmental, non-athcromatous dyspiastic, noninflammatory angiopathy affecting predominantly young and middle-aged women. Cervicocephalic HMD affects less than 1% of the population, occuts mote often in whites than in blacks, and predominantly involves the cervical carotid arteries at the level of the CI to C2 vertebral bodies. FMD of the intracranial arteries is rare and mainly limited to the intrapetrosal internal carotid artery or carotid artery siphon. The cause of FMD is unknown. Immunological and estrogenic effects on the arterial wall may be causal mechanisms. An association with ofl-antitrypsin deficiency has been reported. Four distinct histological types ate recognized: intimal fibroplasia, medial hypetplasia, medial fibroplasia, and perimedial dysplasia. Medial fibroplasia is the most frequent form of FMD, followed by perimedial dysplasia, and intimal fibroplasia. The majority of cases of FMD involves the renal arteries, followed by the carotid and iliac arteries. Some cases are familial. Most often, patients with cervicocephalic FMD are asymptomatic or present with headaches, neck pain, carotidynia, tinnitus, vettigo, asymptomatic carotid bruits, transient retinal or cerebral ischemia, cerebral infarction, or subarachnoid hemorrhage. Cervicocephalic FMD may be associated with atterial dissection. Hypertensive patients may have concomitant renal FMD, Cerebral ischemia is usually related to the underlying atterial stenosis or artetial thromboembolism.

The diagnosis of cervicocephalic FMD is made on the basis of cerebral angiography. Cervicocephalic FMD occurs most often in the extracranial carotid artery and is bilateral in approximately two thirds of cases. The lesions of medial fibroplasia account for the characteristic "siting of beads" angiographical appearance seen in approximately 90% of cases (Figute 57A.12).

The optimal treatment of symptomatic cervicocephalic FMD has not been determined. In view of the benign natural history of this condition, platelet antiaggtegants arc recommended. Surgical intervention with angioplasty and stenting, gradual arterial dilatation, tcsection and reconstruction, or interposition grafting is seldom warranted.

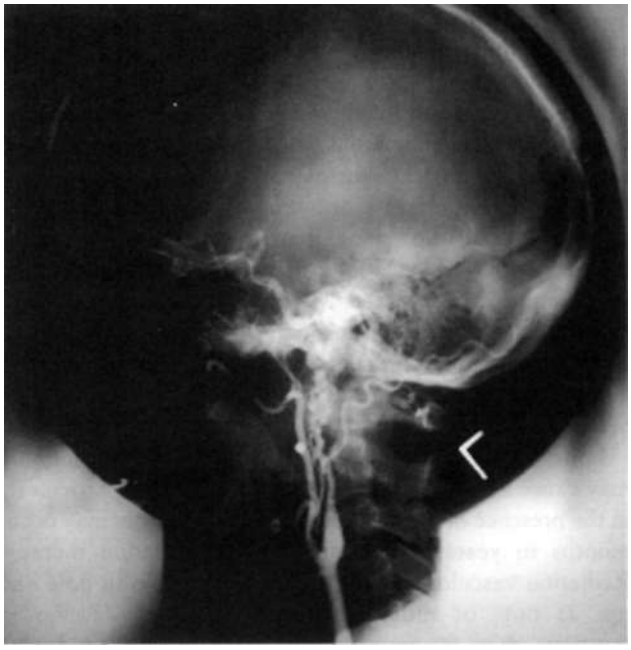

FIGURE 57A.12 Lateral left carotid angiogram in a patient with FMD. Note "string of pearls" appearance at around the C2 level.

Inflammatory vasculitides can involve any size of vessel, including the precapillary arterioles and postcapillary venules. Many infectious and multisystem noninfectious inflammatory diseases cause cerebral vasculitis (see Table 57A.5). Cerebral vasculitis is a consideration in young patients with ischemic ot hemorrhagic stroke; patients with recurrent stroke; patients with stroke associated with encephalopathic featutes; and patients with stroke accompanied by fever, multifocal neurological events, mononeuritis multiplex, palpable purpura, or abnormal urinary sediment. Other manifestations of cerebral vasculitis include headaches, seizures, and cognitive deterioration. Laboratory studies typically show anemia of chronic disease, leukocytosis, and an elevated erythrocyte sedimentation tatc. The diagnosis of vasculitis usually requires confirmation by arteriography or biopsy. Overall, these disorders have a poor prognosis, but corticosteroids and alkylating agents have improved the survival rate.

Intracranial vasculitis and stroke can result from meningovascular syphilis; prodromal manifestations are common before stroke. The MCA territory is most commonly affected. Spinal cord infarction may result from meningomyelitis. Other neurological manifestations in patients with secondary syphilis include headaches, meningismus, mental status changes, and ctanial nerve abnormalities. The cerebrospinal fluid (CSF) may show a modest lymphocytic pleocytosis, elevated protein content, and a positive Venerea! Disease Research Laboratory (VDRL) test result. Concurrent human immunodeficiency virus (HIV-1) infection can lead to rapid progression of early syphilis to neurosyphilis. Luetic aneurysms of the

ascending aorta can extend to involve the origin of the great vessels and can lead to stroke. Treatment schedules for syphilis are listed in standard textbooks; patients with concurrent HIV-1 infection and meningovascular syphilis may require prolonged antibiotic treatment. Worldwide, an estimated 1 billion people arc infected with *Mycobacterium tuberculosis.* Neurotuberculosis affects predominantly the basilar meninges. Predisposing conditions include alcoholism, substance abuse, corticosteroid use, and HIV 1 infection. Strokes can result from tuberculous endarteritis. The exudative basilar inflammation entraps the cranial nerves at the base of the brain, most frequently the third, fourth, and sixth cranial nerves. The basilar arteriolitis most commonly involves penetrating branches of the ACA, MCA, and PCA (medial and lateral lenticulostriate, anterior choroidal, thalamoperforators, and thalamogeniculate arteries). There is usually a modest lymphocytic and mononuclear pleocytosis. The CSF protein is usually elevated, and the glucose level is depressed. In the early stages, a predominantly neutrophilic response may be noted. Smears of CSF demonstrate M. *tuberculosis* in 10-20% of cases. Repeated CSF examinations increase the yield considerably.

Fungal arteritis may result in aneurysms, pseudoaneurysms, thrombus formation, and cerebral infarction. Complications of acute purulent meningitis include intracranial arteritis and thrombophlebitis of the major venous sinuses and cortical veins. Intracranial arterial stenoses have been associated with a complicated clinical course. Varicella-zoster may cause a virus-induced necrotizing arteritis similar to granulomatous angiitis. Cerebral infarction is a complication of the acquired immunodeficiency syndrome (AIDS), and may result from vasculitis, meningovascular syphilis, varicella-zoster virus vasculitis, opportunistic infections, infective endocarditis, aneurysmal dilation of major cerebral arteries, nonbacterial thrombotic endocarditis, aPL antibodies, or other hypercoagulable states, hyperlipidemia resulting from protease inhibitors, and other factors such as HIV-1-related malignancy, cancer chemotherapy, and thrombotic thrombocytopenic purpura (TIP). Large artery cerebrovascular occlusions have been found in association with meningoencephalitis caused by free living amebae. Other infectious agents known to produce cerebral infarcts include *Mycoplasma pneumoniae,* coxsackie 9 virus, California encephalitis virus, mumps paramyxovirus, hepatitis C virus, *Borrelia burgdorferi, Rickettsia typhi* group, cat-scratch disease, *Trichinella* infection, and the larval stage (cysticercus) of *Taenia solium.* Cerebrovascular involvement in ncurocysticercosis is usually ischemic and is caused by chronic meningitis, arteritis, or endarteritis of small vessels (Alarcon et al. 1992). Unilateral or bilateral carotid artery occlusion can complicate necrotizing fasciitis of the parapharyngeal space. Infection with *Chlamydia pneumoniae* accelerates the process of atherosclerosis in animal studies; treatment with azithromycin has been shown to reduce the degree of atherosclerotic lesions in a rabbit model (Moazed et al. 1999; Muhlestein et al. 1998).

Ischemic stroke is a complication of illicit drug use and over-thc-couutet sympathomimetic drugs. Stroke mechanisms associated with the use of illicit drugs are multifactorial, including foreign body embolization, vasculitis, vasospasm, acute onset of arterial hypertension or arterial hypotension, endothelial damage, accelerated atherosclerosis, hyper- or hypocoagulabiliry, cardiac arrhythmias, embolism from a myocardial infarction, or AIDS. The substances implicated most commonly are the amphetamines, cocaine (free-base or "crack"), phenylpropanolamine, pentazocine (Talwin) in combination with pyribenzamine ("T's" and "blues"), phencyclidine, heroin, anabolic steroids, and glue sniffing. Ischemic or hemorrhagic strokes may follow within hours of cocaine use, whether the drug is smoked, snorted, or injected (Figure 57A.13) (see Chapters 57G and 64B). The risk of intracerebral hemorrhage, especially among young women, has led to removal from the American market of phenylpropanolamine (Kernan et al. 2000). Ephedra, also called Ma Huang, widely used in weight-loss products, has been associated with high blood pressure, heart attacks, and strokes. Stroke in young athletes may also be the result of

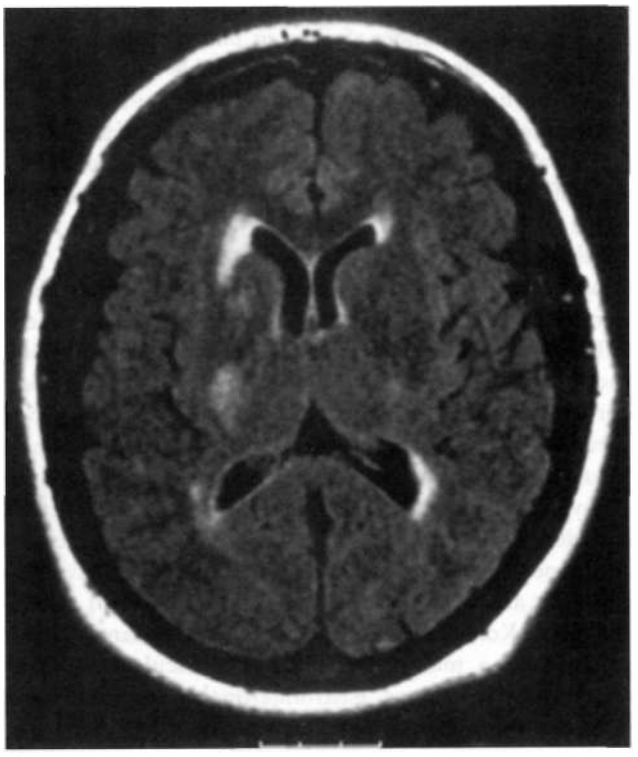

FIGURE 57A. 13 A 41-year-old woman with a history of cocaine ahuse had acute onset of left-sided hemiplegia, left hemibody sensory deficit, and a left homonymous visual field deficit. Axial flu id-attenuated inversion recovery images of the brain demonstrates an area of infarction in the posterior limb of the right internal capsule in the distribution of the anterior choroidal artery territory. There is associated periventricular ischemia.

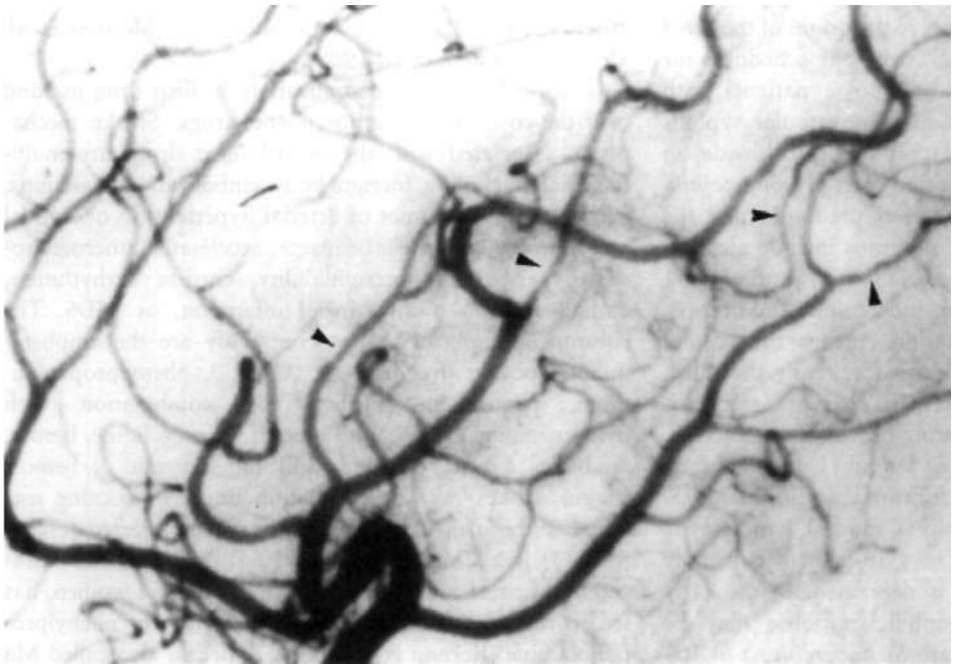

FIGURE 57A.14 Lateral carotid angiogram demonstrates irregular beading appearance *[arrowheads)* of large and medium branches of the anterior, middle, and posterior cerebral arteries in a patient with systemic lupus erythematosus. (Courtesy Vincent Mathews, MD.)

anabolic-androgen steroid abuse and recombinant erythropoietin ("blood doping") administration.

Ischemic stroke is also a complication of a variety of multisystem vasculitides. Stroke in patients with systemic lupus erythematosus may be attributable to cardiogenic embolism (nonbacterial verrucous or I.ibman-Sacks endocarditis, winch occurs in the ventricular surface of the mitral valve), aPL antibodies, underlying vasculopathy, or less often to an immune-mediated vasculitis (Figure 57A.14) (see Chapter 55A).

Behcet's syndrome may involve vessels of any size. Venous thrombosis is more frequent than occlusive arterial compromise. Affected patients arc mainly of Mediterranean or East Asian origin and may have a history of iritis, uveitis, and oral, genital, and mucocutaneous ulcerations. Cerebrovascular complications include strokes, carotid aneurysm formation, and cerebral venous thrombosis, Cogan's syndrome is a rare condition characterized by nonsyphilitic interstitial keratitis, vestibular dysfunction, and deafness. Complications include aortic insufficiency and mesenteric ischemia. The angiitic form of sarcoidosis primarily affects the eyes, meninges, and cerebral arteries and veins, Kohlmeier-Degos disease or malignant atrophic papulosis is a multisystem occlusive vasculopathy characterized by cutaneous, gastrointestinal, and neurological manifestations; it may be complicated by ischemic or hemorrhagic strokes. Cerebral vasculitis may also complicate the course of children with acute poststreptococcal glomerulonephritis. The multisystem vasculitides ate described in more detail in Chapter 55A,

Takayasu's arteritis is a chronic inflammatory artcriopathy of the aorta and its major branches, as well as the pulmonary artery. The cause is unknown, but an immune mechanism is suspected. The disease, prevalent in young women of Asian, Mexican, or Native American ancestry, develops insidiously, causing stenosis, occlusion, aneurysmal dilatation, or coarctation of the involved vessels. The disease has two phases. In the acute ot ptcpulsclcss phase, nonspecific systemic manifestations are present. Patients have skin rashes, erythema nodosum, fever, myalgias, arthritis, pleuritis, carotidynia, and elevated erythrocyte sedimentation rate. Months or years later, the second or occlusive phase develops and is characterized by multiple arterial occlusions. Patients may have cervical bruits, absent carotid or radial pulses, asymmetrical blood pressure recordings, and arterial hypertension. Neurological symptoms result from central nervous system or retinal ischemia associated with stenosis or occlusion of the aortic arch and arch vessels, or arterial hypertension caused by aortic coarctation or renal artery stenosis. Visual disturbances are most often bilateral. The diagnosis can be confirmed by MR A, but the most accurate assessment still requires aortography {Figure 57A.15).

Patients with active disease are treated with oral glucocorticoids; cyclophosphamide, a/athioprine, or methotrexate may be needed in special circumstances. Surgical treatment (angioplasty or bypass) of severely stenotic vessels may be required (Kerr ct al. 1999).

Cranial (giant cell or temporal) arteritis is a polysymptomatic systemic large vessel arteritis with a predilection to involve carotid artery branches (see Chapter 75). Thromboangiitis obliterans, also known as *Ruergcfs disease,* is a rare, segmental inflammatory, oblitcrativc angiopathy of unknown cause. The condition involves small and medium arteries and veins. It is suspected in young men who smoke and have a history of superficial

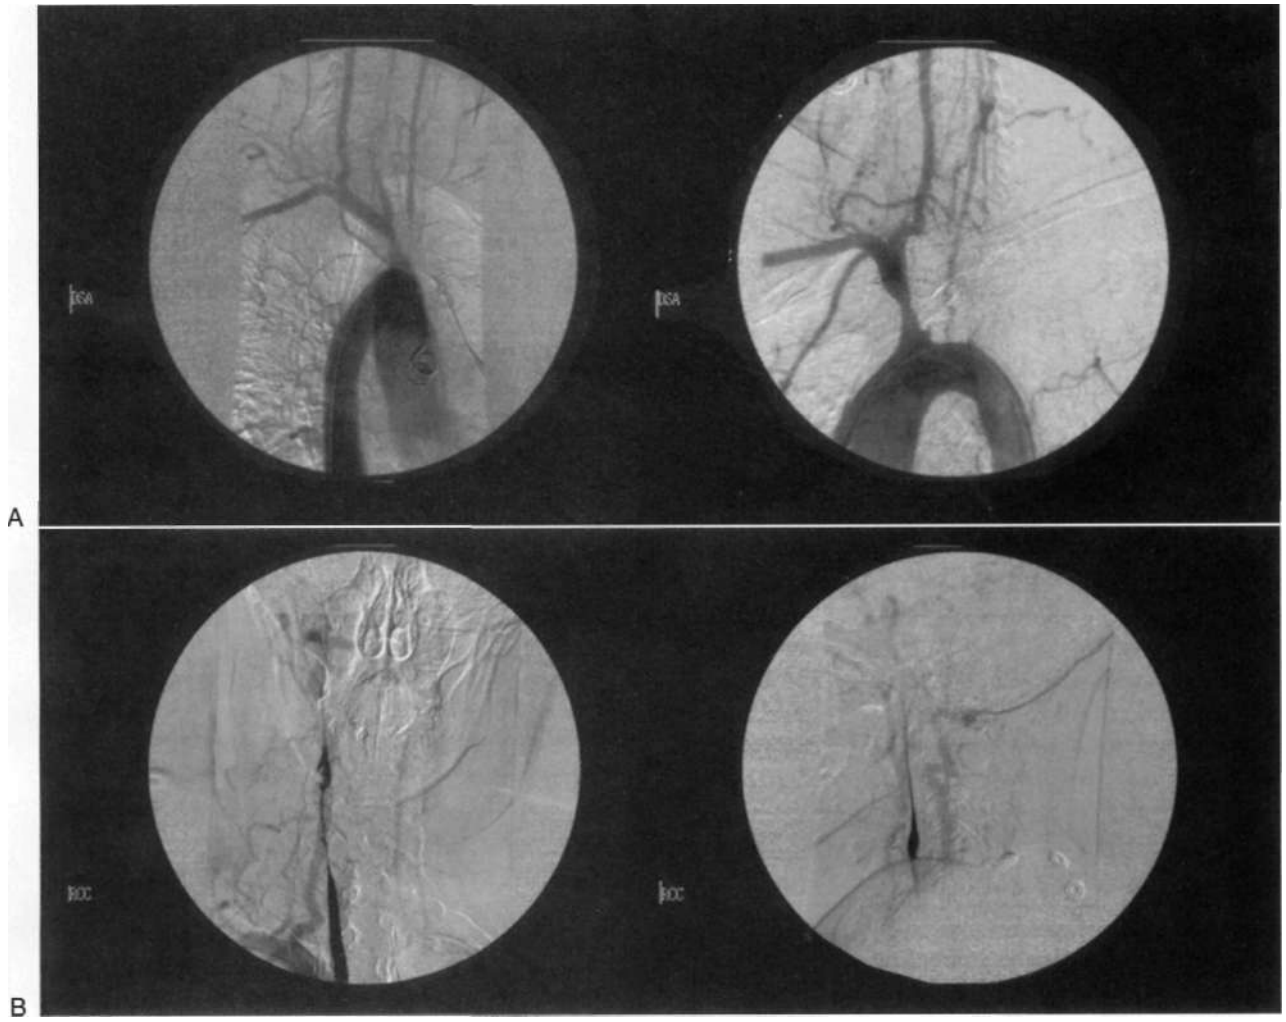

FIGURE 57A.15 (A) Aortogram demonstrates a nonocclusive stenosis of the brachiocephalic artery. There is complete occlusion of the left subclavian artery. The left vertebra is absent or occluded. (B) The right common carotid artery shows a long segment of critical stenosis extending from C3 to C5. *Continued*

migratory thrombophlebitis presenting with distal limb ischemia accompanied by digital gangrene. The disorder is characterized by remissions and exacerbations. Cerebral involvement is uncommon. Strokes can result from isolated angiitis of the central nervous system. Symptoms of large-vessel involvement include strokelike presentations. Small-vessel involvement may be manifested as a mass lesion in the brain or multifocal encephalopathy (Figure 57A.16A and Figure 57A.16B). The erythrocyte sedimentation rate is usually normal or minimally elevated (see Chapter 57G).

Migraine (see Chapters 21 and 75) affects women more often than men, and may start during childhood or adolescence. Epidemiological studies suggest a nonrandom association of both headache and migraine with stroke, particularly among young women. This rare association was limited to women younger than age 35 in a large Italian case-controlled study (Carolci ct al. 1996). The possible association between migraine headache and stroke was also evaluated by the Physician's Health Study; physicians reporting migraine had increased risks of subsequent rotal stroke and ischemic stroke compared with those not reporting migraines (Buring et al. 1995).

The International Headache Society Classification and Diagnostic Criteria require that, to establish a diagnosis of migrainous infarction, one or more migrainous aura symptoms must be present and not fully reversed within 7 days from onset, associated with neuroimaging confirmation of ischemic infarction (see Chapter 75). This definition implies that a firm diagnosis of migraine with aura has been made in the past. Also, the clinical manifestations judged to be the result of a migrainous infarction must be those typical of previous attacks for that individual, and finally, other causes of infarction, including those related to migraine therapy, need to be excluded by appropriate investigations.

Headache accompanies a number of embolic or thrombotic causes of stroke, including cervicocephalic arterial dissections. Migraines also can be a prominent symptom in the aPL antibody syndrome (APAS). Symptomatic migraine

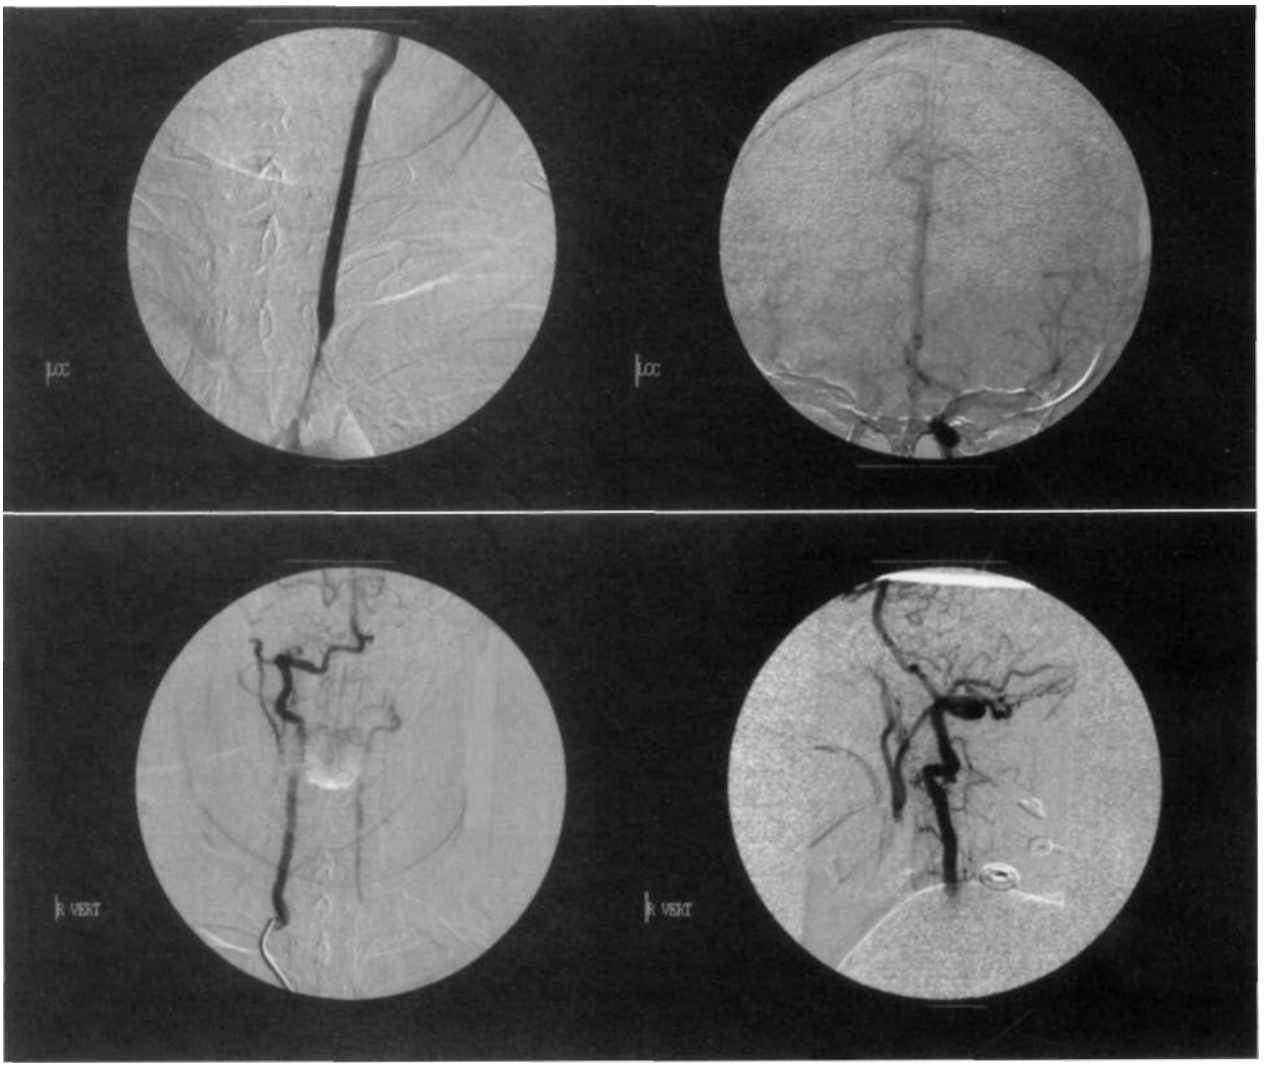

FIGURE 57A.15, cont'd. (C) There is also a very long stenosis of the left common carotid artery. (D) A larger cervical right vertebral artery provides vigorous filling of the intracranial right internal carotid circulation.

attacks are more frequent than migraine-induced ischemic insults. The presence of headache with a stroke is therefore not sufficient to make the diagnosis of migraine as the cause of the patient's symptoms. Furthermore, patchy subcortical abnormalities on MRI in patients with migraine with aura should be interpreted with caution. In other words, migrainous infarction remains a diagnosis of exclusion.

The pathogenesis of migrainous infarction is controversial. Cerebral infarcts complicating migraine are mostly cortical and involve the distribution of the PCA. The usual scenario of migrainous infarction is one of recurrent episodes of gradual buildup of unilateral throbbing headaches, associated with stereotyped visual phenomena occurring in both visual fields simultaneously, in one of which the vision loss becomes permanent. Migrainous infarctions have been subdivided as definite when all the International Headache Society criteria arc fulfilled, and possible when some, but not all criteria, are fulfilled. Patients with migrainous infarction arc at increased risk for recurrent stroke.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a familial nonarteriosclerotic, nonamyloid microangiopathy characterized by migraine with auta, tccurrent subcortical ischemic strokes starting in mid-adulthood, leading to pseudobulbar palsy, cognitive decline, subcortical dementia, and early white matter hyperintensities on MRI. CADASIL is caused by simple missense mutations or small deletions in Notch 3 gene on chromosome 19q12 encoding a transmembrane receptor Notch 3. Pathologically, there is a characteristic gtanular osmiophilic matctial in arterial walls, including dermal arteries (Kalimo et al. 2002}. A subtype of migraine, known as familial hcmiplegic migraine, characterized by transient weakness or frank paralysis during the aura, has also been mapped close to the CADASIL locus (Hutchinson et al. 1995).

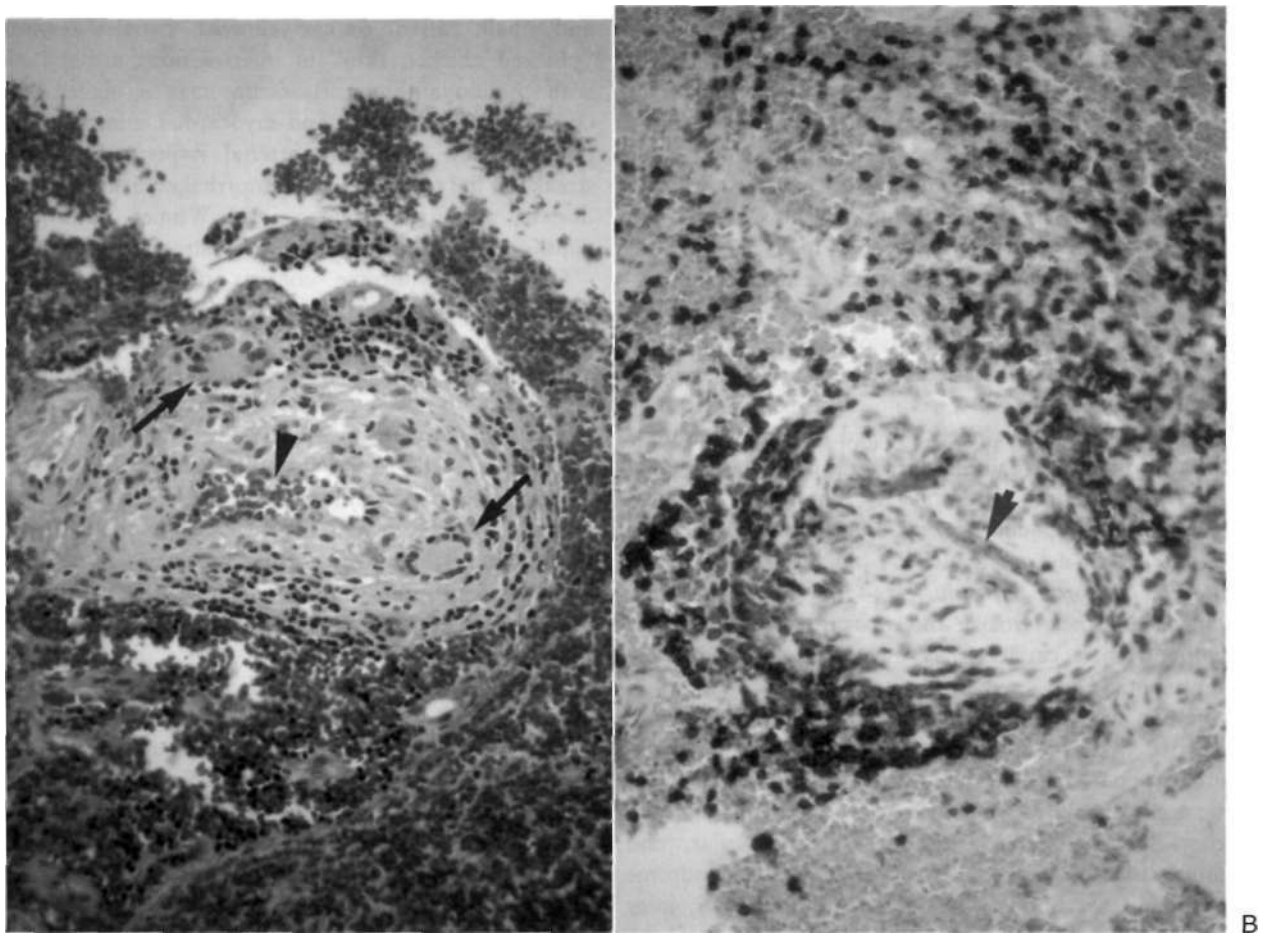

FIGURE 57A.16 Cerebellum. (A) Within an area of recent hemorrhage there is a small blood vessel showing focal infiltration with lymphocytes and a couple of multinucleated giant cells *(arrows).* The lumen of the vessel is marked with an *arrowhead* (x 680 H&E) Cerebellum. (B) The same vessel as in A. Immunostain with CD 3 demonstrates intense perivascular infiltration with T lymphocytes (x 680).

The newer acronym, cerebral autosomal dominant adenopathy with subcortical infarcts, leukoencephalopathy, and migraine, refers to a subvariety of CADASIL characterized by the high frequency of migraine (Verin et al. 1995),

INHERITED AND MISCELLANEOUS DISORDERS

Homocysrinuria, an inborn error of amino acid metabolism, is an unusual cause of stroke {Table 57A.6). Three specific enzyme deficiencies responsible for homocysrinuria have been identified: cystathionine ^-synthetase, homocysteine methyltransferasc, and methylene tetrahydrofolate reductase. The accumulation of homocysteine in the blood leads to endothelial injury and premature atherosclerosis. Patients with homocystinuria may display a marfanoid habitus, malar flush, livedo reticularis, ectopia lentis, myopia, glaucoma, optic atrophy, psychiatric abnormalities, mental retardation, spasticity, seizures, osteoporosis, and a propensity for intracranial arterial or venous

Tabic 57A.6: Inherited and miscellaneous disorders causing cerebral infarction

Cerebral amyloid angiopathy
Coils and kinks
Arterial dolichoectasia
Complications of coarctation of the aorta
Air, fat, amniotic fluid, bone marrow, and foreign particle embolism

thrombosis. Death may result from pulmonary embolism, myocardial infarction, or stroke. Raised levels of plasma homocysteine may be an independent risk factor for cerebrovascular disease, coronary, and peripheral arterial occlusive disease. Elevated levels of homocysteine can be effectively reduced with the administration of folic acid, occasionally requiring the addition of pyridoxine (vitamin BJ and vitamin B12. Other agents that may reduce homocysteine include choline, betaine, estrogen, and N-acetylcysteine.

Fabry's disease is an X-linkcd disorder of glycosphingolipid metabolism characterized by deficient lysosomal *a*-galactosidase activity. As a result, deposits of ceramidc trihexosidasc accumulate in endothelial and smooth muscle cells. Patients have a painful peripheral neuropathy, renal disease, hypertension, cardiomegaly, autonomic dysfunction, and corneal opacifications. Characteristic dark-red or blue lesions that do not blanch on pressure, called *angiokeratoma corporis diffusum,* are found between the umbilicus and knees. Stroke and myocardial infarction are common. Female carriers may have mild disease or are asymptomatic.

Marfan's syndrome is an autosomal dominant inherited connective tissue disease associated with qualitative and quantitative defects of fibrillin. Histopathological studies of aortic segments show cystic medial necrosis. This disorder is characterized by a variety of skeletal, ocular, and cardiovascular findings. Patients with Marfan's syndrome may display arachnodactyly, extreme limb length, joint laxity, pectus excavatum or carinatum, subluxation of the lens, and aortic valvular insufficiency. Marfan's syndrome is associated with a high incidence of dilatation of the aortic root. Other cardiovascular abnormalities include coarctation of the aorta, mitral valve prolapse, and mitral annulus calcification with regurgitation. Progressive dilatation of the aortic root may lead to dissection of the ascending aorta, resulting in ischemia to the brain, spinal cord, or peripheral nerves. Saccular intracranial aneurysms or dissection of the carotid artery can occur. Annual echocardiography studies arc recommended. Patients should avoid contact sports.

Patients with Ehlers-Danlos' syndrome, a fairly common heritable connective tissue disorder, display hyperextensibility of the skin, hypermobile joints, and vascular fragility leading to a bleeding diathesis. Arterial complications have been reported in association with Fhlcrs-Danlos' syndrome types I, III, and IV, especially type IV. Complications include dissections, arteriovenous fistulae, and aneurysms. Other cardiovascular abnormalities in patients with type IV Ehlers-Danlos' syndrome include ventricular and atrial septal defects, aortic insufficiency, bicuspid aortic valve, mitral valve prolapse, and papillary muscle dysfunction, Arteriography carries special risks and should be avoided if possible.

Patients with pseudoxanthoma elasticum, an inherited group of disorders of clastic tissue, often display loose skin and small, raised, orange-yellowish papules resembling "plucked chicken skin" in intertriginous areas. Patients with pseudoxanthoma elasticum have a higher risk of coronary artery disease and myocardial infarction. These patients may also have arterial hypertension, angioid streaks of the retina, retinal hemorrhages, arterial occlusive disease, and arterial dissections. Women with pseudoxanthoma elasticum should avoid estrogens.

Sneddon's syndrome consists of widespread livedo reticularis and ischemic cerebrovascular manifestations. A number of reports have documented a hereditary transmission and a link between Sneddon's syndrome and aPL antibodies. However, the etiopathogenesis remains unknown, although an immune mechanism is suspected. Endothelial cells could be the primary target tissue. Anticndothelial cell antibodies may be present (Frances et al. 1995).

Hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber disease) is a familial disorder transmitted as an autosomal dominant trait. Ischemic stroke as a presenting manifestation of Rendu-Osier-Weber's disease has been reported infrequently. Paradoxical venous emboli passing through a pulmonary arteriovenous malformation can be the source of cerebral ischemia or abscess. Other potential causes leading to cerebral ischemia include air embolism and hyperviscosity secondary to polycythemia.

Neoplastic angioendotheliomatosis, also called *intravascular malignant lymphomatosis* or *angiotropic lymphoma,* is a rare disease characterized by multiple small- and large-vessel occlusion by neoplastic cell of lymphoid origin without an obvious primary tumor. Intravascular lymphomatosis has been reported to involve the skin, lungs, kidneys, adrenal glands, liver, pancreas, gastrointestinal tract, ovary, prostate, testicles, heart, thyroid, and parathyroid glands. Bone marrow, spleen, and lymph nodes arc usually spared. Simultaneous involvement of blood vessels throughout the body and compromise of different cerebral arterial territories is common with this disorder. Patients may present with recurrent multifocal cerebral infarctions, dementia, or myelopathy. Diagnosis requires skin, liver, renal, or brain-leptomcningeal biopsy. Combination chemotherapy has been recommended. Autologous peripheral blood stem cell transplantation after chemotherapy may be useful.

Microangiopathy ot brain, retina, and inner ear (Susac's syndrome), also known as retinocochleocerebral vasculopathy, is a rare microcirculatory syndrome that affects mainly adult women (Petty et al. 1998). The syndrome is unrelated to arterial hypertension or diabetes and is characterized by arteriolar branch occlusions of the brain, retina, and inner ear, with resultant encephalopathy, vision loss, vestibular dysfunction, tinnitus, vertigo, and asymmetrical sensorineural hearing loss. CSF examination may be normal orshow mild inflammatory response. Brain biopsy may show multifocal brain microinfarcts in both gray and white matter. The causal agent is unknown but has been

attributed to a disturbance of coagulation, microemholism, or both. Treatment with corticosteroids, cyclophosphamide, azathioprinc, plasmapheresis, or anticoagulant therapy is empiric, but branch retinal artery occlusions and central nervous system infarctions may recur despite the treatment. Hyperbaric oxygen treatment may be an option for refractory visual symptoms.

Eales' disease, commonly reported in India and the Middle East, is a rare, noninflammatory occlusive disease of the retinal vasculature characterized by repeated retinal and vitreous hemorrhages. The disorder affects mainly young men. Brain infarctions are rare.

Idiopathic reversible cerebral segmental vasoconstriction is an unusual clinical angiographical syndrome characterized by recurrent headaches, and transient motor and sensory findings associated with reversible arterial narrowing and dilatation involving predominantly the arteries around the circle of Willis. The cause is unknown.

The hypereosinophilic syndrome is a rare disorder caused by bone marrow overproduction of eosinophils that lodge in endothelial cells in the microcirculation primarily of heart, brain, kidney, lungs, gastrointestinal tract, and skin. Neurological complications include emboli from involved endocardium and heart valves, and neurological manifestations may result also from a hypercoagulable state with cerebral thromboses, and microcirculatory inflammation and occlusion by eosinophils. Cerebral infarction is a rare complication.

Cerebral amyloid angiopathy occurs both sporadically or in rave instances as a hereditary disorder. Cerebral amyloid angiopathy is characterized by the localized deposition of amyloid in the media and adventitia of small arteries and arterioles of the cerebral cortex and meninges in the elderly. Cerebral amyloid angiopathy is more commonly associated with lobar hemorrhage than with ischemic stroke, but has been associated with an increased frequency of cerebral infarction in patients with Alzheimer's disease (Olichney et al. 1995). Biopsy of the involved cortex and leptomeninges is the only definitive way to diagnose cerebral amyloid angiopathy.

Redundant length of the cervical carotid artery causes coils and kinks and other forms of tortuosity. Occasionally associated with FMD, kinks and coils of the carotid artery are an infrequent cause of cerebral ischemia. Arterial kinking seldom affects the vertebrobasilar circulation. Cerebral ischemia associated with kinking is attributable to a combination of flow reduction caused by obstruction, neck rotation, and distal embolization. Dolichoectasia is an unusual vascular disease that causes enlargement and elongation of arteries, particularly the basilar artery. This arteriopathy causes false aneurysm that leads to ischemic stroke, brainstem compression, cervicomedullary compression, cranial nerve palsies, cerebellar dysfunction, central sleep apnea, and hydrocephalus. The mechanisms of stroke arc penetrating artery occlusion, basilar artery thrombosis, or embolism from the dolichoectatic artery.

Ischemic stroke and intracranial hemorrhage, the latter caused by arterial hypertension or ruptured intracranial aneurysm, are important complications of coarctation of the aorta. Spinal cord ischemia may also complicate surgery for aortic coarctation. Neurological complications can result also from aortic rupture, infective aortitis or endarteritis, associated aortic bicuspid valve, and dissection of the aorta proximal to the coarctation.

Atheromatous emboli (cholesterol emboli syndrome) may follow manipulation of an atherosclerotic aorta during catheterization or surgery. Clinical presentation may include TIAs, stroke, retinal embolism pancreatitis, renal failure, and livedo reticularis. Purple toes may occur also as a result of small cholesterol emboli lodging in the digital arteries. Pedal pulses are normal. Patients also have a low-grade fever, eosinophilia, anemia, elevated erythrocyte sedimentation rate, and elevated serum amylase, Anticoagulation may exacerbate further embolization, and its use should be discouraged.

Accidental introduction of air into the systemic circulation can be a cause of cerebral or retinal ischemia. Air embolism is a dreaded complication of surgical procedures, including intracranial operations in the sitting position; open heart surgery; surgery of the lungs, pleura, sinuses, neck, and axilla; hemodialysis; thoracocentesis; arteriography; central venous catheters; and scuba diving. Symptoms include seizures and multifocal neurological findings such as cerebral edema, confusion, memory loss, and coma. CT scan may be useful in visualizing the gaseous bubbles. Treatment includes prompt resuscitative measures, placement of the patient in the left lateral position, inotropic agents, anticonvulsants, anti-edema agents, and hyperbaric oxygen. Caisson's disease can occur in persons who are scuba diving. Neurological features are caused by multiple small nitrogen emboli leading to ischemia of the brain and spinal cord; signs of spinal cord dysfunction are prominent. Hyperbaric oxygen therapy is the usual treatment.

Fat embolism to the brain complicates long bone fractures, sickle cell disease, cardiopulmonary bypass, soft tissue injuries, and blood transfusions. This syndrome-occurs suddenly within hours to 3 or 4 days after injury and is characterized by dyspnea, fever, tachycardia, tachypnea, cyanosis, cutaneous petcchiae, and coagulopathy. Neurological manifestations arc confusion, disorientation, delirium, hemiparesis, aphasia, and coma. Petechia) hemorrhages may be apparent on funduscopy, conjunctivae, base of the neck, and axillary region. Vigorous respiratory supportive therapy is essential.

Amniotic fluid embolism is a rare catastrophic obstetrical complication caused by the entry of amniotic fluid into the maternal bloodstream during parturition. Vigorous supportive therapy with intravenous fluids and blood replacement to treat shock, correction of respiratory distress syndrome, disseminated intravascular coagulation, and underlying fibrinolytic state are essential. Among other causes of emboli are large intracranial saccular aneurysms

or extracranial false aneurysms of the internal carotid artery. Tumor emboli to the brain have been reported with osteosarcoma, atrial myxoma, and with carcinoma of the lung, breast, pharynx, or esophagus. Talc, cornstarch, and other foreign particles injected as adulterants in illicit drugs can embolize to the brain or retina. Paradoxical embolism during bone marrow infusion is an infrequent complication.

HYPERCOAGULABLE DISORDERS

Alterations in hemostasis are associated with an increased risk of cerebrovascular events, particularly those of an ischemic nature and may account for a considerable number of cryptogenic strokes (Table 57A.7). These disorders account for 1% of all strokes and for 2-7% of ischemic strokes in young patients (Kitchens 1994).

Primary f lypercoagulable States

Inherited disorders predisposing to thrombosis especially affect the venous circulation. These disorders include AT-III deficiency, protein C and protein S deficiencies, activated protein C (APC) resistance, abnormalities of fibrinogen (dysfibrinogencmia), and abnormalities of fibrinolysis. Inherited thrombophilia should be suspected in patients with recurrent episodes of deep venous thrombosis, recurrent pulmonary emboli, family history of thrombotic events, unusual sites of venous (mesenteric, portal, or cerebral) or arterial thromboses, or in patients with thrombotic events occurring during childhood, adolescence, or early adulthood. Approximately one half of all thrombotic episodes occur spontaneously, although these patients arc at greatest risk when exposed to additional risk factors such as pregnancy, surgery, trauma, or oral contraceptive therapy.

Table 57A.7: Hypercoagulahle states

Primary hypercoagulahle states
Antitlirombin III deficiency

Diabetes mellitus
Heparin-induced thrombocytopenia
Homocystinuria
Sickle tell disease (sickle cell anemia, sickle cell-hemoglobin C)
Thrombotic thrombocytopenic purpura
Chemotherapeutic agents

AT-III deficiency is inherited in an autosomal dominant fashion, thus affecting both sexes. There are three categories of inherited AT-III deficiency: classic or type I, characterized by decreased immunological and biological activity of AT-III; type II, characterized by low biological activity of AT-III but essentially normal immunological activity; and type III, characterized by normal AT-III activity in the absence of heparin, but reduced in heparin-dependent assays. Acquired AT-III deficiency may follow acute thrombosis and disseminated intravascular coagulation. It has been associated also with nephrotic syndrome, liver cirrhosis, eclampsia, various malignancies, the use of estrogens or oral contraceptives, L-asparaginase, tamoxifen, and heparin therapy. A normal level of AT-III activity obtained at the time of an acute thrombotic event is sufficient to exclude a primary deficiency. However, a low level of AT-III activity must be confirmed by repeat testing, after resolution of the thrombotic episode and discontinuation of anticoagulant therapy. Confirmation of a low plasma level of AT-III activity on repeat resting is compatible with a primary deficiency and is an indication to investigate other family members. Thrombotic episodes associated with AT-III deficiency are treated acutely with heparin with or without adjunctive AT-III concentrate. Prophylactic therapy in patients with recurrent thrombosis consists of long-term warfarin administration, keeping the therapeutic INK range between 2,0 and .i.O.

Protein C deficiency is inherited in an autosomal dominant fashion. Homozygous protein C deficiency presents in infancy as purpura fulminans neonatalis. Heterozygotes are predisposed to recurrent thrombosis. Thrombotic manifestations are predominantly venous, Acquired protein C deficiency has been associated with the administration of L-asparaginase, warfarin therapy, liver disease, disseminated intravascular coagulation, postoperative state, bone marrow transplantation, and the adult respiratory distress syndrome. Testing for immunological and functional assays of protein C should be performed after oral anticoagulation has been discontinued for at least a week. Heparin does not modify the levels of protein C. Warfarin-induced skin necrosis is a serious potential complication of protein C-deficient patients at the initiation of warfarin therapy; this syndrome often occurs in association with large loading doses of warfarin. The acute

management of thrombosis associated with protein C deficiency consists of prompt administration of heparin followed by incremental doses of warfarin, starting with low doses until adequate anticoagulation is achieved. Long-term management requires the administration of warfarin.

Protein S deficiency also has an autosomal dominant mode of inheritance. Protein S exists in plasma in two forms; approximately 40% of the total protein S is functionally active or free, and the remaining is complexed to a binding protein. Homozygous protein S deficiency presents with venous thromboembolic disease. Heterozygotes are prone to recurrent thrombosis including cerebral venous thrombosis. Acquired protein S deficiency occurs during pregnancy, in association with acute thromboembolic episodes, disseminated intravascular coagulation, nephrotic syndrome, systemic lupus erythematosus, and with the administration of oral contraceptives, oral anticoagulants, and L-asparaginase. Testing for immunological assays of total and free protein S, and functional assay of protein S, should be confirmed after resolution of the thrombotic episode and discontinuation of oral anticoagulants. Heparin therapy is effective in the management of acute thrombotic events associated with protein S deficiency, whereas watfarin is advocated for patients with recurrent thromboembolism.

Resistance to APC is one of the most common identifiable risk factors for venous thromboembolic disease, including cerebral venous thrombosis. The relation of APC resistance to arterial disease is not well established. APC resistance has been identified as 5 to 10 times more common than deficiencies of AT-III, protein C, or protein S. APC resistance also has an autosomal dominant mode of inheritance. APC resistance is associated in most patients with a single point mutation in the factor V gene (factor V Leiden), which involves the replacement of arginine 506 with glutamine 506 (Arg 506 Gin). Testing for resistance to APC must be done after discontinuation of anticoagulants. There are conflicting results about factor V Leiden gene mutation and the risk for acute cerebral arterial thromboses. The contribution of factor V Leiden or prothrombin G20210A to ischemic stroke in the young is less clear. Conversely, both factor V Leiden and prothrombin G20020A mutations are associated with an increased risk for cerebral venous thrombosis (Ludemann et al. 1998; Peuner et al. 1998; Cushman et al. 1998). In the Physicians' Health Study, no association between factor V Leiden or prothrombin G20210A and ischemic stroke was found (Ridker et al. 1995).

Abnormalities of fibrinogen account for approximately 1% of all inherited thrombotic disorders. Fibrinogen cross-links platelets during thrombosis and is an important component of atherosclerotic plaques. High concentrations of fibrinogen increase the risk for stroke and myocardial infarction. Afibrinogenemia is probably transmitted as an autosomal recessive trait; complications include umbilical cord bleeding, gastrointestinal hemorrhage, and intracranial hemorrhage. Hypofibnnogenemia represents the heterozygous lorm of afibrinogenemia; bleeding is rare. Dysfibrinogcnemia reflects a qualitative disorder in the fibrinogen molecule and may be associared with hemorrhagic or thrombotic episodes. Hereditary dysfibrinogcnemia is inherited in an autosomal dominant fashion. Decreased concentrations of fibrinogen are associated with disseminated intravascular coagulation, liver failure, snake bite, treatment with t.-asparaginase, Ancrod, fibrinolytic drugs, and valproate. Treatment consists of infusions of cryoprecipitate.

Decreased levels of plasminogen (hypoplasminogcnemia), qualitative abnormalities in the plasminogen molecule (dysplasminogencmias), and defective release of plasminogen activators occur in families with recurrent thrombotic events. Cerebral venous thrombosis occurs with disorders of plasminogen. Prophylactic therapy in patients with recurrent thrombosis consists of lifelong anticoagulation.

Lupus anticoagulants and anticardiolipin (aCL) antibodies are known collectively as *antipbvspbolipid antibodies* and have a pathogenetic role in arterial and venous thrombosis. Ischemic stroke is the most common arterial thrombotic event in patients with APAS. APAS associates the presence of aPL antibodies in high titers with recurrent arterial or venous thromboses, feral loss, and livedo reticularis. Several aPL antibodies have been described in immunoglobulin (Ig)G, IgA, or IgM isorypes: aCL, antiphosphatidylcthanolaminc (aPL), antiphosphatidylserine, and antiphosphatidykholinc. Affinity-purified aCLs do not bind to cardiolipin in the absence of seium or plasma. The component required for aCL binding is £2-gIycoprotein 1 (/32GP1). It is the 02-GPl -dependent aCL of the IgG isotype that has been significantly associated with sttokes and myocardial infarcts (Brey et al. 2001). Other stroke studies have reported an association with aPE (Gonzales-Portillo et al. 2001).

APL antibodies arc present in patients with systemic lupus erythematosus and related autoimmune disorders, Sneddon's syndrome, acute and chronic infections (including HIV-1), neoplasias, inflammatory bowel disease, administration of certain drugs, early onset severe preeclampsia, liver transplantation, and also in individuals without demonstrable underlying disorders. A distinct group of patients has a *primary* APAS; its association with ischemic cerebrovascular disease is rare.

APL antibodies arc associated with recurrent fetal loss, a prolongation of the activated partial thromboplastin time (aPTT) that does not correct on 1 to 1 mixing with normal plasma, thrombocytopenia, a false-positive VDRL test result, and livedo reticularis. They may also be associated with cerebral and ocular ischemia, cerebral venous thrombosis, migraine, vascular dementia, chorea, transverse myelopathy, myocardial infarction, peripheral arterial thromboembolism, venous thrombosis, pulmonary embolism, and Degos' disease. Multiple cerebral infarctions are

common in patients with aPL antibodies; a subset of patients may present with vascular dementia (Figure 57A. 17). Still another group may have an acute or progressive thrombotic ischemic encephalopathy. Pathological studies of cerebral arteries involved in association with aPL antibodies demonstrate the presence of a chronic thrombotic microangiopathy, but no evidence of vasculitis. Patients with a PI. antibodies have an increased frequency of mitral and aortic vegetations. There are findings resembling verrucous endocarditis (Libman-Sacks endocarditis). Left ventricular thrombus formation is a rare occurrence, Treatment for arterial thrombosis associated with aPL antibodies is not well established. One casc-conttolled study found that high-intensity warfarin (INR > 3.0), with or without aspirin, was more effective in preventing thrombotic recurrences than low-intensity warfarin, with or without aspirin, or aspirin alone (Khamashta et al. 1995). Guidelines published in the United Kingdom have recommended an INR target of 3,5 (British Committee for Standards in Hematology 1998) or 2.5 (Greaves et al. 2000). In the Warfarin Aspirin Recurrent Stroke Study (WARSS), warfarin (median **INR** = 2.09) did not provide additional benefit over aspirin in preventing recurrent ischemic stroke among ischemic stroke patients who were

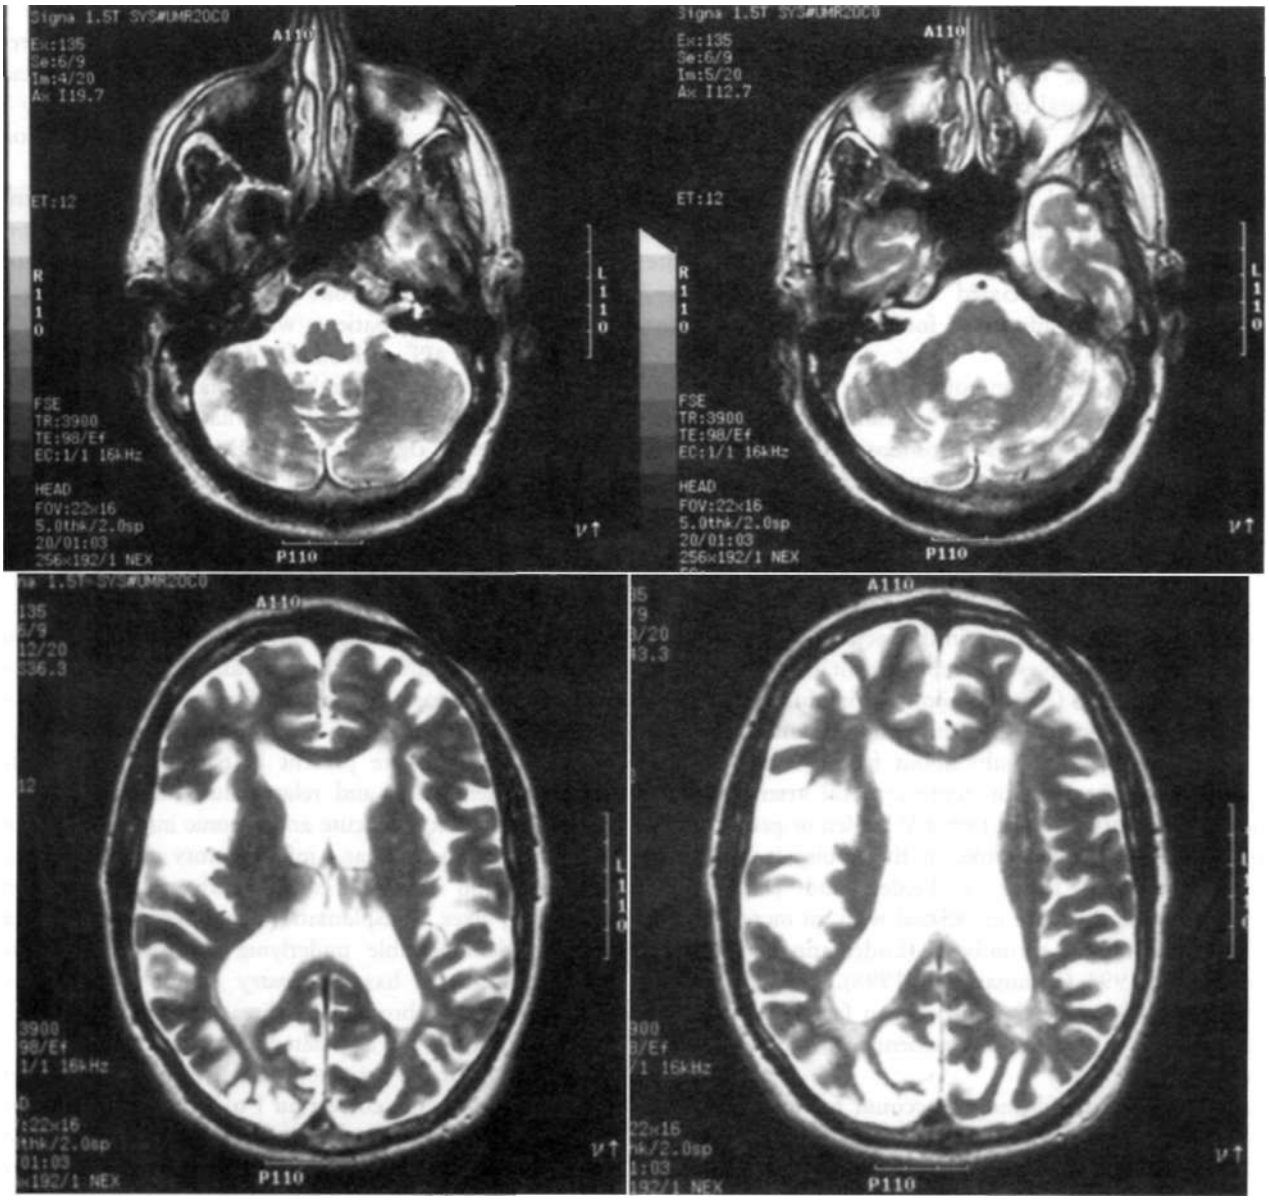

FIGURE 57A.17 A 44-year-old man with elevated anticardiolipin antibodies had a branch retinal vein occlusion in the left eye, progressive balance problems, poor memory, and an overall decline in cognitive functioning, Echocardiography showed thickened mitral valve without significant stenosis, T2-weighted axial magnetic resonance imaging of the brain demonstrates confluent hyperintensities in the periventricular region and basal ganglia consistent with ischemia. There are also bilateral hyperintensities in the cerebellum consistent with infarcts. Cortical ischemic changes are also present bilaterally in the occipital lobes and in the right frontal lobe.

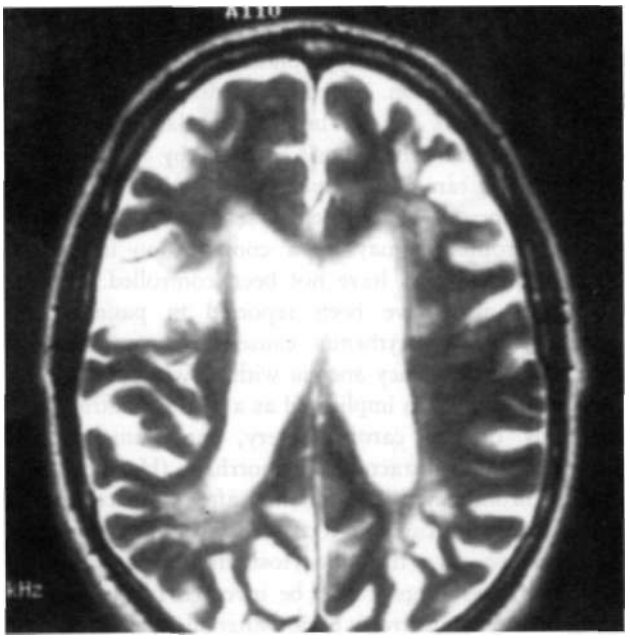

FIGURE 57A.17, cont'd.

aPl. antibody-positive at baseline (Levine et al. 2002). Pregnant patients are often treated with prednisone and low-dose aspirin.

Secondary Hypercoagulable States

Strokes may complicate the clinical course of malignancies. In rare instances, stroke may be the initial manifestation of cancer. Cerebral infarction mostly complicates lymphomas, catcinomas, and solid tumors. Cerebral hemorrhages are more common with leukemia. Hypercoagulability is not an uncommon finding in patients with malignancy, especially with mucin-producing carcinomas of the pancreas, gastrointestinal tract, and lung; myeloproliferative disorders; acute promyelocytic leukemia; and brain tumors. Mucinous adenocarcinomas of the gastrointestinal tract, lung, and ovary may produce infarcts from widespread cerebral arterial occlusions by mucin. The cause of the hypercoagulable state is often multifactorial. The pathophysiology is believed to be a state of low-grade disseminated intravascular coagulation and secondary fibrinolysis, but with the balance shifted toward clotting. Atherosclerosis is still the leading cause of infarction in patients with malignancy. Cerebral infarction in patients with malignancy also may be caused by tumor emboli, bone marrow embolization, emboli originating from mural thrombi, or emboli arising from marantic vegetations associated with nonbacterial thrombotic endocarditis. Many patients with nonbacterial thrombotic endocarditis have associated disseminated inttavascular coagulation, which may cause capillary occlusion of multiple organs, especially the lungs, kidneys, gastrointestinal tract, heart, and brain. Neurological manifestations produce a diffuse encephalopathy secondary to disseminated microinfarcts. Other patients with malignancy and cerebral infarction may have cerebral venous occlusive disease caused by thrombi, tumor invasion, or stroke associated with chemotherapy. In addition, cancer-en ha need arhcrothrombosis, neoplastic angioendotheliomatosis, arterial compression by tumor, occlusive vascular disease secondary to irradiation, intercurrent angiitis, and arterial rupture also may be responsible for cerebral infarction in some patients. Treatment consists of management of the underlying malignancy. Anticoagulants and platelet antiaggregants are used with variable success.

The postpartum period is a hypcrcoagulable state. Characteristically, arterial causes of stroke are more common during pregnancy, whereas venous causes of stroke are more common during the puerperium (sec Chapter 87).

Oral contraceptives cause alterations of the vessel wall with intimal hyperplasia. They also increase blood viscosity. (here arc decreased levels of protein S, AT-III activity, and plasminogen activator content in women taking oral contraceptives. There also may be an increase in the levels of fibrinogen, factors VII and X. Oral contraceptive therapy may enhance arrerial hypertension. Women taking oral contraceptives have an estimated ninefold increased risk of thrombotic stroke. This risk is increased by prolonged use, high dosage of the estrogen component, cigarette smoking, concomitant diabetes, arterial hypertension, hyperlipidcmia, and age older than 35 years. Current users of oral contraceptives are at increased risk of stroke. One study showed that oral contraceptives containing 30-40 ^g of estrogen are associated with a one third reduced risk compared with preparations containing 50 ng. The occurrence of intracranial venous thrombosis as a complication of oral contraceptives is well recognized. A patient on oral contraceptives occasionally presents with stroke caused by paradoxical embolism associated with deep venous thrombosis. Oral contraceptives also increase the risk of subarachnoid hemorrhage.

Oral contraceptives probably should be avoided in women with arterial hypertension. They should also be avoided in the first 2 weeks after delivery. Women older than 35 years of age who smoke cigarettes probably should be advised to choose a different contraceptive method. As part of primary stroke prevention efforts, women who smoke should not use oral contraceptives. The ovarian hypersrimularion syndrome occurs in women after induction of ovulation with clomiphene, human menopausal gonadotropin, human follicle-stimulating hormone extracted from human pituitary, and human chorionic gonadotropin. Evidence of body fluid shifts and hypercoagulability exist with this syndrome, reflected in thromboembolic events. Stroke is a rare but serious consequence of severe ovarian hyperstimillation syndrome.

Thromboembolic events are a feared complication of hormone treatment in ttansscxuals. Cerebral infarction has

occurred as a side effect of exogenous estrogen in a male-to-female transsexual. Likewise, TIAs and cerebral infarction may follow the administration of anabolic steroids for the treatment of hypogonadism and hypoplastic anemias. Cerebral ischemia has occurred also following the use of human recombinant erythropoietin in the treatment of anemia of patients on hemodialysis.

The nephrotic syndrome may be accompanied by venous and arterial thromboses, including cerebral arterial and venous occlusive disease. Ischemic stroke can be the presenting manifestation. The mechanism by which nephrotic syndrome causes hypercoagulability is multifactorial and includes elevated levels of fibrinogen, raised levels of factors V, VII, VIII, and X, thrombocytosis, enhanced platelet aggregation, and reduced levels of AT-III and protein S. The exact role of hyperlipidemia, corticosteroids, and diuretic use is uncertain. Nephrotic syndrome should be considered as a contributing mechanism in any patient with ischemic stroke and pre-existing renal disease. A urinalysis is the initial clue to the diagnosis. The presence of severe proteinuria and a low serum albumin should prompt consideration of a hypercoagulable state. Treatment of thromboembolism associated with nephrotic syndrome consists of anticoagulants until remission of the renal condition.

Polycythemia vera and primary or essential rhrombocythemia are typically disorders of middle-aged or elderly patients. Polycythemia vera is characterized by increased red blood cell mass and normal arterial oxygen saturation. Patients have ruddy cyanosis, painful pruritus, hypertension, splenomegaly, elevated hemoglobin, high hematocrit value, thrombocytosis, leukocytosis, and elevated serum B12 levels. Typically, the bone marrow is hypercellular. Secondary polycythemia may occur in association with cerebral hemangioblastoma, hepatoma, hypernephroma, uterine fibroids, benign renal cysts, carbon monoxide exposure, and administtation of androgens. Cerebral blood flow is reduced, and cerebral hemorrhage, and arterial or venous thrombosis, can complicate the condition. The majority of the intracranial events are thrombotic in origin, the larger cerebral arteries being the most frequently involved. The risk of stroke parallels the hemoglobin level: The higher the hemoglobin and hematocrit values, the greater the risk of stroke. Headaches, dizziness, vertigo, tinnitus, visual disturbances, carotid and vertebrobasilar TIAs, chorea, and fluctuating cognitive impairment are we 11-recognized features of patients with polycythemia vera. Spinal cord infarction is a rare complication. Cautious lowering of the hematocrit is a reasonable therapeutic approach. Because of the potential risk of hemorrhagic intracranial complications, aspirin therapy should be used cautiously.

Cerebral thrombotic and hemorrhagic complications are not uncommon in primary or essential thrombocythemia. Patients may have splenomegaly, mucocutaneous hemorrhagic diathesis, persistently elevated platelet count, usually in excess of 1 million per pi, giant platelets, and a bone marrow megakaryocyte hyperplasia. Neurological complications are common. Headaches, dizziness, amaurosis fugax, and TIAs of the brain are relatively frequent. Cerebral arterial thrombosis caused by platelet-fibrin thrombi is a rare but serious complication of essential thrombocythemia. Papilledema secondary to cerebral venous thrombosis may be a complication in patients whose platelet levels have not been controlled. Cerebral infarctions also have been reported in patients with secondary thrombocythemia caused by iron deficiency anemia. Iron deficiency anemia with or without thrombocytosis also has been implicated as a cause of intraluminal thrombus of the carotid artery, intracranial venous thrombosis, and intracranial hemorrhage (Hartficld et al. 1997), Thrombocytosis is common after splenectomy, but does not seem to catty an inctcascd thromboembolic risk. However, reactive thrombocytosis following cardiopulmonary bypass surgery may be involved in the cause of stroke in the late recovery period after surgery. The role of rebound thrombocytosis in ischemic stroke among heavy alcohol drinkers is uncertain. Treatment of primary thrombocythemia includes hydroxyurea, plateletpheresis, recombinant interferon-a, and aspirin. Vigorous correction of the anemia is indicated for those patients with thrombocytosis associated with iron deficiency anemia,

Paroxysmal nocturnal hemoglobinuria is an acquired clonal stem cell disorder characterized by severe hemolytic anemia and hemosiderinuria. A feared complication is cerebral venous thrombosis. Thrombosis of major cerebral veins or dural sinuses and portal vein thrombosis are the most frequent causes of death. Acute thrombotic episodes involving the cerebral veins may be treated with thrombolytic agents, unless contraindicated, or anticoagulant therapy. High-dose cyclophosphamide and granulocyte-colony stimulating factor are being studied for the treatment of paroxysmal nocturnal hemoglobinuria.

Diabetes is a well-established risk factor for ischemic stroke. Diabetes associated with arterial hypertension or hyperlipidemia adds significantly to stroke risk. There are a variety of platelet, theological, coagulation, and fibrinolytic abnormalities thai may play a role in the pathogenesis ol stroke in diabetic patients. Numerous hemorrheological disturbances appear to affect the development of diabetic microvascular disease and may contribute to cerebrovascular ischemic events. Hemorrheological alterations producing increased blood viscosity may include increased fibrinogen values, increased hematocrit, elevated factors V and VII, increased platelet aggregation, increased platelet adhesion, increased release of /i-thromboglobulin, decreased red blood cell deformability, and decreased fibrinolytic activity.

Heparin-induced thrombocytopenia can cause high morbidity and mortality from thrombotic complications. Heparin therapy may induce two types of thrombocytopenia. The most frequently observed is type I heparin-induced

thrombocytopenia, which is a mild and benign condition with platelet counts around 100,000 per pi. This thrombocytopenia tends to occur early and resolve spontaneously. Complications are rare. Type II heparin-induccd thrombocytopenia is a major, albeit infrequent (< 3% with unfractionated heparin and < 1% with low-molecular weight heparins), adverse side effect of heparin therapy with a delayed onset (5-15 days after heparin administration). An immune-mediated disorder characterized by increased levels of platelet-associated IgG and IgM, it increases the risk for venous and arterial thrombotic complications involving the brain, heart, and limbs. Fatalities arc high, and hemorrhagic complications are rare. Unlike drug-induced immune TTP, petechiae are not seen in cases of heparin-induced thrombocytopenia with thrombosis. Prevention is paramount, requiring an optimal reduction of the time of exposure to heparin to less than 5 days when possible, and daily platelet counts during heparin administration. Treatment requires immediate discontinuation of heparin. If anticoagulant therapy is still needed, the use of danaparoid, recombinant hirudin or argatroban should be considered.

Elevated plasma homocysteine levels are an independent risk factor for atherosclerotic disease. Patients with high plasma homocysteine levels have a greater likelihood of occlusive disease of the extracranial carotid arteries, cerebral arteries, peripheral vascular and coronary beds when compared with the general population. Diagnosis of hyperhomo cy stein cmia may be made by demonstrating elevated basal plasma levels of homocysteine or raised levels after methionine loading. Reduction of homocysteine levels in plasma requires the supplementation of folate, vitamin B<„ and vitamin Bj?. Homocystinuria is covered earlier in this chapter under Inherited and Miscellaneous Disorders.

Cerebrovascular disease is a major cause of morbidity and mortality in sickle cell disease. Strokes in sickle cell anemia (hemoglobin SS [HbSS]) patients manifest as ischemic strokes in children and as intracerebral and subarachnoid hemorrhage in adults. The most common presentations of stroke in patients with sickle cell disease are hemiparesis, seizures, language or visual impairments, and coma. Cognitive impairment may result from silent infarcts. Coma is more suggestive of intracranial hemorrhage rather than cerebral infarction. Patients at greatest risk of stroke are those with (HbSS) severe anemia, higher reticulocyte counts, and lower hemoglobin F levels. Sickle cell disease leads to a hyperviscous condition within the microvasculature. At low oxygen tensions, erythrocytes containing hemoglobin S assume a sicklclike appearance. Sludging in small vessels occurs, resulting in microinfarctions in the affected organs. Although there is pathological evidence that microvascular occlusion and sludging caused by sickling does occur in the brain, the clinical and neurodiagnostic findings are consistent with a large vessel arterial occlusive (intimal hyperplasia with superimposed thrombosis) disease affecting the major intracranial arteries, frequently involving the arterial border zones between major cerebral arteries and adjacent deep white matter. Infarcts are more common in the ACA-MCA boundary zone. Sickle cell disease commonly causes a moyamoya-like angiographic pattern. Sickle cell disease may be accompanied by thrombotic cerebral infarction, cerebral venous occlusive disease, or subarachnoid, intracerebral, or intraventricular hemorrhage. Delayed intracranial hemorrhage may Inllow cerebral infnivrion and lias been described as a complication of bone marrow transplantation. Spinal cord infarction is extremely rare. Neurological symptoms may be triggered by hypoxia, sepsis, dehydration, or acidosis.

The evaluation of the stroke patient with sickle cell anemia must be carefully individualized. Blood cell count, peripheral blood smear, hemoglobin electrophoresis, and sickling test are essential. MRI, MRA, and transcranial Doppler studies are valuable investigations in sickle cell patients; transcranial Doppler is useful in detecting the intracranial vasculoparhy and may make it possible to detect patients at highest risk for cerebral infarction and to initiate treatment prior to stroke. Cerebral angiography can be done safely with the use of low-osmolar contrast media after partial exchange transfusion is performed to avoid complications associated with contrast material. The Stroke Prevention Trial in Sickle Cell Anemia evaluated children with sickle cell anemia and no history of stroke. Children were screened with transcranial Doppler ultrasonography. The trial was prematurely stopped by the National Heart, Lung and Blood Institute after 11 strokes (10 cerebral infarctions and one cerebral hemorrhage) occurred among the standard of care group, while only one ischemic stroke occurred among the transfused group. Maintenance of hemoglobin S below 30% was effective in reducing the risk of cerebral infarction in children with sickle cell anemia (Pegelow et al. 1995). Meticulous hydration, adequate oxygenation, and analgesia are necessary. Iron overload may be prevented by subcutaneous chelation with deferoxamine. If snoring is also identified as a risk factor for stroke patients with sickle cell disease, a more aggressive approach to upper airway obstruction, including surgery, may be indicated.

TTP is a life-threatening, generalized microcirculatory condition of undetermined cause, characterized by fever, tln-ombocytopcmic purpura, microangiopathic hemolytic anemia, renal dysfunction, and fluctuating neurological signs. TTP is exceedingly rare, with a reported incidence of 1 person in 1 million annually. Most cases are idiopathic, but TTP also may be caused by drug exposure or it may be associated with pregnancy and the postpartum state, connective tissue disorders, infective endocarditis, or neoplasms. The pathological response is caused by widespread segmental hyaline microthrombi in the microvasculature. Neurological symptomatology is protean and fleeting. Patients frequently have headaches, visual disturbances, cranial nerve palsies, delirium, seizures, aphasia, paresis,

and coma. Treatment is with infusions of fresh frozen plasma, plasmapheresis, corticosteroids, and platelet anri-aggregants singly or in combination have been used also. If plasma exchange fails, splenectomy combined with corticosteroids and intravenous vincristine may be used.

INFARCTS OF UNDETERMINED CAUSE

Despite an extensive workup, in a considerable percentage of persons with ischemic stroke a causal factor cannot be determined. This percentage is possibly higher in patients younger than 45 years of age. Some of these ischemic strokes may result from asymptomatic episodes of paroxysmal atrial fibrillation; electrophysiological testing may be useful under those circumstances. The role of thrombophilia is also often under-recognized and warrants more detailed investigation in selected patients. The risk of recurrence of stroke of undetermined cause appears to be slightly less than that of ischemic strokes of other types.

ESSENTIAL INVESTIGATIONS FOR PATIENTS WrTH THREATENED STROKES

A basic workup, to be done in all patients with TIAs or evolving ischemic stroke, includes full blood cell count with differential white cell and platelet counts, erythrocyte sedimentation rate, prothrombin time (PT), aPTT, plasma glucose level, blood urea nitrogen, serum creatinine, lipid and cholesterol analyses, luetic serology, urinalysis, chest roentgenography, and ECG. Nonenhanced cranial CT is also being done in all patients because it may detect hemorrhagic or mass lesions that can present as a TIA or evolving stroke (Biller 1994). Approximately 10-40% of patients with TIAs have evidence of cerebral infarction on CT. Attention to early CT signs of ischemic stroke in the MCA territory such as loss of gray-white matter differentiation, sulcal effacement, effacement of the Sylvian fissure, and obscuration of the lentiform nucleus is critical. The horizontal part of the MCA is occasionally hyperdense in the noncontrast CT (dense MCA sign) before the infarction becomes visible (Figure *57A.* 18). This finding is indicative of a thrombotic or embolic occlusion of the MCA. The dense MCA sign often predicts a large cortical infarct, but is not always a poor prognostic indicator. MRI and intracranial and extracranial MRA improve the ability to localize an acute stroke and provide powerful noninvasive means to evaluate the pathological changes that occur following acute ischemic stroke (Figures 57A.19 and 57A.20). MRI is superior to CT in cerebral ischemia. The sensitivity of MRI in differentiating infarction or other lesions from normal tissue depends primarily on changes in tissue Tl and T2 relaxation times, which are related to tissue water content. Diffusion-weighted MRI allows early detection of acute cerebral ischemia,

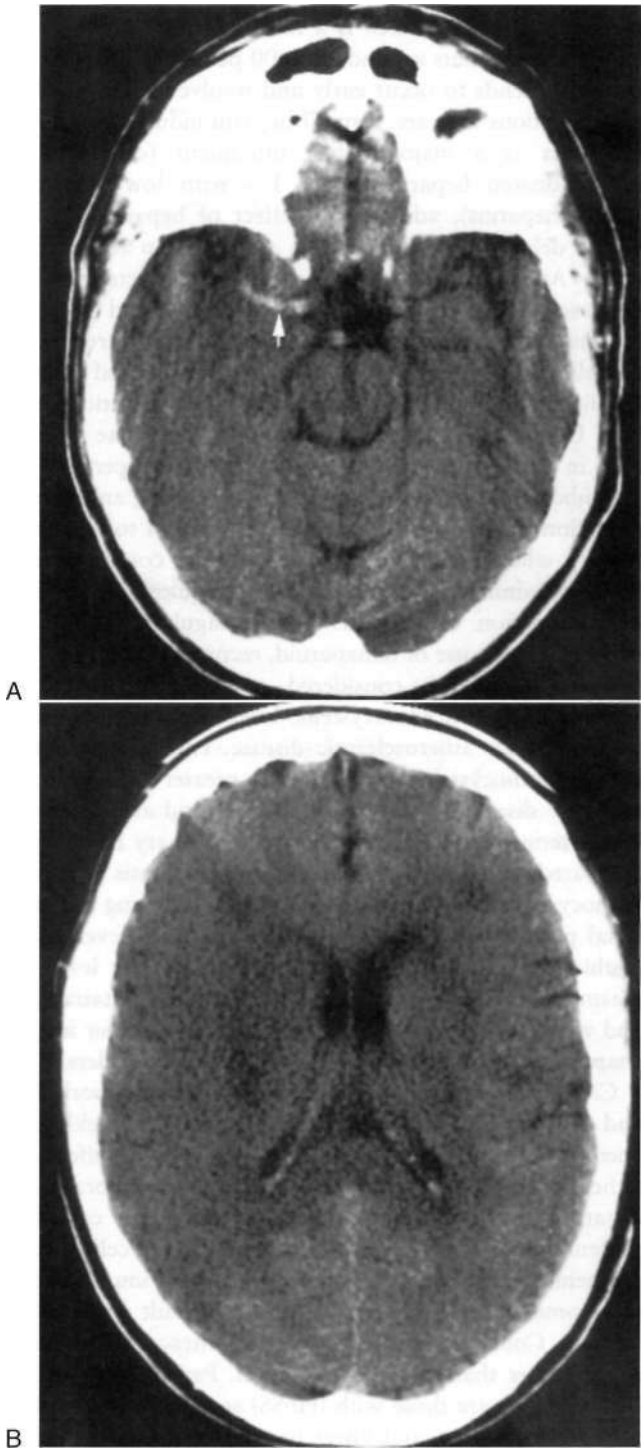

FIGURE 57A.1S Nonenhanced axial computed tomographic scans show (A) a dense right middle cerebral artery (MCA) sign *[arrow)* on the Ml segment and (B) a complete right MCA territory infarction. (Courtesy Vincent Mathews, Ml).)

while also differentiating acute from chronic stroke. Although the reliability of perfusion/diffusion MR imaging for brain tissue in the setting of thrombolytic therapy remains to be determined, studies are highly suggestive that

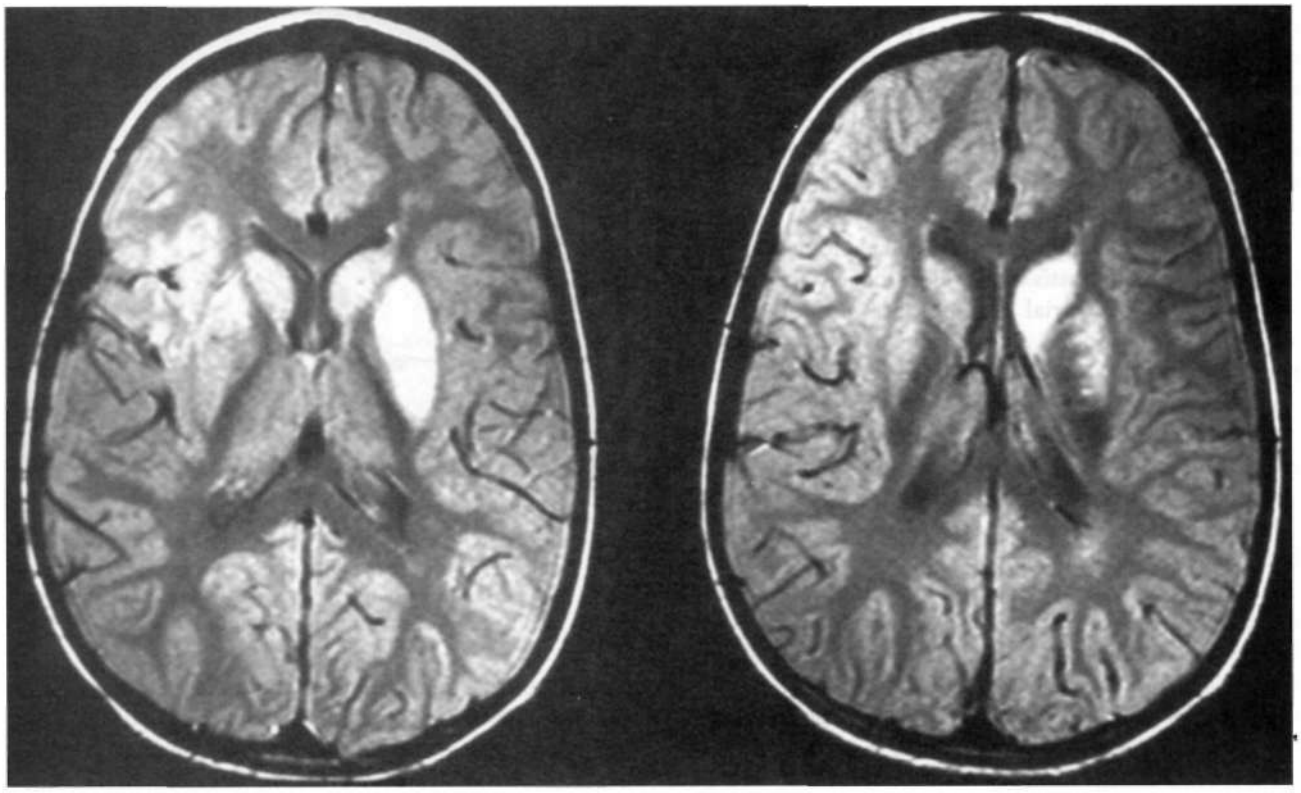

FIGURE 57A.19 Axial proton density magnetic resonance imaging demonstrates areas of increased signal intensity involving the head of the left caudate nucleus and the left lenticular nucleus consistent with infarction. The internal portion of the globus pallidus is spared.

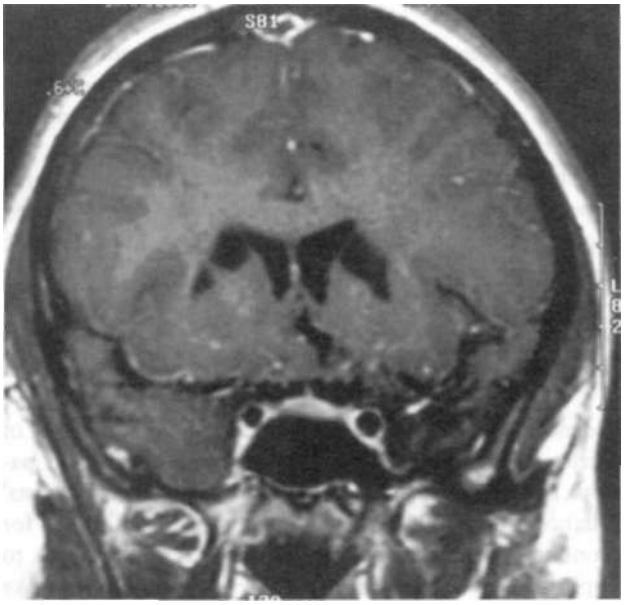

FIGURE 57A.20 Coronal Tl-weighted magnetic resonance imaging with contrast of a 14-year-old boy demonstrates bilateral recurrent artery of Heubner territory infarcts with involvement of the head of the caudate nucleus and anterior limb of the internal capsule. (Courtesy Vincent Mathews, MD.)

diffusion/per fusion mismatches are indicative of brain at risk {Mathews et al. 2001}.

The emphasis in screening is on noninvasive testing, including Doppler imaging, B-mode scanning, duplex scanning, and transcranial Doppler imaging (see Chapter 37D). In studies of duplex Doppler ultrasonography, sensitivity for detection of greater than 50% diameter stenosis ranged from *87-96%* and specificity ranged from 81-96%. Clinicians, however, need to be aware of the practical limitations of the ultrasound techniques. Severe stenosis or occlusion of an artery cannot he determined confidently by sonography. These methods also may fail to detect an intraluminal thrombus or a small atherosclerotic plaque, and some lesions arc anatomically beyond the reach of the scanner. Transcranial Doppler sonography assists in the evaluation of blood flow velocities and patency of the main intracranial arteries and in the identification of high-intensity transient microembolic signals.

Cardiac investigations to determine whether emboli have a cardiac source are advised in selected circumstances. Noninvasive cardiac imaging has expanded the ability to diagnose and assess a variety of cardiac conditions, many of which have been implicated as potential causes of TIA and evolving stroke. These imaging techniques differ widely in the information they provide about the morphology, function, and metabolic status of the heart. Most institutions currently use serial two-dimensional echocardiography to

detect left ventricular thrombus. The morphology of the thrombus predicts its embolic potential; left ventricular thrombi that have a protruding and mobile appearance on echocardiography are most likely to embolize. The sensitivity of two-dimensional echocardiography in detecting left ventricular thrombi varies from 77-92%; specificity varies from 84-94%, and predictive accuracy is 79%.

Patients with atrial fibrillation are likely to develop atrial thrombi caused by stasis of blood in the left atrium or left atrial appendage. Atria! thrombi are not always well visualized with routine studies. The left atrium, and in particular, the left atrial appendage, is often difficult to visualize with M-mode echocardiography. Left atrial thrombi can be detected successfully with two-dimensional echocardiography, but sensitivity and specificity of this technique are difficult to ascertain. Transesophageal echocardiography is used in selected individuals, particularly when the transthoracic images are technically inadequate for the evaluation of mitral and aortic prosthetic valves or vegetations; whenever there is a need for better visualization of the left atrial appendage or interatrial septum; or when a right-to-left shunt, left atrial spontaneous contrast, or aortic atherosclerosis is suspected. Continuous (Holter) ECG monitoring is seldom indicated, except when the history suggests paroxysmal disturbances of cardiac rhythm.

Most patients with TIAs or evolving stroke have cerebrovascular atherosclerosis. The gold standard for establishing the extent of vascular disease remains conventional angiography or intra-artenal digital subtraction angiography. Hither method can accurately determine the size and location of atherosclerotic lesions and aid in reliably assessing the vasculature, detecting tandem arterial lesions and the collateral circulation.

Angiography is not without complications, and its use is being challenged by the increasingly improving quality of MRA. A main disadvantage of MRA is that it overestimates the degree of stenosis related to turbulent flow. Although the risks associated with cerebral angiography have been gradually decreasing, the risk of any complication is approximately 1-5%, of which one half are minor groin hematomas. The risk of permanent neurological disability is approximately 0.2%, and the risk of death has been estimated to be 0.05%.

Cerebral angiography is indicated in several circumstances, particularly when the diagnosis remains uncertain, When a patient's workup fails to confirm the diagnosis, angiography is recommended to differentiate between atherosclerotic cerebrovascular occlusive disease and non-atherosclerotic vasculopathies, such as FMD, cervicocephalic arterial dissections, vasculitis, and moyamoya disease, as well as intracranial aneurysms or vascular malformations (Figure 57A.21).

Angiography is indicated when surgical treatment is planned. A full display of the extracranial and intracranial vasculature is important once potential surgical candidates

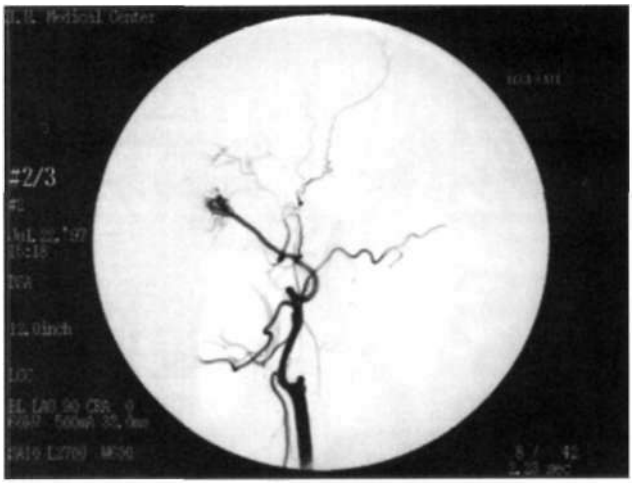

FIGURE S7A.21 A 43-year-old woman with a history of hypertension, hypercholesterolemia, and tobacco use had right-sided hemiparesis. Cerebral angiogram demonstrates an occlusion of the left internal carotid artery just past the bifurcation. There is partial reconstitution via ethmoid collaterals.

are identified. Angiography is indicated in patients with very early evolving stroke symptoms or frequent TIAs. Angiography is also indicated when distinctions affecting treatment are unclear; for example, angiography can assist in cases in which differentiation between carotid and vertebrobasilar TIA or evolving stroke is uncertain on clinical grounds only.

PREVENTING STROKE RECURRENCE: MEDICAL THERAPY

At present, general measures, including control of associated risk factors such as hypertension, hyperlipidemia, cigarette smoking, and the use of antithrombotic agents (platelet antiaggregants and anticoagulants), remain the mainstays of medical therapy for stroke prevention, A large proportion of strokes should be preventable by controlling blood pressure, treating atrial fibrillation, and stopping cigarette smoking,

Platelet Antiaggregants

Evidence from several clinical studies favors the use of platelet antiaggregants as the first line of therapy in patients at high risk for stroke (Antithrombotic Trialists' Collaboration 2002). These agents are indicated for secondary prevention of stroke. There is no evidence to support the use of aspirin in primary prevention of stroke among low-risk, middle-aged people. Although aspirin did not offer a long-term protective effect among 372 asymptomatic patients with carotid bruits and greater than 50% carotid stenosis on duplex ultrasonography, many physicians continue its use in patients with catotid

bruits or asymptomatic carotid stenosis under the assumption that it may be effective. Data regarding intraplaque hemorrhage caused by platelet antiaggregants are conflicting.

Aspirin, the oldest and most commonly used nonprescription drug in the world, is the standard medical therapy for prevention of stroke in patients with transient cerebral ischemia, as well as for reducing the risk of recurrent stroke and postoperative strokes after carotid end antrectomy (CEA). Aspirin is effective, inexpensive, and safe if started within 48 hours of acute ischemic stroke (International Stroke Trial Collaborative Group 1997; Chinese Acute Stroke Trial [CAST] 1997). Meta-analyses have shown that aspirin reduces the combined risk of stroke, myocardial infarction, and vascular death by approximately *25%.* The optimal dose of aspirin remains a source of controversy among neurologists. The range of acceptable management includes daily doses ranging between 50 and 1300 mg of aspirin. There is a suggestion that aspirin is also effective in doses as low as 30 mg daily. Results of primary prevention trials do not support the use of aspirin for primary stroke prevention {Patrono et al. 2001; Hebert ct al. 2000).

The mechanism of action of aspirin is the irreversible inhibition of platelet function by inactivation of cyclooxygenase. The atitiaggrcgant effect is seen within one hour after administration. Aspirin is also anti-inflammatory, antioxidant, and may increase fibrinolytic activity up to 4 hours after administration. The main side effect of aspirin is gastric discomfort. Gastrointestinal hemorrhage occurs in 1-5% of cases.

In the Aspirin in Carotid Endartcrcctomy (ACE) Trial, 2849 patients who were scheduled for CEA were randomly assigned to compare the benefits of low-dose aspirin {81-325 mg daily) with high-dose aspirin (650 or 1300 mg daily). The primary endpoints in the ACE Trial were stroke, myocardial infarction, or death. At 3 months after surgery, the risk of stroke, myocardial infarction, or death was 6.2% in the low-dose aspirin group, compared with 8.4% in the high-dose aspirin group. The difference was less apparent when only stroke or death was evaluated as the endpoint (Taylor et al. 1999).

Ticlopidine and ciopidogrel are structurally related thien©pyridines that have antiplatelet effects. Ticlopidine reduces the relative risk of death or nonfatal stroke by 12% in comparison with aspirin. Ticlopidine acts primarily by irreversibly inhibiting the adenosine 5^1 diphosphate pathways of the platelet membrane. Ticlopidine also reduces plasma fibrinogen levels and increases erythrocyte deformability. The recommended dosage of ticlopidine is 250 mg twice a day. Ticlopidine has more side effects than aspirin, including diarrhea, nausea, dyspepsia, and rash. These side effects tend to occur during the first few months of therapy. The dosage can be temporarily reduced to lessen the side effects for a few weeks, then brought back to 250 mg twice a day administered with food. A more worrisome adverse reaction is reversible neutropenia, which occurs in 2.4% of cases and is severe in 0.85%. This reaction can be encountered during the first 3 months of treatment, and for this reason a complete blood cell count must be obtained every 2 weeks during this period. The drug must be discontinued if the neutrophil count falls below 1200 per u.L. Rarely, thrombocytopenia and thrombotic TTP may occur. One case of TTP has been described for every 2000—4000 patients treated with ticlopidine,

The Ciopidogrel versus Aspirin in Patients at Risk of Ischemic Events study assessed the relative efficacy of ciopidogrel (75 mg daily) and aspirin (325 mg daily) in reducing the incidence of ischemic stroke, myocardial infarction, or symptomatic atherosclerotic peripheral arterial disease. The results of this study showed that ciopidogrel was modestly more effective (8.7% relative risk reduction) than aspirin in reducing the combined risk of ischemic stroke, myocardial infarction, and vascular death in patients with atherosclerotic disease. Ciopidogrel is a platelet adenosine diphosphate receptor antagonist. Overall, the tolerabiliry of ciopidogrel was excellent, with no increased incidence of neutropenia, and a lower incidence of gastrointestinal hemorrhage and peptic, gastric, or duodenal ulcers when compared with aspirin.

Bennett et al. (2000) studied the association of ciopidogrel with thrombotic TTP in 11 patients. In the majority of patients, ciopidogrel had been used for less than 14 days before the onset of thrombotic TTP. Several patients were taking concomitant medications, including statins in five patients, atenolol in three patients, and cyclosporine in one patient. How this serious, potentially fatal, complication will affect the clinical use of ciopidogrel remains to be seen (Bennett et al. 2000). The rate of diarrhea, rash, and pruritus is higher with ciopidogrel than with aspirin (Ciopidogrel versus Aspirin in Patients at Risk of Ischemic Events [CAPRIE] Steering Committee 1996).

Dipyridamole is a cyclic nucleotide phosphodiesterase inhibitor that increases the levels of the cyclic adenosine monophosphate. The European Stroke Prevention Study 2 (ESPS-2), a multicenter, randomized, double-blind, factorial, placebo-controlled trial, randomized patients with stroke or TIA within the previous 3 months to treatment with aspirin alone (25 mg twice a day), modified-rclease dipyridamole alone (200 mg twice a day), the two agents in combination, or placebo. The ESPS-2 investigators concluded that both low-dose aspirin and high-dose dipyridamole in a modified-release form alone were superior to placebo, and that the combination was significantly superior to each drug alone. The ESPS-2 investigators reported an additive effect of the modified-release dipyridamole when prescribed with aspirin with a remarkable 37% relative risk reduction in fatal and nonfatal stroke at 2 years. Benefit was limited to stroke prevention in patients with prior stroke or TIA. There was little effect on fatal stroke and myocardial infarction. The main side effects of dipyridamole are headaches and gastrointestinal distress. The use of low-dose aspirin did not reduce the risk of

bleeding (Diener et al. 1996). The European and Australian Stroke Prevention Reversible Ischaemia trial is currently randomizing patients with TIAs or minor ischemic stroke to oral anticoagulants, the combination of aspirin (30-325 mg) plus dipyridamole (400 mg daily) and aspirin alone (DeSchryer et al. 2000).

There is no persuasive evidence from current or past trials that patients benefit from the use of sulfinpyrazone or suloctidil. GP lib—Ilia antagonists, like abciximab (ReoPro), inhibit platelet aggregation and may have additional anticoagulant, fibrinolytic, and anti-inflammatory activities. In acute ischemic stroke, a dose escalation study of abciximab demonstrated the safety of this agent (The Abciximab in Ischemic Stroke Investigators 2000). A phase II trial of abciximab in acute ischemic stroke of less than 6 hours duration is currently under investigation. Long-chain polyunsaturated omega-3 fatty acids may be considered in patients unable to receive platelet anitaggregants or other antithrombotic agents.

Oral Anticoagulants

Oral anticoagulation with warfarin is indicated for primary and secondary prevention of stroke in patients with NVAF. Six randomized studies evaluated the primary and secondary prevention of stroke in patients with NVAF. Three of these studies also evaluated aspirin at daily doses of 75, 300, and 325 mg. These six studies demonstrated that the relative risk of stroke is reduced by 68% with the use of warfarin (Koefoed et al. 1997). Advancing age increases the risk of major hemorrhage in patients given warfarin for stroke prevention; patients older than 75 years are at greater risk of hemorrhagic complications. The relative risk reduction with aspirin therapy was 21% (18-44%) (The Atrial Fibrillation Investigators 1997). Therefore NVAF patients at high risk of stroke should be treated with dose-adjusted warfarin (INR 2.0-3.0); INR values less than 2.0 and greater than 4.0 should be avoided. Patients younger than 65 years without other risk factors can be given aspirin 325 mg per day. Low-intensity, fixed-dose warfarin plus aspirin is inadequate for stroke prevention in high-risk patients with NVAF. Anticoagulation is also recommended for patients with atrial fibrillation and hyperthyroidism. Patients who cannot tolerate pharmacological cardioversion may benefit from electrophysiological or surgical procedures. Anticoagulant rbiT.ipv has a protective effect against stroke following acute myocardial infarction. To prevent arterial embolism, immediate anticoagulation with heparin is initiated followed by oral anticoagulation for 6 months following an anterior wall myocardial infarction, or a myocardial infarction with apical wall motion abnormalities or left ventricular thrombus. Patients with mechanical prosthetic heart valves should receive lifelong therapy with oral anticoagulants to prolong the INR to a target of 3.5. Patients undergoing cardioversion for atrial fibrillation should receive anticoagulation for 3 weeks before and 4 weeks after cardioversion. Use of long-term anticoagulation in patients with left ventricular aneurysms and mural thrombi is not indicated because of the low risk of embolization. The WARSS randomized 2206 patients to warfarin (1103) or aspirin (1103) 325 mg daily. Warfarin (INR = 1.4 - 2.8) did not offer additional benefit in preventing recurrent ischemic stroke in patients with noncardioembolic infarcts (Mohr et al. 2001). Uncertainty persists about the use of warfarin in the management of patients with symptomatic stenosis of a major intracranial artery.

TREATMENT OF ACUTE ISCHEMIC STROKE

Modern therapy for acute ischemic stroke is currently being approached in four different ways. First, and most important, arc general measures aimed at prevention and treatment of complications. Second are those reperfusion strategies directed at arterial rccanalization. Third are cy to protective strategies aimed at cellular and metabolic targets. The fourth approach aims at the inhibition of the inflammatory processes associated with cerebral ischemia. Eventually, combined therapy will be used for acute ischemic stroke treatment.

Randomized studies of unfractionatcd heparin, low-molecular-weight heparins, or heparinoids for the treatment of acute ischemic stroke showed no proven benefits in the reduction of either stroke-related mortality, stroke-related morbidity, early stroke recurrence, or stroke prognosis. The time window from stroke onset varied from 12 hours to 48 hours in these studies.

Results are available from a randomized double-blind controlled trial of nadroparin-calcium (Fraxiparin), a low-molecular-weight heparin. In this trial, 312 patients were randomized within 48 hours of stroke to receive nadroparin-calcium 4100 antifactor Xa IU subcutaneously either once or twice daily, or placebo. Treatment was continued for 10 days. After 10 days, all patients received aspirin, 100 mg per day. There was no difference between the groups at 3 months. However, after 6 months, there was a significant dose-dependent reduction in the rate of poor outcome among the three study groups in favor of patients treated with nadroparin-calcium twice daily compared with those who received treatment once daily or placebo (Kay et al. 1995). A second randomized double-blind study involving 750 patients in 120 centers (FISS bis) failed to confirm these initial observations.

The International Stroke Trial studied approximately 20,000 patients who were randomized within 48 hours of ischemic stroke onset to receive fixed dose 10,000 or 25,000 units of unfractionated heparin subcutaneously daily (compared with no heparin). Treatment was continued for 14 days or until hospital discharge if shorter. There was no significant difference in the rate of death or

recurrent ischemic or hemorrhagic stroke at 2 weeks (11.7% with unfr actions ted heparin and 12.0% without unftactionated heparin). Patients receiving unfractionated heparin had significantly fewer recurrent ischemic strokes at 2 weeks, but this was negated by a similar increase in hemorrhagic strokes (International Stroke Trial Collaborative Group 1997). This trial used subcutaneous rather than intravenous unfractionated heparin.

Definite data regarding the safety and efficacy of intravenous heparin for acute ischemic stroke or cardioembolic stroke are lacking, but intravenous heparin is sometimes given to some patients with small cardioembolic infarcts associated with intracardiac thrombi, diagnosed by echocardiography, to prevent recurrence. In a small trial performed by the Cerebral Embolism Study Group, 45 patients with acute cardioembolic stroke who presented within 48 hours of symptom onset were randomized to receive either early or delayed treatment. The early treatment group received an intravenous heparin bolus of 5000-10,000 units followed by a maintenance infusion for at least 96 hours before the patient was switched to warfarin. Patients in the control group received no heparin and were given platelet antiaggregants or warfarin 10 days poststrokc. None of the 24 patients who received heparin experienced stroke recurrence or hemorrhage within the 96-hour treatment period. Of the 21 patients who received delayed anticoagulation, 2 experienced early recurrent embolic cerebral infarcts, 1 had a deep venous thrombosis, 2 had hemorrhagic transformations, and 3 died. The study suggested that heparin might be helpful, but the study was terminated prematurely. Heparin should not be used if a patient has a septic embolus or if the CT shows a hemorrhagic or large infarction. When intravenous heparin is given, most physicians do not currently use an intravenous bolus and aim for a target aPTT of 55-75 seconds, or 1.5-2.0 times control.

Intravenous unfractionated heparin appears to be ineffective in patients with acute partial stable stroke. A large randomized study evaluated unfractionated heparin in 225 patients with noncardioembolic stroke. Patients who had progressing deficit in the first hour of observation were excluded from the study because of the prevailing belief, at that time, that stroke in evolution should be anticoagulatcd. There was no significant difference in stroke progression or death at 7 days. The current status of antithrombotic therapy of cerebral ischemia is shown in Table 57A.8.

Although convincing statistical proof is still lacking, anecdotal evidence supports early initiation of intravenous unfractionated heparin to prevent stroke recurrence in several uncommon situations. These indications include cerebral infarction in the setting of inherited or acquired hypercoagulable states, intraluminal arterial thrombus, and extracranial cervicocephalic arterial dissections. Outcome of cerebral venous thrombosis is improved with heparin therapy with improvement beginning early in the course of therapy (Bousser et al. 1985; Kinhaupl et al. 1991).

