Usually noted in the legs and consisting of extension of the great toe, dorsiflexion of the ankle, and flexion of the knee and hip; sometimes seen in the arms
Periodic or quasi periodic at an average interval of 20-40 sec (range 4-90 sec) with a duration of 0.5-5.0 sec and as part of at least four consecutive movements
Occurs at any age but prevalence increases with age
May occur as an isolated condition or may be associated with a large number of other medical, neurological, or sleep disorders and medications
Seen in at least 80% of patients with restless legs syndrome

NREM = non—rapid eye movement.

Tabic 74.19: Causes of symptomatic or secondary restless legs syndrome

Neurological disorders
- Polyneuropathies
- Lumbosacral radiculopathies
- Amyotrophic lateral sclerosis
- Myelopathies
- Multiple sclerosis
- Parkinson's disease
- **Poliomyelitis**
- Isaac's syndrome
- Hyperexplexia (startle disease)

Medical disorders
- Anemia: iron and folate deficiency
- Diabetes mcllitus
- Amyloidosis
- Uremia
- Gastrectomy
- Cancer
- Chronic obstructive pulmonary disease
- Peripheral vascular (arterial or venous) disorder
- Rheumatoid arthritis
- Hypothyroidism

Drugs and chemicals
- Caffeine
- Neurolepsy
- Withdrawal from sedatives or narcotics
- Lithium
- **C.ikmm ..'vniivi** nir,u;nriiits e.g., nifedipine

Table 74.21: Pertinent features of akathisia that differentiate it from restless legs syndrome

Inner restlessness, fidgetiness with jittery feelings, or generalized restlessness
Common side effect of neuroleptic drugs
Can he acute, chronic, or tardive
Characteristic motor restlessness consists of swaying or rocking movements of the body; marching in place; crossing and uncrossing of the legs; shifting body positions in chair; inability to sit still; rhythmic or nonrhythmic, synchronous or asynchronous, symmetrical or asymmetrical limb movements; movements resemble chorea rather than the voluntary movements of restless legs syndrome
Motor restlessness present mostly during the day but may be worse when sitting or standing in one place for a long time
Polysomnography study shows no distinctive features and rarely may show evidence of mild sleep disturbance and periodic limb movements in sleep
No relevant family history
Neurological examination reveals evidence of akathisia and sometimes drug-induced extrapyramidal manifestations
Involuntary movements (e.g., myoclonic jerks) are uncommon and not a prominent feature
Best treated with anticholinergics or ^-adrenergic antagonists

Differential diagnosis of RLS may be considered under two categories: secondary RLS and the entities that may mimic RLS. In secondary or symptomatic RLS, several conditions may be associated with RLS or may cause symptomatic RLS (Table 74.19). The entities that mimic RLS are listed in Table 74.20. An important and often difficult condition to differentiate from RLS is akathisia. Essential features of akathisia that differentiate it from RLS are listed in Table 74.21.

Pathoph ysio logy

The physiological mechanism or the anatomical locus responsible for RLS-PLMS is unknown. Pathophysiological elms may be derived from electrophysiological and imaging studies as well as from state-dependent and circadian factors {Hening et al. 1999; Trenkwaldcr and Winkelmann 200.5; Chokrowrty el al. 200,51. Dopaminergic and peptidergic theories are based on pharmacological responses. On the basis of implications derived from secondary RLS, a vascular hypothesis, a peripheral neuropathy hypothesis, and deficient and toxic states have been suggested as etiologies, but none has been satisfactory. The most likely hypothesis is a functional alteration in the brainstem region, but the exact location is undetermined. Several studies have found inconsistent support for the presence of some hyperexcitable brainstem reflexes. Based on the absence of cortical prepofentials in a jerk-locked back averaging study, it is unlikely that the cortex is the generator of PLMS. Studies have shown that **RLS** was maximum during the falling phase of a body temperature curve, which suggests that there is a circadian factor that modulates severity of RLS, independent of activity state. A functional MR1 study showed increased activity in the contralateral thalamus and in the red nucleus, bilateral cerebellum, and brainstem reticular formation in patients with PLMS and sensory symptoms (Bucher et al. 1997). Two positron emission tomography (PF.T) studies (Turjanski et al. *1999*\ Ruottinen et al. 2000) and two single photon emission computed tomogtaphy (SPECT) studies (Staedt et al. 1995; Michaud et al. 2002) suggested small but significant striatal dopamine abnormalities. However, the small magnitude of these observations and reports of some negative dopamine system imaging studies (Trenkwalder et al. 1999; Eisensehr et al. 2001) raise some