Table S7A.8: Current status of antithrombotic therapy of cerebral ischemia

Therapy	*Coticius/orl*
Antithrombotic Agents	
Aspirin	Positive
Clopidogrel	Positive
Ticlopidine	Positive
Slow-release dipyridamole and aspirin	Positive
Sulfinpyrazone	Negative
Suloctidil	Negative

Warfarin	Positive*
Warfarin	Negative*
Heparin	Negative
Fraxiparin	Negative
Ualteparin	Negative
Certoparin	Negative
i'in/.aparin	Negative
Dauaparoid	Negative

Tor primary and secondary prevention in patients with nonvalvular atrial fibrillation.

[1]No additional benefit {international normalized ratio = 1.4-2.8) in preventing recurrent ischemic stroke in patients with noncardioembolic infarcts.

Thrombolytic Therapy

If patients meet appropriate criteria, thrombolytic therapy may be administered. Thrombolytic therapy is able to recanalizc acute intracranial occlusions, but the question remains whether thrombolytic therapy can recanalizc occlusions of large extracranial or other large intracranial vessels (e.g., carotid terminus). A strong correlation has been shown between arterial recanalization and neurological improvement in acute cerebral ischemia.

In June *1996,* the Food and Drug Administration approved the use of intravenous tPA for ischemic stroke within 3 hours of symptom onset. As late as 2002, only the National Institute of Neurological Disorders and Stroke (NINDS) rt-PA (recombinant tissue plasminogen activator) Stroke Study Group showed that treatment with intravenous tPA within 3 hours of onset of ischemic stroke improved clinical outcome (minimal or no disability on the clinical assessment scales) at 3 months (The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group 1995).

In the NINDS tPA study, treatment did not lessen death rates or account for an excess mortality. The frequency of symptomatic intracerebral hemorrhage was 10 times greater in patients given tPA (6.4% in the treatment group compared with 0.6% in the placebo group). Most hemorrhages occurred within 36 hours of treatment. Intravenous tPA should be administered only by physicians with experience in the diagnosis and management of stroke and who are familiar with the potential hemorrhagic complications associated with thrombolytic therapy.

Subsequent asscssmi-nt of the NINDS ll'A trial using *a* global statistic also demonstrated a sustained benefit of intravenous rt-PA at 6 and 12 months after the intervention in patients treated within 3 hours after onset of ischemic stroke symptoms (Kwiatkowski et al. 1999).

Inclusion criteria for administration of tPA in the NINDS tPA trial were acute ischemic stroke with a clearly defined time of onset (<3 hours), neurological deficit measurable on the NIH Stroke Scale, and CT scan without evidence of intracranial hemorrhage. Exclusion criteria for administration of tPA were rapidly improving or isolated minor neurological deficits, seizute at the onset of stroke, prior intracranial hemorrhage, symptoms suggestive of subarachnoid hemorrhage, blood glucose level less than 50 mg/dL (2.7 mmol/L) or greater than 400 mg/dL (22.2 mmol/L), gastrointestinal or genitourinary bleeding within the .3 weeks before stroke, recent myocardial infarction, current use of oral anticoagulants (PT >15 seconds or INR >1.7), a prolonged aPTT or use of heparin in the previous 48 hours, platelet count less than 100,000 pet j.iL, another stroke or serious head injury in the previous 3 months, major surgery within the previous 14 days, arterial puncture at a noncompressible site within the previous 7 days, or pretreatment SBP greater than 185 mm Hg or DBP greatet than 110 mm Hg.

The use of intravenous rt-PA for Alteplasc Thrombolysis for Acute Noninterventional Therapy in Ischemic Stroke trial was terminated early because of non statistical efficacy at interim analysis (Clatk et al. 1999). Favorable outcome at 3 months was 42.3% for those treated with tPA versus 38.9% for those treated with placebo. Mortality at 3 months was 11.0% for tPA-treated patients versus 6.9% fot those patients receiving placebo. Symptomatic intracranial hemorrhage occurred in 7.0% of tPA-treated patients. The Second European-Australasian Acute Stroke Study investigators recently assessed the safety and efficacy of intravenous alteplasc {0.9 mg/kg of body weight) administered within 6 hours of ischemic stroke onset and failed to confitm a statistical benefit for alteplasc; symptomatic intracranial hemorrhage occurred in 8.8% of altcplasc-treated paricnts and in 3.4% of placebo-treated patients (Hacke et al. 1998). An earlier study, using a dose of TPA of 1.1 mg/kg, also failed to demonstrate therapeutic efficacy among 620 patients treated within 6 hours from ischemic stroke onset (Hacke et a I. 1995). Favorable outcome at 3 months was 35.7% for those treated with tPA vctsus 24.3% for those receiving placebo. Mortality at 3 months was 22.4% for tPA-treated patients vetsus 15.8% for those treated with placebo (Clark et al. 1999; Hacke et al. 1998).

Thrombolysis-related intracranial hemorrhages are usually large volume lobar bleeds, often multiple, with blood/fluid levels; intraventricular and subarachnoid extension is not uncommon. The rate of symptomatic intracranial hemorthage in several phase IV series of tPA in the community setting was similar to that seen in the NINDS Trial (Chiu et al. 1998; Albers et al. 2000). Protocol violations have been associated with higher rates of symptomatic intracranial hemorrhages (Katzan et al. 2000; Buchan et al. 2000).

In spite of a consistently lower frequency of intracerebral hemorrhage with the use of SK rather than tPA, in patients with acute myocardial infarction, current data do not support the use of intravenous SK, 1.5 million units, in acute ischemic stroke.

Recombinant ptoutokinase (r-pro-UK) was tested in the Proutokinase in Acute Cerebral Thromboembolism II trial. In this multicenter, phase III, randomized, controlled trial, 180 patients with angiographically proven occlusion of the MCA (Ml or M2 MCA occlusion) wete given local intra-arterial pro-UK within 6 hours of symptom onset. Of the treated patients, 40% were functionally independent, compared with 25% of the placebo group patients 3 months after treatment {p — .04). The efficacy of treatment seemed to fall off after approximately *5* hours. Treated patients, however, also encountered a higher risk of intracranial hemorrhage with neurological detetioration within 24 hours of treatment (10% versus 2% in the control group; p = .06) (Furlan et al. 1999). The potential therapeutic benefit of intra-arterial thrombolysis and of the combination of thrombolytic and ncuroprotectant agents is being studied. Whether the combined use of intravenous and intra-arterial t-PA in acute ischemic stroke is safe or effective has yet to be determined. Mechanical thrombo-aspiration with newer catheter techniques is being actively explotcd.

The following seem to be predictors of favorable outcome with intravenous thrombolytic therapy for acute ischemic stroke: treatment within 90 minutes of symptom onset, normal baseline CT scan, milder baseline stroke severity, no history of diabetes mellitus, notmal prctrcatment blood glucose level, and normal pretreatment blood pressure. The following seem to portend a less favorable outcome and/or increased risk for cerebral hemorrhage; extended area of low attenuation with mass effect or low attenuation on one third or more of the MCA territory on pretreatment CT scan; advanced age; prior head injury; diabetes mellitus; marked elevation of the blood pressure before, during, and after treatment; hypertension requiring postrandomization antihypertensive treatment; severe pretreatment neurological deficits; and protocol violations according to the NINDS study protocol (Kocnnecke H-C 2002). Although no strict age cutoff exists for administering thrombolytics for ischemic stroke, physicians need to balance the increased risk of hemorrhage in patients aged 75 and older with potential benefit.

Defibtinogciiating Agents

Ancrod, an enzyme extracted from the venom of the Malayan pit viper, lowers fibrinogen and blood viscosity,

Table 57A.9: Current status of thrombolytic therapy of cerebral ischemia

Therapy	*Conclusion*
Thrombolytic therapy	
Streptokinase	Negative
tPA	Positive (within 3 hr of stroke onset; intravenous use)
r-prourokinase	Positive (within 6 hr of stroke onset; intra-arterial use)*
Hemorheological therapy	
Hcmodilution	Negative
Pentoxifylline	Negative
Ancrod	Positive (within 3 hr of stroke onset; intravenous use)*

"Currently, neither r-prourokinase nor Ancrod is available or approved by the U.S. Food and Drug Administration for use in acute ischemic stroke.
tPA = tissue plasminogen activator.

inhibits erythrocyte aggregation, indirectly stimulates thrombolysis, and possibly causes local vasodilatation. It also has a weak anticoagulant effect at high dosages.

Its potential as a treatment for ischemic stroke was shown to be beneficial when initiated within 3 hours of stroke onset in the multicentcr Stroke Treatment with Ancrod Trial (Sherman et al. 2000).

The positive results of this study were not replicated in a European Trial. Currently, neither r-pro-UK nor Ancrod are available or approved by the U.S. Food and Drug Administration for use in acute ischemic stroke. Hemorheologic therapy with isovolemic, hypovolemic, or hypervolemic hcmodilution has been ineffective (Table 57A.9).

Neuroprotective Agents

Despite widespread interest in neuroprotective drug therapy and positive results in experimental animals, no neuroprotective agent has been approved to date by the U.S. Food and Drug Administration for acute ischemic stroke.

Almost 120 controlled clinical trials involving more than 21,000 subjects, and investigating more than 50 neuroprotective interventions, have yielded negative results. New agents (spinal tap agents, oxygenated fluorocarbon nutrient emulsions, a-amino-3-hydroxy-5-merhyl-4-isoxazole propionic acid antagonists, and potassium channel openers) have been proposed.

Intracellular adhesion molecules (ICAMs) arc molecules to which leukocytes adhere and which facilitate migration of leukocytes through the endothelium. Some of these molecules are expressed in the cerebral vasculature during ischemia. Neutrophils in particular can contribute to tissue injury by obstructing capillaries and possibly by liberating cytotoxic products. Prevention of neutrophil adhesion by infusion of monoclonal antibodies directed at ICAMs improved neurological outcome in animal models of transient ischemia, but clinical trials yielded negative results. The sudden decrease in blood flow after ischemia provokes a cascade of events eventually leading to cell death. These events include the release of excitatory amino acids (F.AAs) with secondary opening of ion channels, which leads to an increase in intracellular calcium concentration, activation of enzymes, and generation of free radicals. Several agents have been shown in vitro and in animal studies to interfere at various steps of this cascade, thus potentially protecting the cells from ischemia.

Cerebroselectivc calcium-channel blockers such as nimodipine have been tested in acute stroke, but the benefits for patients with acute ischemic stroke remain unproven.

Endogenous EAA neurotransmitters play a major role in the pathogenesis of cerebral ischemia. In animals, EAA antagonists reduce the size of an infarct after occlusion of a maior artery. From preliminary studies, some of these compounds appear to be safe in humans, but their efficacy has not been demonstrated, and several clinical trials yielded negative tesults. Optimal protective regimens may necessitate blockading of both N-methyl-u-aspartate (NMDA) and non-NMDA receptors.

Free radicals produced during ischemia can degrade polyunsaturated lipids, which arc building blocks of cellular membranes, by means of lipid peroxidation. The central nervous system appears particularly susceptible to free radical injury. The 21 aminosteroid compounds inhibit lipid peroxidation by scavenging free radicals. Tirilazad is one such compound that decreases damage secondary to global ischemia in experimental animal models, but its clinical application in the treatment of patients with ischemic stroke has not been established.

Neurotrophins are factors known to promote cell growth in certain neuronal populations. Studies have shown that some of these factors given intraventricular^ to animals during ischemia reduce infarct size. The mechanism of action is still unknown but could be related to interaction with EAAs.

Calpains are cytosomal enzymes that are normally quiescent but become activated by increases in intracellular calcium concentration. These enzymes have many proteins as their targets, and thus their activation can cause considerable damage. In experimental models of stroke in animals, intra-arterial infusion of calpain inhibitors given after onset of ischemia significantly reduced infarct size compared with controls. The value of calpain inhibitors in humans has not been established.

The value of intravenous magnesium (which is an NMDA antagonist) is under investigation. Treatments with gangliosides, barbiturates, prostacyclin, opiate antagonists, aminophylline, ^-adrenergic receptor blockers, vasopressor therapy, naftidrofuryl, clometbiazole, inhibitors of leukocyte adhesion, fosphenytoin, lubeluzole, basic fibroblast growth factor, and citicolinc have been ineffective (Table 57A.10).

Tabic 57A.10: Current status of neuroprotection of cerebral ischemia: results of selected therapies

Ni modi pi tie	Negative
Tirilazad	Negative

Surgical Therapy

Symptomatic Carotid Artery Stenosis

Stroke is often caused by atherosclerotic lesions of the carotid artery bifurcation; approximately 15% of ischemic strokes are caused by extracranial internal carotid artery stenosis. Carotid atherosclerosis develops in areas of low vessel-wall shear stress, most commonly the carotid bulb. In addition to the degree of carotid artery stenosis, plaque structure has been postulated as a critical factor in defining stroke risk. Ulcers found during CEA have been associated with cerebral artery microemboli detected by transcranial Doppler (Sitzer et al. 1995). Echoluccnt carotid artery plaques may also be associated with an increased risk of stroke. CEA, by removing the atherosclerotic plaque, restores cerebral blood flow and reduces the risk of cerebral ischemia, Results from three major prospective contemporary studies provide compelling evidence of the benefit of CEA performed by experienced surgeons in improving the chance of stroke-free survival in high-risk symptomatic patients. Timely surgical intervention in selected patients with hemispheric TTAs, amaurosis fugax, or completed nondisabling carotid terrirory strokes within the previous 6 months, and with 70-99% diameter-reducing carotid stenosis, can significantly reduce the risk of recurrent cerebral ischemia or death. Other factors that increase the risk of ipsilateral stroke are hemispheric (rather than retinal) site of ischemia, ulcerative nature of the stenosis, presence of contralateral carotid artery occlusion, and vascular risk factors. Benefits of CEA are similar for men and women. Advanced age by itself should not be considered a contraindication for properly selected patients with symptomatic high-grade carotid artery stenosis.

The North American Symptomatic Carotid Endarterectomy Trial (NASCET) confirmed the effectiveness of CEA for preventing stroke in 659 symptomatic patients with TIAs or minor strokes with high-grade (70-99%) diameter-reducing carotid artery stenosis. A uniform and strict technique measured carotid artery stenosis from an arteriogram. For different endpoints, absolute risk reductions in favor of surgery were 17.0% for ipsilateral stroke; 15.0% for all strokes; 16.5% for the combined outcomes of all strokes and death; 10.6% for major ipsilateral stroke; 9.4% for all major strokes; and 10.1% for major stroke and death. CEA was also beneficial and not more dangerous in symptomatic patients with atheromatous carotid artery pseudo-occlusion (carotid string sign). Longer term outcome was also better for surgically treated patients despite an occluded contralateral carotid artery. Morbidity and mortality of early CEA were similar to that of delayed surgery. The European Carotid Surgery Trial (ECST) also indicated the benefit from CEA compared with medical therapy in patients with mild carotid territory ischemic events associated with a diameter-reducing proximal internal carotid stenosis between 70% and 99%. The cumulative risk of any ipsilateral stroke at 3 years was 10.3% for the surgical group and 16.8% for the medical group. The ECST trial used different criteria than NASCET for measurement of carotid artery stenosis on angiography.

A diameter-reducing carotid artery stenosis of 70-99% by NASCET criteria is equivalent to a stenosis of 82-99% by ECST methodology; likewise a stenosis of 70-99% by ECST criteria is equivalent to a stenosis of 50-99% by NASCET criteria (Rothwell et al. 1994).

These methodological differences were more important with mild carotid artery stenosis. The Veterans Administration Trial of Carotid Endarterecromy in Symptomatic Carotid Stenosis was terminated early because of the positive results of NASCET and ECST. The Veterans Administration study also showed that CEA improved outcome in selected symptomatic patients with high-grade extracranial carotid artery stenosis. Among symptomatic patients with less than 30% stenosis, results from the ECST trial favor the use of medical therapy with platelet antiaggrcgants.

The utility of CEA for symptomatic patients with 30-69% carotid artery stenosis has recently been determined. Results were analyzed separately for those patients with 30-49% and those with 50-69% stenosis. Analysis from 1599 patients suggests that CEA is not indicated in most of these patients (European Carotid Surgery Tria lists' Collaborative Group 1996).

With a low surgical risk, CEA also provides modest benefit in symptomatic patients with carotid artery stenosis of 50-69% (Barnett et al. 1998), especially among men with hemispheric ischemia who are not diabetic. CEA

provides no benefit if the stenosis is less than 50% (50% by NASCET criteria is equal to 75% stenosis by ECST criteria). The benefit of CEA is highly dependent on surgical risk. Mortality and morbidity caused by CEA are significantly lower for asymptomatic patients. The acceptable level of surgical risk varies with the indication for carotid artery surgery. Maximal acceptable limits of surgical risks for combined perioperative neurological morbidity and mortality are 3% for asymptomatic patients, 5% for patients with TIAs, 7% for patients with stroke, and 10% for patients with recurrent stenosis.

Whether selected patients should undergo CEA on the basis of duplex scanning alone (without cerebral angiography), or duplex scanning complemented by MRA remains controversial. Carotid artery angioplasty and s ten ting may offer an alternative treatment to CEA, particularly in patients with internal carotid artery stenosis that is in an anatomically high location in the neck, carotid artery restenosis following prior CEA, radiation-induced carotid artery stenosis, and among certain high-risk patients with serious medical comorbidities. Carotid artery angioplasty and stenting should still be regarded as experimental. Results from randomized trials are needed before these techniques can be recommended. The Carotid Revascularization Endarterectomy versus Stent Trial is currently comparing the efficacy of CEA and carotid artery stenting among good-risk symptomatic patients with stenosis of more than 50%.

Asymptomatic Carotid Artery Stenosis

Asymptomatic carotid artery atherosclerosis is prevalent in the general population, especially in the elderly. Compared with symptomatic stenosis, asymptomatic carotid artery stenosis is associated with a relatively low risk of ipsilateral cerebral infarction. Data from four randomized clinical trials concerning the efficacy of CEA in patients with asymptomatic carotid artery stenosis are now available. The study by Clagett and colleagues was a fairly small study that followed only 57 asymptomatic patients with cervical bruits and abnormal ocular pneumoplcthysmography; only 29 were truly randomized to aspirin therapy or CEA. More unfavorable outcomes were noted in those patients undergoing CEA and the authors concluded that most asymptomatic patients with cervical bruits and abnormal ocular pneumopathy sinography are appropriately managed without CEA (Clagett et al. 1984), The Carotid Artery Surgery Asymptomatic Narrowing Operations versus Aspirin trial enrolled asymptomatic patients with 50-90% carotid artery stenosis. Patients with greater than 90% carotid artery stenosis were excluded on the basis of presumed surgical benefit. Overall, the trial showed no difference between the medically and surgically treated groups. The Mayo Asymptomatic Carotid Endarterectomy Trial (Mayo, 1992) was terminated early because of higher rates of myocardial infarction and TIAs in the surgical group. Patients in the surgical group did not receive aspirin, probably explaining those results. The Veterans Affairs Asymptomatic Carotid Endarterectomy Trial evaluated 444 asymptomatic patients with angiographicslly proven carotid stenosis of 50-99%. The study showed n relative risk reduction in the incidence of ipsilateral neurological events in favor of surgery when both TIA and stroke were included as composite end points. However, when ipsilateral stroke was considered alone, only a nonsignificant trend favoring surgery was noted. For the combined outcome of stroke and death, no significant differences were found between the two treatment arms (Hobson et al. 1993). The fifth randomized clinical trial, the Asymptomatic Carotid Atherosclerosis Study (ACAS), found that CEA combined with aspirin and risk-factor reduction is superior to aspirin and risk-factor reduction alone in preventing ipsilateral stroke in patients younger than 80 years who had greater than 60% asymptomatic carotid artery stenosis. The ACAS angiographieal methods were similar to NASCET. All patients randomized to the surgical arm of the study had a catheter angiogram but it was not mandatory in the medically treated patients. The aggregate morbidity and mortality of the ACAS participating surgeons were extremely low. Based on a 5-year projection, ACAS showed that CEA reduced the absolute risk of stroke by *5.9%* (which corresponds to an absolute risk reduction of only 1% per year), and the relative risk of stroke and death by 53%. The surgical benefit incorporated a perioperative stroke and death rate of 2.3% including a permanent artcriographical complication rate of 1.2%. It is also important to note that all patients with a *60—99%* stenosis were analyzed together in this study.

In spite of these results, controversy surrounds the selection of asymptomatic patients for CEA. Based on the low risk of stroke for all deciles until 80-89% carotid artery stenosis demonstrated by the European Carotid Artery Surgery Trialists (The European Carotid Surgery Trialists[1] Collaborative Group 1995), some experts recommend surgery only when the degree of stenosis is greater than 80%, provided that the operation is performed by an experienced surgeon with a complication rate (combined artcriographical and surgical) of 3% or less.

The value of impaired cerebral vasomotor reactivity using intravenous administration of acetazolamide as a predictor of stroke risk in patients with asymptomatic carotid artery stenosis is controversial. The necessity for widespread screening of patients with asymptomatic carotid artery stenosis is not supported by available data. Although concomitant CEA and coronary artery bypass grafting can be achieved with acceptably low operative risk, the best management for symptomatic carotid stenosis patients with coexisting severe carotid and coronary artery disease is still unknown. The risk seems to be low for asymptomatic carotid stenosis patients, and the available data do not justify preoperative prophylactic CEA in patients requiring coronary angioplasty.

GENERAL MANAGEMENT OF ACUTE ISCHEMIC STROKE

Rapid diagnosis of stroke and initiation of treatment are important to maximize recovery, prevent recurrence of stroke, and prevent complications. Patients with an acute stroke should be admitted to the hospital for emergency evaluation and treatment, preferably in a stroke unit or intensive care unit where close medical and nursing observation is available. Treatment of unselected acute stroke patients in specialized stroke units correlated with a lower mortality, reduced length of hospital stay, reduced frequency of discharge to a nursing home, and potentially reduced cost (see Chapter 54). Development of a stroke team is advantageous to expedite emergency care. Emergency care involves attention to the protect ion ol the airway to avoid obstruction, hypoventilation, and aspiration pneumonia. Pulse oximetry or arterial blood gases may be indicated. Supplemental oxygen and ventilatory assistance should be added if needed. Mild hypothermia protects the brain from ischemic injury; mild hyperthermia worsens ischemic outcome. Prevention of pulmonary complications is necessary in (lie bedridden patient or in the patient with impaired oropharyngeal function. The mortality from pneumonia is as high as 15-25% in stroke patients. Aspiration was documented by videofluoroscopical modified barium swallow examination in more than one third of patients with brainstem strokes, in one fourth with bilateral hemispheric, and in one tenth of patients with unilateral hemispheric strokes. It is important to place a temporary enteral feeding tube if there is evidence of oropharyngeal dysfunction to minimize the risk of aspiration. Patients with oropharyngeal dysfunction, even if it appears to be mild, should receive nothing by mouth until evaluation by an experienced speech pathologist and until appropriate swallowing studies arc completed. Good pulmonary toilet is needed.

The next step is assessment of the circulation. This involves evaluation of cardiac function and blood pressure. Because of the high frequency of cardiac dysfunction associated with stroke, cardiac monitoring is recommended for the first 24—48 hours after stroke. An immediate ECG should be obtained. Concomitant cerebral and myocardial ischemia can occur in approximately 3% of cases. Ischemic stroke can be complicated by a variety of cardiac arrhythmias. If ischemic F.CG changes occur, serial creatine kinase and lactate dehydrogenase isoenzymes are indicated. In patients with stroke, the blood pressure should be monitored frequently or even continuously for the first 48-72 hours. It is not unusual for the blood pressure to be transiently elevated after a stroke. One study showed that pharmacological elevation of SBP to a mean of 156 mm Hg appeared to be safe and may improve neurological symptoms in some patients with thrombotic stroke (Rordorf et al. 1997). Within a few days, the blood pressure may return to prestroke levels. Whether transient elevations should be treated is controversial, it is important not to overtreat the blood pressure and cause hypotension. The most important objective is to maintain adequate cerebral blood flow in the presence of impaired autoregulation. If urgent lowering of the blood pressure is indicated, intravenous labetalol can be given (e.g., 10 mg over 1-2 minutes, repeated or doubled every 10-20 minutes until the desired response has been achieved or a maximum dosage of 300 mg has been administered). Contraindications to the use of labetalol include congestive heart failure, asthma, second- or third-degree heart block, or cocaine use. The use of immediate release preparations of nifedipine should be strongly discouraged, because they lower the blood pressure in an unpredictable and sometimes dramatic fashion, and have caused major cerehral infarcts.

Immediately after the patient's arrival in the emergency room, blood should be sent for appropriate studies including a complete blood cell count, PT (INR), aPTT, and a general chemistry screen. A focused neurological examination should be performed to assess neurological stability and to determine the extent of infarction. General signs that point toward a large infarction are forced eye deviation, hemiplegia, and altered consciousness. A National Institutes of Health Stroke Scale value of greater than 15 is another general indicator of a large infarction. Once stability of the airway, breathing, and circulation is determined and a focused neurological examination is performed to assess neurological stability, the patient should be sent immediately for an emergent cranial CT scan without contrast. This can point the way to treat the patient with tPA, or to avoid anticoagulants in patients with intracranial bleeds.

Attention should be directed not only to the treatment of the stroke, but also to the prevention of complications. A variety of neurological and medical complications can arise after a stroke. During the first week after an acute cerebral infarction, the most common cause of deterioration is development of brain edema. Brain edema begins to develop within the first several hours after an ischemic event. The edema reaches its peak 72-120 hours after the stroke. Ischemic edema is initially cytotoxic and later vasogenic. Cytotoxic edema involves predominantly the gray matter, whereas vasogenic edema involves predominantly the white matter. Those at the greatest risk for development of edema are younger patients and those with large infarctions, often caused by large artery occlusions. There is no specific pharmacological agent that has been proven effective against ischemic cerebral edema. Traditional treatment of increased intracranial pressure associated with acute ischemic stroke is shown in Table 57A.11. For cerebellar strokes with edema and herniation, posterior fossa decompression may be life saving. Ventriculostomy may also be performed, but has the risk of upward herniation of the cerebellum and brainstem.

In the second through the fourth weeks, pneumonia is the most common cause of non-neurological death. Many cases

Table 57A.11: Medical management guidelines for elevated intracranial pressure in patients with acute ischemic stroke

Correction of factors exacerbating increased intracranial pressure
Hyperearbia
Hypoxia
Hyperthermia
Acidosis
Hypotension
Hypovolemia
Positional
Avoidance of head and neck positions compressing jugular veins
Avoidance of flat supine position; elevation of head of the bed 15-30 degrees
Medical therapy
Endotracheal intubation and mechanical ventilation, if Glasgow Coma Scale <8
Hyperventilation to a Pco_2 of 30-35 mm Hg (if herniating)
Administration of mannitol (20% solution), 1 g/kg over 30-60 min q4-6 hr, depending on clinical status, serum osmolality, volume status, and intracranial pressure measurements with goal of dehydrating the brain and not the patient; maintenance of serum osmolality around 300-310 mOsm/L
Fluid restriction
Maintenance of euvolemia with isotonic solutions using notmal saline; avoidance of glucose-containing solutions because hyperglycemia is associated with worse prognosis for stroke; replacement of urinary losses with normal saline in patients receiving mannitol

of pneumonia are caused by aspiration of food, saliva or regurgitated gastric secretions, inert substances, or bacterial pathogens in saliva. Rasal ganglia infarcts seem to predispose patients to pneumonia because of frequent aspiration during sleep. Other potential complications include seizures, cardiac arrhythmias, myocardial infarction, deep venous thrombosis, electrolyte disturbances, decubitus ulcers, and urosepsis. Cardiac dysfunction can manifest as ECG changes, arrhythmias, or myocardial ischemia.

Frequent neurological checks are essential for the early recognition of neurological changes associated with herniation, recurrent or progressive stroke, or complications such as seizures. Seizures occur in a small percentage (<5%) of patients after an ischemic stroke. Anticonvulsant medications should be initiated if a seizure occurs.

Lower extremity deep venous thrombosis in the hemiparetic limb is common if prophylaxis is not initiated. The risk of venous thromboembolism persists into the post-stroke period {Brandstater et al. 1992). If there are no contraindications, low-dose subcutaneous unfractionated heparin at a dosage of 5000 units twice a day or low-molecular weight heparin is used. If heparin is contraindicated, intermittent pneumatic compression of the lower extremities is recommended. Prophylactic doses of heparin can safely be given to patients receiving aspirin.

The patient's nutritional status and fluid requirements should be assessed. Patients with a large ischemic stroke may need a fluid restriction of two-thirds maintenance during the first few days. Swallowing function should be assessed before intake of fluid or food is initiated. Patients who have significant oropharyngeal dysfunction require parenteral or tube feeding.

Although urinary incontinence is not uncommon in **the** acute phase of stroke, indwelling catheters should be placed only if absolutely necessary and should be removed at the earliest possible time to avoid urosepsis. The chronic use of an indwelling catheter should be limited to patients with incontinence or urinary retention that is refractory to other treatments. In the presence of an indwelling catheter, treatment of asymptomatic bactcriuria is usually not indicated. However, for significant clinical infections with pyuria and fever, treatment is recommended.

Approximately 15% of patients develop pressure sores after a stroke. Steps to avoid this complication include frequent inspection of the skin, skin cleansing, frequent turning, use of special mattresses and protective dressings, maintaining adequate nutritional status, and trying to improve the patient's mobility early on.

One of the most common causes of injury to the patient with a stroke is falling. Assessments of the risk for falling should be made at regular intervals during the acute hospitalization and also during the chronic rehabilitation phase. Reduction of postprandial SBP has been associated with a higher incidence of falls and syncope. Measures should be instituted to minimize the risk of falls,

Shoulder subluxation can occur in hemiplcgic patients. Chronic sequelae can be minimized if therapy is initiated before severe restriction of movement develops.

Rehabilitation after stroke begins as soon as the diagnosis of stroke is established and as soon as any life-threatening neurological or medical complications have been stabilized (see Chapter 54). Patients are screened to evaluate whether they are candidates for rehabilitation. The criteria used to make this decision, including the stroke survivor's clinical and neurological status and social and environmental factors, are complex (Post-Stroke Rehabilitation Cuideline Panel 1995). The available evidence on the effectiveness of rehabilitation suggests that rehabilitation is beneficial to some patients, but the superiority of one type or the characteristics of patients most likely to benefit are not clear.

Depressive symptoms are common after stroke, occurring in more than 25% of patients. Stroke patients should be questioned and screened for depression. Depression is more common following left hemispheric infarcts, especially in the frontal lobe, possibly caused by disruption of catecholamine pathways. Treatment with antidepressants is often successful in ameliorating symptoms.

CEREBRAL VENOUS THROMBOSIS

Intracranial sinovenous occlusive disease is an infrequent condition with a variety of causes. The increasing

recognition of this condition is probably because of an enhanced clinical awareness and the use of MRI. Intracranial venous thrombosis can be aseptic or septic. Septic intracranial venous thrombosis (resulting from skull osteomyelitis, suppurative infections of the inner ear, and erysipelas) is relatively infrequent in modern times, and **most** often involves the cavernous sinus. Cavernous sinus thrombosis is typically a complication of a facial or orbital infection and often presents with proptosis, chemosis, and painful ophthalmoplegia. Septic lateral sinus thrombosis is an infrequent complication of otitis media or mastoiditis and often presents with headaches, fever, otalgia, vertigo, papilledema, and abducens nerve palsy (Figure 57A.22).

Aseptic intracranial venous thrombosis is divided into dural venous sinus thrombosis, deep venous thrombosis, and superficial or cortical vein thrombosis. The superior sagittal sinus is most frequently involved (Figure 57A.23). Causal factors are protean and the onset often insidious. The most common causa! factors are listed in Table 57A.12. However, in approximately 20% of cases, no cause is found (Bousser ct al. *1997).* Although rare, cerebral venous thrombosis is a well-recognized disorder in children,

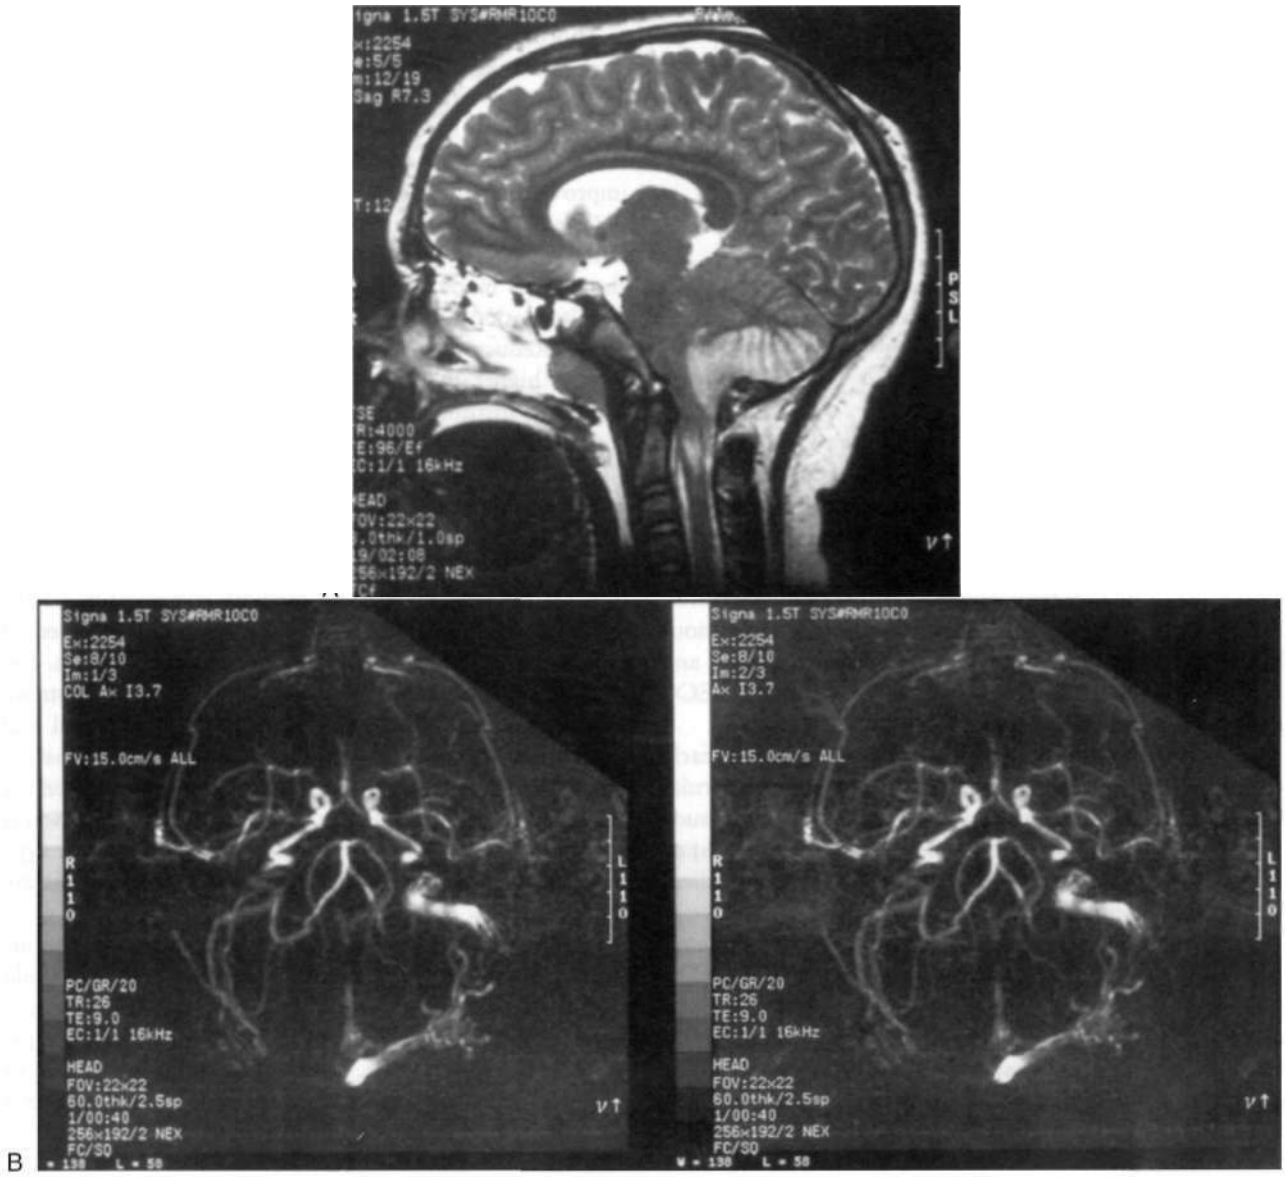

FIGURE 57A.22 A 10-year-old girl with otomastoiditis was evaluated hecause of unresponsiveness. Magnetic resonance imaging shows areas of increased signal in the right cerebellum greater than the left cerebellum, consistent with infarctions. The cerebellar tonsils are herniated. (A) Associated edema occurs in the superior cervical cord and inferior medulla. Phase contrast magnetic tesonance angiographical images demonstrate lack of flow in the straight sinus and the right transverse sinus. Only a small amount of signal in the region of the right sigmoid and internal jugular vein is seen. (B) Some arterial flow is represented in the examination.

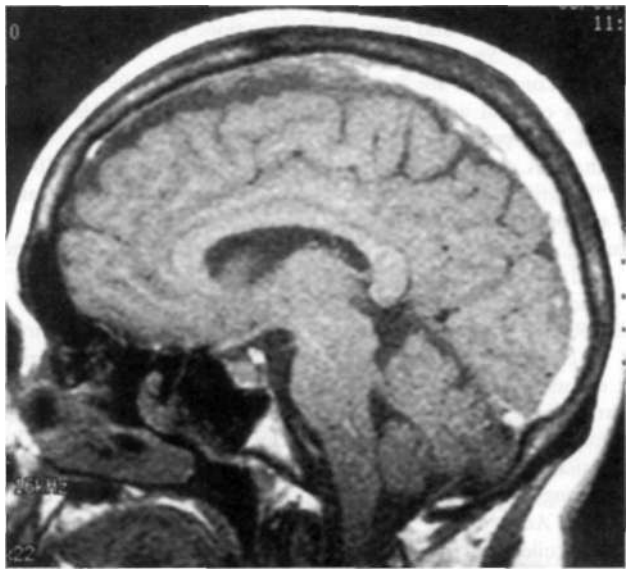

FIGURE 57A.23 Unenhanced sagittal Tl-weighted magnetic resonance imaging shows an area of increased signal and enlargement of the superior sagittal sinus throughout most of its course consistent with superior sagittal sinus thrombosis. It also involves the region of the torcula.

with approximately half of the cases occurring in neonates and young infants (deVeber et al. 1998).

Intracranial venous thrombosis may occur at any time from infancy to old age, but most reported modern cases have been in adult women in association with the pucrperium. Onset of symptoms may be acute, subacute, or chronic. Cerebral venous infarction is the most serious consequence of cerebral venous thrombosis. Intracranial venous thrombosis should be considered a potential cause for pseudotumor cerebri or unexplained hemorrhagic infarctions. Venous infarctions are often multifocal and bilateral, affecting both the gray matter and the subcortical white matter. Evidence of cerebral edema is unusual. Cerebral venous thrombosis may present without focal signs. Chief complaints arc headaches, vomiting, transient visual obscurations, focal or generalized seizures, lethargy, or coma. Papilledema is common. There may be alternating focal deficits, hemiparesis or paraparesis, or other focal neurological deficits according to the location of the venous structure involved. Salient radiological features are the presence of low-density areas of infarction, hemorrhages, and small ventricles. There may be visualization of thrombus within the sinus on postcontrast images (empty-delta sign) or direct visualization of the clot. The availability of MR venography makes it possible to diagnose early and atypical cases. MR venography is a reliable diagnostic tool and has replaced angiography for the diagnosis of cerebral venous thrombosis. Patients with intracranial venous occlusive disease should be screened for thrombophilia.

Accepted therapeutic measures include reduction of increased intracranial pressure, prophylactic anticonvulsants, and antibiotics in cases involving a septic causal factor. Most recent reviews on the subject recommend heparin anticoagulation followed by warfarin for the treatment of intracranial venous thrombosis. The efficacy of heparin has been shown, even in patients who have evidence of some intracranial hemorrhage by neuroimaging studies (Einhaupl ct al. 1991; Ameri et al. 1992).

Table 57A.12: Causes of intracranial sinovenous occlusive disease

Facial/orbital/paranasal sinuses/middle ear infections
Ptegnaney and pucrperium
Carcinoma
Dehydration
Matasmus
Sqisi>
Acute lymphoblastic leukemia

Chapter 57
Vascular Diseases of the Nervous System

B. INTRACEREBRAL HEMORRHAGE

Carlos S. Kase

Intracerebral hemorrhage (ICH) accounts for approximately 10% of strokes. Its clinical importance derives from its frequency and high mortality. Although the latter is strongly dependent on hematoma size and, to a lesser extent, location, the overall mortality for this stroke subtype varies between 25% and 60%. There has been a general decline since the 1980s in the incidence of stroke, including ICH, as a result of improved detection and treatment of hypertension. However, ICH continues to be a major public **health** problem, especially in populations at high risk, such as young and middle-aged blacks and Hispanics, in whom this stroke subtype occurs significantly more frequently than in whites, and the medically indigent who lack hypertension treatment. A growing body of evidence suggests that genetic factors, such as the possession of the 2 and 4 alleles of the apolipoprotein I., play an important role in the occurrence of certain forms of ICH, such as lobar hemorrhages (O'Donnell et al. 2000), Finally, the management of **ICH** is controversial because the value of surgical or nonsurgical treatment of the various types of ICH has not been defined by properly designed prospective clinical trials.

MECHANISMS OF INTRACEREBRAL HEMORRHAGE

Hypertension

The main cause of ICH is hypertension. The primary role of hypertension in ICH is supported by a high frequency (72-81%) of history of hypertension, significantly higher admission blood pressure measurements as compared with patients with other stroke subtypes, and a high frequency of left ventricular hypertrophy.

Broderick et al. *{\993),* studying 188 patients with primary ICH (i.e., with exclusion of patients with hemorrhage associated with ruptured arteriovenous malformations |AVMsj, tumor, anticoagulant and thrombolytic therapy, and cocaine ingestion), determined the cause to be hypertension in 72% of patients. Further support for the importance of hypertension in the pathogenesis of ICH is the steady increase in ICH incidence with advancing age, which is associated also with an increase in the prevalence of hypertension. The role of hypertension as a cause of **ICH** is most relevant for the nonlobar locations, which may be due to hypertension in approximately 50% of the cases (Woo et al. 2002). In both hypertensive and nonhypertcnsive patients, the circadian rhythm of ICH onset, with peaks at 8 AM and 8 PM (Casetta et al. 2002), coincides with the physiological daily peaks of blood pressure, pointing to the importance of blood pressure rises in the pathogenesis of ICH.

The actual vascular lesion produced by chronic hypertension that leads to arterial rupture and ICH is probably lipohyalinosis of small intraparenchymal arteries (Caplan 1994a). The role of microaneurysms of Charcot and Bouchard is uncertain, although their anatomical location at sites preferentially affected by ICH supports their causal importance. The nonhypertensivc causes of ICH are listed in Table 57B.1.

Table 57B.1: Non hypertensive causes of intracerebral hemorrhage

Vascular malformations (saccular or mycotic aneurysms, arteriovenous malformations, cavernous angiomas)
Intracranial tumors
Bleeding disorders, anticoagulant and fibrinolytic treatment

Sympathomimetic agents (including amphetamine and cocaine)
Hemorrhagic infarction
Trauma

Vascular Malformations

Because a detailed discussion of intracranial aneurysms and AVMs (see Chapters 57C and 57D) is provided elsewhere, we limit the analysis here to the role of small vascular malformations in the pathogenesis of ICH. These lesions are often documented either by magnetic resonance imaging (MRI), by pathological examination of specimens obtained at the time of surgical drainage of ICHs or at autopsy. However, cerebtal angiography also plays an important role in the diagnosis of these lesions. In a group of 38 young ICH paricnts (mean age, 46 years) subjected to angiography, Halpin et al. *(1994)* documented AVMs in 23 patients and aneurysms in *9* (a total of 32 of 38, or 84%). The ICH in these 38 patients had computed tomographic (CT) characteristics suggestive of an underlying structural lesion (associated subarachnoid or intraventricular bleeding, calcification, prominent vascular structures, atypical ICH location). However, in a group of 42 patients lacking these CT features, angiography still documented vascular abnormalities in 10 (AVMs in 8, aneurysm in 2).

ICHs caused by small AVMs or cavernous angiomas arc frequently located in the subcortical white mattet of the cerebral hemispheres. The clinical presentation of the ICH in this setting has a few distinctive characteristics. The hematoma is generally smaller and symptoms develop more slowly compared with hypertensive ICH. The presence of associated subarachnoid hemorrhage on CT scan suggests an aneurysm or AVM as the cause in a case of lobar ICH. In addition, those ICHs associated with small vascular malformations generally tend to occur in younger patients when compated with those with hypertensive ICH, and have a female preponderance.

Cavernous angiomas are being increasingly recognized as a cause of ICH in the subcortical portions of the cerebral hemispheres and in the pons, as a result of the high diagnostic yield of MRI. This technique demonstrates a characteristic pattern on T2- weigh ted images, with a central nidus of irregular bright signal intensity mixed with mottled hypointensity. surrounded by a peripheral hypointense ting corresponding to hemosidctin deposits

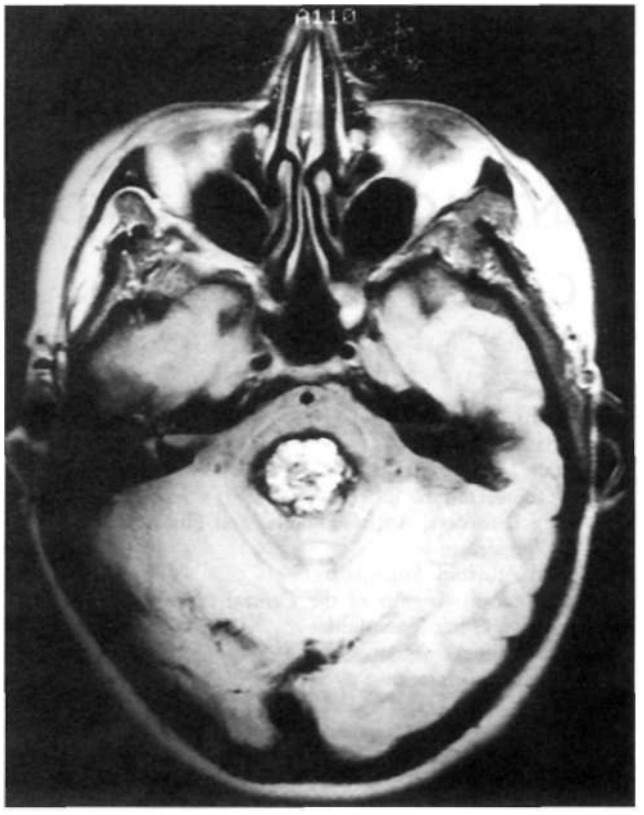

FIGURE .S7B.1 Magnetic resonance imaging (proton density) of large cavernous angioma of the midpons in axial view, showing mixed signal central nidus with peripheral hemosiderin ring.

(Figure 57B. 1), reflecting previous episodes of bleeding, These lesions are predominantly supratentorial, favoring the temporal, frontal, and parietal lobes, whereas the less frequent infratentorial locations favor the pons. They ate generally single lesions, but multiplicity is not uncommon, especially in patients with familial cavernous angiomas. The latter is common among individuals of Mexican-American descent, in whom cavernous angiomas are inherited in an autosomal dominant pattern, linked to a mutation in chromosome 7q. Their clinical presentation is with cithct seizures (27-70%), ICH (10-30%), or progressive neurological deficits *(35%).* Seizures are the most common ptesenting feature of supratentorial cavernous angiomas; ICH occurs in both the supratentorial and infratentorial varieties; and progressive neurological deficits arc a more common presentation of postetiot fossa (especially pontine) malformations. A progressive course, caused by recurrent small hemorrhages within and around the malformation, can evolve over protracted periods, at times suggesting a diagnosis of multiple sclerosis or a slowly growing brainstem glioma.

A clinical profile thus can be suggested for cases of ICH caused by small vascular malformations. These occur in generally young, predominantly female patients, who present with a syndrome of lobar ICH in which

CT scan can document a superficial lobar hematoma with adjacent local subarachnoid hemorrhage or MRI demonstrates the characteristic features of a small AVM or cavernous angioma. Lack of documentation of the vascular malformation on angiography is not uncommon, and definite diagnosis requires cither MRI or the histological examination of a sample of the hematoma and its wall.

Intracranial Tumors

Bleeding into an underlying brain tumor is relatively rare in series of patients presenting with ICH, accounting for less than 10% of the cases. The tumor types most likely to lead to this complication are glioblastoma multiforme or metastases from melanoma, bronchogenic carcinoma, choriocarcinoma, or renal cell carcinoma (Figure 57B.2}. The ICHs produced in this setting may have clinical and imaging characteristics that should raise the suspicion of an underlying brain tumor, including (1) the presence of papilledema on presentation; (2) the location of ICH in sites that are rarely affected in hypertensive ICH, such as the corpus callosum, which in turn is commonly involved in malignant gliomas; (3) the presence of ICH in multiple sites simultaneously; (4) a CT scan characterized by a ring of high-density hemorrhage surrounding a low-density center in a noncontrast study; (5) a disproportionate amount of surrounding edema and mass effect associated with the acute hematoma (Figure 57B.3); (6) enhancing nodules adjacent to the hemorrhage on contrast CT scan; and (7) an MRI pattern of heterogeneous signal changes within a mass lesion, surrounded by a hemosiderin hypointense ring and bright signal edema at the periphery on T2-weighted sequences. In these circumstances, a search for a primary or metastatic brain tumor should follow, including evaluation for systemic malignancy and, if there is none, cerebral angiography, and eventually craniotomy for biopsy of the wall of the hematoma cavity. The confirmation of the diagnosis of ICH secondary to malignant brain tumor carries a dismal prognosis, with a 30-day mortality in the 90% range.

Bleeding Disorders, Anticoagulants, and Fibrinolytic Treatment

Bleeding disorders caused by abnormalities of coagulation are rare causes of ICH. Hemophilia caused by factor VIII deficiency leads to ICH in approximately 2.5-6.0% of patients, one half with ICH and one half with subdural hematomas. The majority of these hemorrhages occur in young patients, generally younger than age 18, and their mortality is high, on the order of 10%. for subdural hematomas and 65% for ICH. Immune-mediated thrombocytopenia, especially idiopathic thrombocytopenic purpura, is associated with life-threatening ICH in approximately 1% of patients. Bleeding can occur when the platelet count drops below 10,000/ul, and the hemorrhages may occur anywhere in the brain. Acute leukemia, especially the acute lymphocytic vatiety, is a common cause of ICH that favors the lobar white matter of the cerebral hemispheres. The occurrence of ICH frequently coincides with systemic bleeding, mostly mucocutaneous and gastrointestinal. These bleeding complications of acute lymphocytic leukemia ate often accompanied by both thrombocytopenia (platelet counts of 50,000/uL or less) and rapidly increasing numbers of abnormal circulating leukocytes of 300,000/uL, or more (blastic crisis). Acute promyelocytic leukemia, a variant of acute myelogenous leukemia, has a particular propensity to produce ICH as a result of disseminated intravascular coagulation, caused by the release of a procoagulant factor from the promyelocyte granules.

Treatment with oral anticoagulants increases the risk of ICH by eight- to 11-fold, in comparison with non-anticoagulated individuals with otherwise similar risk factors for ICH. Anticoagulant-related cases account for 9-11% of ICHs. Potential risk factors for intracranial bleeding in anticoagulated patients include advanced age, hypertension, preceding cerebral infarction, head trauma, and excessive prolongation of the prothrombin time. The latter factor plays a major role in the pathogenesis of ICH in patients receiving oral anticoagulants. In the secondary stroke prevention trial Stroke Prevention in Reversible Ischemia Trial (SPIRIT), 651 patients assigned to warfarin were maintained at an international normalized ratio (INR) of 3.0-4.5, resulting in 24 instances of ICH (14 fatal), in comparison with three ICHs (one fatal) in the gtoup of 665 patients treated daily with 30 mg of aspirin (The Stroke Prevention in Reversible Ischemia Trial Study Group 1997), These data further support the recommendation that oral anticoagulation in patients with cerebrovascular disease should aim at an INR of 2-3 to reduce the frequency of this complication. The presence of severe leukoaraiosis on CT scan is an additional factor that independently increases the risk of ICH in patients on oral anticoagulants (Smith et al. 2002).

These hemorrhages have certain distinctive clinical characteristics. They tend to present with a slowly progressive course, at times over periods as long as 48-72 hours, in contrast with the usually more rapidly evolving p resell rati on of hypertensive ICH. Ik-cause of this longer course, hematomas in anticoagulated patients tend to reach volumes that are, on average, larger than those of hypertensive ICH, in turn resulting in the higher mortality of approximately 65%. Signs of systemic bleeding rarely accompany ICH. Anticoagulant-related ICH may represent bleeding from vessels different from those involved in ICH of hypertensive origin (Hart ct al. 1995). Certain angi opathics with bleeding potential, such as cerebral amyloid angiopathy (CAA), may play a causal role in the ICHs that

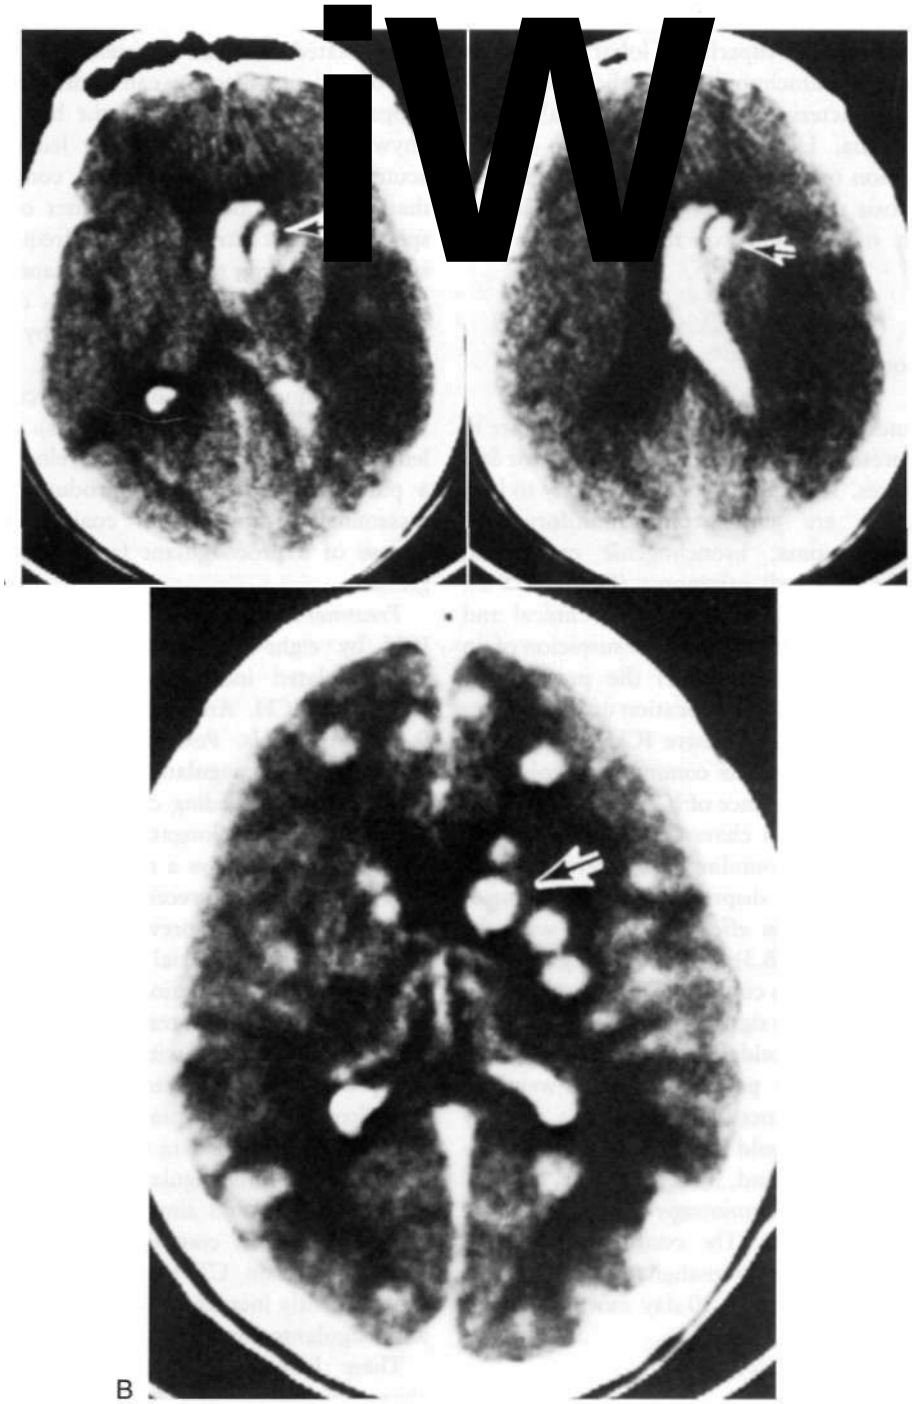

FIGURE 57B.2 (A) I ietnorrhage in the head of the left caudate nucleus *{arrow)*, with extension into the lateral ventricle. Also shown is an unrelated old infarct in the left middle cerebral artery distribution. Noncontrast computed tomographic (CT) scan. (B) 1'ostcontrast infusion CT scan of the same case, showing multiple enhancing metastases from bronchogenic carcinoma. The lesion shown in the area of the head of the caudate nucleus *(arrow)* was related to the hemorrhage shown in A.

occur in patients treated with anticoagulants (Rosand et al. 2000).

In addition to the anticoagulants, other substances with the potential for altering clot formation mechanisms are occasionally associated with ICH. These include *drugs with fibrinolytic properties* such as streptokinase and tissue-type plasminogen activator (t-PA). The use of t-PA for coronary thrombolysis in the early phases of myocardial infarction has been associated with a small (approximately 0.5-0.6%) risk of ICH with the currently recommended dose of lOOmg.

FIGURE 57B.3 Noncontrast computed tomographic (CT) scan of acute left putanunal intracerebral hemorrhage (CTdone3 hours after symptom onset) with a large amount of surrounding hypodensity edema and mass effect. Biopsy of tissue adjacent to the hemorrhage .11 the time nt surgical drainage revealed typical features of gliobastoma multiforme.

There is evidence to suggest that this complication of thrombolytic therapy may be favored by pre-existcnt vasculopathies with bleeding potential, such as CAA. The role of other factors, such as the simultaneous use of heparin anticoagulation and aspirin to prevent coronary reocclusion, is uncertain.

Recombinant t-PA for the treatment of acute ischemic stroke was complicated with ICH in 6.4% of cases (The National Institute of Neurological Diseases and Stroke [NINDS] rt-PA Stroke Study Group 1995}, which is 10 times higher than in untreated patients. Risk factors for ICH in this setting include a severe neurological deficit at presentation and documentation of hypodensity or mass effect on CT before treatment (The NINDS t-PA Stroke-Study Group 1997). Intra-artcrial thrombolysis of middle cerebral artery occlusion with prourokinase leads to improved clinical outcomes, but is associated with an 11% rate of early symptomatic ICH (Furlan et al. 1999). These hemorrhages occur at the site of the preceding cerebral infarct, are generally large (Figure 57B.4), and carry a dismal prognosis (Kase et al. 2001). Hyperglycemia at pretreatment baseline has been identified as a potential risk factor for ICH in patients treated with either intra-arte rial prourokinase (Kase ct al. 2001) or intravenous t-PA (Bruno et al. 2002}. Another potential risk factor for ICH after intraarterial thrombolysis is the presence of incidental "microhemorrhages" (Figure 57B.5), which can be easily detected with gradient-echo (or "susceptibility-weighted") MRI sequences (Kidwell et al. 2002).

Cerebral Amyloid Angiopathy

CAA is characterized by selective deposition of amyloid in cerebral vessels, primarily small and medium-sized arteries of the cortex and leptomeninges. Because the frequency of CAA increases steadily with age, reaching 60% in unselected autopsies of individuals older than 90 years, it characteristically causes ICH in the elderly and is rarely documented before the age of 55 years. In addition, the superficial location of the affected vessels in the cortex and leptomeninges is responsible for a predominantly lobar location of the ICHs. The widespread character of the angiopathy is responsible for the observation of both recurrent and multiple simultaneous, predominantly lobar hemorrhages in elderly patients. An additional characteristic of CAA is its association with histopathological features of Alzheimer's disease. There is clinical and progressive dementia in 10-30% of patients with CAA, and neuritic plaques in approximately 50% of the cases. CAA may present with features other than ICH, such as episodes of transient focal neurological deficit clinically suggestive of either transient ischemic attacks or partial seizures. These often occur days, weeks, or months before the episode of major lobar ICH and may correspond to small foci of hemorrhage that may be documented at multiple cortical sites by gradient-echo MRI sequences.

The histological lesion in CAA is deposition of Congo red-positive, birefriugent amyloid material in the media and adventitia of small cortical and leptomeningeal arteries. The actual mechanism of rupture of an affected artery may be either a weakening of the wall or the formation of microaneurysms at sites of amyloid deposition, particularly when hypertensive fibrinoid necrosis develops in the same location. Other conditions may combine with CAA to produce rupture of affected vessels, including head trauma, neurosurgical procedures, concomitant granulomatous angiitis of the central nervous system (CNS), and use of anticoagulant and fibrinolytic agents.

Granulomatous Angiitis of the Central Nervous System and Other Vasculitidcs

Granulomatous angiitis of the CNS, also referred to as *isolated angiitis of the CNS,* is characterized by

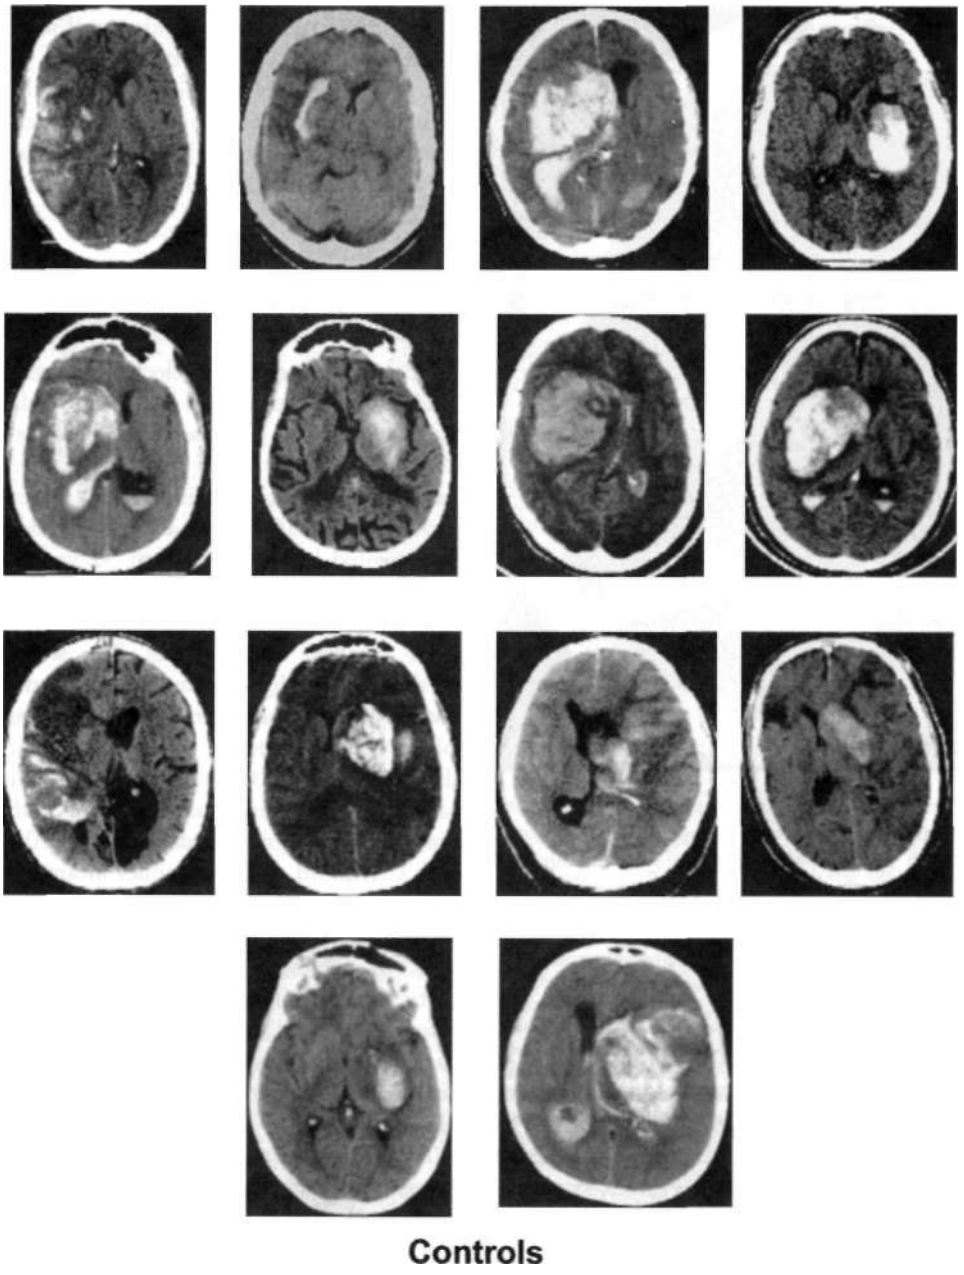

FIGURE 57B.4 Symptomatic intracerebral hemorrhages after infra-arterial thrombolysis of middle cerebral artery occlusion with pmurokinase. (Repriuti'd will) pinimMon from k.tse, C S., 1'mhn, A. |., WVdisli/r, 1, K„ el al. 200], "Cerebral lu-inorrliane after intra-arterial thrombolysis for ischemic stroke: The PRO ACT II trial," *Neurology,* vol. 57, pp. 1603-1610.)

mononuclear inflammation with giant cell formation in the media and adventitia of small and medium-sized intracraniaI arteries and veins (see Chaptet 57G). An associated element of intimal hyperplasia leads frequently to cerebral infarcts and occasionally ICH.

Among the vasculitides, the other variety that is known to present with ICH is polyarteritis nodosa. As opposed to granulomatous angiitis of the CNS, this form of necrotizing vasculitis depicts prominent signs of systemic involvement, including fever, malaise, weight loss, anemia, elevated sedimentation rate, and renal impairment with hypertension (see Chapter 55A),

Sympathomimetic Agents

Amphetamines cause ICH after intravenous, oral, or intranasal use (see Chapter 64B). The hemorrhages have occurred within minutes to a few hours after drug use, and the majority has been located in the subcortical white

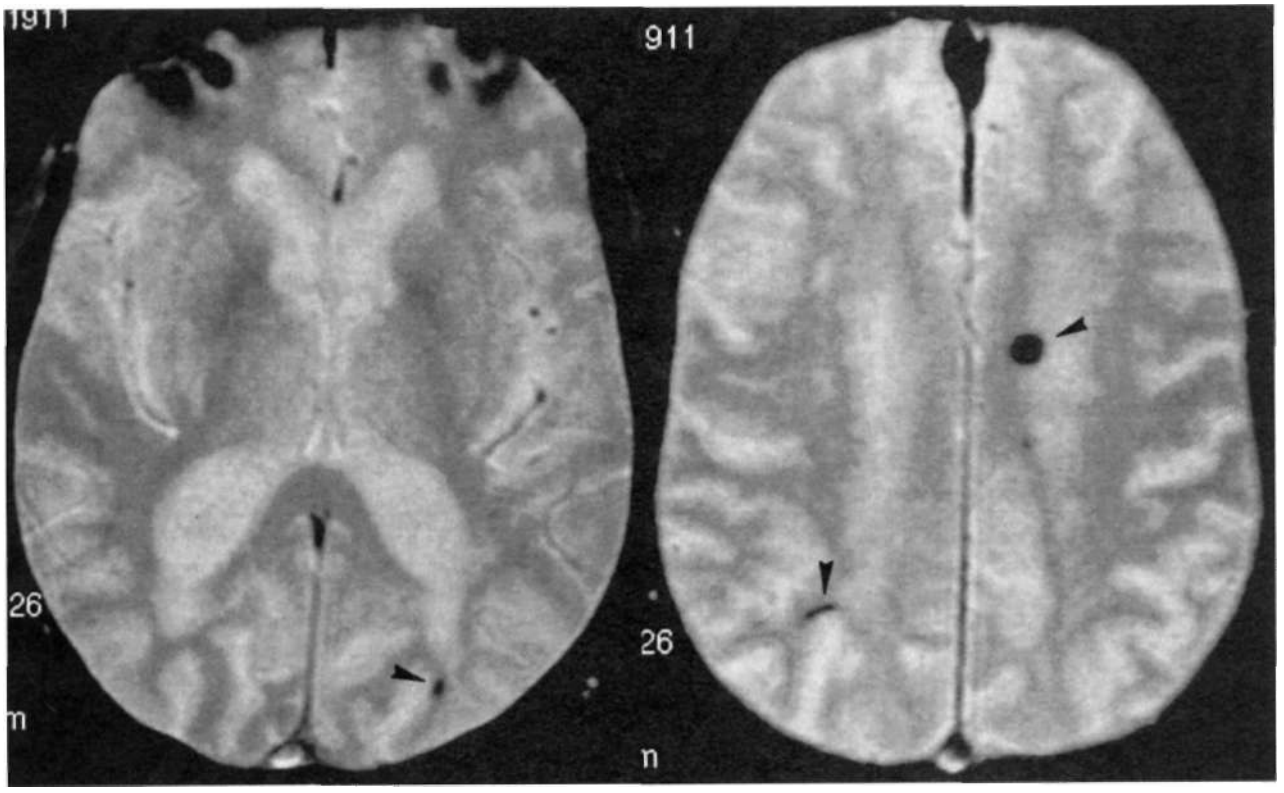

FIGURE 57B.5 Cortical microhcmorrhages *(arrowheads)* on gradient-echo magnetic resonance imaging scan.

matter of the cerebral hemispheres. In approximately one half of the reported cases, transient hypertension has been documented, as well as multifocal areas of spasm and dilatation (beading) of intraeniin.il arteries on angiography. Although the latter is frequently referred to as a *vasculitis* or *arteritis,* histological proof is lacking, and this angiographic picture probably represents multifocal spasm secondary to the drug. The decongestant and appetite-suppressant phenylpropanolamine has been associated with ICH in young patients (median age in the early 30s), predominantly women (Kernan et al. 2000), usually without a history of hypertension but with acute hypertension on admission in one third of patients. Beading of intracranial arteries is frequent on angiography.

Cocaine (see Chapter 64B) has become the most common sympathomimetic agent associated with ICH. Both ICH and subarachnoid hemorrhage can occur within short periods (generally minutes) of the use of both the alkaloidal (free-base) form of cocaine and its precipitate form known as *crack.* The ICHs favor the subcortical white matter, but occasionally occur in the deep portions of the hemispheres (Figure 57B.6). **There** may be multiple simultaneous ICHs, both deep and superficial, the mechanism of which remains unknown. In some instances, the origin of the ICH can be traced to a coexistent AVM or aneurysm, whereas the remainder are probably associated with either cocaine-induced vasoconstriction followed by reperfusion,

Table 57B.2: Differences between intracerebral hemorrhage and hemorrhagic infarction

	Intracerebral hemorrhage	*Hemorrhagic infarction (embolic)*
Clinical		
Onset	Sudden, followed by progression	Maximal from onset
Raised intracranial pressure	Prominent	Absent
Embolic source	No	Yes
Computed tomographic scan		
High attenuation	Dense, homogeneous	Spotted, mottled
Mass effect	Prominent	Absent or mild
Location	Subcortical, deep (gray nuclei)	Cortex more than subcortical white matter
Distribution	Beyond arterial territories	Along branch distribution
Late enhancement	Ring-type	Gyral-typc
Ventricular blood	Yes	No
Magnetic resonance imaging*		
Hypointcnse blood (T2}	Homogeneous	Patchy, mottled
Hyperintense edema (T2)	Thin peripheral halo	Extensive, in vascular territory
Angiogram/magnecic resonance angiography	Mass effect (avascular)	Branch occlusion

^Magnetic resonance imaging depicts the same features as computed tomographic (CT) scanning in regard to mass effect, location, distribution, late enhancement, and ventricular blood. This table lists only the features that magnetic resonance imaging adds to those of CT.

heavy alcohol intake, or rarely, a drug-induced cerebral vasculitis.

Hemorrhagic Infarction

Hemorrhagic infarction is pathologically and pathogenic-.illy different from 1CH in that it results from arterial or venous occlusion, rather than from the vascular rupture that causes 1CH, As a result, its pathological aspect is one of multifocal petechial hemorrhagic staining of an area of the brain primarily affected by ischemic necrosis (i.e., infarction). Hemorrhagic infarction characteristically occurs in the setting of cerebral embolism or, less frequently, cerebral infarction secondary to venous occlusion (e.g., superior sagittal sinus thrombosis); in both, the bleeding reflects the mechanism of the infarct and is not the result of therapeutic measures such as anticoagulant drugs.

Clinical differences between hemorrhagic infarction and ICH usually permit their clear distinction (Table 57B.2), but severe and confluent foci of hemorrhagic infarction may be difficult to distinguish from foci of primary ICH.

Trauma

ICH caused by cerebral contusion characteristically occurs in the surface of the btain, because its mechanism is one of direct brain trauma against its bony covering at the time of an acceleration-deceleration head injury (see Chapter 56A), This explains the sites of predilection for traumatic brain hemorrhages in the basal frontal, anterior temporal, and occipital areas, resulting from the coup and contrecoup mechanisms. Thus traumatic brain hemorrhages are frequently multiple.

CLINICAL FEATURES OF INTRACEREBRAL **HEMORRHAGE**

The clinical presentation of ICH has two main elements: symptoms that reflect the effects of intracranial hypertension, and those that are specific for the location of the hematoma. The general clinical manifestations of ICH related to increased intracranial pressure (ICP) (headache, vomiting, and depressed level of consciousness) are variable in their frequency at onset of ICH. The correlation of these symptoms, especially abnormal level of consciousness, with hematoma size applies to all anatomical varieties of **ICH,** which, in turn, relates directly to mortality.

A characteristic of ICH at presentation is the frequent progression of the focal neurological deficits over periods of hours. This early course reflects the progressive enlargement of the hematoma (Figure 57B.7), which at times amounts to volume increments of more than 300%, as measured by serial CT scans (Brott et al. 1997). Seizures at the time of presentation of ICH are rare, except for lobar ICH, in which they occur in as many as 28% of patients. The subcortical hemorrhage probably creates an area of partially isolated cortex, which reacts with sustained paroxysmal activity.

The CT scan is sensitive to the high-density fresh blood in the brain parenchyma, along with associated features of local mass effect and ventricular extension. MRI adds further precision, especially in determining the time elapsed

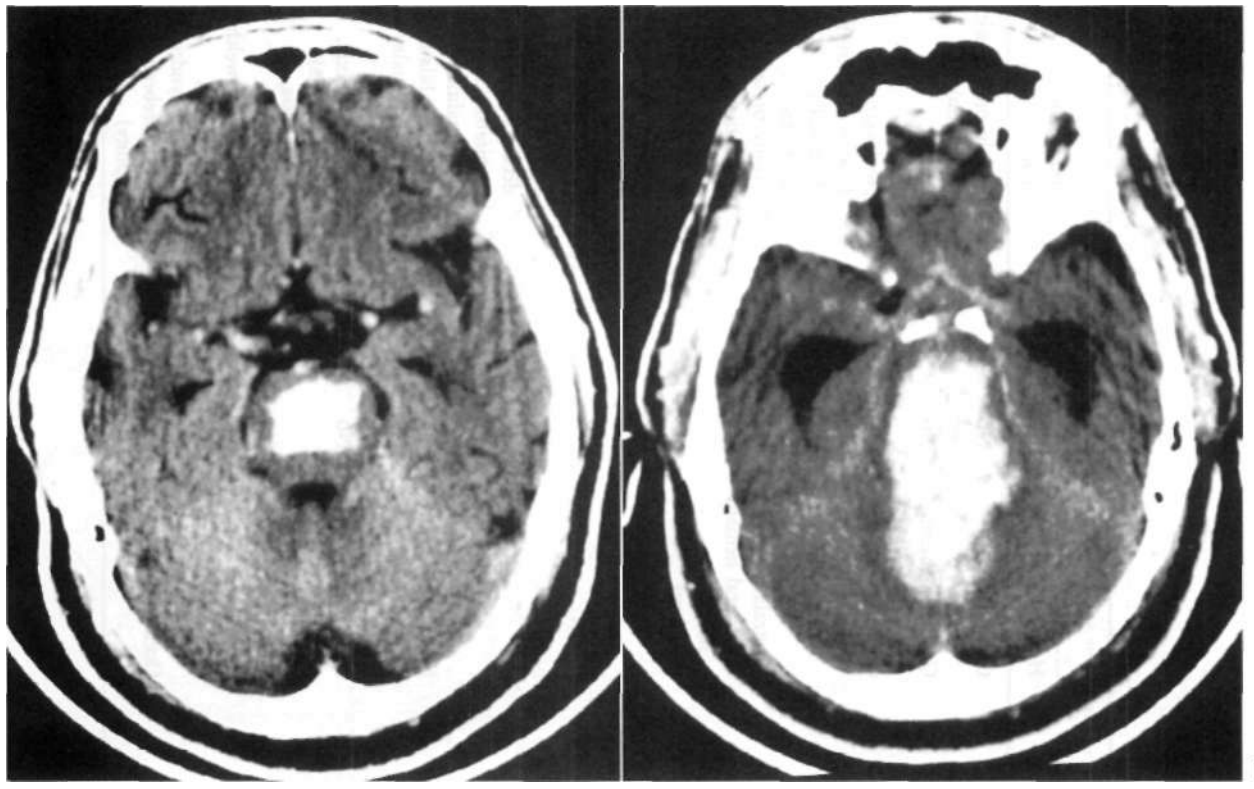

FIGURE 57B.7 (A) Basal-tegmental pontine hemorrhage at the time of admission. (B) Massive enlargement of hemorrhage with extension into the fourth ventricle and hydrocephalus of temporal horns, 6 hours later.

Tabic 57B.3: Temporal changes in magnetic i esonance imaging features of intracerebral hemorrhage

		Magnetic resonance imaging signal intensity	
Stage of intrai-.erebral hemorrhage	*Type of hemoglobin*	*T1 -weighted*	*Tl-wcighted*

Same = equal signal with surrounding brain; - hypointense to brain; + = hyperintense to brain; : marked hypointensity; ++ = marked hyperintensity.

between onset and time of MRI examination. The type of signal intensity change depicted by Tl- and T2-weighted MRI sequences can be correlated with the hyperacute, acute, subacute, and chronic stages of evolution of an intracerebral hematoma (Table 57B.3).

The physical examination findings that relate to the different anatomical locations of ICH are summarized in Table 57B.4.

Putaminai Hemorrhage

The most common variety of ICH, putaminai hemorrhage, represents approximately *35%* of the cases (Kase et ah 1998) (Figure 57B.8). A wide spectrum of clinical severity relates to hematoma size, from minimally symptomatic cases presenting with pure motor hemiparcsis, or slight hemiparesis and dysarthria, to the extreme of coma with decerebrate rigidity in instances of massive hematomas with rupture into the ventricles. Modern CT scan series of putaminai hemorrhage document a mortality of 37%, in contrast to 65-75% from pre-CT data. This difference reflects the description of the full spectrum of hematoma size in recent reports, including smaller hematomas with benign outcomes, which were misdiagnosed as infarcts in the pre-CT scan era.

Ventricular extension carries an invariably poor prognosis in putaminai hemorrhage. This feature in part reflects

Table 57B.4: Clinical features of anatomical forms of intracerebral hemorrhage

Type of intracerebral hemorrhage	*Hemiplegia*	*Hemisensory syndrome*	*Aphasia*	*Homonymous visual defects*	*G*
					Horizontal
Putaminal	Generally dense	Frequent	Global > motor > conduction	In larger hematomas	Contralateral
Caudate	Absent or mild, transient	Absent	No	No	Generally absent
Thalamic	Generally dense	Frequent, prominent	Occasional, thalamic variety	In larger hematomas	Contralateral, occasionally ipsi lateral
Lobar	Prominent in frontoparietal location	Prominent in fronto-parietal location	In dominant temporoparietal location	In occipital hematomas	Contralateral in frontal hematomas
Cerebellar	Absent	Absent	N<.	No	Ipsi lateral
Pontine	Variable, usually bilateral	Variable, usually bilateral	No	No	Bilateral
Mesencephalic	Variable, usually present	Rare	No	No	No
Medullary	Generally absent	Occasional	No	No	No
Intraventricular	Generally absent	Rare	No	No	Occasional

FIGURE 57B.8 Right putaminal hemorrhage.

the larger size of hematomas that track from the laterally placed putamen to the medially placed ventricular system.

Caudate Hemorrhage

Caudate hemorrhage is a rare variety of ICH that accounts for only approximately 5% of the cases (Kase et ah 1998) (Figute 57B.9). It results from rupture of penetrating arteries from the anterior and middle cerebral arteries, and its most common cause is hypertension. Presentation is similar to that of subarachnoid hemorrhage in that the clinical picture is dominated by signs of intracranial hypertension and meningeal irritation, with focal neurological deficits (hemiparesis, horizontal gaze palsy, Homer's syndrome) being minimal and transient, or altogether absent. The main differential diagnosis of caudate ICH is ruptured anterior communicating artery aneurysm with bleeding through the septum pellucidum into the ventricular system. In this instance, CT scan shows blood in the inter/hemispheric fissure and in the lowermost frontal cuts, as opposed to the higher location of the unilateral clot in the head of one caudate nucleus in primary caudate ICH. Ventricular extension of the hemorrhage is a regular feature in caudate ICH, and hydtoccphalus is usually present. Nevertheless, the outcome is generally good. The majority of patients recover without neurological sequelae, because

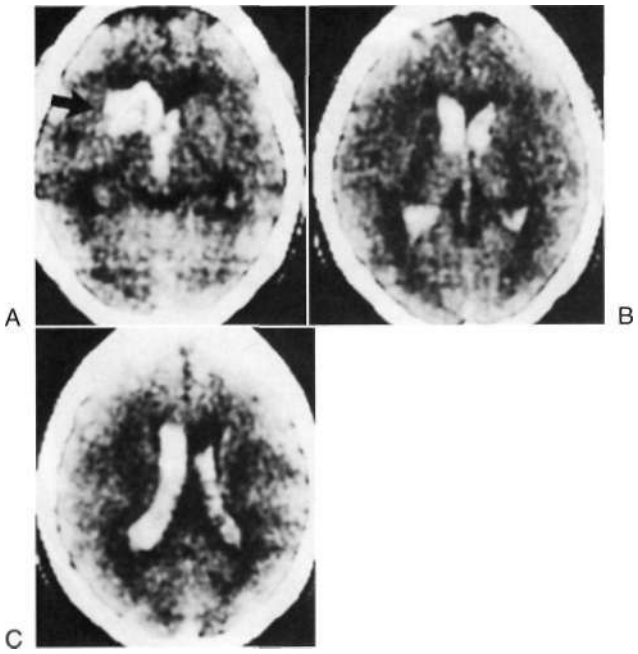

FIGURE S7B.9 Right caudate hemorrhage *(arrow)* (A), with extension into the lateral and third ventricles (A-C).

this type of ICH causes minimal parenchymal destruction, as compared with other forms of supratentorial ICH.

Thalamic Hemorrhage

Thalamic hemorrhage represents 10-15% of the cases of ICH (Kase et ah 1998) (Figure 57B.10). Its onset tends to be more abrupt than that of putaminal hemorrhage, and slow progression of deficits is less common. These features may reflect early communication of the medially located hematoma with the third ventricle. The prognosis in thalamic hemorrhage relates to hematoma size. Thete is a lack of correlation between survival and ventricular cxiciiMtin "i the hemorrhage, again documenting that hematoma size, not ventricular extension per sc, is the most crucial factor related to the vital ptognosis in ICH. Another reliable sign of poor prognosis in thalamic ICH is the presence of hydrocephalus, a complication that occasionally occurs abruptly, as a result of aqucductal obstruction by an intraventricular clot; here, however, ventriculostomy may result in a reversal of symptoms.

Lobar Hemorrhage

Lobar hemorrhage is second to putaminal hemorrhage in frequency, accounting for approximately 25% of the cases (Kase et al. 1998) (Figure 57B.11). Nonhypertensive mechanisms, including AVMs, sympathomimetic agents (in young patients), and CAA (in elderly patients) are frequent causes. The peripheral (subcortical) location of

HGURE 57B.10 Right thalamic hemorrhage with ventricular extension.

these hematomas explains the lower frequency of coma at onset, as compared with the deep ganglionic forms of supratentorial ICH. The clinical fearures reflect location: hemiparesis of upper limb predominance in frontal hematomas, sensorimotor deficit and hemianopia in parietal hemorrhages, fluent aphasia with relatively preserved repetition in dominant temporal hematomas, and homonymous hemianopia in occipital lobe hemorrhages. The mortality rate in lobar ICH is lower than in hematomas in other locations, and the long-term functional outcome may be better also.

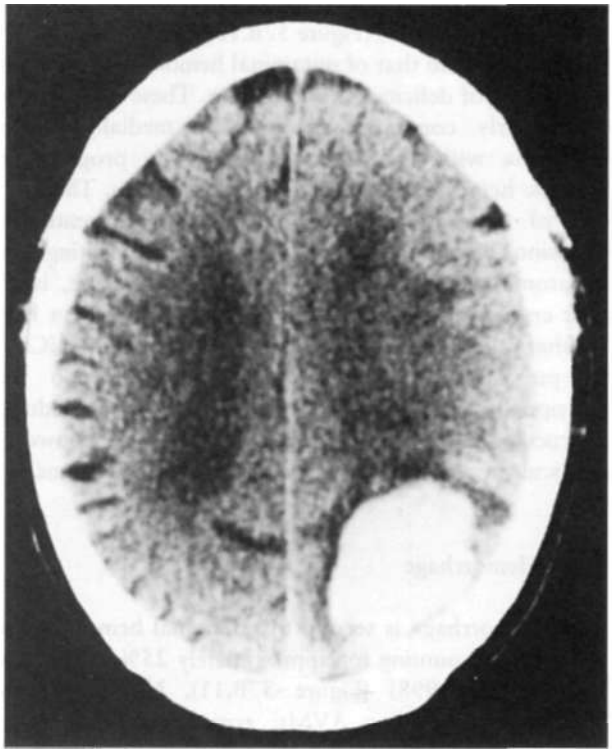

FIGURE 57B.11 Ijeft parieto-ou-ipital lobar hemorrhage.

Cerebellar Hemorrhage

Cerebellar hemorrhage represents approximately 5-10% of the cases {Kase et al. 1998) (Figure 57B.12). Its clinical presentation is characteristic, with abrupt onset of vertigo, headache, vomiting, and inability to stand and walk, with absence of hemiparesis or hemiplegia. The physical findings that allow its clinical diagnosis are the triad of appendicular ataxia, horizontal gaze palsy, and peripheral facial palsy, all ipsilateral to the hemorrhage.

The clinical course in cerebellar hemorrhage can he difficult to predict at onset. There is a notorious tendency for abrupt deterioration to coma and death after a period of clinical stability under hospital observation. This unpredictable course has stimulated a search for early clinical or CT signs that may separate patients with benign outcome from those who deteriorate clinically with onset of brainstem compression and high mortality.

FIGURE 57B.12 Large midline and left-sided hemispheric cerebellar hemorrhage.

Pontine Hemorrhage

Pontine hemorrhage represents approximately 5% of the cases (Kasc et al. 1998) (Figure 57B.13). The massive, bilateral basal-tegmental variety produces the classic picture of coma, quadriplegia, decerebrate posturing, horizontal ophthalmoplegia, ocular bobbing, pinpoint reactive pupils (for which a magnifying glass may be required to allow detection of the light reflex), abnormalities of respiratory rhythm, and preterminal hyperthermia. Since the introduction of CT and MRI scanning, less severe forms of pontine hemorrhage are recognized that are compatible with survival. These hemorrhages are frequently located in the tegmentum, lateral to the midline (Figure 57B, 14), and thus produce syndromes of predominantly unilateral pontine cranial nerve involvement ("one-and-a-half" syndrome, internuclear ophthalmoplegia, fifth and seventh nerve palsies), with variable degrees of long-tract interruption. These hematomas probably result from rupture of distal tegmental branches of a long circumferential artery originating from the basilar trunk.

Mesencephalic Hemorrhage

Mesencephalic hemorrhage is exceptionally rare (Kase et al. 1998). The causal mechanism is hypertension or ruptured AVM in one half of the reported cases, the others being of undetermined cause. Occasional unilateral hematomas (Figure 57B.15) can present with ipsilateral third nerve palsy and cerebellar ataxia, with contralateral hemiparesis. Bilateral cases frequently have prominent tecta I -tegmental signs, with bilateral ptosis, paralysis of upward gaze, and small pupils with light-near dissociation (see Chapter 22). Most patients survive without surgical treatment, but with persistent sequelae.

FIGURE 57B. 13 Large tegmental basal pontine hemorrhage with hydrocephalus of temporal horns.

FIGURE 57B.14 Left tegmental pontine hemorrhage.

Medullary Hemorrhage

Examples of pure primary ICH involving the medulla alone are rare, with most reported cases representing medullary extension of caudal pontine hematomas. The clinical presentation of primary medullary hemorrhage reflects the location of the lesion on one half of the medulla, generally extending beyond the dorsolateral region, both medially (resulting in ipsilateral hypoglossal nerve palsy) and ventrnlly (resulting in contralateral hemiparesis). These two features distinguish most examples of medullary hemorrhage from the classical presentations of Wallenberg's lateral medullary syndrome, caused by infarction rather than hemorrhage (sec Chapter 22).

FIGURE S7B.15 Gradient-echo (T2) magnetic resonance imaging scan of left tegmental midbrain hemorrhage.

Intraventricular Hemorrhage

Extension of hemorrhage into the ventricular system is a common feature of caudate and thalamic hemorrhages and of large putaminal and lobar hemorrhages. As a primary form, not associated with a component of intra parenchymal bleeding, intraventricular hemorrhage is rare, accounting for only approximately 3% of ICHs. The site of origin of the hemorrhage is thought to be the vasculature of the subependymal region, and rarely the source can be identified in the choroid plexus.

The causes of intraventricular hemorrhage are similar to those of ICH elsewhere, including hypertension, aneurysm, AVM, coagulation disorders, cerebral tumors, cocaine use, and rare vasculopathies such as moyamoya disease. Those from aneurysm rupture are generally caused by an anterior communicating artery aneurysm rhat ruprures in an upward direction, bleeding directly into one of the lateral vcntticles; in these instances, basal frontal subarachnoid hemorrhage and interhemispheric hemorrhage accompany the intraventricular hemorrhage and should always raise the diagnostic suspicion of a ruptured aneurysm. AVMs that cause purely intraventricular hemorrhage are generally small and located in the medial aspect ut the basal ganglia or thalamus. Rarely, an inrravcntricular AVM or cavernous angioma may cause a primary inrravenrricular hemorrhage.

The clinical presentation of intraventricular hemorrhage is with acute onset of headache, nausea, vomiting, and decreased level of consciousness, with focal neurological deficits cither minimal or altogether absent (Marti-babreg.is et al. 1999). This presentation is identical to that of subarachnoid hemorrhage from ruptured aneurysm or AVM. If focal deficits such as hemiparesis or ocular motor disturbances are prominent, the picture is not strictly that of a pure intraventricular hemorrhage, but rather one of primary ICH with ventricular extension.

Intraventricular hemorrhage can be diagnosed reliably with CT and MRI, the latter being more sensitive for the detection of a small component of subependymal, intta-parenchymal hemorrhage. Also, MRI can suggest a diagnosis of aneurysm, AVM, or cavernous angioma as the mechanism of the hemorrhage. Even after extensive testing, many intraventricular hemorrhages remain of unknown mechanism.

The prognosis of intraventricular hemorrhage is strongly dependent on the severity of the initial presentation and its mechanism. Patients who are comatose as a result of the initial hemorrhage generally succumb, especially if they have early signs of brainstem involvement (ophthalmoparesis, loss of pupillary reflexes, decerebrate rigidity). Those who remain alert or obtunded, without signs of parenchymal involvement, tend to recover without neurological sequelae, although memory disturbances may be a relatively frequent residual deficit (Marti-Fabregas et al. 1999). Patients with the idiopathic form of intraventricular hemorrhage have the best prognosis.

TREATMENT OF INTRACEREBRAL HEMORRHAGE

Issues related to treatment of ICH have been dominated by two main considerations: (1) the type and intensity of medical interventions required to improve the functional and vital prognosis, and (2) the choice between medical and Surgical therapy. To a great extent, these two important aspects of treatment remain unclarified, largely as the result of a remarkable paucity of prospective clinical trials. These two issues are discussed separately.

General Management of Intracerebral Hemorrhage

Because ICH is associated frequently with increased ICP, most of the therapies used in this setting are directed at lowering ICP or preventing its increase. Among the many medications and procedures available, a small group has come into customary use in most institutions, despite their value not being proven in properly controlled studies.

Initial Evaluation

On arrival in the emergency department, patients with ICH need to be immediately evaluated for stabilization of vital signs and airway protection. If the patient has a depressed

level of consciousness, with a Glasgow Coma Scale score of 8 or less, endotracheal intubation should follow. This is best performed with the concomitant administration of short-acting agents such as thiopental (1-5 mg/kg) or lidocaine (1 mg/kg) to block the increases in ICP that result from tracheal stimulation.

Following emergent evaluation of the vital signs and laboratory studies, clinical examination and CT arc needed to establish the topography and size of the ICH, which determine the plan for further management, These decisions are made in conjunction with a neurosurgical consultant.

Labotatory test data on presentation with ICH should include coagulation studies, especially in instances of hemorrhage in patients receiving anticoagulants or previously treated with thrombolytic agents. Coagulation abnormalities in patients receiving anticoagulants should be treated emergently, because if anticoagulation is not reversed it can lead to progressive enlargement of the hematoma. Patients with ICH in the setting of heparin anticoagulation should be treated with protamine sulfate, 1 mg per 100 units of heparin estimated in plasma, whereas those on warfatin should receive .5-25 mg of parenteral vitamin K| and, most important, fresh frozen plasma (10-20 mL/kg). In view of the expected delays in having fresh frozen plasma immediately ready in these instances, the tecent availability of recombinant factor Vila for intravenous injection offers the option of a more rapid reversal of rhe abnormally prolonged INR in cases of warfarin-related ICH (Deveras and Kcssler 2002), Instances of ICH after thrombolytic therapy are best tteated with 4-6 units of ctyoprecipitate, or fresh frozen plasma, as well as single donor platelets,

General Measures for Prevention of Further Elevation of Intracranial Pressure

General measures include control of hypertension and treatment of seizures. The former can be necessary because persistent hypertension, by causing increased cerebral perfusion pressure, may produce an increase in cerebral edema around the ICH, with further elevation of ICP. However, this potential benefit of antihypertensive therapy must be balanced against the possible harmful effects of drug-induced hypotension with resulting cerebral ischemia and further neurological deterioration. This difficult clinical problem is compounded by the lack of knowledge concerning optimal balance between adequate cerebral perfusion and control of ICP. Pharmacological correction of severe hypertension is mandatory in the acute phases of ICH, with the aim being maintenance of normal cctcbral perfusion pressure levels, on the otder of 50-70 mm Hg, and a mean arterial pressure below 130 mm Hg (Broderick et al. 1999). These parameters for blood pressure control after acute ICH are safe, and do not compromise cerebral blood flow (Powers et al, 2001}, The antihypertensive agent of choice in this setting is the intravenous *0*- and a-blocking agent labetalol, often used in combination with loop diuretics. Although theoretically contraindicated because of their cerebral vasodilator properties, nitroprusside and hydralazine are the most appropriate choices when labetalol fails to control the blood pressure. These agents, in particular nitroprusside, have the advantage of being very effective and easy to titrate, and the feared side effect of increased ICP caused by cerebral vasodilation is rarely, if ever, of clinical consequence,

Seizures, a feature of the lobar rather than deep ganglionic vatieties of ICH, typically occur at onset. In patients who did not have early seizures, there is a negligible risk of late epilepsy. Thus the routine prophylactic use of anticonvulsants in patients with ICH is not justified. Early tonic - clonic convulsions need immediate control because they can contribute to increased ICP. The major anticonvulsants are of comparable value in this situation.

Specific Treatment of Increased Intracranial Pressure

The mainstays of treatment of intracranial hypertension have been hyperventilation, diuretic therapy, and corticosteroids. Hyperventilation is most effective in rapidly lowering intracranial hypertension, usually within minutes of achieving levels of hypocapnia in the range of 25-30 mm Hg. Inttavcnous mannitol (0,25-1.0 g/kg), a rapid and reliable way of lowering ICP, may be used along with hyperventilation in situations of neurological deterioration with impending herniation. Although dexamethasonc is frequently given with the purpose of decreasing intracranial hypertension by reducing cerebral edema, its use is not supported by data from a controlled clinical trial (Poungvarin et al. 1987).

Intensive monitoring of ICP with aggressive medical treatment of intracranial hypertension appears to improve the outcome of comatose patients with ICH. In addition, failure to control raised ICP with these measures can be used as an objective indicator that surgical evacuation of the hematoma is required, because persistently elevated ICP under these circumstances results invariably in progression to coma and death.

Choice between Medical and Surgical Therapy in Intracerebral Hemorrhage

A direct surgical approach is considered frequently in patients with superficial (lobar) hematomas of the cerebral hemispheres or with cerebellar hemorrhage, whereas patients with deep hemorrhages (caudate, thalamic, pontine, mesencephalic, and medullary in location) arc rarely, if ever, surgical candidates. Putaminal hemotrhage occupies an intetmediatc position and is most controversial. Few scientific data are available to assist the clinician in this therapeutic choice.

Six randomized clinical trials compared surgical with nonsurgical treatment of ICH, and the results were generally inconclusive, mostly because of methodological

issues (Fernandas ct al. 2000). A well-designed, prospective, multicenter clinical trial is required to answer rhis important clinical question, and at the same time evaluate conventional craniotomy against other newer surgical approaches.

A promising technique for surgical treatment of intracerebral hematomas involves the stereotactic drainage of the hemorrhage with the aid of local instillation of a fibrinolytic agent (Qureshi etal. 2001). The introduction of the draining cannula is done under local anesthesia and CT guidance, and the procedure allows repeated drainage of liquefied portions of the hematoma following local urokinase or tPA infusion. This can achieve the removal of as much as 80% of the hematoma, without the need for craniotomy. This technique may have a role in the surgical management of deep-seated thalamic or puraminal hematomas, as well as in patients considered to be too high risk for hematoma drainage through a craniotomy under general anesthesia.

Because of the lack of prospective data on tandomized trials of therapy in ICH, most patients are currently treated nonsurgically, with the exception of those with puraminal and lobar hemorrhage with progressive deterioration in the level of consciousness, and most instances of cerebellar hemorrhage. Patients with putaminal and lobar ICH who undergo a steady decline in level of consciousness, with onset of coma, have a mortality of 100% with medical therapy. On the basis of this consideration, occasional patients with putaminal ICH arc treated surgically, with a slight improvement in survival rates, but without any demonstrated improvement in functional outcome. This raises a difficult ethical dilemma conttasting improved survival with poor quality of life in patients with massive basal ganglionic ICHs, in whom severe hemiplegia, hemisensory loss, and aphasia or hemi-inattention syndromes arc the expected permanent sequelae. A somewhat less pessimistic picture exists in the case of lobat ICH with progressing mass effect. The surgically more accessible superficial hematomas suggest the potential for less devastating neurological sequelae, thus justifying surgery in selected cases. The most likely candidates for surgery are patients with lobar hemorrhages of intermediate size (hematoma volumes between 20 and 40 mL), who have a decline in level of consciousness or marked mass effect by CT scan. In addition, the presence ol a lesion with potential tor causing recurrence of ICH, such as an AVM, aneurysm, or cavernous angioma, is another indication for surgical therapy (Broderick et al. I 999).

Hie other group for whom surgery is frequently considered includes patients with cerebellar hemorrhage. Although a benign outcome without surgical evacuation is well documented in small cerebellar hemorrhages, the potential for sudden deterioration to coma and death, not infrequently after a clinically stable course under hospital observation, is well recogni/.ed. CT criteria for early selection of candidates for surgical therapy are large hematomas (diameter of 3 cm or more), presence of hydrocephalus, and obliteration of the quadrigcminal

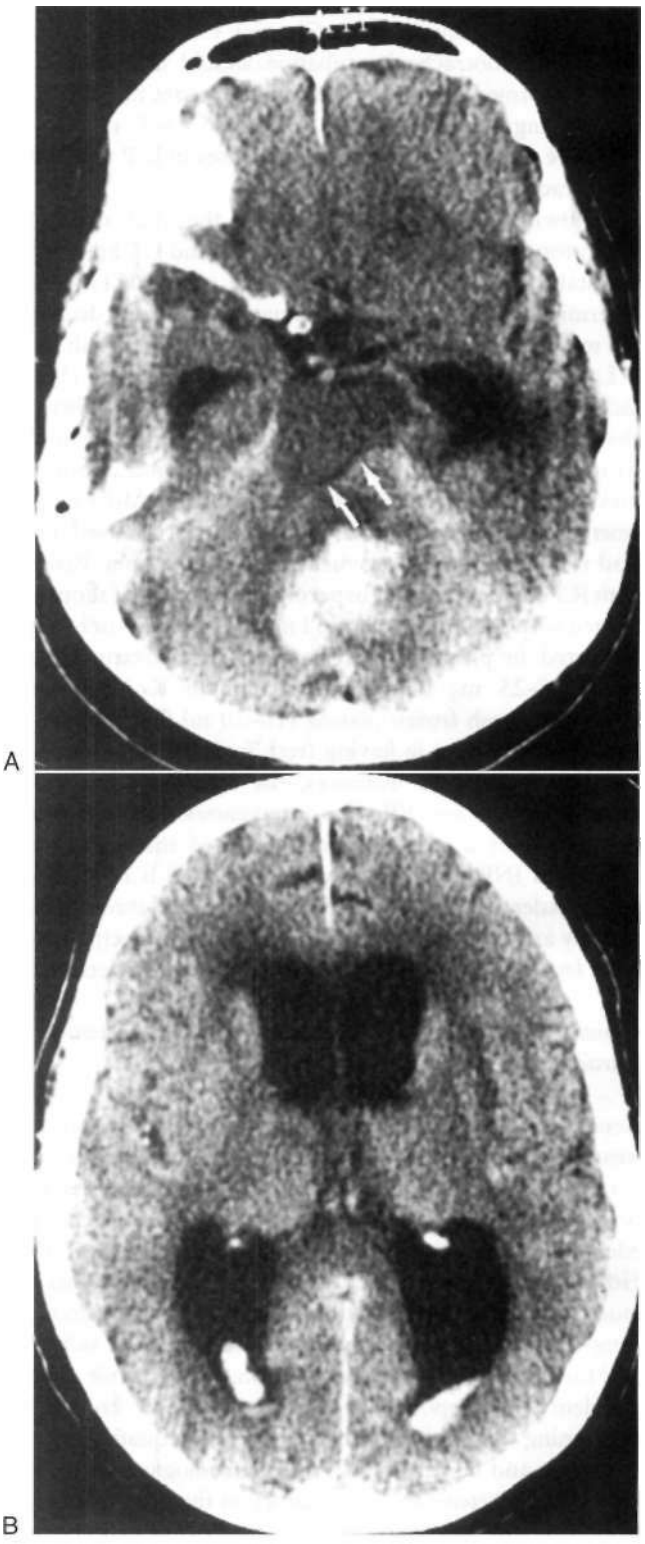

FIGURE 57B.16 Midline cerebellar hemorrhage with brainstem distortion, obliteration of quadrigeminal cistern *[arrows)* (A), and supratentorial hydrocephalus (B).

cistern (Figure 57B.16). In addition to these CT features, early signs of pontine tegmental compression and development of obtundation and extensor plantar responses constitute indications for emergency surgical therapy, hecausc the outcome is otherwise uniformly fatal.

In addition to direct evacuation of a hematoma, there is the option of ventricular drainage for the relief of hydrocephalus and increased ICP in cases of cerebellar, thalamic, and caudate ICH. In cerebellar hemorrhage, massive hydrocephalus can be a major cause of clinical dererioration, and ventricular drainage may provide dramatic improvement. Because ventricular drainage does not diminish compression of the brainstem, and because of the potential for upward transtentorial cerebellar herniation following decompression of the supratcntorial ventricular system, this approach is only rarely the sole form of surgical treatment. It may, however, be used immediately before occipital craniectomy for wide decompression of the posterior fossa and hematoma drainage. Patients with thalamic hemorrhage occasionally show a dramatic reversal of oculomotor signs, coma, or both, after ventricular drainage.

The value of these methods of management of ICH needs assessment by a prospective, multicenter, randomized trial of surgical versus nonsurgical treatment of ICH.

Chapter 57
Vascular Diseases of the Nervous System

C. INTRACRANIAL ANEURYSMS AND SUBARACHNOID HEMORRHAGE

Warren R. Selman, Jeffrey L. Sunshine, Robert W. Tarr, and Robert A. Ratcheson

The importance of proper management of patients with intracranial aneurysms cannot be overestimated. The spectrum of neurological disorders produced by aneurysms ranges from the asymptomatic unruptured aneurysm to the ruptured aneurysm that produces debilitating stroke and death. The most devastating consequences of intracranial aneurysms are from the complications of subarachnoid hemorrhage (SAH). This chapter emphasizes strategies to prevent or ameliorate these complications.

CLINICAL SYNDROMES

The classic manifestations of a major aneurysmal rupture include a sudden explosive headache, decreased level of consciousness, photophobia, moiingisnnis, nausea, and vomiting. Because the prognosis is better if treatment occurs before these manifestations develop, it is important to recognize the signs and symptoms associated with aneurysmal expansion or a minor hemorrhage.

Headaches are one of the most important warning symptoms of aneurysmal rupture. Sentinel headaches occur in approximately one half of patients before rupture. Other associated symptoms may include nausea, neck pain, lethargy, and photophobia.

These symptoms are presumably caused by a noncatastrophic leak of the aneurysm and may be confirmed by demonstrating red blood cells or xanthochromia in the cerebrospinal fluid. Hemorrhage into the wall of an aneurysm can produce thunderclap headache associated with aneurysmal enlargement in the absence of red blood cells in the cerebrospinal fluid (Ostergaard 1993). Thus the absence of blood in the cerebrospinal fluid in a patient with a characteristic history docs not exclude the possibility of a symptomatic aneurysm. Such patients should undergo, at least, noninvasive imaging of the cerebral vessels with magnetic resonance angiography (MRA) or spiral computed tomographic (CT) angiography, and, if these studies are inadequate or if questions remain, then formal cerebral angiography.

Aneurysms may demonstrate evidence of their presence or of growth, before rupture, in other ways besides headache. Premonitory manifestations depend on the location of the aneurysm and include diplopia, visual field deficits, or facial pain (Weir 1994). The difficulty of diagnosing an aneurysm before a major hemorrhage occurs can be appreciated by considering the common occurrence of the alternative diagnoses, including migraine or tension-type headache, meningitis, sinusitis, and influenza. The high morbidity and morality associated with SAH mandates a

high degree of suspicion to allow appropriate treatment of patients whose symptoms indicate they may harbor intracranial aneurysms.

PHYSICAL FINDINGS

Unruptured Aneurysms

Because aneurysms can produce catastrophic hemorrhage before they reach a size that would produce neurological deficits, the lack of clinical findings should not preclude further diagnostic evaluation. The physical findings in patients with unruptured aneurysms are determined in part by the size and location of the aneurysm, although few aneurysms can be diagnosed with confidence on the basis of clinical presentation alone. Thus aneurysms arising from the anterior communicating artery can produce visual field defects, endocrine dysfunction, or localized immal headache. Aneurysms of the internal carotid artery can produce oculomotor paresis, visual field deficits, impaired visual acuity, endocrine dysfunction, and localized facial pain. Aneurysms of the internal catotid artcty in the cavernous sinus can produce a cavernous sinus syndrome when they reach a sufficient size. Those of the middle cerebral artery can produce aphasia, focal arm weakness, or paresthesias. Basilar bifurcation aneurysm can be associated with oculomotor patesis, although the clinical features of posterior circulation aneurysms seldom permit diagnosis before they rupture.

Of primary importance is altered oculomotor nerve function. This nerve is affected most commonly by an internal carotid artery aneurysm arising at or near the origin of the posterior communicating artery. Much less frequently, an aneurysm of the posterior circulation may affect this nerve. A third nerve palsy secondary to an aneurysm usually is associated with a dilated pupil and ptosis, which contrasts with those caused by an ischemic lesion of the nerve, such as might occur in patients with diabetes, in whom pupillary function is usualh preserved. However, this distinction is not uniformly reliable, and aneurysms should be suspected in all cases of new onset painful third nerve dysfunction.

Subarachnoid Hemorrhage

The physical findings in patients with ruptured aneurysms depend in part on the amount and location of the hemorrhage. Aneurysmal rupture can result in hemorrhage into the subarachnoid space alone or in combination with subdural hematoma, intracerebral hematoma, or intraventricular hemorrhage. Thus the immediate physical findings can vary from slight meningismus to profound neurological deficits with coma or death. Because treatment and prognosis depend to a great extent on the clinical Status of the patient, a grading scale based on the neurological presentation of the patient is used routinely. These grading scales are simple to use and should be noted for all patients presenting with subarachnoid hemorrhage. The two systems that are in most common use are the Hunt and Hess classification and the World Federation of Neurological Surgeons grading scale (Table 57C.1), which is based in part on the Glasgow Coma Scale (see Chapter 5, Table 5.4).

Table 57C.1: Hunt and Hess and World Federation of Neurological Surgeons Scale

Hunt and Hess Scale
Grade 0: Asymptomatic
Grade 1: Slight headache, no neurological deficit
Grade II: Severe headache but no neurological deficit other than perhaps a cranial nerve palsy
tirade III: Drowsiness and mild deficit
Grade IV: Stupor, moderate to severe hemiparesis, and possible early rigidity and vegetative disturbances
Grade V: Deep coma, decerebrate rigidity, and moribund appearance
World Federation of Neurological Surgeons Scale
Grade I: GCS 15; motor deficit absent
tirade II: GCS 13 or 14; motor deficit absent
Grade III: GCS 13 or 14; motor deficit present
Grade IV: GCS 7-12; motor deficit absent or present
tirade V: GCS *3-6;* motor deficit absent or present

GCS = Glasgow Coma Scale.

LABORATORY STUDIES

The laboratory evaluation of patients suspected of having a ruptured or unruptured intracranial aneurysm uses a combination of CT scan, magnetic resonance imaging (MRI), lumbar puncture, and angiography.

Unruptured Aneurysms

A conventional CT scan may, on occasion, demonstrate an intracranial aneurysm (Figure 57C.1). Most frequently, these are large or giant aneurysms with peripheral calcification on an unenhanced scan, and central dense enhancement on contrasted studies. Such aneurysms may be quite large and mimic intracranial neoplasms. Smaller aneurysms also have been detected with high-resolution CT.

The CT scanner can also be used in conjunction with software-based reconstruction techniques of maximal intensity projections, surface-shaded displays, or multiplanar reconstructions to produce three-dimensional CT angiograms. These images not only provide documentation of the aneurysm, but can be a useful aid to understanding the morphology of the aneurysm and its relationship to adjacent normal vessels (Plates 57C.I and 57C.II). CT angiography is able to detect calcium within the wall or

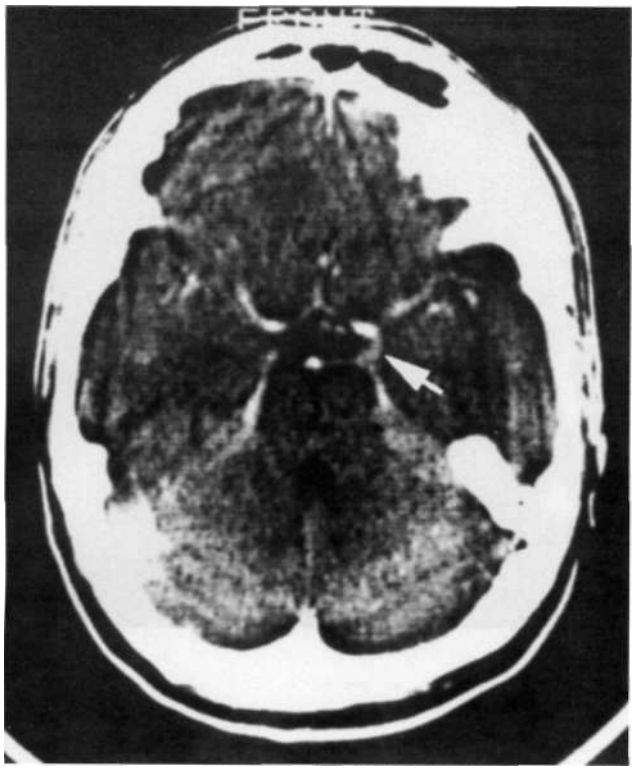

FIGURE 57C.1 Postcontrast computed tomographic scan demonstrating a left posterior communicating artery aneurysm *[arrow).*

neck of an aneurysm, a finding that may have an effect on therapeutic options.

MRI also can detect intracranial aneurysms (Figure 57C.2). Specialized pulse sequences and postprocessing techniques are used to produce MRAs that can visualize aneurysms as small as 4 mm and, unlike CT angiography, does not require administtation of contrast material. Both of these studies are considered noninvasive, and are not associated with the risks of conventional cerebral angiography.

Subarachnoid Hemorrhage

The conventional CT scan is indispensable for delineating the amount and location of blood in the subarachnoid space (Figure 57C.3). The sooner the CT scan is performed in relation to the suspected hemorrhage, the greater the likelihood of visualizing blood. In the setting of a suspected acute SAH, the CT remains the procedure of choice because MRI is less effective in detecting blood early after **the** rupture of an aneurysm. The location of the blood can indicate the site of aneurysmal rupture. Blood in the basal cisterns is seen with ruptured aneurysms in any location, but is most common with those of the internal carotid and basilar artery. Blood in the sylvian fissure is most common in middle cerebral artery aneurysms. Intraventricular blood is associated with anterior communicating and basilar artery aneurysms. Intracerebral hemorrhages of the frontal lobe can be seen with anterior communicating artery aneurysms, and those of the temporal lobe with middle cerebral artery aneurysms.

SAH is not always detected by CT scan. The amount of extravasated blood and the time interval between the SAH and the scan affect the percentage of negative study results. Modern-generation CT scanners can detect the presence of acute SAH in 90-95% of patients who undergo a scan within 24 hours after the hemorrhage. The sensitivity decreases to 80% at 72 hours. A negative CT scan result in a patient with the appropriate history of SAH should he followed by a lumbar puncture. If the CT scan demonstrates a characteristic SAH, there is lirtle to be gained by performing a lumbar puncture.

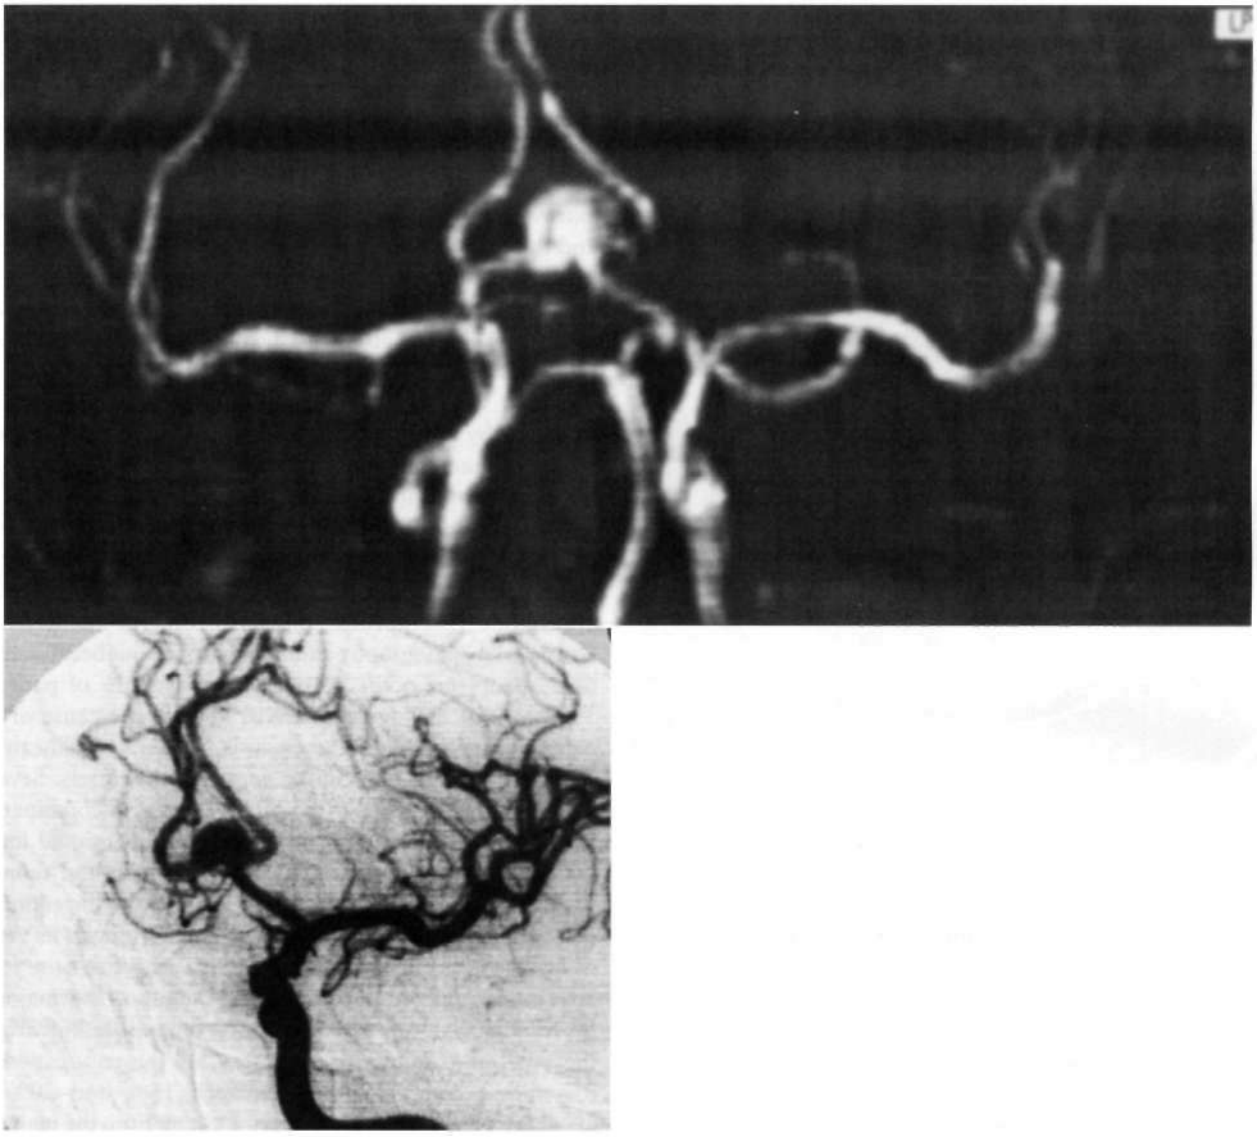
If either the CT scan or the lumbar puncture is positive for SAH, an angiogram should be obtained. Angiography should be performed as soon as reasonably possible so that appropriate therapeutic measures can be undertaken. Four-vessel angiography should be carried out because multiple aneurysms occur in approximately 20% of patients. The goals of angiography are to identify the cause of the hemorrhage and, if an aneurysm is present, to delineate its neck and the relationship to surrounding vessels. Several views may be required to fulfill these goals. A combination of conventional angiography and three-dimensional imaging techniques is often useful in determining and refining treatment strategies for microsurgical clipping or endovascular coiling. The aneurysm is named according to its vessel of origin. Approximately 80-85% of aneurysms arise from arreries located in the anterior circulation, the majority of which occur on the posterior communicating artery, the anterior communicating artery, or the trifurcation of the middle cerebral artery. Between 15% and 20% of aneurysms arise from rhe posterior circulation, the majority of which occur at the bifurcation of rhe basilar artery or at the origin of the posterior inferior cerebellar artery on the vertebral artery.

ANEURYSM PATHOGENESIS AND CAUSE

Several classifications of aneurysms have been proposed. Thar suggested by Weir (1985) is summarized in Table 57C.2. This morphological classification is helpful in defining the different natural history of these lesions. Intracranial aneurysms are classified on the basis of their morphology as saccular, fusiform, or dissecting. Further classification on the basis of presumed cause is also possible.

Saccular Aneurysms

Saccular, or berry, aneurysms are the most common form of aneurysms and are most often responsible for



B

FIGURE S7C.2 (A) Three-dimensional time-of-flight magnetic resonance angiogram reveals an aneurysm of the anterior communicating artery. (B) Left internal carotid artery angiogram, which confirmed the anterior communicating artery aneurysm demonstrated on the magnetic resonance angiogram.

aneurysmal subarachnoid hemorrhage. Saccular aneurysms may arise from defects in the muscular layer of cerebral arteries that occur at vessel bifurcations and from degenerative changes that damage the internal elastic membrane, resulting in weakness of the vessel wall. They usually occur on the first- or second-order arterial branches of the vessel emanating from the circle of Willis. Evidence suggests that both genetic and environmental factors contribute to the development of saccular aneurysms. The evidence that genetic factors are important comes from the documented association of intracranial aneurysms with heritable connective tissue disorders such as autosomal dominant polycystic kidney disease, Ehlers-Danlos' syndrome type IV, neurofibromatosis type I, and Marfan's syndrome. The familial occurrence of intracranial aneurysms also points to a role for genetic factors. In those patients who have a first-degree relative with an aneurysmal SAH, the tisk of a ruptured aneurysm is four times higher than the risk in the general population. A role for acquired factors in the pathogenesis of saccular aneurysm is suggested by the mean age of 50 for patients with aneurysmal SAH, and the increased incidence of hemorrhage occurring with age. Cigarette smoking is a risk factor in all population studies, and a role for systemic hypertension, although not as strong as that of cigarette smoking, in the cause of aneurysm formation appears likely.

Saccular aneurysms may also be caused by infection, trauma, or neoplasm. Mycotic aneurysms result from infected emboli that lodge in the arterial intima or the

vasa vasorum and account for approximately 5% of all intracranial aneurysms. They occur most frequently in patients with subacute bacterial endocarditis, congenital heart disease, or a history of intravenous drug use, and are usually located on more distal branches of the cerebral vasculature. Proper management includes appropriate intravenous antibiotic therapy, with surgery in selected cases. Fungal aneurysms, which are much rarer than bacterial, usually are associated with arteritis and thrombosis and have been uniformly fatal.

Traumatic aneurysms are rare but can be caused by either blunt or penetrating head injury. Such aneurysms occur at sites other than bifurcations. Angiograms are not routinely performed following head trauma, and these lesions may not be detected, hut they should be considered in patients who suffer delayed deterioration.

Early operative repair is recommended because of the high mortality associated with these lesions.

Neoplastic embolization, in rare cases, may produce an aneurysm in patients with choriocarcinoma, atrial myxoma, and undifferentiated carcinoma. In forming an aneurysm, the tumor embolus may remain viable, penetrate the endothelium, grow subintimally, and eventually destroy the arterial wall.

Fusiform Aneurysms

Fusiform or dolichoectatic aneurysms are classified separately from saccular aneurysms, although in some patients these types may overlap. The basilar artery is most commonly affected, although these aneurysms also can be seen in the anterior circulation. Only rarely are these lesions associated with SAH. Their presentation is characterized by cranial nerve or brainstem dysfunction secondary to direct compression or by embolization from intraluminal thrombus.

Dissecting Aneurysms

Dissecting aneurysms result from cystic medial necrosis or a traumatic tear in the endothelium and subadjacent layers of the artery, allowing the formation of a false lumen. The false lumen may connect with the true lumen distally or may rupture through the remaining external arterial wall. Such aneurysms can occur in any portion of the extracranial or intracranial arterial circulation. Trauma is a common cause in the neck and anterior circulation, but is a rare cause in the posterior circulation. Connective tissue diseases such as Marfan's syndrome and other disorders such as fibromuscular dysplasia predispose to arterial dissections. The treatment of these lesions has not been standardized; patent artery occlusion, with or without bypass grafting, using conventional microsurgical or neuroendovascular techniques may be necessary. The use of endovascular stent placement, with or without direct aneurysm obliteration, can eliminate the need for patent vessel occlusion in many instances.

EPIDEMIOLOGY

The incidence and prevalence of unruptured intracranial aneurysms and aneurysmal SAH should be considered separately. Intracranial aneurysms are found on postmortem examination in between 1% and 6% of adults in large autopsy series (Schicvink 1997). The frequency of intracranial aneurysm seen during angiography for patients not suspected of harboring an aneurysm is between 0.5% and 1.0%. The overall incidence of SAH from aneurysms is approximately 7-10 per 100,000 people per year (Mcnghini et al. 1998), but this figure includes children, who have a very low incidence of rupture. The mean age of rupture is approximately 50 years. Among adults older than 30 years of age, the incidence of SAH is approximately 40-50 per 100,000 per year, and nearly one half of these individuals die from their SAH. Various reviews have noted a slight female predominance of SAH from aneurysms, with a mean age of hemorrhage of approximately 50 years. Ruptured aneurysms rarely occur in children, and there is a steady increase in the incidence of rupture from 0.3 per 10,000 persons per year between 25 and 34 years of age to 3.7 per 10,000 persons per year for patients 65 years of age or older.

A special category of patients are those who have a family history of aneurysms and SAH. Familial occurrence of intracranial aneurysms is defined by the presence of aneurysms in two or more first- to third-degree relatives without any known hereditary disease. It is not known whether the pathogenesis of familial intracranial aneurysms differs from that of the general population (Ronkainen ct al. 1998). In a community-based study from Rochester, MN, the relative risk of SAH among first-degree relatives of patients with the familial form of SAH was four times higher than the general population. Other studies have shown that in patients with familial intracranial aneurysms, there is a lower mean age at the time of rupture compared with SAH in the general population (Ronkainen et al, 1998). Screening studies, with MRA, CT angiography, or conventional angiography, for the presence of aneurysms in this group of patients appears warranted.

COURSE OF ANEURYSMAL SUBARACHNOID HEMORRHAGE

The International Cooperative Study on the Timing of Aneurysm Surgery used the Glasgow Outcome Scale to report on Outcomes at 6 months following SAH for 3521 patients and noted the following: 57.6% had good recovery; 9.1% were moderately disabled; 5.5% were severely disabled; 1,8% had vegetative survival; and 26.0% died. Approximately 12% of patients died before reaching a hospital, and approximately 40% of patients who were hospitalized died within 30 days {Olafsson et al. 1997). The total mortality rate in the first year was 63% and was 72% within the first 5 years. The authors noted little change in the initial mortality and morbidity of patients suffering an SAH over the past several decades and concluded that only the detection and treatment of intracranial aneurysms prior to rupture has any influence on the frequency of sudden death from SAH. The subject of detection and treatment of unruptured aneurysms is discussed in the following section of this chapter.

In a study of late morbidity and mortality in patients treated nonoperatively following SAI1 from a single

aneurysm, the main cause of death in patients surviving 6 months was recurrent hemorrhage. Rebieeding occurred at a rate of 3.5% per year during the first decade.

Functional outcome also must be considered when assessing patient management. Subtle cognitive dysfunction and psychosocial impairment can prevent the return to premorbid lifestyle in up to 20% of survivors. Neuropsychological deficits and cognitive dysfunction arc common among survivors after SAH. Cognitive impairment is highest among those patients who experience global cerebral edema, and those who suffer left-sided infarcts (Kreitcr et a I. 2002). Long-term quality of life may be diminished in many SAH survivors in that 41% have memory problems, 35% experience fatigue, 48% undergo personality changes, and 26% complain of insomnia {Ogden et al. 1997). The combination of these changes adversely **affects the** ability of patients who suffer an SAH to return to work, and approximately one half of survivors do not return to previous full-time employment. Wiebers et al. (1992) reported the annual estimated lifetime cost of aneurysmal SAH in the United States to be 1.8 billion dollars.

TREATMENT AND PROGNOSIS

Elimination of an intracranial aneurysm is the cornerstone of therapy. The risk reduction for subsequent SAH afforded by surgery is well documented in population-based studies (Olafsson et al. 1997). Every effort should be made to direct appropriately selected patients toward surgery as soon as possible. In general, patients in good condition are best managed by *early Intervention to secure the aneurysm.* The benefits of early treatment include prevention of rebieeding, improved prevention and management of delayed ischemic deficits from vasospasm, and a shorter hospital course with potentially fewer complications.

The major complications following SAH are the following: ischemic deficits, 27%; hydrocephalus, 12%; brain swelling, 12%; recurrent hemorrhage, 11%; intracranial hematoma, 8%; pneumonia, 8%; seizures, 5%; gastrointestinal hemorrhage, 4%; syndrome of inappropriate antidiuretic hormone (SIADH) secretion, 4%; and pulmonary edema, 1%. As detailed in the following section, the initial management of SAH patients must proceed rapidly and comprehensively to prevent or lessen the chance of demise because of any of these conditions, but especially the two that produce the greatest morbidity and mortality, rebieeding and delayed ischemic deficits. Both immediate and delayed effects must be anticipated and treated (Mayberg et al. 1994; Ratcheson and Wirth 1994; Bederson 1997).

The importance of appropriate intensive care management of SAH patients cannot be overestimated, because secondary **insults are** associated with negative clinical outcomes (Enblad and Pcrsson 1997).

Although aneurysm rupture almost universally results in SAH, the location of the hemorrhage is not confined to the subarachnoid space. Patients with massive intraventricular hemorrhage or intracerebral hematomas tend to die earlier than those with blood in other locations. **The** consequences of bleeding into the brain parenchyma or ventricles include an elevation of intracranial pressure caused by mass effect and acute hydrocephalus. Either of these conditions may require immediate treatment separately or in combination with definitive aneurysm treatment.

Central Nervous System Complications

Hydrocephalus caused by SAH can be immediate or delayed iMcConnick l[L>>L]J-i. Acme dilatation occurs in 20% of patients; it is caused by increased ventricular outflow resistance, appears within 3 days of the SAH, and requires immediate treatment. Delayed ventricular dilatation usually occurs after the tenth day, and is seen in 23% of patients. The development of acute hydrocephalus appears to be related to the degree of intraventricular blood, whereas delayed hydrocephalus can be correlated with the amount of SAH. The amount of cisternal blood on the initial CT, the presence of ventricular blood, and long-term treatment with antifibrinolytic agents are significantly related to the development of hydrocephalus.

Of patients with SAH, 3—5% have seizures during their hospitalisation. The use of anticonvulsants in the acute stage is considered standard therapy for the prevention of seizures, although there is no documentation that prophylactic anticonvulsant therapy has any influence on the development of chronic seizures. Epilepsy develops in approximately 15% of patients who suffer an SAH, and it develops within the first 18 months in more than 90% of these patients. The greatest risk factors for the development of late epilepsy are poor neurological grade on admission, rupture of a middle cerebral artery aneurysm, cerebral infarction secondary to vasospasm, and shunt-dependent hydrocephalus.

Systemic **Complications**

Neurogenic pulmonary edema, considered to be a mixed pressure and permeability edema characterized by the rapid onset of respirarory failure with a protein concentration greater than 4.5 g/dL in the edema fluid, may develop in SAH patients. Most patients with neurogenic pulmonary edema from SAH are comatose. Although initially believed to be secondary to a massive sympathetic discharge producing generalized vasoconstriction, more recent studies suggest that a direct neurogenic effect on the lungs causes pulmonary capillary endothelial damage. Treatment includes monitoring and, if possible, reduction of intracranial pressure, mechanical ventilation with positive

end-expiratory pressure, and monitoring the cardiovascular status to attain the lowest pulmonary wedge pressure **that** maintains an effective cardiac output.

Alterations of the electrocardiogram are the most frequent cardiac abnormality in patients with SAH. The most common changes include prolongation of the QT interval, ST-segment elevation or depression, and increased amplitude or deep inversion of the T waves (neurogenic T waves). These abnormalities are believed to result from disturbances of ventricular repolarization caused by a derangement of autonomic control of the heart. They represent epiphenoniena that reflect intracranial abnormalities without contributing directly to morbidity or mortality, although subendocardial hemorrhages arc common in patients dying from SAH.

Hyponatremia usually is associated with the SIADH secretion, but in some patients with SAH, a ttue natturesis or cerebral salt-wasting syndrome may occur. Assessment of the intravasculat volume status, body weight, and blood volume can differentiate these disorders and allow proper treatment. Patients with a true natrurcsis have evidence of postural hypotension and tachycardia, decreased blood and intravascular volume, elevated hematocrit, and decreased body weight; sodium and volume replacement are needed for proper treatment. SIADH, on the other hand, is associated with a normal cardiovascular status, a normal or low hematocrit, and notmal or increased body weight; the hyponatremia seen in this condition is dilutional or false, as opposed ro the true hyponatremia seen with cerebral salt wasting. Symptoms of SIADH depend on both the level of hyponatremia and the fate at which it develops. Although the best therapy is fluid restriction, this is often balanced by the need to maintain a high intravascular volume to prevent the development of delayed ischemic deficits secondary to vasospasm. In either case, rapid correction is rarely needed, and no more than one half the sodium deficit should be replaced during the first 24 hours.

Prevention of Repeat Hemorrhage and Delayed Ischemic Deficits

Rebleeding

Historically, the most feared complication for survivors of the initial hemorrhage had been recurrent bleeding, which occurred in approximately 15-20% of patients, and was associated with a 40-78% mortality. Treatment of the aneurysm was believed to be best when delayed, because early operative intervention was deemed to be too dangerous. In recent years, a tendency toward early treatment has substantially teduced the tisk of teblccding (Figure 57C.4).

The improved outcome may be related not only to a decrease in the devastating consequences of tchemorrhage, but also to the ability ro provide more effective treatment of vasospasm after the aneurysm has been obliterated. It was believed that cerebral vasospasm and ischemia, the leading

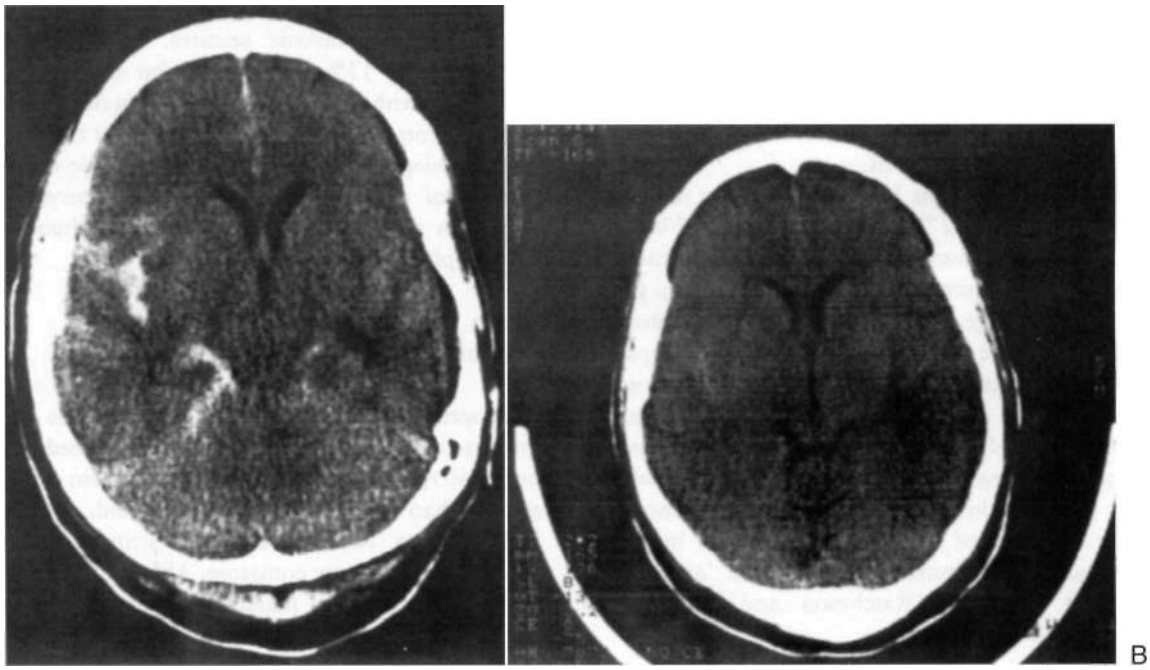

FIGURE S7C.4 (A) Uncontested computed tomography shows a subarachnoid hemorrhage in the right sylvian fissure. (B) The patient suffered a deterioration in neurological status, and a repeat uneontrasted computed tomographic scan performed 2 hours later shows increased blood indicative of aneurysmal rebleeding.

causes of death and disability among survivors of an initial aneurysm rupture, were increased by early surgery and, as such, would negate the benefits of reduced rebleeding following early operation. This was prior to the availability of new treatment options for the prevention and treatment of vasospasm following SAH. According to The International Cooperative Study on the Timing of Aneurysm Surgery (Kassell et al. 1990), 13.5% of all patients who experience aneurysmal SAH suffer delayed cerebral ischemia resulting in permanent disability or death. Of the 1494 patients in that study who died or became disabled, delayed ischemia caused by cerebral vasospasm accounted for 32% of the total; in compatison, the direct effect of aneurysmal rupture resulted in 25% and rebleeding in 17.6% of such outcomes.

Although rehemorrhage can be an immediate, devastating, and itrevcrsible event, the consequences of vasospasm evolve more slowly and are now more predictable, preventable, and treatable. Early aneurysm treatment should be considered for the majority of patients who suffet an aneutysmal SAH. A prospective study from three centers indicates that despite attempts at early surgery, rebleeding is still a significant problem, because only approximately one half of the patients were operared on within 72 hours, and 35% of the patients with a poor outcome had suffered from rebleeding (Roos er a I. 1997). Early recognition of aneurysmal rupture, and prompt treatment at, or transfer to, a facility, with a high volume of SAH patients (Bardach et al. 2002), which is equipped to provide the comprehensive care needed to manage these patients is of utmost importance.

Pharmacological means to prevent rebleeding may be used prior to definitive therapy. Inhibition of the breakdown of the blood clot around and within the ruptured aneurysm wall should lessen the chance of rehemorrhage, and antifibrinolytic agents can reduce the rebleeding rate, but, with long-term use, are associated with increased vasospasm and delayed ischemic neurological deterioration. Thus there was no change in the overall mortality from SAH when antifibrinolytic agents were used in conjunction with delayed sutgery because the decrease in mortality from rebleeding was offset by an increased mortality from ischemic complications. The use of short-tetm antifibrinolytic therapy, however, can prevent rebleeding without provoking increased ischemic complications, and may improve outcome (Hillman et al. 2002).

The definitive method for prevenrion of rebleeding is to secure the aneurysm as soon as possible. Two forms of treatment are widely used for mosr inrracranial aneurysms: microsurgical clipping and endovascular coiling. Surgical clipping is considered the treatment of choice for most intracranial aneurysms. Advances in microsurgical techniques, operative approaches, and clip design have improved the safety of craniotomy for aneurysm clipping. The most common technique for endovascular treatment of intracranial aneurysms involves the placement of detachable coils within the aneurysm sac (Figures 57C.5 and 57C.6). The results of aneurysm occlusion using this method suggest that it is most effective in treating aneurysms smaller than 25 mm in diameter, and with neck width smallct than one half the dome width. In a series of 403 patients with acute SAH treated at eight centers in the United States, complete

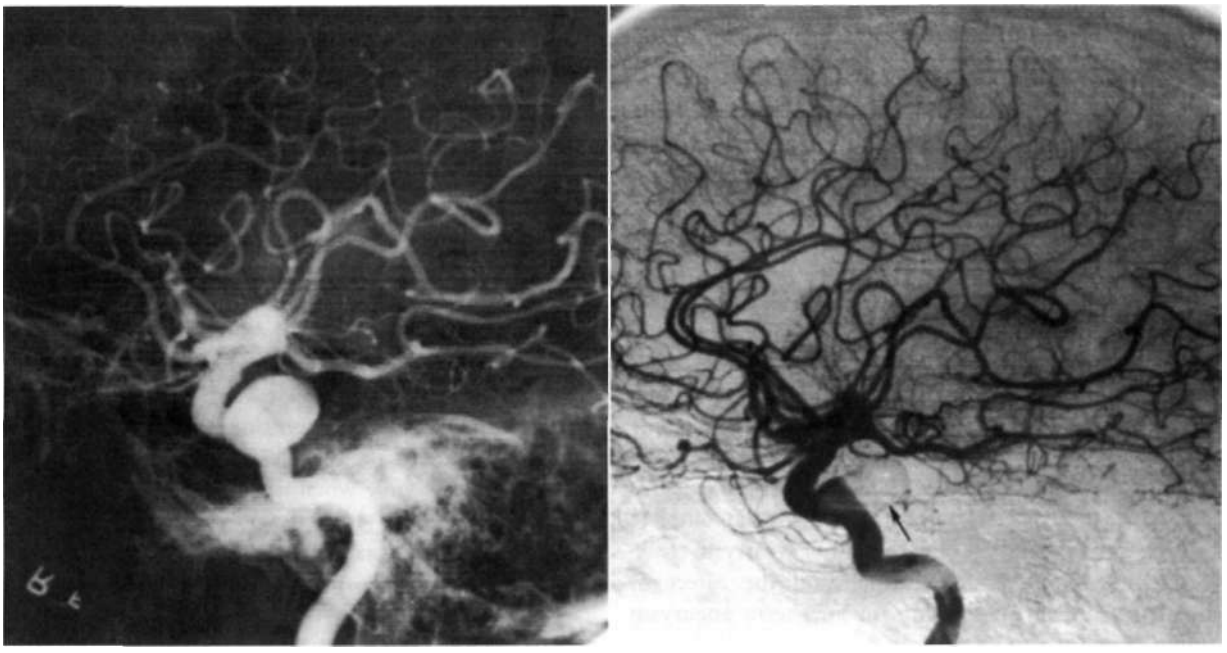

FIGURE 57C.5 (A) Lateral right internal carotid angiogram reveals a large cavernous carotid artery aneurysm. (R) Lateral right internal carotid artery angiogram following balloon embolization *(arrow)* shows almost complete obliteration of the aneurysm.

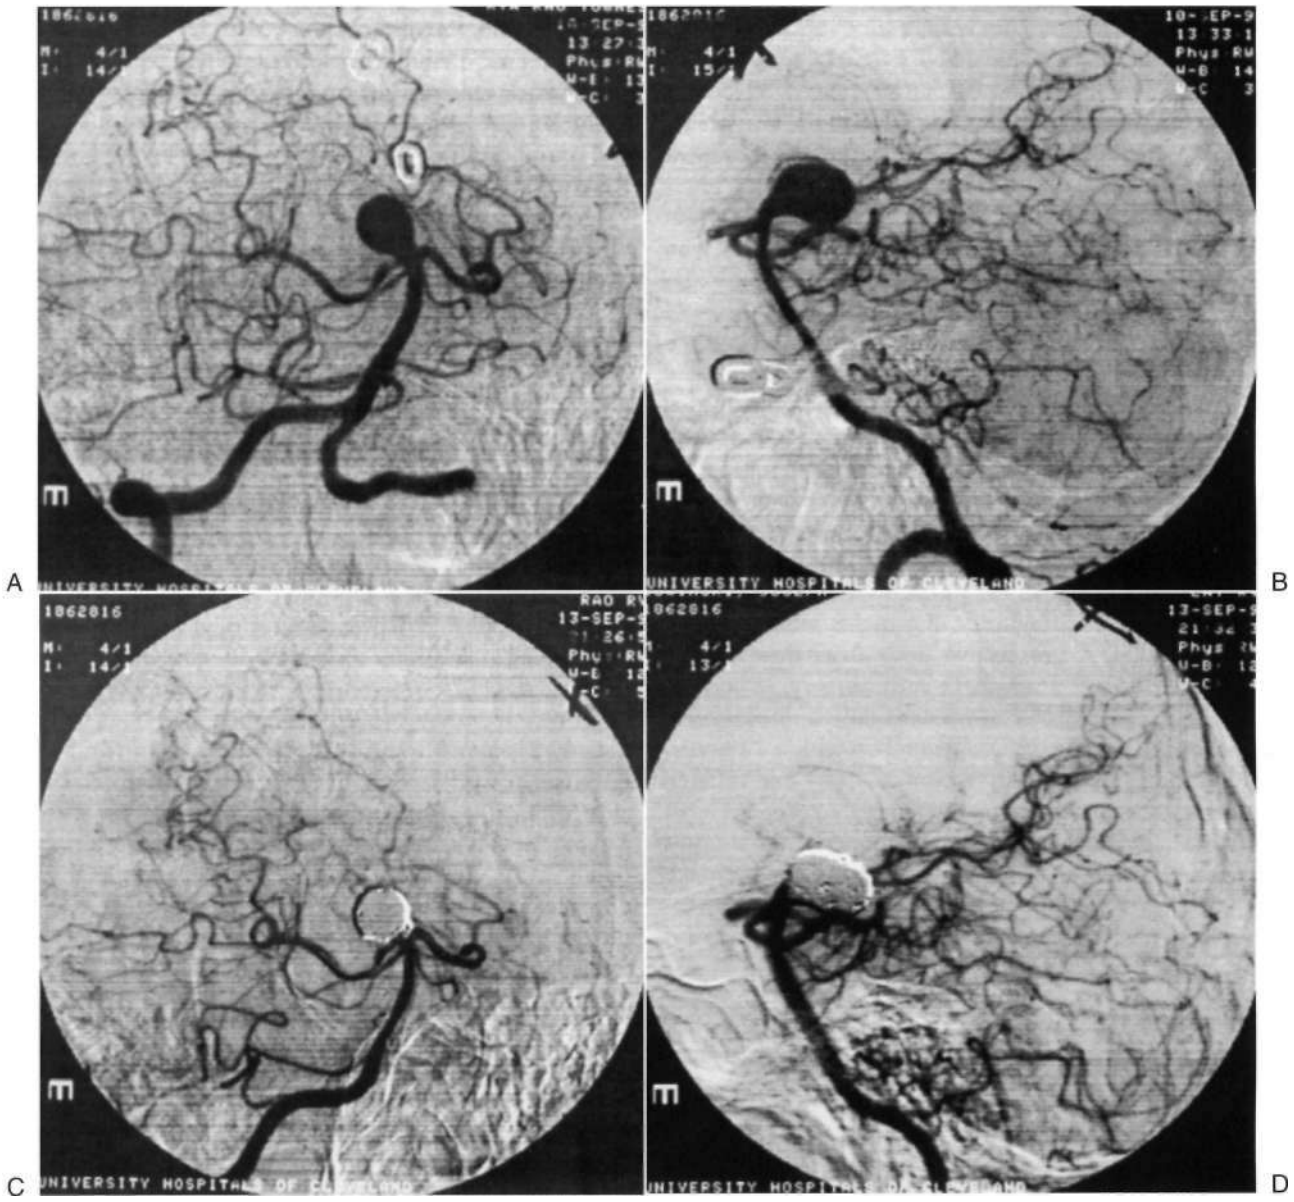

FIGURE 57C.6 Right anterior ohlique (A) and lateral left vertebral artery (B) angiogram demonstrating a large basilar tip aneurysm. Right anterior oblique (C) and lateral angiograms (D) following treatment with Guglielmi detachable coils show obliteration of the aneurysm.

aneurysm obliteration was achieved in 70.8% of aneurysms with a small neck and 35.0% of large aneurysms, and there was an 8.9% immediate procedural morbidity (Vihuelaetal. 1997). Despite advances in coil design and technology, complete aneurysm obliteration rates have remained stable at 29-31% in several recent studies (Gruber et al. 1999; Raftopaulos et al. 2000; Lott et al. 1999). Karly aneurysm rebleeding was not adversely affected by incomplete obliteration in these studies, hut the goal of aneurysm treatment remains complete obliteration, and the affect of incomplete aneurysm obliteration on long-term aneurysm rebleeding remains a concern.

The results of the first prospective randomized trial comparing craniotomy for aneurysm clipping and cndovascular coiling for ruptured intracranial aneurysm by The International Subarachnoid Aneurysm Trial (ISAT) were published in 2002. At 1 year following treatment, patients with aneurysms that were judged by both the neurosurgeon and the interventional neuroradiologist to be suitable for cither clipping or coiling had a reduction in the risk of poor outcome when treated with coiling compared with those patients treated with clipping. The primary outcome measure was the proportion of patients dead or disabled, defined by a modified Rankin scale score of 3-6, at 1 year. Recruitment was stopped after randomization of 2143 eligible patients were selected from 9278 patients with a subarachnoid hemorrhage. Analysis of these paticnts demonstrated an absolute risk reduction of 6.9%

(22.6% relative risk reduction) of dependency or death at 1 year with endovascular treatment. The ISAT report is an important step in defining the roles of endovascular and microsurgical treatment of intracranial aneurysms, although conclusions drawn from this study cannot be generalized to all ruptured and unruptured intracranial aneurysms, and certain caveats are needed in interpreting the results of this study. As noted in the accompanying editorial, "clinical equipoise" did not exist in 80% of the 9278 patients, and in the 7135 patients not randomized, for which follow-up was not available, more patients underwent craniotomy for aneurysm clipping than endovascular aneurysm coiling (Nichols er al. 2002). The differences in outcome between treatments were mainly in the modified Rankin scale score of 3 (significant testriction in lifestyle) and modified Rankin scale score of 2 (some restriction of lifestyle) groups, and there was no difference in mortality. The ability of a questionnaire to reliably differentiate moderate from moderately severe functional disability is uncertain (Nichols et al. 2002). Definitive treatment of an aneurysm should eliminate the risk of post-treatment rebleeding. Post-treatment rebleeding of the treated aneurysm within 1 year occurred in 2.4% (26/1048) endovascular cases, and in 1.0% (10/994) surgical cases. In addition, 139 patients treated by coiling required further treatment compared with 31 patients treated by clipping. Concerns about durability remain with respect to rebleeding rates, risk of recanalization of the aneurysm, and the need for repeat procedures. These issues highlight the necessity of long-term follow-up to determine which of these two forms of treatment is safer and more effective for this subgroup of patients with ruptured aneurysms over their lifetimes. In most comprehensive cerebrovascular centers, these two treatment techniques are considered complementary, and optimal patient care is best achieved by careful consideration of the aforementioned factors in selecting which treatment is most appropriate for each individual patient.

Early treatment to secure an aneurysm can decrease the complications associated with prolonged bed rest, avoid the need for prolonged antifibrinolytic therapy and its attendant complications, and permit more aggressive prevention and treatment of vasospasm and ischemia with blood volume and pressure manipulation, and balloon angioplasty, Advances in microsurgical and endovascular surgery and perioperative management have made carU intervention safer. There is ample evidence that surgery can be performed safely in the time immediately following aneurysmal rupture and may improve outcome (de Gans et al. 2002; Ross et al. 2002).

Early surgery may not be appropriate for every patient with an aneurysmal SAH, but every attempt should be made to secure the aneurysm as soon as possible to prevent rebleeding. Patient selection with respect to grade and timing of intervention is still a matter to be decided by the individual surgeon. Some consider early operation only for patients with good grade aneurysms, whereas others believe the high management mortality associated with patients with grades IV and V hemorrhage, especially younger patients, can be lowered only by early intervention and aggressive postoperative management.

Vasospasm and Delayed Ischemic Neurological Deficits

As indicated earlier, a major cause of morbidity and mortality after SAH is delayed ischemic deterioration. Approximately 5 days after SAH, any or all of the major branches of the circle of Willis that are exposed to blood may develop vasospasm, which may lasr for 1-2 weeks or longer.

SAH can alter the mechanisms that control cerebral blood flow and metabolism (Bcderson 1997). Chemical control of blood flow by carbon dioxide is altered in patients with SAH. Autorcgulation is commonly lost after SAH. Because the degree of impairment of autoregulation may be different in different regions of the brain, a reduction in cerebral perfusion pressure may cause extreme ischemia in some areas but not in others. These changes in the intrinsic control of cerebral blood flow are particularly deleterious because several factors may operate to reduce cerebral blood flow after SAH, including decreased cerebral perfusion pressure from the raised intracranial pressure as a result of acute hydrocephalus or clot formation.

Blood in the subarachnoid space triggers a pathological process that results in spasm of the vessels of the major branches of the circle of Willis. Thus vasospasm can dramatically decrease the caliber of the cerebral vessels and result in a decreased cerebral blood flow. Correlation of pathological specimens from patients with angiographical narrowing has demonstrated changes in vessel morphology, including subintimal cellular proliferation. Specimens obtained the second week after SAH demonstrate thickening of the arterial wall with medial necrosis. However, angiographics I narrowing is reversible and, on the basis of experimental studies, is more likely to be caused by prolonged but reversible smooth muscle contraction. Because flow in a vessel is inversely proportional to the fourth power of the radius, small changes in vessel caliber can have profound effects. If regional flow decreases below the critical thresholds for membrane integrity, ischemic edema formation and infarction can occur. Focal regions of edema can further impair local blood flow despite an overall normal intracranial pressure.

The term *vasospasm* is often used interchangeably to refer to the clinical condition of delayed ischemic neurological deficits and to the vascular narrowing seen on angiography. This terminology is unfortunate in that angiographic findings do not invariably correlate with the clinical picture. Whether such discrepancies are caused by different thresholds of ischemic tolerance, or to other factors, is not clear. This lack of stricr correlation should

not detract from an appreciation of the importance of delayed ischemic deterioration as a cause of serious morbidity and mortality, because its prevention and treatment are clearly a matter of life or death.

Ischemic complications occur in 24-32% of patients after SAH. The amount of blood in the subarachnoid space is an important prognostic factor, and thus the CT scan is critical to predicting the occurrence of vasospasm, A study of 47 patients with aneurysmal SAH who had CT evaluation within 4 days of the initial bleed found that the amount of blood present on the CT scan correlated well with the location and severity of vasospasm. Of the 18 patients with no blood in the subarachnoid space, only one developed spasm. In the presence of subarachnoid blood clots larger than 5 mm by 3 mm, or layers of blood greater than 1 mm thick in the fissures and basal cisterns, severe spasm occurred in 23 of 24 patients.

The modern management of patients with subarachnoid hemorrhage for prevention and treatment of cerebral vasospasm is based on the optimization of volume status and cardiac output (Findlay 1997). In addition, vasospasm appears to be related to an inhibition of reuptake of calcium, which leads to continued vascular smooth muscle contraction. A meta-analysis of nimodipine, a relatively selective cerebral vasculature calcium channel blocker, in the treatment of patients at high risk for cerebral arterial spasm has confirmed the efficacy of the drug for the prevention of delayed ischemia deficits (Barker and Ogilvy 1996). Despite a decrease in severe neurological deficits, there is no reduction in the degree of angiographical vasospasm. It is not clear whether this implies action on smaller vessels than those visualized angiographically, or Other direct anti-ischemic effects of nimodipine. Recently attention has focused on the beneficial effects of magnesium sulfate in the prevention and treatment of vasospasm. Magnesium sulfate may have a role in the prevention or reversal of vasospasm induced by SAH. $MgS0_4$ may prevent vasospasm by acting as a Ca^{2+} antagonist, because Ca^{+} and Mg^{2+} have opposing effects on vascular tone. $MgS0_4$ may have a similar action in blocking the activation of smooth-muscle contraction, as with the dilating effect on cerebral blood vessels exerted by Ca^{2+} channel antagonists. It may also produce beneficial effects by antagonizing the damaging actions of increased intracellular Ca^{2+} concentration induced by cerebral ischemia; the putative mechanism being Mg^{+} competing with Ca^{2+} for intracellular sites or limiting the influx of Ca from damaged cellular membranes (Vcyna et al. 2002).

Despite improvements in hemodynamic augmentation and medical treatment, the development of vasospasm is still a harbinger of potential deterioration from ischemic deficits. New methods of predicting and detecting vasospasm permit the use of more aggressive treatment modalities such as endovascular balloon dilatation of spastic arteries. Transcranial Dopplcr studies permit bedside evaluation of blood flow velocity (which increases with a reduction in vessel diameter) in the intracranial portion of the internal carotid artery and proximal branches of the circle of Willis. With early detection of velocity changes, it is possible to select patients who should be considered for treatment prior to the development of fixed neurological deficits. Other physiological techniques such as positron emission tomography (PET), single photon-emission computed tomography (SPECT), or Xenon CT may be more accurate depicters of cerebral blood flow in patients with threatened vasospasm, but have the disadvantage of not being available at the bedside.

Endovascular treatment, such as angioplasty with a silicone balloon to treat vasospasm, has become an indispensable treatment modality in the comprehensive management of SAH patients, and can provide dramatic improvement in the function of these patients (Eskridge et al. 1998) (Figure 57C.7). Intra-arte rial administration of vasodilators such as papaverine has somewhat unpredictable results. Although it may be useful for distal spasm, questions remain regarding the longevity of the response of intracerebral blood vessels. Additionally, intra-arterial papaverine may have deleterious effects such as increasing intracranial pressure or inducing systemic hypotension (McAuliffe et al. 1995). F.arly experience with intra-artcrial infusion of verapamil appears to be free of these potentially harmful side effects (Lei et al. 2002).

SPECIAL TREATMENT CONSIDERATIONS

Unruptured Aneurysms

The only method of lowering the initial mortality from SAH is to detect and treat unruptured aneurysms, especially in those patients deemed to be at high risk for aneurysm rupture. Because of the poor overall outcome of patients with intracranial aneurysms after SAH, a strong case can be made for surgical treatment of unruptured aneurysms.

The International Study of Unruptured Intracranial Aneurysms (ISUIA) (1998) examined the issue of treatment for unruptured aneurysms. This study, which included both a retrospective and a prospective component and involved 2621 patients enrolled at 53 participating centers, is the largest study on the natural history and the risks of intervention in patients with unruptured intracranial aneurysms. It revealed a lower rate of rupture of unruptured intracranial aneurysms than was previously thought, and an apparently higher rate of combined morbidity and mortality from treatment than reported in most surgical series. The risk of rupture of an aneurysm of less than 10 mm was 0.05% per year. The risk of rupture was increased to 0.5% per year in patients with a history of previous SAH. Aneurysms greater than 10 mm had an approximately 1% per year risk of rupture, with or without a previous history of subarachnoid hemorrhage.

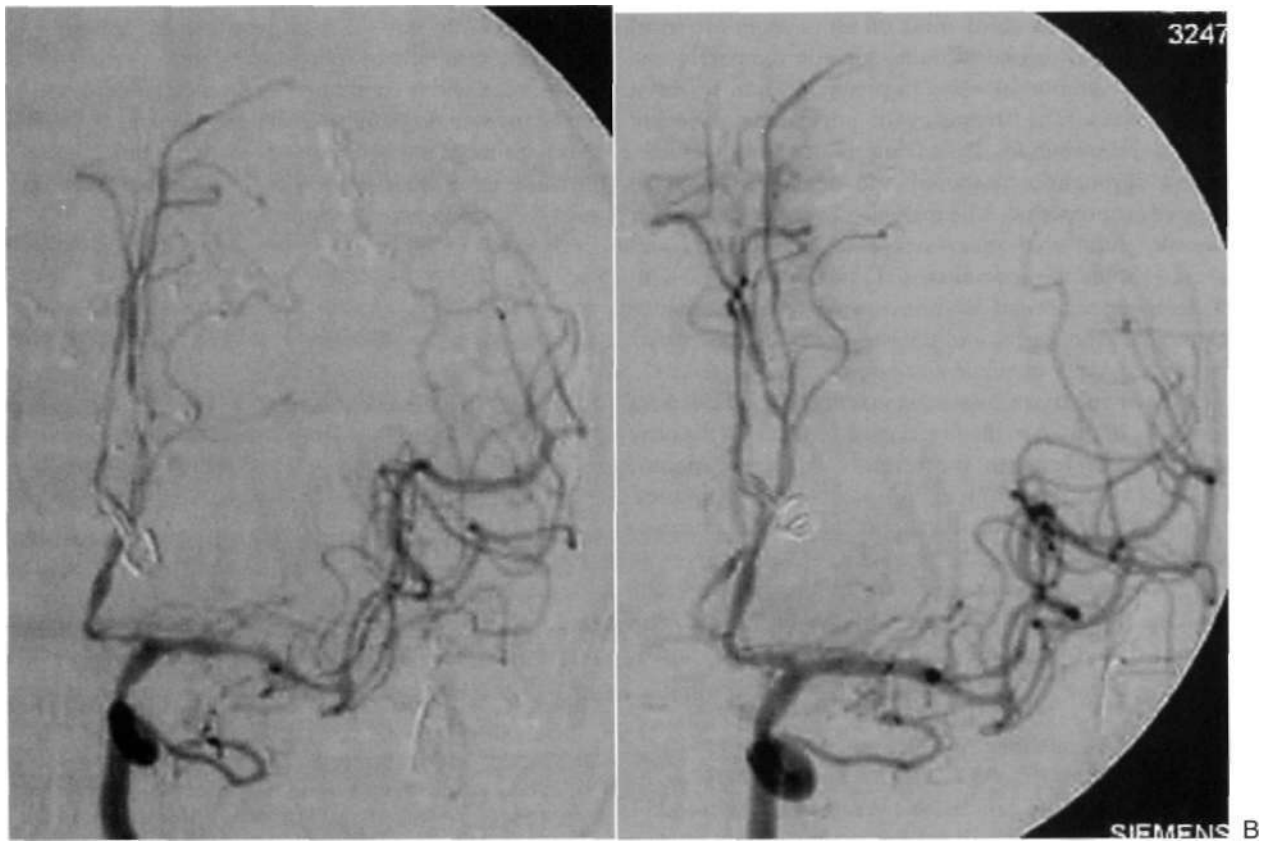

FIGURE S7C.7 (A) Posterior-anterior left internal carotid artery angiogram demonstrates moderate vasospasm of the supraclinoid segment of the left internal carotid artery, the Ml segment of the left middle cerebral artery, the Al segment of the left anterior cerebral artery, as well as multiple segments of the distal left anterior cerebral artery. (B) Posterior-anterior left internal carotid angiogram following angioplasty and intra-arterial papaverine infusion demonstrates improved vessel caliber.

Issues of a selection bias may have influenced the low incidence of ruptute noted in the ISUIA, and the large number of ruptured aneurysms that are smaller than 10 mm argues strongly against accepting a benign prognosis for all lesions below this size (Caplan 1998), Other recent studies noted a higher tate of ruptute of unruptured aneurysms, between 1-2% per year, which is in keeping with rates proposed by earlier investigators (Juvela ct a I. 2000; Tsutsumi et al. 2000; Winn et al. 2002). In a thorough review of the literature, "Weir (2002) noted that although the latgest diameter of an aneurysm is an important factor, the current state of knowledge about unruptuted aneurysms does not support the use of the size of the lesion as the sole criterion on which to base treatment decisions.

The decision to treat an unruptured aneurysm depends on several factors and is complicated because the rupture of an incidental aneurysm is a long-term risk spread out over many years, whereas the risk of surgery is immediate. Factots to be considered are the size of the aneurysm, the morbidity and mortality after SAH, the surgical morbidity and mortality, experience of the surgeon and institution, the life expectancy of the patient, and the attitude of the patient toward shott-term and long-term risk. In the prospective atm of the ISUIA study, the ovetall surgical morbidity and mottality at 1 yeat ranged between 13,1-15.7%. This combined surgical morbidity and mortality rate included analyses of the Rankin score and cognitive status. A meta-analysis of 28 surgical series containing 733 patients undetgoing elective surgery for asymptomatic, unruptured intracranial aneurysms found a morbidity of 4.1 % (95% confidence interval 2.8, 5.8%), and a mortality of 1.0% *(95%* confidence interval 0.4, 2.0%) (King et al, 1994). Elective aneurysm surgery has been demonstrated to be cost effective, provided that the surgical morbidity and mortality remain at low levels, that patient life expectancy is at least 13 years, and that the patient's quality of life is decreased by the knowledge of the aneutysm (King et al. 1995). In light of the devastating consequences of aneurysmal rupture, there must he strong contraindications not to considet the surgical treatment of incidentally discoveted aneurysms in young patients.

Subarachnoid Hemorrhage in Pregnancy

Special consideration needs to be given to the management of SAH during pregnancy (see Chapter 87). The frequency of discovery of cerebral aneurysms is increased during

pregnancy. SAH, the third most common nonobstetrical cause of maternal death, accounts for approximately one half of all intracranial bleeding in pregnancy and carries a grave prognosis. The frequency of aneurysmal bleeding parallels the elevation in cardiac output and blood volume, increasing throughout gestation and extending into the early postpartum period. The management of patients with incidentally discoveted aneurysms is not well defined and treatment should he individualized, but in patients with SAH neurosurgical consideration should take precedence over obstetrical concerns, and the patient should be treated in the same manner as those who are not pregnant.

The time of aneurysm rupture in normal pregnancies is as follows: 8% ruptured in the first 3 months, 22% in the next 3 months, *59%* between the seventh and tenth month, 3% during labor, and 8% in the puerperium. Ruptured aneurysms should probably be clipped as soon as possible, regardless of the state of the pregnancy. If the patient is near term, an expeditious cesarean section may prevent the burden of labor being added to the difficult course following aneurysm rupture and repair.

Subarachnoid Hemorrhage of Unknown Cause

A normal angiogram can be seen in patients with SAH because, occasionally, localized hemorrhage with intense spasm or thrombosis can prevent filling of the aneurysm. Because of the drastic consequences of missing a ruptured aneurysm, repeat angiography 7-10 days later is recommended. Repeat angiography reveals an aneurysm in 19% of patients in whom it was not visualized by the initial angiogram (Kaim 1996). Despite a thorough and complete angiographical evaluation, diagnostic studies fail to reveal a cause for the SAH in a substantial number of patients (see Perimesencephalic Hemorrhage, later in this chapter). Although trauma is the most common cause for SAH, the difference in distribution of blood and the antecedent history rarely make the distinction from aneurysmal SAH difficult. Other causes for nonaneurysmal subarachnoid hemorrhage include angiographically occult vascular malformations, hemorrhagic infarctions, and hypertensive hemorrhages. SAH of unknown cause is not associated with the high morbidity and mortality of aneurysmal SAH, and the risk of fatal rebleeding is well under 1% per year.

Perimesencephalic Hemorrhage

A distinct pattern of SAH that can occur without a detectable aneurysm is perimesencephalic hemorrhage. This entity may be caused by rupture of a capillary telangiectasia of the pons (Wijdicks and Schievink 1997). Patients with this pattern of hemorrhage and a normal angiogram should be considered to have a distinct subset of SAH and generally do not suffer from repeat hemorrhage. These patients have a relatively benign clinical course, although symptomatic vasospasm may occur. Although knowledge of this condition can provide an explanation for a negative angiogram result in the presence of definitive SAH, it should not be used as a reason to omit angiography because localized perimesencephalic hemorrhage can be seen with aneurysmal rupture.

Chapter 57
Vascular Diseases of the Nervous System

D. ARTERIOVENOUS MALFORMATIONS

Warren R. Selman, Robert W. Tarr, Jeffrey L. Sunshine, and Robert A. Ratcheson

Arteriovenous malformations (AVMs) are developmental abnormalities of blood vessels in which one or more primitive direct communications between otherwise normal arterial and venous channels are preserved. The most devastating consequences of these lesions occur as a result of intracranial hemorrhage. Prior to a hemorrhage, these lesions may be uncovered in patients with seizures or may be discovered fortuitously during evaluation for an unrelated disorder. The proper management of AVMs is complex and requires an understanding of their natural history, their effect on cerebral circulation and metabolism, and the capabilities and limitations of the treatment options, including microsurgical resection, neuroendovascular embolization, and stereotactic tadiosurgery.

PATHOLOGICAL CHARACTERISTICS

Vascular malformations may be divided into four major types: (1) venous angiomas, (2) cavernous malformations, (3) capillary telangiectases, and (4) AVMs.

Venous angiomas, which are the most common type of vascular malformation, are composed entirely of venous structures and are almost always clinically silent. The presence of a large dilatated enhancing vein extending to the cortical or cpendymal surface with a radial configuration of smaller veins, as seen on a contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI), is diagnostic (Figure 57D.1). Angiography is rarely needed to confirm the diagnosis.

Cavernous malformations are low-flow vascular anomalies consisting of sinusoidal vascular channels lined by a single layer of endothelium. The walls of the dilatated vessels are thin and contain no smooth muscle or elastic tissue. Marked hyalinization of the vascular channels is common. There is no intervening brain parenchyma within the collagenous stroma separating the individual vascular channels. Of all the vascular anomalies, cavernous malformations are most likely to occur with other lesions, such as a venous angioma. As noted later, cavernous malformations are responsible for the clinical presentation in these mixed lesions.

Capillary telangiectases, or angiomas, are small, solitary groups of abnormally dilatated capillaries. They rarely give rise to spontaneous hemorrhage and usually are detected only in postmortem examinations. There is one case report that suggests that capillary telangiectasia may be associated with the syndrome of perimesencephalic hemorrhage (see Chapter 57C), but this finding awaits confirmation (Wijdicks and Schievink 1997).

True AVMs are congenital lesions that arise from aberrant connections within the primitive arterial and venous plexus overlying the developing cortical mantle. This area of altered vasculature becomes incorporated into the brain parenchyma. The AVM itself is composed of abnormal arteries and veins. Larger vessels resemble veins in that they contain a small amount of muscularis and lack elastica. The amount of gliotic tissue that intervenes between the abnormal vessels varies greatly. Most AVMs show evidence of microscopic hemorrhage in this tissue regardless of whether the patient has experienced a symptomatic hemorrhage. There is no normal capillary bed in the nidus of an AVM.

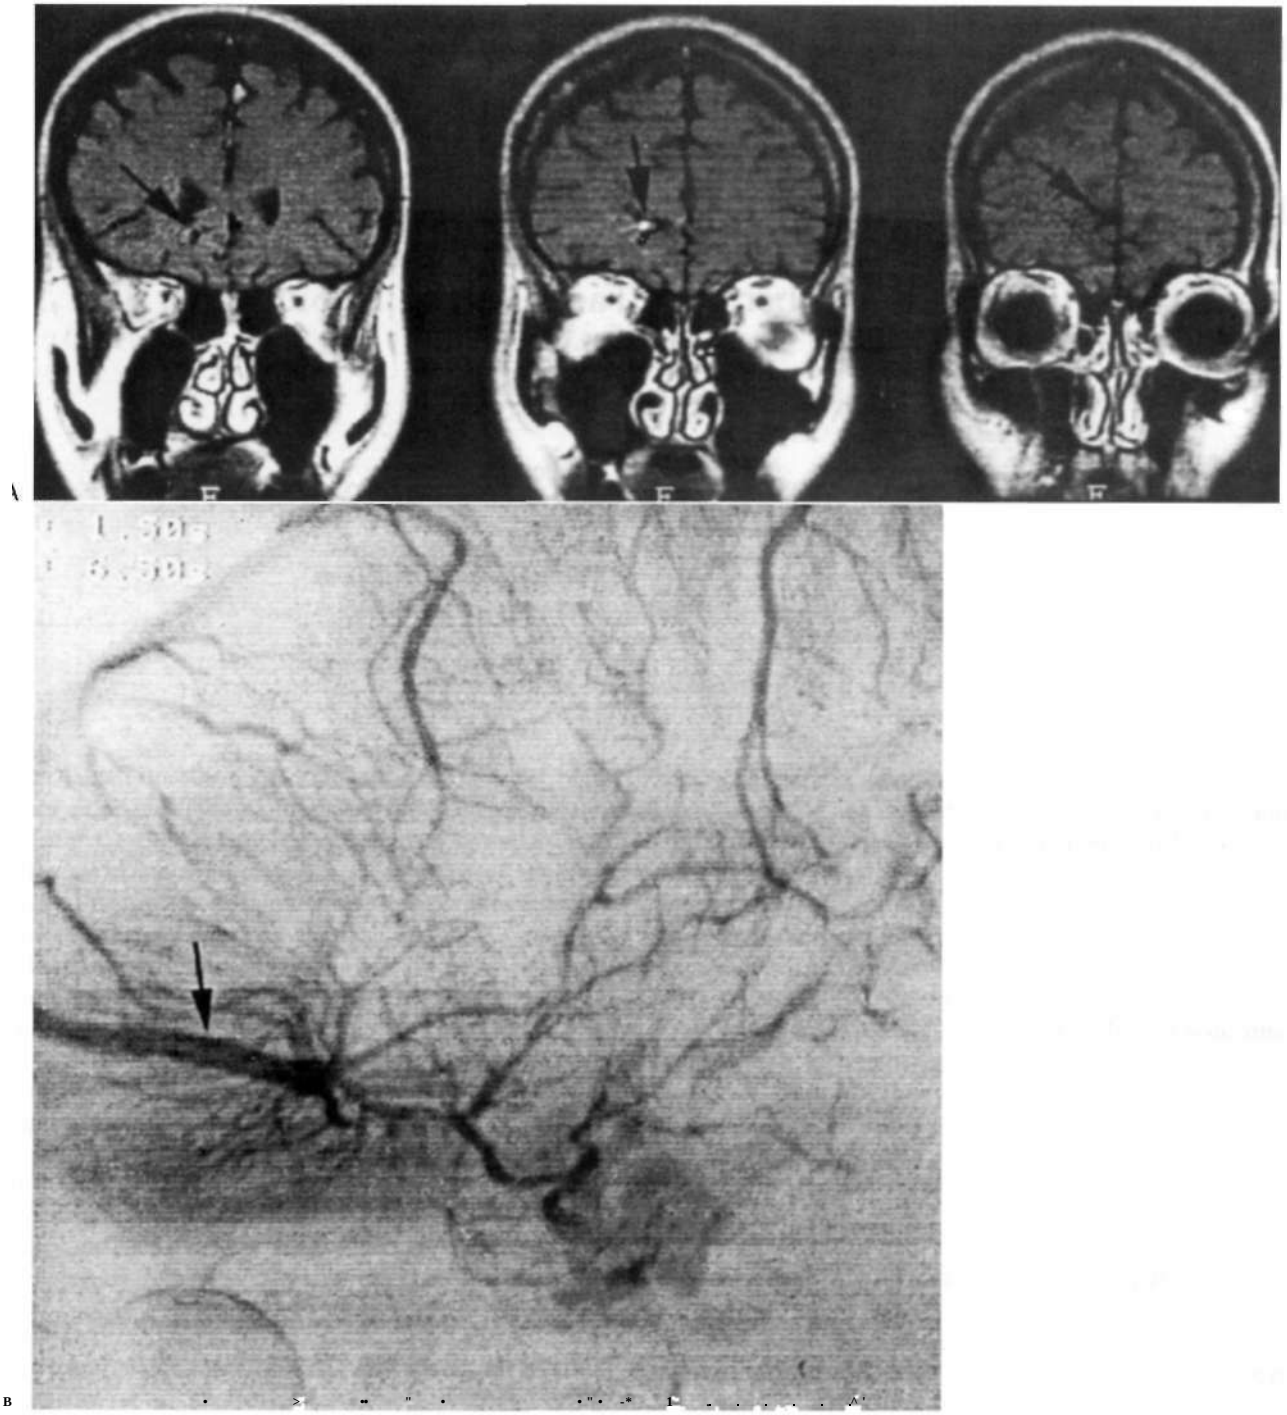

FIGURE 57D.I (A) Coronal Tl-weighted magnetic resonance images demonstrate the venous tributaries and large draining vein characteristic of a venous angioma *(arrows).* (B) Lateral venous phase from a right internal carotid artery angiogram confirms the right frontal venous angioma *(arrow)* draining toward the anterior portion of the superior sagittal sinus.

EPIDEMIOLOGY AND CLINICAL SIGNS

Cavernous Malformations

The frequency of cavernous malformations depends on the mode of study. In major autopsy series, the frequency is 0.02-0.53%. Studies based on MRI have reported a higher frequency of 0.4-0.9% (Maraire and Awad 1997). Familial forms of cavernous malformations, characterized by multiple lesions, appear to be transmitted in an autosomal dominant fashion (Notelet et al. 1997). Cavernous

malformations occur in all age groups, but the majority of patients present in the second to fourth decade of life. Most cavernous malformations are solitary lesions, but multiple lesions occur in approximately one thud of sporadic cases, and in more than two thirds of familial cases.

Cavernous malformations are dynamic lesions, and intralesional hemorrhage, thrombosis, organization, calcification, cyst formation, and involution of the caverns all contribute to the changes in these lesions. Cavernous malformations, unlike venous angiomas, have no distinctive CT scan appearance, but do have a characteristic MRI signature (Figure 57D.2). The MRI pattern of a central core of increased intensity surrounded by a rim of decreased intensity on T2-weighted sequences, or multiloculated rounded areas of increased signal on Tl-weighted sequences, allows their radiographical identification. Although the MRI picture is characteristic, the differential diagnosis should include cryptic or partially thrombosed AVMs, primary hemorrhagic or metastatic tumors, infectious and granulomatous diseases, and inflammatory lesions.

Cavernous malformations are rarely visualized on angiography because of the small size of the afferent vessels, the presence of thrombosis, and the relatively low flow in these lesions. *Cryptic malformation* is a term used to describe a small malformation that is undetectable by angiography but is demonstrated by pathological examination to be responsible for intracranial hemorrhage. Cavernous malformations account for 25-50% of such occult lesions. The remainder are considered to be angiographically occult AVMs. Because the natural history of the two lesions is different, in the presence of a new hemorrhage, follow-up angiography after the resolution of any mass effect may be needed to exclude the presence of a small AVM.

Solitary and multiple lesions may be clinically silent. The most common clinical manifestations of cavernous malformations are seizures, hemorrhage, and progressive neurological deficit. Seizures occur with approximately twice the frequency in patients with cavernous malformations compared with patients with AVMs and have been reported in between 38% and 100% in clinical series.

Cavernous lesions with calcification, evidence of chronic intralesional hemorrhage with thrombus organization, and thick pseudocapsules are more likely to present with seizures than gross hemorrhage. Women are more likely to present with gross hemorrhage and neurological deficits, whereas men are more likely to present with seizures.

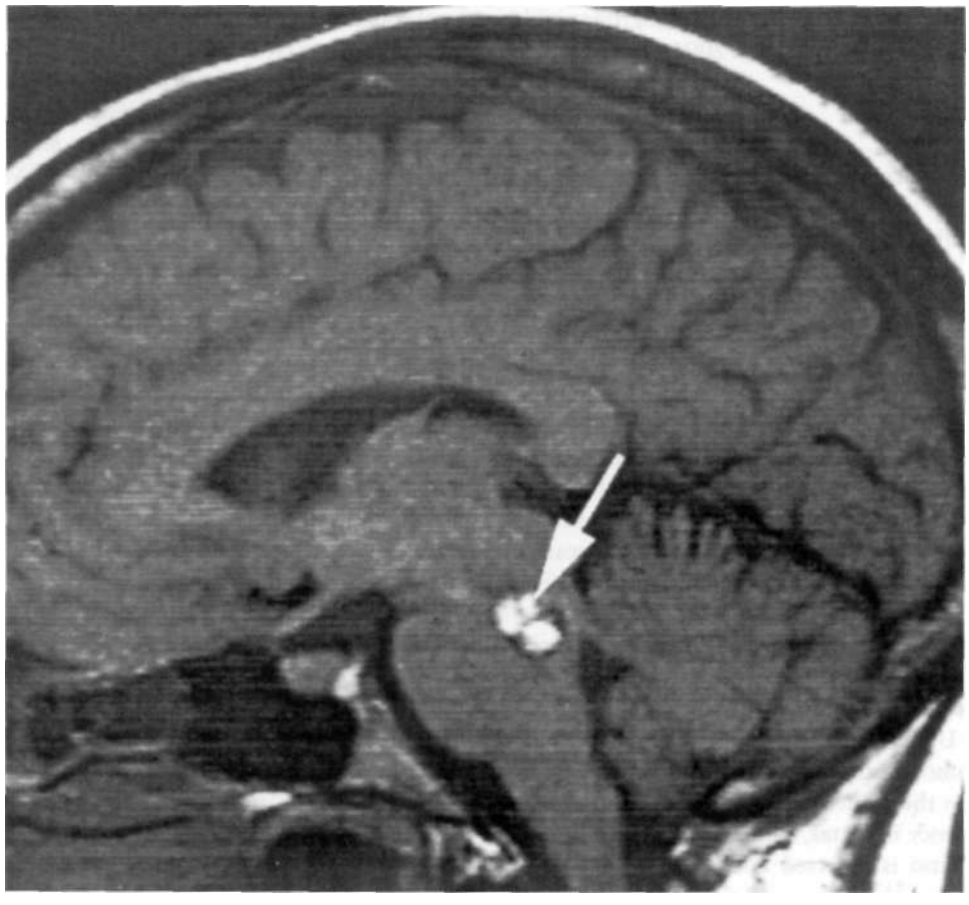

FIGURE 57D.2 Sagittal Tl-weighted magnetic resonance image demonstrates a cavernous angioma involving the dorsal midbrain *(arrow).* Note the characteristic surrounding areas of high signal intensity caused by walled-off microhemorrhages.

Clinically significant hemorrhage has been reported in between 8% and 37% of lesions in large clinical series (Maraire and Awad 1997). It is imporrant to distinguish between intralcsional and extralesional hemorrhages, and defining a clinical and radiological event as a bleeding episode is sometimes problematic. Although variable, the annualized risk of hemorrhage is between 1.6% and 3.1% per patient per year {Moriarity et al. 1999; Porter et al. 1997). In contrast to primary hemorrhage occurring from an AVM, the clinically significant bleeding noted with cavernous malformations is rarely life threatening, and the initial bleed is self-limited and patients usually have a good or fair outcome. There is, nonetheless, an increased risk of recurrent hemorrhage after an initial bleeding episode, which has been estimated to be between 207o and 85%. The risk of re hemorrhage has been shown to decrease over time. Cavernous malformations have a temporal clustering of hemorrhages where the rehemorrhagc rate is high initially, and decreases 2 to 3 years after a previous hemorrhage. In one study of 141 patients who presented with hemorrhage, during the first *iVi* years after a hemorrhage, the monthly hemorrhage hazard was 2%, and then the risk decreased to less than 1% per month (Barker et al. 2001). Most studies indicate that brainstem cavernous malformations have a rate of recurrent symptomatic hemorrhage up to 69%, and a significant morbidity; there may be some subgroups with a more benign course (Kupersmith et al. 2001; Moriarity etal. 1999; Porter et al. 1997).

Arteriovenous Malformations

AVMs occur with equal frequency in men and women, rarely produce clinical symptoms before the first decade, and commonly present in the second and third decades of life. Because many remain asymptomatic throughout life, determining the prevalence of AVM is extremely difficult. Autopsy series, showing prevalence rates between 500-600 per 100,000 undoubtedly reflect selection bias. Currently, we can only estimate the detection rate for symptomatic AVMs, which is 0.94 per 100,000 person years (Berman et al. 2000). Determining the prevalence of asymptomatic AVMs would necessitate performing random MRI scans on more than 1 million people, and would disclose a figure only within 20% of the true rate.

The ratio of AVMs to aneurysms in different populations is influenced by geography and ethnicity, as well as by referral patterns that probably distort the true figures. For instance, in the United States, aneurysms are more than 5 times more common than AVMs, but arc almost 14 times more common in the United Kingdom, and seem to occur with equal frequency in Qatar, Saudi Arabia, and China. In Singapore, the ratio is reversed and AVMs may be four times more common than aneurysms {Ohacghulam 2001).

Patients with AVMs may seek medical attention for one or a combination of the following problems: (1) intracranial hemorrhage, (2) seizures, (3) focal neurological deficits, (4) impairment of higher cortical function, {5) headache, and (6) bruit.

Headaches may occur in 5-35% of patients with AVMs. They characteristically begin during the second decade of life; they may be generalized, unilateral, focal, continuous, or intermittent. They are nonspecific and, in the absence of hemorrhage or hydrocephalus, the relation of the headache to the AVM is not always apparent.

In contrast to aneurysms, which produce predominantly subarachnoid hemorrhage, AVMs tend to produce localized intracerebral hemorrhage. Intraventricular, or subarachnoid hemorrhage, also may be present. The resulting neurological deficit depends on the location and size of the hemorrhage. There is no characteristic clinical picture that is specific for AVM hemorrhage. In most cases there is nothing remarkable about the history other than the sudden onset of severe headache, which is characteristic of any intracerebral hemorrhage.

Seizures may occur in patients at any age. Seizures are the presenting feature in 28-67% of patients with AVMs. More than 50% of patients found to have an AVM are likely to have had at least one seizure by the age of 30. A seizure is more common as an initial symptom between the ages of 11 and 20 years; hemorrhage is more common as an initial symptom between the ages of 21 and 30 years. Patients with large AVMs are twice as likely to have seizures in contrast to hemorrhage as their presenting symptom, with the converse relation holding for smaller lesions.

In addition to headaches, seizures, and hemorrhage, less frequent clinical manifestations of AVMs include focal neurological deficits caused by ischemia (steal phenomenon); cardiomegaly; and high-output congestive failure caused by the high-volume shunt, obstructive hydrocephalus, communicating hydrocephalus, and cranial nerve compression. The occurrence of these problems is in part related to the patient's age. Cardiomegaly and cardiac failure are usually manifested only during infancy and early childhood in a patient with a vein of Galen aneurysm, which is something of a misnomer because the underlying lesion is an AVM. Similarly, obstructive hydrocephalus is usually a disease of childhood secondary to aqueductal compression from an enlarged vein of Galen aneurysm or AVM, but communicating hydrocephalus may occur at any age from an intraventricular hemorrhage.

PHYSICAL FINDINGS

The physical examination should be tailored to the age of presentation. In infancy, evidence of a hyperdynamic cardiovascular state should be sought. It is necessary to measure head circumference. At any age, auscultation of the head may reveal a bruit, which may often be of some help in localization. Finally, the presence and character of a neurological deficit can localize the site of hemorrhage.

PHYSIOLOGY AND METABOLISM

In 1928 Cushing and Dandy both described alterations of normal blood flow patterns in the brain surrounding AVMs. They reasoned, on the basis of finding red blood (arterialization) in the venous channels, that the brain was not using the flow for metabolic purposes. The paucity of filling of surrounding cortex in the presence of an AVM, as noted on angiography, was described as *cerebral steal.*

Blood flow to and from AVMs is conducted through normally located channels. Because there is not a separate AVM circulation, the relationship between cortical nutrient branches and the arteries diverting blood into an AVM is important. A simplified model to describe the relationship of pressure in nutrient branches of a feeding vessel to AVM flow is depicted in Figure 57D.3. A decrease in pressure along a feeding artery is directly proportional to the time-average velocity of flow and the length of the artery. Thus the higher the flow to the AVM, the less the pressure in the nutrient arteries. Increased venous pressure associated with an AVM also leads to a further decrease in nutrient flow.

Although many high-flow AVMs demonstrate angiographic cerebral steal, not all produce ischemic symptoms (Taylor et al. 2002). This is explained in part by the auto regulatory response of the normal cerebral vasculature to a decrease in local perfusion pressure. In addition, neurons maintain normal electrophysiological function until flow is reduced from normal levels of 50 mL/100 g per minute to less than 20 mL/100 g per minute. Nonetheless, chronic hypoperfusion in the nutrient vessels surrounding an AVM may result in maximal dilation such that autoregulation is lost in this area. Such changes make the involved territory susceptible to alterations in systemic pressure and could result in cerebral ischemia.

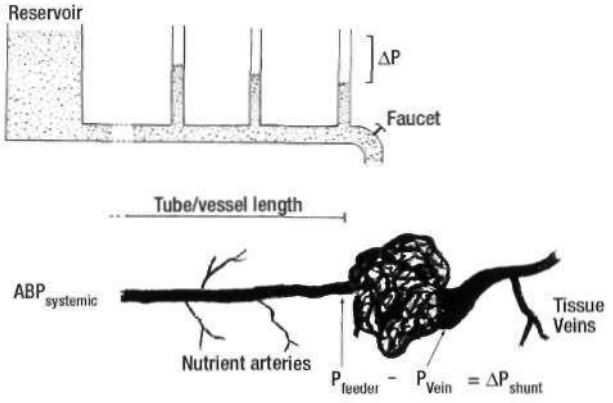

FIGURE 57D.3 Relationship of pressure (P) in the nutrient branches (those supplying surrounding normal cortex) to the flow in the feeding vessel supplying an arteriovenous malformation. (ABP =i arterial blood pressure.) (Adapted from Nornes, H. & Grip, A. 1980, "Hemodynamic aspects of cerebral arteriovenous malformation," 7 *Neurosurg,* vol. 53, p. 456.)

LABORATORY STUDIES

The identification of patients suspected of having an AVM has been made easier by the development of modern noninvasive diagnostic imaging techniques including CT scan, CT angiography, MRI scan, and magnetic resonance (MR) angiography (see Chapter 37B). If an AVM is found, conventional angiography (see Chapter 37C) is essential in determining the optimal treatment. An AVM may receive arterial input from any of the major cerebral arteries. If the AVM is located solely within the territory of a single cerebral artery, then the blood supply to the malformation may come solely from that artery. In larger AVMs, or those bordering more than one territory, the arterial supply is usually from more than one arterial distribution. Thus complete four-vessel angiography is needed to define these lesions. The venous drainage may be through the superficial or deep venous system, or directly into a major sinus, or some combination of these patterns.

The CT scan is often the first study that suggests the presence of a vascular malformation in a patient with headaches, seizures, or a neurological deficit. Information can be gained from both noncontrast and contrast-enhanced scans. The noncontrast scan can establish the presence and location of hemorrhage. A lobar hemorrhage should increase the suspicion of a vascular malformation as the underlying cause. Other diagnostic considerations include hypertensive hemorrhage, aneurysmal rupture, and hemorrhage into a tumor. Enhancement occurs because of collection of the contrast material in the intravascular compartment as well as in surrounding areas with altered blood-brain barrier permeability. The presence of a serpentine enhancement pattern is highly characteristic. High-resolution (2.0-min slice thickness) dynamic CT imaging after contrast administration allows accurate measurement of the size of the AVM nidus (Figure 57D.4).

Standard sequences such as Tl- and T2-weighted MRIs provide precise information on the size and location of an AVM (Figure 57D.5). The relation of feeding arteries and draining veins can be appreciated using MR angiography. Three-dimensional tlme-of-flight techniques are especially helpful for visualizing arterial flow, and two-dimensional time-of-flight is best for showing the slower flow in the venous drainage (Figure 57D.6).

Functional imaging (see Chapter 37E) is helpful in determining the effects of the AVM on the blood flow and regulatory capacity of the surrounding brain. Stable xenon CT scanning has been used to delineate the response to acetazolamide. The presence of a steal phenomenon may indicate a loss of autoregulation in the brain surrounding the AVM (Figure 57D.7). The relation of the AVM to vital cortical areas can be appreciated by the use of functional MRI (Figure 57D.8). These newer imaging modalities provide information that influences therapeutic planning.

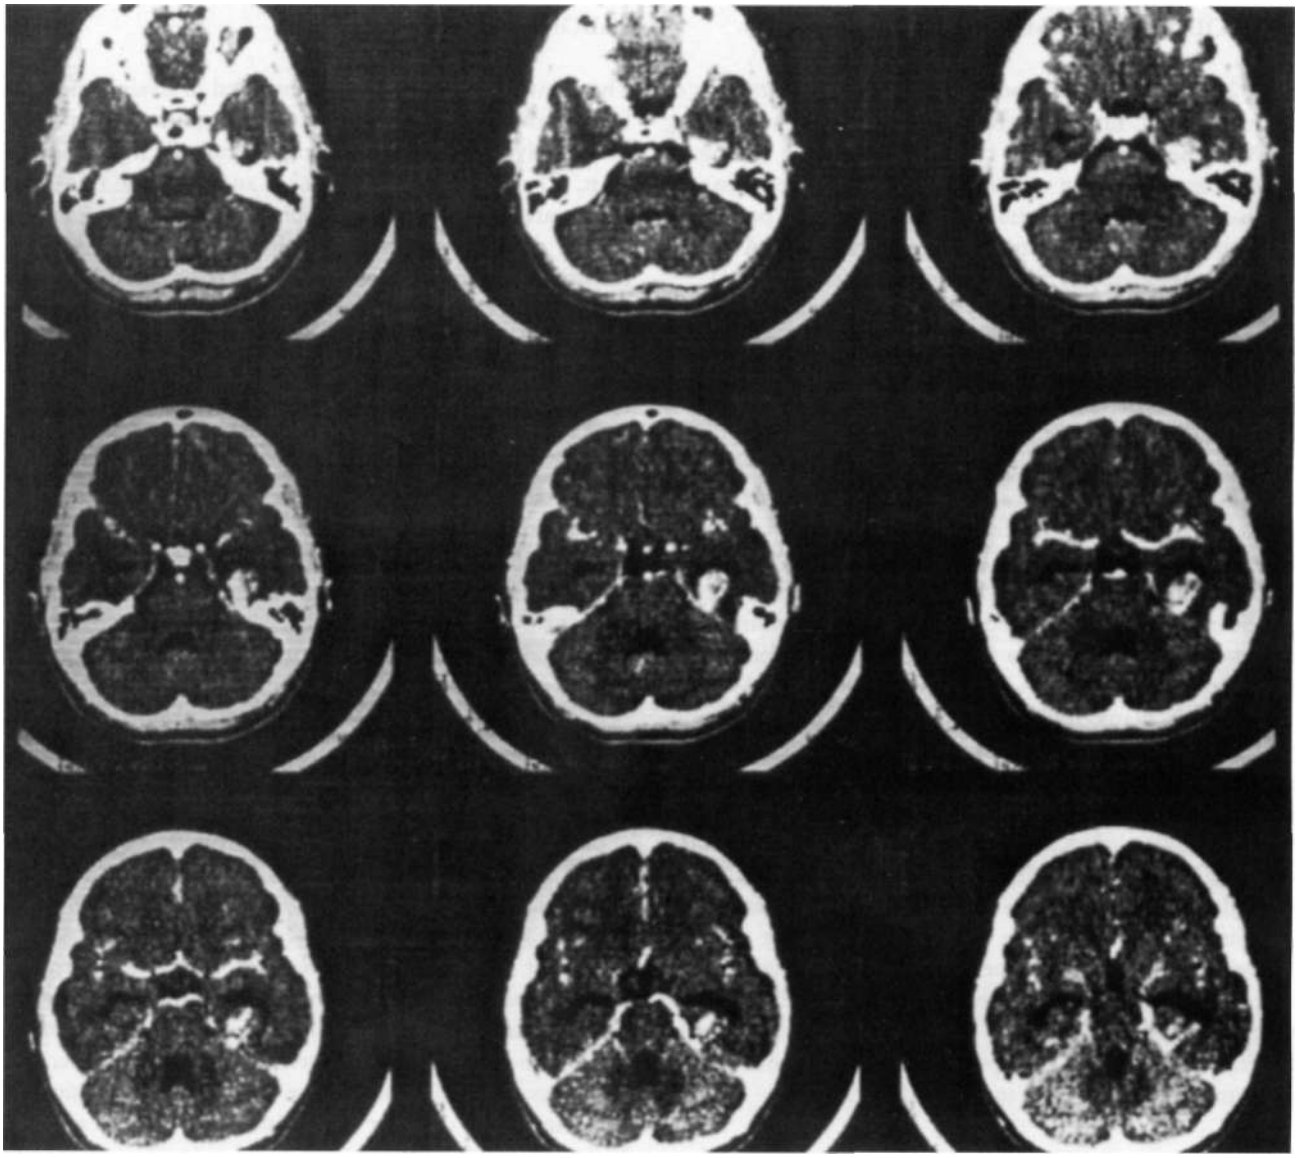

FIGURE 57D.4 Dynamic contrast enhanced computed tomography (2-mm slice thickness) delineates the nidus of a left posterior temporal lohc arteriovenous malformation. Standard sequences such as Tl- and T2-wcightcd magnetic resonance imaging provide precise information on the size and location of an arteriovenous malformation (see Figure 57D.5). The relation of feeding arteries and draining veins can be appreciated using magnetic resonance angiography. Three-dimensional timc-of-flight techniques are especially helpful for visualizing arterial flow, and two-dimensional time-of-flight is best for showing the slower flow in the venous drainage (see Figure 57D.6).

COURSE AND PROGNOSIS

Intracranial hemorrhage is the most significant clinical manifestation of an AVM. All studies have demonstrated a relatively constant and high risk of hemorrhage associated with AVMs. It is important to stress that the cumulative rate of hemorrhage is the same regardless of the presentation. Even an unruptured AVM carries a 4% yearly risk of hemorrhage. The mortality from the first hemorrhage varies between 6% and 14%. Once an AVM has bled, the likelihood of recurrent hemorrhage is approximately *6%* for the first year and 4% for subsequent years. Any estimate of the risk of hemorrhage for an individual patient must take into account specific considerations that may not be entirely reflected in cumulative data. For example, untreated AVMs in the posterior fossa appear to have a particularly poor prognosis. Children arc at relatively greater long-term risk for rehemorrhage, in that they normally have a longer lifespan during which rehemorrhage may occur. Patients with smaller AVMs, because of differences in the flow patterns and pressure within the nidus, may be more likely to hemorrhage than large AVMs.

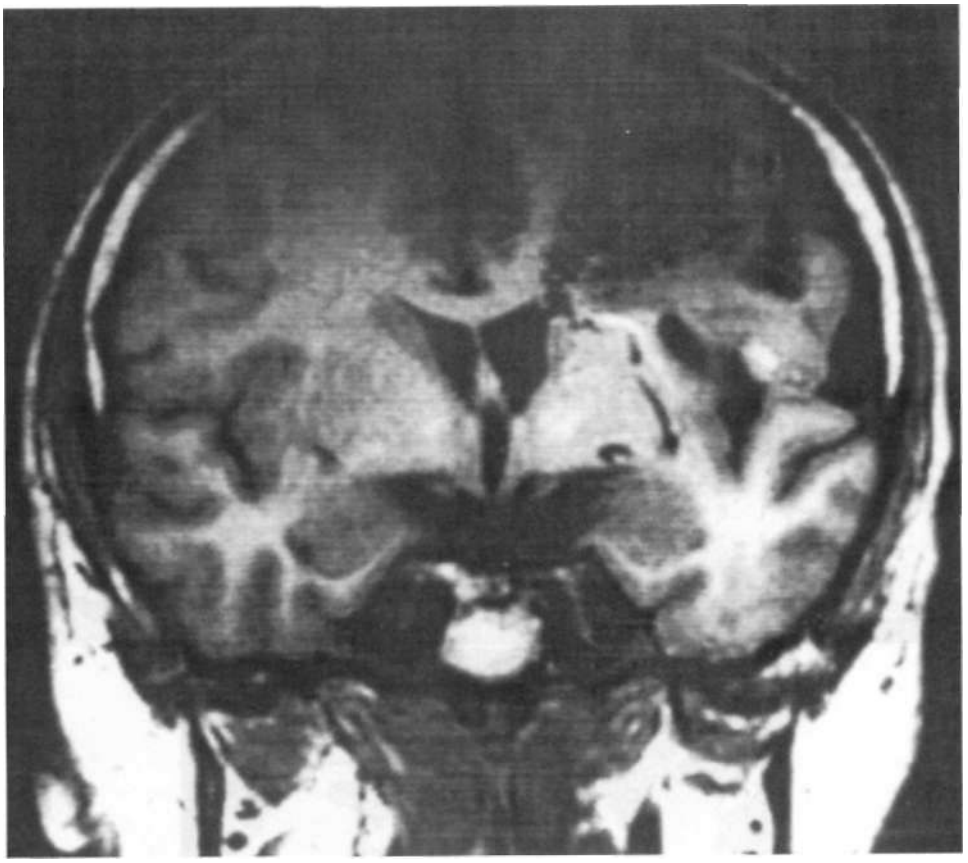

FIGURE 57D.5 Coronal Tl-weighted magnetic resonance image demonstrates a left frontal arteriovenous malformation nidus that extends to the ventricular surface.

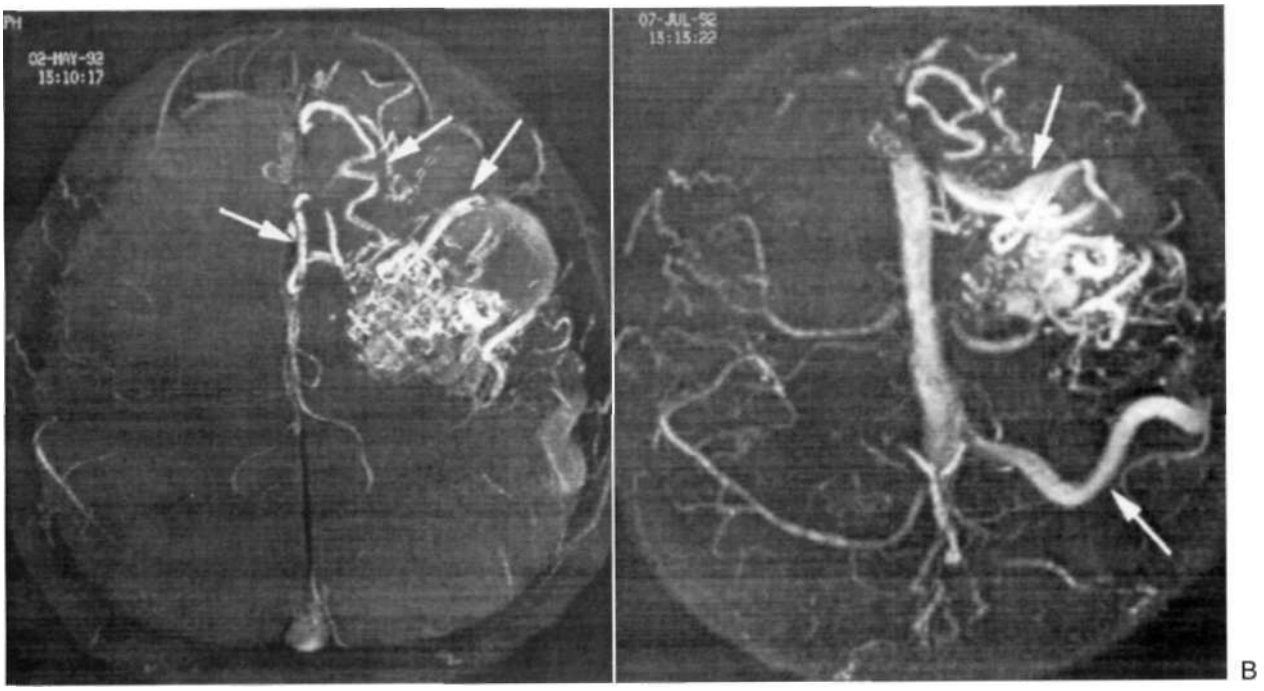

FIGURE S7D.6 (A) Three-dimensional time-of-flight magnetic resonance angiography demonstrates arterial pedicles *(arrows)* as well as a venous varix. The entire venous drainage pattern cannot be defined on this study. (B) Two-dimensional time-of-flight magnetic resonance angiography of the same patient details the venous drainage of the arteriovenous malfotmation into the superior sagittal sinus *(arrows).*

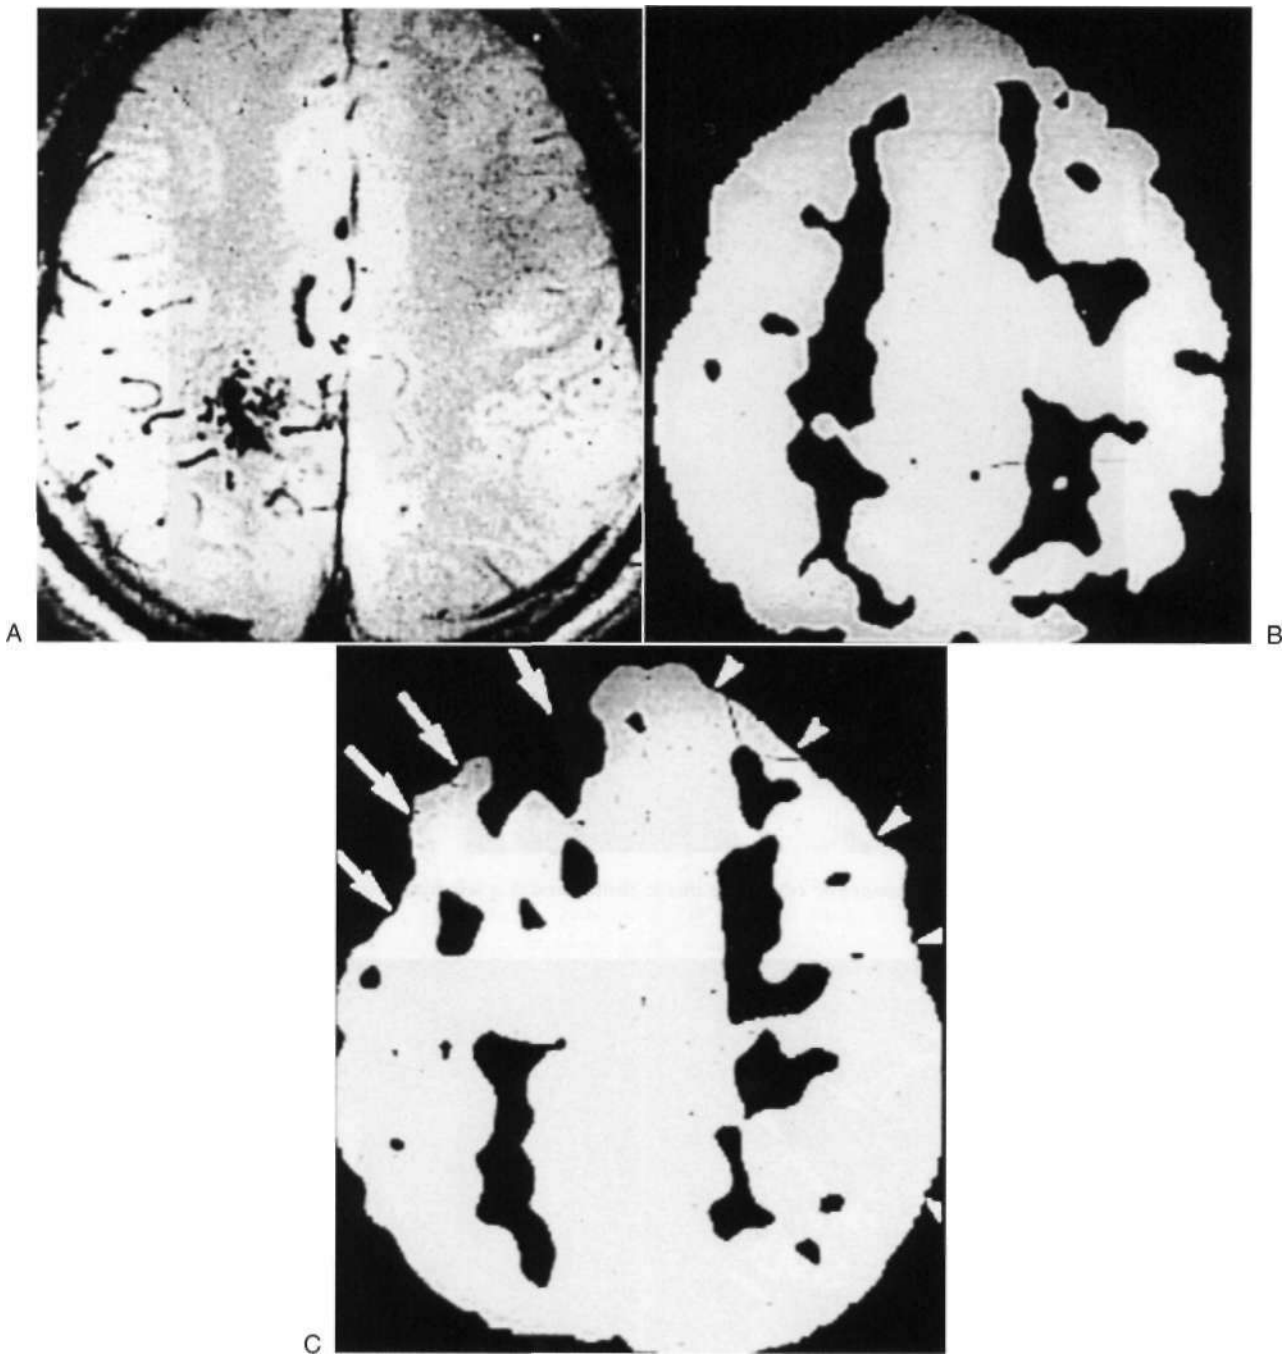

FIGURE 57D.7 (AJ Axial proton density-weighted magnetic resonance image shows a right parietal lobe arteriovenous malformation. Xenon computed tomographic scan cerebral blood flow analysis (B) before and (C) after the administration of acetazolamide (Diamox) demonstrates normal augmentation of blood flow with acetazolamide in the left hemisphere *{arrowheads}*, but a diminution of flow or vascular steal phenomenon *(arrows)* in the right ftontal lobe.

Systemic hypertension increases the risk of AVM hemorrhage. AVMs that have aneurysms on intranidal vessels, and those that have areas of venous outflow restriction, are more prone to hemorrhage (Figure 57D.9).

The overall course of patients harboring an AVM is not benign. In addition to the effects of a major hemorrhage, neuronal damage from repeated minor hemorrhages or ischemia of adjacent brain from cerebral steal can result in progressive neurological deterioration. The yearly mortality in a large series with long-term follow-up was 1-2%; the rate of mortality plus morbidity was 5%; the rate of morbidity alone was 3.5%. Other series have reported a mortality of approximately 0.9% per year. Mortality and morbidity for individuals younger than 20 years and

older than 40 may be lower than in the intervening age group.

TREATMENT

Cavernous Malformations

The therapeutic options for cavernous malformations include medical management of seizures or surgical excision for control of seizures, prevention of hemorrhage, or prevention of recurrent bleeding. With seizures, surgical therapy is used if medical management is unsuccessful, or if medical management can be optimized by removal of the lesion and the seizure focus.

The use of stereotactic radiosurgical therapy for treatment of cavernous malformations is being investigated, but the standard doses used for true AVMs are associated with a poor clinical response and a high complication rate. With lower doses, there are fewer complications reported, bur the i'] id points for therapeutic success are harder to define than with the criteria of angiographic obliteration used for true AVMs. Although some reports indicate that there is a reduction in the risk of reblccding 2 years following stereotactic radiosurgery for cavernous malformations (Hasegawa et al. 2002) the natural history of reduced hemorrhage risk after two years makes it difficult to ascribe the reduced hemorrhage rate solely to the effects of treatment (Barker et al. 2001).

In general, the role of surgery is defined by the status of the patient and the location of the lesion. Asymptomatic lesions are usually followed with observation only. In patients presenting with asymptomatic hemorrhage, surgical resection should be considered for any accessible lesion in the supratentorial region, and for any brainstem lesion that has a presentation on the pial surface or the floor of the fourth ventricle (Maraire and Awad 1997; Porter et al. 1997; Moriarity et al. 1999).

Arteriovenous Malformations

In light of a better understanding of the natural history of AVMs, and with refinements in therapeutic options, consideration of treatment should be given to most patients who harbor an AVM. With respect to determining which mode of therapy is optimal, microsurgery, radiosurgery, and endovascular surgery are all compatible and complementary (Ogilvy et al. 2001).