Table 74.20: Entities that may mimic restless legs syndrome

Myoclonus (essential myoclonus)
Hypnic jerks ("sleep starts")
Anxiety-depression
Growing pains

pertinent questions about whether these abnotmalities arc primary rather than epiphenomcna. The most exciting current development in RLS research is the hypothesis that brain iron depletion causes alteration of brain dopaminergic system thereby producing symptoms of RLS (Allen and Earley 2003).

Periodic Limb Movements hi Sleep

PI.MS is a PSG finding and is characterized by periodically recurring limb movements during NREM sleep; most commonly, patients dorsiflex the ankles and flex the knees and hips every 20-40 seconds (tange 4-90) seconds. ( )cc.iMOiiali\, I'l MS i- noted ill [lie np;vr li:r.;v,.]:, .,i least 80% of patients with RLS, PLMS is also seen, whereas RLS is found in about 30% of patients with PLMS. Additional criteria for PLMS are listed in Table 74.18. Limb movements may be accompanied by partial arousal, causing sleep fragmentation. A PLMS index fnumbci ul I[1]! MS per hour ol sleep) ol *S* is considered within normal range.

PLMS is seen most commonly in RLS but may also occur in a large number of othet medical, neurological, and sleep disorders (Montplaisir et al. 2000), and in association with medications (e.g., tricyclic antidepressants, selective serotonin reuptake inhibitors, and r dopa . Whether PI MS occurs as a primary condition unassociated with RLS causing repeated awakenings and sleep fragmentation as described in the *ICSD* under the heading of PLMD remains controversial. There is a growing body of evidence that PLMS may not have a specific clinical significance and is simply a PSG observation seen in a wide variety of sleep disorders but is present in most patients with RLS (Montplaisir et al. 2000; Mahowald 2002).

(arcadian Rhythm Sleep Disorders

Orcadian rhythm sleep disorders result from a mismatch between the body's internal clock and the geophysical environment (Mahowald et al. 1997; Dagan 2002) either because of a malfunction in the biological clock (primary circadian rhythm disorders) or because the clock is out of phase due to a shift in environment (secondary circadian dysrhythmias). Jet lag and shift work are two common sources of secondary circadian dysrhythmias resulting from exogenous factors.

Delayed Sleep-Phase Syndrome

The *ICSD* defines DSPS as a condition in which the major sleep episode is delayed in relation to the desired clock time. This causes symptoms of sleep-onset insomnia or difficulty awakening at the desired time. Typically, the patient goes to sleep late (e.g., 2:00-6:00 AM) and awakens in the late morning or afternoon (e.g., 10:00-2:00 PM), Patients with this disorder have great difficulty in functioning adequately in the daytime if they have to wake up early in the morning to go to school or work. They have severe sleep-initiation difficulty and cannot function normally in society because of the disturbed sleep schedule. They often try a variety of hypnotic medications or alcohol in an attempt to initiate sleep sooner. Sleep architecture is generally normal if these individuals are allowed to follow their own uninterrupted sleep-wake schedule.

DSPS may represent 5-10% of complaints of insomnia in some sleep disorders centers. Onset occurs during childhood or adolescence. Sometimes there is a history of DSPS in other family membets. Some patients may have depression. Primary DSPS results from an unusually long intrinsic circadian period due to abnotmalities in • In- biological clock in the Si \. Aclii;rapliic recordings over several days document the charactetistic sleep schedule.