Although the mam indication for treatment is prevention of neurological morbidity caused by hemorrhage, there is a reduction in the occurrence of seizures with successful AVM treatment, whether microsurgical or radiosurgical (Ogilvy et al. 2001). As noted in the previous section, the major morbidity and mortality from an AVM result from hemorrhage, and surgical excision is the most direct and immediate method of eliminating the risk of subsequent hemorrhage.

The factors to be considered in determining the difficulty of surgically excising an AVM include the size of the lesion, the number of feeding arteries, the amount of flow through the lesion, the degree of steal from the surrounding brain, the location of the lesion, the functional importance of the surrounding brain, and the path of the venous drainage. Some of these variables are inter-related, and to facilitate surgical decision making, grading systems are used for predicting the operative risks in patients with different AVMs. The scale used most commonly is the Spetzler-Martin scale {Spet/ler and Martin 1986), which, for ease of grading, focuses on size, pattern of venous drainage, and the function of the surrounding brain. A sum of points assigned determines the grade of the AVM (Table 57D.1). Both retrospective and prospective experience have demonstrated a correlation between the grade of the AVM and the surgical risk, although the confidence intervals for these correlations are continuing to be defined.

The decision to pursue treatment must be made in light of a comparison between the natural history of AVMs and the risks of therapy for each individual. The wide variations both in the natural history and in treatment outcomes mandate careful consideration of diverse factors. If a hemorrhage has occurred from a small, accessible AVM located in a noncritical area of the brain, therapeutic intervention is clearly warranted. A large lesion with a complex blood supply that is located in a critical area and that has never bled generates considerably more controversy with regard to its best management.

Decision analysis has been used to determine the role of microsurgical excision in the management of patients with AVMs. The hazards of an uncritical use of decision analysis are evident when applied to AVM treatment. Decision-analysis techniques suggest that unless surgical mortality is on the order of 1% and surgical morbidity no more than 7%, nonoperative therapy is the preferred method of management. For these calculations, a 20-year follow-up was used, and the bleeding rate was assumed to be 1% per year. There are several problems with this application

Table S7D.1: Spet/ler-Martin gradi ng scale

of decision analysis to AVM management. First, the probability of bleeding is a critical issue. With longer periods of follow-up, it has become apparent that the rate of rebleeding is higher than previously believed. Thus a 1% rate of bleeding severely underestimates the 4% per year rate of hemorrhage now known to occur in patients who present with or without hemorrhage. Second, an observation period of 20 years may be too short for general application. As stated previously, most AVMs are detected in the second, third, and fourth decades of life. Longer periods of observation, compatible with a normal life expectancy in the nonoperated group, necessarily increases the overall probability of hemorrhage. Furthermore, the likelihood of hemorrhage appears to be increased during these early decades, whereas patients in this age group, in general, are considered low-risk surgical candidates. Individual factors that may influence the frequency of hemorrhage and microsurgical outcome are not always considered in treatment algorithms. For example, small lesions are more likely to bleed, and these lesions also are associated with a lower surgical morbidity and mortality. Finally, surgical series of between 70 and 100 patients have reported outcomes compatible with decision analyses favoring operative intervention, with mortalities of approximately 1% and morbidity of well less than 7%. Thus although decision-analysis schemes may help to provide a framework for considering the optimal management of AVMs, care must be taken to accurately estimate the risk of all of the factors that can influence the decision for each individual.

The role of surgery in the management of AVMs is expanding. Sisti and colleagues *(1993)* reviewed their experience with *67* AVMs less than 3 cm in diameter and reported angiographic obliteration in 94%, with a surgical morbidity of 1.5% and no operative mortality. Of these lesions, 45% were in regions that some would consider surgically inaccessible, such as the thalamus, brainstem, medial hemisphere, and paraventricular regions. The immediate protection against hemorrhage provided by microsurgical removal and the avoidance of any risk of development of delayed radiation related brain injury are distinct advantages over stereotactic radiosurgery. These results emphasize that small size and location should not dictate which form of treatment is offered to a patient.

Large lesions previously classified as unresectable also may be managed surgically by using a regimen of preoperative embolization and staged resection. Preoperative embolization can cause thrombosis of much of the vascular nidus and decrease the number of feeding arteries. The role of endovascular techniques in the management of AVMs is continuing to expand with the development of improved catheters and embolization material (n-BCA Trial Investigators 2002). In particular, the preoperative use of both diagnostic and therapeutic endovascular techniques has allowed safer and more effective use of microsurgery and radiosurgery for the treatment of complex AVMs {Dion and Mathis 1994).

Radiosurgery has become an important tool for the treatment of some AVMs. The role of stereotactic radiation in the treatment of AVMs is both expanding and being better defined (Figure 57D.10). The results of the previous series demonstrate that stereotactic radiation is most effective in the obliteration of small AVMs. Because of the delayed reaction of the vessels, the patient remains at risk for bleeding until complete thrombosis is attained. The patient also should be advised of the possibilities of incomplete AVM obliteration and the risk of delayed development of radiation-induced brain injury. Even in the most favorable circumstances with a lesion less than 3 cm in diameter, the percent of lesions completely obliterated after 3 years is approximately 85%. An analysis of microsurgical and radiosurgical treatments concluded that microsurgical treatment of AVMs of grades I through III was associated with significantly fewer postoperative hemorrhages, fewer post-treatment neurological deficits, and fewer deaths. A life-table analysis confirmed the statistically significant difference in hemorrhage-free survival time between the microsurgical and stereotactic radiosurgical treatment groups (Pikus et al. 1998). The risks and benefits of the therapeutic options for patients with AVMs can he appreciated by direct comparison (Table 57D.2).

Special consideration must be given to the management of AVMs in pregnant women (see Chapter 87). Intracranial hemorrhage in pregnancy is caused as often by AVMs as by aneurysms. Although increased blood volume and venous pressure may be important in the pathogenesis of AVM hemorrhage, the time of hemorrhage does not always occur with the peak in cardiovascular changes of pregnancy. Labor and delivery is a high-risk period for AVM-associated hemorrhage, when 11% of these incidents occur. The decision about the diagnostic workup, time of surgery, and preoperative management should be based on neurosurgical rather than obstetrical criteria. If a hemorrhage has occurred during pregnancy, the risk of repeat hemorrhage is higher than in the patients who are not pregnant. Because of this high rate of reblccd, some have suggested that surgical excision of AVMs that have ruptured should be undertaken as soon as the patient is stable. The stage of pregnancy must be considered also; for those near term, an elective cesarean section at 38 weeks' gestation may carry the smallest combined risk to mother and child.

In general, to ensure that patients with AVMs receive appropriate therapy, the importance of a comprehensive team approach, which includes specialists with expertise in microvascular neurosurgery, endovascular techniques, and stereotactic radiation, cannot be overemphasized. Large lesions previously classified as unresectable may be safely managed with a combination of endovascular techniques, followed by surgical excision, and small lesions can be immediately and effectively eliminated with microsurgery.

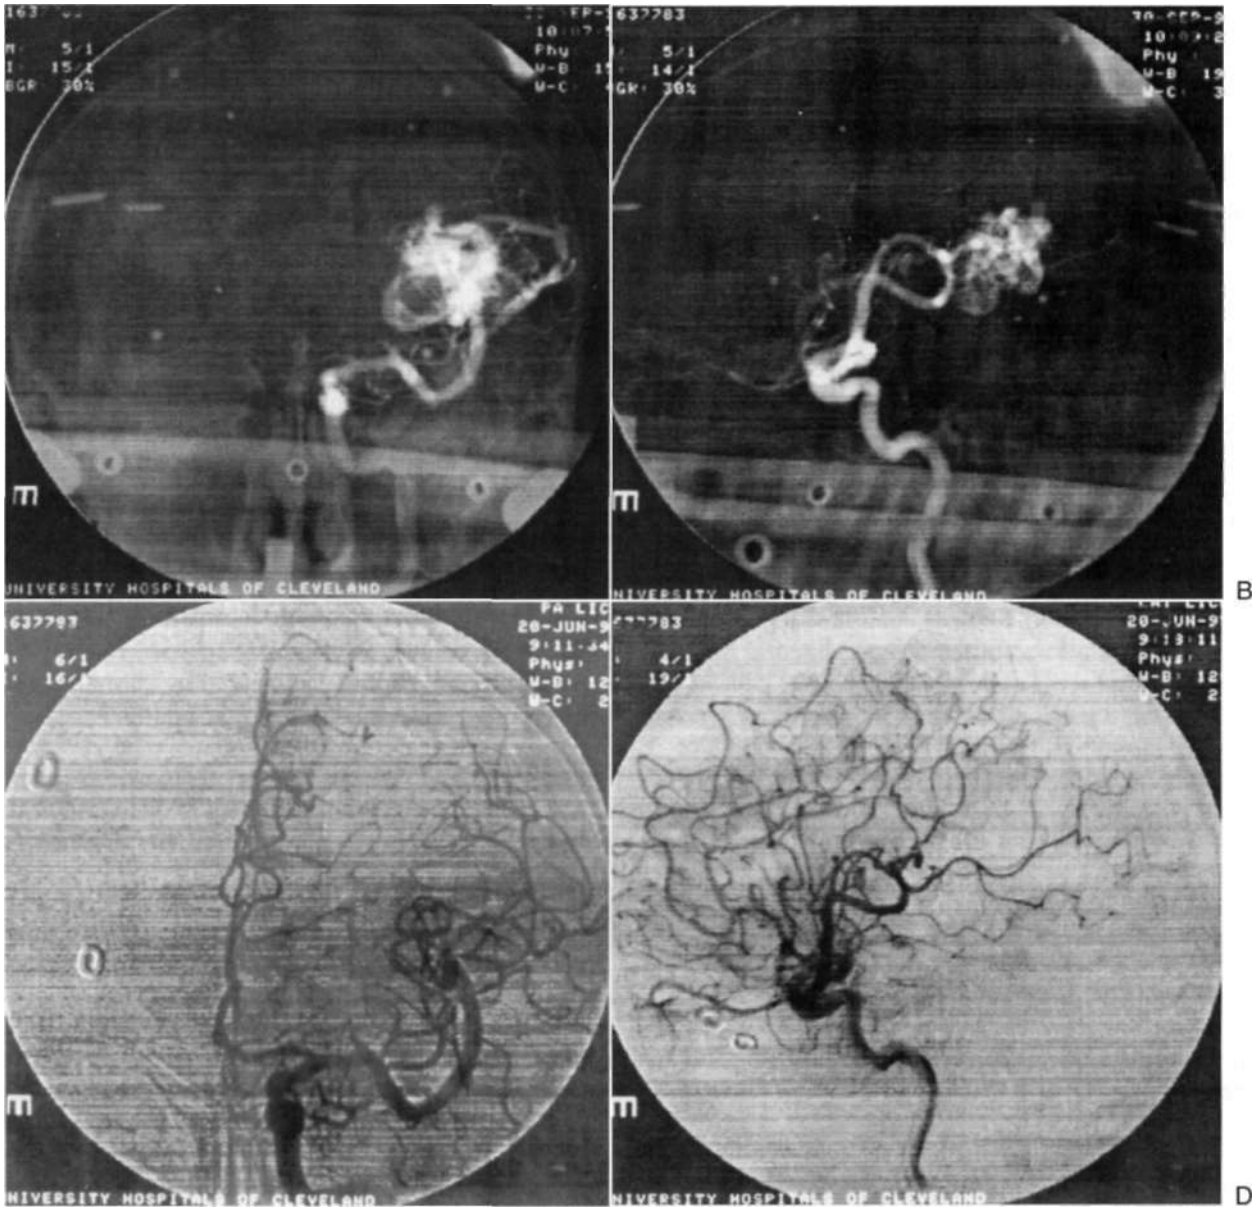

FIGURE 57D.10 (A) Posteroanterior and (B) lateral stereotactic left internal carotid artery angiogram demonstrates a left temporal arteriovenous malformation supplied by the left middle cerebral artery. Two-year follow-up (C) posteroanterior and (D) lateral left internal carotid attery angiograms after radiosurgery show obliteration of the arteriovenous malformation.

Table 57D.2: Comparison of tteatment modalities

Treatment modality	*Advantages*	*Disadvantages*
Microsurgical excision	Immediate elimination of risk of hemorrhage	Risk of immediate new neurological deficit
Endovascular embolization	Immediate reduction in size of AVM; immediate closure of intra n id a I aneurysms; no general anesthesia; short hospitalization	Rarely achieves total and permanent obliteration of AVM; risk of immediate new neurological deficit from hemorrhage or ischemia
Stereotactic radiosurgery	Noninvasive treatment; short hospitalization	Latency of 13 yr with risk of hemorrhage until complete obliteration ol AVM; risk ot delayed neurological deficit from radiation damage

AVM = arteriovenous malformation.

Chapter 57
Vascular Diseases of the Nervous System

E. STROKE IN CHILDREN

Meredith R. Golomb and Jose Biller

STROKE AND THE DEVELOPING CEREBROVASCULAR SYSTEM

Stroke in the older adult is usually due at least in part to chronic vascular injury. Obesity, cigarette smoking, arterial hypertension, diabetes mellitus, and a sedentary lifestyle are contributory to the majority of strokes in this population. In most children with sttoke, chronic lifestyle factots make little contribution to the cause of stroke. Developmental, genetic, and environmental factors are all possible contributors to cerebrovascular injury in the child.

EPIDEMIOLOGY

Premature and Term Neonates

Neonates are at higher risk for sttoke than older children, with risks for different stroke types partially determined by gestational age. The germinal matrix, an important site of neutonal development in the developing fetus, is highly vascularized with thin-walled vessels prone to rupture with increases in blood pressure. Premature infants often experience such shifts in blood pressure as a result of ventilators and othet sttessors, putting them at high tisk for intraventricular hemorrhage (IVH). Thorp et al. (2001) found that severe intracranial hemorrhages affected 2.9% of premature neonates 34 weeks' gestational age and younget, and 7.2% of premature neonates under 1500 g. (IVH in the premature neonate is discussed in further detail in Chaptet 86.) Neonates with gestational age older than 36 weeks are at lower risk of IVH. Gradnitzer et al. (2002) found that intracranial hemorrhage affects 1 in 100 term neonates.

Term and near-tctm neonates may also be at relatively high risk of arterial ischemic infarction when compared with older children, for reasons which are not completely clear. Lynch et al. (2001) at the National Institutes of Health estimated rates of 1 in 4000 and 1 in 5600 term births, but Gunthet et al. (2000) in Germany found a rate of only 1.35 per 100,000 tetm births.

There are few studies looking at the rate of cerebral venous thrombosis (CVT) in neonates. DeVeber et al. (2001) found a tate of 0.67 cases per 100,000 children per year, with neonates making up 43% of cases; the tates were not described in relation to the number of term births.

The General Population of Children

Estimates of the incidence of all pediatric stroke have ranged from 2.5 to 13 cases per 100,000 children per year

(Giroud ct al. 1995), with some variation among studies on the inclusion of neonates, traumatic strokes, and meningitis. ,md whether to use 16 or 18 as the age cut-off for pediatric stroke. There is also variation among studies as to whether hemorrhagic or ischemic strokes predominate. Estimates of the rate of hemorrhagic stroke have varied between 1.2 and 5 per 100,000 children per year (Giroud et al. 1995), and estimates of the rates of ischemic stroke have varied between 0.6 and 8 per 100,000 children per year (Giroud et al. 1995; deVeber 2002).

High-Risk Subgroups

Certain subgroups of children are at high risk of stroke, with rates approaching or surpassing those in older adults. Some medical conditions place children at risk for intracranial hemorrhage, ischemic stroke, or both,

Vascular malformations may present with intracranial hemorrhage. At the Hospital for Sick Children in Toronto, 80% of children diagnosed with arteriovenous malformations presented with spontaneous intracranial hemorrhage (Humphreys et al. 1996). It is not clear what percentage of children with arteriovenous malformations never have hemorrhage or other neurological signs, because neuroimaging is generally precipitated by neurological symptoms. Cavernous malformations and aneurysms may run in families and can present in childhood (Figure 57E.1). Risk may vary depending on the mutation involved. Intracranial hemorrhage may lead to vasospasm and resultant ischemic stroke, but may be rarer in children than in adults.

Children with bleeding disorders are at high risk for intracerebral hemorrhage. Of patients with hemophilia, 4% have intracranial bleeds, and 48% of these bleeds are intracerebral (Klinge et al. 1999).

Children with sickle cell anemia are at risk for ischemic stroke because sickling red blood cells may lead to thrombosis, and in some patients may be associated with moyamoya. The rate of stroke in children with sickle cell anemia has been estimated at 285/100,000 children per year (Earley et al. 1998), which is higher than the stroke rate reported in several adult stroke registries. Of children with sickle cell anemia, 11% have strokes and 17% have clinically silent infarcts (Figure 57E.2) (Pegelow 2001). Children with sickle cell anemia may also develop aneurysms and resultant hemotrhage, but this is more common in adults with sickle cell.

Children treated with extracorporeal membrane oxygenation (ECMO) are at high risk for both intracranial hemorrhage and embolic ischemic stroke. The rates of infarction after ECMO vary dramatically between scries, with rates ranging from 0% to 26%; Jarjour et al. (1994) examined the brains of 44 patients dying while on ECMO, and found evidence of focal ischemic infarct in 50% and intracranial hemorrhage in 52%.

Children with complex congenital heart disease arc at risk fot cardioembolic stroke, thrombotic stroke, watershed infarcts from drops in perfusion pressure, and CVT {Figure 57E.3). The rates of stroke in children with complex congenital heart disease also vary among series, with some of the variation resulting from the severity of the malfotmation, the number of corrective surgeries required, anesthetic techniques during surgery, patient selection, and length of follow-up. Miller et al. (1994) found evidence of focal infarction in *6* of 20 children with magnetic resonance imaging (MRI) performed at least 2 years after surgery. However, their data suggested that the patents of childten

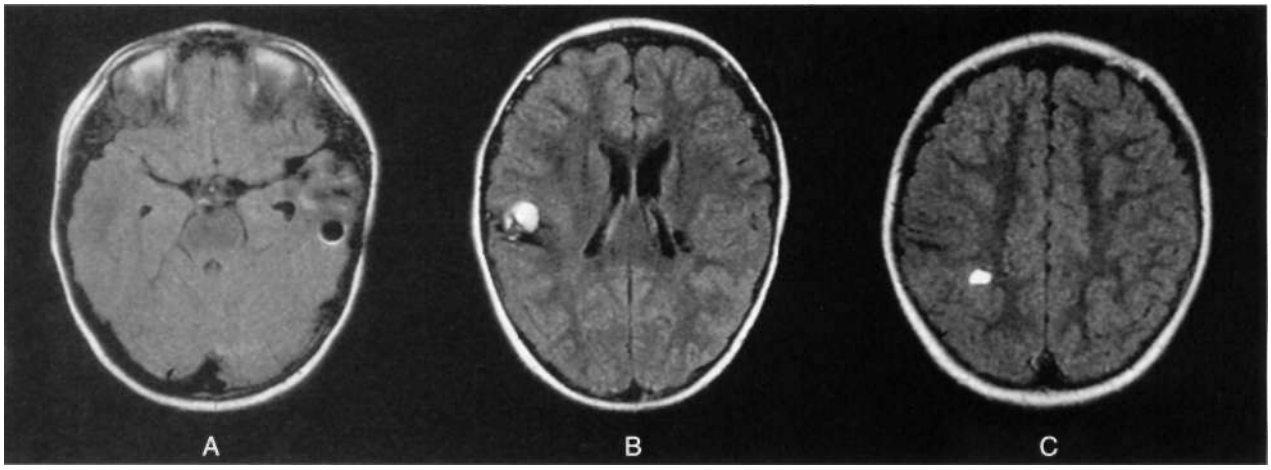

FIGURE .i71'.. 1 [his is ;i 5-ycar-oUI hoy with a history ot multiple cavernous malformations ami partial temporal lobectomy for resection of a cavernous malformation who presented with seizures. (A-C), Fast spin echo inversion recovery magnetic resonance imaging demonstrates multiple h y peri n tense new and hypo intense old parenchymal hemorrhages consistent with cavernous malformations, with evidence of recent hemorrhage and increased size of the right posterior frontal lesion and a new small hemorrhage in the right centrum semiovale. (Courtesy Section of Neuroradiology at Riley Hospital for Children, Indianapolis, Indiana.)

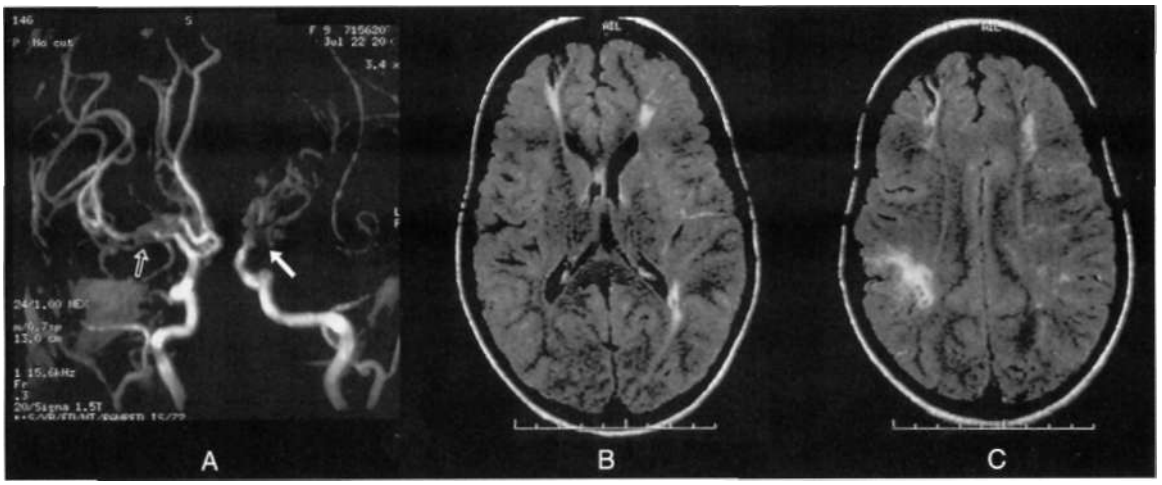

FIGURE 57E.2 This is a 10-year-old girl with sickle cell anemia. At age 5 she presented with a left hemiparesis. Magnetic resonance imaging (MR!) then showed acute ischemia in the right middle cerebral artery (MCA) territory and chronic ischemic changes in the left cerebral hemisphere. Magnetic resonance angiography (MRA) showed stenoses in both anterior circulations. These stenoses progressed over time, and she was treated with pial synangiosis and burr holes. There was no clear progression of ischemic lesions. (A) MRA demonstrates complete occlusion of the left Ml segment of the MCA *{solid arrow),* and severe stenosis of the M1 segment of the right MCA *[open arrow)* and both Al segments of the anterior cerebral arteries. There are multiple small vessels at the stenotic sites consistent with moyamoya. There appears to be an anastomosis between the left superficial temporal branches and the distal left M1. (B and C) Fast spin echo inversion recovery MRI demonstrates multiple old infarcts in the bilateral frontal and parieto-occipital regions and centrum semiovale. (Courtesy Section of Neuroradiology at Riley Hospital for Children, Indianapolis, Indiana.)

with minimal neurological impairment were less likely to participate in their study; the parents of 20 of 104 children with congenital heart disease declined participation in a long-term study, and the families of 37 of the 57 children who received psychometric assessment declined MRI. Mayer et al. (2002) found evidence of cerebrovascular complications in 5 of 77 *(6.5%)* pediatric patients with heart transplants and an average of 59.2 months of follow-up;

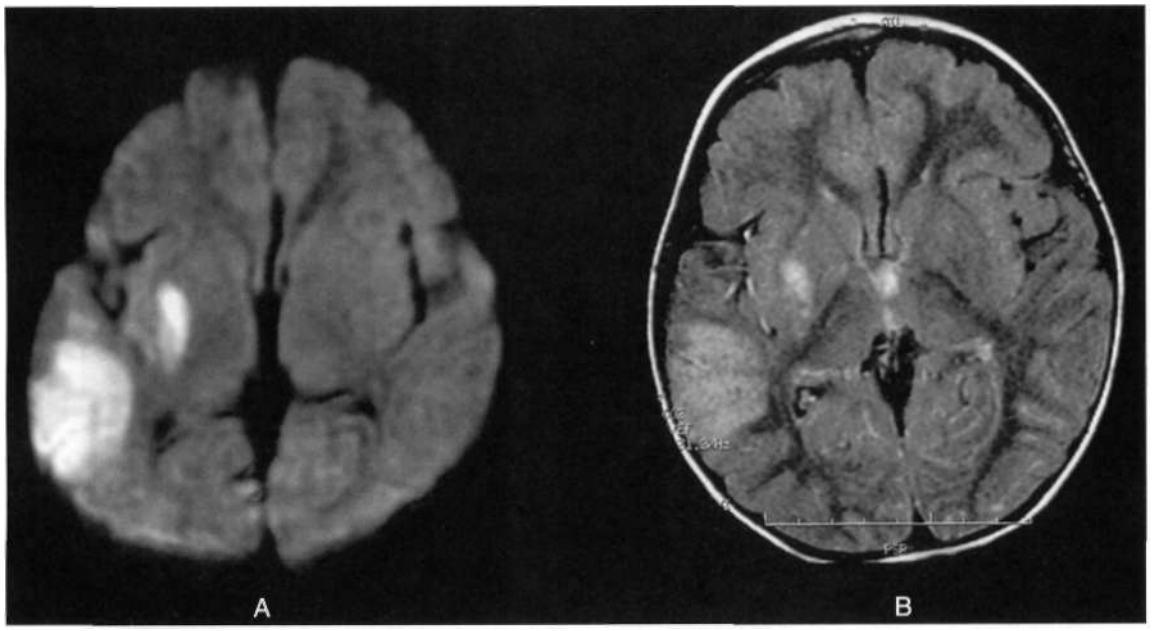

FIGURE 57E.3 This is a 3-year-old girl with a history of complex congenital heart disease. At age 10 months she had a procedure to repair a double inlet left ventricle and left transposition of the great arteries. She presented with seizures and dysconjugate ga?e 3 weeks later, and was diagnosed with an acute right pontine infarct. Magnetic resonance angiography and catheter angiography demonstrated narrowing of the distal basilar artery and the right superior cerebellar artery. At age 3 she presented with acute left hemiparesis and the following imaging: (A) Diffusion-weighred-imaging magnetic resonance imaging (MRI) and (B) fast spin echo inversion recovery MRI demonstrate multiple infarctions in the right temporal lobe, inferior parietal region, and Icntiform nucleus, consistent with cardiocmbolic stroke. (Courtesy Section of Neuroradiology at Riley Hospital for Children, Indianapolis, Indiana.)

25 of the 77 patients (32.5%) died. The times of greatest risk for children with congenital heart disease occur at the time of surgery or cardiac catheterization (Roach 2000a).

Children with cancer are at risk for both intracranial hemorrhage and ischemic infarction. Intracranial hemorrhage may occur secondary to thrombocytopenia from bone marrow suppression and/or bleeding of brain metastases or primary tumors. Children with cancer may develop ischemic infarction or CVT as a result of leukostasis in the setting of leukoma; complications oi chemotherapy Mich as with [.-asparaginase, which causes decreases in antirhrombin, fibrinogen, and plasminogen (Figure 57E.4); fungal or bacterial meningitis leading to arteritis; vasculopathy secondary to radiation; or complications of intracranial surgery. Bowers et al. (2002) observed 807 pediatric brain tumor patients for ;i ror.il of *M'14* uonpenoperarive years and found that 1.6% had a nonperioperative stroke.

Children with certain syndromes are at increased risk for stroke, sometimes for multiple reasons. Those with Down syndrome have higher than average rates of leukemia, which may lead to hemorrhagic stroke; moyamoya, which may lead to ischemic or hemorrhagic stroke; complex congenital heart disease, which may lead to cardioembolic stroke; and atlantoaxial instability and other abnormalities of the cervical spine, which may place them at increased risk for vertebral artery dissection. Children with neurofibromatosis type 1 also have higher than average rates of moyamoya and other occlusive vasculopathics that are sometimes associated with radiation. Connective tissue disorders, such as Marfan's syndrome, Ehlers-Danlos syndrome, and pseudoxanthoma elasticum may predispose to cervicocephalic arterial dissection or aneurysmal dilatation. Metabolic syndromes that damage the endothelium such as homocystinuria, Fabry's disease, and the familial hyperlipemias, may predispose to vascular damage and thrombosis.

PR] SLNTATIONS

The most common presentation of IVHs, arterial ischemic strokes, and CVT in term neonates is seizures. Seizures are a presenting sign for 6S% of term neonates with IVH, for at least 80% of term neonates with arterial ischemic stroke (Volpe 2001), and for at least 70% of neonates with CVT (deVeber et al. 2001). Other presenting signs include apnea, irritability, jirteriness, lethargy, and bulging fontanel. **The** immature central nervous system may not demonstrate focal signs, and hemiparcsis may not be apparent until a child is older than 6 months of age.

Children older than 6 months of age may present with seizures or focal signs similar to those seen in adult stroke, with hcmiparesis, ataxia, or aphasia. Although severe headaches such as those seen with intracranial hemorrhages often prompt parents to seek medical attention, parents may not detect focal motor weakness seen with a young child who has not yet started to walk, or aphasia in a young child who is just starting to speak. Parents may interpret the sudden onset of focal neurological signs as behavioral rather than neurological. It is easier to detect focal neurological signs and symptoms in older children, but these are also often missed in the first minutes to hours, possibly because many parents do not realize that children can have strokes.

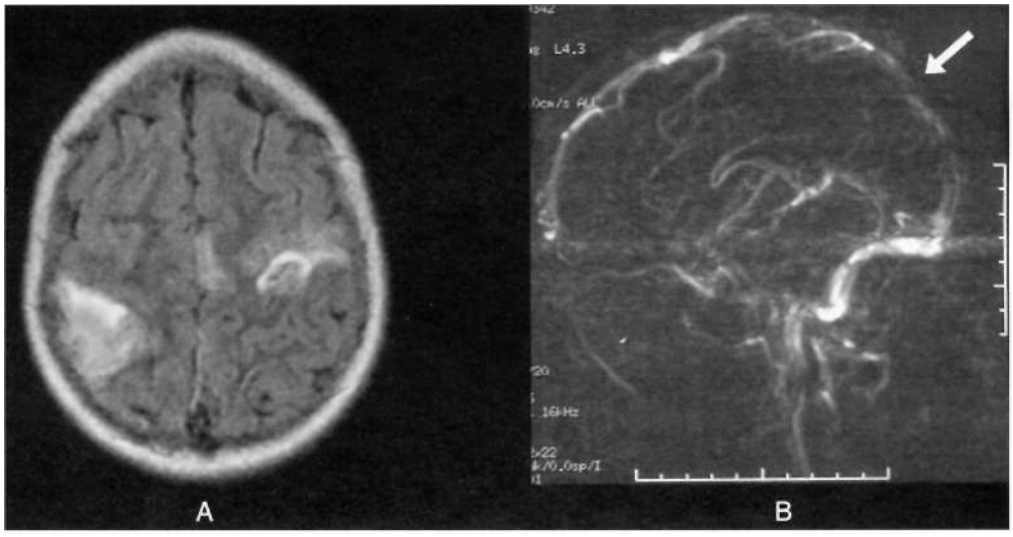

FIGURE 57E.4 This is an 8-year-old boy with leukemia who developed headaches and left hand numbness during induction chemotherapy with L-asparaginase. (A) Fast spin echo inversion recovery magnetic resonance imaging demonstrates multifocal bilateral hemorrhagic infarctions. (Bj Magnetic resonance venogram demonstrates irregularity of the superior sagittal sinus consistent with thrombosis *(arrow).* (Courtesy Section of Neuroradiology at Riley Hospital for Children, Indianapolis, Indiana.)

Some children may have no symptoms, or only gradual onset of developmental delay. As described previously, up to 17% of those with sickle cell disease have silent infarcts. The rates of silent infarction in other cerebrovascular disorders are not clear because radiological investigations are usually not initiated in the absence of clinical symptoms.

CAUSES

Cardiac Causes

Complex congenital heart disease may lead to thrombosis and ischemic stroke through several mechanisms. Abnormal cardiac anatomy or associated cardiac arrhythmias lead to abnormal flow and may predispose to the formation of intracardiac thrombi. Septal defects may lead to right-to-left shunts that allow venous thrombi to cross to the arterial side and cause cerebral infarction. Surgery and cardiac catheterization can disrupt the endothelium and lead to thrombosis. Cardiac surgery in itself may lead to a temporary prothrombotic state {Petaja ct al. 1996). An abnormal heart valve can serve as a nidus for bacterial vegetations that may cause cardioembolic stroke. Chronic hypoxemia in severe cases of congenital heart disease may lead to polycythemia, and the increased blood viscosity may promote thrombosis. Patent foramen ovale is associated with arterial infarction in both children and adults, again because of presumed right-to-left shunting.

Hematological Causes

Any hematological disorder that disrupts coagulation can place a child at risk for hemorrhagic stroke. Newborns have lower levels of coagulation factors and have a drop in the vitamin-K-dependent factors in the first days of life. Bleeding caused by vitamin K deficiency was more common before intramuscular or oral administration to neonates became widespread; Cornelissen et al. (1996) found that administering vitamin K lowered the incidence of vitamin K deficiency bleeding from 7 to 1.1 per 100,000 births per year. Accidental ingestion or overdose of warfarin has the same effect as a vitamin K deficiency, and may occur when a young child finds an older family member's medications. Congenital coagulation factor deficiencies may place the child at risk for abnormal bleeding. The most common are deficiencies of coagulation factor VIII (hemophilia A), coagulation factor IX (hemophilia B), and von Willcbrand's factor. Intracranial hemorrhage remains the most common cause of death from bleeding in patients with hemophilia.

A deficiency of factors involved in regulating coagulation may place the child at risk for thrombosis. Pediatric ischemic stroke is associated with deficiencies of protein C, protein S, and antithrombin III; activated protein C resistance caused by the factor V Leiden mutation; the prothrombin gene 20210 mutation, the methylene tctrahydrofolatc reductase (MTHFR) gene defect, and elevated lipoprotein (a); the plasminogen activator inhibitor promoter polymorphism (PAI 1); elevated antiphospholipid antibodies and lupus anticoagulant; elevated factor VIII levels; and low plasminogen or high fibrinogen levels.

Abnormalities of blood cells or blood cell concentration may place the child at risk for hemorrhagic or ischemic stroke. Low platelet count resulting from autoimmune thrombocytopenia or bone marrow suppression may lead to hemorrhage. Anything that increases blood viscosity, such as sicklcd cells, polycythemia, or chronic hypoxia, may predispose to arterial or venous infarct. Dehydration is associated with arterial strokes and CVT, possibly because it increases viscosity. Anemia is a risk factor for arterial ischemic infarction and CVT, possibly because of alterations in hemodynamics or imbalances in thrombotic pathways.

Trauma

Trauma can injure vessels directly, leading to hemorrhage from torn vessels and thrombosis in damaged intima (Figure 57E.5). The role of trauma in neonatal stroke is controversial; there is one clear, highly cited pathology case report documenting a neonatal stroke caused by forceps trauma (Roessmann et al. 1980). Subdural hemorrhages, subarachnoid hemorrhages, and ischemic infarctions all occur in both accidental and nonaccidenta! head injury. It is important to ascertain the cause of the trauma; 95% of serious intracranial injuries in children younger than 1 year of age are due to abuse, and *5%* of children who return to abusive parents without any intervention are killed (Johnson 2000). Bony abnormalities of the verrebrae, or abnormalities of vessel walls resulting from collagen-vascular disease or metabolic disease may predispose to cervicocephalic arterial dissection after mild rrauma. There may also be a prothrombotic state associated with trauma that can promote thrombosis and worsen outcome; disseminated intravascular coagulation worsens the outcome in trauma patients.

Infection

Bacterial meningitis may lead to disseminated intravascular coagulopathy and vascular inflammation, and subsequent arterial or venous thrombosis and infarction. Group B streptococcus meningitis is an important cause of stroke in neonates and may be transmitted vertically from the mother or horizontally by nursery staff. During the first 2 months of life, infants arc susceptible to bacteria found in maternal flora or in the local environment, including group B streptococcus, gram-negative enteric bacilli, and *Listeria*

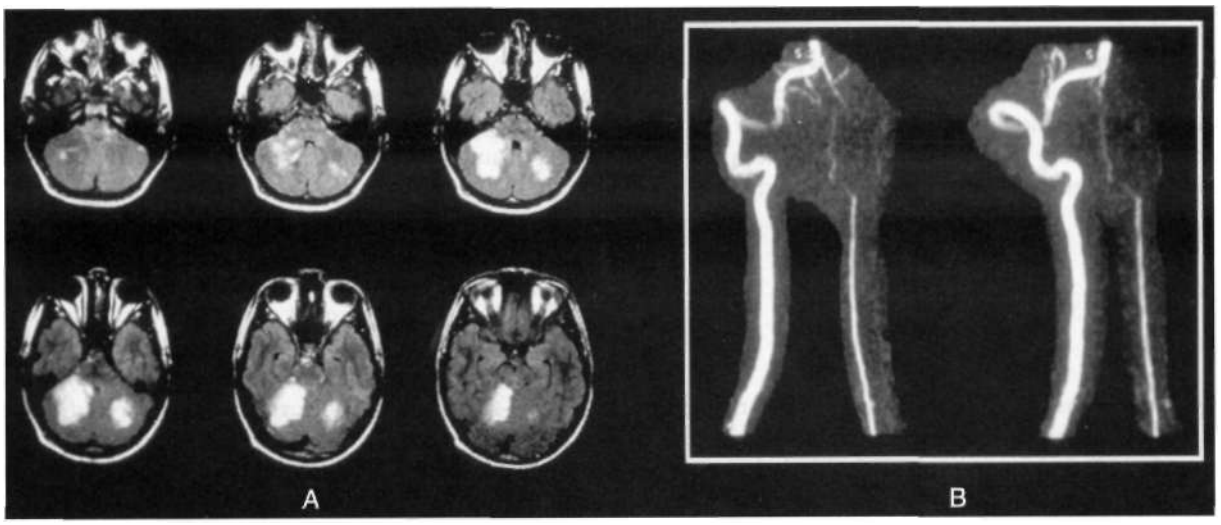

FIGURE S7E.5 A previously healthy 14-year-old boy developed vertigo, emesis, dysarthria, right handed dysmctna, and impaired tandem gait. Four days previously, he fell during hockey practice. (A) Magnetic resonance imaging demonstrated multiple cerebellar infarcts; (B) magnetic resonance angiography demonstrated left vertebral artery dissection.

monocytogenes. After 2 months of age, *Streptococcus pneumoniae* and *Neisseria meningitidis* are the most common causes of bacterial meningitis. The institution of *Haemophilus influenzal* type B vaccination at 2 months of age has led to a dramatic drop in *H. influenzal* B meningitis, In immunosuppressed children with cancer or acquired immunodeficiency syndrome (AIDS), *Aspergillus* species may lead to vasculitis and infarction. Patients with AIDS may also develop arteriopathy of medium and small vessels or aneurysms, and although the presumed cause for most cases is direct or secondary infection, the exact pathophysiology is not always clear. Tuberculosis leads to meningitis in 1-2% of cases, and may lead to vasculitis and infarction. Lyme disease is a rare cause of infectious vasculitis and aneurysm formation. Varice 11a-zoster virus may cause vasculitis by direct infection of the arterial wall or by a postinfectious inflammatory reaction that manifests weeks to months after the primary infection.

Vascular Mai formations/Vasculopathy/Migraine

As discussed in the Trauma section, vascular malformations may present with intracerebral hemorrhage. Resulting vasospasm may lead to ischemic infarction.

There are rare reported cases of primary angiitis of the central nervous system in children that may be fatal unless treated with aggressive immunosuppression. There are more frequently reported cases of less virulent vasculopathics in children, often occurring after varicella infection, that respond to aspirin alone and do not require immunosuppression (Lanthier et al. 2001).

There are many case reports of ischemic stroke in children after migraine. Arterial vasospasm in some children with stroke may be due to migraine.

Drugs/Toxins

Maternal usi' ol cocaine may lend to vasospasm and cere bra I infarction in the fetus, and use of cocaine by children may lead to intracranial hemorrhage or ischemic stroke. Other drugs such as amphetamines, which lead to sudden increases in blood pressure or vasospasm, also raise the risk of infarction. Accidental ingestion or overdose of medications used to treat thrombosis may lead to hemorrhage,

Metabolic Causes

The mitochondrial diseases may lead to metabolic infarction, particularly during times of metabolic stress. MRI usually demonstrates infarction in nonvascular territories (Figure 57E.6}.

Other metabolic diseases lead to cerebral infarction by contributing to arterial damage that results in thrombosis. Homocystinuria may lead to infarction, presumably through elevated homocysteine levels and subsequent vascular injury. The MTHFR gene defect has been associated with childhood stroke. Study results vary regarding the degree of associated risk, and carriers do not always have elevated homocysteine levels at the time of infarction. Fabry's disease is an X-linked lysosomal storage disease that causes a deficiency of alpha galactosidase and resultant accumulation of glycolipids in the endothelial wall, Both male and female heterozygotes arc susceptible to cerebral thrombosis, possibly because of an increase in v a so reactivity in damaged vessels or endothelial and leukocyte activation. Men may be more severely affected, and rarely show cerebrovascular involvement before the third decade of life. a_L Antitrypsin deficiency may lead to decreased structural integrity of the arterial wall by

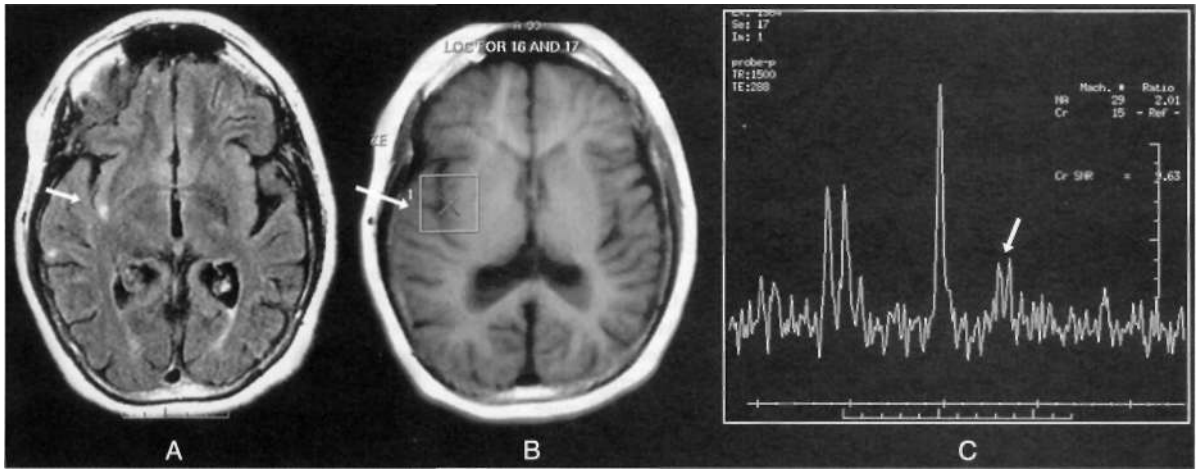

FIGURE 57E.6 This is an 18-year-old girl who presented at age 12 with headaches and went on to develop hilateral incoordination, decreased attention span, decline in school performance, and fatigability. (A) Fluid spin echo inversion recovery magnetic resonance imaging demonstrates multiple hilateral lesions not in vascular territories. (B) A M-ution of the involved area is selected for evaluation using magnetic resonance (MR) spectroscopy. (C) MR spectroscopy demonstrates a lactate doublet peak consistent with mitochondrial disease in an area of signal abnormality *(arrows).*

disrupting the balance of activity between proteases and antiprorcases. a_t Antitrypsin deficiency has been associated with aneurysm formation, arterial dissection, and vascular changes consistent with fibromuscular dysplasia. The hypcrlipidcmias may lead to atherosclerotic vascular changes in children similar to those seen in older adults.

Combinations of Multiple Factors

Some children have more than one factor contributing to the cause of their stroke. Hemorrhages in children with hemophilia are often precipitated by trauma. Children with ischemic stroke may have multiple prothrombotic abnormalities. Children with congenital heart disease or with leukemia may be at higher risk for developing thrombotic complications during hospitalization if they also have a prothrombotic abnormality.

Differential Diagnosis

Children with stroke often present with seizures. In the first hours after a seizure, before cranial imaging is performed, it can be difficult to determine whether a new hemiparesis is due to a temporary postictal Todd's paresis or to infarction. A Todd's paresis usually does not last more than 24 hours, although in rare cases it may persist for several days. Migraine may lead to temporary motor impairment or infarction and permanent weakness. A strong family history of hemiplegic migraine or documentation of a missense mutation of the CACNAIA calcium channel on chromosome 19*p*\3 may help diagnose familial hemiplegic migraine (Terwindt et al. 2002). However, there is variation in mutations among families; many families with familial hemiplegic migraine have a different gene locus. Alternating hemiplegia of childhood is a progressive neurodegenerative condition. The pathological condition is generally unclear, although cerebrovascular factors and mitochondrial disease may be contributory in some cases. Neuroimaging studies in alternating hemiplegia of childhood are usually normal. Edema, bleeding, or shifting of brain tumor may cause sudden onset of neurological signs, Encephalitis or meningoencephalitis may lead to sudden onset of focal neurological symptoms. Several metabolic diseases, including glutaric aciduria and carbohydrate-deficient glycoprotein syndrome can present with strokelike episodes; serum and urine testing and MRI help make the diagnosis. Acute disseminated encephalomyelitis (ADEM), multiple sclerosis, and vasculitis can all cause sudden onset of focal or multifocal neurological symptoms, and all cause multiple T2 bright lesions on MRI. Although ADEM lesions tend to occur more commonly at the grey-white junction than vasculitis lesions, and multiple sclerosis usually affects the periventricular areas in addition to other white matter tracts, the MRI findings may overlap.

EVALUATION

History and Physical Examination

In the young patient, the history should include questions about delivery and pctinatal period, attainment of hand preference, and basic developmental milestones. Prematurity places the child at increased risk of stroke, as described earlier, and a history of neonatal seizures may have been the first sign of neonatal stroke. Development of a hand preference before I year of age may be a sign of a

Table 57E.1: The physical examination in the child with stroke

Finding	*Possible significance/suggestive of:*
Head circumference	
Macrocephaly	Hydrocephalus caused by IVH, SDH, SAH, or vascular malformation
Microcephaly	Failure of brain growth resulting from stroke or genetic disorder
Eyes	
External/Iris	
Epicanthal folds, Rrushfield's spots	Down syndrome
Horner's syndrome	Carotid dissection (post ganglionicj/vertebral dissection (central)
Pulsating exophthalmos	Carotid-cavernous fistula
Lens subluxation	Marfan's syndrome, homocystinuria
Aiigioid streaks	Pseudoxanthoma elasticum
Xanthelasma on lids, corneal arcus	Hyperlipidemia
Corneal opacity	Fabry's disease
Retina	
Papilledema	Increased ICP resulting from hydrocephalus, vascular malformation, or acute edema
Hemorrhages	Trauma (consider child abuse), bleeding diathesis, ruptured aneurysm, collagen disease, emboli
Vasculopathy	Systemic vasculitis
Angioid streaks	Pseudoxanthoma elasticum. Paget's disease, sickle cell
A in; ion l.i	Familial cavernous angiomatosis, von Hippel-l.indau disease
Skin	
Bruising	Weeding diathesis (consider child abuse)
Petechia e	Platelet count low or dysfunction; DIC
Purpura	Henoch-Schonlein purpura
Pallor	Anemia
Erythema	Polycythemia
Cyanosis	Complex congenital heart disease, other cause of hypoxia
Skin necrosis	Meningococcemia
Cafe-au-lait spors	Neurofibromatosis type 1
1 lypopigmented macules, shagreen patches, facial angiofibromas	Tuberous sclerosis
Yellow papules	Pseudoxanthoma elasticum
Premature aging	Progeria

Continued

mild hemiparesis in the nondominant hand that could be due to what is presumed to be a perinatal infarction. Any early hemorrhagic or ischemic infarction may lead to slowed development. Medical history should include questions about previous hemorrhages, abnormal bruising, petechiae, or thromboses, and about other medical conditions that may raise the risk of early stroke, such as complex congenital heart disease, renal failure, or sickle cell anemia. Family history should include questions about abnormal bleeding in other family members, strokes or heart attacks before age 4.5, peripheral arteriopathy, or deep venous thrombosis. A history of multiple miscarriages may be suggestive of antiphospholipid antibody syndrome.

Physical examination should include examination of the face for signs of dysmorphic features suggestive of a genetic syndrome. Head circumference should be assessed. **Early** stroke may lead to macroccphaly caused by hydrocephalus or microcephaly caused by tissue loss and poor brain growth from infarction. Examination of the skin should document signs of bruising or petechiae; livedo reticularis suggestive of Sneddon's syndrome, systemic lupus erythematosus, or other autoimmune disorders; cafe au lait spots for neurofibromatosis type 1; hypopigmented macules for tuberous sclerosis; excess skin laxity for a collagen disorder such as Ehlcrs-Danlos' syndrome; cyanosis for heart failure and anoxia; and pallor for anemia. Head and neck should be auscultated for vascular bruits, the heart should he auscultated for murmurs and arrhythmias, peripheral pulses should be compared, and the abdomen should be auscultated for renal bruits suggesting a more systemic-vascular disorder. Neurological examination should be used to detect signs of focal abnormality, with the caveat that signs may not localize well in the very young child, or may be difficult to assess in the frightened or uncooperative child (Table 57E.1).

Imaging Studies

Ultrasound is useful in assessing IVH or periventricular leukomalacia in the premature infant, or assessing carotid

Table 57E.1: The physical examination in the child with stroke—cont'd

Finding	*Possible significance/suggestive of:*
Malar rash	Systemic lupus erythematosus
Skin laxity	Ehlcrs-Danlos syndrome type IV
Telangiectasias	Oslcr-Wcber-Rendu disease (hereditary hemorrhagic telangiectasia)
Oral/genital ulcers	Behcet's disease
Angiokeratomas	Fabry's disease
Lentigines in non-sun-exposed areas	Predisposition to dissection or to cardiac atrial myxoma, which may lead to cardioembolic stroke
Discoloration of fingers with cold: white, blue, then red	Raynaud's phenomenon as sign of collagen disease ot systemic lupus erythematosus
Subcutaneous nodules on elbows, forehead, tendons	Rheumaric fever, systemic lupus erythematosus, rheumatoid arthritis
Erythematous macules that evolve to clear, fluid-filled vesicles	Acute varicella (chicken pox); shingles if in a dermatomal distribution
Multiple round, white, puckered sc:irs	Past varicella infection
Needle tracks	IV drug addiction, with risk for endocardiris and HIV
Mouth	
High, arched palate	Mar fan's syndrome
Petechial hemorrhages	Infecrive endocarditis
Heart and Peripheral Pukes	
Murmur	Complex congenital hcarr disease, valve abnormality
Decreased pulses	Takayasu's arteritis
Increased pulses	Hypertension
Abdomen	
Hepatomegaly	Infection, cancer, liver failure
Bruit	Renal artery stenosis
Back	
Scoliosis, vettebral anomalies	Possible increased risk of dissection
Hands	
Long, tapering fingers	Marian's syndrome
Other anomalies of bones of hands	May be seen in association with congenital heart disease
Clubbing of fingers	Congenital heart disease
Joints	
Painful, with restricted movement	Arthritis due to autoimmune disease, past bleeds (hemophilia)
Warm	Autoimmune disease, infection
Overall Size	
Tall	Marfan's syndrome, homocystinuria
Short	Progeria, mitochondrial disease, dwarfism (risk of vertebral anomalies)

DIC = disseminated inttavascular coagulation; HIV = human immunodeficiency virus; ICP = increased intracranial pressure; rv = intravenous; IVH intraventricular hemorrhage; SAH = subarachnoid hemorrhage; SDH = subdural hematoma.

flow in any child, but its sensitivity for detecting arterial stroke in the neonate is probably less than 50% (Goiomb er al. 2003). Power Dopplcr ultrasound may be useful in detecting CVT in the neonate.

Cranial computed tomography (CT) is better at assessing hemorrhage in the older child and ischemic stroke in the neonate and older child, but may not detect arterial stroke until 24 hours or more after the event.

MRI is the imaging tool of choice for most types of childhood stroke, and diffusion-weighted imaging (DWl) can detect brain ischemia within hours. DWI stays bright for approximately 2 weeks in the older child or adult, bin ma\ "normalize" ipseuJonnrm.ili/.irion) within days in the neonate (Mader et al. 2002). Stroke imaging at any age should include DWI, T2, and fluid attenuated inversion recovery of (FLAIR) to detect areas of early infarction. Magnetic resonance angiography may be helpful in diagnosing vasculitis and dissection involving larger vessels.

Magnetic resonance proton spectroscopy and single photon emission CT demonstrate changes in regional blood flow and may be helpful in assessing patients with moyamoya disease and other sources of vasculopathy. Magnetic resonance spectroscopy provides the earliest detection of ischemic lesions.

Conventional angiography can clarify the structure of vascular malformations and is the most accurate method for detecting vasculitis and dissection. An interventional radiologist experienced in cranial angiographyis required, and angiography may not always be possible in the acutely ill child. All forms of ncuroimaging should be used in combination with other laboratory and physical findings, because no one technique has perfect sensitivity or specificity for detecting vasculopathy.

Prothrombotic Evaluation

The basic evaluation for prothrombotic disorders may include prothrombin time (international normalized ratio) and activated partial thromboplastin time; a complete blood cell count including platelets, protein C, protein S, and antithrombin III levels; activated protein C resistance; plasminogen, fibrinogen, and homocysteine levels; anti-phospholipid antibody screen; lipoprotein a level, and a cholesterol panel. Genetic testing may include screening for the factor V Leiden mutation, the prothrombin 20210A gene, and the MTHFR mutation (Andrew and de Verber 1999); genetic counseling should be provided before these tests are ordered, however {see the section Caveat for Genetic Workup).

Cardiac Evaluation

The basic cardiac evaluation may include electrocardiogram with rhythm strip and a transthoracic echocardiogram with injection of agitated saline to screen for a patent foramen ovale. If there is any suspicion for cardiocmbolic events and those two studies are unrcvcaling, transesophageal echocardiography and a Holter monitor study should be performed.

Other Studies

Electroencephalogram may help localize the lesion in children with seizures, and is helpful for evaluating cerebral function in the unresponsive, and possibly locked-in, patient with a brainstem stroke. Visual evoked potentials and brainstem auditory evoked potentials may be particularly helpful in evaluating the very young or somnolent patient.

Serum and plasma studies may help identify the cause of the stroke. Thrombocytopenia, deficiencies of factors I, VII, VIII, IX and XIII, and deficiency of von Willebrand factor are all risk factors for intracranial hemorrhage, whereas polycythemia, thrombocythemia, and anemia are all risk factors for ischemic stroke. Abnormalities in platelet count and fibrinogen may be markers for disseminated intravascular coagulation, which may lead to thrombosis and ischemic stroke. Elevated serum lactate is a marker for mitochondrial disease, but not all patients with mitochondrial disease have elevated serum lactate, and genetic tests may be required to confirm the diagnosis. Serum studies for plasma «-galacrosidase identify Fabry's disease. Serum ammonia, amino acids, and organic acids may help identify metabolic disease that can lead to stroke, such as hyperhomocysteinemia and mitochondria! diseases. Skin biopsy is often necessary to confirm the diagnosis of collagen vascular disease. Muscle biopsy may help confirm mitochondrial disease.

Caveat for Genetic Workups

Identifying a patient as having a genetic disorder may affect current ami future medical, life, and disability insurance status. In some cultures, genetic disorders stigmatize a family and affect social interactions and ability to marry within the group. Screening a family may identify asymptomatic patients who may stay asymptomatic. Whereas the risk with some genetic disorders, such as protein C deficiency, is clear and warrants screening other family members, the degree of risk attached to pediatric carriers of the factor V Leiden mutation are not clear, particularly if the carriers are nonsmokers and do not use oral contraceptives. Some mutations are very common, and the number of asymptomatic carriers may be very high; more than 40% of healthy children in a European study were either homozygous or heterozygous for the MTHFR mutation (Koch et al. 1999). These issues should be discussed with the family before genetic tests are ordered on asymptomatic family members.

THERAPIES

The Acute Period

Children with intracranial hemorrhage or hemorrhagic stroke require close observation in the first hours. Children with hemophilia need immediate factor replacement and may require blood transfusion. Children with large hematomas with significant mass effect may need surgery. Any child presenting with unexplained or poorly explained intracranial hemorrhage should also be evaluated for child abuse and other sites of injury.

There are only a handful of case reports describing children with ischemic stroke treated with intra-arterial or intravenous tissue plasminogen activator. Few children present within the mandated 3 hours of infarct onset. There are currently no clear guidelines on using intravenous or intra-arterial thrombolytics in children. It may not be helpful in neonates, who have lower levels of plasminogen than older children. Centers trying thrombolytic therapy in children should have stroke neurologists experienced in its use to assist in management, 24 hour access to a CT scanner to monitor for intracranial hemorrhage, and a pediatric neurosurgeon and operating room on-call in case of disastrous intracranial hemorrhagic complication.

There also arc no clear guidelines on the use of heparin in pediatric arterial stroke and SVT patients. Pilot studies and case series have described good results with heparin and low molecular-weight heparin (dcVcbcr et al. 1998). Large-scale studies with catheter-related, noncranial thrombosis have shown good results (Andrew et al. 2000). Other low-molecular weight beparinoids such as danaparoid are currently being studied, and may be good alternatives for patients with heparin-induced thrombocytopenia.

In sickle cell anemia, acute stroke is usually treated with exchange traiislusimi. Tin.' Srroko Prevention in Sickle Cell Trial showed that in children with evidence of vasculopathy by transcranial Doppler ultrasound screening, treating with regular transfusions reduced the risk of recurrent stroke by 90% (Adams 2000). However, chronic transfusions carry the risk of infection and cause increases in serum ferritin. Some children require treatment with deferoxamine chelation to prevent iron overload,

Attempts at treating and preventing metabolic stroke and cerebrovascular disease have been made by addressing the pathological defects in metabolic pathways. Therapy with coenzyme Q10 and other antioxidant vitamins for different mitochondrial diseases have had varying results. Folate, vitamin B_6, and vitamin Bj2 all play a role in homocysteine metabolism, which is impaired in homocystinuria and in carriers of the MTHFR gene defect. Several different enzyme abnormalities may lead to homocystinuria, and the enzyme affected determines whether supplementation with folate, vitamin B_{ft}, or vitamin $B|_2$ are helpful. Dietary supplementation with folate lowers serum homocysteine levels in adults with the MTHFR gene defect, and may also be helpful in children. Enzyme replacement with alpha galactosidasc decreases the symptoms of Fabry's disease, normalizes cerebrovascular reactivity (Moore et al. 2002), and may decrease the risk ot stroke.

There are several case reports and pilot studies dealing with replacing deficient coagulation pathway proteins. Protein C concentrate has been tried for protein C deficiency secondary to meningococcemia (Ettingshausen et al. 1999} and protein C deficiency (Dreyfus et al. 1995). Antithrombin concentrate has been used to treat consumptive coagulopathy and patients with antithrombin III deficiency at the time of acute stroke with good results, but it does not appear to prevent thrombosis in leukemia patients treated with L-asparaginase (Hongo et al. 2002).

Chronic Therapy

Patients with hemophilia and severe bleeding may require prophylaxis with regular factor transfusions. Young or ataxic children with hemophilia may need to wear protective helmets until their balance improves.

Patients with genetic, chronic thrombotic abnormalities such as protein C or S deficiency, or with lupus anticoagulant, may require long-term care with low-molecular-weight heparin or warfarin (Andrew et al. 2000), but for many patients, the best long-term therapy is not clear. Low-molecular-weight heparin may be used for 3-6 months after cervicoccphalic arterial dissection or CVT (Andrew and dc Verber 1999). Warfarin or aspirin arc more often used for long-term therapy (Andrew et al. 2000). Families of children on warfarin need to be counseled about regulating vitamin K levels in the diet, bony changes, possible teratogenicity, and the risks of under- or over-treatment. Families of children on aspirin are generally concerned about Reye's syndrome, but no cases have been reported in children taking aspirin for stroke prophylaxis (Roach 2000b).

There arc few clinical trials in this area. Stratcr ctal. (2001) did a prospective follow-up study of 135 children with first onset of ischemic stroke. The children received prophylactic treatment with either low-dose, low-molecular-weight heparin or aspirin and were followed for a median of 36 months. Low-dose, low-molecular-weight heparin was not superior to aspirin in preventing stroke recurrence.

Surgery or interventional procedures play a role in treating some types of cerebrovascular disease. Surgical procedures such as encephalodurosynangiosis or arterial bypass may be used to treat children with moyamoya disease. Surgery or neurointerventional procedures may be used to treat vascular aneurysms or malformations that place the patient at risk for intracranial hemorrhage.

Other Issues

Pregnancy often occurs in adolescent women, but carries special risks for women with a history of hemorrhagic or ischemic stroke. Ideally, such pregnancies should be planned, and patients should meet with their physician and a high-risk obstetrician before conception. Other medications used by women with stroke, such as warfarin and antiepileptic medicines such as valproate, may act as teratogens. This should be explicitly discussed with patients and their families, preferably before patients become sexually active. If pregnancy is accidental, a meeting with a high-risk obstetrician should be arranged as soon as possible, and neurologist, hematologist, and obstetrician should work together in planning care.

Oral contraceptives carry a very small risk for the general population, but may carry more risk for women with pro thrombotic disorders (Glueck et al. 2001). Oral contraceptive use raises the risk of both peripheral and cerebral venous thrombosis. These issues should also be explicitly discussed with patients and their families, preferably before adolescence, because some oral contraceptives are used to treat acne or menstrual disorders in adolescent women.

The issue of physical restrictions on stroke patients is a difficult one. Hemophiliacs are already restricted from contact sports because of their tendency to easily bruise and bleed. Ischemic stroke patients may make good motor recoveries, and the issue of physical restrictions should be discussed early. The cause of the stroke and the medications required to treat it should be considered.

OUTCOMES

The outcomes of childhood stroke can be very difficult to predict. Children with stroke are at risk for future cognitive

impairment, motor impairment, and epilepsy. Preterm infants are at particularly high risk; their outcomes are described in more detail in Chapter 86.

In term neonates, it is difficult to predict outcome based on initial cranial imaging. It is not clear whether the side of the infarct affects language development, because studies have not agreed. It is difficult to predict degree of hemiplegia from initial cranial imaging. Evidence of degeneration of corticospinal tracts and resulting asymmetry in the midbrain seen on MRl performed during the second 6 months of life does predict hemiplegia.

Studies in both infants and older children show that larger infarcts and multiple infarcts are more likely to cause cognitive impairment, as well as motor impairment and epilepsy. Overall, **the** intelligence of children with stroke falls within the normal range, but some children with stroke require extra help in school. Involvement of the cortex, internal capsule, and basal ganglia together is more likely to cause motor impairment than involvement of one of those alone.

The prognosis for children with progressive cerebrovascular diseases is much less benign. Children with severe forms of sickle cell or moyamoya disease who are **not** treated or do not respond to therapy may be left with significant cognitive and motor disabilities and epilepsy.

FUTURE DIRECTIONS

Screening and Prevention

As we begin to understand more about why children have strokes, we will begin to understand how to prevent them. The improved understanding of thrombotic disorders has helped some families prevent thrombotic events through screening and medical therapy. However, there are other causal factors that have yet to be discovered.

Therapy

Clinical trials are needed to assess the best therapies for children with stroke, and to form the infrastructure needed to assess new therapies used to treat adult stroke. Children may be able to benefit from some of the therapies developed for adults.

Chapter 57
Vascular Diseases of the Nervous System

F. SPINAL CORD VASCULAR DISEASE

David S. Geldmacher and Brian C. Bowen

The spinal cord is subject to many of the same vascular diseases that involve the brain, but its anatomy and embryology render it susceptible to some syndromes that do not have intracranial counterparts.

VASCULAR ANATOMY OF THE SPINAL CORD*

The embryonic arterial supply to the spinal cord derives from radicular arteries that enter at each spinal level and divide to follow the dorsal and ventral roots. The ventral radicular branches join along the midline to form the anterior spinal artery. Irregular anastomoses among the dorsal roots, as they enter the cord on each side, form paired posterior spinal arteries. The anterior and posterior spinal artetics constitute longitudinal arterial plexuses. Circumflex vessels (arteria vasocorona) connect the anterior and posterior arterial systems around the lateral margins of the cord (Figure 57F.1).

During development, a few predominant radicular arteries provide most of the flow to the spinal cord through the anterior spinal artery. Five to eight large anterior radicular arteries and a similar number of posterior radicular arteries exist in adults. The largest and most frequently identified of the anterior vessels is the arteria radicularis magna or great artery of Adamkiewicz, which courses along one of the lower thoracic or upper lumbar anterior roots to join the anterior spinal artery (Figure 57F.2). It provides a major portion of the blood flow to the lower thoracic cord and the lumbar enlargement. The sacral cord, conns medullaris, and cauda equina are supplied by small lower segmental arteries. The cervical and upper thoracic spinal cord is richly vascularized by a plexus arising from branches of the ascending cervical and vertebral arteries.

In contrast to the lumbar and cervical regions, the blood supply to the midthoracic cord is relatively tenuous, often consisting of only one significant radicular vessel. At thoracic levels, the anastomotic network is less intricate, and the anterior spinal artery may become discontinuous. The midthoracic region of the spinal cord is considered traditionally to be the most vulnerable to compromise from hypoperfusion or occlusion of a single artery, but more recent evidence suggests that lower cord levels are at greatest risk (Duggal 5c" Lach 2002}.

The main blood supply to spinal gray matter, as well as to anterior and lateral funiculi, is derived from anterior sulcal arteries. These arise from the anterior spinal artery in

"The nomenclature for spinal vessels is potentially confusing. In the section on Vascular Anatomy presented here, the term *radicular* refers to intradural vessels that follow the course of a corresponding nerve root. Some anatomists identify arteries or veins that supply or drain the spinal cord at sevetal vertebral levels as *medullary* vessels, which are distinguished from the much smaller radicular vessels that supply or drain the nerve roots at every vertebral level (Gil I Man 1970). However, in the neuroimaging litetature, medullary vessels are sometimes referred to as *radkuktmedullary* vessels and the terms *radicular, medullary,* and *radiculomedullary* are often used interchangeably. Thus the "radicular" vessels described in Figure 57F. 1 and Figure 57F.2 correspond to the medullary vessels as defined by Gillilan (1970) and others (Bowen et al. 1996), which are shown in Figure parts 57F.5C and 57F.5D.

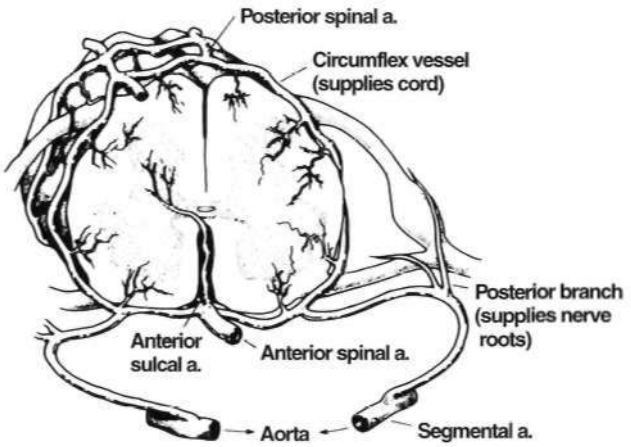

FIGURE 57F.1 Arterial supply to the spinal cord and nerve roots at rhe level of a radicular, artery. (Adapted from Henson, R. A., Parsons, M, 1967, "Ischaemic lesions of the spinal cord: An illustrated review," *QJM*, vol. 36, pp. 205-222.)

the midline and course into the ventral median fissure. Each anterior sulcal artery distributes blood to only the left or right half of the spinal cord. The greatest distance between sulcal arteries is in the thoracic segments; the vascularity is proportional to the numbers of neurons located throughout the cord at that level. The dorsal columns and extreme dorsal horns (approximately one third of the cord cross section) are supplied by penetrating branches from the posterior spinal arteries. The superficial white matter also receives blood flow via the circumflex anastomotic vessels (sec figure **57K** 1).

The venous system of the spinal cord parallels the arterial supply. A group of radial veins flows outward to the surface of the cord, ending in a coronal plexus, and deep parenchymal veins empty into central sulcal veins in the median fissure. Unlike the arteries, however, each parenchymal vein drains both the right and left sides of the **cord.** There are few venous anastomoses within the substance of the cord, but sulcal veins often have intersegmental anastomoses. The anterior median spinal vein, which lies external to its corresponding artery, is filled from the sulcal veins. As with the other spinal veins, the median spinal vein is more irregular than the corresponding artery and may be doubled. Extramedullary venous channels are also prominent along the dorsal cord, and the dominant vessel is usually the posterior median spinal vein. There is no corresponding artery in the midline. Paramedian and posterolateral veins are variably observed. The posterolateral veins may have segments that course adjacent to the posterior spinal arteries, but the veins and arteries do not parallel each other in general. Eight to 12 major anterior radicular veins arise from the anterior median spinal vein. They are joined by anterolateral anastomoses from the coronal venous plexus at the nerve roots before passing through the dura. There is typically a large vein that drains the levels of the lumbar enlargement {vena radicularis magna). Posterior radicular veins are present throughout, but are particularly prominent in the cervical region, Venous blood from the entire cord runs into the epidural and paravertebral venous plexuses, forming a large, valveless system from sacrum to occiput (Batson's plexus). The absence of valves to resist retrograde flow in this continuous venous network may be a factor in the pathogenesis of some spinal cord vascular disease.

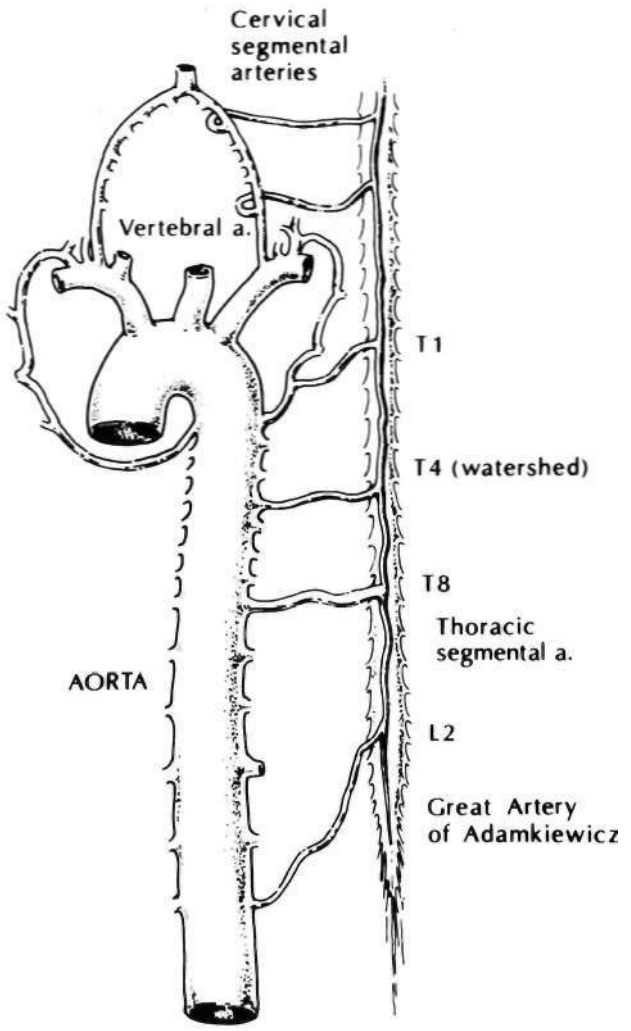

FIGURE 57F.2 Relationship of rypical anterior radicular arteries and spinal cord segments.

SPINAL CORD ISCHEMIA

Animal studies of aortic compression resulting in paralysis were reported as early as 1667, and, clinically, paraparesis resulting from aortic obstruction was recognized in the mid-1800s. By the early twentieth century, cardiac embolism, atheromatous disease, and decompression sickness were described as causes of spinal cord ischemia. Although it is less common than cerebral vascular disease, the

true prevalence of spinal cord infarction is not known. It probably represents less than 1% of all acute strokes.

Clinical Presentation and Course

Weakness, numbness, pain, and urinary complaints are common presenting symptoms of spinal cord ischemia. The weakness may progress gradually over hours or be maximal at onset. Because of the vulnerability of the thoracic cord to flow-related ischemia, paraparesis is more frequent than quadriparesis. Numbness, accompanied by paresthesias, often parallels the weakness and occasionally precedes it. Back pain in a radicular distribution is common. Visceral referred pain can mistakenly suggest an intra-abdominal process. Urinary dysfunction is typical, usually in the form of retention, but bladder and bowel incontinence may develop after the initial spinal shock resolves.

Examination of the patient initially reveals flaccid paresis with diminished superficial (abdominal, cremasteric) and tendon reflexes below the level of ischemia. Spasticity and hyper-reflexia, accompanied by extensor plantar responses, usually evolve with ischemia above the lumbar segments. A posterior spinal artery syndrome occurs only rarely and is notable for preservation of strength and reflexes.

Sensory loss is nearly universal in spinal cord ischemia. The location of a lesion may be predicted by the cutaneous distribution of sensory loss and the modalities involved. Occlusion of the anterior spinal artery impairs pain and temperature perception below the lesion, whereas in a posterior spinal syndrome there is derangement of touch, vibration, and proprioceptive senses below the lesion. A smaller lesion, such as that from the occlusion of a central sulcal artery, can present with a partial Brown-Sequard's syndrome or a suspended dissociated sensory loss (loss of pain and temperature sensation over the segment affected by the lesion, with preserved sensation above and below the lesion).

The course of spina! ischemic syndromes is variable. Transient ischemic attacks of the cord may occur, with weakness and numbness lasting 15 minutes. A slowly progressive myelopathy attributed to chronic constriction of radicular vessels in the neck has been suggested, but not established. Infarction of the spinal cord typically becomes evident as paresis within minutes of the initial symptoms or precipitating event. Intervals of many hours from the onset of pain, however, are recognized. Pain is often persistent and is a major contributor to long-term disability in spinal cord vascular syndromes. Return of function depends on the degree of parenchymal damage; there may be complete recovery. The duration of dysfunction is useful in determining prognosis. Unless significant motor recovery occurs in the first 24 hours, the likelihood of major improvement is low. The clinical presentation of spinal cord syndromes is presented in more detail in Chapter 27.

Investigations

Magnetic resonance imaging (MRI) is the imaging procedure of choice for detecting spinal cord ischemia, although the results can be normal even in the presence of significant symptoms. The pattern of signal changes, and their time course, are similar to those for cerebral infarction (Mascalchi et al. 1998; Rovira et al. 1998). After spinal cord infarction, typical spin-echo MRI findings are cord enlargement and hyperintense signal on T2-weighted images initially (8 hours to several days), with or without gadolinium enhancement, followed by cord atrophy months later. Abnormal signal and enhancement may demonstrate a double-dot ("owl's eyes") pattern in the region of the anterior horns, an H-shape pattern involving the central gray matter, or a more diffuse pattern involving both gray and white matter (Figure 57F.3). The diffuse pattern may be difficult to distinguish from venous infarction. When cord infarction results from compromise of a segmental artery, branches supplying the ipsilateral half of the vertebral body may be affected also. Vertebral body infarct is best detected on sagittal T2-wcighted images, usually appearing as a triangular area of increased signal near the endplate, the deep medullary portion of the vertebral body, or both. Other laboratory and radiographic studies are not diagnostic in noncomprcssive spinal cord ischemia. Myelography is usually normal. In many cases, the cerebrospinal fluid (CSF) protein is elevated, but CSF pleocytosis is rare.

Causes of Spinal Cord Ischemia

Typical causes of spinal ischemia are summarized in Table 57F.1.

Regional hemodynamic compromise from mechanical disruption of the aorta is the most common cause of spinal cord infarction, accounting for nearly 40% of one series of 44 patients (Cheshire et al. 1996). Complications of aortic aneurysm repair represent the largest proportion of those cases. Clamping of the aorta above the renal arteries for more than 20-30 minutes or operative ligation of lower thoracic intercostal vessels places the cord at risk for ischemia and infarction. Thoracoabdominal aortic aneurysm repairs arc associated with 5-20% risk of significant neurological deficits. There is emerging evidence to suggest that intraoperative interventions, like distal aortic perfusion and CSF drainage, may contribute to a lowered complication rate (Estrera et al. 2001). Modern endovascular aneurysmal repair techniques continue to present risks for spinal cord ischemia (Gravereaux et al. 2001). Aneurysmal aortic dissection causes spinal ischemia by diversion of blood flow around the ostia of intercostal and segmental arteries. In this condition, there is infarction of gray matter with preservation of superficial white matter. The longitudinal anastomotic network is apparently able to

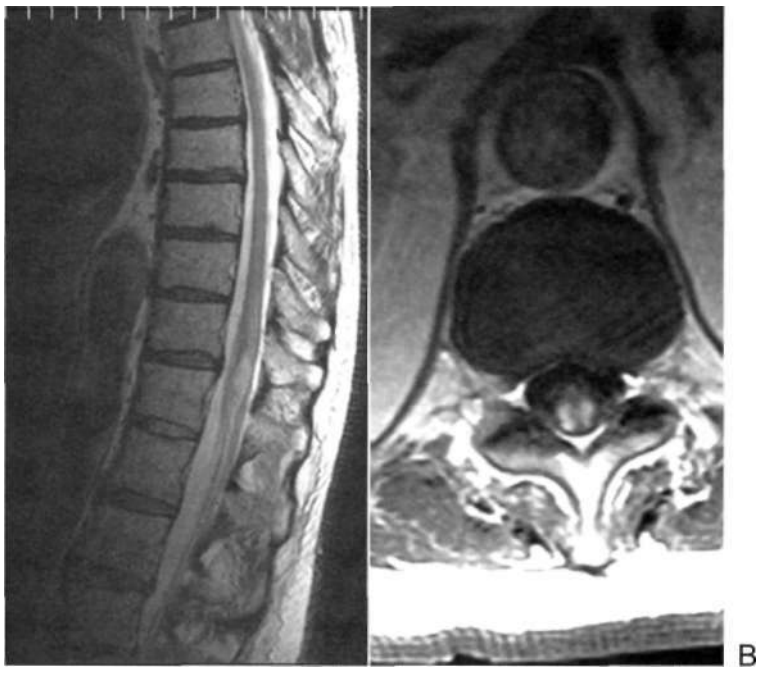

FIGURE 57F.3 Magnetic resonance imaging of a subacute, arterial infarction of the conus medLilians. A 69-year-old man had sudden onset of paraparesis and loss of bowel and bladder function 8 days prior to the magnetic resonance study. (A) T2-weighted, fast-spin-echo image shows focal enlargement and hyperintense signal within the conus medullaris. (8) Postcontrast Tl-weightcd axial image (T12 level) shows abnormal enhancement in an H-shaped pattern involving the central gray matter. (From Bourn, Ji, (. '. , . Saraf-Lavi, E. 2003, "Imaging of spinal vascular lesions," in *Advanced Imaging and Image-Guided Therapy of the Nervous System,* eds R. **E.** Latchaw, J. Kucharc/yk, M. E. Moseley, Mosby, Philadelphia. With permission.)

maintain sufficient blood supply to perfuse the perimeter of the cord, but not its central zones. Vertebral artery dissection may also lead to posterior cervical cord infarction. Nonpenetrating aortic trauma may cause torsional occlusion of vessels supplying the cord, with resultant ischemia.

Systemic hypotension produces cord ischemia, but because encephalopathy is common after resuscitation, isolated spinal cord syndromes are infrequent. Lower cord levels are especially susceptible to hypoperfusion. If there is prolonged hypoxemia, however, the pathological lesions arc distributed diffusely throughout the spinal gray matter. Localized thoracic cord ischemia may result from disordered autoregulation following percutaneous radiofrequency spinal rhizotomy.

Atherosclerotic plaques in the aorta may overlie the origin of branches to the spinal cord and diminish their blood flow or be a source of embolism. Transesophageal echocardiography may identify such plaques in the descending aorra. The spinal cord vessels are of a size that is generally not subject to occlusive atheromatous disease, but they are prone to luminal narrowing from arteriosclerotic hyalinization. Either of these conditions may result in intermittent claudication of the spinal cord manifested by activity-induced, transient symptoms of myelopathy. As with cerebral vascular disease, these transient ischemic attacks may precede spinal cord infarction. Intermittent spinal claudication may respond positively to aortobifemoral bypass.

Radiotherapy may produce myelopathy in part from occlusive changes in parenchymal spinal cord arterioles. The degree of myelopathy depends on the total radiation dose, dose per fraction, and the length of the irradiated segment of the cord.

Thromboembolism causes both acute and stepwise spinal cord dysfunction. Emboli arising from the mitral valve in rheumatic heart disease and from acute bacterial endocarditis may cause acute paraplegia. Similarly, thromboembolism from an atrial myxoma may cause multiple spinal cord infarcts. Myelopathy associated with decompression sickness results from circulating nitrogen bubbles that block small spin;i] aru'riev Spinal cord ischemia also may complicate therapeutic renal or bronchial artery embolizations.

Fibrocartilaginous emboli from inter vertebral disks are occasionally the cause of an ischemic syndrome unique to the spinal cord. The anterior portion of the cervical cord is the site of multiple arterial and venous microcmboli from a ruptured intervertebral disk in up to 70% of such cases. Women are affected twice as often as men. Fragments of disk material are traumatically forced into bone marrow sinusoids by local fracture and increased tissue pressure may introduce the emboli into the spinal vertebral

Table S7F.1: Causes of spinal cord ischemic syndromes

Venous occlusion

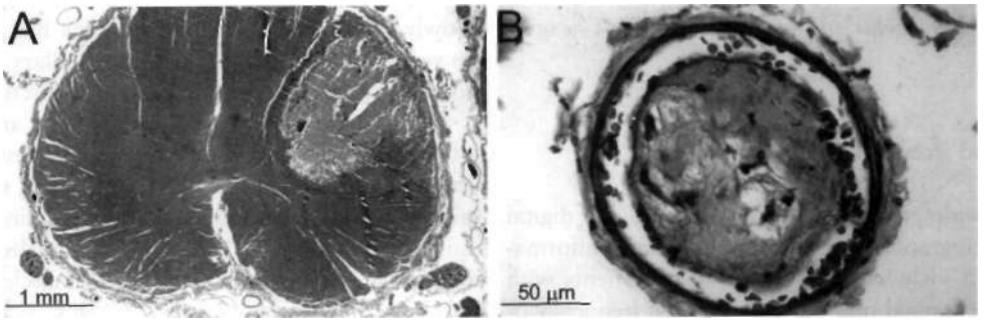

FIGURE 57F.4 Pathological sections from a 19-year-old man who died after tervical fibrocartilaginous embolism. (A) Segmental infarction in the posterolateral cord. (B) Intraluminal fibrocartilaginous material in the infarcted region. (From Fre yal den hove n, T. E., Mrak, R. E. 2001, "Fibrocartilaginous embolization," *Neurology,* vol. 56, p, 1354. With permission.)

plexus and arterial channels leading to cord infarction (Freyaldenhoven and Mrak 2001) (Figure 57F.4) Approximately one half of these events ate purely arterial; the rest have mixed arterial and venous involvement.

Vasculitic and thrombotic causes of spinal cord ischemia are well known. Before the antibiotic eta, meningovasculat syphilis was a common cause of anterior spinal artery ischemic syndromes and spinal meningitis continues to be occasionally associated with pataplcgia of vasculat origin. Systemic inflammatory conditions such as Crohn's disease, polyarteritis nodosa, and giant cell arteritis may also lead to myelopathy. Sickle cell disease, intrathecal chemical irritants, angiographic contrast material, the postpartum state, and intravascular neoplastic invasion all predispose to thrombosis and spinal cord infarction.

Venous infarction without hemotrhage is clinically indistinguishable from the arterial ischemic syndromes. There may be an associated systemic thrombophlebitis that propagates into the spinal canal via the venous plexus. A subacute necrotizing myelitis (Foix-Alajouanine's syndrome), causing stepwise spinal cord dysfunction, may occur with extensive spinal cotd thrombophlebitis and no systemic foci of venous inflammation, or in association with chronic obsttuctive pulmonary disease, or a neoplasm (usually of the lung). This condition may also be the end-stage tesult of chronic venous hypertension and congestion secondary to dural venous fistula. Polycythemia rubra vera may be associated with noninflammatory spinal venous thrombosis that results in cord ischemia,

Treatment

'['he medical management of spinal cord ischemia is generally supportive and focused on reducing risk for recurrence. This includes maintenance of adequate blood ptessute, early bed rest, and reversal of proximate causes such as hypovolemia or arrhythmias. Acute thrombolytic and antithrombotic therapy (e.g., heparin) have not been systematically studied. Such interventions will continue to be difficult to study because of the low incidence of spinal cord infarction and the variability of its natural course. Over the longer term, care is directed toward minimizing the complications of autonomic dysfunction and immobility. Physical and occupational therapy are useful in promoting functional recovery. Overall mortality is approximately 20%, and more than minimal improvement can be expected in only 35^0% of spinal infarction (Cheshire et al. 1996). Nonetheless, with appropriate rehabilitation, most patients are able to return to home.

SPINAL VASCULAR MALFORMATIONS

Spinal vascular malformations consist of normal-sized to enlatgcd arteries and enlarged, tortuous veins without an intervening capillary network. A commonly accepted classification system (Anson and Spetzlet 1993) categorizes spinal vascular malformations into four types:

1. Type I—dural arteriovenous fistula (AVF); subtypes IA (single feeding artery) and IB (multiple feeding arteries).
2. Type II—intramedullary glomus-type arteriovenous malformation (AVM).
3. Type III—intramedullary juvenile-type AVM, which is more extensive than a glomus-type AVM, frequently having an extramedullary component and sometimes an extradural component.
4. Type IV—intradural, extramedullary (pcrimedullary) AVF: subtypes IVA, IVB, and IVC correspond to lesions with progtessively increased arteriovenous shunting manifested as increased number, size, and tortuosity of feeding arteries.

Spinal vascular malfotmations not included in this tadiological-pathological classification system include cavernous angiomas (or cavernous malformations), venous angiomas (or preferably "developmental venous anomalies"), and epidural/paraspinal AVMs. Other classifications are based on whether the malformations are

amenable to cndovascular surgical intervention (Caraginc etal. 2002).

Distribution and Prevalence

Prior to the widespread use of selective spinal digital subtraction angiography, patients with vascular malformations were often included as a subgroup of patients with manifestations of spinal tumors. The reported frequency of vascular malformations as a subset of spinal tumors ranged from 3-11 %. The frequency could be higher because patients with small, asymptomatic or misdiagnosed lesions may be overlooked. Spinal dural AVF, which is the most common type of spinal vascular malformation in the previously noted classification, is typically found in older adult men, accounting for a reported prevalence of up to 9 to 1 for vascular malformations in men compared with women. For the same reason, the diagnosis of vascular malformation is nude most freqiiuurly between ages 3(1 and 70. When symptoms develop during childhood, the vascular malformation is more likely to be an AVM (Type II or III vascular malformation). The predominant locations for vascular malformations arc the lower thoracic and lumbar spine regions, again because these are the favored locations for dural AVFs. These usually drain to the dorsal surface of the cord.

Clinical Presentation and Course

Spinal vasculat malformations, especially dural AVFs, are frequently misdiagnosed. The onset of manifestations can be acute or insidious and the course may include remissions and relapses. The most common complaints at onset are pain, weakness, and sensory symptoms. The predilection of spinal vascular malformations for the lower thoracic and lumbar regions results in complaints referable to those levels. Later, the initial signs and symptoms persist and are joined by bowel and bladder complaints. The onset of symptoms is frequently associated with trauma, exercise, pregnancy, or menstruation. Misdiagnosis, especially as demyelinating disease, was common before MRI of the spine. Nonetheless, the interval between symptom onset and accurate diagnosis may be years. Severe locomotor disability develops in approximately 20% by *6* months after onset of symptoms and in 50% by 3 years. Once leg weakness or gait difficulties start, they tend to progress rapidly.

The signs and symptoms of spinal vascular malformations are attributable to mass effect and ischemia. Although it is unusual for an unruptured spinal AVM to cause sufficient mass effect to cause spinal cord dysfunction, epidural, subdural, and intramedullary hemorrhage can occur and produce spinal cord compression. Dural AVF rarely produces hemorrhage and typically presents as a slowly progressive myelopathy, which has been attributed to venous hypertension and intramedullary venous congestion that eventually can progress to infarction.

Pain may be local, radicular, diffuse, or any combination of these. There may be upper motor neuron weakness, lower motor neuron weakness, or both. A spinal bruit is a highly specific, though uncommon, finding that is diagnostic of a spinal AVM. Vascular malformations may coexist in the skin or paraspinal muscles. In cutaneomeningospinal angiomatosis (Cobb's syndrome}, dural angioma may coexist with a cutaneous angioma in the corresponding dermatome. Foix-Alajouanine's syndrome (see Causes of Spinal Cord Ischemia, earlier in this chapter) has been associated with end-stage dural AVF with thrombosis and venous infarction. Spinal hemorrhage usually has an abrupt onset and may be associated with the typical symptoms of spinal subarachnoid hemorrhage {SAH), including headache, meningeal infection, and cord and nerve root damage. Even in the absence of SAH, the CSF may be abnormal, with mild pleocytosis and elevated protein.

Vascular malformations (AVMs and dural AVFs) may cause increased local venous pressure, decreased perfusion pressure, decreased tissue perfusion, and finally tissue ischemia. This explains the coexistence of deficits in more than a single arterial territory and the symptomatic improvement that results from ligation of feeding vessels. The sometimes confusing and widely varied presentation of spinal vascular malformations results in a large differential diagnosis, which includes neoplasms, herniated discs, multiple sclerosis, intracranial SAH, subacute combined degeneration, meningovascular syphilis, and transverse myelitis (sec Chapter 27).

Investigations

MRI, with contrast-enhanced three-dimensional magnetic resonance angiography (MRA) (see Chapter 37B), is the diagnostic procedure of choice in the initial evaluation of suspected spinal vascular malformations. MRI can discriminate extramedullar from intramedullary lesions, document thtombosis of the malformation following ligation or embolization of the feeding vessels, and demonstrate changes in the spinal cord (edema, hemorrhage) distinct from, yet caused by, the vasculat malformation.

Routine MRI is sensitive in detecting intramedullary AVMs (Types II and III vascular malfomations). The findings include intramedullary low signal with surrounding normal cord tissue, focal cord enlargement at the location of the nidus, and serpentine signal voids within the subarachnoid space in the region of the nidus (Figure 57F.5). MRA augments the MRI study by confirming the locaton of the nidus and allowing better visualization of the AVM drainage to the coronal venous plexus (perimedullary veins) on the surface of the spinal cord. Preliminary studies

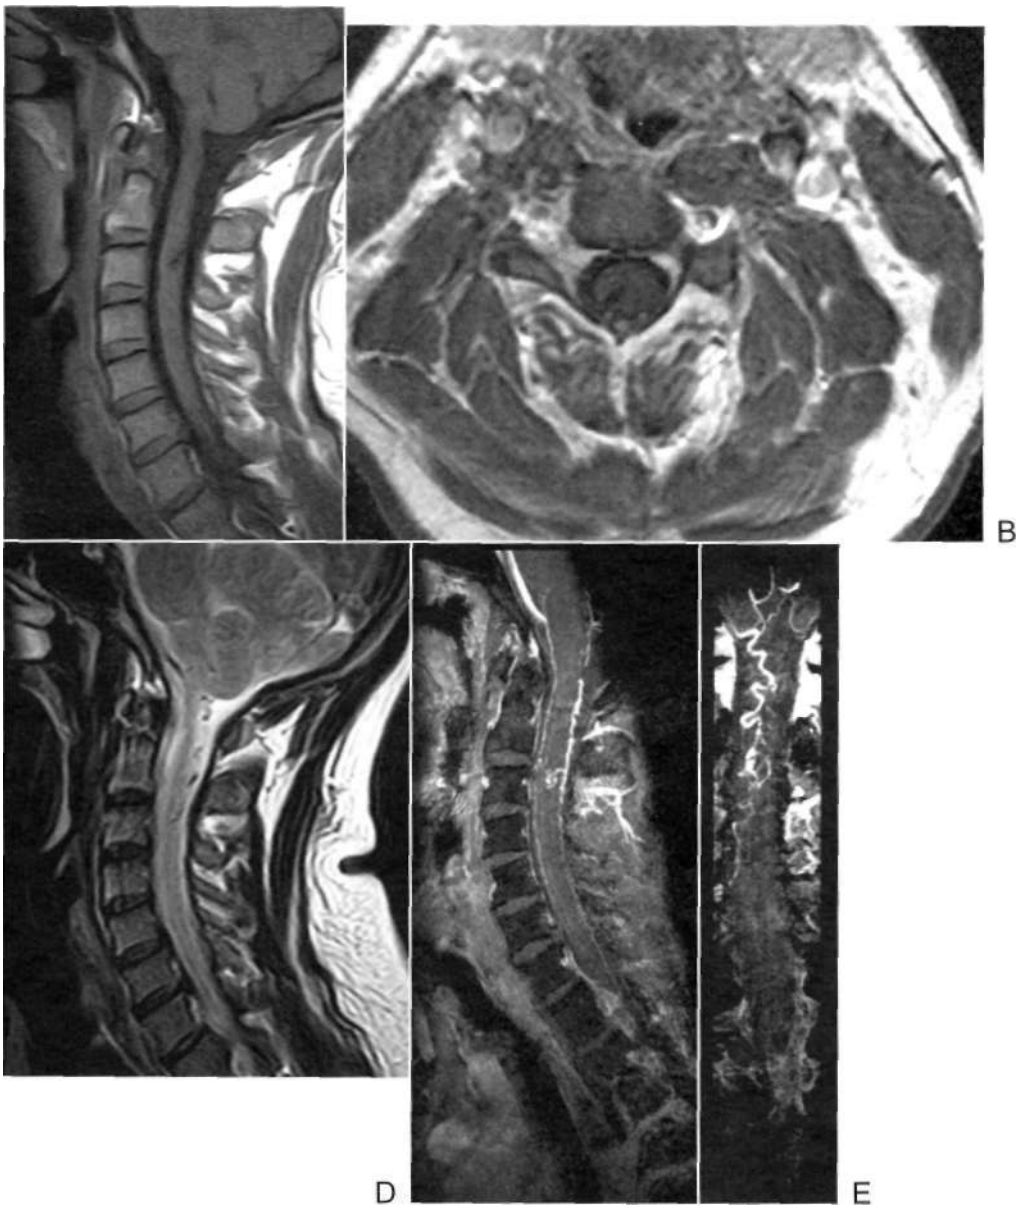

FIGURE 57F.5 Magnetic resonance imaging and contrast-enhanced three-dimensional magnetic resonance angiography (MRA) of a cervical intramedullary, glomus-type arteriovenous malformation. (A) Precontrast Tl-weighted sagittal image shows a focal hypointense intramedullary lesion at C3. The cord is not enlarged. (B) Posteontrast Tl-weighted axial image confirms the intramedullary location of the lesion. (C) T2-weighted, fast-spin-echo sagittal image shows serpentine flow voids posterior to the cervical cord from CI to C3. (D, E) Sagittal (D) and coronal (E) targeted MRA demonstrate the intramedullary nidus communicating with an enlarged posterior median vein. (From Rowen, B. C. & Saraf-Lavi, E. 2003, "Imaging of spinal vascular lesions," in *Advanced Imaging and Image-Guided Therapy of the Nervous System,"* eds R. E. Latchaw, J. Kucharczyk, M. E. Moseley, Mosby, Philadelphia. With permission.)

using newer dynamic contrast-enhanced MRA techniques have shown improved detection of the feeding arteries of AVMs compared with older techniques.

In cases of dural AVF (Figure 57F.6), **MRI** abnormalities involving the spinal cord have heen observed with variable frequency: slight enlargement of the cord; cord hypoiintensity on Tl-weighted images and h y peri men sity on T2-wcighted images involving the central region of the cord and extending over several levels; scalloping of the cord contours on sagittal images; and enhancement of the cord on posteontrast Tl-weighted images. Of these findings, the most consistently observed is hypcrintensity within the center of the cord on T2-wcighted images. In general, however, these findings are nonspecific and, like the clinical findings, can mimic those of cord neoplasm, infection, or ischemia from arterial occlusive disease. Thus detection of blood flow related signal abnormalities in the subarachnoid space is crucial to achieving high diagnostic accuracy for dural AVF, As shown by Saraf-l.avi and colleagues (2002), the detection of intradural flow voids on T2-weighted

images and the detection of intradural serpentine enhancement on T1-weighted images, extending for more than three contiguous vertebral levels, are each associated with the presence of dural AVF. Contrast-enhanced three-dimensional spinal MRA provides more direct and extensive visualization of the abnormal intradural vessels (veins), and when added to standard MRI can improve detection of dural fistula. The principal benefit of MRA is in the improved localization of the vertebral level of the fistula, which potentially expedites the subsequent invasive catheter angiograph) study.

In the pretreatment evaluation of vascular malformations, plain radiography is rarely helpful. Supine myelography, which, with careful technique, is able to detect the serpentine filling defects caused by abnotmal intradural vessels (although these may be confused with nerve roots in the lumbar region), has been supplanted by MRI with MRA. I hr definitive radiological procedure in the pretreatment evaluation of vascular malformations is selective spinal (catheter) angiography using digital subtraction techniques. Many institutions perform this procedure while the patient is intubated and under general anesthesia. Selective spinal angiography is tedious and typically requires that each segmental artery in the region being examined be injected. The effect of noninvasive spinal MRA on the of the indications for and performance of catheter angiography has yet to be reported in the neuroimaging literature. Catheter angiography remains the gold standard for characterizing vascular malformations in terms of location, size, configuration, blood flow, feeding arteries, and draining veins (see Figure 57F.6).

Treatment

The treatment of spinal vascular malformations is by surgical resection and/or angiographically directed embolization

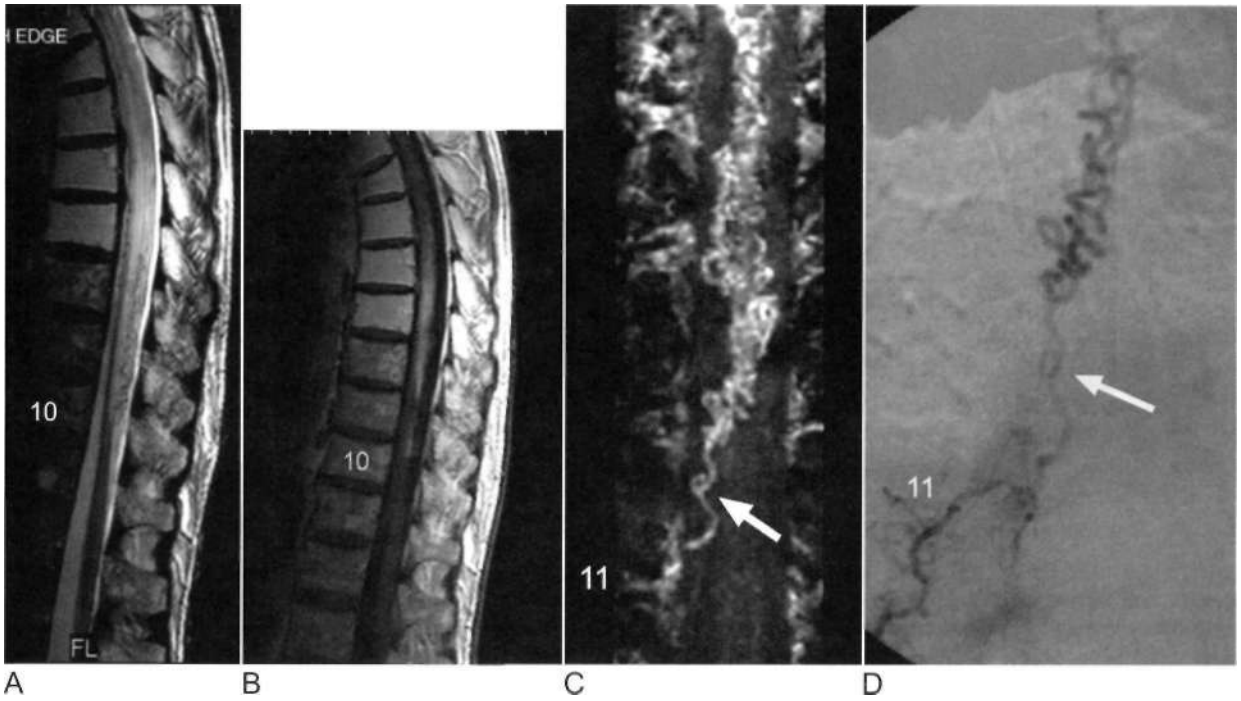

FIGURE 57F.6 Magnetic resonance imaging (MRI) and contrast-enhanced three-dimensional magnetic resonance angiography (MRA) of a right Til dural arteriovenous fistula. At the time of the MRI study, this 68-year-old man had a 3-year history of progressive myelopathy. His symptoms began approximately 6 months after radiotherapy and surgical excision of a carcinoma of the right lung apex. His progressive neurological deficits were initially attributed to radiation myelitis of the upper thoracic cord. After surgical obliteration of the fistula, his symptoms improved. (A) Fast-spin-echo T2-weighted image shows hyperintense cord from T6 to T10 and serpentine flow voids, consistent with enlarged intradural vessels, posterior to the cord from TS to T10. (B) Postconttast Tl -weighted image shows hyperintense vertebral bodies from T4 to T7, as seen in A, and consistent with radiation changes. There is patchy enhancement within the cord from T6 to T10. (Q MRA (tatgeted to posterior half of the spinal canal) demonstrates an enlarged, tortuous vessel *{arrow}* extending ftom the right Til foramen to the posterior cord surface, where numerous, convoluted vessels are seen. The right Tl 1 vessel corresponds to the posterior medullary vein draining the fistula. (D) Digital subtraction (catheter) angiogram (anteroposterior view) following injection of the right Til posterior intercostal artery demonstrates a fistula in the region of the right neural foramen with drainage into the canal via the medullary vein *(arrow).* (From Kowen, B. C. & Pattany, P. M. 1999, "Vascular anatomy and disorders of the lumbar spine and spinal cord," in *The Lumbar Spine,* ed J. Ross, Magnetic Resonance Imaging Clinics of North America, W.B, Saunders Co., Philadelphia. With permission.)

of the malformation. Once lodged within the abnormal vessels, these iatrogenic emboli promote thrombosis and decrease blood flow. A sequential approach of embolization, followed by definitive surgical therapy, is common (Caragine et al. 2002).

SPINAL HEMORRHAGE

Subarachnoid, intramedullary, subdural, and epidural hemorrhage may affect the spinal cord and its meninges. The onset is usually sudden and painful and most commonly is related to trauma or vascular malformations.

Subarachnoid Hemorrhage

Spinal SAH accounts for less than 1% of all SAHs. The most common cause is a spinal angioma, but these account for only approximately 10% of the total. Other associated conditions include coarctation of the aorta, rupture of a spinal artery, mycotic and other aneurysms of the spinal artery, polyarteritis nodosa, spinal tumors, lumbar puncture, blood dyscrasias, and therapeutic thrombolytics and anticoagulants.

Clinical presentation of spinal SAH is characterized hy the sudden onset of severe back pain, which is often localized near the level of the hemorrhage. Within minutes. the pain becomes diffuse and signs of meningeal irritation become prominent. Multiple radiculopathies and myelopathy may be present. Headache, cranial neuropathies, and a decreased level of consciousness are associated with diffusion of blood above the foramen magnum. The CSF is grossly bloody, intracranial pressure is frequently elevated, and papilledema may be present.

Correct diagnosis requires a strong clinical suspicion. The evaluation of spinal SAH frequently follows negative radiological studies of the intracranial structures. 11istory- may reveal the initial severe back pain or prior anticoagulant use. Physical examination may reveal a spinal bruit, cutaneous angioma, sensory level, the stigmata of collagen vascular disease, or evidence suggesting septicemia. Radiological studies arc discussed under spinal vascular malformations. Treatment is directed toward the underlying CailSC.

Hematomyelia

Intramedullary spinal hemorrhage most often results from trauma. Hematomyelia may follow direct trauma to the spinal column or hyperextension injuries of the cervical spine. Spontaneous hematomyelia is caused usually by bleeding of a spinal vascular malformation, hemorrhage into a spinal tumor or syrinx, a bleeding diathesis, anticoagulant drugs, or venous infarction. The hemorrhage tends to disrupt spinal gray matter rather than white matter. There are no recognized intraspinal counterparts to intracerebral hypertensive hemorrhage and amyloid angiopathy, Hematomyelia most commonly presents as spinal shock associated with the sudden onset of severe back pain, which is often radicular. Spasticity develops below the level of the lesion and fasciculations, atrophy, and areflexia may occur in the myotomes corresponding to the lesion.

MRI is the best imaging modality to detect intramedullary hemorrhage. Lumbar puncture may be consistent with SAH. The initial treatment is supportive. Laminectomy and drainage of the hematoma, followed by resection of the tumor or vascular malformation, can be performed if neurological deficits are incomplete or progressive.

Spinal Epidural and Subdural Hemorrhage

Spinal epidural hemorrhage (SEH) occurs more frequently than spinal subdural hemorrhage (SSH). SF.H is more commonly observed in men and has a bimodal distribution, with peaks during childhood and the fifth and sixth decades of life. Cervical lesions are more common in childhood, whereas thoracic and lumbar lesions predominate in adults. Hemorrhages can he spontaneous but often occur following trivial exertion or minor trauma. SFH is ;i complication of both lumbar puncture and epidural anesthesia and is more likely in patients who arc anticoagulatcd. Other causes include blood dyscrasia, thrombocytopenia, neoplasms, and vascular malformations.

SSH is most common in women. It may occur at any age but tends to predominate in the sixth decade. Most occur in the thoracic and lumbar regions. Hemorrhagic diatheses, including treatment with anticoagulants, blood dyscrasias, and thrombocytopenia, ate the precipitating factors most commonly associated with SSH. Other factors include trauma, lumbar puncture, vascular malformation, and spinal surgery.

The clinical presentations of SEH and SSH are indistinguishable. Tin- initial symptom is severe back pain at the level of the bleed. Myelopathy or cauda equina syndrome with motor and sensory findings corresponding to the level of the lesion develops over hours to days. The diagnosis should be suspected in patients with disorders of coagulation who have undergone recent lumbar puncture and develop back pain or signs of spinal cord or root dysfunction. Patients with a rapidly decreasing platelet count or less than 20,000 platelets/uL are at particular risk of developing SEH or SSH with a spinal tap and should receive a platelet transfusion prior to lumbar puncture. Clotting studies and a platelet count are important in the initial evaluation. In SEH and SSH, the CSF may be normal, xanthochromic, or contain increased protein,

MRI, the imaging modality of choice, delineates the hematoma and its location referable to the dura. In addition, gadolinium-enhanced MRI and MRA may show

an underlying vascular malformation. In patients unable to tolerate MRI or where it is unavailable in the acute phase of the illness, myelography with computed tomographic scanning provides an alternative. Myelography reveals a filling defect or complete blockage to the flow of contrast material at the level of the lesion. The myelographic appearanees of SEH and SSH may be indistinguishable.

Treatment is directed toward the underlying defect. Laminectomy with evacuation of the clot should be performed as soon as possible. The prognosis for recovery is better when surgery is performed early and the pre-operative deficits are not severe.

Chapter 57
Vascular Diseases of the Nervous System

G. CENTRAL NERVOUS SYSTEM VASCULITIS

James W. Schmidley

Isolated vasculitis of the central nervous system (CNS) is rare. Only one or two cases are encountered each year in large medical centers, but it is frequently among differential diagnoses, which puts the neurologist on the hotns of a dilemma. There are no characteristic clinical features; the results of routine laboratory investigations, both medical and neurological, are either normal or nonspecific. The single test, short of a biopsy, that is sometimes helpful in establishing the diagnosis is catheter angiography. This invasive test has the drawbacks of low sensitivity and specificity: The result may be negative in pathologically documented cases of CNS vasculitis. The consequence of missing the diagnosis is the death of the patient; the consequence of delay in diagnosis is likely to be severe disability. The only therapies that appear to be effective are also highly toxic, and one should feel uneasy administering them without solid evidence supporting vasculitis.

TYPES OF CENTRAL NERVOUS SYSTEM VASCULITIS

When vasculitis is clinically and pathologically restricted to the CNS, it is referred to as a *primary* or *isolated* CNS vasculitis. Early descriptions of this disorder included the term *granulomatous,* but this histological feature, although frequent, is not required for diagnosis. This section covers isolated CNS vasculitis and the CNS vasculitides associated with cutaneous herpes zoster infections, drug abuse, lymphomas, and amyloid angiopathy.

The CNS also may be involved by widespread systemic vasculitis, usually polyarteritis nodosa or Wegener's granulomatosis. These disorders, which are discussed in Chapter 55A, rarely present with isolated CNS manifestations.

Isolated Central Nervous System Vasculitis

The mode of onset is acute or subacute. Although the classic picture is one of progressive, cumulative, and multifocal neurological dysfunction, there are abundant exceptions, including patients whose presentation suggests cerebral tumor, chronic meningitis, demyelinating disease, acute encephalitis, myelopathy, simple dementia, and degenerative disorders. When isolated CNS angiitis presents as a stroke, it is usually because of intracerebral hemorrhage, which occurs in approximately 15% of patients at some time in the illness. The disease rarely causes cerebral infarcts or transient ischemic attacks in the absence of clinical or laboratory evidence of a widespread CNS inflammatory disorder, such as a cerebrospinal fluid (CSF) plcocytosis.

Nonfocal symptoms such as headache and confusion are the most common presentation. Aside from confusion, the most common sign at presentation is hemiparesis. Ataxia of limbs or gait, focal cortical dysfunction including aphasia, and seizures are also frequent. Virtually every neurological sign or symptom has been reported at least once (Calabrese et al. 1997), Nonspecific visual complaints occur in approximately 15% of patients, but disorders of specific ocular motor nerves, optic nerve, or visual fields are much less common. Systemic symptoms are generally absent. Fully developed cases almost invariably show signs and symptoms of progressive, widespread neurological dysfunction; however, occasional patients present with a multiple sclerosis-like course of early relapses and remissions, or

clinical manifestations largely restricted to one part of the nervous system, such as the spinal cord or cerebellum.

Pathology of Isolated Central Nervous System Vasculitis

The vascular inflammation is usually of a chronic granulomatous nature, with monocytes and histiocytes, lymphocytes, and plasma cells infiltrating the walls of small (200 urn) arteries and veins, particularly in the leptomeninges. Larger vessels may be involved but never to an extent exceeding that of smaller ones. Although present in most autopsy cases, giant cells are not required to make a diagnosis. There is no predilection for bifurcations, as in polyarteritis nodosa, although fibrinoid necrosis can occur; eosinophils are not present in large numbers. Small, clinically silent, foci of vasculitis are occasionally present in one or more viscera but, by definition, produce neither laboratory nor symptomatic evidence of organ dysfunction.

Cause and pathogenesis are unknown. Many vasculitis syndromes are a result of deposition of immune complexes, but there is little support for this mechanism in isolated CNS vasculitis. The infiltrating cells have been $CD4^+$ T lymphocytes in the few cases in which leukocyte typing has been done. There is no convincing evidence of infection with *Mycoplasma,* or any other microorganism, in human CNS vasculitis, although *Mycoplasma* does cause CNS vasculitis in animals.

Laboratory Findings in Isolated Central Nervous System Vasculitis

General medical laboratory investigations are usually unremarkable. Some patients have an elevated sedimentation rate, but usually not to the degree seen in temporal arteritis. The laboratory is of use only in eliminating systemic vasculitis, neoplasm, infection, or other alternate diagnoses. Electroencephalography and computed tomographic scan are not specific, although they are usually abnormal; there is less experience with magnetic resonance imaging (MRI), but it is unlikely to be any more specific. Although some literature has stressed the contrary, the CSF has been abnormal (in some way) in almost all autopsy-documented cases. Unfortunately, the abnormalities are totally nonspecific, namely a mild lymphocytic plcocytosis and a mild to moderate elevation in protein. Oligocional bands and elevated immunoglobulin (lg)G index are occasionally encountered, as are low glucose values and leukocyte counts of several hundred per pi. The major value of CSF examination in investigating suspected CNS vasculitis is to rule out infections, including syphilis, or neoplastic infiltration of the meninges.

Although some publications emphasize the value of angiography in making the diagnosis, (1) cerebral angiography has been entirely normal in many pathologically documented cases, and (2} the arteriography changes of vasculitis, when seen, are not specific (Alhalabi and Moore 1994). Given its lower spatial resolution, magnetic resonance angiography is unlikely to be useful.

The typical findings of vasculitis in cerebral angiography are widespread segmental changes in the contour and caliber of vessels. Small aneurysms, usually on vessels much smaller than those bearing congenital saccular aneurysms, arc occasionally present, but cannot be distinguished from aneurysms complicating atrial myxoma or infective endocarditis. Occlusion of large cerebral vessels is rare.

It is my opinion that many published cases of angiographically diagnosed CNS vasculitis, including the so-called isolated, benign variant, represent misinterpretation or overintcrprctation of nonspecific angiographic changes, unconfirmed by a tissue diagnosis. Until the pathological processes underlying these cases are established, the use of more circumspect terms such as *reversible cerebral vasoconstriction* or *cerebral angiopathy* is appropriate.

APPROACH TO DIAGNOSIS

All patients in whom CNS vasculitis is suspected should be evaluated thoroughly to exclude a systemic vasculitis. A careful history and physical examination, with attention to the skin, eyes, testicles, paranasal sinuses, and lungs, are likely to be more revealing than a "shotgun" laboratory approach. The CSF should be examined in all cases to exclude infectious and neoplastic meningitis. An MRI scan should be performed to exclude other diagnoses such as multiple cerebral metastases, multicentric primary CNS tumors, hydrocephalus, or demyelinating diseases. Other conditions mimicking CNS vasculitis may include atrial myxoma, cholesterol embolization to the CNS, infectious endocarditis, Sneddon's syndrome, the antiphospholipid-antibody syndrome, encephalitis, neoplastic angioendotheliosis, malignant hypertension, and eclampsia.

Patients whose neurological illness is compatible with isolated CNS vasculitis, but which resists diagnosis by physical examination, routine laboratory testing, imaging, and CSF analysis, should be studied with catheter angiography. Although nonspecific and present in only a minority of proven cases, the classic angiographic picture can be supportive of a diagnosis of CNS vasculitis provided that the many other conditions capable of producing an identical appearance have been excluded. In my opinion, if therapy with cyclophosphamide or another potent immunosuppressive agent is contemplated, then the diagnosis must be confirmed by biopsy. If possible, the biopsy should be directed to lesions visible on MRI, and the specimen should include lep to meninges. If no lesion is available for biopsy, then the nondominant frontal or temporal pole should be sampled, again taking care to ensure that leptomeninges are included.

Among 30 brain biopsies examined at Duke University to rule out vasculitis, Chu et al. (1998) found nine with

isolated, noninfectious, CNS vasculitis. No diagnosis was possible on five specimens; the remainder had non-vasculitic conditions. Of the 30 patients, 22 had cerebral angiography, which proved to be an extremely poor predictor of pathological findings. Multifocal stenoses, with "sausaging" of luminal profiles—considered to be the typical picture of CNS vasculitis by many—was seen more often in the patients with other diagnoses, or negative biopsies, than in those with histologically proven CNS vasculitis.

Alrawi et al. (1999) reported a similar distribution of findings among 61 patients who underwent biopsy at the University of Michigan (28% revealed definite CNS vasculitis, and 8% revealed probable CNS vasculitis). More important, biopsy results that were negative for vasculitis provided another diagnosis, often with entirely different therapeutic implications, in an equal number of patients. The most frequent nonvasculitic diagnoses were neoplastic and infectious. Angiography in 14 patients showed the classic abnormalities of vasculitis in four patients with and in five without biopsy-proven vasculitis.

Both papers agreed on MRPs lack of specificity. Only the University of Michigan study (Alrawi et al. 1999) analyzed clinical features and concluded that the presence of CSF pleocytosis, headache, or both, predicted a biopsy with positive results. They experienced no complications of the biopsies, 75% of which were done stereotactically. The complication rate in the Duke University study (Chu et al. 1998) was 20%, with one persistent hemiparesis. More than 90% (28 of 30) of the biopsies in the Duke study were open-wedge resections. Whether these complication rates reflect differences in technique or more careful scrutiny is not clear. Only the Michigan series had sufficient numbers to allow comparison, and the yield of a diagnostic biopsy was similar with both approaches. The authors of both papers concluded that brain biopsy, although not infallible, was the most reliable method for establishing a diagnosis of isolated CNS vasculitis. Both studies also emphasized the lack of specificity of angiography and the importance of considering the entire clinical picture.

Therapy

High-dose prednisone plus cyclophosphamide is currently the treatment of choice (Calabrese et al. 1997). Some patients recover or stabilize on corticosteroid therapy alone, but most progress. The results of therapy are difficult to interpret because of (1) the rarity of the disorder, so that centers do not accumulate large numbers of patients; (2) the difficulty of unequivocally establishing the diagnosis, other than by biopsy; (3) the inclusion of patients with the so-called benign form of CNS vasculitis; and (4) the inclusion of patients with diagnoses based only on angiography. Intravenous Ig has been administered with success a few times, but in poorly documented cases.

CENTRAL NERVOUS SYSTEM VASCULITIS ASSOCIATED **WITH** SYSTEMIC DISORDERS

Cutaneous Herpes Zoster Infection

CNS vasculitis associated with herpes zoster usually presents as a severe hemispheric stroke in the weeks or months following an ipsilateral ophthalmic division infection in an older adult patient (Cilden et al. 2002). Angiography shows ipsilateral segmental stenoses of proximal middle and anterior cerebral arteries. Evidence of varicella zoster virus is found in the same segments of these vessels, although histologically, necrosis has been more prominent than inflammation. Presumably, the virus reaches the affected arterial segments via intracranial projections of the ophthalmic division of the trigeminal nerve. The effectiveness of acyclovir and corticosteroids for this syndrome is unknown, but their use seems reasonable. A second type of cerebral vasculitis associated with herpes zoster is less common and less well understood. It is a diffuse, small-vessel vasculitis, in the absence of parenchymal infection, which can follow noncephalic, as well as ophthalmic, eruptions of zoster.

Intravenous Drug Abuse

The usual scenario in CNS vasculitis associated with intravenous drug abuse is subarachnoid or intracerebral hemorrhage following the use of intravenous, or even oral, methamphetamine or another sympathomimetic, including "look -a like," diet pills. It is uncertain whether the "vasculitis" reported in the angiograms of these patients is a true inflammatory process or a vasculopathy induced by an unusual reaction to the drug, hypertension, or other factors. When the case reports are examined critically, it becomes obvious that (1) in only one has vasculitis been pathologically documented; (2) the "vasculitis" has sometimes occurred after first use of the drug, an event unlikely to be immunologically mediated; and (3) the course is usually monophasic rather than progressive and multifocal, as one would expect in a true vasculitis. Because drug abusers (to say nothing of dealers) are famously unreliable, it is sometimes difficult to be certain what illicit drugs actually were used and in what doses, and it is virtually impossible to trace inert substances used as fillers, which nonetheless might be responsible for the clinical events in some cases.

Experimental animals given sympathomimetic drugs chronically do nut. in mosl models, develop a CNS vasculitis. Many case reports claim cure using corticosteroids, but this may only represent the natural history of the

syndrome. Before entertaining this diagnosis in intravenous drug users, it is also important to exclude the other, definitely treatable causes of stroke in this population, subacute and acute bacterial endocarditis being the most important. Additional causes of cerebral embolization in drug abusers include talc and air emboli, the latter caused by inadvertent injection of air into the internal or common carotid artery while attempting to puncture the internal jugular vein in the neck. Intravenous drug abusers are at risk for hepatitis-associated polyarteritis nodosa, which can involve either the peripheral, or the central, nervous systems. A rather nonspecific cerebral vasculitis may occur in cocaine users, although vasculitis is not present in the brains of most patients with cocaine-associated strokes (Aggarwal et al. 1996).

Lymphoma

Patients with systemic lymphoma, nearly always Hodgkm's disease, rarely also have an isolated CNS vasculitis, in the absence of parenchymal or meningeal involvement by lymphoma (Yuen and Johnson 1996). This association, not noted for other malignant neoplasms, naturally leads to speculation that the Hodgkin's disease somehow triggers or provokes the vasculitis. In some patients, the CNS vasculitis has developed concurrent with, or following, disseminated herpes zoster infection, further confounding the picture. In the nonzoster cases, the CNS disorder improves with remission of the Hodgkin's disease brought about by chemotherapy or radiotherapy.

Amyloid

Cerebrovascular amyloid may coexist with a CNS vasculitis (Fountain and Ebcrhard 1996). In most instances, the vascular amyloid is the same type that accumulates in senile plaques as well as vessels in Alzheimer's disease. The relationship, if any, between these two usually distinct processes is not clear. Amyloid deposited in any location frequently evokes a limited degree of giant cell macrophage response and may elicit a sparse lymphocytic infiltrate as well. Thctcforc the vasculitis may just represent an excessive degree of inflammatory response to the vascular amyloid. The vasculitis also could cause amyloid deposition. Cytokines, such as interleukin-1, increase production of amyloid precursor protein by endothelium, at least in vitro. If cytokines or other by-products of inflammation cause amyloid deposition in vessel walls, they seem to do so only in the vasculature of the CNS. When they oceut independently, both amyloid and vasculitis preferentially affect cortical and leptomeningeal vessels; the fact that the two are found together in approximately the same distribution makes it difficult to draw conclusions as to which is cause and which is effect. In some cases, amyloid deposits are found in the walls of noninflamed vessels, suggesting they cannot be the result of the inflammation. However, even these cases have not been studied in serial histological sections.

Most pa lien Is have presented with a progressive cluneal picture consistent with vasculitis, including abnormal spinal fluid. Although cerebrovascular amyloid angiopathy without vasculitis almost always presents with inrrapa-rcnchymal hemorrhage (see Chapter 57B), this is true in only approximately 30% of patients with amyloid-associated CNS vasculitis. In the absence of a better understanding of this disorder, treatment should be the same as for isolated CNS vasculitis.

GRAFT-VERSUS-HOST DISEASE

A CNS vasculitis may occur in survivors of leukemia who have chronic graft-versus-host disease (GvHD) after allogeneic bone marrow transplantation (Padovan et al. 1999). CNS disease of any kind is regarded as rare in GvHD, but the same authors, in another study, found a correlation between GvHD and clinical and imaging abnormalities, suggesting CNS dysfunction (Padovan et al. 1998).

Chapter 58
Cancer and the Nervous System

Tracy T. Batchelor

Neuro-oncology is an interdisciplinary medical specialty involving neurologists, neuropathologists, neurosurgeons, oncologists, and radiation oncologists in the care of patients with brain tumors. The number of newly diagnosed primary brain tumors continues to increase on a yearly basis in the United States, with an estimated 39,455 patients diagnosed in 2002. It was estimated that 359,000 persons with primary brain tumors were living in the United States in 2000 (Central Brain Tumor Registry of the United States [CBTRUS| 2002), In addition, the prevalence of neurological complications from systemic cancer continues to increase as the number of patients diagnosed with cancer increases and patients survive for longer periods. These observations strongly indicate that neuro-oncology patients will represent an increasing fraction of general neurology practices in the future. Thus neurologists need to become more informed about the basic clinical features and management of this group of disorders.

Neuro-oncology as an academic discipline is growing rapidly in the United States and abroad. Most university or academic medical centers have developed neuro-oncology programs, and most programs employ neurologists as the primary physicians. A growing number of these institutions now offer clinical and research training fellowships in neuro-oncology. Two periodicals *(journal of Neuro-Oncology* and *Neuro-Oncology)* are now devoted exclusively to neuro-oncology, and the biomedical literature on the biology, epidemiology, and treatment of brain tumors is rapidly increasing. Three federally funded clinical trials consortia have been formed for the study of adult and pediatric brain tumors (www.nabtc.org, www.nabtt.org, and www.phtc.org). An intramural neuro-oncology branch was formed at the National Institutes of Health in 2000 under the sponsorship of the National Cancer Institute and the National Institute of Neurological Disorders and Stroke. A successful and expanding academic organization, The Society for Neuro-Oncology (www.soc-neuro-onc.org), exists and serves as a forum for exchange of scientific and clinical information.

In this section, "Cancer and the Nervous System," leading experts have compiled a thorough review of neuro-oncology geared toward the neurologist. The first six chapters focus on primary nervous system tumors while the final two chapters cover metastatic tumors of the nervous system and paraneoplastic disorders of the nervous system. The rising incidence of primary brain tumors and the frustrating search for the cause of brain tumors are discussed in Chapter 58A. Very little is understood about the causation of primary brain tumors. Despite a large number of observational studies, important environmental risk factors for this tumor have not been identified. However, ongoing, prospective cohort studies may offer future insight into the causation of primary brain tumors. The biology, classification, and pathology of primary brain tumors are reviewed in Chapter 58B. The molecular mechanisms of tumor infiltration, progression, and resistance to therapy are becoming increasingly well understood for this diverse group of neoplasms. Based on a better understanding of the molecular pathology of these tumors, entirely new classes of anti-tumor therapies are being developed, including angiogenesis inhibitors, tyrosine kinase inhibitors, and anti-invasion drugs. These new classes of anti-tumor therapies offer hope that effective treatments for these tumors are on the horizon. The clinical features of brain tumors, as well as some of the common medical and neurological complications that occur in this patient population, are reviewed in Chapter *SHC* It is critical for physicians to understand the significant risk of venous thromboembolism in this patient population and the proper method in which to manage such a complication. It is also important for physicians treating seizures and epilepsy in these patients to understand the potential interaction of cytochromc-P450 inducing anti-epileptic drugs with chemotherapcutic agents. The characteristic neuroimaging features of the common nervous system tumors are reviewed in Chapter 5SD. The critical radiographic distinction between primary central nervous system lymphoma versus other types of brain tumors is discussed in this chapter. The multidisciplinary management of nervous system tumors in adults and children are reviewed in Chapters 58E and 58F. The potential roles of surgery, radiation, and chemotherapy are reviewed for each of the major tumor types in adults and children, '['lie chapters on primary brain tumors are followed by a review of metastatic disease of the nervous system in Chapter 58G and paraneoplastic neurological disorders in Chapter 58H. In the latter chapters the major metastatic complications, including brain metastases, epidural metastases, and spinal cord compression, as well as leptomeningeal metastases, are

discussed. Finally, the major paraneoplastic disorders that affect the nervous system are reviewed.

These chapters will hopefully provide a practical yet thorough review of the major clinical topics in neuro-oncology. Readers interested in further material **are** referred to some of the standard textbooks cited in the following Bibliography.

Chapter 58
Cancer and the Nervous System

A. EPIDEMIOLOGY OF PRIMARY BRAIN TUMORS

Tracy T. Batchelor, Molly V. Dorfman, and David J. Hunter

Primary brain tumors are a diverse group of neoplasms arising from different cells of the central nervous system (CNS). Light microscopy is used to classify these tumors according to predominant cell type, and to grade them for malignancy based on the presence or absence of standard pathological features. Gliomas are the most common brain tumors and may arise from astrocytes (astrocytomas), oligodendrocytes (oligodendrogliomas), or ependymal cells (ependymomas). Astrocytomas account for approximately 80% of all malignant brain tumors. The cause of brain tumors remains unknown despite a large number of epidemiological studies. This type of cancer is associated with a unique set of challenges for observational study designs (Table 58A.1). Despite a slow start, observational brain tumor studies may yet yield important clues into the pathogenesis of this cancer.

CLASSIFICATION

Histopathological Classification

The different cellular origins of brain tumors have contributed to the difficulty in achieving a single, widely accepted classification system. Historical attempts at developing a classification system for brain tumors date back to the 1830s. The German pathologist Rudolf Virchow introduced the term *glioma* in 1860 and was the first to attempt a correlation of microscopic to macroscopic features of CNS tumors.

Bailey and Gushing devised the first major classification system for brain tumors in 1926 and proposed that this type of cancer arose from primitive neuroectoderm. Their system consisted of fourteen distinct tumor types, each arising from a cell arrested at a different stage of neuronal development, and morphologically different from its normal counterpart. In 1912 Tooth argued that their histological features determined the biological characteristics of brain tumors. Yet, it was not until 1949 that Kcruohan and colleagues suggested that different histopathologic appearances do not represent separate tumor types but rather degrees of tumor differentiation. The Ringertz system of 1950 was based on the notion that different brain cells give rise to different histological types of brain tumors. In addition, Ringert/ proposed that astrocytoma consisted of three different grades: astrocytoma, astrocytoma with anaplastic foci, and glioblastoma multiforme (GBM). In 1981 Daumas-Duport and colleagues organized a tumor grading system (St. Anne-Mayo system) based on the absence or presence of four criteria: nuclear atypia, mitoses, endothelial cell proliferation, and necrosis. In 1979 the World Health Organization (WHO) published a classification system that encompassed all CNS tumors. The WHO classification system was subsequently revised in 1993 and 2000, and includes 10 major categories and 126 subcategories of brain tumors (Klcihues et al. 2000). In this system, the most common type of glioma, astrocytoma, is assigned different grades of malignancy (I-IV) based on the presence or absence of the criteria previously described. Malignant astrocytomas (anaplastic astrocytoma |III/IV| and GBM |IV/IV]) are the

Table 58A.1: Challenges in brain tumor epidemiology studies

1. Uncommon form of cancer
2. Diversity of histological brain tumor types
3. Lack of uniformly accepted classification system
4. Changing methods of ascertainment (clinical, radiographic, histological)
5. Variable reliability of exposure assessment (cognitive impairment of subjects, remote exposures)

most common subtypes and account for 80% of all malignant brain tumors. Table 58A.2 shows a comparison of the major classification systems currently in use.

Molecular Classification

Interest in a genetic classification of gliomas is based on studies demonstrating a predictable set of genetic changes in the progression from low-grade to high-grade gliomas and the observation that certain genetic changes predict prognosis better than histopathological characteristics for specific brain tumor types. Formation of brain tumors involves an accumulation of lesions in genes important for the regulation of cell proliferation, differentiation, and death (Table 58A.3).

As with other types of cancer, both oncogenes and tumor suppressor genes play critical roles in glioma pathogenesis. Oncogenes are dominantly acting genes coding for protein products that accelerate cell growth and proliferation. Typically, genetic alterations of oncogenes involve amplification and activating mutations, Conversely, protein products coded by tumor suppressor genes repress cell growth. Alteration of these genes by physical elimination (deletions) or inactivating mutations leads to cell proliferation.

Low-gtade astrocytomas (WHO grades I/IV and II/IV) are characterized by a high frequency of imitations in the p53 tumor suppressor gene (^50%) and amplification of the oncogene, platelet-derived growth factor (=^60%) (Kleihucs et al. 2000). Progression to anaplastic astrocytoma (AA) is associated with loss of heterozygosity (I.OH) on chromosome 19q and alterations in the retinoblastoma tumor suppressor gene. Progression to GBM (^80%) correlates with I.OH on chromosome lOq and amplification of epidermal growth factor receptor (EGFR). Two studies examining these genetic alterations have suggested possible prognostic significance in GBM. Leenstra et al. (1998) reported shorter survival among GBM patients with I.OH on chromosome 10 (60-85% of GBMs) and EGFR amplification (40%) (Batchelor and Louis 2001). Similarly, Lin et al. (1998) reported LOH at the PTEN/MMAC1 (25% of cases) locus was more common in high-grade astrocytomas and was predictive of shorter survival. Another study has demonstrated the age-dependent prognostic effects of specific genetic alterations. For example, EGFR amplification is a negative prognostic marker in young patients, but associated with a better prognosis in the elderly (Simmons et al. 2001). Future classification will undoubtedly incorporate many of these genetic markers of prognosis.

DESCRIPTIVE EPIDEMIOLOGY

Incidence

The traditional source of descriptive data on brain tumors has been the Surveillance, Epidemiology and End Results (SEER) program sponsored by the National Cancer Institute. This program collects population-based cancer data on approximately 26% of the U.S. population (including 15 state cancer registries) to gauge national trends in cancer incidence and survival (Ries et al. 1998). However, this data encompasses only *malignant* tumors. In contrast, the Central Brain Tumor Registry of the United States (CBTRUS) includes both benign *and* malignant brain tumors. The CBTRUS, established in 1992, is the nation's largest population-based registry of primary brain tumors, compiling information from 16 state cancer registries (Central Brain Tumor Registry of the United States [CBTRUS] 2002).

Incidence estimates differ according to the inclusion or exclusion of benign brain tumors. SEER data estimated approximately 17,000 new primary brain tumor cases in the United States for 2002 (Ries et al. 2002). CBTRUS

Tabic 58A.2: Pathological grading systems for astrocytomas

WHO	*Modified Ringertz*	*UCSF*	*St. Anne-Mayo*
		Mildly anaplastic astrocytoma	AMIncyiom.i grade I
Astrocytoma (grade II)	Astrocytoma (grade 1)	Moderately anaplastic astrocytoma	Astrocytoma grade 2
Anaplastic astrocytoma (grade III)	Anaplastic astrocytoma (grade 2)	Highly anaplastic astrocytoma	Astrocytoma grade 3
		Gemistocytic astrocytoma	
Glioblastoma multiforme (grade IV)	Glioblastoma multiforme (grade 3)	Glioblastoma multiforme	Astrocytoma grade 4

Table 58A.3: Gene and chromosomal alterations in gliomas

Ccne	*Gene function*	*Chromosome*	*Comment*
p53	Tumor suppressor	17pl3.1	33% of all grades of astrocytomas, 65% of low-grade astrocytomas
MDM2	Tumor suppressor	12ql4.3-ql5	10% of glioshlastoma
p!5 and p16	Tumor suppressor	9p21	IVlitrd 111 ()""•,. ni j-liom.i cell lines
CDK4 and CDK6	Promoter of cell proliferation	I2ql3-14 and 7q21-22	Amplified in 15% of cases without pi 5 or p!6 mutations
Retinoblastoma	Tumor suppressor	13ql4	33% of high-grade astrocytoma
		19	Frequent in high-grade astrocytomas
		22q	20-30% of all grades of astrocytomas
EGFR	Oncogene	7	33-50% of high-grade astrocytomas, always associated with 10 loss
PDGF	Oncogene		Expressed in all grades of astrocytomas
	Tumor suppressor	l0q	80% of all glioblastomas
		lp	Nearly all oligodendrogliomas, usually associated with 19q loss

EGFR = epidermal growth factor receptor; GBM = glioblastoma multiforme; PDGF = platelet-derived growth factor.

data estimated approximately 35,550 new cases of both malignant and benign brain tumors for the same year. The annual incidence of malignant brain cancer for all races from 1995-1999 was 6.8 per 100,000 person-years, compared with 4.2 per 100,000 person-years for primary benign brain tumors.

Mortality and Prognostic Factors

Although brain tumors account for only 2% of all cancers and are one fifth as common as breast or lung cancer, they result in a disproportionate share of cancer morbidity and mortality. The 5-year survival rates for brain tumors are the sixth lowest among all types of cancer (following pancreas, liver, esophagus, lung, and stomach, respectively) (Legler et al. 1999). The 5-year survival rates for the most common histological subtypes, A A and GBM, are 30.0% and *33%,* respectively. The U.S. mortality rate for malignant brain cancer was 4.7 per 100,000 persons for 1999 and represented a *46%* increase in mortality since 1950 (CBTRUS 2002). Approximately 13,100 deaths will be attributed to malignant brain and nervous system tumors in 2002; this number has been increasing for the last 30 years. Age-specific mortality rates from brain tumors among all races demonstrate gradual increases with each decade until the age of 55, after which the rate increases dramatically. When stratified by race or gender, these trends arc present, although whites exhibited greater mortality (5,1 per 100,000 persons) than blacks (2.8 per 100,000 persons) from 1995-1999 (Figure 58A.1). Finally, for all primary brain tumors, the 5-year survival rates have risen from 22% to 32% over the past 30 years.

Young age, high Karnofsky performance status, and lower pathological grade are favorable prognostic factors for primary brain tumors. Less significant predictors of favorable prognosis include long duration of symptoms, absence of mental changes at the time of diagnosis, cerebellar location of tumor, small preoperative tumor size, and completeness of surgical resection.

Gender and Race

There is a slight male predominance in the incidence of malignant brain tumors (8.02 per 100,000 person-years for men versus 5.62 per 100,000 person-years for women). However, when all brain and CNS tumor types are examined, the disparity between the sexes is less apparent (14.22 per 100,000 person-years for men versus 13.86 per 100,000 person-years for women) (Ries et al. 2002). This is partially explained by the predominance of meningiomas, a benign brain tumor, in women (5.19 per 100,000 person-years) as compared with men (2.66 per 100,000 person-years). Figure 58A.2 compares the incidence rates of malignant brain tumors among white and black individuals. Whites have a higher incidence of malignant brain tumors as compared with blacks for both genders: white males have an incidence rate of 9.1 per 100,000 person-years compared with black males at 5.1 per 100,000 person-years, whereas white females have an annual incidence of 6.1 per 100,000 person-years versus an annual incidence rim- nf 2.8 per 1 00.000 person years among black females (CBTRUS 2002). Comparisons between other racial groups within the United States are difficult because of the small numbers of cases, but malignant brain tumor incidence rates among Asian Americans, Latinos, and Native Americans arc lower than those of cither whites or blacks.

Temporal Trends

Several studies have documented rising incidence rates for brain tumors in several industrialized countries. These increases seem confined mainly to the older adult population with no clear ethnic, gender, or geographical differences. Overall, the incidence increased 18% from 1973-1994 and 80% from 1950-1994 (white population only). However, other population-based data suggest that incidence rates have recently stabilized among all age groups (Legler et al. 1999). From 1992-1999, the incidence of all

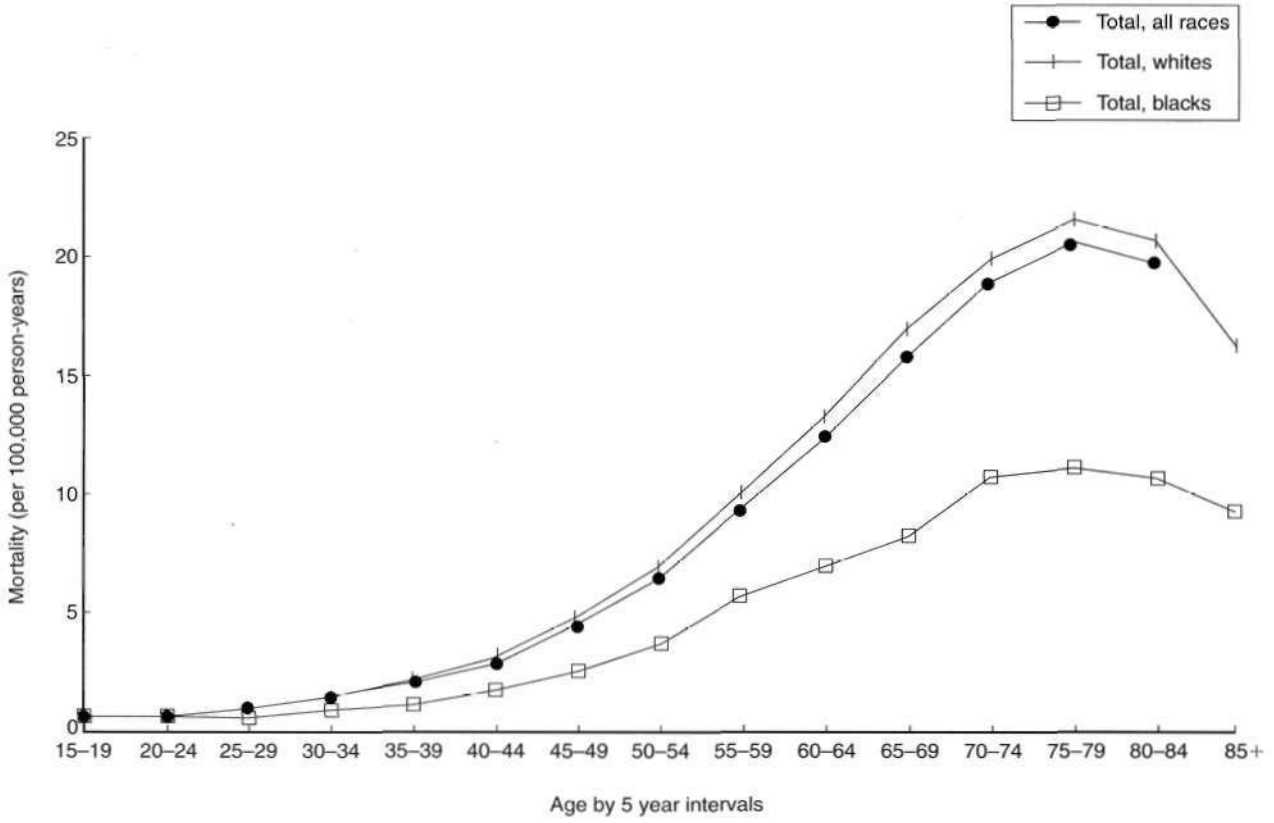

FIGURE 58A.1 1995–1999 invasive brain tumor mortality rates for U.S. whites and blacks, stratified by age. (From Ries, L. A. G., Eisner, M. P., Kosary, C. L., et al., eds. 2002, *SEER Cancer Statistics Review, 1973–1999*, National Cancer Institute, Bethesda, MD.)

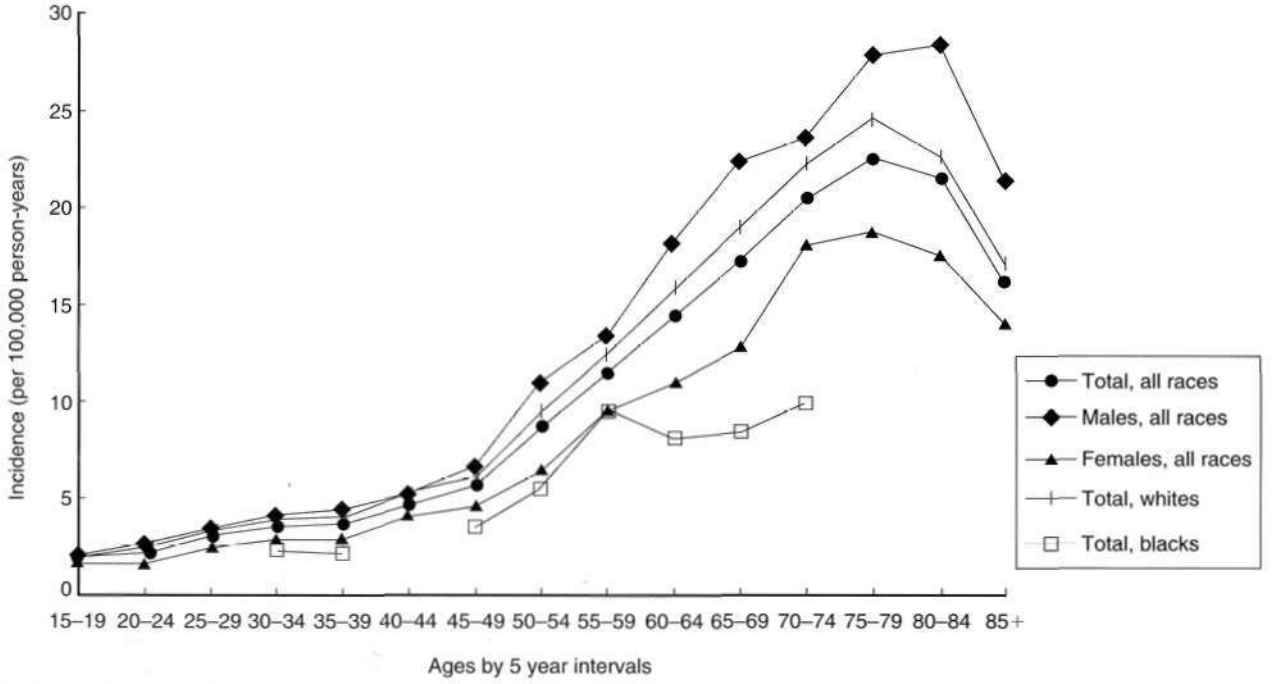

FIGURE 58A.2 1995–1999 invasive brain tumor incidence rates for U.S. whites and blacks, stratified by age. (From Ries, L. A. G., Eisner, M. P., Kosary, C. L., et al., eds. 2002, *SEER Cancer Statistics Review, 1973–1999*, National Cancer Institute, Bethesda, MD.)

malignant brain tumors decreased by 0.4%. This reduction in incidence was observed in both males (—0.7%) and females (—0.1 %) and was associated with a reduction in mortality resulting from brain tumors across all races (-0.5%). These data support the concept that the increasing incidence observed prior to 1992 may have been the result of better ascertainment.

The increases in incidence observed in the United States for all age strata and racial groups are in accordance with observations in other parts of the world. Although the responsible factors remain unclear, there is agreement that at least part of the increase is the result of more complere case ascertainment because of improved diagnostic technology, better access to health care, and clinical specializarion. Some investigators have argued that the increase in brain tumor incidence correlates with the introduction of noninvasive diagnostic technology including computerized tomography (CT) in the 1970s and magnetic resonance imaging (MRI) in the 1980s. Medicare data from 1986-1994 suggest that although the use of CT and MRI has stabilized among the 85-years-and-older age group, the use of CT continues to increase among the younger-than-85 age group. This may reflect a more aggressive diagnostic approach to the very elderly and may account for the stabilization of brain tumor incidence rates in people 85 years of age and younger, and a continued increase among those older than 85. Other contributing factors include access to better health care for older adulrs and increased availability' of neurological physicians. The number of neurologists in the United States increased 3.6-fold from 1970 to 1987 (Preston-Martin and Mack 1996). However, others have concluded that improved diagnostic capability does not fully account for the magnitude of the observed increase and that changing environmental exposures may play a role.

Geographical Trends and Migrant Studies

Increasing brain tumor incidence rates have been observed in many orher counrrics during the last 30 years. The highest rates are noted in industrialized nations such as the United States, Canada, Australia, and the United Kingdom, whereas developing nations have lower incidence rares. Generally, it appears that brain tumor incidence is associated with the level of economic development, and concomitant differences in the availability of diagnostic-methodology (CT, MRI, neurosurgical technology) may account for some of the observed disparities. Even within the United States, a significant variation in the incidence of brain tumors exists between the states. Hawaii has the lowest rate for males (5.1 per 100,000 person-years) and for females (4.1 per 100,000 person-years) (CBTRUS 2001). Maine has the highest rate (9.9 per 100,000 person-years) for males and Montana (7.3 per 100,000 person-years) has the highest rate for females. In contrast to international trends, a clear relationship between these rates and economic conditions does nor exist.

Migrant srudies have typically exhibited elevated incidence rates in the host country compared with the country of origin, with increases in brain tumor incidence and mortality developing among migrants. This suggests environmental factors may influence the development of brain tumors. However, disparities in case ascerrainment in the countries under study complicate the interpretation of this data.

Primary Central Nervous System Lymphoma

The descriptive epidemiology of primary CNS lymphoma (PCNSL), a type of non-Hodgkin's lymphoma (NHL), deserves special comment. A dramatic increase in the incidence of PCNSL has occurred during the past few decades. This parallels a doubling of the incidence rate of systemic NHL during the past four decades (Preston-Martin and Mack 1996). The incidence of PCNSL peaked in the early 1990s and has since decreased. The primary factor behind the rising incidence is the acquired immunodeficiency syndrome (AIDS) epidemic. Of individuals with AIDS, 2-6% develop PCNSL at some point in their disease course (Fine and Loeffler 1999). The incidence of AIDS has decreased along with the rate of PCNSL since the beginning of the 1990s. However, AIDS does not fully account for the total increase in incidence. In a population-based study that excluded never-married males, a group previously considered at highest risk for HIV infection, there was nearly a threefold increase in the incidence rate of PCNSL from the 1970s to the 1980s. This increase was reported among both young and older adult populations, with a clear predilection toward males (71%) and whites (83%) (Kadan-Lottick ct al. 2002). Some have speculated that PCNSL may become the most common primary brain tumor; however, such speculation may be premature because some cancer centers are reporting decreased numbers since the early 1990s (Corn et al. 1997). Clearly, updared, population-based data will be needed to address this issue.

ANALYTIC EPIDEMIOLOGY

Study Designs

Analytic epidemiology involves the application of case control and cohorr study designs to identify risk factors for particular diseases. The *case control study* has been the most commonly used study design in the search for risk factors for brain tumors. In a case-control study, subjects are classified based on the presence (case) or absence (control) of the outcome of interest (e.g., brain tumor). An exposure of inrerest (e.g., head trauma) is then determined in a uniform manner for cases and controls. An odds rario (OR) of disease for the exposed compared with the

unexposed is generated. Case control studies are most useful in the study of uncommon diseases (brain tumors) or those with a long period between the exposure of interest and the development of disease. In a *cohort study* subjects are classified on the basis of the presence or absence of a particular exposure and are followed forward in time to ascertain the development of the outcome or disease of interest. Cohort studies are most useful when the outcome under study is common. Because brain tumors are uncommon, ven few cohnn studies ol risk ['actors for brain tumors have been accomplished.

Methodological Challenges

Because brain tumors are an uncommon and heterogeneous form of cancer, prospective cohort studies have not been feasible and most case control studies have small numbers of cases. Despite these limitations, several case control studies have examined putative risk factors for brain tumors. In addition to the usual problem of selection bias with the case control study design, recall bias may be an especially important limitation in retrospective case control studies of this population. Individuals with brain tumors often have cognitive and language difficulties and reliable exposure assessment are therefore difficult to achieve. Another shortcoming of observational studies in this population has been the tendency to group all brain tumors together as one entity. Although this may identify risk factors common to all brain tumors, it will potentially miss important exposures for specific histopathological types. Although exceptions exist, most exposures analyzed are characterized by small effects and marked inconsistencies across studies. The major categories of exposures are reviewed in the following text.

Occupational Studies

A large number of occupational studies of brain tumor risk were conducted in cohorts of workers presumed to share common exposures. Most of these studies report standardized incidence or mortality ratios using expected rates from the general population. Detection bias is a risk in these studies because working adults with health insurance may be more likely to have diagnostic tests. This may lead to better ascertainment of brain tumors in the worker cohort as compared with the general population. Overestimation of the true association may then occur.

In general, the data on occupational exposures and brain tumors are inconsistent. Small numbers of cases, imprecise methods of exposure assessment, potential confounding, and bias have complicated the interpretation of many studies. Study validity is often weakened by the lack of biological measures of exposure and specific chemical identities, and the tendency to group all types of brain tumors into one category. However, moderate risks cannot be excluded for most of these occupational exposures and well-designed case control studies are needed to further address this issue.

Observational studies have found that workers in "white collar'" professions have higher rates of brain tumors. Some of these occupations involve chemical exposures of some type, such as laboratory researchers and health professionals. However, the existence of detection bias is real because these professionals arc more likely to have health insurance and seek medical attention (Carozza et al. 2000). McLaughlin (19H7) analyzed the potential effect of detection bias in a Swedish study where health care is free and available to all citizens. Despite universal access, higher reported brain tumor rates among professionals suggest that detection bias docs not fully account for this observation.

Electrical workers have been the subject of several occupational cohort studies based on possible exposures to electromagnetic fields (EMFs). A review of seventeen studies concluded that few were of sufficient size and design to ascertain KMF exposure accurately. Despite these limitations, most have failed to detect a significant association between EMF exposure and risk of brain tumors. However, a study of Swiss railway workers found that exposure to low frequency EMF among shunting yard engineers may accounr for the higher mortality of brain tumors in this group. Yet the study failed to yield a dose-response relation between brain tumor mortality and similar exposure to low frequency EMF (Minder and Pfluger 2001).

At least 10 occupational cohort studies of workers in the oil refinery industry have reported an increased risk of brain tumors. However, a working group from the International Agency for Research on Cancer concluded that only I of these 10 studies was without significant methodological or statistical limitations. This single study reported an increased risk of brain tumors only among oil refinery workers employed in the industry for a short duration of time, raising doubts about the validity of the results. No specific chemical exposure has been identified as a risk factor in these studies, and the weight of the evidence to date does not establish employment in this industry as a risk for the development of brain tumors.

Agricultural workers are exposed to a large number of chemicals in the form of pesticides, herbicides, and fungicides. However, each of these categories consists of many different combinations of chemicals. Similar to other occupational cohort studies, one limitation of studies among these workers is the use of job classification as a proxy for nonspecific chemical exposures. Biological markers ot exposure are lacking in most studies. Farming as an occupation and residence on a farm have been associated with an increased risk of brain tumors. An increased risk of brain tumors has been reported among Italian farmers exposed to fungicides and copper sulfate (RR = 2.0, 95% CI 1.22-3.23), Swedish horticulturists (standardized mortality ratio |SV1R| 3.2, 95% CI 1.6-5.7),

and Chinese farming women exposed to pesticides (standardized incidence ratio = *3.6, 95%* CI 1.2-8.5). However, no consistent evidence exists to indicate that any one chemical exposure is responsible for the apparent increased risk of brain tumors among agricultural workers.

Increased risks are also reported for workers in the vinyl chloride, petrochemical, and rubber industries. Other studies have found an increased risk among aircraft pilots, firefighters, welders, glass manufacturers, tile makers, and metal cutters. However, these findings have been in con si stent over nine.

Despite the large number of studies in several occupational settings, an increased risk of developing a brain tumor based on occupational status is not established. The studies conducted to date, characterized by significant design flaws, have yielded conflicting results.

Radiation

Ionizing radiation and two forms of nonionizing radiation (electromagnetic radiation [EMR| and radiofrcquency |RF] radiation) have been studied as potential risk factors for brain tumors. Ionizing radiation exposure from radiation therapy has been established as a cause of certain types of brain tumors, especially meningiomas and nerve sheath tumors. Biological studies have suggested meningeal cells may be more susceptible to radiation than other parts of the body. A cohort of 10,000 children treated with 1.5 Gy of cranial radiation for tinea capitis had elevated risks of nerve sheath tumors (RR = 33.1, 95% CI 9.4-116.5) and meningiomas (RR = 9.5, 95% CI 3.5-25.7), but less elevation of risk for malignant gliomas (RR = 2.6, *95%* CI 0.8-8.6). Ionizing radiation was also associated with an increased risk of pituitary adenoma in a study of patients with tinea capitis who received scalp irradiation at doses ranging from 1-2 Gy (mean 1.4 Gy) (Juven and Sadetzki 2002). Less dramatic but still significant elevations of risk for meningiomas and nerve sheath tumors have been reported in individuals treated with variable doses of ionizing radiation for thymic enlargement, enlarged tonsils and adenoids, and thyroid and nasopharyngeal conditions. In a mutagen sensitivity assay, peripheral blood lymphocytes from glioma subjects were more prone to chromosomal damage when exposed to y-radiation. In this study, mutagen sensitivity of lymphocytes was associated with an increased risk of glioma (OR = 2.09, *95%* CI 1.43, 3.06) (Bondy et al. 2001).

Exposure to diagnostic x-rays as a risk factor for brain tumor development is less well established. Dental x-rays have been the subject of at least 10 studies with ORs of brain tumor risk ranging from 0.4-4.0 (Preston-Martin and Mack 1996). Three U.S. studies and an Australian study have demonstrated an increased risk of meningioma associated with frequent dental x-ray examinations. This effect was strongest for younger age of exposure and exposure in the remote past when doses were higher. Prior to the introduction of fast speed film in 1956, exposures were several orders of magnitude higher than exposures used today. All such studies showed only modest elevations in glioma risk.

Since an initial report in 1979 suggested that electric wiring configurations may be associated with increased risks for leukemia and brain tumors, occupational cohort studies have also suggested an increased risk of brain tumors among electric utility workers, possibly because of the effects of EMR. Two large occupational cohort studies of electric utility workers with direct measurements of magnetic fields have demonstrated elevated risks of brain tumors with apparent dose response relationships (RR = 2,6, 95% CI 1.4-4.9 and RR = 3.0, 95% CI 1.0-8.8 in highest exposure groups). However, the role of other occupational carcinogens cannot be excluded in these studies. Other studies have not found an excess risk of brain tumors among electrical workers. Twenty-one studies of EMF exposure of varying methodology, starting as early as 1948, have reported ORs from 0.3-13.1 and SMRs ranging from 1 14-340 (Preston-Manii] and Mack 1996), Other observations have cast doubt on the possibility that EMR causes brain tumors. Biological plausibility is yet to be established, subsequent studies have reported conflicting results, and the probable roles of bias and confounding in earlier studies have been emphasized. Studies using more rigorous methodology, including direct in-home measurement of EMR, have concluded that EMR does not increase the risk of adult and childhood brain tumors.

RF radiation exposures mainly involve microwave and radar equipment, and occupational exposures (sealers, plastic welders, amateur radio operators, medical personnel, and telecommunications workers). Biological plausibility of RF radiation as a risk factor for cancer is not established. The limited data available are equivocal with respect to any cancer risk.

Cellular telephones are a source of RF exposure and have received attention as a potential risk factor for brain tumors. This is based, presumably, on exposure of the head of the user to RF energy. Unlike mobile cellular phones, portable cellular phones include an antenna as part of the headset, theoretically increasing cranial exposure to RF energy. Despite limited biological plausibility and little human data, coverage in the popular media has caused public concern. Several epidemiological studies have addressed this controversial issue. FLxposure to RF energy is difficult to quantify, even under laboratory conditions (Rothman et al. 1996). Therefore proper assessment of exposure will involve a proxy measure such as phone billing records. Studies to validate billing records as an accurate measure of exposure to cellular phone use are published. In a cohort of 250,000 portable and mobile cellular phone customers, the age-specific rates of mortality were similar between the groups (portable/mobile mortality ratio of 0.86, 95% *(A* 0.47-1.53} (Rothman et al. 1996).

In a large case control study, there was no evidence for an increased risk of astrocytomas, meningiomas, or acoustic neuromas among those subjects who used these devices for an extended time (Inskip et al. 2001). Additionally, the side of the tumor and the side of the cranium exposed did not correlate. These data do not support cell phone use as an important risk factor for primary brain tumors.

In summary, biological and epidemiological studies have established ionizing radiation as a cause of brain tumors in animal models and humans. Credible evidence supports causation of meningiomas and nerve sheath tumors, while support for causation of the most common type of primary brain tumor, glioma, is equivocal. Although some support from occupational cohort studies exists for an increased risk of brain tumors among electric utility workers, presumably resulting from KMR, the weight of evidence does not support EMF/EMR as an important causal factor. Less evidence is available supporting RF radiation as a risk factor for cancer. Biological plausibility is not established for these nonionizing forms of radiation. Despite the evidence supporting ionizing radiation as a cause of brain tumors, this exposure is responsible for only a tiny fraction of brain tumors in the United Stales.

Trauma

Head trauma has been implicated as a potential risk factor for brain tumor development. The evidence is strongest for meningiomas and less convincing for gliomas (Wrcnschet al, 2000; Nygren et al. 2001). Anecdotal reports of brain tumors arrsing after head trauma date back to the reports of Harvey Cushing in 1922. Gushing reported the presence of a head scar or skull depression in 8% of meningioma patients. Experimental studies have also implicated physical trauma as a cocarcinogen. Certain occupations with increased risk of head trauma {e.g., farmers, carpenters) are associated with a possible excess of brain tumors. An excess risk of meningiomas in persons with a history of serious or repetitive head trauma has been reported in three case-control studies (Preston-Martin et al. 1998). Childhood brain tumors may be more common in firstborn children because of a higher risk of birth trauma and in children with a documented history of birth trauma (e.g., forceps delivery, prolonged labor, and cacsarian section). Other studies have not confirmed an increased risk among these groups.

Studies of head trauma and brain tumors may be confounded by ionizing radiation. Individuals with a history of head trauma are more likely to have had skull x-ray examinations. Recall bias is another factor complicating interpretation of case control studies of head trauma and risk of brain tumors. Persons with brain tumors may be more likely to recall minor and major episodes of head injury than controls. One study reporting a positive association between head trauma and risk of brain tumors found no association when the definition of head trauma was restricted to episodes requiring medical attention. Future studies should standardize the definition of head trauma to include only episodes requiring medical attention and should document concurrent x-ray studies.

Acoustic neuroma (nerve sheath tumor of the VHI/ auditory cranial nerve) was associated with acoustic noise of 10 years' duration in a case control study (OR = 2.2, *95%* CI 1.12-4.67). Noise exposure was based on a blinded review of job histories. A dose response relationship was observed in this study because 20 or more years of exposure was associated with an OR of 13.2 (95% CI 2.01-86.98) (Ries et al. 1998). Experimental studies of tissue destruction and repair following acoustic trauma support the biological plausibility of this association.

N-Nitroso Compounds

N-nitroso compounds (NOCs) are broadly acting and potent carcinogens in animal models (Lijinsky 1999), It has been known for 40 years that NOCs arc present in foods treated with sodium nitrite. Although NOC levels in many foods have declined during the last 20 years, even small amounts may be important because humans are more sensitive than laboratory rodents to the carcinogenic effects of NOCs. A prevalent and long-standing hypothesis in the epidemiology of gliomas is that NOC exposure may increase risk. NOCs include nitrosamines, which require metabolic activation to a carcinogenic form, and nitrosamides, which do not. Transplacental exposure to ethylnitrosourea, a nitrosamide, results in formation of brain tumors, including gliomas, in rodents and primates. The addition of vitamin C to the diet prevents tumor formation in this model. Human NOC exposures are divided equally between exogenous and endogenous sources. The exogenous (environmental) sources of NOC exposure arc best established for nitrosamines: tobacco (mainly second-hand smoke), cosmetics, automobile interiors, and cured meats (Preston-Martin and Mack 1996). Other sources include rubber products {e.g., baby pacifiers, bottle nipples) and certain drugs, including antihistamines, diuretics, oral hypoglycemic agents, antibiotics, tranquilizers, and narcotics. N-nitrodiethanolaminc, a carcinogen in animal models, occurs mainly as a contaminant in cosmetic products, soaps, shampoos, and hand lotions (Batchelor et al. 2001). Some environmental sources may contain both nitrosamines and nitrosamides (Preston-Martin and Mack 1996). Endogenous formation of NOCs is a complex process that occurs in the stomach. This process depends on the presence of NOC precursors, gastric pH, the presence of bacteria, and othct physiological parameters (Davis and Preston-Martin 1998).

Measurement of NOC exposure is difficult, given the many exogenous and endogenous sources. Thus Reclassification of exposure is a major limitation for any

study of this topic. However, because processed and cured meats arc sources of exogenous NOC exposure, dietary assessment may serve as a useful surrogate marker of this form of NOC exposure. These foods contain nitrates and nitrites that can react with secondary amines or amides to form NOCs.

The NOC hypothesis is controversial. Some studies report an increased risk of gliomas in persons exposed to environmental sources of NOC and others do not. F.pidemiological support for NOC exposure as a risk factor for brain tumors comes mainly from nine studies of pediatric brain tumors and childhood and maternal diet. Studies in children present fewer methodological challenges because dietary exposures arc relatively recent or characterized by a fixed period of interest (e.g., gestation). An elevated risk of brain tumors in children has been reported for increased maternal consumption of nitrite-cured or processed meats (e.g., cooked ham, processed pork, corned beef, and fried bacon) (Bunin 1998). Studies of dietary NOC exposures and risk of gliomas in adults yield inconsistent results. Retrospective, casc-comvol studies in adults are complicated by inaccurate measurement of remote diet. Moreover, many studies of diet and risk of brain tumors have not used valid, reliable instruments to measure dietary intake over time. A population-based, retrospective case control study in Germany (115 gliomas, 418 controls) reported a significantly increased risk of glioma in adults with higher levels of dietary meat, processed pork, fried bacon, and cooked ham. In a smaller case control study in Los Angeles County in the United States (94 gliomas, 94 controls), an increased risk of glioma was associated with consumption of cured meats, especially bacon (Blowers et al. 1997). In a case control study in the San Francisco Bay area, higher consumption of cured foods was associated with an increased risk of glioma in men but not women (Lee ct al. 1997). Case control studies of glioma risk and other environmental sources of NOC like drinking water, tobacco, and medications, have yielded inconsistent but mainly negative results. Despite the existence of both experimental and observational data that NOC exposure may increase the risk of glioma, this hypothesis remains tenuous. In addition to the problem of inaccurate measurement of the exposure in these studies, all of these retrospective case control studies are subject to recall bias. The magnitude and direction of errors in dietary recall data may be influenced by disease status, casting doubt on the results of many retrospective studies (Wilkins and Bunn 1997). Some authorities have called for studies with prospective cohorts as the best method to address definitively the NOC hypothesis (Blot ct al. 1999),

Vitamins and Fruit Juices

Indirect support for the NOC hypothesis includes the observation that certain modulators of the nitrosation process, vitamins (C, E) and fruit juices, appear to reduce brain tumor risk in adults and children. Dietary studies show a reduced risk of brain tumors in children and meningiomas in male adults who consume increased amounts of fruits and fruit juices (Preston-Martin e\ Mack).

Tobacco and Alcohol

The presence of nitrosamines in tobacco smoke has stimulated interest in tobacco exposure as a potential risk factor for brain tumors. Studies of active and passive smoking and brain tumor risk have been inconclusive. A 1970 case control study suggested a protective effect of smoking, but was flawed because exposure was assessed after diagnosis and probably reflected persons who stopped smoking after learning their diagnosis. Subsequent case control studies in Los Angeles found no association of smoking and risk of glioma or meningioma (Ries ct al. 1998). Studies of maternal smoking (active and passive) and risk of brain tumors in offspring have also resulted in conflicting results. Conclusive evidence is not available that establishes cither active or passive smoking as a risk factor for brain tumors (Filippini et al. 2002; Zheng et al. 2001).

Because beer and liquor contain nitrosamines, there has been speculation that consumption of alcoholic beverages may increase the risk of brain tumors. In one study, a correlation was established between childhood brain tumors and paternal use of hard alcohol (white distilled alcohol up to 60% by volume) (RR = 3.72, 95% CI = 1.91-7.26) for less than 15 years, and an even more elevated risk of 4.06 (95% CI = 1.09-15.21) for greater than sixteen years of hard liquor use (Hu et al. 2000). However, no consistent association between maternal consumption of alcoholic beverages and risk of gliomas or meningiomas has been demonstrated (Preston-Martin and Mack 1996).

Infections

Although several reports have implicated infectious agents in the development of different types of brain tumors, these associations have been inconsistent.

The detection of viruses and virus-like particles in brain tumor specimens has resulted in speculation that viral infection may be a risk factor for brain tumor development. Interest in simian virus 40 (SV40), a polyoma virus, was stimulated by animal studies documenting brain tumor development after intracerebral inoculation with SV40 and human studies in which SV40 was isolated from brain tumor tissue. Poliomyelitis vaccine administered between 1955 and 1962 was contaminated with SV40. This cohort has been studied over subsequent decades. These individuals did not experience an overall increase in brain tumors during the ensuing 20 years, but some uncommon brain

tumor types (mcdulloblastoma and spongioblastoma) appeared more often than expected (Klein at al. 2002). Other nonpolyoma viruses (adenovirus, cytomegalovirus, other herpes viruses, arboviruses, and retroviruses) are known to induce brain tumors in experimental animal models. Most of these vituses have not been subjected to rigorous cpidemioiogical study as possible risk factors for brain tumors. Human cytomegalovirus (HCMV) is a /J-herpes virus that has been implicated in glioma development. In one study, HCMV gene products were found in 27 of 27 malignant glioma specimens, but were not found in other types of CNS tumors or non-neoplastic neurological diseases (Cobbs et al. 2002). The investigators raised the possibility that HCMV could play a causative factor in glioma growth. However, one cannot exclude the possibility that infection with HCMV could have occurred after glioma formation.

Studies of maternal infection have generally found no increased risk of brain tumors in offspring of mothers infected with varicella, rubella, or mumps during pregnancy. One large case control study reported an increased rink (R!l 2.4, 95% CI 1.5-4.0) of all types of brain rumors after different neonatal infections (Linct et al. 1996).

Infection with *Toxoplasma gondii* has been associated with an increased risk of meningioma and astrocytoma in two case control studies. However, despite this parasite's propensity to infect the nervous system, it has not been established as a risk factor for the development of brain tumors.

At the present time, epidemiological evidence implicating infectious agents as important factors in the causation of brain tumors is not conclusive.

Genetic Syndromes

Approximately 1-5% of brain tumors are caused by genetic syndromes that increase the risk of nervous system tumors {Ries et al. 1998). Neurofibromatosis type I (NF I) occurs in I in every 3000 persons and is linked to a gene on chromosome 17. Approximately 5-10% of persons with NF I develop brain tumors, primarily nerve sheath tumors, astrocytomas, and meningiomas. NF II is defined by the presence of bilateral acoustic neuromas and a corresponding link ro a gene on chromosome 22. Individuals with NF II also have astrocytomas and other brain tumor types. Table 58A.4 reviews other inherited syndromes associated with an increased risk of nervous system tumors.

Several familial cancer syndromes are associated with an inctcascd risk of brain tumors. Li-Fraumcni's syndrome, an autosomal dominant condition, may involve a mutation in the tumot suppressor gene p53, conferring an increased risk of brain tumors, sarcomas, and breast cancer (Chomprct 2002). Persons with nevoid basal-cell carcinoma (Gorlin's syndrome) and Wilms' tumor have an incteased risk of mcdulloblastoma. Turcot\s syndrome is associated with adenomatous polyps and increased risk of mcdulloblastoma and GBM. Familial clustering of brain tumors is also recognized outside of these defined syndromes. The chance of having a family member with a brain tumor is twice as high in adult brain tumor patients (8%) as in controls (4%). This familial clustering is even more pronounced for children and certain histological types of brain tumors (mcdulloblastoma). Although genetic syndromes account for only a small fraction of brain tumors in the United States, further study of the affected genes may provide insight into the molecular pathogenesis of sporadic brain tumors.

Genetic Polymorphisms

Genetic polymorphisms in specific detoxification and metabolic enzymes have been implicated in the pathogenesis of certain neoplasms. Despite conflicting results from the small number of studies, a sound rationale exists for further investigation into this category of potential risk factors (Kelsey et al. 1997; Trizna et al. 1998). In addition to the possible association of NOC and gliomas, other xenobiotics, including polycyclic aromatic hydrocarbons, have been shown to induce brain tumors in animal models. These associations between chemical carcinogens and brain tumors in experimental models raise the possibility that susceptibility may be related to genetic polymorphisms at loci encoding phase I cytochrome P450 (CYP450) and phase II glutathione 5-transferase enzymes. Several potential ncurocarcinogens (polycyclic aromatic hydrocarbons, nitrosoureas, and methyl halide) are substrates for these enzymes. Several case control studies of brain tumors have assessed other polymorphic enzymes (GSTT1, GSTM1, GSTP1, CYP2D6, NAT2, HRAS1) implicated in the activation or detoxification of potential neurocarcinogens.

Tabic 58A.4: Genetic syndromes associated with nervous system tumors

Syndrome	*Chromosome*	*Inheritance*	*CNS tumors*
NFI	17ql	**Al)**	Glioma, meningioma, nerve sheath tumors
NF1I	22 q	A I)	Nerve sheath, optic glioma, meningioma
Tuberous sclerosis	9q32-34	Al)	Ependymoma, astrocytoma, ganglioneuroma
Von Hippel-Lindau syndrome	3pl3-143 3p25-26	AD	Hemangioblastoma
St urge-Weber disease		AD	Choroid plexus papilloma

AD = autosomal dominant; CNS = central nervous system; NF = neurofibromatosis.

Tabic 58A.5: Metabolic polymorphisms and risk of astrocytoma and meningioma

Tumor	*Enzyme system*	*Polymorphism*	*Cases*	*Controls*	*OR [95% CIj*
Astrocytoma	CYP450	CYP2D6 PM	109	412	4.17 [1.57, 11.09]
Meningioma	CYP450	CYP2D6 PM	48	412	4.90 11.39, 17.26]
Astrocytoma	Glutathione S-transferase	GSTTl Null	109	494	2.67 [1.53, 4.65]
Meningioma	Glutathione S-transferase	GSTTl Null	47	494	4.52(2.18,9.34]
Gliomas	HRAS	"Rare" HRAS1	52	109	2.72 [1.17-6.32]

OR = odds ratio.

In most studies, an elevated risk of glioma and other primary brain tumors has been associated with polymorphisms in these enzymes {Table S8A.5). The study of genetic polymorphisms in different detoxification and metabolic enzymes as potential risk factors for brain tumors is a new and promising area of investigation.

CONCLUSION

Brain tumors are an uncommon but especially lethal form of cancer, and their incidence has increased dramatically over the past five decades. The only established environmental risk factor, ionizing radiation, accounts for only a small fraction of incident cases, and genetic predisposition exists in only a small percentage of cases. The study of brain tumors has been complicated by several factors. Brain tumors are an uncommon form of cancer, making centralized reporting and multi-institutional collaboration essential for effective observational study. Such reporting and collaboration are recent developments and promise improved study design and execution in the future. Because brain tumors arc a heterogeneous group of cancers arising from different cell types, perhaps by different molecular mechanisms, future studies of brain tumors should focus on biologically distinct tumor types such as astrocytoma and meningioma. Molecular classification of these tumors may allow even greater refinement of tumor classification. The WHO system is now the most widely accepted histopathological classification system with high inter-rater reliability (94%) and serves as the basis of reporting to the CBTRUS. Use of WHO criteria supplemented with genetic classification will improve case definition in future studies.

Future studies of brain tumors are needed to explore more fully the role of dietary NOC compounds, physical trauma, and viral infection. Collaboration and centralized reporting will improve these studies. Ongoing prospective cohort studies arc likely to accumulate enough eases in the future for more detailed assessment of diet, comorbid illnesses, and drug exposures as potential risk factors. Understanding the molecular pathology "I gliomas may also allow correlation of candidate exposures with specific molecular subtypes o! tumors that nia\ shed light on the molecular mechanisms of disease causation and progression.

Chapter 58
Cancer and the Nervous System

B. PATHOLOGY AND MOLECULAR GENETICS OF NERVOUS SYSTEM TUMORS

Arie Perry, Reid R. Heffner, Jr., and David N. Louis

GENERAL PRINCIPLES OF NERVOUS SYSTEM TUMOR BIOLOGY

Nervous system tumors, like other human neoplasms, are clonal proliferations that develop as a result of changes in key growth regulatory genes. Such genes fall into several different classes: (1) growth-promoting oncogenes, which are abnormally activated in tumors; (2) growth-checking tumor suppressor genes, which are inactivated in tumors; (3) cell death genes, which are impaired in rumors; and (4) DNA repair genes, which arc improperly regulated in tumors. In combination, these genetic changes result in a powerful growth advantage that enables the cells to proliferate, evolve, and disseminate (Maherctal. 2001).

The specific genes affected in human nervous system tumors are in the discovery stage and are discussed in the following text with each tumor type. Most of these genes are also deregulated in othct types of human cancers, and the manner in which the deregulation specifically affects nervous system cells remains unclear. Certain nervous system cells are probably more susceptible to neoplastic transformation than others. For example, the far greater frequency of gliomas over neuronal tumors has been attributed to the greater "neoplastic vulnerability" of glial cells; because oncogenic transformation requires cell division, postmitotic cells such as neurons should not be susceptible to tumorigenic events. However, it remains possible that nervous system tumors arise when oncogenic changes occur in precursor cells rather than in mature glial

cells or neurons; such precursors are now known to reside in the brain even into adult life. In this sense, the greater frequency of gliomas may relate to the particular paths of differentiation that are followed after specific tumorigenic genetic changes {Bachoo et al. 2002); in other words, transformed neuroepithelial progenitors may have to undergo specific molecular events to become tumors, with these same events essentially restricting cells to glial differentiation.

It is not clear why nervous system cells, rather than other cells, are transformed, because the cause of brain tumors remains unknown. At this time, ionizing radiation and hereditary predisposition arc the only two clear causal factors implicated in the genesis of nervous system tumors. Prior therapeutic irradiation of the nervous system for other tumors is a risk factor for the development of gliomas, meningiomas and schwannomas. Hereditary brain tumor predisposition is rare and confined to the neurocutaneous syndromes: neurofibromatosis (NF) 1 and 2, tuberous sclerosis (TS), von Hippel-Lindau (vHL) disease, Li-Fraumeni's syndrome, Turcot's syndrome and Gorlin's syndrome. These conditions highlight the critical roles played by specific genes in brain tumorigenesis.

HISTORY OF NERVOUS SYSTEM TUMOR CLASSIFICATION

The first comprehensive classification of nervous system tumors, formulated by Percival Bailey and Harvey Cushing in 1926, was founded on presumed parallels between embryological and neoplastic cells. In large part, this hisrogenetic "cell of origin" model still forms the basis for today's nomenclature. Interest in the role of developmental pathways in tumorigenesis has recently been renewed. In 1949, as a means of enhancing the clinical utility of tumor classification, Kernohan contributed a tumor grading system for the purpose of assessing patient prognosis. Russell and Rubinstein modified and updated the Bailey and Cushing system during the 1960s, 1970s, and 1980s. Further updates were incorporated into the World Health Organization (WHO) classification, first completed in 1979 and then revised in 1993 and 2000 (Kleihues and Gavenee 2000). Although not universally accepted, the WHO classification is currently the one most widely used by neuropathologists.

The WHO currently lists more than 100 types of nervous system tumors and their variants (Kleihues and Cavcncc 2000). This level of complexity seems daunting at first, but consideration of key clinical and imaging characteristics typically narrows the differential diagnosis to a few common possibilities (Table 58B.1). For example, the differential varies substantially for suprarentorial versus infra tentorial diagnosis, pediatric versus adult, and enhan cing versus nonenhancing tumors. The following sections ilisaiss basic techniques and histopathologic^! terms used in the diagnosis of nervous system tumors.

GENERAL HISTOPATHOLOGIC AL FEATURES AND TECHNIQUES

General Histopathological Features

Most classification and grading schemes of nervous system tumors are based on light microscopic examination of hematoxylin and eosin-stained sections. The approach to nervous system neoplasia follows the standard approach to classifying human tumors from other parts of the body. Therefore many neuropathological terms are borrowed from the discipline of general pathology. The lexicon that follows includes the terms most frequently used in clinical practice.

Anaplasia

Anaplasia suggests that tumor cells have gone from a more differentiated to a less differentiated state. Anaplasia is recognized by a histological appearance characterized by lack of cytoplasmic differentiation, a high nuclear-to-cytoplasmic ratio, increased nuclear size, and marked pleomorphism.

Tumor Grading

The fundamental concept of tumor grading is that the level of tumoral differentiation predicts biological behavior. In the WHO scheme, grade I is equivalent to benign; II is low-grade malignant; III is intermediate-grade malignant, often associated with the term "anaplastic"; and IV is high-grade malignant. Grading, which depends on histological assessment, should not be confused with tumor staging, which depends on gross and radiographic characteristics and the extent of tumoral spread. Staging of central nervous system (CNS) tumors has been defined and systematized primarily for use in clinical trials. Computed tomography (CT) and magnetic resonance imaging (MRI) have increased the accuracy of tumor staging,

Palisading and Pseudnpalisading

Palisading or lining up of tumor cells is characteristic of schwannomas, where collections of palisaded nuclei are referred to as *Verocay bodies.* The term describes a collection of neoplastic cells arranged in parallel arrays or palisades. Necrosis never occurs in true palisading, but pseudopalisades consist of serpiginous zones of necrosis lined by hypcrccllular, viable tumor nuclei, Pseudopalisading necrosis is often found in glioblastoma (Figure 58B.1) and may rarely be seen in other malignant CNS tumors.

Rosettes

The term *rosette* is confusing because it has been applied to several histological structures. The two most commonly

Table 5SB.1: Common central nervous system tumor diagnoses by location

Location	*Chitd/young adult*	*Older adult*
Cerebral/supratentorial	Ganglioglioma	Gr. 11-111 glioma (NE)
	DNT	Glioblastoma (ring E)
	PNET	Mets (E)
	AT/R1	Lymphoma (E)
Cerebellar/infratentorial	Pilocytic Astrocytoma	Mets (E)
	Medulloblastoma	I lemangiohlasroma
	Ependymoma	Choroid plexus papilloma
	Choroid plexus papilloma	
	AT/RT	
Brain stem	"BS glioma"	Gliomatosis cerebri
	Pilocytic astrocytoma	
Spinal cord (intra-axial)	Ependymoma	Ependymoma
	Pilocytic astrocytoma	Diffuse astrocytoma (ill-defined)
		Paraganglioma
Exrra-axial/dural	Secondary lymphoma/leukemia	Meningioma
		Mets
		Secondary lymphoma/leukemia
Intra sellar	Pituitary adenoma	Pituitary adenoma
	Craniopharyngioma	Rathke's cleft cyst
	Radike's cleft cyst	
Suprascllar/hypothalamie/optic patbway/third v.	Germi 110ma/germ cell tumor	Colloid cyst
	Craniopharyngioma	
	Pilocytic astrocytoma	
Pineal	Germinoma/germ cell tumor	Pineocytoma
	Pineocytoma	Pineal cyst
	Pineoblastoma	
	Pineal cyst	
Thalamus	Pilocytic astrocytoma	AA/glioblastoma
	AA/glioblastoma	Lymphoma
Cerebellopontine angle	Vestibular schwannoma (NF2)	Vestibular schwannoma
		Meningioma
Lateral ventricle	Central neurocytoma	Central neurocytoma
	SEGA (tuberous sclerosis)	SEGA (tuberous sclerosis)
	Choroid plexus papilloma	Choroid plexus papilloma
	Choroid plexus carcinoma (infant)	Subependymoma
Nerve root/pa raspinal	Neurofibroma (NFl)	Schwannoma
	MPNST (NFl)	Meningioma
		Secondary lymphoma
		Neurofibroma (NFl)
		MPNST

AA = anaplastic astrocytoma; AT/RT = atypical teratoid/rhabdoid tumor; DNT = dysembryoplasric neuroepithelial tumor; E = enhancing tumor; Gr. • grade; Mets •• metastases; MPNS1 • malignant peripheral nerve sheath tumor; NE • non-enhancing tumor: NFl = neurofibromatosis type 1; NF2 = neurofibromatosis type 2; PNET = primitive neuroectodermal tumor; SEGA= subependymal giant cell astrocytoma.

encountered rosettes are Homer Wright rosettes and perivascular rosettes. A Homer Wright or neuroblastic rosette is a ring of cells surrounding neuropil (i.e., delicate fibrillary processes) and represents axon formation by primitive neuronal elements. Because Homer Wright rosettes are identical to those encountered in neuroblastomas of the peripheral nervous system, their presence is oken Liken .is evidence of neuroblastic differentiation. They are associated, as a focal finding, in primitive neuroectodermal tumors (PNETs) such as medulloblastoma and pineoblastoma. CNS tumors with extensive Homer Wright and neuropil formation are sometimes referred to as *central* or *cerebellar neuroblastomas.*

Perivascular pseu do rosettes are characterized by a peripheral ring of tumor nuclei, surrounding a central blood vessel with a nuclear-free eosinophilic zone between (Figure 58B.2). The nuclear-free zone is derived from tapering cellular processes that radiate from the tumor cells to the vessel. Perivascular rosettes are typical of ependymomas and the perivascular processes are highlighted with glial fibrillary acidic protein (GFAP) immunostains. Similar axon-bearing structures may occasionally be seen

in neuronal tumors, such as central neurocytomas, pinc-ocytomas, and various forms of PNET.

Desmoplasia

Desmoplasia is a form of fibrosis induced by resident fibroblasts within regions of the CNS that normally harbor them, such as the meninges and perivascular spaces. Desmoplasia is a reactive rather than a neoplastic change and may be seen in any tumor as it infiltrates the lep-tomeninges. It also represents a characteristic feature of certain tumor types, such us desmoplastic gangliogliomas and medulloblastomas.

Microvascular Proliferation

Microvascular (endothelial and pcricytic/smooth muscle cell) proliferation represents an important and interesting response to tumor- and hypoxia-associatcd angiogenesis factors. It is encountered in both benign and malignant CNS neoplasms, but is more common in malignant tumors. In pilocytic astrocytoma, the new vessels often take on a glomeruloid configuration, usually with a single-layered flat endothelial lining. In malignant tumors, such as glioblastoma, these vessels are also glomeruloid, but additionally display multilayering with enlarged or "hyper-plastic" endothelial cells (Figure 5KB.3). In either case, these neovascular structures lack the tight junctions that nor-mally contribute to the blood-brain barrier and typically leak intravascular contrast material. This accounts for the tumor-associated enhancement detected radiologically.

Frozen Sections and Touch Imprints/Smears

Intraoperative frozen sections are more difficult to interpret than fixed tissue sections, but have the advantage of speed, requiring only minutes to prepare. They are requested for several reasons that include simple curiosity and a desire to provide rapid feedback to the patients and their families. However, the most important reasons for performing this technique are to ensure that a representative sample is obtained for permanent sections and to provide informa-tion that may affect the surgical procedure. For example, a neurosurgeon may stop at a limited biopsy for a suspected lymphoma, aggressively resect an ependymoma, or send additional material to the microbiology laboratory for an abscess. Because the process of tissue freezing produces significant cytological artifacts, another popular technique has been the preparation of touch imprints or smears from fresh tissue. Although the underlying architecture is lost, the tissue requirements are minimal and the cytologic preservation is excellent (Figure 58B.4). This may be critical for diagnoses based primarily on nuclear cytology, such as reactive gliosis versus low-grade diffuse glioma. It is also important to realize that the frozen section technique

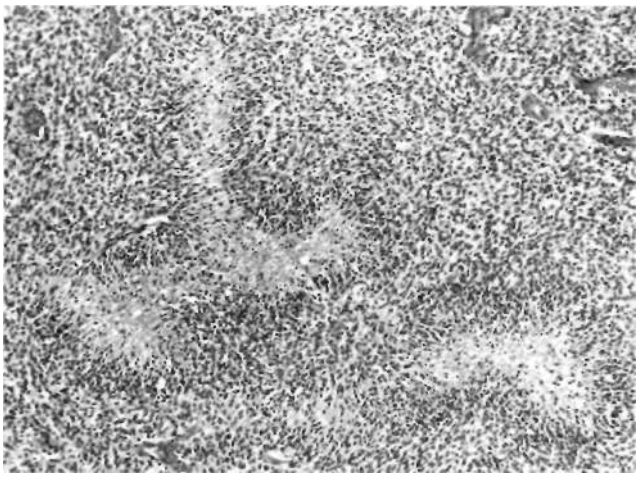

FIGURE 58B.1 Glioblastoma. Nuclear pseudopalisading surrounding foci of central necrosis (hematoxylin-eosin stain; xlOO).

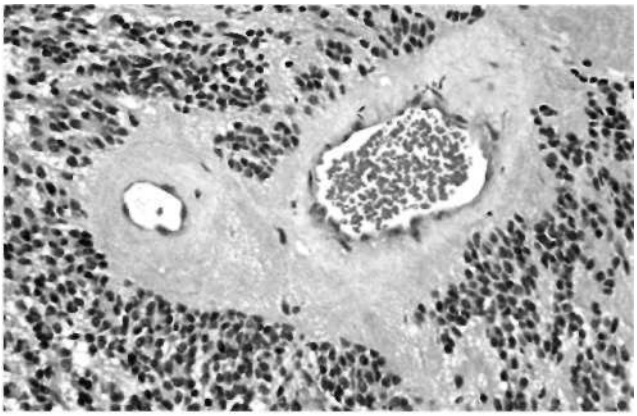

FIGURE 58B.2 Ependymoma. Characteristic perivascular pseu-dorosette characterized by a fibrillary-appearing perivascular nuclear-free zone (hematoxylin-eosin stain; ×200).

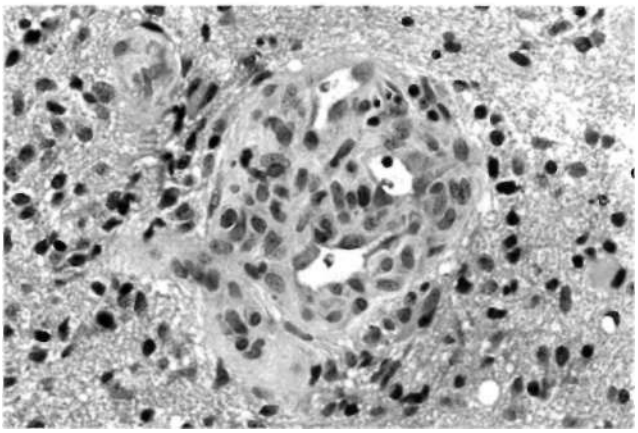

FIGURE 58B.3 Glioblastoma. Focus of endothelial hyperplasia with glomeruloid, multilayered vessel (hematoxylin-eosin stain; x400).

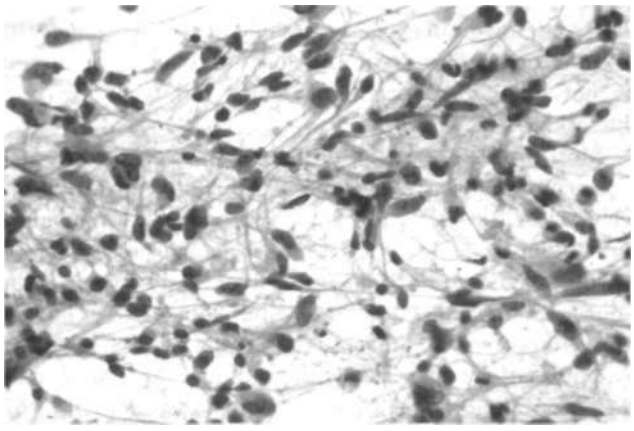

FIGURE 58B.4 Diffuse astrocytoma on an intraoperative smear. Cyrological preservation is superior to that of a typical frozen section and cytoplasmic processes are easier to discern. The oval to spindled, hyperchromatic nuclei arc typical of diffuse astrocytoma (hematoxylin-eosin stain; x400).

results in substantial tissue loss and morphological artifacts in the thawed residual specimen. Therefore it is best omitted in limited biopsies for which the surgical procedure will not be altered and supplemented by additional tissue. In other words, it is impetative that at least some optimally fixed, nonfrozen tissue is saved for final diagnosis on permanent sections.

Electron Microscopy (Ultrastructural Pathology}

The use of electron microscopy in the diagnosis of tumors is labor intensive, time consuming, and expensive, with interpretation typically delayed by 1-2 weeks. For these reasons, it has been supplanted by immunohistochemistry in most pathology laboratories. Nevertheless, it is extremely valuable in the diagnosis of certain tumors and remains the only method capable of proving epcndymal differentiation. Ultrastructural pathology is used to gain insight into forms of diffctcntiation, primarily by visualizing specific organelles and other components of the cytoplasm and cell sutfacc (intermediate filaments, neurosecretory granules, synapses, pinocytotic vesicles, intercellular junctions, cilia, microvilli, basement membrane, and so on), and is therefore of particular utility in the diagnosis of poorly differentiated neoplasms.

Immunohistochemistry

Immunohistochemistry is an ancillary diagnostic technique for detecting protein expression within tumor nuclei, cytoplasm, and cell membranes. It is used most commonly to determine lines of cellular differentiation, proliferation indices, oncogene overexpression, or losses of tumor suppressor expression. Monoclonal antibody technology and recently improved antigen-retrieval methods have greatly expanded the versatility of this technique in routine formalin-fixed paraffin-embedded tissue. However, several pitfalls remain and considerable experience is needed for accurate determinations. Commercial antibodies vary greatly in terms of sensitivities, specificities, and clinical utilities. Most laboratories use the immunoperoxidase staining technique with horseradish peroxidase and a brown diaminobenzidine dye, because staining is permanent and the reaction is visible by conventional light microscopy. Several antibodies are commonly applied to die study of CNS tumors.

Glial Markers

Immunorcactivity for GFAP, an intermediate filament, is fairly specific for the glial lineage. Although it is commonly considered an astrocytic marker, it docs not reliably distinguish astrocytic from oligodendroglial or epcndymal ontogeny. Some degree of glial differentiation and/or GFAP expression may also be encountered in choroid plexus tumors, mcdulloblastomas/PNFTs, gangliogliomas, and even some peripheral nerve sheath and cartilaginous tumors. Lastly, some astrocytomas are associated with minimal cytoplasm ot intermediate filament synthesis and may appear GFAP-negative as a result. S-100 protein provides a useful, though less specific, glial marker in such cases.

Neuronal Markers

Neurofilaments are heteropolymers composed of three subunits, with molecular weights of 68, 150, and 200 kD that are unique to neurons and their axonal processes. Each triplet protein is immunochemically distinct and is the product of a different gene. Normal neurons and mature neuronal tumors (e.g., gangliogliomas) stain for neurofilament protein, but primitive neuronal tumors such as mediilloblastoma arc often negative. Nevertheless, the staining of axons is also of great utility for highlighting a tumor's growth pattern. For example, discrete tumors, such as metastases and ependymomas push axon-bearing parenchyma to the side, whereas diffuse gliomas contain entrapped neurofilament-positive axons within their substance.

Another commonly used neuronal cell marker is synaptophysin, a 38-kD glycosylated polypeptide, which is a component of presynaptic vesicle membranes. Thought to be an oligomeric protein that avidly binds calcium within the neurotransmitter vesicles, synaptophysin is important in the calcium ion-depcudent release of neurotransmitter molecules. It is a relatively reliable marker of neuronal differentiation and is typically found even in the most primitive neuronal tumors, such as mediilloblastoma and PNET. The characteristic staining of neuropil on synaptophysin immunohistochemistry, however, sometimes makes it difficult to decipher whether the synaptophysin-positive neuropil belongs to the tumor or represents entrapped nonneoplastic tissue. This marker, along with chromogranin,

is useful for highlighting normal and neoplastic ganglion cells, as well as neuroendocrine tumors, such as pituitary adenomas, carcinoids, and paragangliomas. Neu-N, a marker of relatively mature neuronal differentiation, has the advantage of clearly marking tumor nuclei rather than surrounding neuropil.

Epithelial Markers

Cytokeratins are a class of intermediate filaments with molecular weights of 40-67 kD, primarily located in epithelial cells. Antibodies against cytokeratin are most commonly used in the diagnosis of metastatic carcinomas, but can also be used to identify craniopharyngiomas, chordomas, and choroid plexus tumors. Epithelial membrane antigen (EMA) is a glycoprotein constituent of normal and neoplastic epithelial cells. In the CNS, EMA is a particularly useful marker for meningiomas, which, unlike true epithelial tumors, display minimal to no cytokeratin expression in most cases, except in the secretory meningioma.

S-100 Protein

S-100 protein is a soluble 21-kD protein, composed of three antigenically distinct portions. It is common to neuroectodermal cells, including melanocytes, glia, Schwann cells, chondrocytes, and the sustentacular cells in tumors such as paraganglioma, pheochromocytoma, and olfactory neuroblastoma. To a lesser extent, it also stains neuronal tumors and fibrous meningiomas. Therefore as a glial marker it typically displays a higher sensitivity and a considerably lower specificity than GFAP. The S-100 protein is also particularly useful for demonstrating Schwann cell differentiation in benign and malignant peripheral nerve sheath tumors (MPNSTs).

Methods of Assessing Cell Proliferation

The simplest and least expensive method for estimating cellular proliferation is the mitotic index, usually expressed as cither the average or maximal attainable count per 10 high-powered fields (HPF). Difficulties stem from pyknotic nuclei mimicking mitoses in poorly preserved specimens, variable field sizes among microscopes, and lack of uniform methods for counting. The proliferation index is often underestimated as well, given that the cells undergoing mitosis represent only a small fraction of cycling cells within a tumor.

Flow cytometry (FCM) is a method by which cells suspended in fluid move in single file past sensors that record selected physical or chemical characteristics. Tumor assessment by FCM uses mainly fresh or frozen tissues and body fluids, but newer modifications allow the use of fixed or paraffin-embedded specimens. It has the advantage of rapid assessment of thousands of cells, but it is a labor-intensive and expensive technique, which precludes its routine use. Furthermore, because morphology is lost, it is not possible to determine which cell types arc proliferating,

Most proliferation antigens are nuclear constituents that are manifest during one or more proliferative phases in the cell cycle, allowing the recognition of cycling cells by routine immunohistochemistry. These markers are already valued in the diagnosis and management of brain tumors. The murine monoclonal antibody Ki-67 binds to a human nuclear protein in the growth fraction (Gi, S, G2, and M phases of the cell cycle), with maximum expression in the M phase but not in the Go phase, MIB-1, a variant of Ki-67 that works in paraffin sections, is gaining popularity as an ancillary marker for tumor grading (Giannini et al. 1999a). In most tumor types, the Ki-67 or MIB-1 labeling index increases with degree of malignancy.

Molecular Diagnostics

As previously stated, tumors arise when alterations occur in key growth regulatory molecules. It is anticipated that measurements of such molecular alterations will change the way tumors arc classified. Molecular changes can be detected at the genomic DNA, messenger RNA (mRNA) or protein levels. In situ hybridization can be used to detect tumor related mRNAs. For example, diagnostic elevations of hormone specific mRNAs are detectable in pituitary adenomas, and the same techniques could be useful in other CNS tumors. Other gene products, such as proliferation antigens, growth factors, and their receptors, are similarly identifiable by RNA probes, although the degradation that occurs in paraffin-embedded tissue makes this technique somewhat challenging for archival or routinely processed tissue specimens.

Molecular DNA probes are also well suited to the study of chromosomes and genes, alterations of which are central to the development of neoplasia. Some tumors are associated with "signature" cytogenetic abnormalities, such as chromosomal translocations and deletions. However, abnormalities at the submicroscopic or molecular levels, such as gene rearrangements and single gene defects that may affect oncogenes and tumor suppressor genes, cannot be detected by routine karyotyping (conventional cytogenetics). The most common and practical approaches to detect deletions of chromosomal regions or specific tumor suppressor genes include loss of heterozygosity (LOH), fluorescence in situ hybridization (FISH), and quantitative polymerase chain reaction (PCR) techniques, for detection of oncogene amplification, FISH, Southern blot, and quantitative PCR are most practical. Thus far, no specific translocations of fusion transcripts are associated with primary CNS neoplasms, as in hematopoietic and soft tissue tumors. Comparative genomic hybridization (CGH), CGH microarray, spectral karyotyping/multiplex FISH, and oligonucleotide

or complementary DNA expression profiling techniques are **also** very useful techniques for surveying entire genomes for abnormalities, but these techniques are still primarily used for research, rather than diagnostic pathology.

Few molecular diagnostic tests have become routinely used or "standard of care" in neuro-oneology. The most notable is the use of chromosome lp and 19q testing as a prognostic/management tool for patients with oligodcn-droglial tumors; this is currently performed in only a few laboratories. Nevertheless, the clinical interest in this test is growing and it is expected to soon become commonplace. FISH has the advantage of simplicity, morphological preservation, minimal tissue and purity requirements, and lacks the requirement for microdissection or matching blood and nonneoplastic tissue. However, accurate interpretation requires experience, especially in cases with ancuploid populations of tumor cells. It also uses large probes (100-300 Kb) and is insensitive to very small deletions. LOH has the advantage of simplicity, and the probes arc smaller and capable of detecting losses even in the presence of mitotic recombination (loss of wild type allele and duplication of mutant allele), but it requires normal DNA for comparison and may yield false negative results if the tumor sample is not relatively pure. Other clinical applications of FISH include epidermal growth factor receptor (EGFR) amplification to distinguish small-cell glioblastoma from anaplastic oligodendroglioma, 22q deletion ro distinguish atypical teratoid/rhabdoid tumor (AT/RT) from variants of medulloblastoma, and meningioma-associated deletions *{NF2, DAL1,* lp, 14q) to distinguish anaplastic meningiomas from other malignancies or benign meningiomas from foci of meningothelial hyperplasia. Ir is likely that many more applications of molecular diagnostics will become incorporated into diagnostic neuropathology laboratories in the near future.

PRIMARY NEUROEPITHELIAL TUMORS

Primary neuroepithelial tumors are those nervous system neoplasms that arise from the primary cells of the nervous system (i.e., glia, neurons, or their precursors). From both a clinical and pathological standpoint, gliomas constitute the largest and most heterogeneous group of neuroepithelial tumors. The term *astrocytoma* has been applied broadly, but only four types have clinical importance: diffuse astrocyroma, pilocytic astrocytoma, pleomorphic xanthoastrocytoma (PXA), and subependymal giant cell astrocytoma (SEGA). Each has a distinctive topography, histology, and natural history. Diffuse astrocytoma (grade II), anaplastic astrocytoma (grade III), and glioblastoma (grade IV) form a continuum of malignancy for the diffuse astrocytoma, whereas the other forms are considered distinct entities. The term *diffuse glioma* is also used commonly in neuro-oncology to encompass the diffuse astrocytomas, oligodendrogliomas, and mixed oligoastrocytomas (OAs) (grades I1-1V), all infiltrative gliomas with overlapping clinical, radiographic, and histological features.

Diffuse Astrocytoma (WHO Grade **II)**

Referred to loosely as well-differentiated, low-grade, diffuse, grade II, or simply "astrocytoma," this slow-growing tumor regularly undergoes malignant progression to anaplastic astrocytoma and GBM. Survivals of 5-10 years are expected, but a remarkably wide range exists among individual patients. The median age of onset is roughly 35 years, and young patients have a considerably better prognosis than older patients. Radiographically, these tumors are ill-defined, nonenhancing cerebral masses, often with a subcortical epicenter. A much smaller proportion of diffuse astrocytomas occur in the spinal cord, cerebellum, or brain stem. Brain stem gliomas deserve special mention, because these tumors typically present in childhood, expand the pons, and have a uniformly poor prognosis, regardless of the histological grade.

Diffuse astrocytomas are poorly circumscribed, and, although the CNS parenchyma may be expanded, the overall anatomy is minimally disrupted. Given its diffusely infiltrative nature and lack of solid mass formation, large portions of the tumor are not seen by gross inspection or on radiographs (i.e., microscopic disease). The infiltrative growth pattern makes therapy challenging, because microscopic foci of disease cannot be adequately treated with surgery, radiation, or chemotherapy. Widespread infiltration involving multiple lobes and even the brain stem *(gliomatosis cerebri)* is rare and has a poor prognosis regardless of histological grade.

Microscopically, there is a slight to moderate increase in cellulariry and the primary distinction from reactive astrocytosis rests on the finding of cytological atypia. Diffuse astrocytoma cells can take on several morphological types, including fibrillary, gemistocytic and protoplasmic. The fibrillary type is most common and consists of irregular, elongated, hyperchromatic nuclei, eirher appearing "naked" in an otherwise fibrillary background or displaying discernible cytoplasmic processes (see Figure 58B.4). The latter may be highlighted by imnumohistochemical stains for GFAP, but this is neither absolutely sensitive nor specific for the following reasons: (1) Some astrocytomas harbor minimal quantities of GFAP-positivc cytoplasm, (2) interpretation may be difficult as a result of staining of non-neoplastk astrocytic elements or high background in general, and (3) other gliomas display GFAP immunoreactivity. By definition, grade II astrocytomas lack mitotic activity, microvascular proliferation, and necrosis. Ancillary staining for M1B-1 (Ki-67) generally reveals a low proliferative index as well.

Chromosome 17p losses and mutations of *TPS3* are seen in roughly half of the cases. Those with *TI'53* gene

mutations usually display strong nuclear immunostaining for p53 protein, although the association is imperfect because die protein can be stabilized by other mechanisms and many immunopositive cases lack *TPS3* mutations (Louis et al. 1993). Those cases that evolve to glioblastoma (secondary glioblastoma) typically retain evidence of *'IPS 3* mutation and may even show additional *TP53* gene mutations or clonal expansion of the tumot cells with mutation (on the other hand, *de novo,* or primary glioblastomas, rarely display such mutations; see the following text}. Other common alterations include the over-expression of platelet-derived growth factot teccptor alpha in astrocytomas of all grades and losses of chromosome 22. Other than these two events, little is known about the earliest changes in these low-grade gliomas, their progenitor cells, or the .cause of transformation. The only known risk factors for the development of astrocytomas are prior therapeutic radiation to the brain and rare hereditary brain tumor syndromes such as Li-Fraumeni syndrome, Turcot's syndrome and NFl. By the time a patient comes to clinical attention with a diffuse astrocytoma, it is likely thai the tumor has been growing for years.

Anaplastic Astrocytoma (WHO Grade III)

The clinical ptesentation and radiographic features of anaplastic astrocytoma are similar to those of grade II astrocytoma, except the mean age of presentation is roughly a decade later and more cases show contrast enhancement. The average survival is 3 years after diagnosis, with great in ret- individual variability. Patient age is one of the most powetful prognostic variables and younger patients survive significantly longer than older ones.

Histologically, anaplastic astrocytomas ate more cellulat than grade II astrocytomas and display a greater degree of proliferation. They are primarily defined by the ptesence of mitotic figures. Some cases display endothelial prominence or hypertrophy, but lack the multilayered microvascular proliferation and necrosis of glioblastomas. The gemistocytic ("stuffed cell") astrocytoma is an astrocytoma variant that commonly ptcscnts at the anaplastic level. Characterized by strongly GFAP-positive cells with eccentric bellies of eosinophilic cytoplasm, this tumor type has a high incidence of progression to glioblastoma. Interestingly, it is primarily the small cell astrocytoma elements in the background that constitute the proliferating element, Another feature that may hklp to distinguish anaplastic astrocytomas from gtade II astrocytomas is the generally higher Ki-67 or MIB-1 proliferative index on immunostains (Giannini ct al. 1999a).

Anaplastic astrocytomas share the high frequency of *TPS3* mutations seen in grade II astrocytomas. Inactivation of the *Rb* cell cycle regulatory pathway is also common and may be ptimarily responsible tor the increased proliferation observed histologically. Homozygous deletion of the *CDKN2A/pl6* gene is the most common mechanism for disabling this pathway, although deletions of the *KB* gene and *CDK4* amplifications are alternate aberrations (Ueki et al. 1996). Amplifications of the *EGFR* gene and losses of phosphatidylinositol phosphate 3'-phosphatase *(PTEN)* on lOq occur less frequently in anaplastic astrocytomas than glioblastomas, and when present, may suggest eithet a worse prognosis or the possibility of undersampling or undergrading in a glioblastoma.

Glioblastoma (WHO Grade IV)

Glioblastoma (previously known as glioblastoma multiforme) is the most common primary brain tumor in adults, comprising approximately 50% of all gliomas. The peak age at onset is 50-60 years, roughly a decade later than anaplastic astrocytoma. Unfortunately, scvetal decades of basic and clinical research have had little impact on the prognosis of glioblastoma. The avctage sutvival remains approximately 1 year after treatment with radiation,

Glioblastoma most commonly occurs in the deep white matter, hasal ganglia, or thalamus and is rarely found in the cerebellum or spinal cord. As the designation *multiforme* implies, the gross and microscopic appearances are heterogeneous. The affected portion of the brain is usually replaced hy a single mass that grossly may appear well circumscribed, but microscopically infiltrates widely, often spreading to the opposite hemisphere via the corpus callosum ("butterfly lesion"). Multifocal tumors may occut and in most cases likely tepresent separate regions of malignant transformation within a widely disseminated lowet-grade astrocytoma, such as gliomatosis cetebti. In advanced stages, the tumor may extend into the meninges or the ventricle. Seeding of the neutaxis as multiple implants in the brain or ventricular surfaces is an atypical growth pattern and extracranial metastases ate extremely rare.

The cut surface has a variegated appearance (Figure 58B.5), characterized by central yellow or white zones of necrosis and hemorrhage surrounded by a hyperemic ring (endothelial hyperplasia) and "edematous" brain with varying mixtures of edema, gliosis, and tumor infiltrates. Microscopically, all the features of anaplastic astrocytoma plus endothelial hyperplasia and/or necrosis characterize GBM. Endothelial hyperplasia is defined as thickened or glomeruloid vessels with multilayering (see Figure 58B.3). It is a form of tumor-induced angiogenesis and a potential target for novel thetapies. The necrosis is often associated with a characteristic serpiginous distribution and associated nucleat pscudopalisading (sec Figure 58B.1). Several histological variants are recognized, including giant cell glioblastoma, small cell glioblastoma, and gliosarcoma. The latter is characterized by a sarcomatous clement, currently believed to arise from mesenchymal metaplasia within a glioblastoma. No significant clinical differences have been identified in these variants when

F1GURF, 58B.5 Glioblastoma (cut in axial imaging plane). This patient's right hemispheric glioblastoma demonstrates central necrosis, a deceptively demarcated hyperemic rim (endothelial hyperplasia), and an infiltrative component that extends well beyond the grossly discernible margins (note the expansion of the right thalamus with blurring of the grey-white junctions).

compared with conventional glioblastoma, although gliosarcomas arc more frequently noted in the temporal lobes.

Glioblastomas are among the genetically best characterized CNS tumors and often harbor numerous cytogenetic and molecular genetic aberrations (Maher et al. 2001). Mutations of *TP53* are less common than in diffuse astrocytomas or anaplastic astrocytomas and are primarily seen in "secondary glioblastomas" arising in younger patients after malignant transformation of a lower-grade precursor (Louis et al. 2001). In contrast, 30^40% of glioblastomas harbor EGER amplifications, often with an associated constitutively activating mutation. These are mainly encountered in the "primary" or "de novo" glioblastoma (Louis el al. 2001). The latter is defined by the lack of a precursor lesion, typically in an older patient with rapid clinical onset. Such gene amplifications are also particularly common (—70%) in the small-cell variant of glioblastoma. These tumors are composed of small round cells with minimal cytoplasm and a remarkably brisk mitotic index. They are sometimes misdiagnosed as anaplastic oligodendrogliomas because of their rounded, more uniform nuclei. However, they share the demographic features and dismal prognosis of glioblastomas and do not harbor the Ip and 19q deletions seen in oligodendrogliomas (see the following text). Alterations of the *pl6/CDK4/RB* pathway are nearly universal in glioblastoma and many cases harbor chromosome 10 losses (mostly primary glioblastomas). The PTENgeneon 10q23 is mutated in a subset of these and may have prognostic significance in certain patient populations. Additional tumor suppressor genes on both the long and short arms of chromosome 10 are suspected in the remaining group of PTEN-wild type tumors wirh demonstrable LOH. The list of additional glioblastoma-associated alterations is growing rapidly and a detailed discussion is beyond the scope of this text. Nevertheless, intensive research is currently focused on mechanisms of invasion, cellular migration, proliferation, angiogenesis, apoptosis dysregulation, and therapeutic resistance {Maher et al. 2001).

Circumscribed ("Favorable") Astrocytomas

Pilocytic astrocytoma, PXA, and SEGA are examples of circumscribed or "favorable" astrocytomas that grow slowly, with relatively discrete demarcation and a significantly better prognosis than the diffuse astrocytomas. These tumors are more common in children and young adults.

Pilocytic Astrocytoma (WHO Grade I)

Pilocytic astrocytomas are usually well circumscribed grossly and radiologically, although limited degrees of infiltration are nearly always found microscopically. They are most commonly found in the cerebellum, hypothalamus, third ventricle, optic nerve, spinal cord, and dorsal brainstem, but may also involve the cerebrum. Nonspecific clinical terms such as *cerebellar astrocytoma, optic nerve glioma,* and *tectal glioma* generally refer to pilocytic astrocytomas, but should be avoided because diffuse gliomas can also present in these sites. Likewise, the adjective *juvenile* often added to pilocytic astrocytoma is misleading, because most adult cases are histologically and clinically indistinguishable from those in children. Outcome depends on the surgical accessibility of the tumor, but is usually excellent (80% 20-year survival) and many are curable with surgery alone. The gross appearance varies somewhat with anatomic location. Cerebellar tumors, which arc often hemispheric, are typically composed of a large, fluid-filled cyst with an enhancing mural nodule. Hypothalamic and optic nerve tumors are usually solid. Optic nerve gliomas appear as a focal, segmental nerve swelling. Both unilateral and bilateral optic nerve gliomas are particularly common in NKl, a setting in which most are indolent and do not require surgical intervention.

The distinctive histological feature of pilocytic astrocytoma is a biphasic pattern with compact pilocytic areas interspersed with microcystic, spongy, or loose areas (Figure 58B.6). Dense portions contain piloid (hairlike) or bipolar astrocytes with long, spindle-shaped processes.

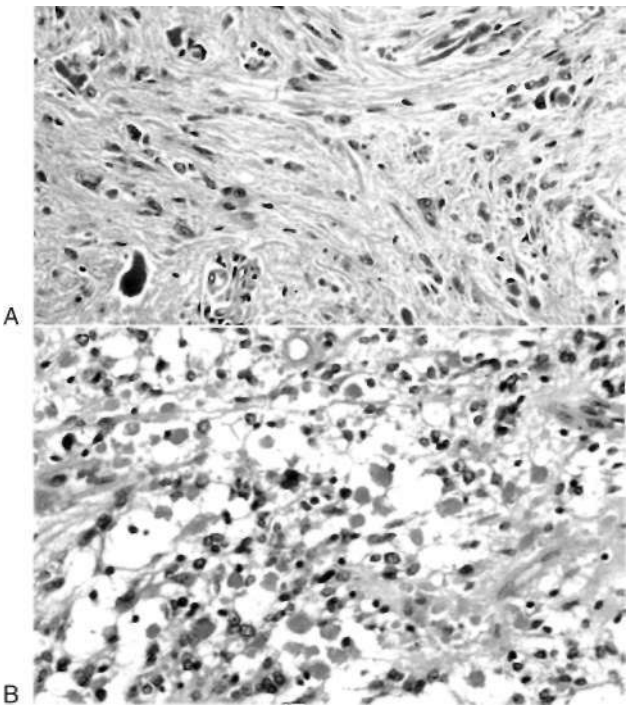

FIGURE 5 SB.6 Pilocytic astrocytoma. Classic examples are hiphasic wiih druse IAI ;nij lonw iO) regions. Helpful markers include bright red, corkscrew-shaped Rosenthal fibers (A) and mul berry-shaped eosinophilic granular bodies (B) (hematoxylin-cosin stain; x200).

Rosenthal fibers (RFs) are common. These arc masses of intracellular astrocytic filaments that are fusiform or corkscrew-shaped, with a hyaline appearance {Figure 58B.6A). Mu I berry-shaped eosinophilic granular bodies (EGBs) are also found in most cases (Figure 58B.6B). Although not entirely specific, both RFs and EGBs are generally signs of an indolent process and represent important diagnostic clues that distinguish pilocytic from diffuse astrocytomas. Evidence for *NF1* gene inactivation has been found in Nil-associated pilocytic astrocytomas, hut not in sporadic tumors. Little else is known about the molecular pathology of this tumor type.

Pleomorphic Xanthoastrocytoma (WHO Grades II or III)

PXA is a rare and distinctive form of "favorable" astrocytoma, often misdiagnosed in the past as GBM. The average age at diagnosis is 26 years, and history of seizures often precedes diagnosis (Giannini et al. 19991}). PXA usually involves the cerebral cortex and overlying meninges, and the preferred site is the temporal lobe. The histological features are hypercellulanty with many atypical and pleomorphic tumor astrocytes. Bizarre giant cells are present, but mitoses are unusual. Probably the most helpful finding is that of EGBs, because these arc generally not seen in glioblastomas. Despite its name, xanthomatous cells (lipidized astrocytes) with foamy, lipid-filled cytoplasm are only encountered in roughly a quarter of cases. PXA (WHO grade II) has a relatively favorable prognosis with postoperative survival times averaging 81% at 5 years and 70% at 10 years. However, 15-20% are estimated to undergo malignant transformation (WHO grade III) and/or follow an aggressive clinical course. Little is known about the tumorigenic events associated with PXA, hut they seem to differ from those of diffuse astrocytomas.

Subependymal Giant Cell Astrocytoma (WHO Grade I)

Most SEGAs arc associated with TS and those lacking other features of TS may have a form fruste. An elongated, sausagelikc, or lobulated gross appearance is typical. Histologically, identical smaller masses resembling candle gutterings (the drippings of tallow from a burning candle) on the wall of the lateral ventricle are often seen in TS-associated cases. Hydrocephalus results from obstruction of the foramen of Monro.

The rich vascularity of the tumor gives the cut surfaces a red and beefy appearance. Calcification is an almost constant feature and is so extensive at times that the mass becomes hard as a stone. The tumors are moderately cellular, consisting of closely packed astrocytes with abundant cytoplasm. Tumor cells are often arranged in sweeping fascicles or around blood vessels, analogous to the pseudorosettes in ependymomas, and may have a gemistocyte-like or spindled morphology.

Some tumor cells are clearly of astrocytic origin and the cytoplasm is filled with GFAP. Other tumor cells resemble neurons having prominent nucleoli and many have intermediate features with astrocytoma-like cytoplasm and neuronal-like nuclei. Neuronal differentiation is further suggested by positive immunohistochemical staining for 68-kD neurofilament protein. Tumor cells may stain with both neuronal and glial markers or with neither, explaining the preference of some neuropathologists for the term subependymal giant cell *tumor* rather than SEGA. Because TS is characterized by hamartomas of many organs, SF.GAs may also be hamartomas rather than neoplasms. This is consistent with their benign behavior.

Oligodendroglioma (WHO Grades II or III)

As opposed to astrocytomas, most of which are high-grade at the time of diagnosis, oligodendrogliomas usually present at the grade II stage. They typically present in young to middle-aged adults and are distinctly uncommon in children. The majority are hemispheric masses, mainly in the frontal lobe, and location in the brain stem, cerebellum,

and spinal cord is unusual. The prognosis for grade II oligodendrogliomas is significantly better than for grade II astrocytomas, with average survival times of 10 years or more after diagnosis and inter-individual improved chemosensitivity profiles. As with astrocytoma[1];, individual variability exists in time to progression and overall survival.

The most classic and uniformly accepted oligodendroglial features include uniformly round nuclei, bland chromatin, clear perinuclear haloes imparting a "fried egg" appearance, and a rich, branching capillary network reminiscent of chicken wire (Figure 58B.7). Less specific findings include cortical involvement, microcalcifications, mucin-nch microcystic spaces, and perineuronal satellitosis. Although helpful in diagnosis, the "fried egg" appearance is a formalin fixation artifact that is neither necessary for diagnosis nor encountered in frozen sections or rapidly fixed specimens. The morphological spectrum includes two strongly GFAP-positive cells: mini- or microgemistocytes and gliofibrillary oligodendrocytes. The former are gemistocytc-like cells with small bellies of eosinophilic cytoplasm, round, bland nuclei resembling those of classic oligodendroglioma nuclei, and no cytoplasmic processes. The latter arc histologically identical to classic oligodendroglioma cells, but exhibit a thin perinuclear rim of GFAP immunoreactivity. These two cell types (1) ate commonly encountered in otherwise classic-appearing oligodendrogliomas, (2) are reminiscent of normal GFAP-positive oligodendroglial precursor cells, and (3) do not impact negatively on prognosis (although the presence of numerous microgemistocytes should prompt a cateful search for anaplastic features), Anaplastic- oligodendroglioma (grade III) is defined by hypercellularity, numerous mitoses, and microvascular proliferation. Some oligodendrogliomas have regions that are histologically similar to diffuse astrocytoma, which can cause diagnostic difficulties because no specific oligodendroglioma markers arc available.

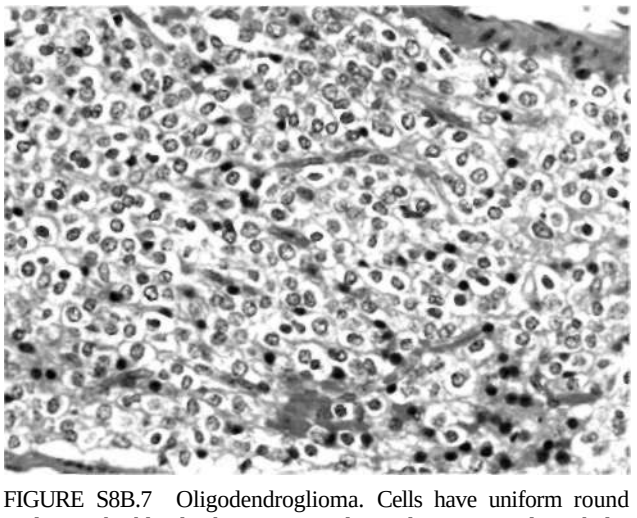

FIGURE S8B.7 Oligodendroglioma. Cells have uniform round nuclei with bland chromatin and a clear perinuclear halo, producing a fried-egg appearance. The rich, branching capillary network has been likened to chicken wire (hematoxylin-eosin stain; x200).

The genetic characterization of oligodendrogliomas has provided some of our most important clues in the diagnosis and treatment of diffuse gliomas. A characteristic loss of chromosomal arms Ip and 19q is found in 50-80% of cases. More importantly, this genetic signature is associated with both prolonged survival and a favorable response to procarbazine, chloroerhyleyelohcxylnitrosourea, vincristine chemotherapy and/or radiation therapy (Gairncross etal. 1998). Based on these findings, ancillary testing for Ip and 19q status is often requested by both clinicians and patients, with some centers now performing genetic testing routinely. The most commonly used techniques include FISH and LOH, each with advantages and disadvantages (Perry et al. 2003). Additional progression-associated alterations, such as those commonly seen in astrocytomas, are occasionally reported in anaplastic oligodendrogliomas as well.

Oligoastrocytoma (WHO Grades II or III)

As a group, patients with OA have survival rates intermediate between those of pure astrocytomas and oligodendrogliomas. Of all the gliomas, OAs remain the most difficult to define and most likely to receive discordant diagnoses from expert neuropathologists. Nevertheless, the WHO recognizes two basic patterns: (1) a biphasic ("compact") variant in which the two elements arc spatially distinct, and (2) an intermingled ("diffuse") variant in which the cell types are interspersed (Kleihues and Gavencc 20001. Although the biphasic form is easier to accept and conceptualize, the intermingled variant is more common. Cases are most often characterized by the presence of some rounded nuclei (? oligodendroglial), some irregular hyperchromatic nuclei (? astrocytic), and many difficult to characterize cells with intermediate or indeterminate features (i.e., morphologically ambiguous). The diagnosis of "diffuse glioma, not otherwise specified" is appropriate in some of these cases. Nonetheless, these tumors are usually graded and treated in the same fashion as pure oligodendrogliomas.

Generally, OAs and morphologically ambiguous diffuse gliomas have been understudied genetically, precisely because the typical study design is to exclude the cases with diagnostic uncertainty. A few have focused on the biphasic variant, in which microdissection is feasible (Maintz et al, 1997). In these, the same mutations have characteristically been found in both components, consistent with a monoclonal process, rather than a collision tumor (i.e., coexistence of two neoplastic clones). Therefore most biphasic OAs have genetically resembled either pure oligodendroglioma or astrocytoma, with only rare cases showing mixed patterns.

Ependymoma (WHO Grade II or III)

Ependymomas compose 4% of all brain tumors and arc die third most common CNS tumor in children. They may occur at any age, bur in children they are most frequent in the first decade. Patients younger than 3 years of age have a significantly worse prognosis. Ninety percent of tumors are in the brain, with an infratentorial site twice as common as a supratentorial site, and 10% are in the spinal cord, often in adults. The typical infratentorial ependymoma occupies the fourth ventricle. Obstructive hydrocephalus develops when rumors are large enough to obstruct the flow of cerebrospinal fluid (CSF). Some are periventricular or may not have any obvious association with native ependyma (e.g., spinal cord or cerebral hemispheres).

Ependymomas are remarkably well-circumscribed masses that tend to compress rather than infiltrate the adjacent parenchyma. As such, some tumors may be surgically curable and the extent of resection constitutes a much more important prognostic variable in ependymomas than in diffuse gliomas. Cystic tumors are more likely to be found in the cerebrum. Ependymomas in contact with CSF pathways may seed subarachnoid spaces and generate drop metastases in approximately 5% of cases. This is associated with a poor prognosis. Ependymomas are characterized by sheers of cells interrupted by perivascular rosettes, and by nuclear free /.ones surrounding a central blood vessel (sec Figure 58B.2). True ependyma! rosettes (i.e., containing a central lumen) and canals (i.e., slitlike structures resembling small ventricles) are more specific, but encountered in only approximately 10% of cases. Ependymoma is one of the few remaining tumors in which the diagnosis in morphologically ambiguous cases can only be verified by ultrastructural examination. Electron microscopy shows a combined glial and epithelial-like appearance with intermediate filaments (GEAP), microvilli, zipperlike intercellular junctions, intracellular lumina, cilia, and their basal attachments, known as basal bodies or blepharoplasts. Immunohistochemistry for CFAP may be particularly helpful in highlighting the thin processes radiating toward vessels in pseudorosetr.es. Anaplastic ependymoma (grade III) is diagnosed in the presence of hypercclularity, increased mitotic activity, and microvascular proliferation. Regions of infarctlike necrosis are fairly common in tumors that otherwise appear to be low-grade, and this is not a reliable grading criterion. In fact, the predictive value of histological grading of ependymomas is questionable, because its prognostic significance has not been consistent in reported series,

Ependymomas arc often aneuploid with complex, albeit nonspecific alterations. Chromosome 22q deletions are among the most common, with associated *NF2* mutations primarily restricted to spmal examples, a fact that fits with the spinal localization of most ependymomas in NF2 patients (Singh et al. 2002).

Myxopapillary Ependymoma (WHO Grade I)

Myxopapillary ependymoma is a distinct variant that is virtually restricted to the filum terminale. These tumors may also occur in the presacral soft tissue. They are more common in adults than in children, and have a red appearance because of their lush vascularity. They have a variably papillary architecture with numerous hyalinized vessels, surrounded by mucin and an outside layer of tumor cells. A thin collagenous capsule typically surrounds the tumor. The prognosis is excellent, particularly when the capsule has not been breached intraoperativeiy. Those removed piecemeal with mucin spillage have a higher likelihood of recurrence. These tumors may metastasize to the lungs or other sites, despite their benign appearance.

Subcpendymoma (WHO Grade I)

Subcpcndymomas are slow-growing tumors that are increasingly detected by MRI in the absence of clinical manifestations. Among subependymomas, 90% occur in adults, in whom they are small and incidental. In children, subependymomas are more likely to be large and symptomatic. Subependymomas appear as glistening, pearly whirr, tabulated, intraventricular protuberances, most often in the fourth ventricle. Earge tumors may obstruct the ventricle and cause hydrocephalus. Microscopically, they are characterized by clusters of bland, rounded nuclei, embedded in a fibrillary matrix with microcysts and foci of calcification. The proliferative index is typically low. Rare cases contain foci of classic ependymoma and are referred to as mixed ependymoma/subependymoma. These cases are graded and treated according to the potentially more aggressive ependymoma component. The histogenesis of subependymomas remains controversial, with candidates including subependymal glia, astrocytes, ependymal cells, or some mixrure of these. Genetic changes are largely unknown.

Choroid Plexus Tumors

Choroid Plexus Papilloma (WHO Grade I)

Choroid plexus papillomas compose only 0.5% of intracranial tumors. As a rule, they are confined to the portion of the ventricular system that contains normal choroid plexus. Approximately half arc in the fourth ventricle; in adults, they often occupy the cerebellopontine angle. Tumors in the lateral ventricle arc more common in children and may cause hydrocephalus by a combination of outflow obstruction and excess CSF production. The onset of symptoms is usually in the first decade and may be congenital, hi most cases, papillomas arc surgically curable tumors.

Choroid plexus papillomas have a pink or red, highly vascular polypoid or cauliflower appearance, often with chalky calcifications (Figure 58B.8). Large tumors in the third or fourth ventricles may occlude or even distend the ventricle, causing hydrocephalus. Histologically, choroid plexus papillomas resemble normal choroid plexus in terms of a well-formed papillary structure, with true fibrovascular cores and in most cases, a single-layered epithelial covering. However, the lining of papillomas lacks the cobblestone-like appearance of normal choroid plexus, and tends to form instead a uniform layer of tall cuboidal to columnat cells without intervening spaces. Calcifications and clear intracytoplasmic vacuoles are common. The mitotic index is low.

Immunohistochemically, they are consistently positive for cytokcratin, sometimes revealing a paranuclear ball-like pattern of staining, Immunoreactivity for transthyretin/prealbumin is also typical. A subset expresses GFAP focally and this is thought to reflect cpendymal differentiation.

Choroid Plexus Carcinoma (WHO Grade III)

The diagnosis of choroid plexus carcinoma in adults is exceedingly rare and should be made only after exclusion of metastatic adenocarcinoma, most often from the lung. Carcinoma of the choroid plexus tends to arise in the lateral ventricle of infants and then invade the adjacent brain parenchyma and seed throughout the subarachnoid space. Systemic metastases occur occasionally. The clinical course is generally quite aggressive and mortality rates are high.

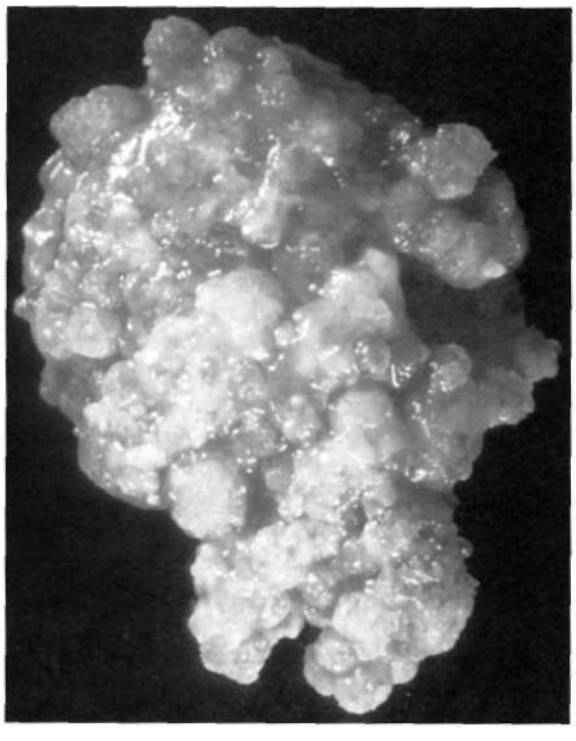

FIGURE 58R.8 Choroid plexus papilloma. Polypoid or cauliflower-like lesion with a nodular and partially calcified surface taken from the fourth ventricle.

Histologically, choroid plexus carcinoma resembles high-grade papillary adenocarcinoma, but docs not sectete mucin, an important distinction from the majority of metastatic adenocarcinomas. Some cases have a small-cell appearance reminiscent of PNET or rhabdoid cells similar to AT/RT (see the following text). Little is known about the genetics of these high-grade malignancies, although the possible involvement of the *INI-l/hSNF5* gene on 22qll.2 has recently been raised; if shown in other studies, this could suggest genetic similarities to AT/RT.

Neuronal/Glioneuronal Tumors

GangUoglioma/Gangliocytoma (WHO Grades 1, II, or III)

Most gangliogliomas occur before age 21 and compose 4-8% of pediatric brain tumors. They grow slowly and tend to be benign in their biological behavior. The temporal lobe is the most common site of occurrence, but other lobes of the cerebral hemispheres, the cerebellum, and the spinal cord are sometimes affected. Seizures are a typical clinical feature. The tumots are often cystic, well circumscribed, and extend to the surface of the brain. The solid portions are firm, gray, and gritty as a result of calcific deposits that are evident on CT.

Portions of the tumor resemble a low-grade astrocytoma, either pilocytic or fibrillary in nature. Unlike native entrapped neurons within an infiltrative glioma, some of the tumor ganglion cells have a dysmorphic appearance, as evidenced by their lack of polarity, clustering, cytoplasmic vacuolation, increased nuclear pleomorphism, or multinucleation (Figure 58B.9). Binucleate or multinucleate neurons are particularly helpful, when present. Otherwise, the most useful features in the distinction from diffuse gliomas include relative circumscription and EGBs. Perivascular lymphocytic cuffing, microcystic spaces, and fibrosis with collagen deposition are other common findings and RFs are found in many cases, particularly at the edges of the lesion. Those without an obvious astrocytic component are sometimes referred to as *gangliocytoma*, although it is not yet clear that this distinction has any clinical relevance. The term *ganglion cell tumor* is less committal and incorporates both entities. Rare cases demonstrate signs of anaplasia (grade II or III), most often in the glial component, but the grading criteria and their predictive value have yet to be firmly established. GFAP activity is abundant in the astrocytic component, whereas the ganglion cell component expresses most markers of mature neurons, such as synaptophysin, chromogranin, neurofilament, and Neu-N. Tumor genetics remain largely unknown.

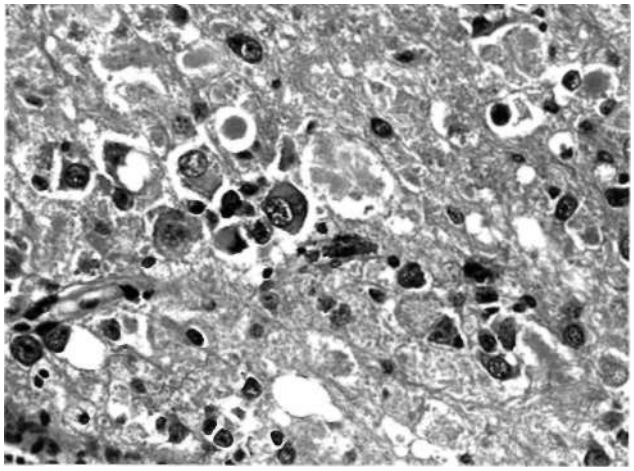

FIGURE S8B.9 Ganglioglioma. Haphazardly arranged and clustered dysmorphic ganglion cells, including the binucleate Form seen centrally (hematoxylin-eosin stain; x400).

Dysembryoplastic Neuroepithelial Tumor (WHO Grade I)

Dysembryoplastic neuroepithelial tumor (DNT) is a benign, quasihamartomatous tumor with an excellent prognosis. DNTs occur throughout childhood and early adulthood, with a mean age of onset of 9 years. They are usually supratentorial and intracortical in location and arc often associated with a long history of intractable seizures. The temporal lobe is the most common location for DNTs, although histologically similar tumors have been described in rarer sites, such as the basal ganglia, thalamus, lateral ventricle, septum pellucidum, and brain stem. They are we 11-demarcated, multinodular intracortical growths that may be associated with adjacent cortical dysplasia.

Histologically, there is a wide range of appearances, although the most characteristic features include patterned (i.e., with ribbons or arcades) mucin-rich cortical nodules and "floating neurons," the latter consisting of ganglion cells that appear to float within a lacunelike, mucin-filled space. The cytology of tumor cells varies, although most resemble oligodendroglioma cells. In fact, on a small biopsy, it may he virtually impossible to distinguish these two entities, but the presence of diffuse cortical and subcortical invasion on larger samples argues against a diagnosis of DNT. Little is known regarding the genetic basis of this tumor, although recent studies suggest that they do not carry the lp and 19q deletions, typical of oligodendroglioma {Perry et al. 2003).

Central Neurocytoma (WHO Grade II)

Central neurocytomas are slow-growing tumors, located in the lateral or third ventricle near the foramen of Monro, frequently involving the septum pellucidum (Schild et al. 1997). Age at onset is usually in the second or third decade. They are usually sharply demarcated, sometimes lobulated masses that fill the ventricular space without significant infiltration of the surrounding brain.

The main histological feature is a proliferation of uniformly rounded tumor cells that mimic oligodendroglioma. Unlike oligodendrogliomas, however, they often display "neurocytic rosettes," exaggerated or irregular Homer Wright-like rosettes with central axon-rich neuropil. These rosettes are indistinguishable from the pinocytic rosettes encountered in pineocytoma, another tumor of small, mature neurons with cytological features similat to those of central neurocytomas. Ultrastructurally, their cytoplasm contains microtubules, synapses, and neurosecretory granules, belying their neuronal nature. Further, central neurocytomas are generally immunoreactive for the neuronal markers synaptophysin and Neu-N. Central neurocytomas with elevated proliferative indices (e.g., >2%) and vascular hyperplasia tend to have a higher rate of recurrence and are sometimes referred to as *atypical neurocytomas,* although grading criteria have not been firmly established. Rare examples of extravcntricular neurocytomas and liponeurocytomas {with fat metaplasia) have been described in the cerebral hemispheres, cerebellum, and spinal cord, but it has yet to be determined whether these represent the same family of tumors. The WHO, however, has recognized the cerebellar liponeurocytoma as a distinct entity. The genetic alterations of neurocytoma are largely unknown, although, as expected, central neurocytomas do not harbor the lp and 19q deletions seen in oligodendrogliomas (Perry et al. 2003).

Embryonal Tumors/Primitive Neuroectodermal Tumors

The precise definition of PNET has long been debated among the philosophic lumpers and splitters of medicine, but basically refers to an extra cerebellar "small, blue, cell tumor" which othctwise resembles medulloblastoma and in most cases shows evidence for primarily neuronal differentiation, albeit immature. Glial, mesenchymal, and melanotic elements may be seen as well. Sometimes referred to as *cerebellar PNET,* the medulloblastoma therefore represents the prototype and most common member of the PNET family. Adding further confusion to the nomenclature is the existence of a peripheral nervous system PNET, which is felt to represent a completely different small, blue, cell tumor type with homologous genotypic and phenotypic features to those of Ewing's sarcoma (t[l I;22][q24;q12| with *EWS-FLI1* or variant fusion products). Other than medulloblastomas, the CNS variants are relatively uncommon and may include supratentorial PNET (sPNET), pineoblastoma, central neuroblastoma, ependymoblastoma, and medulloepithelioma. Despite the morphologic and immunohistochemical overlap among these entities, and the convenience of using an umbrella term of PNET fot all of them, this is likely over simplistic, lr is now known,

for example, that sPNETs have a significantly worse prognosis than medul lob la stomas and seem to differ genetically (Reddy et al. 2000). Therefore the overall heading of *embryonal CNS neoplasms* may be preferable to discuss this group of tumors, **and** this term allows the inclusion of an important and newly recognized member, the AT/RT. In a somewhat looser context, this includes PNETs of specialized sensory organs, such as retinoblastoma and olfactory neuroblastoma.

Tumors resembling PNET can be induced in animals with various viruses or genetic manipulations, such as transgenic or knockout mice. In humans, the importance of genetic factors is exemplified by retinoblastoma, from which Knudsen's two-hit hypothesis was formulated and the tumor suppressor gene *Rb* was identified on chromosome 13. Much has been learned recently about the genetic alterations of medulloblastomas and its variants (see the following text). For the rarer forms of PNET, the molecular pathogenesis is still a mystery.

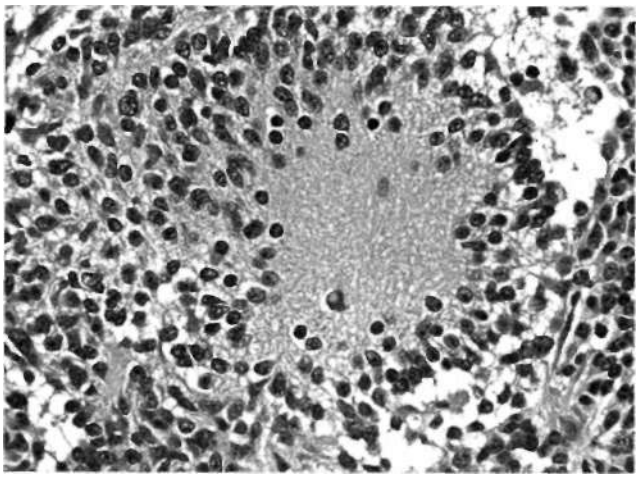

FIGURE 58B.10 Medulloblastoma. Cellular tumor composed of small, poorly differentiated cells with Homer Wright (ncuroblastic) rosette formation (hematoxylin-eosin stain; x400).

Medulloblastoma **(WHO** Grade IV)

The name *medulloblastoma* is misleading because it is doubtful that any cell identifiable as a mcdulloblasi exists during histogenesis. Instead, research suggests that medulloblastomas arise from the external granular layer (e.g., desmoplastic variant), subependymal matrix cells of the fourth ventricle (e.g., classic variant), or both. Much progress has been made in the multimodality treatment of medulloblastomas, with 5-year survival rates often quoted to be as high as 70-80%. Unfortunately, life-saving therapy, such as craniospinal irradiation, may be associated with significant long-term toxicities to the developing brain, with cognitive decline, psychomotor and growth retardation, or hormonal deficits.

Medullohlastoma is thi- most common torm of I'NKT. More than 50% of medulloblastomas occur in children younger than 10 years of age. A second, smaller frequency peak occurs between the ages of 18 and 25. Medulloblastoma, by definition, originates in the cerebellum. It is generally well defined, soft, friable, and focally necrotic. Medulloblastomas have a proclivity to invade the ventricle and disseminate along CSF pathways. The potential aggressiveness of medulloblastomas is affirmed by rare reports of metastases to bone, lymph nodes, and other extracranial sites.

Classic medulloblastomas consist of small, immature cells with hyperchromatic round- to carrot-shaped nuclei with minimal cytoplasm, as well as numerous mitoses and apoptotic bodies. They typically display limited degrees of neuronal maturation with neuropil formation, synaptophysin immunoreactivity, and occasional Homer Wright (ncuroblastic) rosettes (Figure 58B.10). Cases with extensive rosette formation or neuronal maturation are sometimes referred to as cerebellar neuroblastomas or ganglioneuroblastomas, respectively. Recently recognized variants with clinical significance include the anaplastic/large cell variant (poor prognosis) and the extensively nodular variant (favorable prognosis) (Eberhart et al. 2002). There is also some evidence that the nodular or desmoplastic variant is encountered most frequently in adults, in the lateral cerebellar hemispheres, and in patients with Gorlin's nevoid basal cell carcinoma syndrome (NBCCS). There is decreased proliferation and a greater degree of neuronal maturation within the center of these nodules or pale islands. Glial differentiation is also fairly common and it is unclear whether cases with prominent glial features have a worse prognosis. Rarer forms of differentiation are encountered most often in infants and include mesenchymal (e.g., medullomyoblastoma) and melanin-producing neuroectodermal forms (e.g., melanotic medulloblastoma).

Much has been learned in recent years regarding medulloblastoma tumor biology, and the reader is referred to a recent review for greater detail (Ellison 2002). Familial forms of medulloblastoma have provided some of the important clues for both inherited and sporadic forms of the disease. These include the hedgehog/patched signaling pathway implicated from studies of NBCCS and the *APCJ Wttt* pathway associated with a form of Turcot's syndrome (polyposis coli and brain tumors). Unfortunately, medulloblastoma appears to be a fairly heterogeneous disease genetically, with no single alteration accounting for the majority of the cases. Cytogenetically, a characteristic isochromosome 17q has been reported in one third to one half of cases. The *Tl'S.i* gene has essentially been excluded as a potential 17p-associated tumor suppressor and other regions of the short arm are currently being investigated. Both A1YCC and MYCN gene amplifications have been associated with particulatly aggressive medulloblastomas and are more commonly encountered in the anaplastic/large cell variant. On the other hand, expression

of the neurotrophin receptor, TrkC, is associated with a significantly better prognosis. Interestingly, genomic screening with expression profile mictoarrays that characterize thousands of genes simultaneously may be a useful method for predicting biologic behavior (Pomeroy et al. 2002). Tberefotc the routine diagnostic workup of medulloblastoma may soon involve a number of histopathologic and genetic techniques for furthet sttatification and individualized therapy.

Atypical Teratoid/Rhabdoid Tumor (WHO Grade IV)

AT/RT is a relatively recently recognized form of embryonal CNS neoplasm that has been often misdiagnosed as medulloblastoma or PNET, because of the prominence of small, blue cells in many cases (Packer et al. 2002), Irs awkward name derives from the fact that it may resemble either epithelial tumors ("tetatoid") or the malignant thabdoid tumor (MRT) seen in the kidney, soft tissue, and other organ sites throughout the body. Mostly restricted to infants, AT/RT is one of the most aggressive human tumors. Average survival times are in the range of 6-8 months following diagnosis, and they typically do not tespond to conventional medulloblastoma-associated therapies. Because of these dramatic biologic differences, it is critical to distinguish AT/RT from medulloblastoma, and it is probable that part of the poor prognosis reported in patients with medulloblastoma who are younger than 3 years of age stems from prior inclusion of misdiagnosed AT/RTs.

Although small, blue cells are common and may predominate in some cases, the defining feature is the rhabdoid cell, an enlarged cell with an eccentric oval- to kidney-shaped nucleus with vesicular (open or clear) chromatin, as well as an eosinophilic rounded, paranuclear inclusion, often highlighted by imniLinostains for vimentin. Carcinoma-like and sarcoma-like foci are also evident in some cases. Ultrastructurally, the paranuclear inclusions consist of whorled bundles of intermediate filaments. AT/RT teprcsents a classic example of "polyphenotypic tumot," defined by the coexpression of antigens normally associated with differing liistogenetie line (e.g., epithelial, mesenchymal, neuronal, glial, and so on). The list of potentially positive immunostains is long, but as opposed to PNET, the vast majority of AT/RTs express EMA, smooth muscle antigen, and vimentin. Despite the name *teratoid,* these tumors are not related to germ cell tumors and generally do not express germ cell markers.

Genetically, AT/RTs are known to harbor monosomy 22 or 22q deletions in the majority of cases. Recently, the *iNl-l/bSNFS* tumor suppressor gene on 22qll.2 was identified and the inactivation of this gene is thought to be involved in the formation of these tumors and malignant rhabdoid tumors (MRTs). Germline mutations have also been reported in familial or disseminated forms of this disease.

MEN1NGEAL/EXTRA-AXIA1, TUMORS

The most common extra-axial brain and spinal tumors ate meningiomas, although hemangiopericytomas, sarcomas, lymphomas, metastatic tumors, schwannomas, and inflammatory masses also occut adjacent to the brain and spinal cord.

Meningioma (WHO Grade I)

Meningiomas compose 20-25% of all intracranial tumors. They are most ptcvalent after age 50 and constitute less than 2% of CNS tumors in children. The female-to-male ratio is 2 to 1 in adults, nearly 10 to 1 in the spinal cord and 1 to 1 in pediatric or malignant forms. Although most (roughly 80%) are benign, a subset are aggressive with high-grade histology, recurrences, and substantial morbidity and mortality. Even some of the histologically benign meningiomas ate associated with disfigurement, neurological deficits, and ma jot therapeutic challenges, particularly when located in sites at the skull base that prevent complete resection. Because growth is typically slow, tecurrences many years after primary resection are not uncommon, and long follow-up times are required to determine whether a surgical cure has been achieved. Generally, the extent of surgical resection and histological grade represent the most important prognostic variables. For example, the 5-year recurrence rates are roughly 5% for gross totally resected versus 30% for subtotally resected benign meningiomas. In contrast, this figure rises to 40% in atypical meningiomas, even when they are believed to be totally resected (see the following text).

The locations of meningiomas, in descending order of frequency, are the cerebral convexity, parasagittal tegion, sphenoid wing, parasellar region, and spinal canal. Postetior fossa and lateral ventricle locations arc mote common in children. Multiple meningiomas suggest the possibility of NF2, although non-NF2 associated forms are also encountered. Interestingly, a number of such cases show identical mutations in each of the meningiomas atising from a single patient, suggesting that dura! dissemination may account for multifocality in some patients, despite a histologically benign appearance.

Benign meningiomas are well demarcated and compress father than invade the adjacent brain or spinal cord. Nevertheless, bone and soft tissue invasion may occur and is typically associated with hyperostosis. Notably, this type of invasion does not constitute evidence for malignancy and those that are gross totally resected share the same excellent prognosis as those without invasion. A pattern of diffuse, carpetlike tumor spread along the dural surface is referred to as *meningioma en-plaque.* Meningiomas are generally firm in consistency and often gritty because of the presence of sandlike calcifications, referred to as psammoma bodies.

Meningiomas are hisrologically heterogeneous; the most recent WHO classification includes 13 morphological types {Kleihues and Cavenee 2000). Four rare variants are considered more aggressive by definition: clear cell (grade 11), chordoid (grade II), papillary (grade III), and rhabdoid (grade III). The other nine subtypes arc considered benign, unless they fulfill additional criteria for atypical (grade II) or anaplastic (grade **IIII)** meningioma. The majority of meningiomas have two basic histological patterns: meningothelial or fibroblastic, with the transitional variant having features of both. Meningothelial tumors are composed of arachnoidal epithelioid cells, arranged in lobules, often with prominent whorls and psammoma bodies (Figure J8B.11), which represent laminated calcifications "I degenerated meningothelial whorls. Fibroblastic meningiomas are distinguished by theit spindled appearance, fascicular or storiform architecture, and abundant collagen deposition. The most helpful immunohistochemical marker is EMA, which can be detected at least focally in the vast majority of meningiomas.

Meningioma was one of the first solid tumors to be characterized by a cytogenetic alteration. More than half are associated with losses of chromosome 22, or portions thereof. The tumor suppressor gene primarily involved in most of these cases is *NF2,* a finding that correlates well with the fact that meningiomas are the second most common tumor type in NF2 patients. A second gene with a high degree of homology, *DAIJ* or protein 4.IB on 18pll.3, has recently been implicated as well (Gutmann et al. 2000), Losses of both *NF2* and ptotcin 4.IB are common in meningiomas of all grades, suggesting they are early events. Progesterone receptors (PRs) arc present in more than 50% of cases. Their significance is unclear, other than the fact that meningiomas can enlarge dramatically with pregnancy and regress after delivery.

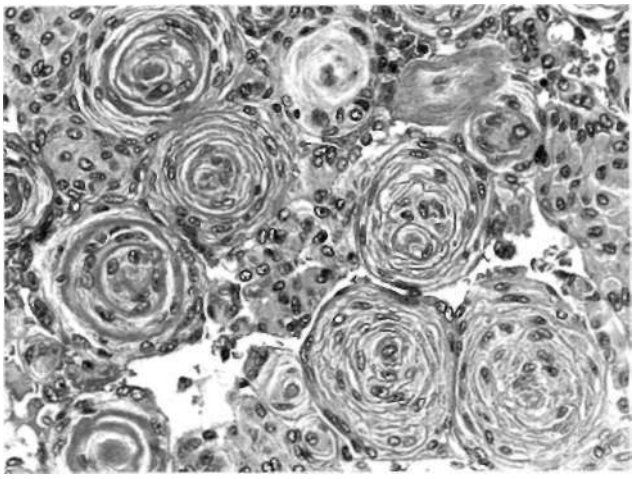

FIGURE 58B.11 Meningioma. Typical meningothelial nests and whorls with focal hyalinization, the first step in the formation of concentrically laminated calcifications or psammoma bodies (hematoxylin-eosin stain; x400).

Atypical Meningioma {WHO Grade **II)**

The intermediate grade category of atypical meningioma was created to define a meningioma type that has considerably increased risk of recurrence, even when gross rotal resection is achieved. These tumors are also associated with a slight, but statistically significant increase in mortality, when compared with age and sex matched controls. Using current criteria, atypical meningiomas account for 15-20% of all meningiomas.

In most pathology series, the mitotic or proliferative index is the most powerful predictor of outcome. Based on a large Mayo Clinic series, the finding of at least 4 mitoses per 10 HPFs, even focally, qualifies for the diagnosis of atypical meningioma (Perry et a!. 1999). With fewer mitoses, the presence of at least 3 of 5 additional parameters (sheeting architecture, hypercellularity, macronucleoli, small-cell formation, necrosis) also suffices. The issue of brain invasion has also been debated, and, although once considered the ultimate manifestation of malignancy, recent studies suggest that in the absence of frank anaplasia, these tumors have similar recurrence and mortality rates as those of atypical meningioma. Similar to mitotic counts, **MIB-1** (Ki-67) labeling indices may be helpful for predicting the risk of recurrence, particularly in borderline atypical cases. Meningioma grade is also inversely proportional to PR expression, so that in general, fewer atypical meningiomas are PR immunoreactive than their benign counterparts.

A growing number of cytogenetic alterations have been associated with malignant progression of meningiomas, although the genes have yet to be identified. Most common in atypical meningiomas ate deletions of lp, 6q, 10, and 14q (Weber et al. 1997).

Anaplastic Meningioma (WHO Grade **111)**

With the omission of brain invasion as a criterion for anaplastic meningioma, these tumors have become quite rare, accounting for no more than 1-2% of all cases. Many of these tumors start as benign or atypical meningiomas and progress over time, although de novo presentation is also encounteted. As a group, they are highly aggressive, rapidly-growing, and highly infiltrative with an associated median patient survival rate of less than 2 years (Perry et al. 1999). Nevertheless, extent of resection remains important and long-term survival is still possible in a subset. Subsequent to surgical and radiotherapeutic failure, effective treatment options are generally lacking for these patients.

Histologically, anaplastic meningiomas ate defined by the presence of excessive mitotic activity (>20 per 10 HPF) and/or frank anaplasia with a carcinoma-like or sarcoma-like appearance. They are highly cellular tumors with extensive sheeting, necrosis, and nuclear atypia. Lower grade elements, more easily recognizable as meningioma, are

often seen. For those lacking this feature, immunohistochemistry or electron microscopy arc often necessary to exclude hemangiopericytoma, other dural-based sarcomas, metastatic carcinoma, or melanoma.

Anaplastic meningiomas shatc the genetic features of lower-grade meningiomas, but additionally harbor chromosome 17q gains/amplifications and 9p/pl6 losses in many cases. In most, the MIB-1 (Ki-67) labeling index is markedly elevated and there is no discernible PR expression.

Hemangiopericytoma (WHO Grade II or III)

Hemangiopericytoma, once considered a variant of meningioma, is now generally accepted to be a highly vasculat dural-based sarcoma, analogous to those encountered in soft tissue sites. Despite the implication of pericytic origin, they remain of uncertain histogenesis. They occur at all ages, peaking in the foutth to sixth decades. Unlike meningiomas, one gender is not affected more than another, they are EMA-negative, and no association exists with NF2 or any other meningioma-associated genetic alterations. Hemangiopericytoma is also a more aggressive tumor with recurrences rate of 60-80% and systemic metastasis rates as high as 25%.

Histologically, the tumor is a highly cellular, reticulin-rich neoplasm with numerous, characteristically branching ("staghom") thin-walled vessels. Tumor cells are oval to spindled and display variable proliferative indices. Using Armed Forces Institute of Pathology (AFIP) criteria, those with more than 5 mitoses/10 HPF and/or hemorrhage/necrosis are considered high-grade (grade III), although even the low-grade (grade II) examples are considered malignant by definition (Mena et al. 1991).

NERVE SHEATH TUMORS

Schwannomas and neurofibromas represent the most common peripheral nerve sheath tumors, but may be encountered "centrally" when they arise from paraspinal nerve roots or cranial nerves. Multiple neurofibromas or schwannomas should suggest NF1 and NF2, respectively, particularly in younger individuals. Even the most cellular and mitotically active schwannoma virtually never undergoes malignant transformation, although plexiform and intraneural neurofibromas harbor a small but significant risk of this complication, MPNST may therefore develop de novo or within a pre-existing tumor, most often a plexiform neurofibroma from a patient with NF1. The risk of developing MPNST is also increased in previously irradiated tissue (e.g., mediastinal radiation for Hodgkin's lymphoma), both in patients with and without NF1. Generally, MPNSTs are encountered in soft tissue sites, but may be seen more centrally, because of paraspinal localization. These sarcomas are usually high-grade and have a dismal prognosis.

Schwannoma (Neurilemoma) (WHO Grade I)

The frequency of schwannomas peaks in the fourth and fifth decades. Most are located on the vestibular portion of the eighth cranial nerve. Other cranial nerves, particularly the trigeminal, are much less frequent sites. Bilateta! vestibular schwannomas (acoustic neuroma) are diagnostic of NF2, Vestibular schwannomas erode the internal auditory meatus and occupy the cerebellopontine angle; with increasing si/.e, they compress and deform the pons. Spinal schwannomas compose approximately 30% of intraspinal tumors. Most arise from the dorsal roots, preferring sensory nerves, like their cranial counterparts. Spinal schwannomas may extend through the dura or, in some cases, through the intervertebral foramen as a dumbbell-shaped mass that is partly within and partly outside the spinal canal.

As opposed to neurofibromas, schwannomas are pure Schwann cell proliferations, typically arranged in two architectural patterns. Cellular, dense zones, known as Antoni A areas, contain spindle-shaped ceils arranged in nuclear palisades, termed *Veroaty's bodies.* Antoni B areas arc myxoid and microcystic in appearance with thin, wavy cells and foci of collagenization, highly reminiscent of neurofibromas. Degenerative changes are common and include hemorrhage, cystic breakdown, vascular hyalinization, and calcification. As opposed to neurofibromas, schwannomas typically have a discernible capsule and push the parent nerve aside rather than invading it. Immunohistochemical studies reveal strong and diffuse S-100 immunoreactivity, diffuse collagen IV positivity teflecting the rich network of Schwann cell-associated basement membrane, and a relative lack of neurofilament-positive entrapped axons.

The vast majority of both sporadic and familial schwannomas are associated with loss of expression for the NF2 protein product, merlin or schwannoma (Stemmer-Rachamimov et al. 1997}. *NF2* gene deletions and LOH are common, although other mechanisms may also be involved.

Neurofibroma (WHO Grade I)

Neurofibromas arc less commonly located in the CNS" than are schwannomas. Multiple spinal nerve root involvement is virtually pathognomonic of NFL They more typically originate from nerve terminals in the dermis and from large nerve trunks, such as the brachial plexus. Unlike the eccenttic globular growth pattern of schwannomas, neurofibromas grow within the substance of a nerve, generating a fusiform intraneural mass. A plexiform ("bag of worms")

growth pattern results from the involvement of multiple nerve fascicles and is virtually diagnostic of NF1. On gross inspection, neurofibromas are typically gray and gelatinous.

Histologically, bundles of thin, wavy cells with thin wavy nuclei are suspended haphazardly in a myxoid or mucin-rich stroma. The degree of collagen ization is variable, depending on the age of the lesion. The resulting hyaline silhouettes arc likened to "shredded carrots," As opposed to schwannomas, neurofibromas are a mixture of cell types that includes not only Schwann cells, but also fibroblasts, perineurial-like cells, mast cells, and entrapped elements from the parent nerve. Most cases are hypocellular, and therefore foci of marked cellularity, increased cell size, and mitotic activity should cause concern for malignant transformation to MPNST. Immunostains demonstrate patchy S-100 and collagen IV expression, because only a portion of the inttatumoral cells are Schwann cells. Entrapped neurofilament-positive axons are nearly always found except in dermal neurofibromas. The MIB-1 (Ki-67) index is generally low and p53 protein is negative, except in foci of transformation to MPNST.

Studies suggest that the Schwann cell is the neoplastic component of neurofibromas, and thar the remaining cell types are probably reactive or entrapped elements (Perry et al. 2001). Deletions of the *NF1* gene and losses of its protein product, neurofibromin, have been detected in a subset of both familial and sporadic neurofibromas.

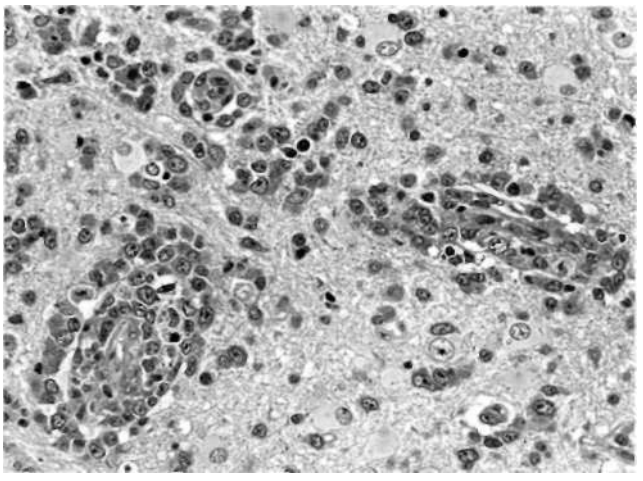

FIGURE 58K.12 Central nervous system lymphoma. Infiltrative neoplasm with distinctive a ngioccn tricky (aggregating around and within the vessel walls), composed of immature lymphoid elements with high nuclear to cytoplasmic (N/C) ratio, vesicular nuclei, and prominent nucleoli (hematoxylin-eosin stain; x400).

MISCELLANEOUS TUMORS

CNS Lymphoma

CNS involvement by lymphoma may be cither primary or secondary. Secondary CNS involvement occurs in 25-30% of systemic non-Hodgkin\ lymphomas, but is exceptional in Hodgkin's disease. Systemic lymphomas tend to infiltrate the leptomeninges and spare the parenchyma. The epidural spine is a favored site and spinal compression is a common complication. In contrast, primary CNS lymphomas typically present deep in the brain parenchyma (e.g., periventricular) and usually spare the leptomeninges, which may explain why the CSF cytological examinations contain tumor cells in a minority of patients. The incidence of lymphoma is increased in immunodeficicnt patients, such as patients with acquired immunodeficiency syndrome and organ transplant recipients. Such cases are typically associated with Epstein-Barr virus (LBV) and CSF PCR studies take advantage of this common finding. Primary CNS lymphoma is also increasing in the older adult, immunocompetent population for reasons that are poorly understood. These cases are generally unassociatcd with EBV. Survival without treatment is typically less than 1 year, but prolonged survivals are now being reported with methotrexate-hased chemotherapy regimens. Primary CNS lymphoma is unique in that approximately half are multifocal, they may disappear entirely after steroid therapy (in the early forms of disease), and they often recur in a completely different site from that of the initial lesion.

The vast majority of primary CNS lymphomas are diffuse large cell lymphomas of B-ccll type. They show a distinctive angiocentric pattern, in which malignant cells surround and invade blood vessels in concentric layers (Figure 58B.J2). Reactive T cells are often numerous as well. Cases from immunosuppressed patients are characteristically necrotizing and KBV immunoreactivc, whereas those from immunocompetent patients are not. Biopsies from patients treated preoperatively with steroids are a diagnostic challenge for pathologists, because the tumor cells often die, leaving behind a reactive component that resembles either an inflammatory or dcmyelinating disorder. In such cases, an accurate diagnosis may be delayed until the time of recurrence. Also, because of the sometimes low cellularity in comparison to lymph node biopsies and the typically mixed infiltrate, wherein reactive T cells may outnumber tumor cells, FCM is often less sensitive for establishing the diagnosis than routine histology and may waste a considerable amount of precious tissue. The molecular profiles of primary CNS lymphomas have not been extensively studied, although a recent study suggests that coinactivation of the 9p tumor suppressors, p16 and $p14^{ARt;}$ may be important in tumorigenesis (Nakamura er al. 2001),

Germ Cell Tumors

Nervous system germ cell tumors are most common in school-aged children, and they arc analogous to germ cell tumors in the gonads, retroperitoneum, and mediastinum. The pineal region is the most common site of occurrence, followed by the suprasellar/hypothalamic region. Germ cell

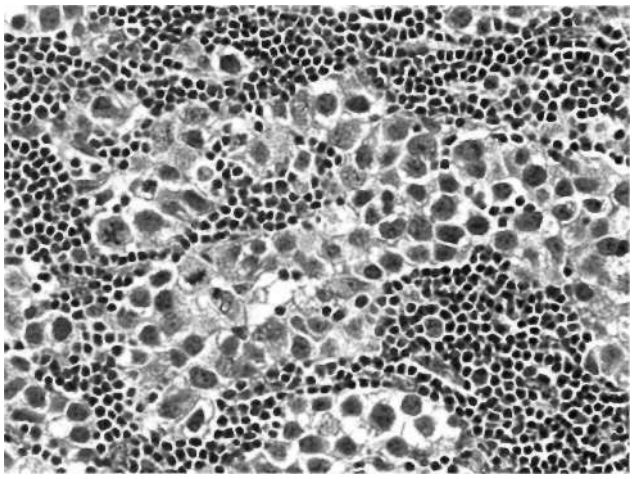

FIGURE 58B.13 Pineal germinoma. The dual cellular population consists of numerous small, reactive lymphocytes and large clear tumor cells, which resemble primordial germ cells (hematoxylin-eosin stain; x400).

tumors as a group grow rapidly, with a propensity to seed the subarachnoid space. *CSV* examination for both cytology and marker levels may be diagnostic. Elevations of placental alkaline phosphatase (PLAP) are most suggestive of germinoma, ^-fetoprotein of yolk sac tumor, and #-human chotionic gonadotropin (jft-HCG) of choriocarcinoma or a syncytiotrophoblastic element. For reasons that are not understood, pineal germ cell tumors arc virtually restricted to hoys and in some cases, the clinicoradiographic features may be deemed so typical that a biopsy is not felt to be necessary prior to therapy. Pure germinoma is most common, and is virtually 100% curable because of its exquisite radiosensirivity. Mature teratoma is less often a pure tumot, and is slow growing, cystic, and does not respond well to chemotherapy or radiation. However, these tumors are often well demarcated and may be surgically curable. Most of the remaining cases consist of mixed germ cell tumors with various malignant elements, such as embryonal carcinoma, yolk sac tumor, choriocarcinoma, and immature teratoma. Such cases have a significantly worse prognosis, but survival rates have improved with multiple agent chcmothcrapcutic regimens. In occasional cases that are successfully treated, the only viable element remaining on "recurrence" is matute teratoma.

Histologically, germinomas are identical to tcsticulat seminoma and ovarian dysgerminoma, with two distinct cell populations (see Figure 58B.13). The neoplastic clement tcscmbles primordial germ cells with abundant glycogcn-ncll clear cytoplasm and PI.AT' immunorcactivity. The stroma is often rich in reactive lymphocytes, primarily T cells. Sarcoidlike granulomas are also quite common and may obscure the diagnosis in biopsies in which the tumot cells are overshadowed by the teactive response. Embryonal carcinoma resembles a poorly differentiated catcinoma. Endodermal sinus tumor (yolk sac tumor) forms lose papillary epithelial sttuctutes, known as Schiller-Duvall bodies. Choriocarcinoma is characterized by a combination of mononucleate cytottophohlasts and multinucleate syncytiotrophoblasts. It is highly vascular and particularly prone to massive hemorrhage. Teratomas differentiate into elements from all thtee germ layers. The common benign form contains mature components (teeth, hait, muscle, cartilage, and bronchial wall) arranged in a haphazard, nonfunctional manner. Immature teratoma contains the same elements, but its appearance is fetal rather than mature. Foci of immature brain, with neural tubclike structures arc particularly common.

Hemangioblastoma (WHO Grade I)

Hemaiigi obi a stomas arc benign, highly vascular tumors <i uncertain histogenesis. Approximately 10% of patients with hemangioblastoma have VHL disease. The rest are considered to be sporadic in origin. The age at diagnosis ranges from adolescence to the sixth decade, with the peak incidence at 40 years. Hemangioblastomas are more common in men. The tumor usually presents as a cyst with an enhancing mural nodule in the cerebellum, and is the most common primary cerebellar neoplasm in adults, Hemangioblastomas are sometimes located in the tetina, brainstem, spinal cord, or paraspinal nerve roots, sites commonly involved in association with VHL disease.

Hemangioblastomas are cystic and sharply demarcated, often allowing total surgical resection. The cyst contents arc usually clear and yellow; a rusty color indicates previous bleeding. Solid portions of the tumor are dark red because of an elaborate vascular supply, which predisposes to spontaneous hemorrhage. Histological examination shows abundant capillaries coursing throughout the tumor mass, although the actual tumor cell is believed to be the foamy, lipid-laden stromal cells in between. These cells consistently stained positive for S-100 protein and neuron-specific enolase (NSE). Patchy GFAP expression is also encountered occasionally. An eryrhropoietin-like substance is identified in the cyst fluid of 20% of tumors. It may be associated with pure red cell hyperplasia in the patient and extramedullary hematopoiesis in the tumor.

The *VHL* gene on 3p25-26 is a growth regulator that behaves as a classic tumor suppressor gene, with patients with VHL hathoring a germlinc mutation ("first hit"). In these patients, it predisposes to a variety of tumors and malformativc lesions, but the majority of the morbidity and mortality result from renal cell carcinomas, CNS hemangioblastomas, and in a subset of patients, phcochromoeytomas.

Craniopharyngioma (WHO Grade I)

Craniopharyngiomas compose 2-5% of CNS tumors. Most become symptomatic in the first two decades but can occur at any age. Craniopharyngiomas are thought to arise from

cell rests of Rathkc's pouch, an evagination of the primitive stomatodeum. Remnants of Rathke's pouch may be identified as nests of squamous epithelium on the anterior surface of the infundibulum and the pars tuberalis in infants and adults. Craniopharyngiomas may he intrascllar or more frequently suprasellar in location, often involving the hypothalamus and the optic nerve or chiasm. The expanding mass causes hydrocephalus by encroaching on the third ventricle.

The advancing margins of the craniopharyngioma may appear deceptively sharp but microscopic finger like extensions into surrounding tissue are common. Both solid and cystic areas arc intermingled. The cysts can become large and are typically filled with a dark, viscous, cholesterol-rich fluid, likened to motor oil. Irregularly shaped calcific deposits, varying in size from grains of sand to fine gravel, are found in approximately 75% of cases. The microscopic appearance has been compared to that of adamantinoma of the tibia and ameloblastoma of the jaw. Therefore the classic craniopharyngioma is sometimes referred to as adamantinomatous craniopharyngioma. The tumor demonstrates benign-appearing epithelium with central cobweb-like loosening ("stellate rcticulin") and peripheral palisading. Squamoid foci may be seen and the pattern of kcratinization with ghostlike nests of keratinocytes is known as *wet keratin.* Wet keratin differs from the dry, flaky keratin of epidermoid and dermoid cysts (see the following text) and is unique to craniopharyngioma. Therefore it is diagnostic on a biopsy, even without the presence of viable epithelium. A rarer variant is the papillary craniopharyngioma. These often present in the third ventricles of young adults. They are characterized by a true, nonkeratinizing squamous lining over fibrovascular cores. Goblet cells may also be seen. It is still uncertain whether this variant has a better prognosis,

Epidermoid and Dermoid Cysts

Epidermoid and dermoid cysts are presumed implantation or sequestration cysts derived from misplaced ectoderm. They may he congenital or acquired. The congenital type is caused by inclusion of ectodermal tissue during embryonic closure of the neural groove or during coalescence of epithelial fusion lines in the cranium. Sequestration cysts accompany dysraphism, such as spina bifida, and may communicate with the skin surface through a sinus tract.

Epidermoid cysts occur in young adults and are usually found in the cerebellopontine angle or skull. Dermoids are more common in children and tend to occur near the midline m the cerebellar vermis, parasellar or parapoiitmc region, and spinal canal, especially in the lumbosacral region. Intact tumors are enveloped by a fibrous capsule that has a glistening white surface, like mother-of-pearl, and are thus called *pearly tumors.* The lining and contents of the epidermoid are composed of keratinizing squamous epithelium that may be attenuated or focally stratified. The thin wisps of flaky intraluminal keratin are known as *dry keratin,* in contrast to the type seen in craniopharyngiomas. The adjacent collagenous wall is often partially calcified, producing a linear or speckled pattern on CT images. The inner layer of a dermoid is also composed of squamous epithelium, but the presence of hair follicles and other skin appendages distinguishes dermoid cysts from epidermoid cysts. The cyst contents, once introduced into the meninges by spontaneous rupture or during surgery, can incite a severe chemical meningitis that is typically granulomatous.

Neuroenteric, Colloid, and Rathke's Cleft Cysts

Cysts lined by cuboidal to columnar, mucin-producing epithelial cells, resembling those of respiratory or enteric lining may occur in several sites throughout the CNS. Such cysts are referred to as Rathke's cleft cyst in the sella, colloid cyst in the third ventricle, and neuroenteric (also known as enterogenous, bronchogenic, neuroepithelial, and so on) cyst when they occur in the anterior spinal region or rarely at intracranial sites. These cysts are thought to be developmental rather than neoplastic, but their precise origin has not been established. Although the presumed embryology may differ at these sites, the histological appearance is otherwise similar.

Lipomas

Most lipomas are located in the midline and are sometimes associated with other developmental abnormalities, such as agenesis of the corpus callosum. Typical locations include the dors.il aspect ol the midbrain, cerebellar vermis, and spinal cord. The most common location is the surface of the corpus callosum. Lipomas of the spinal cord often become symptomatic by causing cotd compression, but lipomas of the brain arc usually asymptomatic and are incidental findings on neuroimaging studies and on postmortem examination.

Lipomas are yellow and resemble normal fat. Tumors of the brain, particularly those adjacent to the corpus callosum, may seem to infiltrate the parenchyma, but are benign in histological appearance and biological behavior. Lipomas of the spinal canal are almost invariably in an epidural or subdural position and are well demarcated from the adjacent spinal cord.

METASTATIC TUMORS

Metastatic tumors are actually more common than primary brain tumors. Most occur in middle-aged and older adults, with multiple CNS metastases detected commonly. Metastases often lodge in the corticomedullary junction,

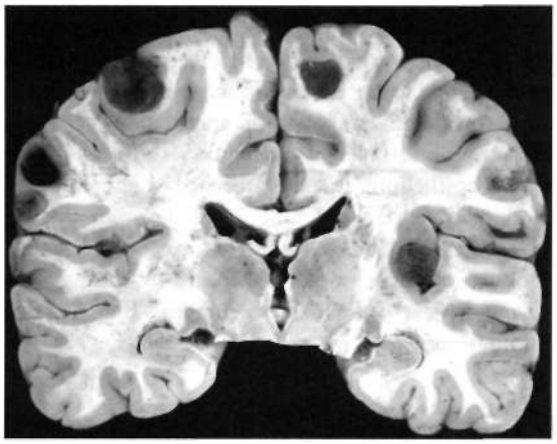

FIGURE 58B.14 Metastatic small cell carcinoma. Foci of well demarcated tumor, primarily localized to corricomcdullary junctions.

A zone of edema customarily surrounds even small metastatic lesions,

The typical metastasis is round and sharply demarcated with central necrosis or hemorrhage (Figure 5SB.14). Spontaneous bleeding is characteristic of choriocarcinoma, melanoma, or renal carcinoma metastases. However, lung carcinoma, the most common primary to metastasize to the brain, accounts for many hemorrhagic cases. Most other primaries metastasize to the lung before they gain access to the brain. The histological appearance is variable and recapitulates the morphology of the primary tumor. Most metastatic lesions are carcinomas or melanomas, rather than sarcomas or lymphomas,

Chapter 58
Cancer and the Nervous System

C. CLINICAL FEATURES AND COMPLICATIONS

Pierre Giglio and Mark R. Gilbert

Primary and metastatic brain tumors may present with acute changes in neurological function, like seizures or sudden confusion, or with gradual and progressive changes in motor or sensory function, personality, or cognition. Both patient and physician may overlook initial symptoms, especially when slowly ptogrcssivc and not severe. Headache is probably the most common initial symptom. Unfottunately, the cause of the headache is often misdiagnosed as migraine, stress, tension headache, or neuralgia. This chapter discusses the clinical features of brain tumors with an emphasis on useful indicators for suspecting an intracranial tumot in clinical practice.

HEADACHES

Headaches are an important indicator of increased intracranial pressutc in patients with brain tumots. Howcvet, increased intracranial pressure is not always the mechanism of brain tumor headache. In the absence of incteased intracranial pressure, direct impingement or traction of pa in-sensitive structures, such as the meninges or blood vessels, is the explanation of the headache mechanism. A "referred" frontal headache may occur secondary to a supratentorial tumor impinging on cranial nerve-innervated structures, whereas postetior fossa tumors may cause cervical pain from irritation of sttuctures innervated by cranial nerves IX and X {Wall ct al. 2001}.

Approximately 20% of patients with brain tumots have headache at ptesentation, usually in association with some other symptom or symptoms. La let in the course, approximately 60% eventually develop headache. The incidence is higher in patients with posterior fossa tumors. The description of headache is usually a dull ache or pressure, often resulting in an initial diagnosis of tension headache. In others, the headache is throbbing and intetmittent, simulating migraine headache. Head pain with features of cluster headache are less common and occur with pituitary tumots (Porta-Etessam 2001). Most headaches seen in practice are bilateral and sometimes desctibed as a "band" around the head.

Some patients desctibe a progressive increase in the severity of their headache or an increase in frequency of intermittent headaches. Such a history should always arouse suspicion, even in patients with a history of prior migraine or tension headaches. Acute headache may be a presenting featutc of hemorrhage into a tumor, but also occuts as a presenting feature of a brain tumor without evidence of hemotrhage on imaging.

An often cited and important feature of headaches in brain tumor is increased severity in the morning, with a tendency toward improvement by afternoon or evening. The explanation of this phenomenon is increased intracranial pressure with nocturnal recumbence, but this is, by no means, a constant characteristic of brain tumor headaches. Many patients describe little or no relationship of headache severity to time of day.

Changes in position, coughing, sttaining, and Valsalva's maneuver may exacerbate headache. Analgesics and anti-migraine medications may make the headache better and result in a delay in diagnosis. A good response to simple

analgesics is often reported, and brain tumor headache maybe relieved with triptans (Pascual 2000),

SEIZURES

The recorded incidence of seizures in patients with brain tumors is as high as *35%*. Seizures are often the feature that precedes brain tumor diagnosis. Seizures may be focal at onset and reflect the brain tumor location, or may be generalized secondarily from a primary irritative focus. Temporal lobe tumors may present as stereotyped automatisms, such as lip smacking. Focal motor activity may follow, and in more than half the cases, secondary generalization occurs. After the episode, confusion and retrograde amnesia arc common. Some patients with brain tumors describe auras of anxiety, fear, or euphoria as their "warning." Viscerosensory auras arc probably the most common auras in seizures of temporal lobe onset (Palmini andGloor 1992).

Frontal lobe tumors may also present with seizures and accompanying auras. Depending on the location (anterior versus posterior frontal), speech arrest or motor manifestations may be more prominent. Common auras reported in frontal lobe seizures are dizziness, a rising epigastric sensation, and fear (Qucsncy 1990).

Visual auras may precede seizures arising from tumors in the occipital lobe. Secondary generalization, in at least some of the episodes, is common in patients with brain tumors. Sensorimotor phenomena often herald parietal lobe seizures.

COGNITIVE DYSFUNCTION

Cognitive dysfunction is probably the most common problem in patients with brain tumors. Initially, this dysfunction is often overlooked. Subtle problems with language function, such as word finding difficulty or memory failure, are attributed to stress or fatigue. As with seizures, tumor location determines the specific clinical features. Frontal lobe tumors often cause executive dysfunction. Similar dysfunction is also encountered in patients with tumors in other locations (Lilja et al. 1992), probably because of a disconnection syndrome involving the frontal lobes. Memory problems may also be present. With left hemispheric tumors, language dysfunction is often noted concurrently. Right hemispheric tumors may result in problems with visual perception and scanning; patients may report getting lost while driving in familiar places (Schicbcl et al. 1996).

The his to pathology of a brain tumor influences the development of cognitive dysfunction. Low-grade tumors may not cause appreciable deficits despite their location (Meyers etal. 1992). Cerebral plasticity and reorganization allow for transfer of function when the underlying process develops slowly. In children, this plasticity may be striking. The functional magnetic resonance imaging (MRI) scan in Plate 58C.I shows right hemisphetic activation with motor function of both arms in a patient with *a* low-grade astrocytoma of the left frontal lobe diagnosed about 10 years earlier. Compensation of language, memory, and other cognitive domains may be similar. High-grade tumors such as glioblastoma multiforme grow rapidly and cause focal cognitive deficits based on location, as well as more generalized impairment secondary to mass effect and increased intracranial pressure.

NAUSEA AND VOMITING

Nausea and vomiting may result from increased intracranial pressure. In addition, tumors of the posterior fossa may have a direct effect on the emetic centers near the fourth ventricle (area postrema). In such cases, vomiting is usually repetitive and intractable but may respond ro focused radiation therapy to the posterior fossa (Cohen et al. 2002),

SYMPTOMS RELATED TO ENDOCRINE DYSFUNCTION

Hypothyroidism, decreased libido, and other symptoms of endocrine dysfunction may follow treatment of brain tumors. In some cases, endocrine dysfunction is the initial feature. Tumors of the hypothalamic-pituitary axis may cause gonadotrophs and growth hormone deficiency as well as hypopituitarism (Paja et al. 1995).

VISUAL SYMPTOMS

When brain tumor patients complain of visual blurring or other visual complaints, the precise nature of the complaint must be fully explored. Contralateral flashing lights may be due to seizures from an occipital lobe tumor, whereas loss of vision on one side may indicate a visual field loss from a tumor more anteriorly placed in the parietal or temporal lobes. The complaint of diplopia may indicate increased intracranial pressure, especially when associated with nausea and vomiting, as in patients with a brainstem glioma.

SYMPTOMS FROM PLATEAU WAVES

Patients with brain tumors may complain of transitory episodes of altered consciousness and visual disturbances. The cause of such episodes may be transitory elevations of intracranial pressure. These elevations or "plateau waves," first described by Lundberg, are important to recognize because they are treatable with acctazolamidc

(Watling and Cairncross 2002). A correct diagnosis also prevents unnecessary treatment with anticonvulsants. The episodes are often mistaken for seizures.

CLINICAL EVALUATION AND INVESTIGATIONS IN BRAIN TUMOR PATIENTS

Clinical Evaluation

Careful examination for evidence of cognitive or other neurological dysfunction is required for patients with symptoms that are suspicious for intracranial tumors. Besides helping to guide investigative procedures, a good clinical examination serves as part of a baseline assessment that helps determine the efficacy of any treatment. A bedside mental status assessment is mandatory in all patients. In cases presenting with evidence of cognitive decline, a more formal neuropsychological assessment may be useful.

Neurological examination must focus on the elicitation of signs that help confirm localization based on symptoms. In patients presenting with personality changes and occasional word finding difficulties, a rigorous language assessment, evaluation for apraxia, unilateral weakness, and frontal release signs are important. Prominent visual symptoms may indicate an occipital lobe tumor or pressure on the optic chiasm. Careful documentation of either visual field deficits or diminished visual acuity may then constitute the most important part of the assessment.

Investigations in Brain Tumor Patients

Imaging (Computed Tomography Scan and Magnetic Resonance Imaging)

If clinical suspicion for an intracranial tumor is high, MRI is the investigation of choice. In many cases, computed tomography (CT) scans are obtained first, particularly when patients present acutely with seizures or severe headache. CT scans can be helpful in excluding hemorrhage into an intracranial mass as well as provide some estimation of the degree of mass effect and midline shift caused by the mass. Vasogenic edema surrounding a tumor typically appears as abnormal, fingerlike white matter hypodense areas. Resolution and artifact, especially "beam hardening," limit the use of CT, particularly in the posterior fossa. The size and number of lesions may be underestimated, especially with regard to metastasis.

MRI scans provide better definition of brain tumor size, edema, mass effect, and midline shift, as well as evidence of herniation (Figure 58C.1). These studies allow distinction between intra-axial and extra-axial mass lesions. Meningiomas and other dural-based lesions are more easily distinguished from parenchymal tumors such as gliomas.

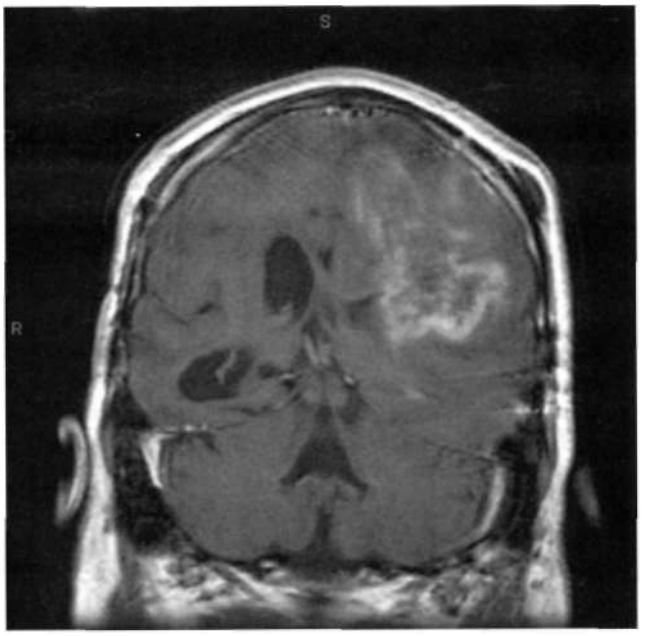

FIGURE 58C.1 Magnetic resonance imaging scan with mass effect and subfalcine herniation from a left glioblastoma multiforme.

Another obvious advantage of MRI is its sensitivity for leptomeningcal disease, which produces abnormal linear and nodular enhancement of the leptomeninges and T-2 signal abnormalities.

Electroencephalograph y

Often, electroencephalography (EEG) is obtained when patients present with seizure activity, particularly when the postictal state (drowsiness, confusion) is prolonged and nonconvulsive status epilepticus is suspected. Routine EEG studies are not indicated in patients in whom seizure activity is controlled.

Evaluation for Primary Tumors in Suspected Metastases

Intracranial masses consistent with metastatic lesions should prompt investigation for evidence of systemic cancct. Traditionally, contrast CT scans of the neck, chest, abdomen, and pelvis have been used to look for the primary cancer. More recently, positron emission tomography has been used in an attempt to increase the sensitivity for detection of primary tumors such as lung cancer (Chin et al. 2002) as well as melanoma (Holder et al. 1998).

Lumbar Puncture

In cases in which clinical evaluation or imaging is suggestive of leptomeningcal metastases, examination of the cerebrospinal fluid is warranted. Imaging should always precede this and in patients with evidence of increased

intracranial pressure, mass effect, or midline shift, lumbar puncture is contra indicated.

THE DIAGNOSIS AND MANAGEMENT OF BRAIN TUMOR-RELATED COMPLICATIONS

Seizures, cerebral edema, and deep venous thromboses may complicate the course of patients with brain tumors. These complications may lead to tumor diagnosis in some cases, or develop during the course of tumor evaluation and management in others. Management of these symptoms can be challenging, but timely investigation and treatment can dramatically improve quality of life in these patients.

Seizures

The clinical presentation of seizures in brain tumor patients was discussed previously in this chapter. This section covers management.

Surgery

Improved seizure control often follows surgical removal of the tumor. A more controversial issue has been the need to resect surrounding "epileptogenic" cortex identified by electrocorticography. Some investigators have favored epilepsy surgery where possible, consisting of a mass resection and a subtotal lobectomy. Others have advocated "mass" surgery only. The extent of surgery is individualized based on the eloquence of the area where the **tumor** is located and the expertise of the neurosurgical team.

Radiation Therapy

Both conventional and stereotactic radiation therapy may result in better seizure control. In contrast, seizures may increase in frequency during radiation therapy, probably as part of the "immediate" response to radiation. This has been reported in radiosurgery patients and often responds to adjustments in corticosteroid dosage (Werner-Wasik et al. 1999).

Corticosteroids

A reduction in the inflammatory response around a tumor may help in reducing seizures. The management of cerebral vasogenic edema is discussed in the following text.

Antiepileptic Drugs

Broadly speaking, antiepileptic drugs may be subdivided into "conventional" versus "new" and enzyme-inducing versus nonenzyme inducing (see Table 58C.1). In patients

•^Usc restricted because of hepatic toxicity,

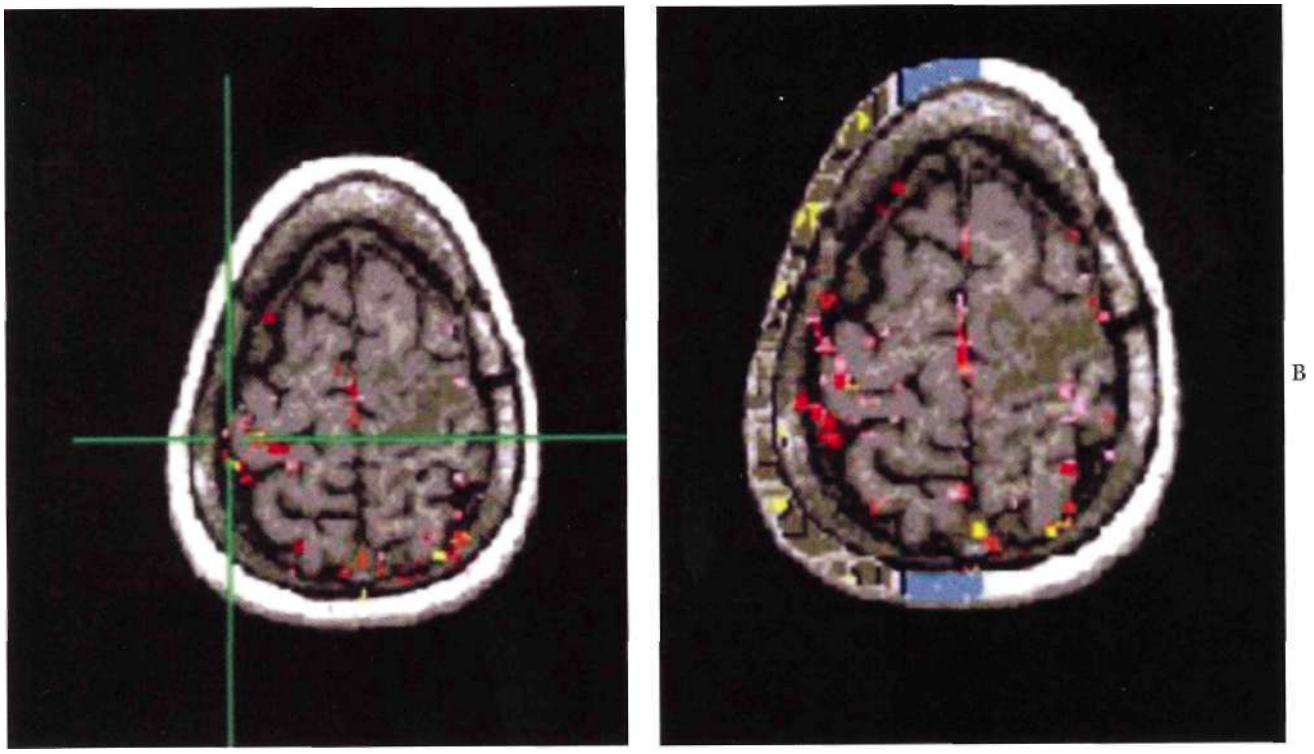
with brain tumors presenting with seizures, the emetgent administration of an intravenous antiepileptic drug such as fosphenytoin is usual. The dtug is often maintained in cases with good seizure control. Increasingly, however, newer antiepileptic drugs are being used because of better tolerance in some patients. The newet generation of antiepileptic drugs is sometimes preferred because of less potential for drug interactions. Gahapentin and levetiracetam are examples of nonenzyme-i inducing Lintiepileptic drugs (NE1AED). Because most brain tumot patients ate tteatcd with chemotherapeutic agents, drugs that do not interfere with hepatic metabolism, and thctcfotc with bioavailability of chemotherapy, represenr an advantage, particulatly with chemothctapy agents such as vincristine (Villikka et al. 1999), CPT-11" (Mathijsscn et al. 2002), and paclitaxel (Chang et al. 1998), This effect is so important that patients enrolled into brain tumor trials ate often stratified according to whether they are using an enzyme-inducing antiepileptic dtug or an NEIAED.

Cerebral Edema

Both primary brain tumors and metastases usually induce cetcbral edema. This may result in headache, altered mental status, and neurological deterioration. Brain tumor edema is usually of the *vasogenic* type; that is, it results from passage of fluid from the intravascular compartment to the interstitial space. When brain tumors cause obstructive hydrocephalus, increases in intraventricular pressure may result in transependymal spread of fluid into the periventricular interstitial space, or *interstitial* edema.

Management of Cerebral Edema

Vasogenic edema may result in acme increased intracranial pressure. Such patients usually tequire hospitalization and, in severe cases, arc best managed in an intensive care unit. In this setting, intravenous mannitol is often used to reduce intracranial pressure. By effecting an osmotic diuresis, the drug results in intravascular volume depiction, resulting in fluid return to the intravascular compartment. The side



PLATK 58C.I Functional magnetic resonance imaging scan shows activation of right motor area for the hand with activity of both the right hand (A) and left hand (B). Notice the abnormal signal related to low-grade tumor in left frontal lobe.

effects of hypovolemia and electrolyte imhalance limit repeated dosing of mannitol. The benefit of mannitol is short-lived, lasting on average 24-48 hours befote a rebound increase in intracranial pressure occurs.

Urea and glycerol are also used to achieve the same effect as mannitol, an osmotic diuresis. In practice, both drugs are used less often than mannitol. The osmotic diuretic effect of urea and glycerol is also short-lived and a rebound phenomenon may occur with both agents when they are stopped. Glycerol is usually better tolerated than urea, which may cause prominent nausea. The usual oral dosage of glycerol is 1.5 g/kg per day in divided doses.

Corticosteroids are the mainstay of treatment in patients symptomatic from vasogenic cerebral edema. Unlike osmotic diuretics, the effect of corticosteroids is sustained. Unfortunately, the long-term use of corticosteroids is associated with a multitude of side effects, including hyperglycemia, osteopenia, proximal muscle weakness, and limb swelling. In patients with severe cerebral edema and increased intracranial pressure, very high doses of dexamethasone (30-36 mg daily in divided doses) are used. The dexamethasone dosage is tapered once clinical improvement is noted.

Venous Thrombosis

Deep venous thrombosis is a common complication in brain tumor patients. In a retrospective study of 381 patients with malignant glioma, 97 (36.7%) were found to have venous thrombosis confirmed by venography {Ruff and Posner 1983). The reasons for this high incidence are probably multiple. An obvious explanation in some patients may be the immobility following hospitalization for surgery or immobility of limbs secondary to hemiplegia, although deep venous thrombosis also occurs in patients with malignant brain tumors who have retained mobility. Intracranial neoplasms have also been shown to inhibit purified plasmin in an in vitro assay (Sawaya et al. 1984).

Clinical Presentation

The typical initial feature is unilateral foot, calf, or thigh pain or swelling. Likewise, arm or forearm swelling and pain may be prominent in upper extremity thrombosis. Superficial venous distension, increased temperature, and erythema may be present. Some patients present with symptoms of pulmonary thromboembolism, pleuritic chest pain and shottness of breath that may be accompanied by changes in the lower extremities. Corticosteroids may blunt symptoms related to inflammation. In such cases, local swelling and erythema at the site of thrombosis may be minimal and pulmonary symptoms absent. Anxiety may be the only initial manifestation of pulmonary thromboembolic disease.

Investigation

When deep venous thrombosis is suspected, venous Doppler studies of the lower extremities are required. Both lower extremities should be studied. Ventilation-perfusion scans or CT angiograms should be ordered when Doppler studies are positive or when symptoms suggest pulmonary embolism,

Management

Despite the high frequency of deep venous thrombosis in brain tumor patients, there are aspects of management that are still controversial. The most important aspect of management is prevention. Intermittent pneumatic compression of the calf reduces the incidence of venous thrombosis in the perioperative period. Low-molecular weight heparin is also used, but some investigators have found a significant increase in postoperative intracranial hemorrhage when used at typical doses for prophylaxis (Dickinson et al. 1998). Passive and active physical therapy should be incorporated in the prevention of deep venous thrombosis.

Immediate anticoagulation is indicated once deep venous thrombosis is confirmed. Patients are anticoagulated with low-molecular weight or fractionated heparin and started on warfarin. In deep venous thrombosis, oral anticoagulation is continued for at least 6 months. When pulmonary embolism has occurred, treatment is continued indefinitely. Another method that is often used in the management of deep venous thrombosis is vena caval interruption. A recent review on the indications for vena caval interruption indicated two accepted indications for the procedure: a temporary or definitive contraindication to anticoagulant treatment and failure of anticoagulation (Girard et al. 2000). Vena caval interruption is usually achieved with Greenfield titanium or steel filters. Although filter placement may be considered convenient in patients who may be at high risk of bleeding, thrombosis at or above the filter site may result in pulmonary embolism. Extensive inferior vena caval thrombosis may sometimes complicate filter placement, resulting in severe venous insufficiency, lower extremity gangrene, sepsis, and death (Figure 58C2), Decousus et al. (1998) examined vena caval filters in the prevention of pulmonary embolism m a multicenter, randomized open trial comparing vena caval filter with no filter and anticoagulation. This study demonstrated initial efficacy of vena cava) filters in preventing pulmonary embolism. However, at 2 years, an excess recurrence of deep vein thrombosis was noted in the vena caval filter group. There was also no effect on immediate or long-term mortality in this group. Our clinical experience has been that thrombosis at the filter site may be a frequent problem unless patients are also maintained on low-molecular weight heparin at prophylactic doses or warfarin after filter placement {see Figures 58C.2 and 58C.3).

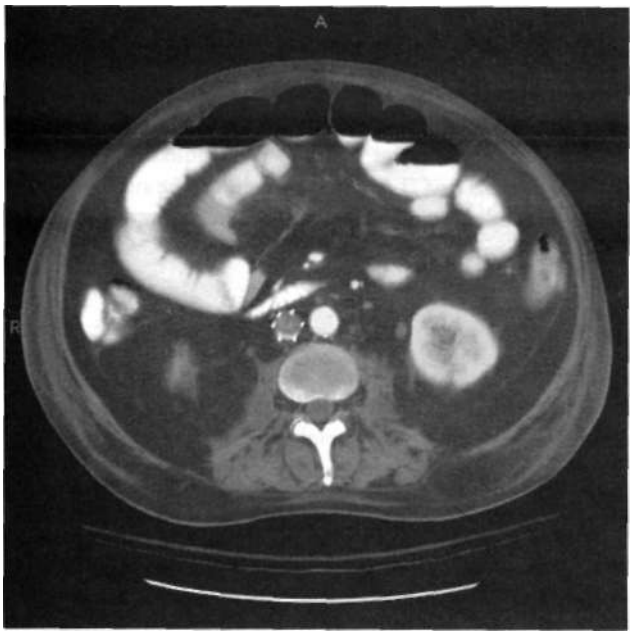


FIGURE S8C.2 Extensive clot formation at the site of an inferior vena caval filter. Note the small elliptical area of contrast in the vein indicating flow and the hypodense area within the vein representing clot formation.

SUMMARY

Brain tumors can present in a dramatic way, such as with seizure activity or in a more progressive fashion with worsening headache, weakness, and numbness. In either case, modern imaging facilitates the diagnosis, although a careful clinical assessment is critical in assessing performance status, suitability for experimental or conventional therapies, and determining practical needs such as walking aids and home safety alterations. Because cognitive dysfunction is often present in patients with brain tumors, bedside cognitive evaluation is mandatory in all patients and formal neuropsychological evaluation is necessary in a few. Until therapies that are more effective are developed, the emphasis of follow-up care musr be on the quality of life of patients. Besides ascertaining cognitive and physical function, this requires monitoring for brain tumor complications and preventing or treating them in a timely fashion. The use of anticonvulsants, prophylactic anticoagulation, physical therapy, and corticosteroids may help patients achieve a better quality of life with control of symptoms and prevention of complications.

Chapter 58
Cancer and the Nervous System

D. NEUROIMAGING

John W. Henson and R. Gilberto Gonzalez

Neuroimaging has many important roles in neuro-oncology, including preoperative differential diagnosis, operative planning, assessment of response and tumor progression, and identification of treatment-related side effects. In the practice of neuro-oncology, gadolinium-enhanced magnetic resonance imaging (MR1) is the imaging modality of choice. It is extremely sensitive to pathological alterations in brain tissue and the anatomic resolution is significantly better than computed tomography (CT) (Atlas et al. 2002). Despite significant advances in imaging technology, several significant limitations exist in the specificity of imaging for determining tumor type, tumor grade, response to treatment, and detecting treatment-related complications. Functional and spectroscopic MRI techniques hold the promise of increased imaging specificity, as well as allowing better understanding of tumor physiology.

CENTRAL NERVOUS SYSTEM METASTASIS

Brain Metastasis (Figure 58D.1)

Brain metastasis may arise from almost any primary tumor in the body. Prostate cancer and skin tumors other than melanoma are exceptions; brain metastases are highly unusual in both. Lung, breast, and melanoma are the most common sites of primary tumors in patients with brain metastasis. Melanoma comprises only 1% of all cancers, and thus has a clear predilection to produce brain metastasis. Brain metastases typically occur in patients with advanced systemic metastatic disease. In such patients, the presence of a typical appearing brain lesion on imaging is sufficient for the diagnosis of brain metastasis. However, the first sign of cancer in 10% of patients with lung cancer is metastasis. Therefore a broader ncuroradiological differential diagnosis is required in the absence of known metastatic cancer. The peak age incidence of brain metastasis mirrors that of the primary tumor. In 50% of patients, metastases are multiple and distributed to various brain regions according to relative blood flow. Brain metastases arc most commonly located at the gray-white junction, but also appear in the white matter and other sites. The lesions have prominent, well-circumscribed homogeneous or ring enhancement, and typically are associated with a substantial degree of vasogenic edema. Hemorrhage and cystic changes may occur, but calcification is rare.

Leptomeningcal Metastasis (Figure 58D.2)

Leptomeningcal metastasis (LM) results in multifocal neurological deficits. Similar to other metastatic complications,

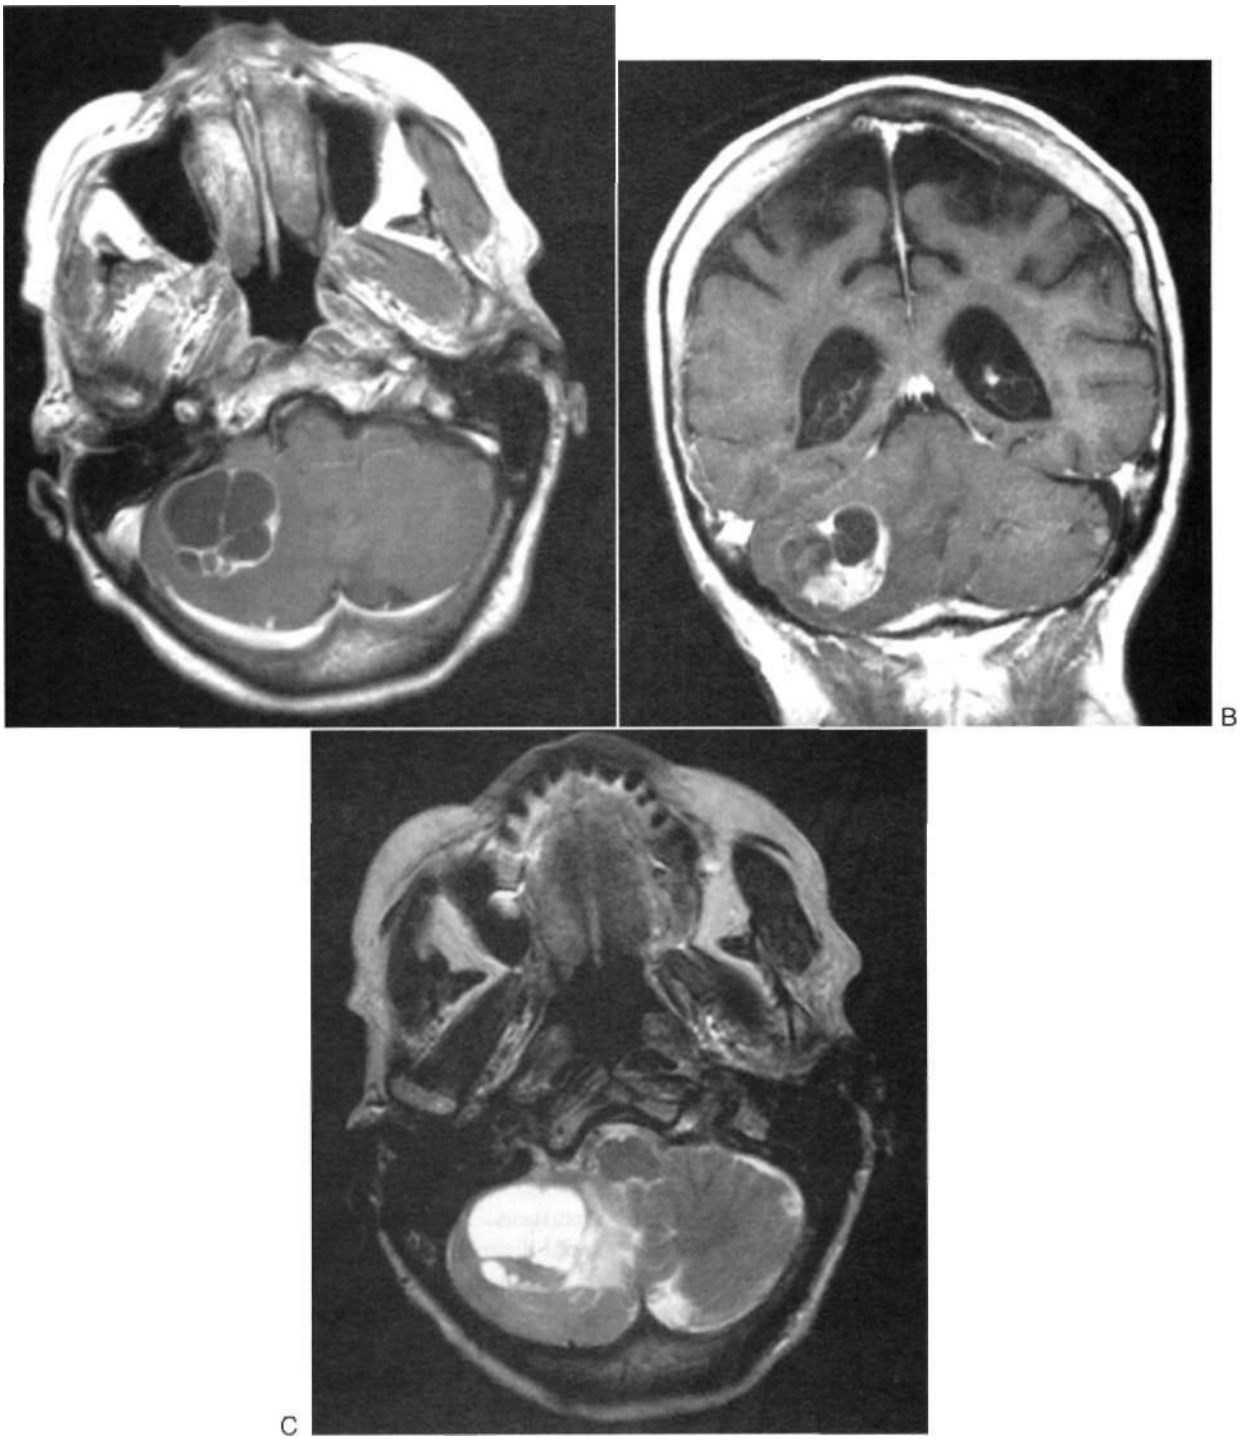

FIGURE 58D.1 Brain metastasis. A gadolinium-enhanced T1W1 in a 79-year-old woman with metastatic ovarian adenocarcinoma shows a septated, cystic-appearing lesion with an inferior mural nodule (A, B). There is mass effect on the fourth ventricle and medulla. Hyperintense T2-weighted signal is seen wirhin the cystic portion of the lesion, whereas the solid portion of the lesion is isointense to brain (C).

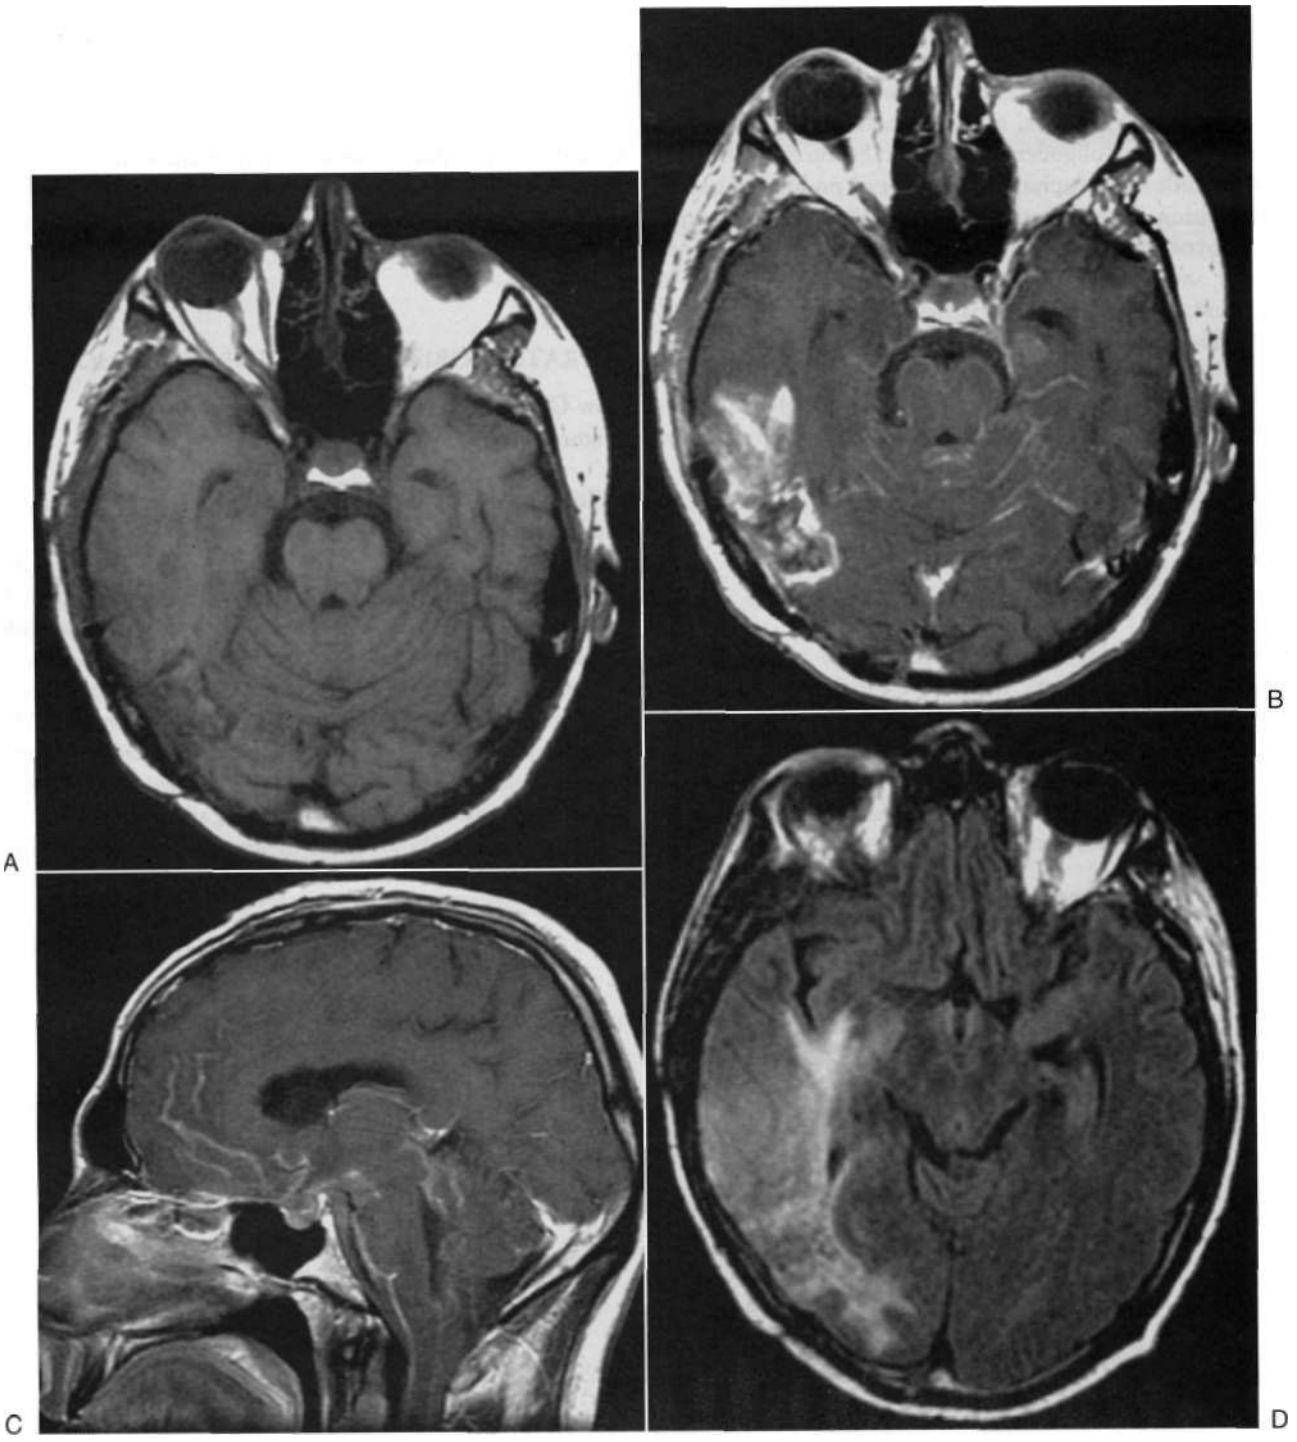

FIGURE 58D.2 Lcptomeningeal metastasis. A 34-year-old man developed multifocal symptoms along the neuraxis 1 year after diagnosis of a glioblastoma arising in oligodendroglioma. There had been three craniotomies for tumor resection. No abnormalities are detected in the subarachnoid spaces on T1WI prior to gadolinium administration (A). After gadolinium, prominent linear enhancement is seen on the surface of the midbrain and along the cerebellar folia (B), in sulci in the frontal lobes and along the ventral pons and medulla (C), Fluid-attenuated inversion recovery (FLAIR) images do not show clearly hyperintense signal in the subarachnoid spaces (D), although this finding is often seen in cases of leptomeningcal tumor spread.

LM usually occurs in patients with advanced systemic cancer. In addition, several primary brain tumors can produce LM, including primitive neuroectodermal tumors (PNETs), ependymomas, primary central nervous system lymphoma, and oligodendrogliomas. Features of LM on MRI include hydrocephalus and linear or nodular enhancement within the subarachnoid space. FLAIR images may show hyperintense signal within the subarachnoid space (Singer and Atlas 1998). Gadolinium-enhanced imaging of the cauda equina may be particularly useful in patients with clinical features suggestive of LM but with normal brain MRI and cerebrospinal fluid (CSF) cytology. In the appropriate clinical setting, the presence of nodular enhancement along the cauda equina is strong evidence to support the diagnosis of LM.

Metastatic Epidural Spinal Cord Compression (Figure 58D.3)

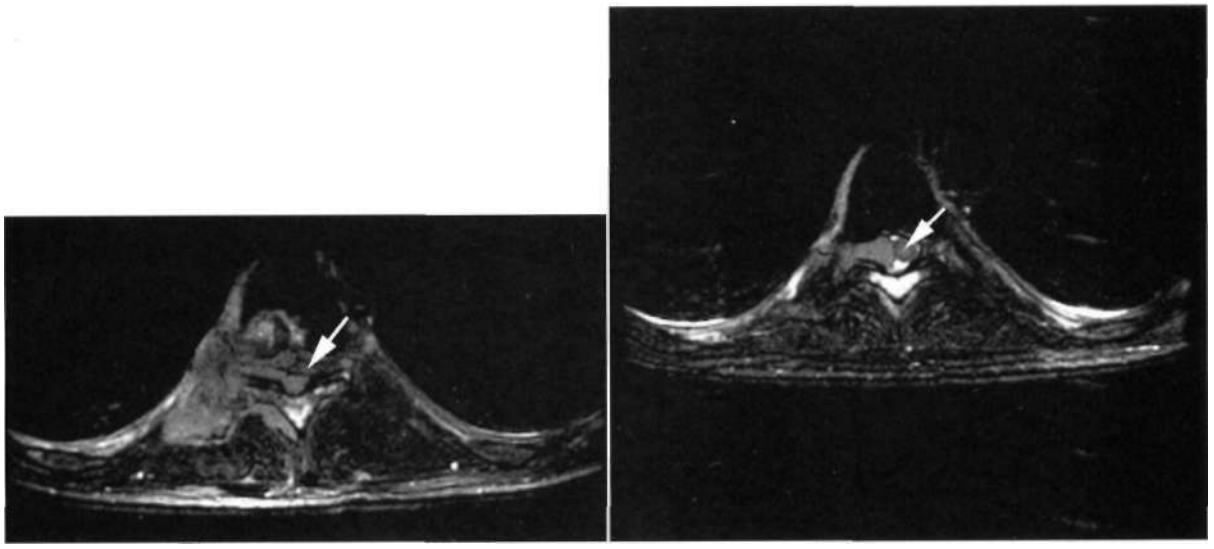
Epidural spinal cord compression (ESCC) is also a late complication of systemic metastatic cancer. Patients typically present with a few weeks of back pain followed by lower limb weakness. On rare occasion, FSCC may be the initial manifestation of cancer. The most common mechanism of ESCC is a vertebral body metastasis with extension into the adjacent spinal canal. Paraspinal tumors may also gain access to the epidural space by growing through neural foramina. The radiological evaluation of a patient with suspected ESCC! requires sagittal II and T2WI through the entire spine, because a 25% incidence of synchronous lesions exists. Axial images through the epidural mass permit further assessment of the severity of cord compression and are valuable for surgical and radiation planning.

SUPRATENTORIAL PRIMARY BRAIN TUMORS

Low-Grade Diffuse Fibrillary Astrocytomas (Figure 58D.4)

Mildly in creased eel hilarity and tumor cell infiltration into surrounding brain tissue characterizes low-grade astrocytoma (LGA). Vascular endothelial proliferation, mitotic activity, and necrosis do not occur. The average age at diagnosis is 34 years, although the age range is quite wide (Kleihues and Cavence 2000). On MRI, LGA demonstrates ill-defined T2WI hyperintensity in white matter and cortex, with mild mass effect. Vasogenic edema is minimal. The periphery of the lesion may show linear enhancement, but enhancement within the mass suggests high-grade histology. However, the absence of gadolinium enhancement is not reliable evidence of low-grade histology; one

FIGURE 58D.3 Metastatic epidural spinal cord compression. A 45-year-old man with progressive systemic non-Hodgfcin's lymphoma complained of thoracic back pain and lower extremity weakness. Sagittal T1WI (A) and T2WI (B) reveal an epidural mass lesion compressing the thoracic spinal cord at T8. There is minimal, if any, abnormal 12 weighted signal abnormality in the spinal cord parenchyma. Marrow signal is abnormal in the dorsal aspect of the T8 vertebral body. Axial T1WI (C) and T2W1 (D) show a right paraspinal mass with invasion of tumor into the spinal canal via a neural foramen. There is also a lesion in the dorsal right vertebral body. The thoracic spinal cord (C, D, *arrows)* is deviated to the left, but there is residual surrounding cerebrospinal fluid space remaining. The more common mechanism of metastatic epidural cord compression is direct extension of a vertebral lesion into the spinal canal.



third of patients with nonenhancing gliomas have high-grade tumors at biopsy (Barker et al. 1997). Cyst formation is common. Calcification is uncommon except with oligodendroglioma.

Repeat imaging studies are useful to follow tumor activity, particularly to detect anaplastic progression to a higher-grade astrocytoma. Comparison of new studies with the postoperative baseline examination, and to the most recent prior study, is the best method to detect the gradual growth ot I GA. New foci of contrast enhancement suggest anaplastic progression, but transitory radiation-induced enhancement and radiation necrosis are also

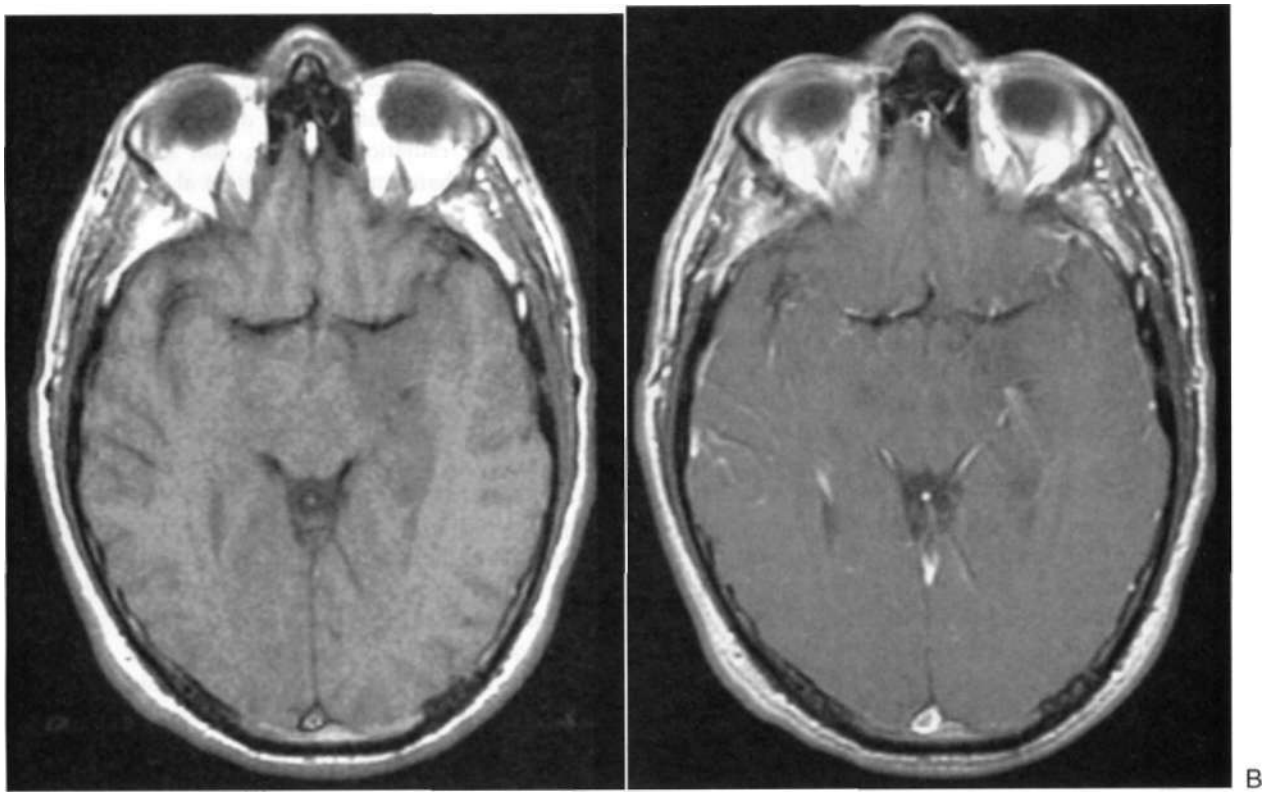


FIGURE 58D.4 Low-grade diffuse fibrillary astrocytoma. Axial T1WI in a 43-year-old man with new onset partial complex seizures demonstrates a slightly hypointense mass lesion within the medial left temporal lobe (A). There is no evidence of enhancement after gadolinium administration (B). A poorly circumscribed, hyperintense lesion expanding cortex and white matter of the medial lobe is seen on T2WI (C) and FLAIR (D) images. There is no evidence of vasogenic edema. Serial follow-up magnetic resonance imaging scans revealed an enhancing nodule and extension of the T2-weightcd signal abnormality 6 months after diagnosis (not shown). Low-grade astrocytomas in middle aged and older adults should be followed closely for evidence of early anaplastic progression.

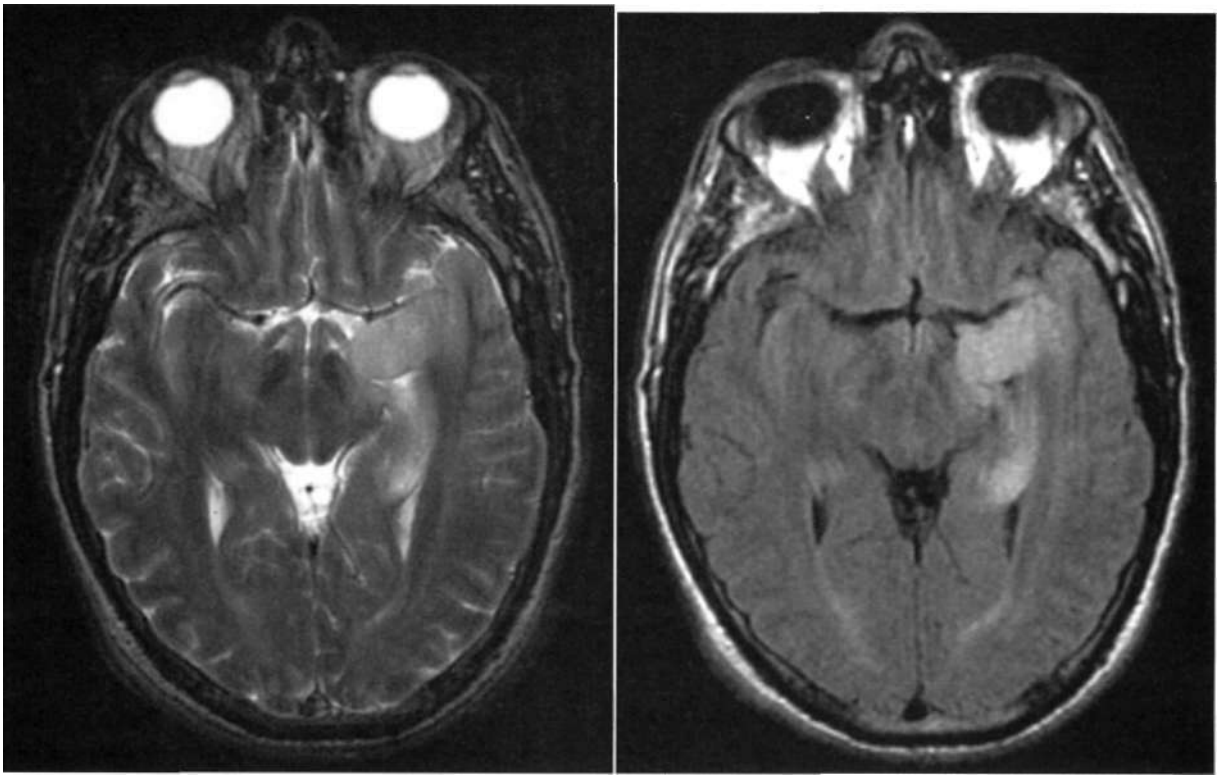

FIGURE 58D.4, cont'd.

considerations in patients who have received irradiation (Peterson et al. 1995).

Anaplastic Astrocytoma (Figure 58D.5) and Glioblastoma Multiforme (Figure 58D.6)

Anaplastic astrocytoma (AA) and glioblastoma multiforme (GBM) are both high-grade diffuse fibrillary astrocytomas and have high cell density, mitotic figutes, and vascular endothelial proliferation. GBMs also show necrosis. Five percent of high-grade astrocytomas are multifocal. The peak age incidence is 41 years for AA and *53* years for GBM (Kleihues and Cavcnee 2000). More mass effect occurs than in LGA, and areas of hemorrhage may produce heterogeneous signal on T1WI and T2WI. Irregular ring-enhancement after gadolinium administration implies the presence of necrosis and is suggestive of GBM. Fluid-filled cystic structures may show smooth linear enhancement. A combination of vasogenic edema and infiltrating tumor cells produces extensive surrounding areas of hyperinteusity within the white matter surrounding the tumor on T2WI. As noted previously, high-grade gliomas occasionally do not demonstrate enhancement after administration of gadolinium.

Most high-grade astrocytomas do not exhibit marked shrinkage following treatment. However, glucocorticoid therapy for peritumoral edema can lead to a significant decrease in the size of both the contrast-enhancing component and the peritumoral edema. Enlarging areas of contrast enhancement are common findings on follow-up studies. The differential diagnosis includes tumor progression, radiation necrosis, and transient radiation-associated enhancement (Peterson et al. 1995).

Low-Grade Oligodendroglioma (Figure 58D.7)

Low-grade oligodendrogliomas (LGOs) are tumors of low to moderate cell density with abundant proliferation of capillaries and absence of necrosis. The cortex and white matter are prominently involved, and calcification is common. Peak age incidence is 42 years (Kleihues and Cavencc 2000). On MRI, LGO are hypointense on T1WI and hyperintense on T2WI, and margins are well defined and may expand the cortex. Vasogenic edema is minimal. Contrast enhancement, calcification, and cyst formation may be present. Gradual enlargement may occur over several years, and comparison of new studies with a postoperative baseline examination is valuable. Unlike astrocytoma, oligodendroglioma may shrink significantly after treatment.

Anaplastic Oligodendroglioma

Anaplastic oligodendrogliomas (AOs) usually show more mass effect, contrast-enhancement, and vasogenic edema than LGO. Ring-enhancement may portend a more aggressive and less responsive tumor than does more

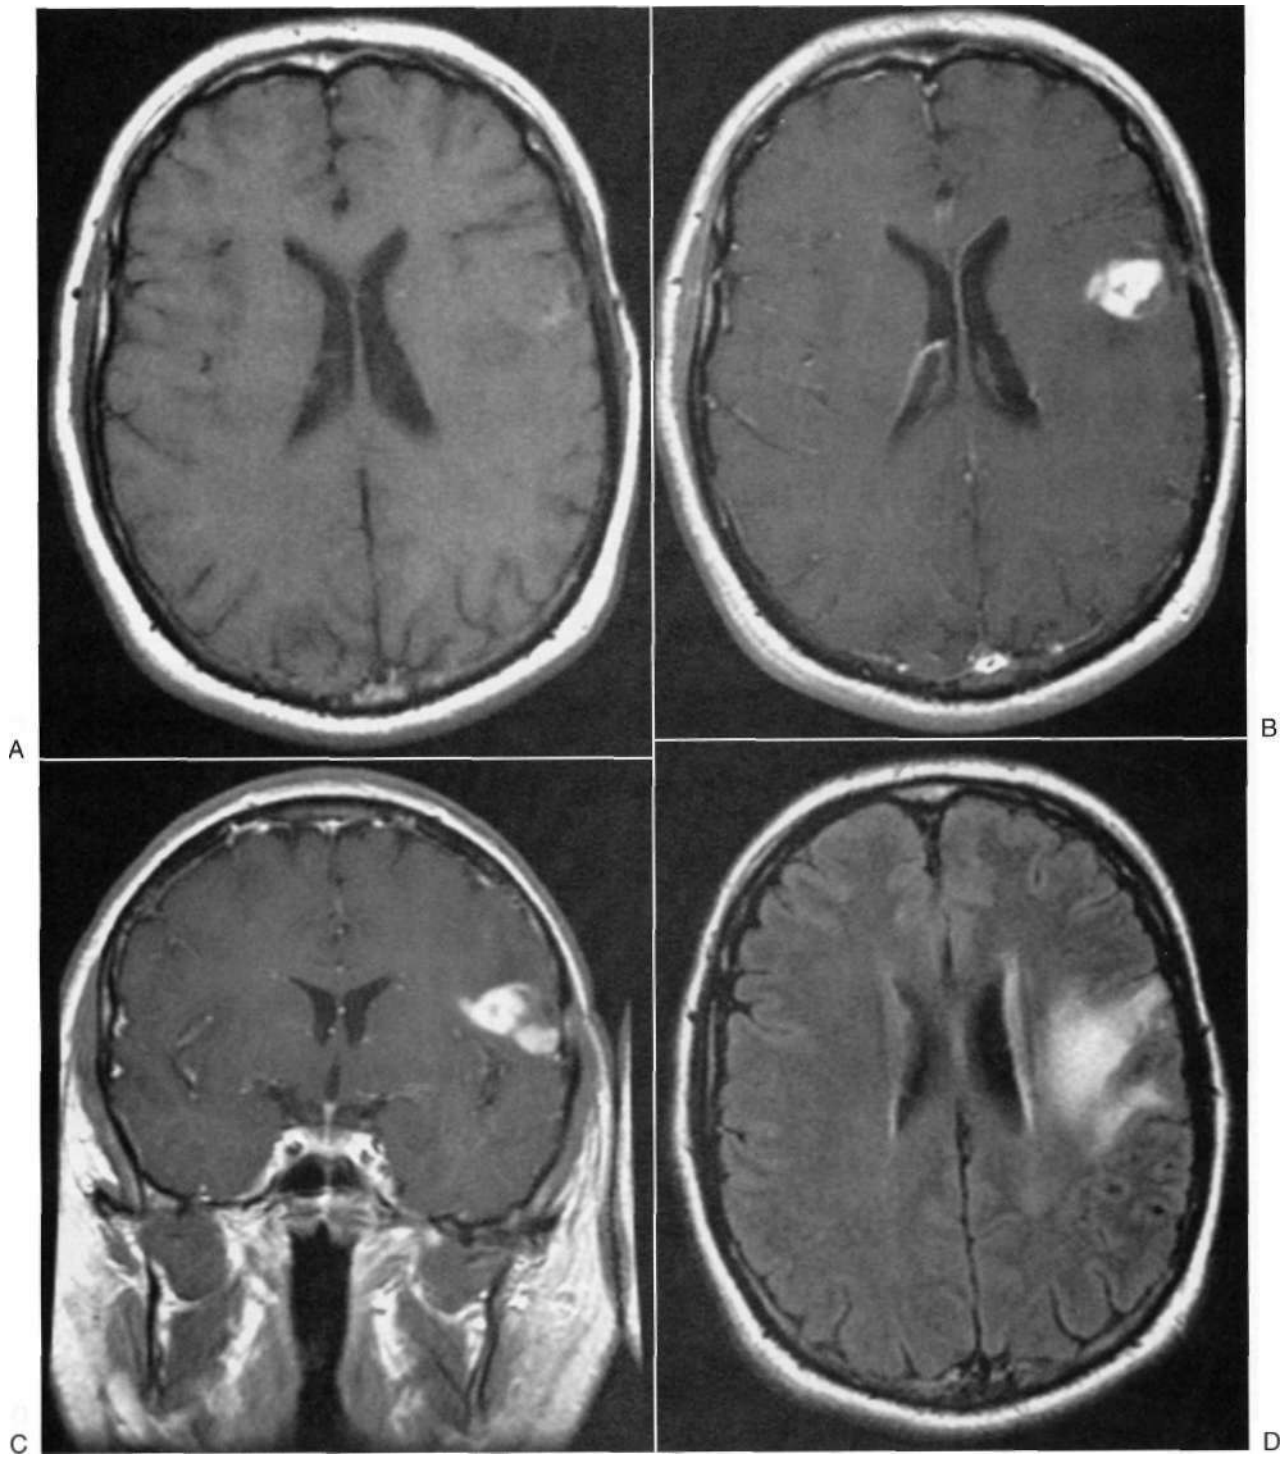

FIGURE 5SU.5 Anaplastic astrocytoma. TIWI before (A) and after (B, C) gadolinium administration in a 36-ycar-old man with brief episodes of aphasia demonstrate a small area of minimal hypointensity in the left frontal lobe that exhibits focal enhancement. There is no clear evidence of ring enhancement. A FLAIR image (D) shows a poorly circumscribed area of heterogeneous hyperintensity centered within the white matter and cortex.

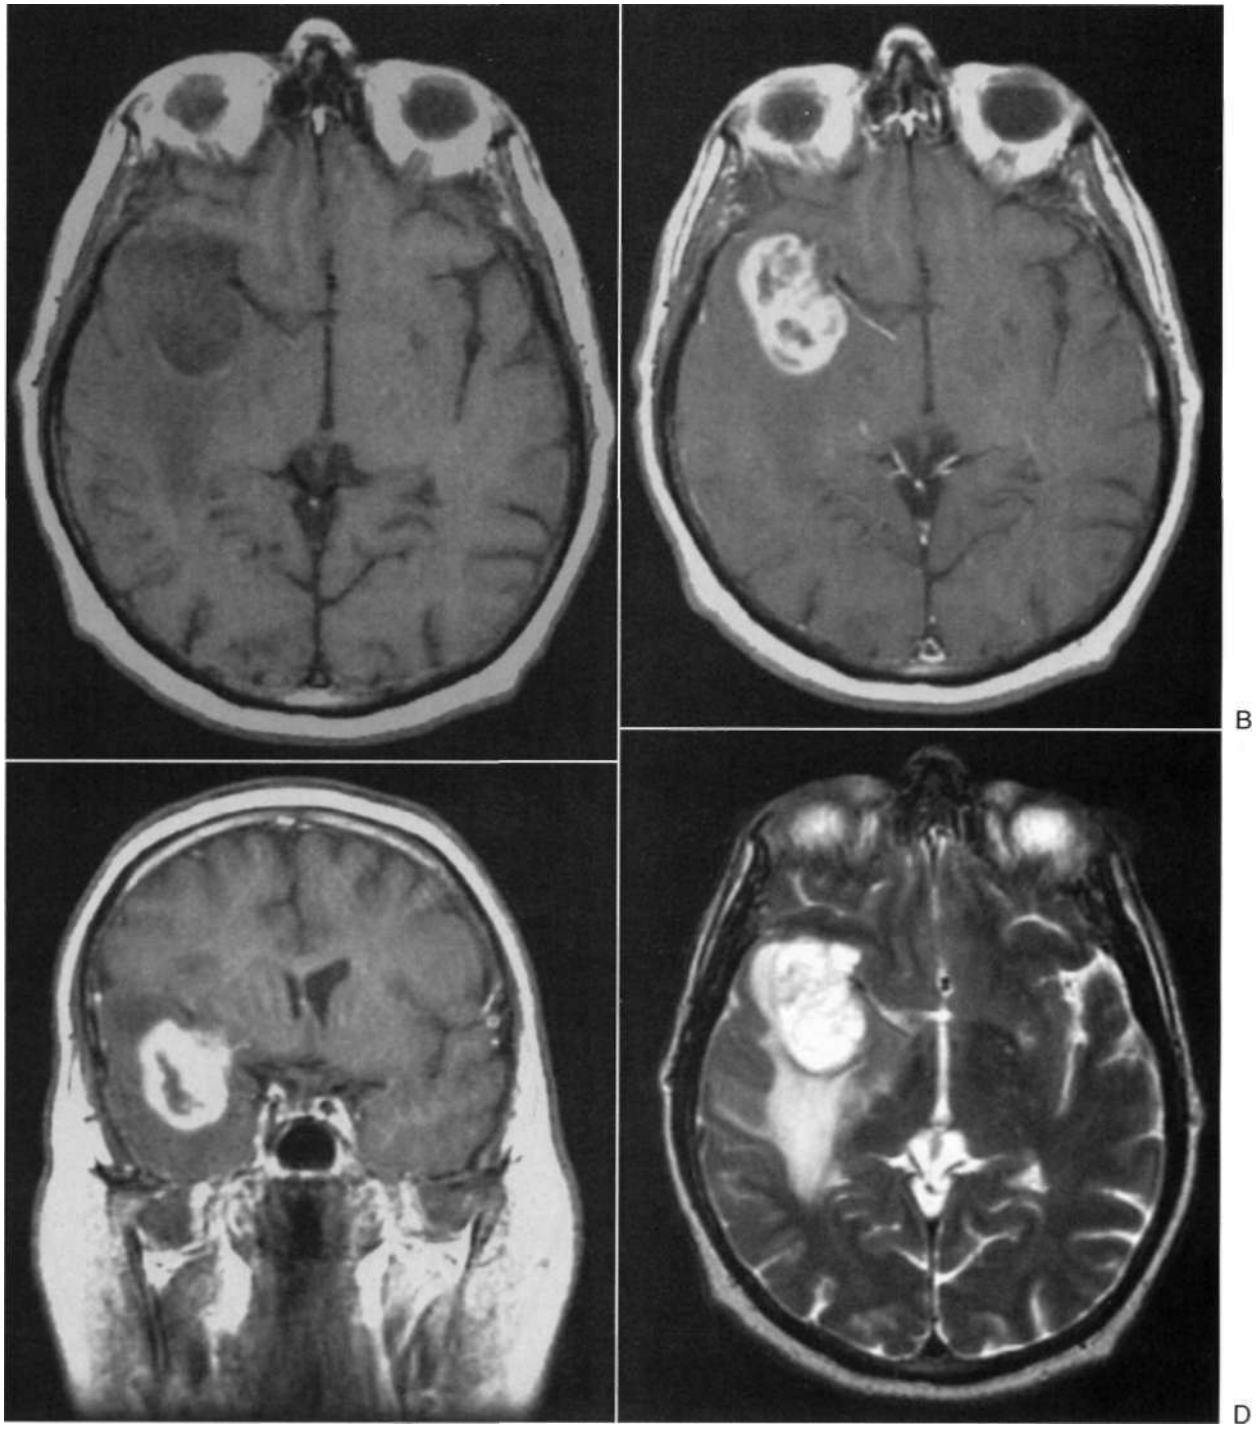

FIGURE 58D.6 Glioblastoma multiforme. A 64-year-old man developed partial complex seizures that included olfactory hallucinations. T1WI before gadolinium (A) shows a hypointense mass lesion within the right temporal lobe that has a central, cystic-appearing region of even lower intensity. Irregular ring enhancement is seen after administtation of gadolinium (B, C). T2WI (D) demonstrates that the cystic-a p pea ring component of the lesion is vety hyperintense, representing a large area of necrosis, as confirmed at the time of surgery. Vasogenic edema and infiltrating tumor produce a posterior region of milder hyperintensity with ill-defined margins within the white matter.

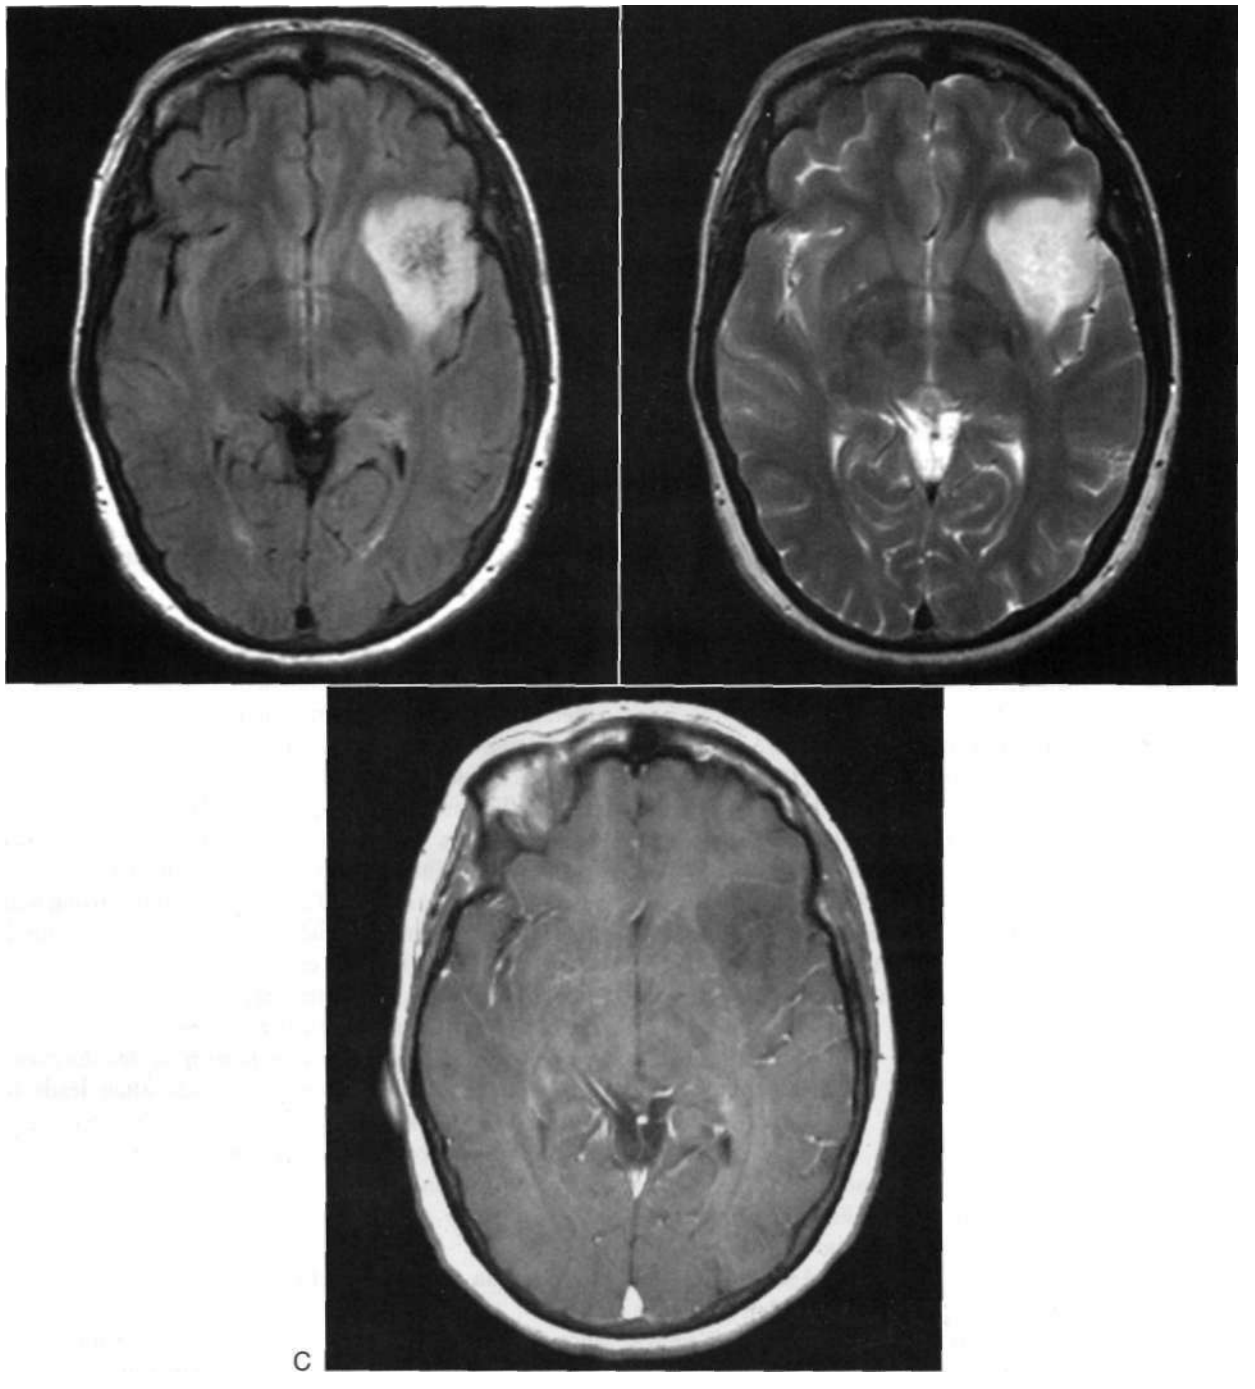

FIGURE 58D.7 Low-grade oligodendroglioma. Axial FLAIR images (A) and T2W1 (B) demonstrate a well-circumscribed lesion within the left frontal insular region in a 50-year-old woman who had a 10-month history of episodes of aphasia and right hemi paresis. There is prominent cortical expansion as well as involvement of white matter, effacement of sulci in the left frontal region, but no evidence of significant surrounding vasogenic edema or mass effect on the left lateral ventricle. After administration of gadolinium, there is no evidence of enhancement (C). Low-grade oligodendrogliomas often demonstrate some enhancement. Computed tomography showed no evidence of calcification (not shown).

homogeneous enhancement (Cairncross et al. 1998). Seventy-five percent of AOs exhibit a marked response to therapy. This prominent response correlates with the loss of heterozygosity on the short arm of chromosome 1p.

Optic Pathway Glioma (Figure 58D.8)

The origin of optic pathway glioma is most commonly as a pilocytic astrocytoma in the optic nerves and optic chiasm of children. These tumors are usually of low malignant potential. Bilateral optic nerve gliomas are associated with neurofibromatosis (NF) type 1 (Klcihues and Cavenee 2000). Adults have a more aggressive, higher-grade, diffuse astrocytoma. High-grade tumors enlarge the affected optic pathway structures and show contrast enhancement (Kornreich et al. 2001). Hyper intensity on T2WI that extends posteriorly along the optic tracts indicates tumor infiltration and vasogenic edema.

Subependymal Giant Cell Astrocytoma

Subependymal giant cell astrocytomas (SEGAs) develop at the foramen of Monroe in approximately 10% of patients with tuberous sclerosis (TS) by age 20. Neurological complications usually result from hydrocephalus. Because of a high rate of spontaneous mutation, only one half of patients have a family history of TS (Kleihues and Cavenee 2000). Enhancement is present, and calcification and hemorrhage may be seen (Nishio et al. 2001). Other features of TS, cortical tubers and subependymal nodules, are present as well.

Ganglioglioma

Gangliogliomas contain a combination of dysplastic large neurons and neoplastic astrocytic cells. They are designated *anaplastic ganglioglioma* when the glial component appears to have high-grade features. Age at time of diagnosis may range from childhood to adult life. The temporal lobes arc the most common location (Kleihues and Cavenee 2000). Calcification and cystic changes are common. On MRI, these tumors show nodular areas of contrast enhancement and may be solid or cystic.

Dysembryoplastic Neuroepithelial Tumor

Composed of glial and neuronal elements, dysembryoplastic neuroepithelial tumors (DNETs) are benign lesions that rarely regrow after total or even subtotal surgical resection. They are most often located in the medial aspect of the temporal lobes. Peak age incidence is the second and third decades (Kleihues and Cavenee 2000). DNETs usually expand the cortex and subcortical white matter, and may have small rings of enhancement. Calcification is common, whereas macroscopic cyst formation is rare.

Central Neurocytoma (Figure 58D.9)

Intraventricular masses arising from the region of the foramen of Monro, central neurocytomas are slow growing, densely calcified tumors that contain homogenous populations of small round cells, histologically indistinguishable from oligodendroglioma (Kleihues and Cavenee 2000). However, tumor cells express neuronal proteins. Average-age at diagnosis is 29 years, with a wide range. Hydrocephalus is common.

Primary Central Nervous System Lymphoma (Figure 58D.10)

Primary central nervous system lymphoma (PCNSL) is a non-Hodgkin's B-cell lymphoma that arises in the brain and often involves the eye (intraocular lymphoma). This tumor has become much more common over the past several decades. Peak age of incidence is from 50 years to late sixties. Twenty-five percent of PCNSLs are multifocal. Tumor masses favor deep cerebral and periventricular structures (Kleihues and Cavenee 2000). The lesions are relatively hypointensc on T2WI, demonstrate strong homogeneous enhancement, and have extensive surrounding vasogenic edema (Buhring et al. 2001). Abnormal diffusion, a common finding, probably represents dense ccllularity. PCNSL may shrink markedly or even disappear after administration of glucocorticoids such as dexamethasone. Preoperative administration of steroids often leads to a nondiagnostic brain biopsy. The likelihood of leptomeningeal dissemination requires gadolinium-enhanced imaging of the entire spine.

Germinoma (Figure 58D.11)

Intracranial gcrminomas may arise in the suprasellar or pineal regions. In the suprasellar location, pure germinomas are more common than mixed germinomas and arc highly radiosensitive lesions that Jo noi secrete tumor markers. Mixed germinomas are more common in the pineal region, may secrete ^-fetoprotein or jft-human chorionic gonadotropin, and are highly resistant to treatment. Peak age incidence is 10 years (Kleihues and Cavenee 2000). Gcrminomas are hyperdense on CT and show strong enhancement. Invasion of adjacent brain is common (Liang etal. 2002}. Teratomas, a type ol mixed germinoma, may contain calcification and fat. The high incidence of leptomeningeal dissemination requires gadolinium-enhanced imaging of the entire spine for staging purposes.

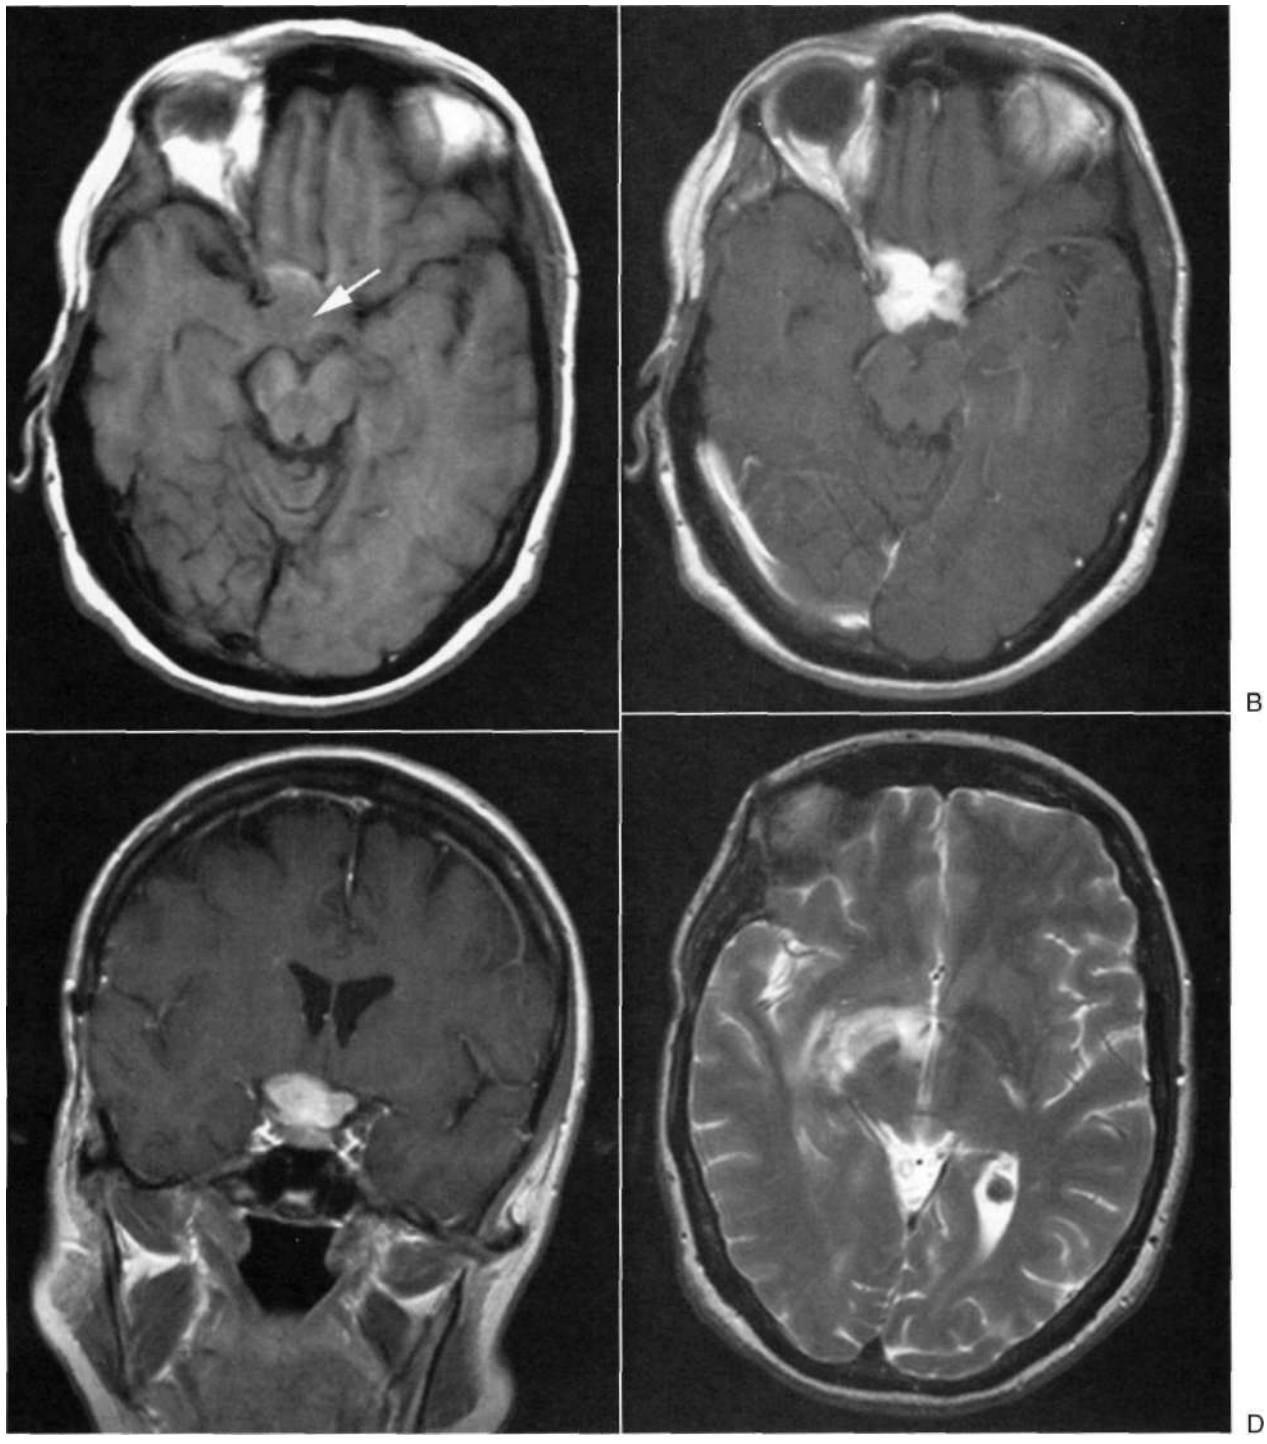

FIGURE 58D.8 Optic pathway anaplastic astrocytoma. T1WI before gadolinium (A) shows an isointense mass centered in the optic chiasm *{arrow)* with extension along bilateral optic nerves and tracts in a 54-year-old woman with several weeks of progressive blurring of vision in both eyes. There is heterogeneous contrast enhancement (B, C). The mass fills the majority of the suprasellar cistern. On T2WI (D) the rumor shows hypei intensity within the lesion, as well as hyperintense signal in the optic ttacts and the medial right temporal kibe. Involvement of the adjacent temporal lobe occurs by direct extension from the optic tracts. Tumor may sometimes spread posteriorly to the lateral geniculate nucleus.

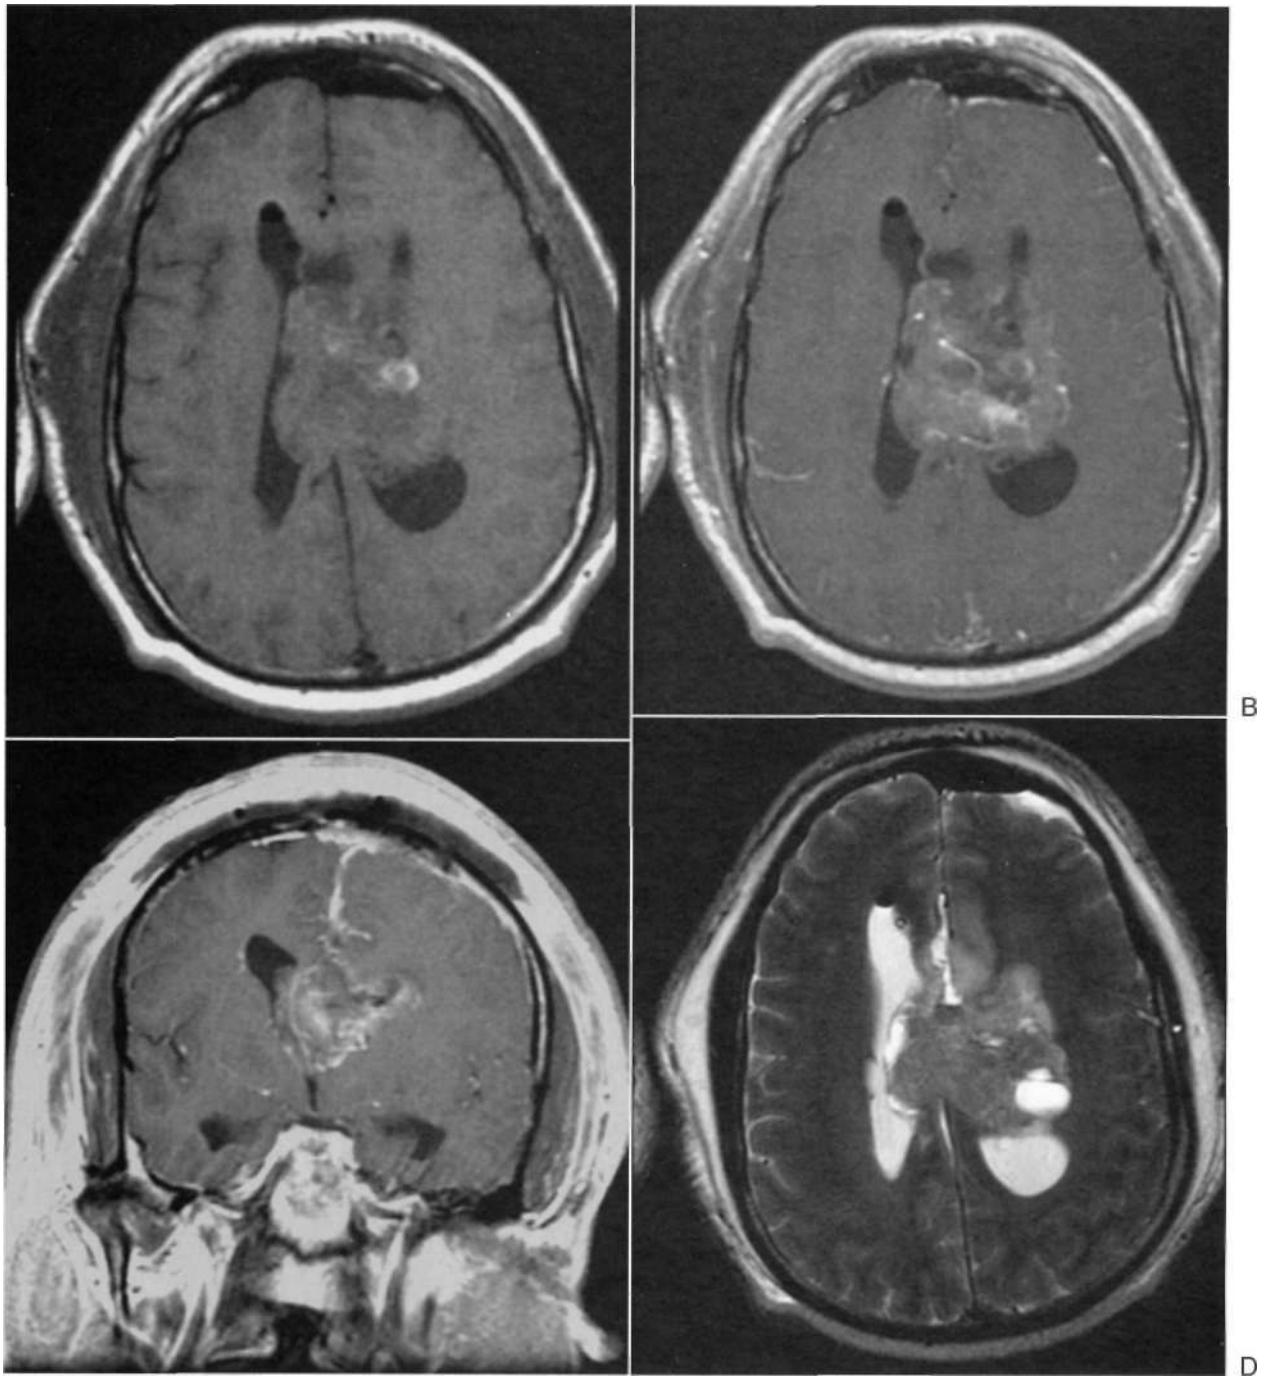

FIGURE 58D.9 Central neurocytoma. On T1 Wl (A) rumor is seen as a heterogeneous-signal mass lesion within the left lareral ventricle in a 45-year-old man with several weeks of headache, heaviness in his legs, and decreased visual acuity. Areas of hyperintensity likely represent calcification. After administration of gadolinium (B, Q, there is mild heterogeneous enhancement. The temporal horns of the lateral ventricle are dilated. On T2WI (D), the tumor is isointense to brain, with small areas of hyperintensity resulting from cystic change. A small amount of postbiopsy air is present within the frontal horn of the right lateral ventricle. Foci of dense calcification arc seen on computed tomography (E).

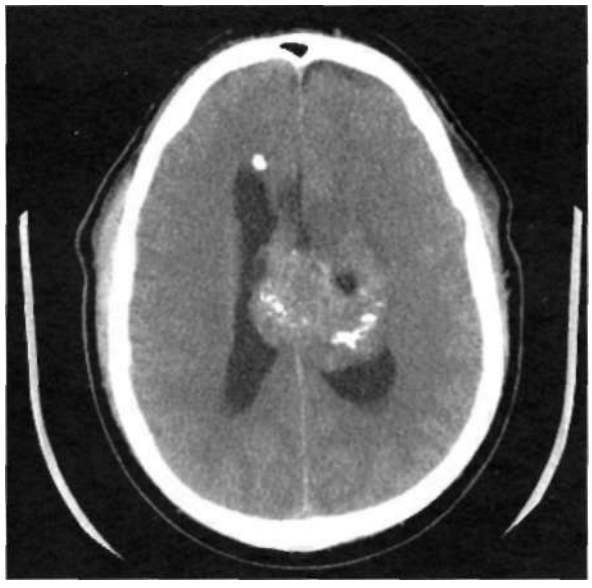

FIGURE S8D.9, cont'd.

Choroid Plexus Papilloma (Figure 58D.12)

Papillomas of the choroid plexus arise in the lateral ventricles (50%), third ventricle (5%), and fourth ventricle (40%). This is usually a tumor of childhood and young adulthood (Kleihues and Cavenee 2000). MRI shows a lobulated, well-circumscribed, enhancing, intraventricular lesion, often associated with hydrocephalus (Pencalet et al. 1998). Calcification is uncommon. Choroid plexus carcinoma is rare and shows brain invasion and necrosis.

Colloid Cyst (Figure 58D.13)

Colloid cyst is a rare lesion of adults in early middle age. Chronic or intermittent symptoms of hydrocephalus bring the tumor to clinical attention. The cyst arises in the anterior aspect of the third ventricle (Kleihues and Cavenee 2000). High concentrations of protein and cholesterol are present within the cyst, producing variable signal intensity on TIWI and T2WI. Peripheral enhancement may be present (Armao et al. 2000).

INFRATENTORIAL PRIMARY TUMORS

Ependymoma and Anaplastic Ependymoma (Figure 58D.14)

Ependymomas arise from cpendymal cells lining the surfaces of the ventricles. The most common location is the fourth ventricle. Spinal, lateral ventricular, and

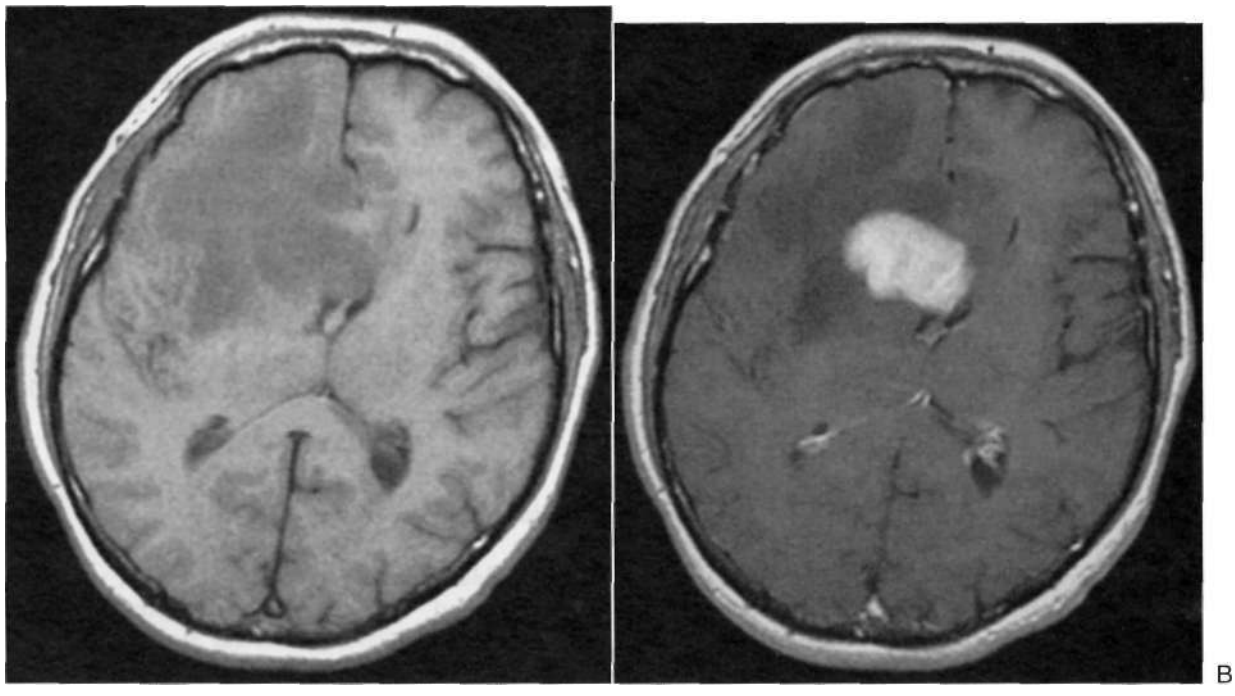

FIGURE 58D.10 Primary central nervous system lymphoma. TIWI before gadolinium (A) shows a single, minimally hypointense mass lesion in the region of the right caudate head, producing marked midline shift and subfaleine herniation in a 65-year-old man with 3 weeks of progressive cognitive changes and gait ataxia. There is strong, homogeneous contrast enhancement (H). On T2WI (C), the tumor is isointense to normal brain and is surrounded by a large area of vasogenic edema. Markedly abnormal diffusion is seen on diffusion-weighted images (D), suggesting high cell density.

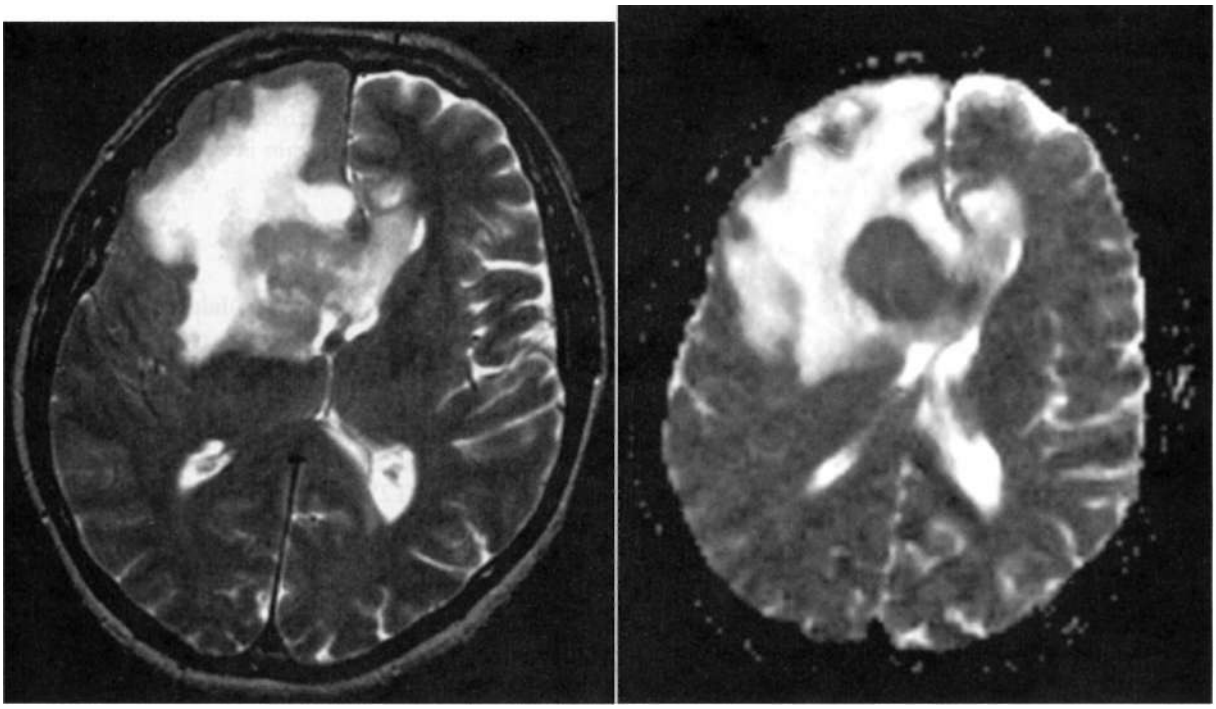

FIGURE 58D.10, cont'd.

extraventricular supratentorial tumors are less common. These lesions expand the fourth ventricle (Kleihues and Cavenee 2000). They are well circumscribed and show variable amounts of enhancement. The risk of leptomcningeal spread requires spinal imaging as part of staging.

Subependymoma

Subependymomas arise as a nodular mass lesion along the ventricular surface in middle to late adulthood, usually along the floor of the fourth ventricle (Kleihues and Cavenee 2000). Calcification and enhancement arc sometimes present. They are rarely symptomatic and the prognosis is excellent.

Juvenile Pilocytic Astrocytoma (Figure 58D.15)

Juvenile pilocytic astrocytoma (JPA) is a low-grade pilocytic astrocytoma of childhood. It usually arises as a cystic mass lesion with a mural nodule within the posterior fossa or the hypothalamic region. These tumors do not show aggressive growth or brain invasion (Kleihues and Cavenee 2000). The lesions arc hypointense on TIWI and hypcrintense on T2WI, and associated vasogenic edema is minimal. The cystic component may follow CSF signal. A nodule or mass lesion that shows strong, homogenous enhancement is present. Occasionally, tumors lack a cystic component.

Brainstem Glioma (Figure 58D.16)

Diffuse pontine astrocytomas are childhood tumors that enlarge the pons, show indistinct margins, and do not enhance. This type of brainstem glioma is the most common and has the poorest prognosis (Guillamo et al. 2001; Kleihues and Cavenee 2000). Cervicomedullary junction tumors are less common and grow more slowly. They are nonenhancing, well circumscribed, and have an exophytic component. The least common and most benign type of brainstem glioma is the tectal astrocytoma, a nonenhancing lesion that enlarges the tectal plate and produces obstructive hydrocephalus. Enhancement in a brainstem glioma usually indicates a high-grade tumor. In adults, brainstem gliomas may occur as low-grade, diffuse pontomedullary lesions, or as enhancing high-grade lesions.

Medulloblastoma (Figure 58D.17)

Medullobla stomas arc malignant cerebellar vermis tumors of childhood that have a pronounced tendency for leptomeningeal invasion. Peak age at diagnosis is 7 years. Adult mcdulloblastomas are much less common, and tend to arise in a lateral cerebellar hemisphere location. The fourth ventricle is compressed rather than expanded (Kleihues and Cavenee 2000). Medullobla stoma may be hypointense on T2WI and have abnormal diffusion due to high cell density (Tortori-Donati et al. 1996). They are rarely

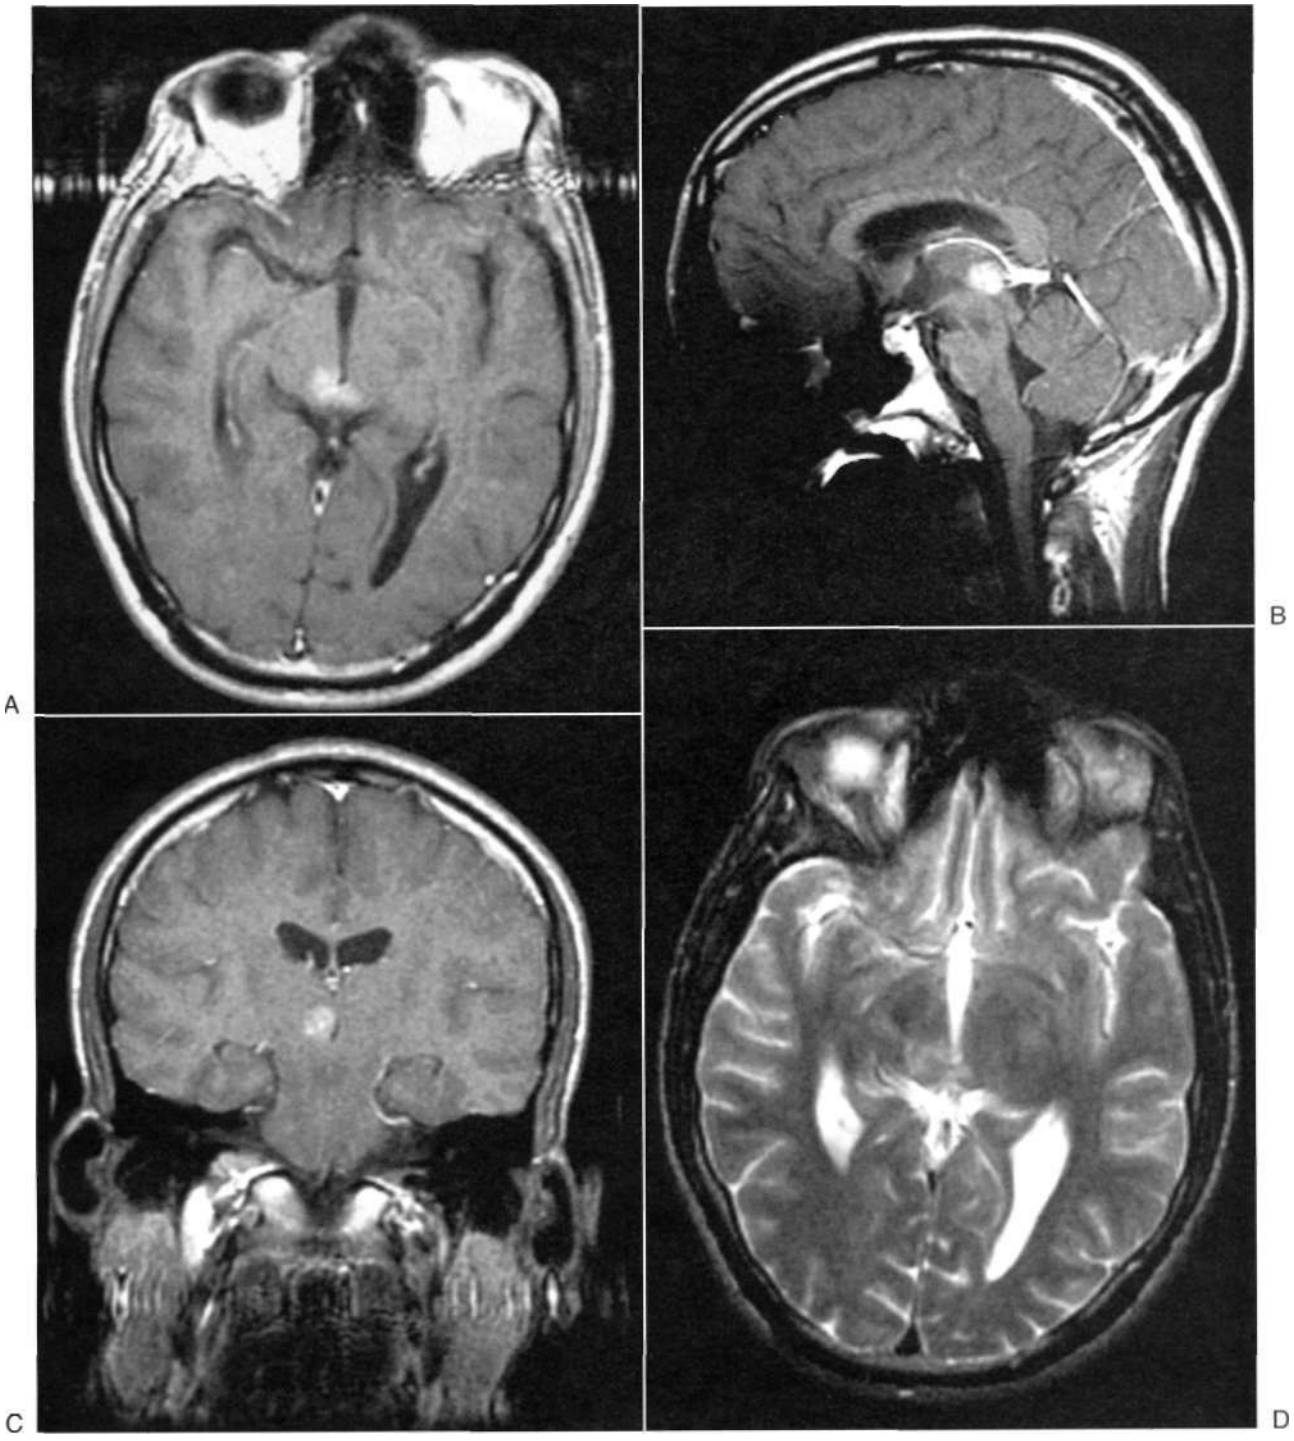

FIGURE 58D.11 I'ineal region germinoma. Gadolinium-enhanced T1WI (A, B, C) show a homogeneously enhancing lesion within the pineal region and walls of the posterior third ventricle in a 19-year-old man with 3 weeks of intermittent lightheadedness and vertical diplopia. There is invasion of the medial thalamic nuclei. On T2W1 (D), the tumor is mildly hyperintense.

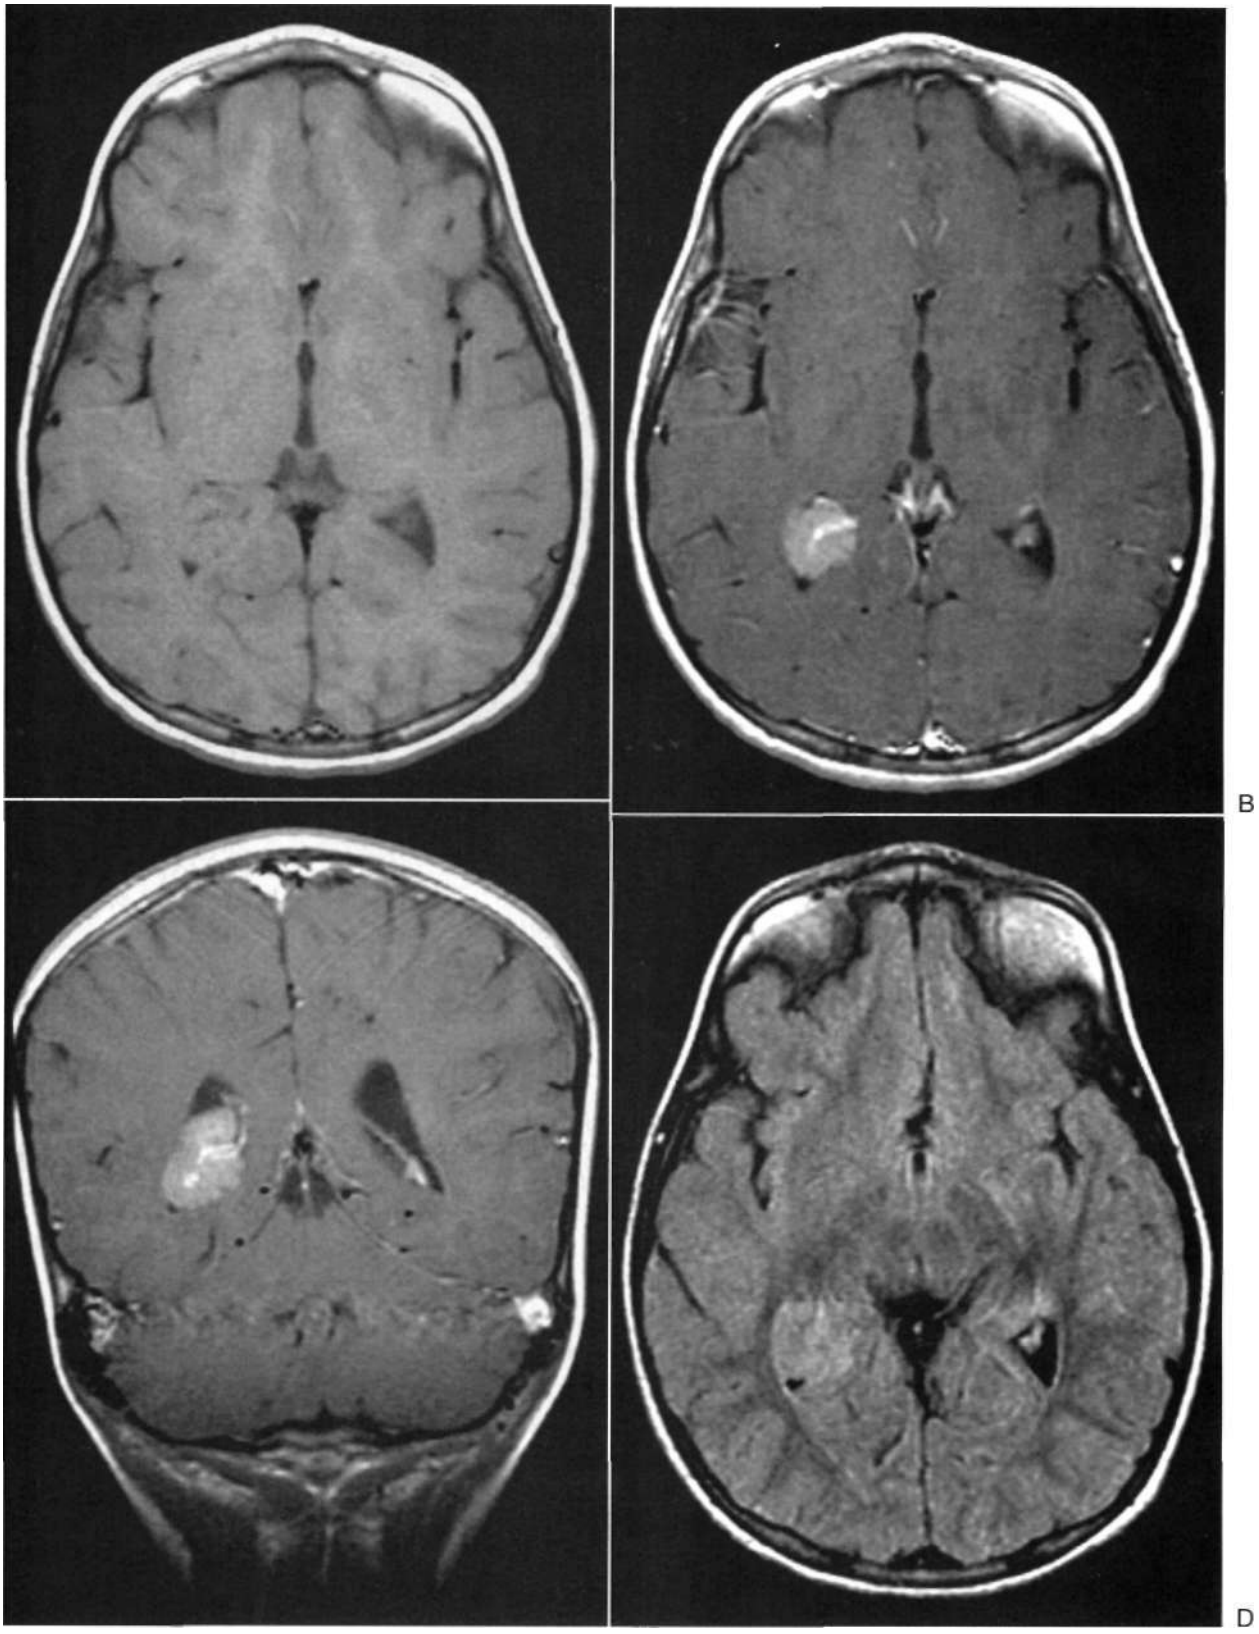

FIGURE 58D.12 Choroid plexus papilloma. T1WI before gadolinium (A) shows an isointense mass lesion within the trigone of the right lateral ventricle in an asymptomatic 4-year-old boy. The border of the lesion appears lobulated. There is homogenous enhancement (B, C). The tumor is mildly hyperintense on FLAIR (D). There is no evidence of brain invasion, vasogenic edema, or hydrocephalus. These tumors are commonly associated with hydrocephalus,

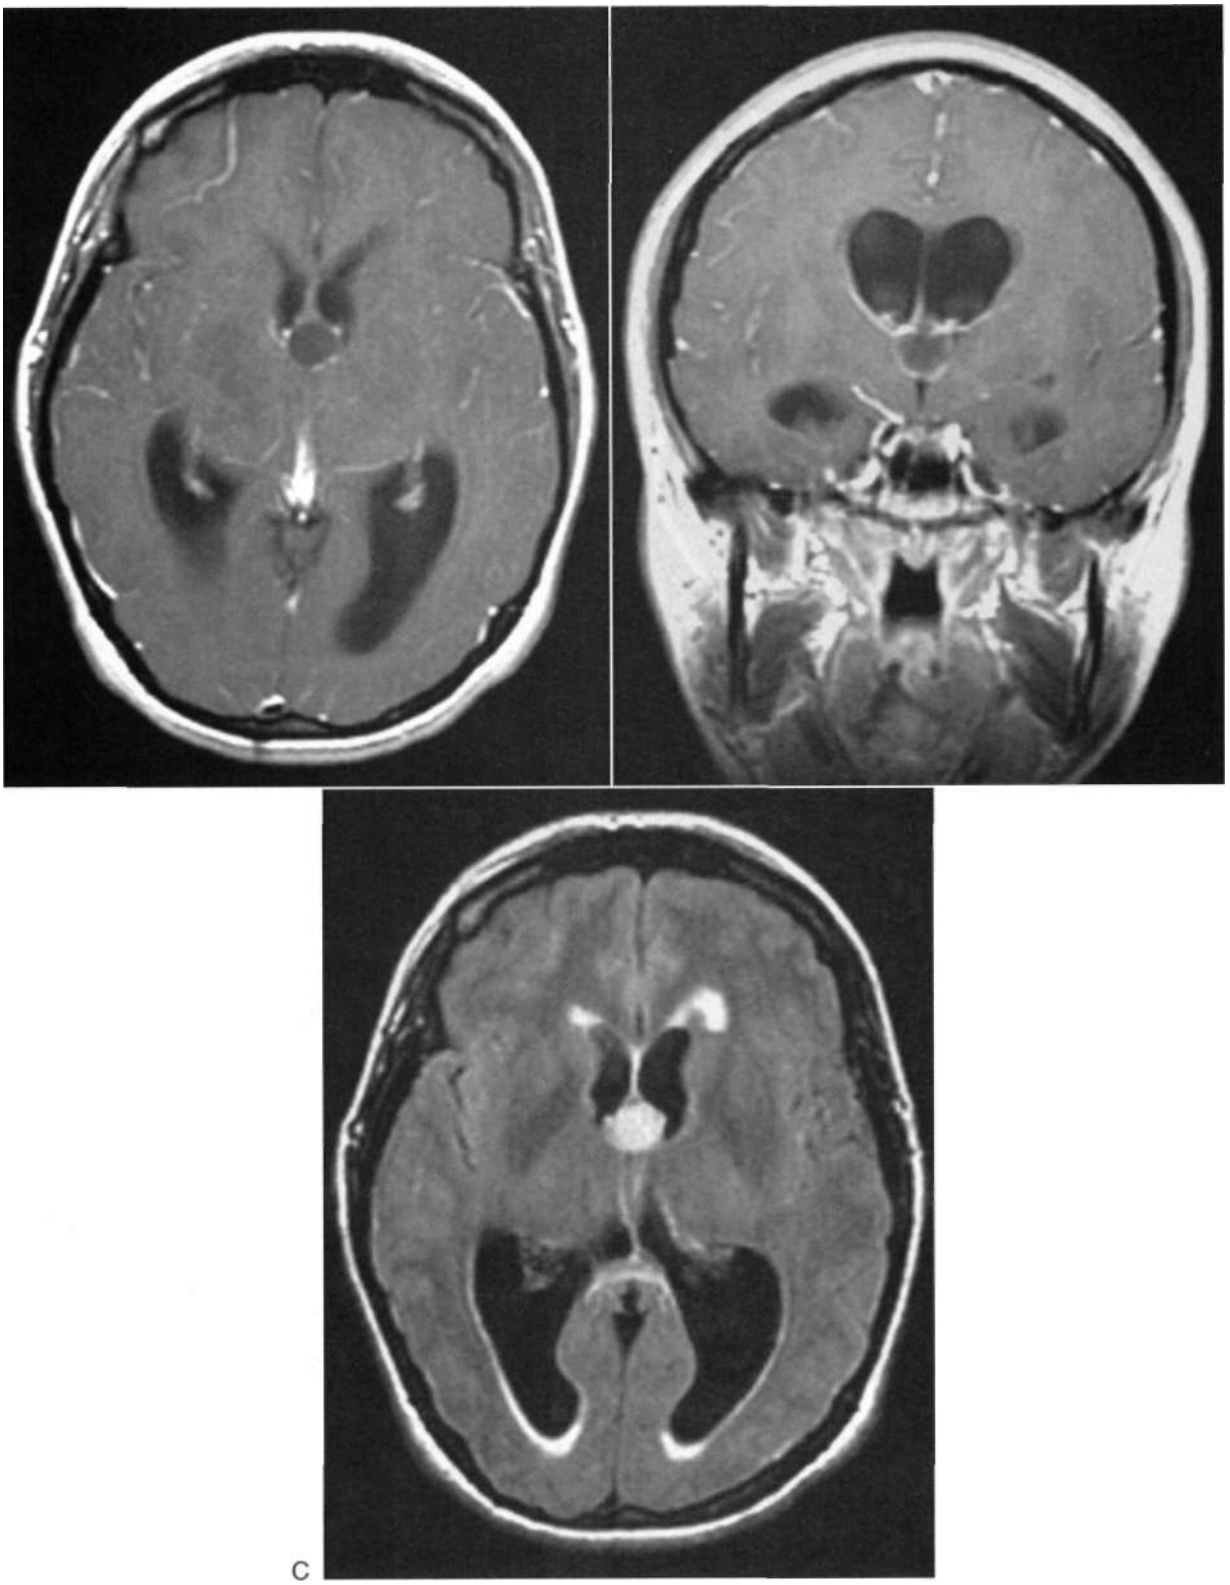

FIGURE 58D.13 Colloid cyst. A spherical, centrally hypo in tense structure with mild peripheral enhancement is present in the region of the foramen of Monro on the gadolinium-enhanced axial (A) and coronal (B) TIWI of a 35-year-old woman with 2 weeks of severe headache, nausea, and vomiting. The lateral ventricles arc dilated. The lesion is hyper in tense on an axial Fl.AIR image (C). TIWI and T2W1 signal intensities of colloid cysts are variable, depending on the concentrations of protein and cholesterol.

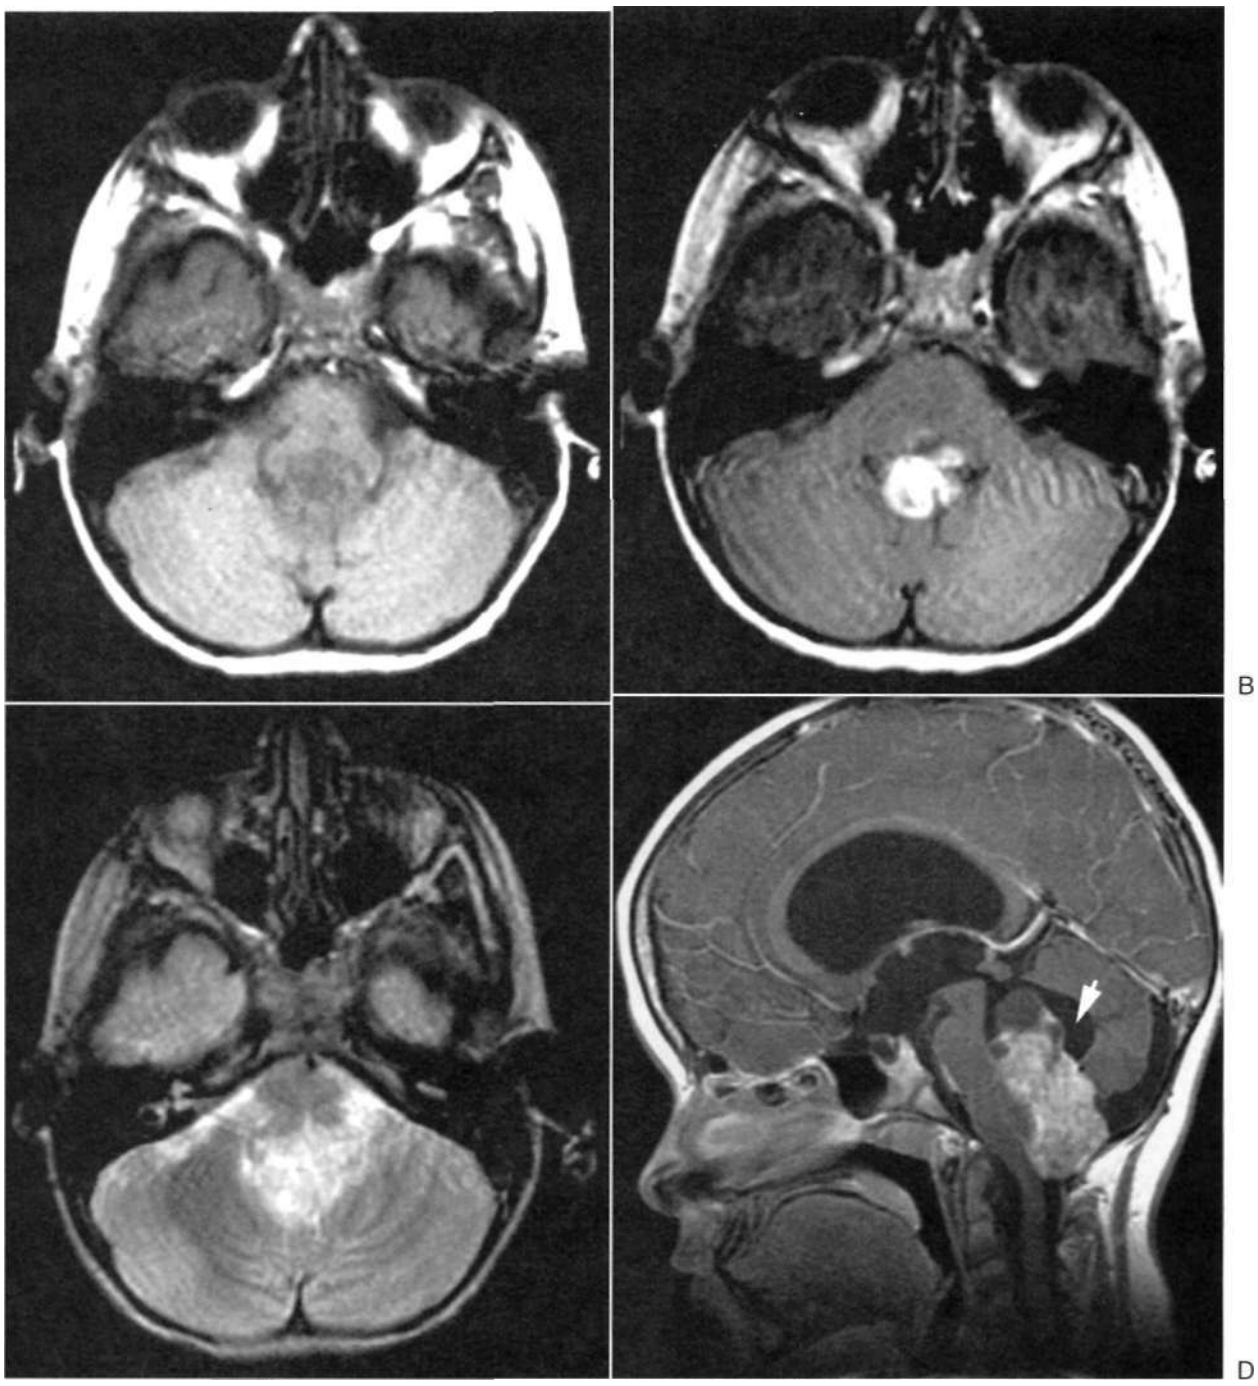

FIGURE 58D.14 Ependymoma. TIWI (A) shows a hypointense mass lesion within the fourth ventricle with well-circumscribed margins in a 5-year-old boy with a 5-month history of worsening nausea and vomiting. After gadolinium (B), the lesion shows strong enhancement. On T2WI (C) the lesion shows heterogeneous hyperintensity compared with brain. A sagittal, gadolinium-enhanced TIWI (D) in another patient with ependymoma clearly demonstrates expansion and filling of the fourth ventricle *(arrow).*

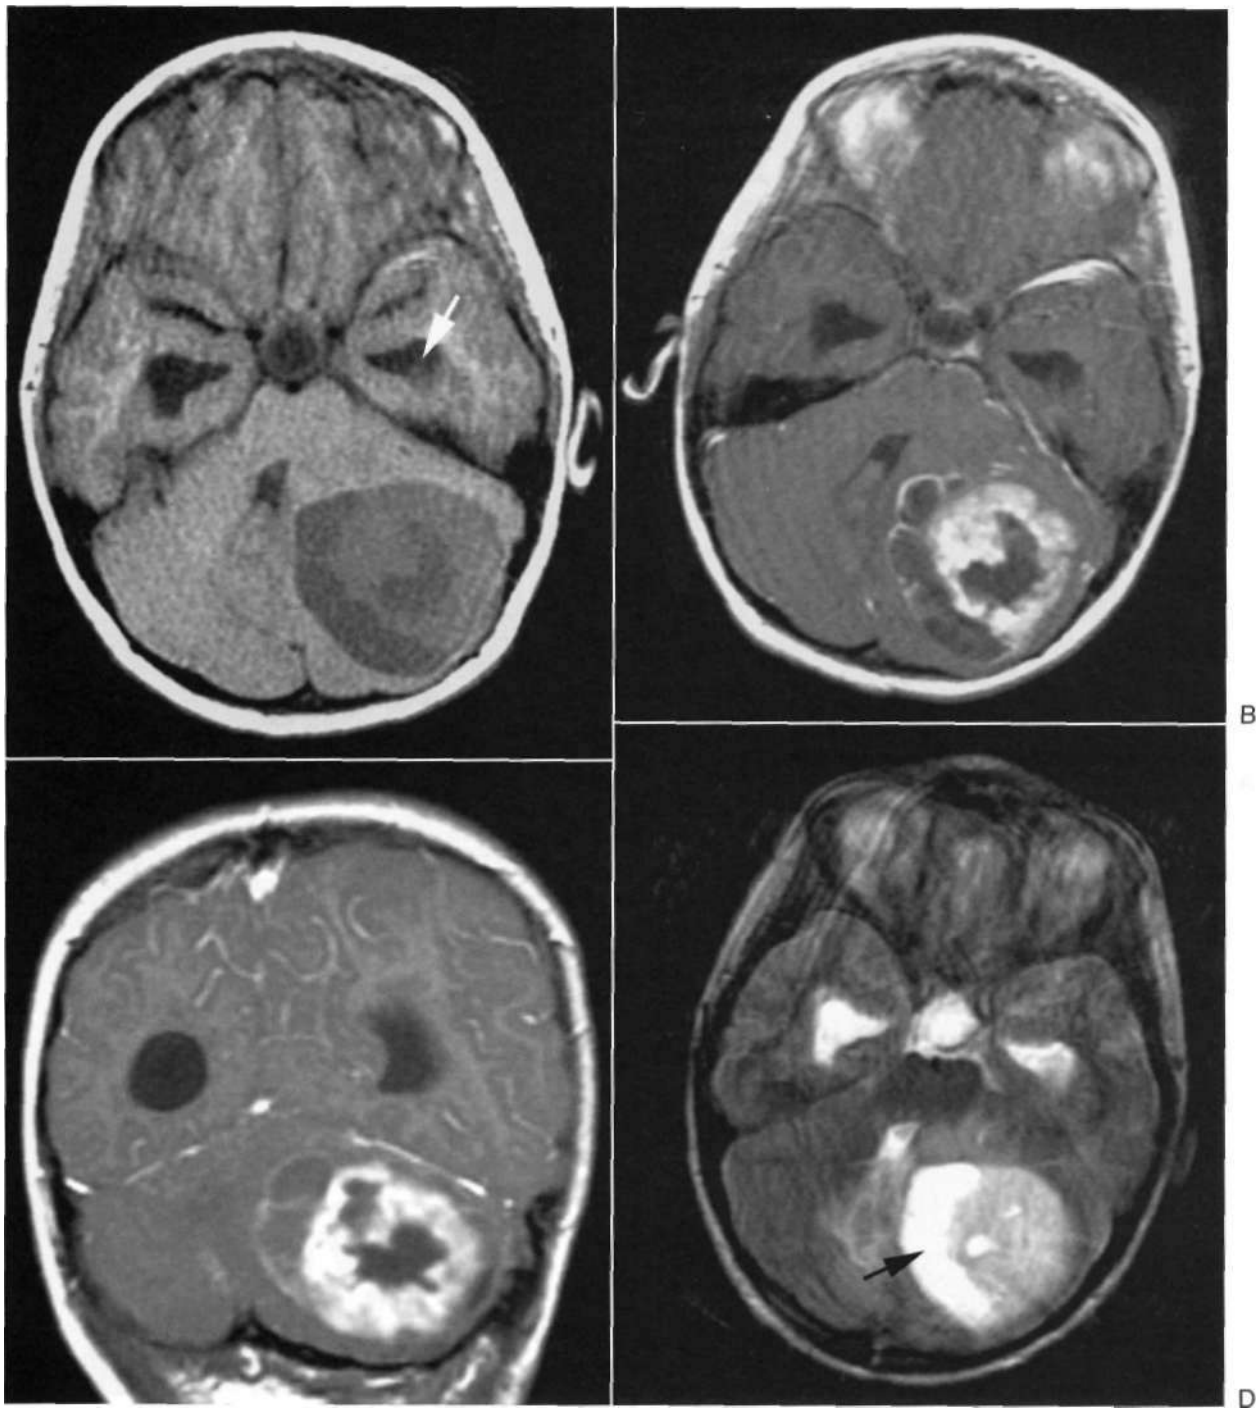

FIGURE 58D.15 Juvenile pilocytic astrocytoma. An 8-year-old child had a 7-month history of progressive headache and clumsiness. Axial **T1WI** before gadolinium (A) shows a we 11-circumscribed, hypointense lesion with internal signal heterogeneity in the left cerebellar hemisphere. There is compression of the fourth ventricle and dilation of the temporal horns of the lateral ventricles *[arrow).* Irregular ring enhancement is seen after administration of gadolinium on axial (B) and coronal (C) T1WI. There is thin, smooth enhancement of the medial, multicystic appearing structures. On T2WI (D), the bulk of the tumor (lateral aspect of the mass) is mildly hyperintense to brain. The medial, cystic areas are markedly hyperintense *[arrow),*

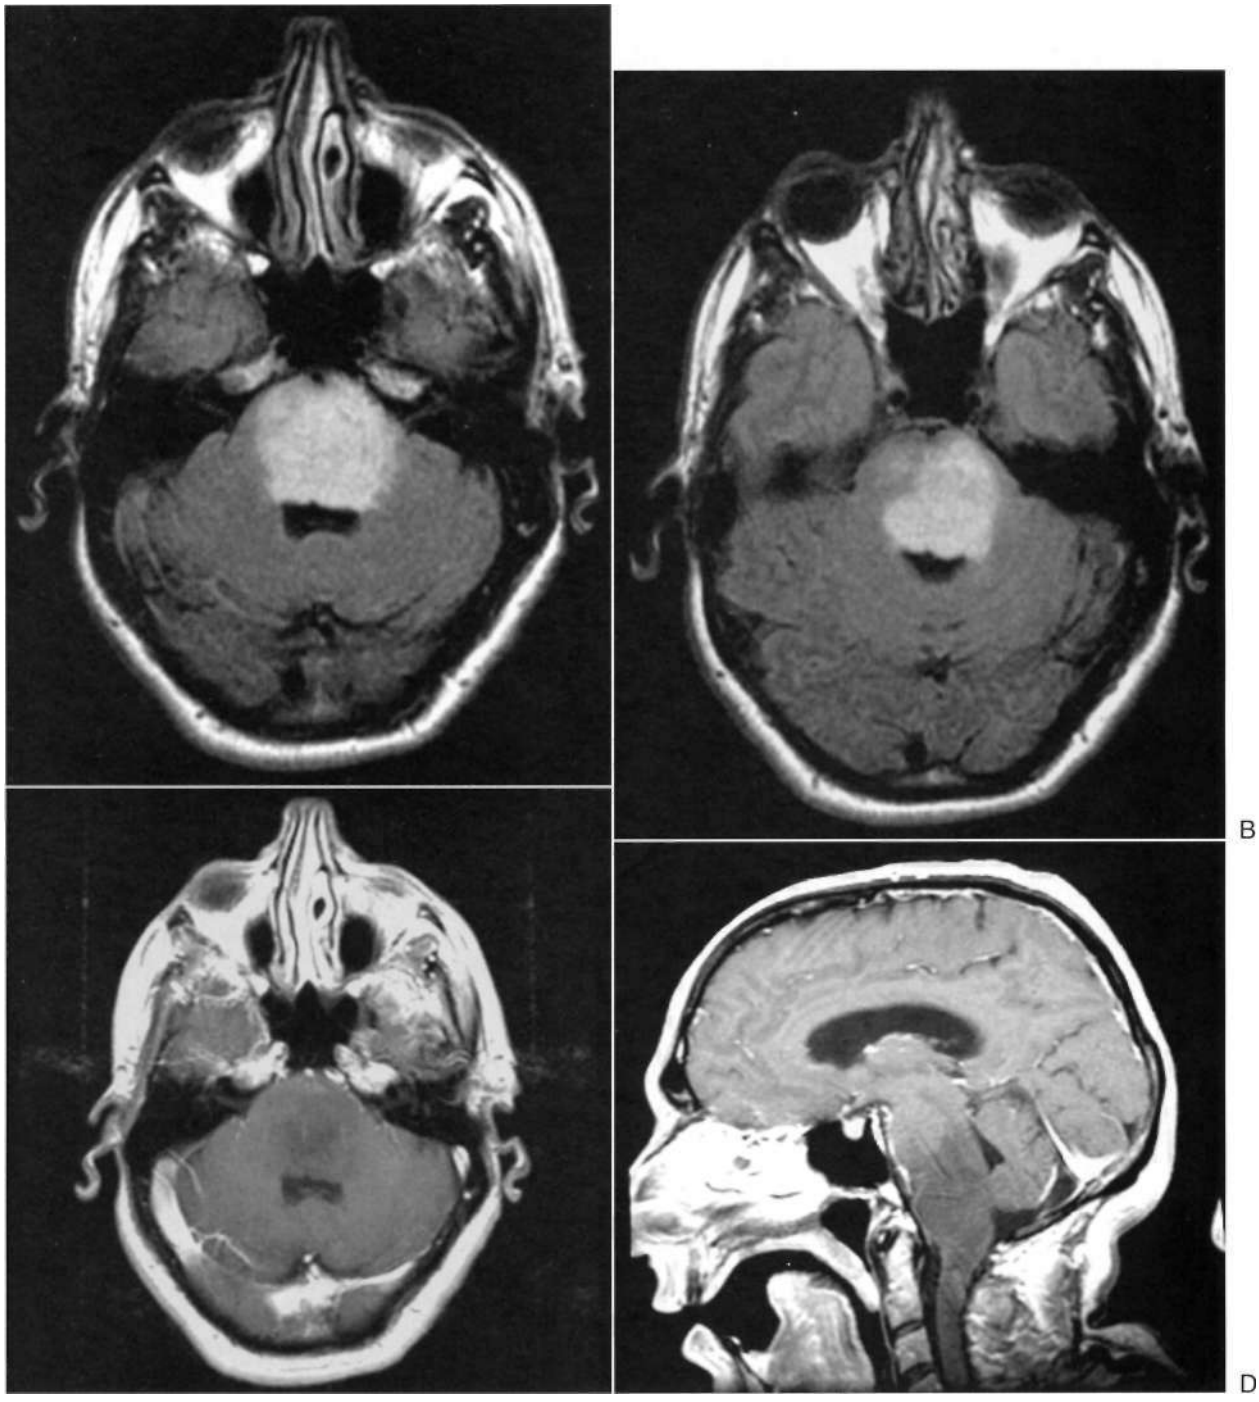

FIGURE 58D.16 Brainstem glioma. A T2 hypcrititcnsc mass lesion with ill-defined margins is seen to expand **the** pons on serial axial FLAIR images I A, B) in a 54-year-old **man** with a 2-month history of progressive gait ataxia *i\i\d* slurred speech. After administration of gadolinium, there is no evidence of enhancement on axial (C) or saginal (D) TIWI within the pontomedullary tumor.

nonenhancing. Gadolinium-enhanced spinal imaging is important for staging.

Hemangioblastoma (Figure 58D.18)

Hem a ngi obi a stomas arc cystic tumors with a mural nodule that occur in the posterior fossa and spinal cord. When multiple, these tumors arc associated with von Hippcl-I.indau disease, an autosomal dominant trait (Kleihucs and Cavenee 2000). The cystic component usually follows CSF signal, and an associated enhancing tumor nodule or mass lesion is present (Conway et al. 2001). Hemorrhage is rare, even on susceptibility images. Lesions may enlarge after years of quiescence, and new lesions may appear, necessitating life-long surveillance.

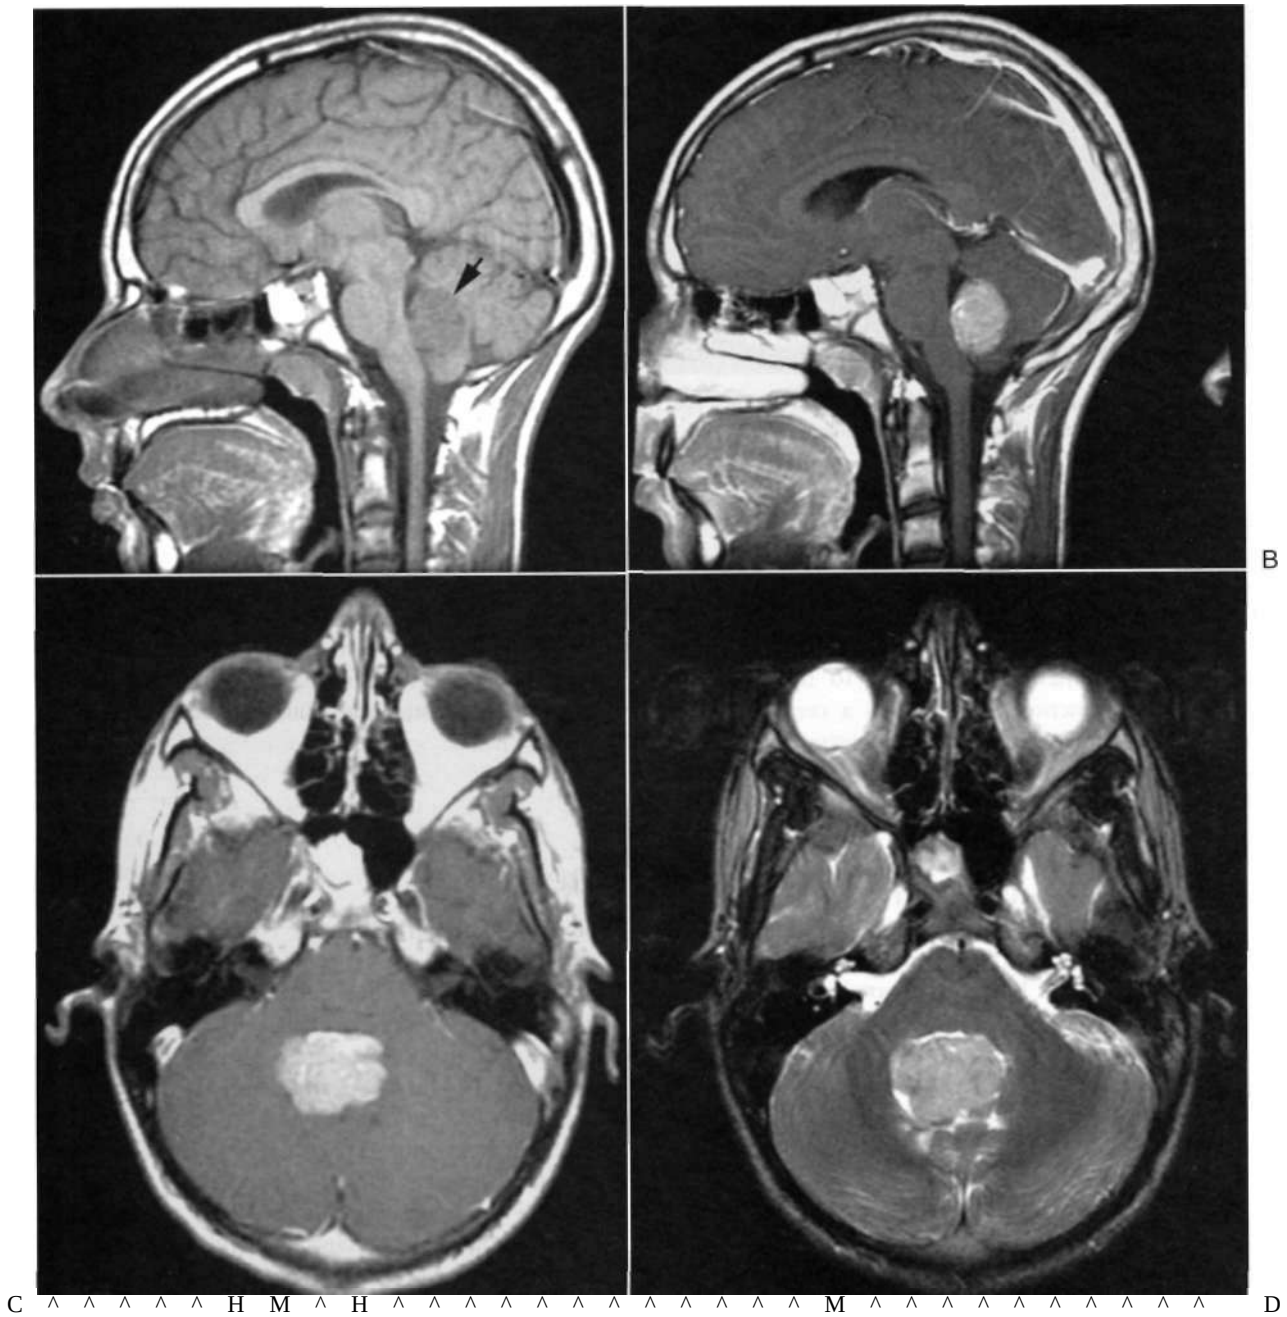

FIGURE **58D.17** Medulloblastoma, Sagittal T1WI (A) before contrast administration demonstrates a well-demarcated, hypomrense mass lesion *(arrow)* expanding the fourth ventricle in a 15-year-old boy who had a 2-week history of gait ataxia, nausea, and vomiting. There is moderate heterogeneous gadolinium enhancement (B, C). The tumor is slightly hypetintense on T2WI (D).

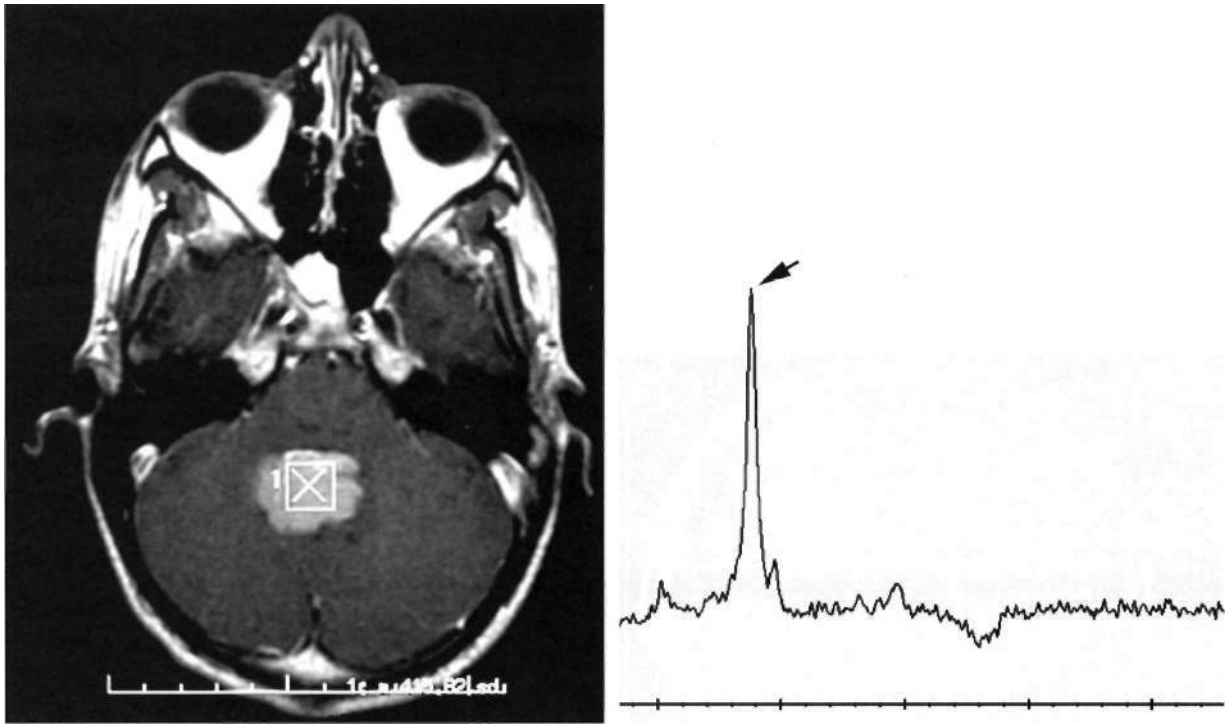

FIGURE 58D.17, cont'd. Single-voxel magnetic resonance spectroscopy (E, F) shows high choline *(arrow),* extreme elevation of the choline/creatine ratio, and absence of N-acetyl aspartate.

Lhermitte-Duclos' Disease (Figure 58D.19)

Dysplastic cerebellar gangliocyroma, or Lhermitte-Duclos' (LD) disease, is a hamartoma of neuronal cells rather than a true neoplasm (Kleihues and Cavenee 2000). LD disease comes to clinical attention secondary to hydrocephalus or cerebellar dysfunction. MRI shows a cerebellar mass lesion, without evidence of contrast enhancement, or vasogenic edema. A characteristic linear striated appearance on T2WI is characteristic (Klisch et al. 2001).

Vestibular Schwannoma (Figure 58D.20)

Vestibular schwannoma (VS) may occur as unilateral, sporadic tumors or as bilateral tumors as part of NF2 (Kleihues and Cavenee 2000). Schwannomas are mildly hypointense on T1WI, show heterogeneous, mild hyperintensity on T2WI, and have strong, heterogeneous enhancement (Somers et al. 2001). Cystic changes may occur.

Epidermoid

Epidermoids and dermoids are ectodermal heterotopias rather than neoplastic masses. Epidermoids usually arise in the cerebellopontine angle; a parasellar location is next most common. Dermoids are midline in location and contain fat. Epidermoids often come to attention as a result of cranial nerve dysfunction as the cyst gradually enlarges (Kleihues and Cavenee 2000). The cyst follows CSF intensity on T1WI and T2WI, but may be hyperintense to CSF on FLAIR images. Importantly, diffusion-weighted images show very hyperintense signal, permitting easy distinction from an arachnoid cyst (Annet et al. 2002).

OTHER TUMORS

Meningiomas (Figure 58D.21)

Meningiomas arise from the leptomeninges, and therefore may occur in supra tentorial, infratemorial, or spinal locations. Rarely, these tumors occur along the optic nerve sheath or within the trigone of the lateral ventricle, where they arise from meningothelial cells in the choroid plexus (Kleihues and Cavenee 2000). Meningiomas are dural-based mass lesions, which are relatively isointense to brain on T1WI and T2WI and demonstrate strong, homogeneous enhancement (Nakano et al. 2002). The amount of vasogenic edema in the adjacent brain is variable. Dural tails, when seen, are a nonspecific characteristic of many dural-based tumors. Calcification is common. Brain invasion suggests a malignant meningioma.

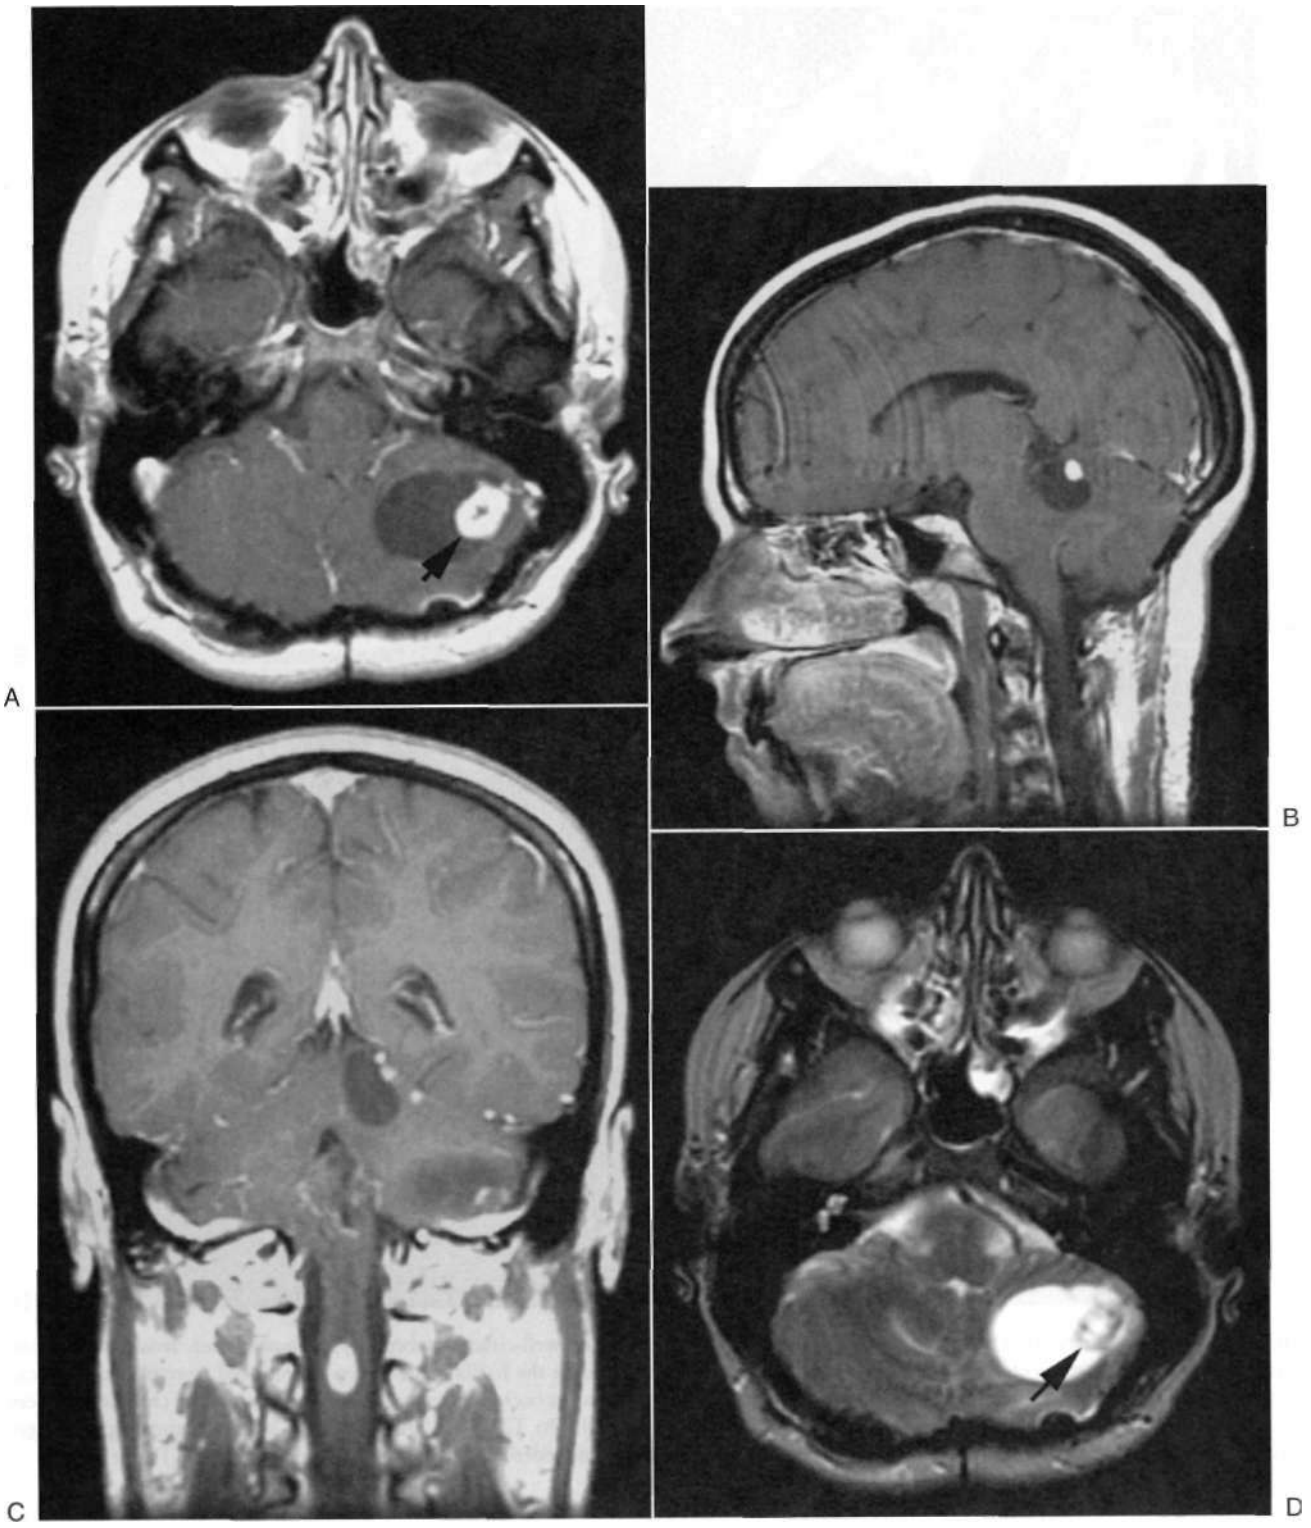

FIGURE 58D.18 Hemaneioblasroma. Gadolinium-enhanced TlWl (A, B, C) show multiple cystic lesions within the cerebellum and cervical spinal cord, with associated nodules *(arrow)* of densely enhancing hemangioblastoma, in a 35-year-old woman with *1* weeks of severe headache and a history of von HippeHJndau disease. There is minimal enhancement of the cyst walls. A T2W1 (D) shows the mural nodule *(arrow)* is heterogeneous in signal intensity.

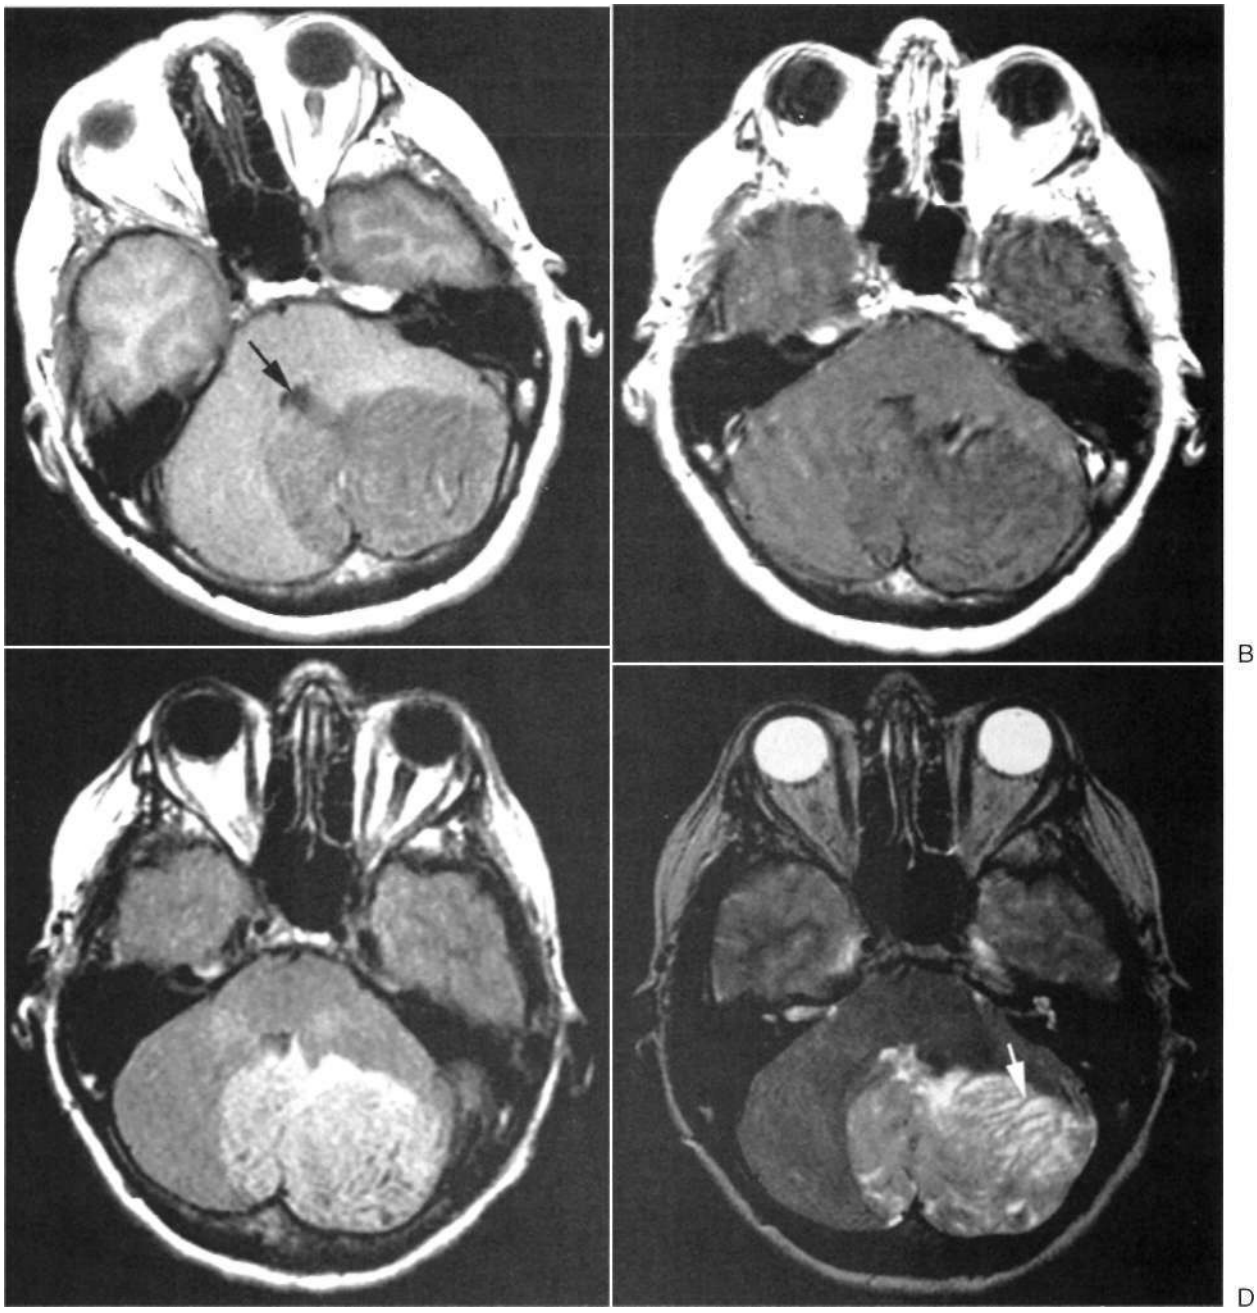

FIGURE 58D.19 Lhcrmitte-Duclos' disease. T1WI (A) shows a large, well-circumscribed, hypo intense mass lesion within the cerebellum, producing mass effect on the fourth ventricle *(arrow)* and effacing the basilar cistern in a 52-year-old woman with a 2-ycar history of gait difficulty. Linear foci of hypoiutcnsity arc seen, and the adjacent occipital bone is remodeled, suggesting chronicity. There is no evidence of enhancement after administration of gadolinium (B, C). On T2WI (D) there is linear heterogeneous signal ("tiger stripes") within the mass *[arrow*), but no evidence of surrounding vasogenic edema. Calcification was detected on CT (not shown},

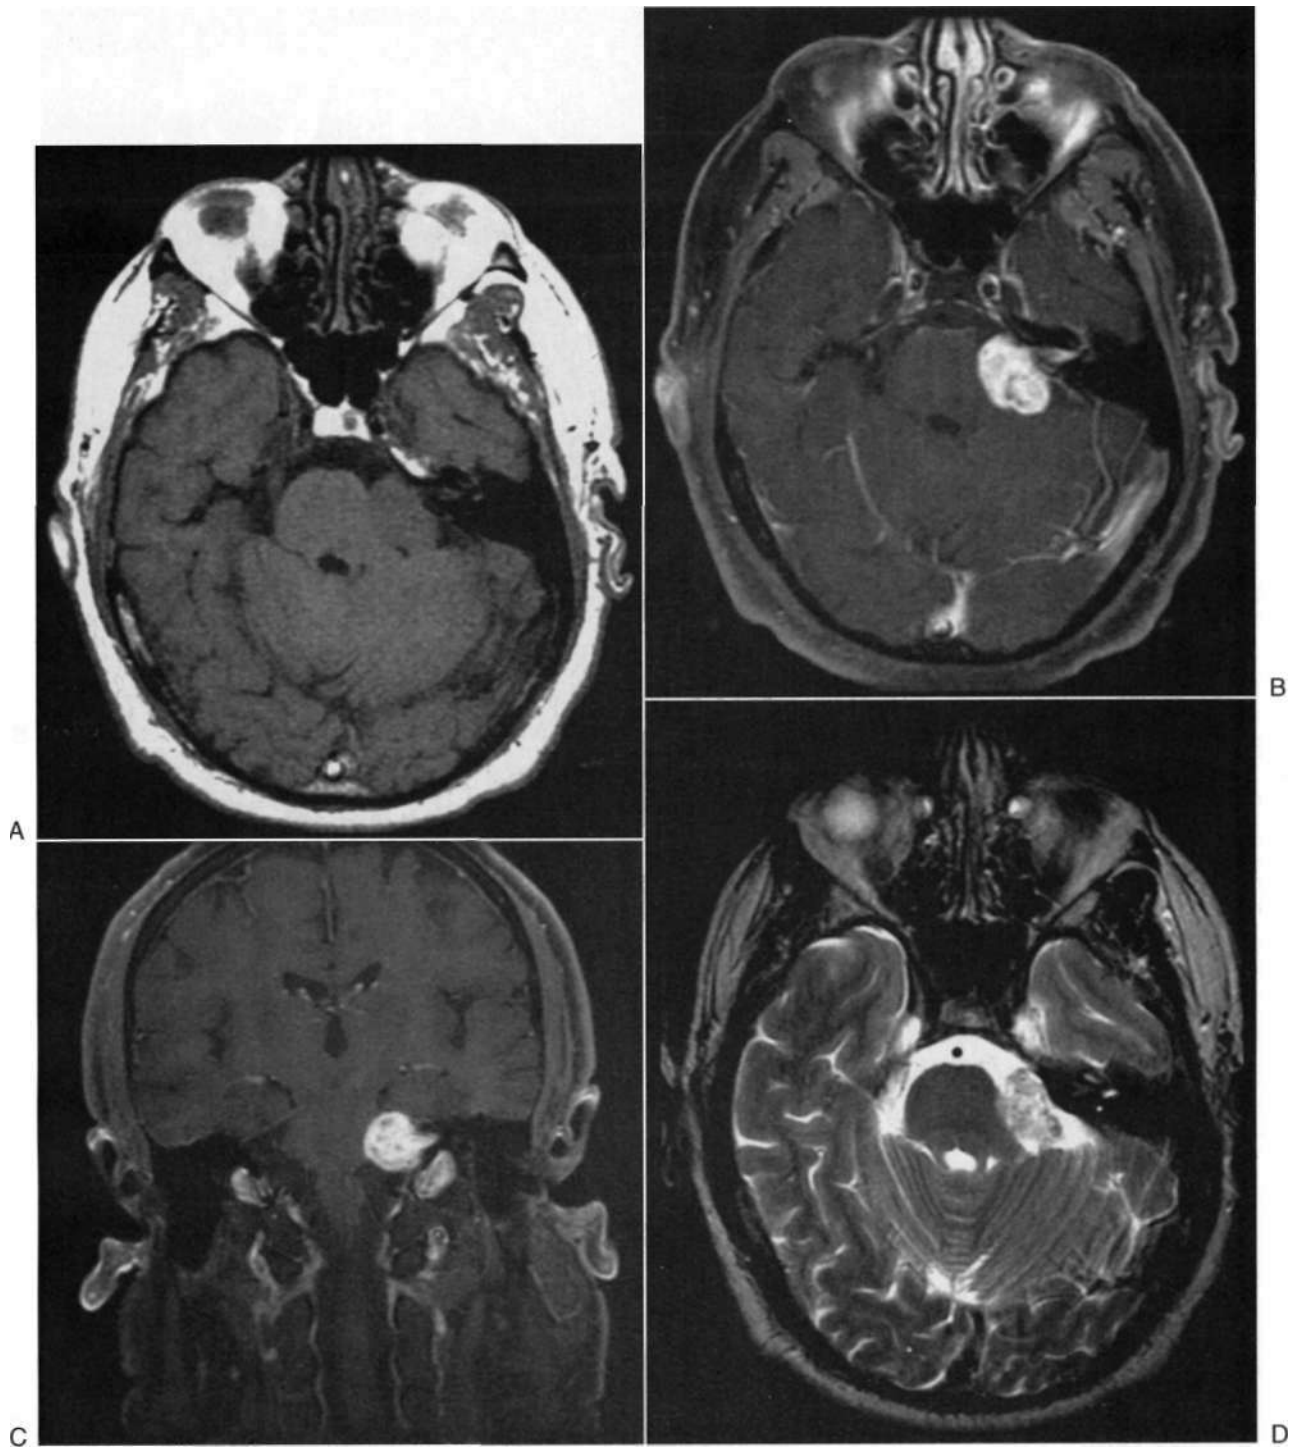
Pituitary Adenoma (Figure 58D.22)

Pituitary adenomas are slow-growing tumors of the adenohypophysis. They are located within the gland, disrrihuted in accordance with the normal cells from which they arise. Prolactinoma (lateral location) and non-functioning tumors comprise more than one half of cases. Thyroid-stimulating hormone-producing tumors arc the least common. Microadenomas, defined as less than 10 mm in greatest diameter, arc much more common than are macroadenomas. Endocrine dysfunction is the usual presentation. Macroadenomas (10 mm or larger) produce symptoms from compression of parasellar structures. Onset is at all ages. Microadenomas show subtle

Tex! continued on p. 1399



FIGURF 58D.20 Vestibular schwannoma. T1W1 (A) shows an isointcnsc mass lesion within the left cerebellopontine angle, with mass effect on the adjacent brainstem and middle cerebellar peduncle and extension into **the** left internal auditory canal in a 58-year-old man who had a several-year history of hearing loss and tinnitus in the left ear. The tumor demonstrates heterogeneous gadolinium enhancement (B, C). T2WI (D) shows heterogeneous signal intensity. Vestibular schwannomas often show cystic changes, and may-occasional ly calcify.

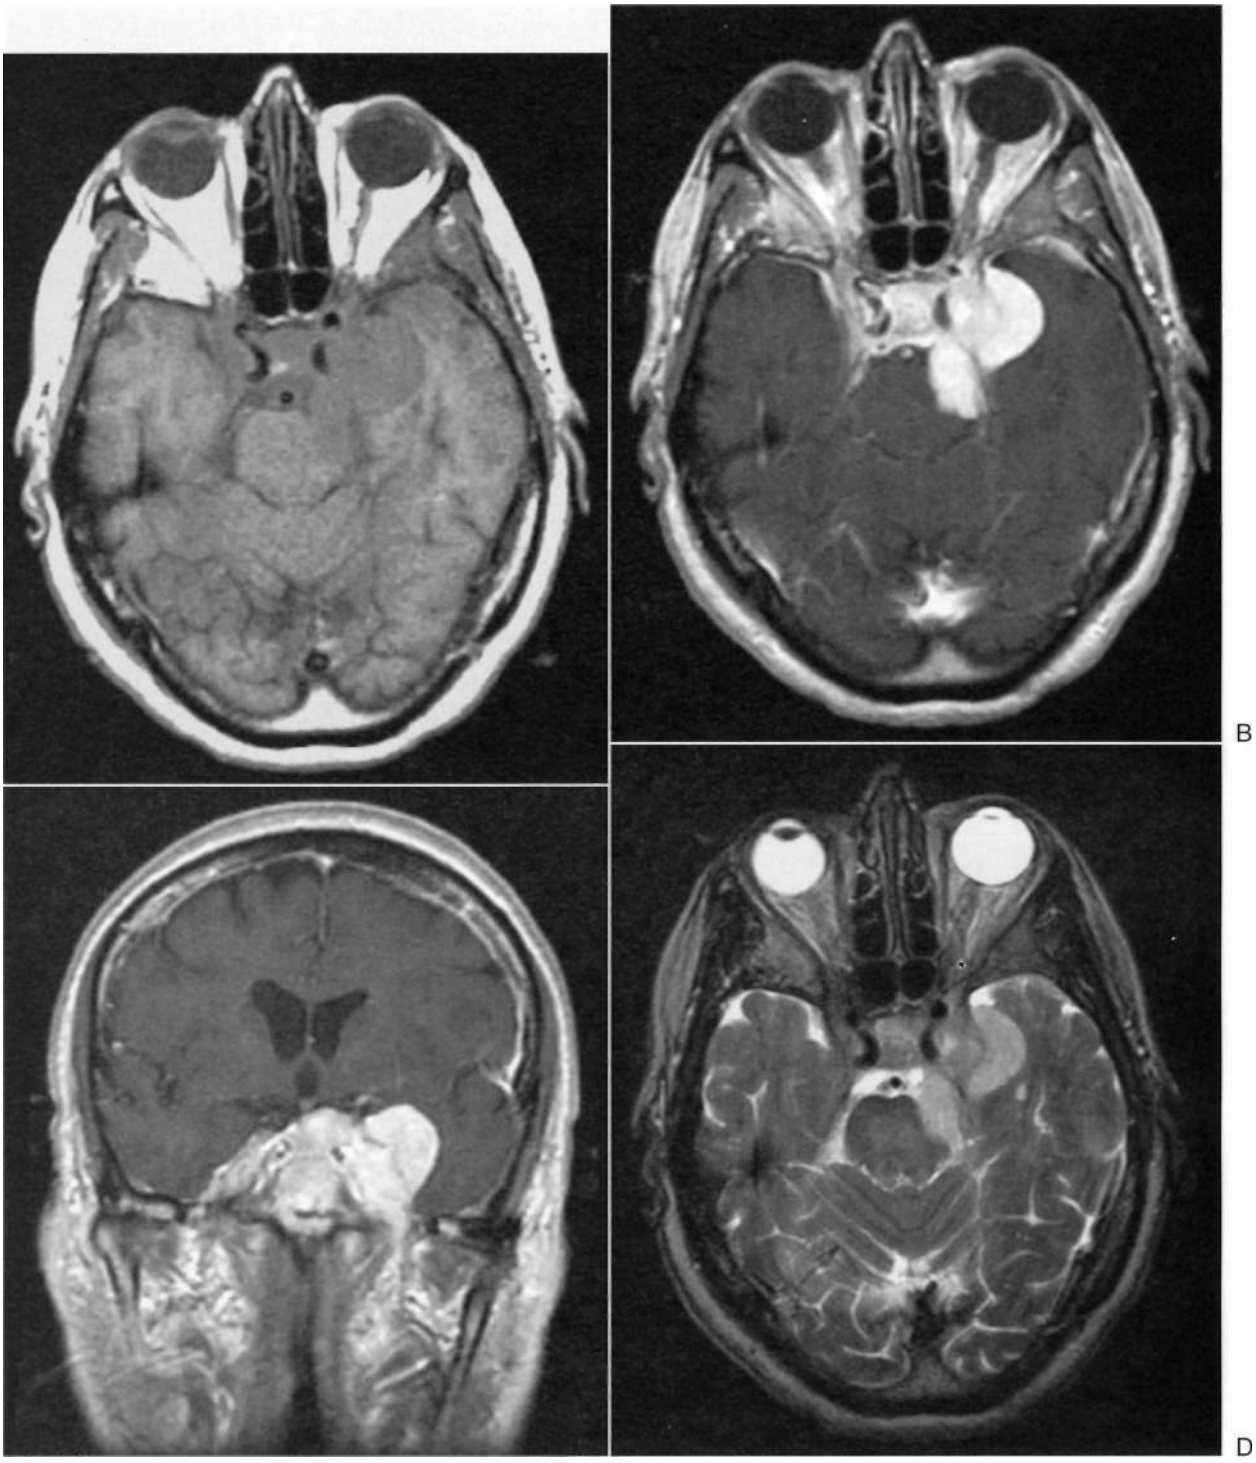


FIGURE 58D.21 Meningioma. A **TIWI** shows an isointense mass lesion, centered in the left cavernous sinus (A), with extension into the sella, right cavernous sinus, and middle cranial fossa and posterior fossa in a 77-year-old woman with a 2-year history of diplopia. There is mass effect on adjacent brain without evidence of brain invasion. Homogeneous enhancement is seen after gadolinium administration (B, C). There may be extension into the left foramen of ovale, and vascular structures are encased. Dural tails are present. The mass is mildly hyperintense to brain on T2W1 (D).

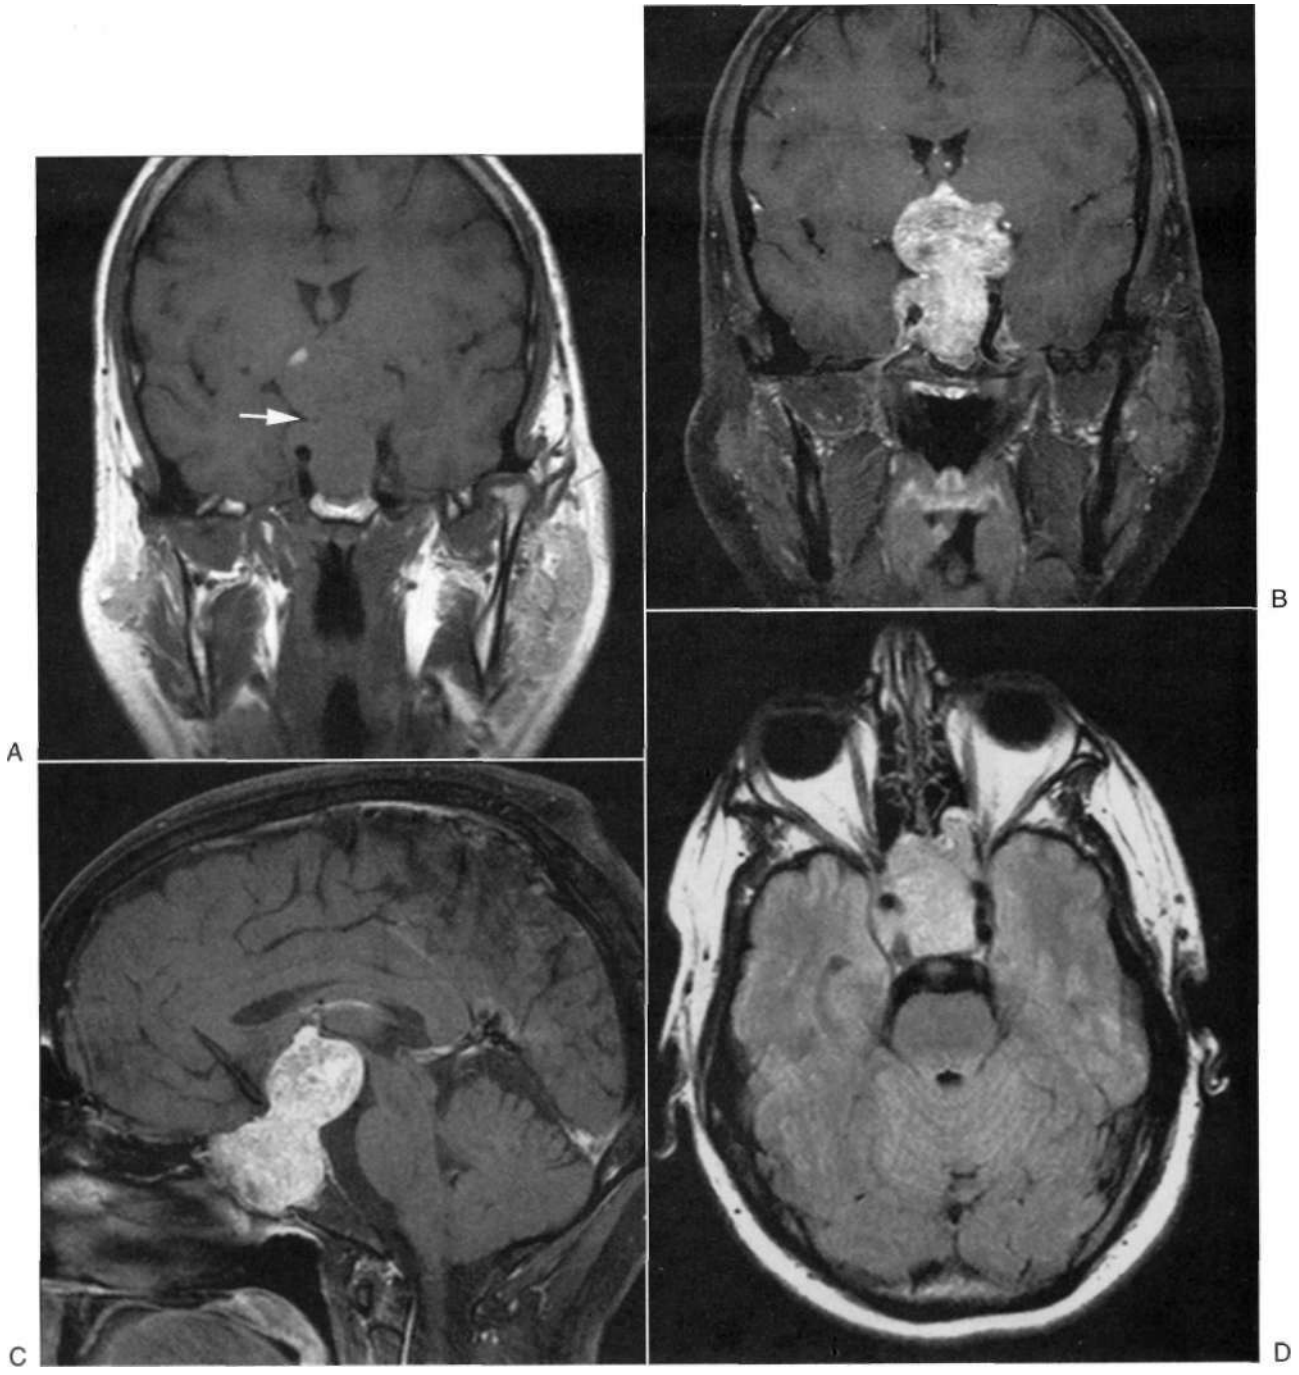

FIGURE 58D.22 Pituitary microadenoma. A ITWl (A) demonstrates a large, isointense mass lesion expanding the sella turcica and filling the suprasellar cistern in an asymptomatic 42-year-old man who participated in a magnetic resonance imaging study. The tumor is constricted into a waistline by the diaphragma sella *(arrow).* There is heterogeneous enhancement after administration of gadolinium (B, C). There is mass effect on the floor of the third ventricle and encasement of the left internal carotid artery. The optic chiasm is deviated superiorly. FLAIR (D) shows the lesion to he isointense to brain.

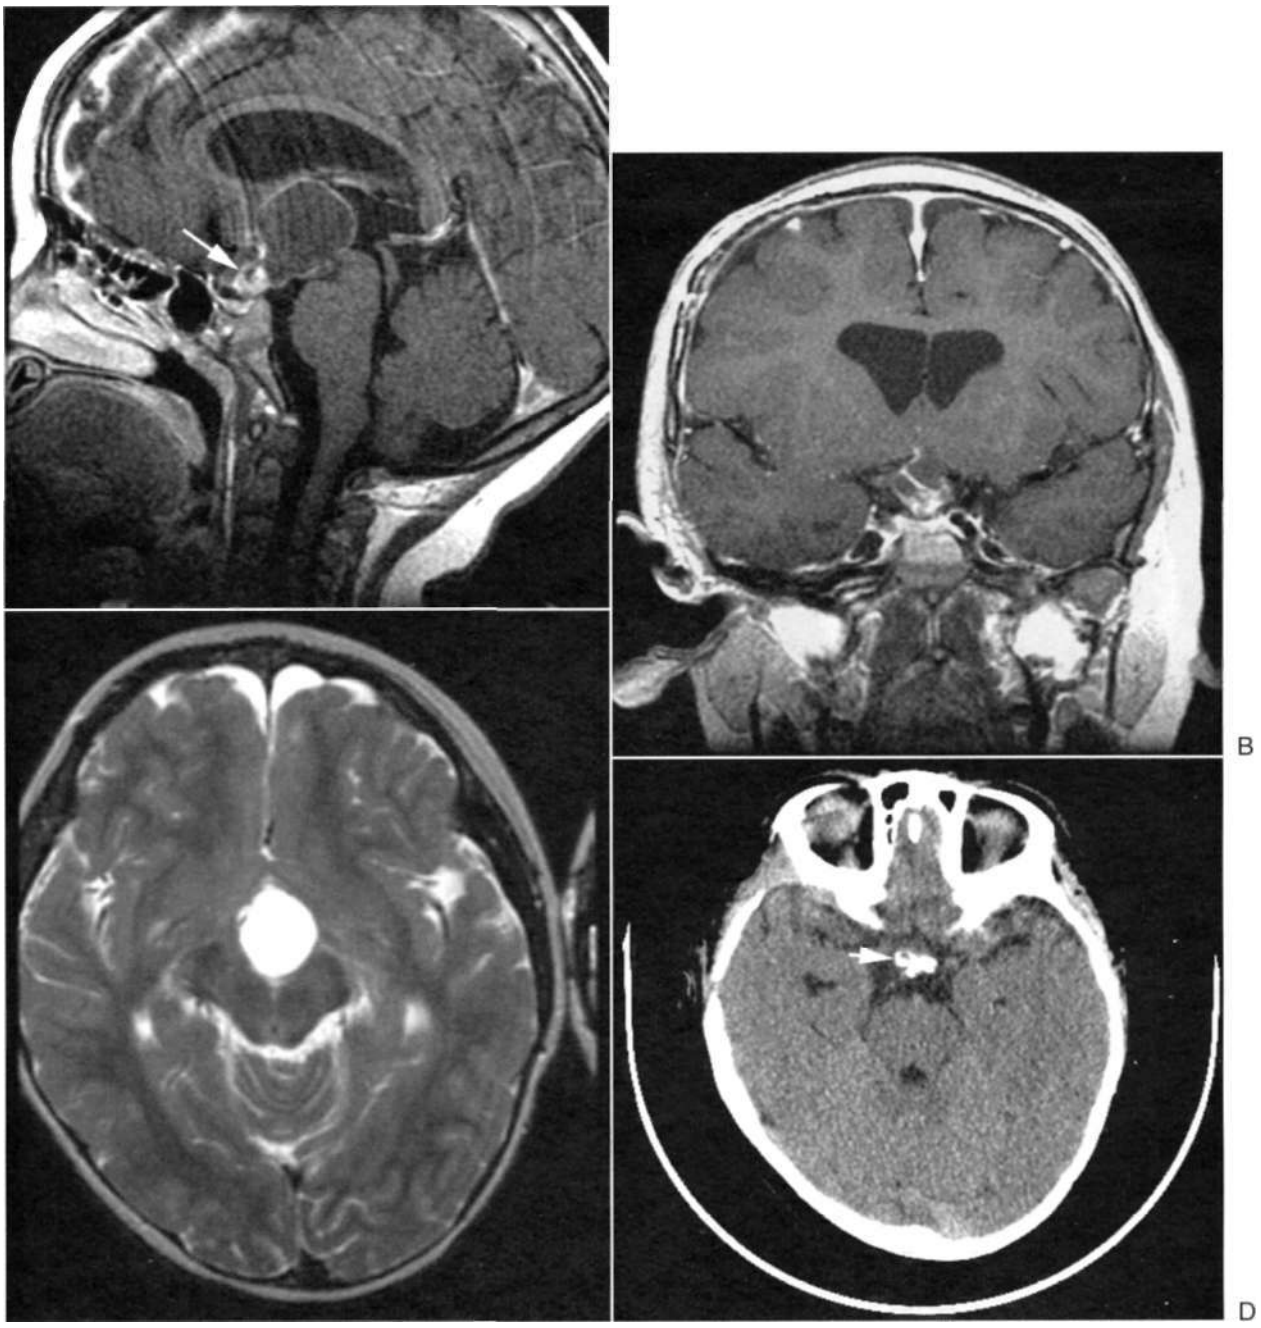

FIGURE 58D.23 Suprasellar adamantinomatous craniopharyngioma. Gadolinium-enhanced T1WI (A, B} show a mass lesion within the suprasellar cistern that has an inferior, enhancing, nodular component *(arrow)* and a superior, cystic-appearing structure that produces mass effect on the floor of the third ventricle. The patient was a 4-year-old boy with headache, lethargy, and vomiting. The cyst has a smooth rim of peripheral enhancement. T2WI (C) shows marked hyperintensity in the cystic component. There is dense calcification in the region of the enhancing nodule *(arrow)* on CT (D).

hypointensiry to the normal gland on TIWI (Rand et al. 1996). T2W1 are less sensitive. For a short interval after administration of gadolinium, adenomas enhance less than the normal gland. Indentation of the floor of the sella and deviation of the infundibulum are secondary evidence of tumor.

Craniopharyngioma (Figure 58D.23)

(iraninpliaryngioma arises as a suprasellar, cystic, epithelial tumor that may originate from Rathke's pouch (Kleihues and Cavenee 2000). The common form of craniopharyngioma, called *adamantinomatous craniopharyngioma,* arises in children, is located in the suprasellar cistern, and is calcified and cystic (Sartoretti-Schefer et al. 1997).

Chapter 58
Cancer and the Nervous System

E. MANAGEMENT OF PRIMARY NERVOUS SYSTEM TUMORS IN ADULTS

Joachim M. Baehring and Fred H. Hochberg

High-grade gliomas, which account for the majority of primary brain tumors diagnosed each year in the United States, carry a grim prognosis. Most patients with glioblastoma multiforme die within 1 year of diagnosis. The exceptions are younger patients with completely resectable tumors and minimal neurological dysfunction. Despite the provision of radiation therapy and chemotherapy as adjuvant treatment, fewer than 10% of patients are alive 2 years after diagnosis. Because these tumors are rare and therapies complicated to perform, muchofthe burden of patient care has shitted from the general oncntogisi and ncurologisl to tertiary centers with collaboration among radiation oncologists, neurosurgeons and neuro-oncologists. These specialists often provide novel therapies under the sponsorship of the National Cancer Institute as part of collaborative brain tumor programs such as the New Approaches to Brain Tumor Therapy consortium, the North American Brain Tumor Consortium, the Pediatric Brain Tumor Consortium, or the Radiation Therapy Oncology Group.

Novel approaches to therapy have been designed to address issues specific to brain tumors. The blood-brain barrier (BBB) prevents access to the brain by hydrophilic chemotherapeutic agents and large molecules. Cells of brain tumors arc uniquely able to resist chemotherapeutic agents by overexpressing membrane proteins that eliminate these drugs or by inducing enzymes to inactivate them. Even when drugs enter brain tumors, not all cells are sensitive. The hypoxic areas of tumors are in cell-cycle arrest and resistant to cell cycle-dependent agents ot radiation. Other factors confounding therapy include corticosteroids that alter the BBB penetration of drugs, the host immunologic reaction to the tumor, as well as the cytotoxic effects of chemotherapy. There is a cascade of molecular events that carry benign tumors toward malignancy; thus inhibition of a single pathway may not induce cell cycle arrest ot apoptosis. Despite these factors, there have been improvements in treatment. Surgical techniques have been refined and now allow the use of the operating microscope and intraoperative magnetic resonance imaging (MRI) to achieve microscopic decompression. Operative morbidity has been reduced by the performance of operations done with the patient awake and talking, with available intraopetative cortical stimulation and functional mapping or electroenccphalographic monitoring. Functional MRI or positron emission tomography (PET) studies provide precise delineation of speech or motor areas in proximity to tumors. As surgery has become more precise, so has radiation therapy. Highly focused external radiation

strategies have improved local tumor control with reduced damage to contiguous normal brain. Chemotherapy, long unproductive, now improves survival and function of patients with lymphoma or oligodendroglioma of the brain.

This chapter is an overview of current therapy for brain tumors in adults. The physician, awate of current therapies as well as the rationale for future therapies, is provided an approach to specific brain tumors.

TREATMENT STRATEGIES

Surgery

Surgery is the primary modality of management for patients with brain masses. Stereotactic or open biopsy provides indispensable diagnostic information necessary for treatment planning. Surgery can be curative for brain tumors such as meningioma or ganglioglioma. Operative intervention may also alleviate symptoms of mass effect or obstruction of cerebrospinal fluid (CSF) circulation. Similarly, surgery often affords time in which other therapies can he provided or serves as a method to insert cither drugs or viral therapies into brain tumors. More controversial is the subtotal resection of infiltrative brain tumors.

Biopsy

A histological diagnosis is necessary prior to rational therapy. Up to 10% of clinically apparent neoplasms may actually be of infectious or demyelinative origin. Stereotactic biopsy uses targets acquired by computed tomography (CT) or MRl. A stereotactic frame or fiducial markers placed on the patient's head provide precise sampling strategy. Prior to biopsy "activation," MRI or PET studies are performed to identify contiguous, eloquent areas of the brain. These studies can be coregistcred on three-dimensional MRI reconstructions from which biopsy coordinates are drawn. A probe is then passed through a small drill hole that retrieves cylindrical samples 1 cm in length and 1-2 mm in diameter. The procedure is safe, commonly performed in most large hospitals, and is associated with less than a 2% risk of seizure, hemorrhage, or infection. In many centers, a neuropathologist in the operating room provides immediate analysis of frozen or smear preparations to confirm the tumor,

Resection

A number of brain tumors can be cured by complete surgical resection (grade I gliomas such as ganglioglioma, papilloma of the choroid plexus, pleomorphic xanthoastrocytoma (PXA), pilocytic astrocytoma of the cerebellum, dysembryoplastic neuroepithelial tumor, pituitary adenoma, meningioma). Less clear is the benefit of resecting the infiltrating diffuse astrocytoma or "partial" decompression of an aggressive tumor. Resection provides prolonged survival for oligodendrogliomas and oligoastrocytomas and most clinicians support "subtotal" resection in the setting of increased intracranial pressure; steroid-obligating mass effect, hemorrhage or impending herniation; the presence of necrotic tumor cysts; and uncontrollable seizures. Often the decision to operate depends on preoperative MRI mapping of both gray and white matter functions. Aids to the surgeon also include tumor resection based on intraoperative MR] or "MRI roadmaps," intraoperative cortical stimulation mapping, and monitoting of somatosensory evoked potentials. It is often argued that surgery will reduce the burden of tumor prone to malignant degeneration, but this view is countered by tbc occurrence of infiltrates of tumot extending at distances from the main mass. The advocates of subtotal resection often cite the diminished likelihood of the sampling error associated with stereotactic biopsy. Carefully performed tumor resection, with the patient awake and within an operating room offering MRI guidance, commonly improves clinical deficits; in general, resection benefits tumors lying in the poles of the frontal or temporal cortex.

Following operation, within 48 hours, a contrast-enhanced MRI is recommended as an objective mcasiifc of residual tumor. After 48 hours, perioperative changes occur in the brain and prevent accurate determination of residual tumor.

Radiation Therapy

Radiation therapy is commonly provided to treat brain tumors. Some tumors, such as gcrminomas, can be cured and others are slowed in their progression. Survival is improved in many glial and nonglial tumors, and symptoms, including seizures, are reduced. Palliation is the goal for older adult patients or those with leptomeningcal tumor.

The target for radiation cell death is DNA within the cell. High-energy beams cause breaks in the DNA double strand either by ionization of the target atom of by production of free radicals. The effect of radiation depends on the dose applied, how often it is applied, and how much time is available for the target to repair the damage. Dividing cells are more susceptible to itradiation than ate nondividing cells, especially during the M-(mitotic) and G2 phase of the cell cycle.

Photons are the most commonly used particles 111 the radiation therapy of brain tumors. Examples of nonphoton irradiation modalities (available in experimental facilities) include neutrons, protons, helium ions, pions, and heavy-ions (carbon, argon, neon).

External Beam Radiation Therapy

Radiation therapy is most commonly delivered by a linear accelerator (LINAC), which uses high-frequency

electromagnetic waves to accelerate electrons to high energies. The electron beam is used directly for the treatment of superficial tumors or indirectly by producing x-ray beams for the treatment of dccp-scatcd lesions. Shielding blocks are built for each patient to restrict the beam to the target volume. The size of the treatment field depends on the tumor type. For infiltrative tumors, such as malignant gliomas, therapy is provided to the volume of enhancement V or T_2 abnormality on MRI and a margin of 1-3 cm. For sharply demarcated cystic astrocytomas, a margin of 0.5 cm suffices. On the other hand, whole-brain radiation therapy (WBRT) is provided to treat multifocal infiltrating tumors seen in gliomatosis cerebri, the multiple masses of recurrent brain lymphoma, and the potential seeds within the neuraxis of primitive neuroectodermal tumors (FNETs). Numerous strategies, mainly of experimental nature, have been developed to improve tumor cell kill and minimize damage to normal tissue. These include increasing the number of treatment fractions to two or more per day (thereby reducing the time for tumor repair of damage), the use of multiple fields (to diminish damage to normal tissue), the use of radiosensitizing agents, localized high-field strength sources (brachytberapy or radiosurgery), and MRI-based treatment planning (to reduce damage to contiguous sensitive areas such as the optic chiasm).

Conventional Fractionated Radiotherapy

Conventional radiation therapy is provided in daily fractions of 1.8 to 2.0 Gy. The total dose seldom exceeds 60 Gy, at which point there is an increased risk of radiation necrosis, or damage to normal brain. Fractionation is more likely to leave surviving cells compared with single fraction irradiation. However, tumor, as early responding tissue, is more likely damaged than is nondividing normal brain (late responding tissue).

"Hypcrfractionation" protocols decrease the dose per fraction, but increase the number of fractions per day. With accelerated fractionation, the dose is applied over a shorter period by increasing the number of daily treatments. In theory, this reduces repopulation of tumor cells during irradiation. Fractionation strategics require immobilization devices such as bite blocks and thermoplast molds that allow reproducible positioning of the patient with each treatment. The use of multiple radiation fields or three-dimensional conformal irradiation limits the exposure of overlying skin and normal brain tissue.

Brachytberapy

In brachytberapy, radiation is delivctcd by implanting the irradiation source close to or into the target tissue (Brain Tumor Cooperative Group 2002). Interstitial therapy uses iridium-192 or iodine-125 seeds. Iridium-192 has a longer half-life (74 days) and penetrates deeper into the surrounding brain tissue. Scalp infections have been described after therapy with high activity brachythcrapy seeds, and there is a 50% risk of the development of contrast-enhancing necrotic tissue in the radiation site. Nearly half of patients require a second craniotomy after seed implantation. Intratumoral positioning of miniature x-ray-gencrating devices or intracavitary application of radionuclide is another form of local radiation delivery.

Sensitization of Tumor Cells to Ionizing Radiatton

Hypoxic tumor cells likely evade the lethal effect of irradiation. Rapidly growing tumors such as malignant gliomas contain a significant fraction of hypoxic cells that in.i\ represent one third ot the tumor burden. Fractionation of irradiation allows reoxygenation of tumor tissue during the resting intervals. In addition, these cells can be manipulated through pharmacological and physical strategies. Drug strategies include nitroimidazoles such as metronidazole, misonidazolc, or etanidazole, and the hypoxic cytotoxin tirapazamine. Increased oxygen can be carried to the tumor by the application of hyperbaric oxygen or the provision of agents that alter hemoglobin-oxygen dissociation curves (RSR13). Examples for non-hypoxic radiosensitizers are halogenated pyrimidines such as 5-bromodeoxyuridine and hydroxyurea. Flalogenated pyrimidines are incorporated into dividing cells and thus selectively increase radiation sensitivity of tumor cells. Radiosensitization is also provided by certain chemotherapeutk agents (cis dianunincdichloroplatinum [ei.spl.um! *:>v* doxorubicin); the antitrypanosomal agent suramin, or the angiogenesis inhibitor thalidomide.

Stereotactic Radiosurgery Techniques

Radiosurgery is the name given to single fractions of stereotactic radiosurgery (SRS) and multiple fractions of stereotactic radiation therapy (SRT). These techniques deliver large doses of radiation to well-circumscribed tumor sites while minimizing exposure to normal tissue. Three types of facilities are typically used. *LINAC radiosurgery* uses a modified LINAC to produce high-energy photon beams. The radiation source moves through multiple noncoplanar arcs, as a flashlight would move around the perimeter of a circle. Heavy charged particle beams such as helium or protons *{proton radiosurgery)* offer optimal physical characteristics for stereotactic applications. The beam penetration into tissue reflects the energy-imparted to the particle. The particle penetrates to relatively finite depths (Bragg peak), after which there is a sharp dose decrease. ('The "flashlight beam" penetrates only so far and no further, thus protecting surrounding normal tissue.) An onsite cyclotron is needed to generate high-energy heavy particle beams restricting its use. *Gamma knife* provides irradiation using 200 separate and collimated cobalt-60 sources in a hemispherical array aimed at the target tumor (multiple "flashlights" all aimed at the target).

These radiosurgery techniques require some means of fixation of the patient's head in space. These devices include immobilization masks, rigid frames affixed to the patient's skull or fitted mouthpieces. The acute complications of these therapies include cerebral edema and seizures. The major late complication is radiation necrosis manifested as early as 2-4 months after treatment, but maximal at 18 months. The mass, indistinguishable from viable-tumor, may have characteristic neuroimaging features like low choline/creatine ratios and increased lactate peak on magnetic resonance (MR) spectroscopy, and does not accumulate FDG isotopes on PET scans. Surgical biopsy or decompression may be required for this complication.

Chemotherapy

Chemotherapy is provided to most patients with malignant brain tumors. Less commonly treated are nonresected low-grade but symptomatic tumors prior to or following radiation therapy. Chemotherapy is becoming increasingly important for patients with brain lymphoma or anaplastic oligodendroglial tumors.

An exhaustive description of chcmothcrapcuric agents is beyond the scope of this chapter; the reader is referred to texts that list both commonly provided and experimental drugs.

Alkylating Agents

Alkylating agents are the major agents used against brain tumors. The antitumot effect of this class of drugs is based on covalent binding of alkyl groups to DNA, which results in DNA intra- and interstrand crosslinks. However, gliomas are prone to resist these effects by reducing drug uptake, ovcrexprcssion of cellular sulfhydryl groups, and elimination of alkylated nucleosides by cellular repair mechanisms. The active metabolites of these drugs often produce myclosupprcssion, whose variable time course indicates that alkylating agents affect hematopoicsis at different levels of differentiation. Nausea and vomiting are frequent, but can be avoided; however, male sterility and teratogenicity are sources of profound morbidity. Secondary malignancies occur in 5-10% of patients, but commonly the tisk is cited as 2% pet yeat aftet exposure.

Nitrogen Mustards

Nitrogen mustard derivatives of mechlorethamine are administered orally or intravenously. Cyclophosphamide and ifosfamide are activated by the microsomal mixed oxidase system of the liver, which is the main site of clearance. Characteristic dose-limiting toxicity is leukopenia, which occurs 10-12 days after the drug is given. However, cyclophosphamide does not suppress hematopoietic stem cells and thus cumulative damage is rarely seen or is reversed with the use of bone marrow stimulating agents. The dtugs cause alopecia and may induce sterility and bladder damage. Cyclophosphamide is used with carboplatin and E topoxide VP-16 to treat PNETs and I'lop'i-.ide esthesinneiu-tibkisiiiuia before radiation is given. Ifosfamide is an analogue of cyclophosphamide used to treat soft-tissue sarcomas such as those of muscle or peripheral nerve sheath. The hemorrhagic cystitis that follows both drugs as a result of the active metabolites present in the urine, can be prevented by hydration, frequent bladder emptying, and use of mercaptoethane sulfonare (MESNA).

Thio-TEPA

Trierhylenethiophosphoramide (Thio-TEPA), the pro-drug, is converted to TEPA and other alkylating moieties in the liver by microsomal oxygenases. It is used as an intrathecal agent to treat leptomeningeal tumors as well as primary central nervous system (CNS) lymphoma. Dose-limiting toxicity ismyelosuppression (leukopenia nadir after 2 weeks, thrombocytopenia nadit aftet 3 weeks).

Nitrosoureas

BCNU, CCNU. The chloroethylnitrosoureas, intravenous bischloroethy I nitrosourea (carmustine, BCNU) and oral cyclohexylchloroethylnitrosourea (lomustine, CCNU) are lipid soluble and readily cross the BBB. These agents have represented the major drugs provided for grade 3 or 4 glioma and add 4-8 weeks of survival to patients with glioblastoma multiforme. Resistance to these agents reflects induction of guaninc-O -alkyl transferase. This resistance is reduced by concomitant treatment with O^6 benzyl guanine. Delayed myelosupptession occurs on day 21 after treatment with reductions of granulocytes and platelets. With prolonged therapy, cumulative myclosuppression (usually by cycle 5 after standard doses) occurs, as well as lung, liver, and rena! .llleianniis eniimicmly .lipidoses approaching 1200 mg/m^{-}). Alternative modes of drug administration include implantable wafers of BCNU (polifeprosan 20 with carmustine implant |Cliadel]l and intra-arterial BCNU.

Nonclassic Alkylating Agents

Procarbazine

Procarbazine (PCZ), an oral agent, represents a major active agent in the procarbazine-CCNU-vincrisrinc (PCV) regimen provided to patients with oligodendroglial tumors. As with other alkylating agents, it requires activation and induces resistance through guanine-O -alky] transferase. Cells deficient in DNA mismatch repair are not susceptible to *PCZ.*. Limiting usefulness are extended interactions with

drugs and foods, as well as interaction with drugs that share or induce rhe hepatic microsomal cytochrome P4S0 (CYP450) oxidoreductasc system. Dose-escalation trials in patients on CYP450-inducing seizure medications have shown that high doses may be required above those commonly used. PCZ, an inhibitor of monoamine oxidase, cannot be used concomitantly with tricyclic antidepressants, tyramine-rich food or alcohol. Side effects include nausea, mild leukopenia, and thrombocytopenia 1 week after treatment. Transient central and peripheral neurotoxicity has been observed. Hypersensitivity reactions can frequently be controlled with corticosteroids. The toxic effects on gonads are profound and can be irreversible, PCZ is currently being used as a single drug or in combination protocols for malignant gliomas and the salvage therapy of primary CNS lymphoma.

Antifolates

Methotrexate

Methotrexate is a potent inhibitor of dihydrofolate reductase (DHFR), an enzyme necessary for the synthesis of tetrahvdrofolates. These are one-carbon carriers essential for synthesis of thymidylatc and purines. After transportation into the cell along the reduced-tolate carrier system, methotrexate (or a variety of analogues) undergoes polyglutamation. Cytotoxicity reflects the duration of cell exposure to the drug as well as drug concentration. Thus the area under the concentration x time curve correlates with response. To achieve therapeutic concentrations within the brain, spinal fluid, nerve roots, and eye, methotrexate is given by vein in gram-equivalent doses. These doses, above 3.5 g/m^2, and commonly 8 g/m^2, are used for the treatment of primary CNS lymphoma (PCNSU and primary sarcomas of the nervous system. The drug mandates the establishment of alkaline diuresis, because concenttations in urine can exceed the level of solubility depending on urine pH. Methotrexate is excreted in the proximal tubule and reabsorbed in the distal tubule. Competing for this excretion are other organic acids such as acetyl salicylic acid, penicillin C or probenecid, which should be avoided during treatment, The drug has a two-phase pattern in plasma—an initial half life of 2-3 hours, and another of 8-10 hours. A late component of excretion exists in those with a third space or obesity. Thus potential toxicities include the kidney (from late excretion or precipitation of metabolites with low solubility), mucosa, and liver, where hepatocytes may store polyglutamated metabolites for months after treatment. With diminished renal function, enteral elimination can be facilitated by administration of cholestyramine or can be circumvented by dialysis of the drug,

Neurotoxicity reflects the prior use of radiation therapy or localized accentuated drug concentrations around ventricular catheters in the brain. A myoclonic dementia is reflective of microcalcifications in white matter. Cellular mechanisms of resistance result from altered transmembrane transport of the drug, decreased affinity of DHFR, or ovcrexpression of the enzyme.

Cytidine Analogues

Cytosine Arabinoside

The deoxycytidine analogue cytosine arabinoside (ara-C) is used as a second-line intrathecal or high-dose intravenous agent to treat primary CNS lymphoma. Its active phosphorylated metabolite (arabinosylcytosine triphosphate) competitively inhibits DNA polymerase A. After incorporation into DNA, there is inhibition of chain elongation and template function. This water-soluble drug can achieve therapeutic concentrations within the brain parenchyma and spinal fluid, where it is eliminated by deaminases, Molecular mechanisms underlying ara-C resistance in humans have not been clearly identified. It is presumed that downregulation of enzymes required for pro-drug activation, upregulation of inactivating enzymes, and modifications in the cellular response to ara-C-mediatcd DNA damage are involved. Toxicities include early and severe myelotoxicity (after intravenous use), gastrointestinal side effects, and encephalopathy, particularly at high doses and in patients older than 40 years.

Ara-C provided by lumbar puncture or through an Ommaya reservoir in continuity with the subarachnoid space or ventricle treats leptomeningeal lymphoma or esthesioneutoblastoma. Doses between 30 and 50 mg/m are given. This approach, requiring twice-weekly administration, has led to the provision of drug encapsulated in microscopic lipid-based particles that release the drug over 2 weeks' time. Seizures and chemical leptomeningitis can complicate intrathecal administration and may require the use of anticonvulsants or oral corticosteroids.

Antimicrotubule Agents

Microti!bular components of the mitotic spindle apparatus can be inhibited within rumor cells with resulting reduction of cell division, intracellular transport, and secretion. Vinca alkaloids are used to treat glioma as well as PNET. However, it is unclear whether these drugs play any effective role in therapy.

Vinca Alkaloids

The vinca alkaloids, naturally found in *Catharantbus roseus*, inhibit polymerization of tubulin and the disassembly oi micro tub ILLS, .uid thus produce cell cycle arrest in metaphase. Vinca alkaloid resistance mechanisms include the overexpression of P-glycoprotein, a large

transmembrane protein encoded by the MDR1 gene that functions as a drug-pump transporting a variety of drugs from the intracellular to the extracellular compartment, Vinca alkaloids arc administered by bolus injection or short infusion. Complications are neurological and include noncumulative autonomic neurotoxicity, constipation, paralytic ileus, dysuria, and blood pressure in stability. The main cumulative side effect is peripheral neuropathy.

Vincristine

Vincristine as a bolus injection {1.4 mg/m" up to 2 mg) is metabolized in the liver and excreted into bile. This drug is part of PCV chemotherapy for the treatment of oligodendroglial tumors. The uncertainties regarding efficacy may reflect its poor penetration of the BBB. Toxicity to peripheral or cranial nerves ensues after cumulative doses higher than 5 to 6 mg. The nerve damage may be painful or dysesthetic. An encephalopathy with seizures has followed inadvertent high dose usage.

Compounds Based on Elemental Platinum

Platinum compounds form hifunctional bonds to DNA to produce intrastrand adducts linking two nucleotides. The cell repair of these links makes use of nucleotide excision-DNA repair. Defects in the DNA mismatch repair system may prevent recognition of platinum adducts and result in failure to initiate apoptosis. Platinum-based compounds, usually in combination with other drugs, are being used for the treatment of neuroblastomas, pineal parenchymal tumots, embryonal tumors and nongenninomatous germ cell tumors, as well as for salvage therapy of recurrent malignant gliomas.

Cisp latin

Cisplatin is administered intravenously at doses of 50-90 mg/m^2 every 2-3 weeks. The drug is eliminated mostly through renal excretion. Cisplatin is highly emctogenic. Othct significant adverse reactions include peripheral neuropathy, as well as central neurotoxic effects (papilledema, seizures), ototoxicity, renal toxicity resulting in loss of magnesium, calcium and heavy metal ions requiring prophylactic supplementation, and myelosuppression (particularly thrombocytopenia).

Carboplatin

The commonly used carboplatin dose is 4–6 mg/m^2 x min (area under the concentration x time curve). Virtually all of the intravenous dose is excreted in urine within 24 hours. In general, the agent is easier to use than cisplatin, having fewer side effects of emesis, neuropathy, confusion, and renal damage, but is likely more myclosuppressive. The drug is used alone by vein or artery or in high doses with stem cell support to treat glioma and as part of regimens for PNETs.

Topoisomcrasc Inhibitors

DNA is a dynamic molecule that coils and bends to form supercoils. To replicate, DNA must temporarily uncoil and link/unlink its double strands (catenation/decatenation). This process is catalyzed by topoisomcrascs. Topoisomerase I introduces single-strand breaks into the DNA molecule. Topoisomcrasc II catalyzes linking and unlinking by causing double strand breaks. The topoisomcrascs bind to the free ends of the cut DNA molecule using a specific tyrosine residue.

Topoisomcrasc I Inhibitors

A large number of eamprothecms are potent against glial cell lines in vitro. These drugs, y-aminocamptothecin, topotecan, irinotecan (CPT-11), and the experimental agents karcnitecin (BNP1350) and gimatecan (ST1481), inhibit topoisomerase I.

Topotecan

Topotecan is hydrolyzed to its active metabolite. It is inactivated by carboxylation and excreted rcnally. After a 30-minute infusion in doses of 1.5 mg/m^2 on days 1 to 5 of a 21-day cycle or 2.6 mg/m over 72 hours weekly, there is excellent penettation of the BBB. The agent is a second line drug fot methotrexate-resistant PCNSL, but has shown no effect on malignant gliomas. Dosing is limited by leukopenia and thrombocytopenia.

Irinotecan

Irinotecan (CPT-1 I) undergoes hydrolysis to form the active moiety, SN-38. The latter is inactivated by liver glucuronidation and passed into the bile. As this process is inhibired by valproic acid, this anti-epileptic drug is prohibited in CPT-11 recipients. Adverse reactions include an acute cholinergic syndrome, delayed diarrhea, myelosuppression, nausea, vomiting, and alopecia. The typical dosing schedule is 125 mg/m Avk for 4 weeks, followed by 2 weeks of rest, or 300-350 mg/m every 3 weeks.

Topoisomcrasc II Inhibitors

During the catenation/decatenation process, topoisomerase II forms a complex with two DNA double strands—the cleavage complex. Etoposide and teniposide, semisynthetic

derivatives of podophyllotoxin, a substance found in mayapple extracts, inhibit the re-ligation of DNA from the cleavage complex.

E *top oside*

Etoposidc (VP-16) is being used as part of polychemotherapy regimens against PNETs, ependymoma, pinealoma and pineocytoma, embryonal tumors, and nongerminomatous germ cell tumors, as well as a salvage treatment for malignant gliomas and PCNSL. As a bolus infusion of TOO to 150 mg/m on two or more consecutive days, it is without significant nonhematological toxicity. It is used experimentally as an intrathecal agent {new formulation), an oral agent (new formulation), and in high-dose chemotherapy protocols followed by stem-cell rescue. Cytotoxicity may depend on persistent cleavage complex formation. This is the rationale for prolonged oral administration of low-dose etoposide (50 mg/m) even in prior recipients of bolus etoposide chemotherapy. Penettation through the intact BBB is poor (CSF concentration less than 5% of plasma level). The drug is almost completely bound to plasma protein. Dose-limiting toxicity is myelosuppression. Leukopenia and thrombocytopenia are mild and occur during the second week after initiation of bolus treatment. Cell count nadir after a 21-day course of oral etoposide is reached within days after drug administration. Etoposide is eliminated in part unchanged through the kidney and in part metabolized in the liver, Resistance to etoposide is based on ATP-dependent transporters such as P-glycoprotein and mutations within the topoisomcrase gene.

Delivery Strategies

The major anatomical obstacle for chemotherapy of primary brain tumors is the BBB, which is composed of the endothelial cell layer of cerebral capillaries sealed by intercellular tight junctions, the vascular basal membrane, and astrocytic foot processes. Whether this barrier is functional in brain tumors is controversial; few studies have directly measured brain concenttations of systemically administered agents. Delivery strategies developed to circumvent the barrier include the following: (I) Intrathecal administration of methotrexate, thio-TEPA, or cytosine-arabinoside for leptomeningeal metastases from high-grade gliomas or esthesioneuroblastomas. However intraparenchymal brain and nerve root tumors in excess of 3 mm cannot be effectively treated via this route. (2) Intracarotid infusion of hypertonic solutions such as 25% mamiitol or 15".. glycerol to produce reversible opening ol the BBB. This approach, selectively used in specialized centers, produces 1-2 hours of barrier lysis during which hydrophilic cbemotberapeutic agents such as methotrexate or cyclophosphamide may penetrate the brain parenchyma. The permeability change favors normal brain over tumor tissue. This technique has been used to treat PCNSL and malignant glioma. The technology obligates general anesthesia and serial angiographic procedures and is associated with significant toxicity, including seizures and ttansient encephalopathy. (3) Biodegradable polymers impregnated with BCNU increase local drug concentration without notable systemic toxicity (Engelhard 2000). Dime-sized wafers of p-carboxyphenoxy (poly bis) propane and scbacii acid degrade over 7 in 10 days into tumor surrounding the resection site. The polymer-based delivery strategy is associated with survival improvements of less than 2 months in patients with recurrent malignant glioma. I lowevcr, the approach may benefit from the use of wafers containing higher concentrations of BCNU. Complications include infection, wound healing impairment, brain necrosis, and CSF leak. Future use of polymers may include the provision of antiseizure medications, corticosteroids, or other antineoplastic agents.

High-Dose Chemotherapy with Stem Cell Rescue

Mycloablative doses of chemotherapy followed by autologous bone marrow or peripheral blood stem cell transplantation have l.nled to produce higher response rates in malignant gliomas when compared with conventional adjuvant chemotherapy (Einlay 1996). Moreover, this approach is associated with significant treatment-related morbidity and mortality, and thus has not found widespread use. Early results of high-dose chemotherapy with peripheral blood stem cell rescue in patients with potentially chemosensitive brain tumors like anaplastic oligodendroglioma or PCNSI. are more promising.

New Treatment Strategies

Over the preceding decade, numerous new treatment strategies have been developed, mostly based on the rapidly growing insight into molecular mechanisms of tumorigenesis. The better understanding of tumor development has yet to result in prolonged survival and improvement of quality of life for patients with brain tumors. However, after decades of little progress in glioma therapy, a number of new approaches raises hope.

New Cytotoxic or Cytostatic Cbemotberapeutic Agents

Temozolomide is a nonclassic alkylating agent. It is spontaneously converted under physiological conditions to monomcthyltriazene imidazole carboxamide, the same intermediate obtained from metabolic degradation of dimethyltriazenyl imidazole carboxamide (DTTC, dacarbazinc). Its metabolism is much more predictable than that of other alkylating agents because it is independent

from interindividual differences in the rate of enzymatic conversion. It has shown mild to moderate efficacy in malignant glioma. Critical for its antineoplastic activity is the methylation at the O^{s} position of guanine. Resistance to temozolomide is the result of guanine-0 -alkyi transferase-incdiatcd repair of O"-methylated guanine residues, defects in the cellular DNA mismatch repair system, and induction of poly (adenosine diphosphate ribose) polymerase, a constituent of the nucleotide excision repair system. Oral bioavailability is excellent, and therapeutic concentrations are reached within brain parenchyma and spinal fluid. Dose limiting toxicity is myelosup press ion resulting in neutropenia and thrombocytopenia 3-4 weeks after initiation of each cycle.

Tumor Therapy Targeting Control of Cell Growth

How cells conttol theit growth is an essential issue in the development of primary brain tumors, STI-571, a synthetic inhibitor of the tyrosine kinase receptors abl and c-kit, has been of value in the therapy of chronic myelogenous leukemia and gastrointestinal stromal tumors. This has inspired the use of similar agents to target analogous brain tumor pathways. Cell growth control can be attacked at different levels: gtowth factors, growth factor receptors, intracellular signal transducers, nuclear transcription factors, and cell-cycle conttol proteins. Various strategies are available to interfere with proteins or the transcription/ translation of their encoding genes at each level. Antisense oligonucleotides injected into tumors hybridize with transcripts of growth control genes and inhibit their translation. Ribozymes degrade transcripts with high specificity. Monoclonal antibodies directly target growth control proteins. Gene therapy may restore the function of mutated cell-cycle control proteins. Modified peptides or peptidomimctics are molecules designed to bind to the active sites of proteins such as the tytosine kinase domain of growth factor teceptors. Modification of peptides is neccssaty to prevent rapid degradation by ubiquitous proteases. Pep ti do mime tics are small organic molecules that mimic peptides but are not subject to proteolytic degradation.

Growth Factor Receptors

Epidermal Growth Vector Receptor. Epidermal growth factor receptor (EGFR) is overexprcssed in patients whose glioblastoma multiforme is not the apparent product of malignant change of a more benign tumor *[de novo* glioblastoma multiforme). The rearranged EGFR gene results in aberrant transcripts. For instance, the in-frame deletion of exon 2 to 7 is translated into a ptotein with a truncated extracellular domain (EGERvIll). Although EGFRvIII does not bind epidermal growth factor (EGF), it is constitutivcly phosphor y la ted at its car boxy [-terminal tyrosine residues and thus may continuously transduce downstream signaling.

To target the mutated EGFR, monoclonal antibodies have been developed. These antibodies can be "cold" or conjugated to radioisotopes or cytotoxins. In clinical trials, either alone or with radiation therapy, are ZD1839 (Iressa) and ryrphostin (AG1478, [4-(3-chloroanilino)-6,7-dimethoxyquinazoline]}, small molecule inhibitors of EGFR tyrosine kinase that block downstream effects on cell growth control.

Platelet-Derived Growth Factor Receptor. STI-571 is a tyrosine kinase inhibitor of the 2-phenylaminopyrimidine class. In addition to its effects on abl and c-kit, it is a selective inhibitor of platelet-derived growth factor receptor (PDGFR). It is being evaluated in phase I trials either alone, with radiation therapy, or with tcmo/olomidc. Leflunomide (N-[4-(trifluoromethyl)phenyll 5-methylisox-a7.ole-4-carboxamide, SU-101) inhibits PDGER signaling. Because objective responses in a phase I trial were observed in malignant glioma patients, the dtug is being explored in phase II/III clinical trials.

Vascular Endothelial Growth Factor Receptors. Kinase insert domain receptor (KDR) and FMS-related tyrosine kinase 1 are tyrosine kinase receptors for vascular endothelial growth factor (VEGF). Treatments targeting these receptors are described in the section on antiangiogenic strategies.

Intracellular Signal Transducers

Inhibition of Protein Kinase C. Protein kinase C (PKC) is one of the plasma membrane serine threonine kinases essential for the signal transduction of growth factors and hormones. PKC alpha is overexpressed in high-grade gliomas. Inhibitor-; of PKC include antisense oligonucleotides and tamoxifen. Tamoxifen is an oral, nonsteroidal, mixed estrogen receptor agonist and antagonist that inhibits PKC via an estrogen receptor independent pathway. It is used in high doses (to 240 mg/day) for the treatment of recurrent malignant glioma, but catries the risk of venous thromboembolism.

Inhibition of the Ras Signaling Pathway. The Rasproteins (p2 1 tas) arc guanine nucleotide-binding proteins with guanosine triphosphatase activity. These proteins play a central role as signal transducers for a variety of critical processes such as proliferation and differentiation. Activation of the Ras pathway depends on signaling from tyrosine kinase receptors such as EGFR. Ovcrcxprcssion of Ras-proto-oncogene product has been found in malignant gliomas.

Proper functioning as a signal transducer requires anchoring of the protein in the inner leaflet of the cell membrane. This is mediated through a farnesyl moiety that is covalently linked to a cysteine terminus of the protein, Farnesyltransferase, the enzyme that catalyzes the bond formation between farnesylpyrophsophate and Ras protein, can be inhibited. Inhibition of this transferase reverts transformation of cells containing mutated Ras.

Farnesyl transferase inhibitors are currently in clinical trials, as are inhibitors of /i-hydroxymethylglutaryl coenzyme A reductase. Two surprising inhibitors of the Ras signaling pathway are lovastatin and simvastatin, which alter synthesis of steroids and polyisoprenoids such as farnesyl pyrophosphate or geranylpyrophosphate.

l'roteasome Inhibitors. The proteasome is a cellular protein degradation complex that recognizes and degrades polyubiquitinated substrates such as cell-cycle control proteins. Although a fairly nonspecific apparatus, the overall effect of some proteasome inhibitors such as PS-341, a dipeptidyl boionic acid derivative, is the induction of apoptosis. PS-341 is currently the subject of clinical trials for patients with recurrent malignant glioma.

New Delivery Strategies

New delivery strategies are designed to circumvent the BBB to treat malignant gliomas. The bradykinin analogue cereport (RMP-7) increases capillary permeability by inducing contraction of endothelial cells, loosening of tight junctions, and stimulating transendothelial transport. Intraoperative injection of resection margins with various therapeutic agents (viral vectors, oncolytic viruses) docs not depend on BBB permeability. Tissue penetration can be improved using convection-enhanced delivery. This technique requires intraoperative placement of infusion catheters in the wall of the resection cavity. Using microinfusion pumps, therapeutic agents are provided postoperatively.

Modulation of Drug Resistance

Several methods are under investigation to reduce resistance to alkylating agents. O^b-henzylguanine is a potent inhibitor of 0^6-alkyl-guanine-DNA-alkyirransfcrase. Chemotherapy with carmustine preceded by 0^6-benzylguaninc decreases the maximum tolerated dose of the alkylating agent because there is increased myelotoxicity. It remains to be shown whether this combination lends to increased survival. The rationale for combination therapy of temozolomide with other alkylating agents such as BCNU is the favorable toxicity profile combined with O^6-alkyl-guanine-DNA-alkyltransfcrase-deplcting properties of temozolomide.

Inhibitors of Angiogenesis and/or Ceil invasion

Gliomas greater than a few millimeters in size stimulate new blood vessel formation. This induction is affected by promoters including VEGF (hypoxia-inducible endothelial cell mitogen, vascular permeability factor), basic fibroblast growth factor (bFGF), platelet-derived growth factor, EGF, transforming growth factor (TGF), and tenascin. Endogenous inhibitors of angiogenesis include angiostatin, endostatin, thrombospondin, and heparin. FMS-relatcd tyrosine kinase 1 (Flt-1, VEGF-R1) and KDR (VEGF-R2) are tyrosine kinase receptors for VEGF.

Matrix metalloprotcinases (MMPs) are a family of more than 20 en do peptidases that degrade macromolecules of the extracellular matrix. They are produced by a variety of different cells, including inflammatory cells and endothelial cells and may influence tumor cell migration through brain parenchyma and the growth of new blood vessels. The control of the MMPs depends on tissue inhibitots in the vicinity of primary and metastatic brain tumors. Marimastat, Ag3340, and Col-3 (6-demethyl-4-dedimethyl-aminotetracycline) are synthetic inhibitors of MMP currently the subject of study in several clinical trials.

Thalidomide inhibits tumor necrosis factor-^ (TNF-u) and angiogenesis induced by VF.GF. Expression of *0*-integrins is decreased and endothelial cell migration is reduced. Daily doses to 1200 mg have been administered to treat recurrent malignant gliomas. SU5416 is an inhibitor of KDR (VEGF-R2) and FMS-related tyrosine kinase 1 (Flt-1, VF.GF-Rl). It has antitumor activity in xenograft glioblastoma models. O-chloro-acetyl-carbamoyl-fomagillol (TNP-470} is an analogue of material produced by the fungus *Aspergillus fumigatus fresenius.* It exerts growth arrest in endothelial cells. Angiostatin, an endogenous fragment of plasminogen, inhibits neovascularization. Administered pa rente rally over prolonged periods, it inhibits visceral tumor growth in animal models. Local administration can he achieved with direct intratumoral injection, or it can be delivered using adenovirus (Ad)-associated vectors. Kndostatin, a carboxyterminal fragment of collagen XVIII, shows promise as an antiangiogenic agent in animal experiments. Other potential therapies targeted to endothelial cells include squalamine, anti-VEGF antibodies, interleukin ((L) 12, cyclooxygenase II inhibitors, and EMD121974, a cyclic pentapeptide inducing apoptosis of growing endothelial cells through inhibition of their wvAi intcgrin interaction with the matrix proteins vitronectin and tenascin.

Gene Therapy

Gene therapy of brain tumors encompasses a wide spectrum of various sttategies (Lam et al. 2001). Viral vectors create localized inflammation while expressing transgenes that activate cytokines and chemotherapies. Transfection efficiency depends on the agent and the mode of introduction. Cells are killed not only by transfection but by the cellular reaction that damages adjacent tumor cells: the "bystander effect," The delivery of a therapeutic gene can be enhanced by improving the vector or delivering it through infusional clysis. Modified retroviral vectors lacking infectivity as a result of fusion of an envelope protein to a polypeptide through a protease sensitive linkage are locally activated by releasing the polypeptide in the vicinity of metalloproteinase rich tumors, l.igands or antibodies targeted at receptors expressed on tumor cells (EGFR, transferrin receptor,

integrin receptor) can be incorporated into the capsid of adenoviral vectors. Tumor-specific expression systems make use of the human telomerasc reverse transcriptase (hTERT) promotor. hTERT is the catalytic subunit of the telomerasc ribonucieoprotein and is expressed in glioma cells but not in normal glia cells. Delivery of recombinant proteins can be achieved by fusion with transducing proteins such as TAT protein of human immunodeficiency virus or VP22 of herpes simplex virus (HSV). Tumor selectivity can also be accomplished by using replication-conditional viral vectors, retroviruses, or placement of genes essential to virus replication under the control of promotors that are selectively active in gliomas (such as the nestin promotor).

Currently used vector systems are either replication-defective or replication-conditional and include recombinant HSV, Ad, retrovirus, and hybrid vectors. Replication-conditional vectors replicate selectively in tumor cells. Examples are recombinant HSV lacking the gene encoding thymidine kinase, the IISV double mutant G207 with defective y34.5 and ribonucleotide reductase gene, and Ad mutants that lack expression of the El B gene and thus replicate only in p.53 deficient cells (ONYX-015). Retroviruses replicate only in dividing cells. These viruses are unstable in body fluids. Transduction efficiency can be increased by using vector producer cells as delivery .systems.

Gene therapy delivery involves stereotactic injection into the tumor or intraoperative insertion into the wall of the resection cavity, intra-arterial or intraventricular application. Nonviral strategies have made use of naked DNA, polycationic polymers, and liposomes.

Transfection of Tumor Cells with Bacterial Enzymes Followed by Application of Pro-Drugs. The herpes simplex virus thymidine kinase gene has been inserted into tumor cells using adenoviral or retroviral vectors. Transfected cells phosphorylate systemiealty administered ganciclovir to form a nucleotide-like precursor, incorporation of which into the nascent DNA strand blocks DNA replication. Only dividing cells arc transfected limiting the cytotoxic effects on normal tissue. Transformation efficiency is low but n on trans fee ted tumor cells can be eliminated through the release of phosphorylatcd ganciclovir from dying adjacent tumor cells ("bystander effect"). Other examples of "suicide gene therapy" arc the *Escherichia coli* cytosine deaminase/5-fluorocytosine system and rat CYP450 2Bl/cyclophosphamide system. Cytosine deaminase converts 5-fluorocytosine into 5-fluorouracil. Because of its high membrane diffusibility, the "bystander effect" is pronounced. CYP450 2B1 converts cyclophosphamide to phosphoramide mustard. This "suicide gene therapy" concept is the basis for several ongoing phase I clinical trials.

Other Gene Therapy Concepts. Gene therapy concepts can target a poptosis-resistance mechanisms of glioma cells. Transfection of glioma cells with wild type p53 can restore tumor suppressor function and induce apoprosis. Synergies exist with radiation and chemotherapy. Similarly, apoptosis can be induced by transfection with dominant-negative forms of Ras or ribozymes against Ras messenger RNA, which leads to upregulation of Fas expression or by transfection of caspases or TNF-a. Transgenes can also block angiogenesis by providing dominant negative forms of the VEGF receptor (KDR/ELK1), VEGF antisensc oligonucleotides, and antagonists of the endothelial cell tyrosine kinase receptor TIE2. Other gene therapy strategies confer drug resistance to endogenous hematopoietic cells, thus allowing higher doses of chemotherapy without an increase in myelotoxicity.

Novel transgenes or gene therapy targets include the following: (1) fusogenic membrane glycoproteins (measles virus proteins F and H, mutated form of the retroviral envelope protein of the gibbon ape leukemia virus), which fuse tumor cells; (2) sodium iodide symporter gene transfer followed by I-I31 administration; (3) transfection of tumor cells with gap junction protein «-l (conncxin-43) to enhance intercellular communication; (4) tissue inhibitor of metalloproteinascs-2 and antisensc integrin /j-'l cDNA; (5) ovcrcxpression of tyrosine kinase receptor type 3 by mcdulloblastoma; (6) telomerase, which elongates telomeric DNA; (7) granulocyte-macrophage colony-stimulating factor cDNA that induces antitumor immune response, as can IL-12 or IL-4.

Immune-Mediated Therapy

Whether primary brain tumors suppress immune reaction, are poorly recognized by the immune system, or are protected by the immunosuppressive effects of concurrent glucocorticoid administration is uncertain. Therapies based on immune-mediated strategies aim to increase immune responses to the tumor. Extraneurally injected brain tumor cells ("tumor vaccination") and immune cells communicate in the absence or the presence of antigen presenting cells. The communication is mediated by rcccptor/ligand interaction or the production of cytokines. Cytokines have been used to increase the local tumor response to brain tumors by in vivo or ex vivo stimulation of cytotoxic I -lymphocytes. Recombinant cytotoxins combine receptor-mediated specificity with the toxicity of a bacterial protein. (.t)[ij-.iLV-IU'S ni antibodies with radioactive isotopes deliver cytotoxic doses of radiation to cells expressing surface antigens recognized by the antibody.

Vaccination Strategies. Tumor vaccination makes use of attenuated autologous tumor cells or dendritic cells loaded with tumor antigens. These tumor antigens create an immune reaction enhanced by irradiation, transfection with cytokine genes, or transfection with major histocompatibility complex (MHC) class II genes. The antigen

can be presented in subcutaneous tissues, after which cytotoxic T-cells infiltrate the site of injection as well as the brain.

Cytokines. Interferons are cytotoxic and indirectly immunomodulatory, Interferon *a* and *fi* have been administered alone or in chemotherapy combinations to treat recurrent malignant gliomas. Interferon *y* induces expression of MHC class I molecules on glioma cells as well as MHC class I and II molecules on immune cells. It potentiates lymphokiue-activated killer (LAK) cell attack on glioma cells and induces the expression of CD95 (Fas) to inhibit glioma cell growth,

IL-2 has been used in combination with LAK cells. Tumor-infiltrating T lymphocytes (TILs) express low levels of tlw IL-2 receptor. However, clinical trials using di:\vi injections of IL-2 did not improve tumor control.

Apoptotic pathways may be exploited to kill brain tumor cells (Roth ct al. 1999). TNF-a, CD95 ligand (FasL, ApolL), and Apo2 ligand cytokines induce apoptosis. Fas (CD95) is expressed on glioma cells. Fas-negative glioma cells can be transfeeted with Fas cDNA. CD95 is not present in normal brain. Thus CD95 is a logical target on glioma cells. The ligand Apo2L (TNF-related apoptosis-inducing ligand [TRAIL]), the receptors DR4 (TRAIL-R1), and DR.S (TRA1L-R2), as well as the decoy receptors DcRl (TRAIL-R3) and DcR2 (TRA1L-R4), are involved in apoptotic activities. Binding of Apo2L to DR4 or DR5 leads to induction of apoptotic cell death. Apo2L is expressed on malignant gliomas but not normal brain. These ligands lend themselves to local application within brain tumors.

Recombinant Cytotoxins. Cytokines can be linked to bacterial toxins as genetically engineered fusion proteins. Currently in phase I clinical trials are IL-4 and IL-13 linked to pseudomonas exotoxin. These constructs are injected into the wall of the resected tumor or administered through convection-enhanced delivery. The targets are glioma cells ex pressing II receptors (Puri et al. 1999),

Antibody- and Cell-Mediated Therapy of Gliomas. Antibodies alone or conjugated with toxins or radioactive isuropes cm target epitopes on tumor cells. These approaches are hampered by insufficient delivery, lack of tumor specificity, and concerns regarding ventricular or subarachnoid exposure.

Locoregional radioimmunotherapies currently use monoclonal antibodies against LGFR, neural cell adhesion molecule, or tenascin labeled with iodine-131 or yttrium-90 (Brady et al. 1992). Yttrium-90 is the favorable isotope because it delivers high-energy beta rays and provides a stable conjugate. The antibodies are injected by vein, artery, or into the operative site. With intracavitary injection, radiation doses to the cavity wall approaching 280 Gy have been achieved.

Iinimine cells can he used to target glioma eel Is. i \1\ cells can kill autologous glioma cells, but clinical results have been disappointing. Although it is possible to isolate and stimulate TILs, these strategies have not been translated to human use.

Restoration of Local and Systemic Immune Response in Glioma Patients

Although glioma biopsies reveal perivascular lymphocytes, it is generally assumed that there exists subtle glioma-related immunosuppression. Potential mediators include inhibitory cytokines (TGF-/J, prostaglandin F., IL-10) and defective cytokine receptors on tumor-infiltrating T cells. Glioblastoma can be made immunogenic by transfection with antisense TGF-^3 or decorin, a TGF-0-binding and TGF-/i-inhibiting proteoglycan. Although IL-2 transfection has been unrewarding, other cytokines have been used with success (IL-4: intratumoral delivery of IL-4 using a transfeeted plasmacytoma cell line, IL-7), Transfection of tumor cells with the costimulatory molecule B7 leads to inhibition of glioma cells. Other strategies improve antigen presentation and T-cell costimulation by using cytokines (interferon-)' and TNF-c) to enhance the expression of MHC class I and II molecules.

Insulin-like growth factor is integral to glioma proliferation. Antisense oligonucleotides directed against the insulin-like growth factor type I receptor restore a glioma-specific CD8-I- lymphocytic response. This approach has led to responses in a clinical human trial.

Oncolytic Viruses

Oncolytic viruses are modified viruses that preferentially replicate in and destroy cancer cells (Mineta et al. 1995). An example for this therapeutic strategy is a replication competent, EIB-attenuated adenovirus. E1B is a viral protein that binds and inactivates p53, a prerequisite for the virus's ability to replicate in its host cell. Ad lacking El B can only replicate in TP53-deficient cells. Loss of TP53 function is an early event in the pathogenesis of gliomas and thus renders them susceptible to lytic infection with this attenuated vitus (Alemany et al. 1999). Clinical trials have proven safe and continue.

Genetically Modified Neural Stem Cells

Neuroprogenitor cells may deliver vectors or therapeutic genes to tumors. Animal experiments have shown that systemically administered neural stem cells home to brain tumors. Progenitor cells have been found within experimental brain tumors following injection into the contralateral cerebral hemisphere—an observation that may indicate the stem cells' ability to track down migratory brain tumor cells (Noble et al. 2000).

MANAGEMENT OE SPECIFIC BRAIN TUMORS

Astrocytic Tumors

Low-Grade Astrocytomas

Clinicians arc divided into advocates of early biopsy followed by radiation thcrapv and tliose who prefer to observe their patients and not treat. Our approach is to provide early diagnostic biopsy or gross total resection. Radiation or chemotherapy is reserved for nonresectable, symptomatic patients.

Surgery establishes a diagnosis and identifies the existence of oligodendroglial-containing tumors. Symptoms are alleviated, including those associated with mass effect, hydrocephalus, hemorrhage, cyst formation, or seizure activity. Surgery reduces the cell pool at risk of malignant degeneration and removes potentially more aggressive foci within radiographically benign tumors. Less clear is the survival benefit of resection of infiltrating diffuse astrocytoma or "partial" decompression of a mass. Most surgeons safely resect tumors in the poles of the frontal or temporal cortex. The introduction of preoperative MRI mapping of gray and white matter functions as well as intraoperative monitoring, and resections performed under the guidance of intraoperative MRI have expanded the surgical options (Bcrgcr et al. 1997).

Radiation therapy has a limited role in the initial treatment of low-grade astrocytomas except in those eases with a high proliferative index (Yi-67 index), large tumor size, or tumor in proximity to vital structures. Asymptomatic individuals with incompletely resected or nonresectable diffuse astrocytomas are usually followed without treatment with quarterly MRI scans, and then scans every *6* months. Radiation is provided for patients with progressive symptoms or tumor expansion, uncontrolled seizures, or steroid dependence (Knisely et al. 1997). When the tumor exhibits changes suggestive of focal anaplasia (as gadolinium enhancement on MRI, glucose uptake on PET, or increased perfusion on single photon emission-computed tomography fSPECT] scans above 5%) proliferative index external beam radiation therapy in fractions of 180 to 200 cGy, 5 days per week, to a total dose of 50-60 Gy is an option. The radiation field includes the area of radiographically identifiable tumor (Fluid Attenuated Inversion Recovery |FLAIR] or T2 margin) and an additional margin of 1-2 cm. The latter includes presumed tumor infiltrates. The clinician should be **aware** of radiation therapy complications, which can become apparent within 2 years. These include acute, early-delayed and late-delayed toxicities. Within 10 days of the start of irradiation, patients may become fatigued and experience altered appetite and sleep patterns reflecting brain edema. I'here is likely demyelination seen as increased permeability to dye as well as FLAIR changes on MRI. Six to 18 months after radiation, contrast-enhanced masses reflect radiation-induced white matter necrosis. ^{lft}FDG-PET or ^{201}Thallium SPF(T disclose diminished uptake of lig.md. Th:s prvi,v^s often responds to corticosteroid treatment and surgery, Additional complications include pan-hypothalamic-pituitary dysfunction, elevated prolactin levels, impotence, or amenorrhea.

Chemotherapy for infiltrative astrocytomas is restricted to patients whose unresectable tumors arc progressively symptomatic, or in those tumors with anaplastic foci. Radiation therapy should be tried first in such cases unless an oligodendroglial component is present. Chemotherapy may be a logical approach to radiation-resistant multifocal low-grade tumors. Chemotherapy carries the long-term risk of inducing hematological malignancies (5% at *5* years) or sterility. Nitrosoureas are the most widely used group of chemotherapeutic agents. Carmustine as a single agent (dose of 200 mg/m^2 given as an intravenous infusion every 6 weeks) or lomustine (oral dose of 110 mg/m^2) in combination with PCZ (60 mg/m^2, days 8 through 21), and vincristine (1.4 mg/m^2, maximum dose 2 mg; days 8 and 29) (PCV) in 6 weekly cycles are considered standard treatment regimens. Temozolomide is currently undergoing clinical evaluation at different dosing schedules (e.g., 150 to 200 mg/nr on days 1 to 5 of a 28-day cycle) in the treatment of symptomatic infiltrative astrocytomas prior to and after irradiation,

After surgery, therapy with radiation or drugs does not prolong the recurrence-free interval (7 years) nor influence the expected survival (median up to 12 years). Favorable outcomes follow gross-total resection of tumors in young patients with high levels of performance (Piepmeyer et al. 1996). Less than one fourth of recipients of gross total resection are likely to relapse after 1 I years.

Pilocytic Astrocytoma. Composing 85% of infra tentorial astrocytomas, most pilocytic astrocytomas ate benign tumors located in the cerebellum. Surgical removal is often feasible and potentially curative (Dirven et al. 1997). Those growing in the hypothalamus, the walls of the third ventricle, the optic pathway, and the brainstem are not amenable to resection. Radiation thetapy is seldom administered because the 25-ycar survival rate is between 50% and 94% following surgical resection alone. For the unresectable case exhibiting progressive growth or symptoms refractory to treatment, involved field radiation therapy is given with a margin of 0.5 cm. Chemotherapy can be used prior to irradiation or for tumor progression, Malignant transformation of pilocytic astrocytoma is unusual and may reflect the effect of prior therapy with ionizing radiation.

Pleomorphic Xantho astrocytoma. PXA is a rare, usually benign, superficial cortical glioma. Complete resection is feasible in most patients and potentially curative. As w[r]ith other low-grade gliomas, radiation or chemotherapy is provided for aggressive or recurrent tumors. The survival is more than 80% after 5 years and 70% after 10 years,

with well-resected lesions faring the best. Anaplastic transformation occurs in 15-20% of patients for whom the natural history may be indistinguishable from that of glioblastoma.

Subependymal Giant Cell Astrocytoma. Subependymal giant cell astrocytoma occurs in patients with tuberous sclerosis. Hydrocephalus emerges before the third decade as tumors in the wall of the lateral ventricles or in the interventricular foramina obstruct CSF outflow. Surgery is curative and required when the masses outgrow the i on fines of the ventricle.

Neuroepithelial Tumors of Unknown Origin: Chordoid Glioma of the Third Ventricle. Chordoid gliomas occur in the third ventricle of adult women. As with other tumors in proximity to the hypothalamus or median eminence, there is hypogonadotropic hypogonadism, amenorrhea, hypothyroidism, or fluid-balance disorders requiring hormonal replacement. The excellent prognosis reflects the extent of surgical resection. This procedure has been aided by the use of endoscopic techniques or intraoperative MR] scanning.

High-Grade Astrocytomas

Anaplastic Astrocytoma, Glioblastoma. High-grade astrocytomas are the most common primary brain tumor in adults. Although surgical resection is often performed, total resection is seldom achieved; and resections greater than *95%* are the only ones that improve outcome. Gross total resection is recommended whenever feasible. Biopsy for histological confirmation is offered to older adult patients with lesions in proximity to sensitive cortical areas or deep-seated locations.

Radiation therapy, the most effective treatment for malignant glioma, doubles the median survival of patients with glioblastoma. The treatment consists of fractionated external beam irradiation provided at a daily dose of 1.8-2 Gy 5 days a week up to a total dose of 55-60 Gy. Stereotactic radiation is used in an attempt to reduce recurrence of malignant glioma within the field of standard radiation. Whether applied from external sources (SRS), radiation seeds (brachytherapy), or x-ray-emitting devices, control of the local tumor is improved in selected cases. SRS is noninvasive and reduces exposure of normal brain. Local infections and wound healing problems are not issues after SRS, and fewer patients require craniotomy for removal of necrotic tissue or recurrent tumor. When radiosurgery "boosts" are added to conventional radiation, selected patients experience a survival advantage. Thus patients with small, radiographically distinct areas of residual or recurrent tumor should be considered for additional stereotactic treatment (Alexander et al. 1998). The adverse effects of this aggressive approach include seizures, transient focal neurological deficits, and radiation-induced necrosis developing within 3-18 months. One third of patients treated with stereotactic radiation techniques have local recurrence; and half, a marginal recurrence (2-5 cm from the original tumor volume). Distant recurrences occur in the remainder. It is often difficult to distinguish tumor recurrence from radiation necrosis. The clinical presentation seldom varies, and imaging results {MRI, SPECT, PET) arc conclusive in only a minority of patients. Evidence of residual tumor is found in more than 90% of radiation necrosis specimens after stereotactic radiation.

The role of adjuvant chemotherapy in the management of high-grade astrocytic tumors is controversial. Since the early 1970s nitrosoureas have been the standard chemotherapeutic agents. Survival benefit has been shown in several clinical trials and in meta-analyses, but this benefit is marginal. The prognosis of patients more often reflects the tumor grade, age at diagnosis, and performance status prior to treatment. Those patients who live longer have grade III tumors, younger age (younger than 60 years), and Karnofsky performance score greater than 90%. The combination of drugs such as PCZ/lomustine/vincristine (PCV) may be superior compared with single drugs such as BCNU. Intra-artcrial drug delivery as well as marrow intensive regimens arc associated with toxicity and likely are not widely applicable. Temozolomide, unptoven in the therapy of glioblastoma, is an alternative to classical alkylating agents (Friedman et al. 2000). Given in 4-week cycles (150-200 mg/nr on days 1-5), the agent is increasingly used in clinical trails prior to or during radiation therapy, or at continuous low doses (75 mg/m^2). There arc relatively few side effects (leukopenia, thrombocytopenia, and emesis).

Neoadjuvant approaches are not standard treatment for malignant astrocytic tumors, but are increasingly used in clinical trials. At tumor recurrence, nitrosoureas arc still provided, but their benefits are limited by prior myelosuppression or drug resistance. Paclitaxel; combination chemotherapy with mechlorethamine, vincristine, and PCZ; PCZ monotherapy; platinum compounds (ciplatin, carboplatin); combination therapy with ifosfamide, carboplatin, and etoposidc; and CPT-11 among others have been evaluated as alternative salvage treatments. A detailed description of more recently developed treatment sttategies can be found in the first section of this chapter.

Median survival of glioblastoma is less than 1 year, with exceptional survivors beyond 2 years. The median survival of patients with anaplastic astrocytoma ranges from 2 to 5 years.

Others

Gliomatosis Cerebri. Patients with gliomatosis cerebri do not benefit from surgery because the tumor extends widely along white matter tracts. Symptoms reflecting brain swelling as well as focal areas of malignant degeneration determine the onset of therapeutic intervention. Involved

field or whole-brain radiation is standard therapy, but provides only marginal benefit. Thus chemotherapy is often used with agents including PCV or temo/.olomide. The infiltrating tumor may be slow growing. Therefore the clinician is advised to evaluate focal areas of glioblastoma, whoso control m.n bench! prognosis.

Oligodendroglial Tumors

Oligodendroglioma and Oligoastrocytoma

Gross total resection prolongs survival for patients with oligodendroglioma and oligoastrocytoma containing varying proportions of oligodendroglia and fibrillary or protoplasmic astrocytes. Microscopic infiltrates are likely always present. Debulking is needed for symptoms of mass effect and hemorrhage. A MIB-1 proliferation index greater than 5% even in grade 2 tumors predicts aggressive behavior. Benefit is achieved with adjuvant radiation therapy and chemotherapy. Oligodendrogliomas may respond to PCV chemotherapy. PCV may be administered to low-grade oligodendrogliomas that cannot be resected, are symptomatic, or contain more aggressive features. The median survival time of patients with oligodendrogliomas is between 4 and 11 years. Key prognostic variables are extent of resection and the provision of chemotherapy. Features suggesting more aggressive behavior include contrast enhancement with gadolinium, MR spectroscopy with choline/creatine ratio higher than 3:1, elevated MR perfusion, location in deep-seated areas of the brain, frequent mitoses, unci Ki 67 staining vales higher than S%.

Oligoastrocyromas are managed in a similar way as oligodendrogliomas.

Anaplastic Oligodendroglioma and Anaplastic Oiigoas trocytoma

Resection, radiation, and chemotherapy are important modalities of therapy for patients with anaplastic oligodendroglial tumors (anaplastic oligodendroglioma and anaplastic oligoastrocytoma). Gross total resection oi biopsy is followed by adjuvant radiation and chemotherapy. Grade III or IV "malignant" oligodendroglial tumors share with their low-grade counterparts remarkable sensitivity to various types of monochemotherapy or combination chemotherapy. The most widely studied regimen is PCV. The majority of patients have at least a partial response. Tumors with chromosome lp loss, or the combined loss of Ip ai:J l''\], are more likch to respond to l'C\ and live longer (Fortin et al. 1999). PCV administered prior to radiation may be as effective as postradiation chemotherapy, and may allow better tolerance of the drugs and improved delivery. Patients without residual postoperative, contrast-enhancing disease or with only residual FLAIR changes are often first treated with radiation therapy as an endpoint of chemotherapy benefit is difficult to define. Alternative treatment strategies include temozolomide, BCNU, or melphalan, or high-dose, myeloablative chemotherapy followed by peripheral stem cell rescue. However, the latter approach is still considered experimental in this disease setting.

Ependymal Tumors

Ependymoma and Anaplastic Ependymoma

Ependymomas occur along the neuraxis, usually in proximity to the ventricles or subarachnoid space. Intracranial ependymoma is more common in children (infratentorial more frequent than supratentorial), spinal ependymoma in adults. Ependymoma is the most common intramedullary spinal cord tumor in adults and is typically in proximity to the conus medullaris. In this location, most are of the myxopapillary subtype. Only a small fraction of ependymomas are high-grade. Local recurrence and leptomeningcal spread have been described in a small fraction of low-grade and a larger fraction of high-grade tumors.

Complete surgical removal is indicated and may cure the patient with a low-grade ependymoma. Resection of tumors in the conus medullaris is technically difficult because the masses adhere to nerve roots and have indistinct surgical "planes" or margins that separate them Iron- norm.-! tissue of the base ;>l the spina' cord Chant; er al. 2002). Radiation therapy is beneficial to patients with residual symptomatic tumor after operation, at recurrence, or with aggressive histology (Scbild et al. 1998). Low-grade tumors, especially those located within the spinal cord, require only involved field radiation. Craniospinal irradiation is needed if leptomeningcal spread occurs. The benefits of prophylactic craniospinal irradiation for high-grade ependymoma are unclear. Local failure tends to herald leptomeningcal spread. Chemotherapy for ependymoma includes carboplatin, PCV, combination chemotherapy with cisplatin, lomustine, and vincristine, or alternating cycles of cisplatin/etoposide and cyclophosphamide/ vincristine (Chamberlain 2002).

Siibependymoma

Subependymomas are benign tumors in proximity to the ventricles. Not uncommonly, their dereccion as calcific masses is incidental, and therapy is onl\ indicated v. hen symptoms ensue. The fourth ventricle is the most common location, followed by the septum pellucidum and the lateral ventricles. The tumor is well demarcated and surgical removal is curative. Subtornlly resected tumors should be followed with serial MRI studies. Symptomatic residual tumors and those that show progressive growth should be irradiated.

Choroid Plexus Tumors

Choroid Plexus Papilloma and Carcinoma

Choroid plexus papillomas are tumors of childhood. In adults they account for only 0.5% of all intracranial neoplasms. The tumor is located in the fourth ventricle, the lateral ventricles, or the cerebellopontine angle. Patients most commonly present with deficits of the eighth cranial nerve, signs of cerebellar dysfunction, or overproduction of CSF.

Total resection is accomplished in fewer than half of cases. Frequently the tumor is attached to lower cranial nerves. Thus morbidity of surgical intervention is significant. In one small series, transient worsening ot neurological deficits occurred in up to 25% of cases, and postoperative mortality approached 2(i%. Preoperative selective microembolization has been used. There is no role for adjuvant treatment modalities at diagnosis because long-term survival follows even subtotal resection. At progression or recurrence, treatment with conventional external beam radiation ot SRS is of benefit. Obstructive hydrocephalus, a frequent complication of choroid plexus papilloma, is relieved by tumor removal, and shunt procedures are only indicated in a few cases (Tacconi et al. 1996).

Choroid plexus carcinoma in adults is the subject of case reports only. Adjuvant treatment after surgical removal includes irradiation and chemotherapy. Therapeutic efficacy has been shown for lomustinc.

Neuronal and Mixed Neuronal-Glial Tumors

Ganglioglioma and Gangliocytoma

Gangliogliomas contain two cell populations: gangliocytes and mature glial elements derived from precursor cells that can differentiate into both elements. Although commonly benign, anaplastic changes develop in 4-32% of cases. Gross total resection results in survival ranging from 7 to 17 years. Thus adjuvant irradiation is not indicated. Radiation therapy is provided to tumors that are incompletely resected or those with anaplastic progression. These have a worse prognosis with an overall survival of 3 years or less (Hakim ct al. 1997). Chemotherapy is used with the assumption that the astrocytic component will respond. For the anaplastic glial component, regimens are identical to the ones used for high-grade gliomas.

Central Neurocytoma

Central neurocytoma, a neuronal tumor, occurs in young adults in proximity to the supratentorial ventricular system. The tumor arises from the fornix, septum pellucidum, or the walls of the lateral ventricles. A benign tumor, surgical removal is performed by operations through the corpus callosum or cortex with attendant memory and cognitive problems, which are transient, Fewer than 50% of patients experience cure; for the remainder there is bleeding or adherence of tumor to adjacent structures. However, long-term tumor control can be achieved with partial resection. Instances of anaplasia or dissemination along CSF pathways are rare. Thus radiation therapy is recommended for tumors with a high proliferative index or growth. For tumors smaller than 3 cm, SRS may be beneficial. Adjuvant chemotherapy benefits a minority of patients treated with a combination of cisplatin, etoposide, and cyclophosphamide (Schild et al, 1997; Brandes ct al. 2000).

Pineal Parenchymal Tumors

Although a variety of tumors appear in the region of the pineal gland or the subarachnoid space surrounding it, cells of "pineal" origin can form tumors: pineocytoma, pineal parenchymal tumors of intermediate grade, and pineobi asroma. The more malignant tumors are seen in younger patients; more than 90% of patients with pineoblastoma are younger than age 23, whereas in patients older than the age of 40 years, one third of the masses are tumors of low or intermediate grade (Chang et al. 2000).