Advanced Sleep-Phase Syndrome

Advanced sleep-phase syndrome (ASPS) is the converse of DSPS: The patient goes to sleep in the early evening and wakes up earlier than desired in the morning (e.g., 2:00-4:00 AM). If these patients do not go to sleep at an early hour, they experience sleep disruption and daytime sleepiness. Occasional familial cases have been described.

ASPS is most commonly seen in elderly individuals. The basic mechanism is thought to be an inherent shortening of the endogenous circadian timing. The diagnosis is based on sleep logs and characteristic actigraphic recordings over several days. ASPS is easy to distinguish from the early morning awakening of depression because sleep architecture is normal and does not exhibit the shortened REM latency and other REM sleep abnormalities seen in depressed patients.

Hypernychthemeral Syndrome

Hypernychthenteral syndrome, also cailed non-24-hour sleep-wake disorder, is characterized by an inability to maintain a regular bedtime. Sleep onset wanders around the clock. Affected patients have a gradually increasing delay in sleep onset by about 1 hour per sleep-wake cycle, causing eventual progression of sleep onset through the daytime hours and into the evening. These individuals fail to be entrained or synchronized by usual time cues, such as sunlight or social activities.

Hypernychthemeral syndrome is an extremely uncommon disorder and is most often associated with blindness. Approximately one third of blind individuals are affected because of impairment of the retinohypothalamic pathway, which normally cues circadian patterns. The syndrome also may be associated with hypothalamic tumors. Sometimes depression and anxiety disorders are associated with this syndrome.

Neurological Disorders and Sleep Disturbance

Sleep disorders are very common in neurological illnesses, which ma; adversely affect punnus' •deep. llm.s (here is an interrelationship between sleep and neurological disorders. Sleep dysfunction may result from central or peripheral somatic and autonomic neurological disorders. Neurological diseases may cause insomnia or EDS as well as parasomnias. Neurological causes of excessive sleepiness have been described previously, and neurological disorders that cause insomnia are described under Insomnia, earlier in this chapter.

Sleep and Epilepsy

There is a distinct and reciprocal relationship between sleep and epilepsy (Chokroverry and Quinto 1999; Dinner 2002). Sleep affects epilepsy, and epilepsy affects sleep. In the beginning of the last century, before the availability of encephalography, several authors emphasized that many seizures are predominantly nocturnal and occur at certain times at night. The modern era of combining the clinical and EEC findings on sleep and seizures began with the observation of Gibbs and Gibbs in 1947 that EEG epileptiform discharges were seen more often during sleep than during wakefulness (Chokroverry and Quinto 1999). A basic understanding of the mechanism of epileptogenesis and sleep makes it clear why seizures are often triggered by sleep. The fundamental mechanism for epileptogenesis includes neuronal synchronization, neuronal hypcrexcitability, and a lack of inhibitory mechanism. During NREM sleep, there is an excessive diffuse cortical synchronization mediated by the thalamocortical input, whereas during REM sleep, there is inhibition of the thalamocortical synchronizing influence in addition to a tonic reduction in the interhemispheric impulse traffic through the corpus callosum. Factors that enhance synchronization are conducive to active ictal precipitation in susceptible individuals. NREM sleep thus acts as a convulsant by causing excessive synchronization and activation of seizures in an already hyperexeitable cortex. In contrast, during REM sleep, there is attenuation of epileptiform discharges and limitation of propagation of generalized epileptiform discharges to a focal area.

Sleep deprivation is another important seizure-triggering factor, and the value of sleep-deprived ERG studies in the diagnosis of seizures is well known. Sleep deprivation increases epileptiform discharges, mostly during the transition period between waking and light sleep. Sleep deprivation causes sleepiness, which is one factor for activation of seizures, but it probably also increases cortical excitability, which triggers seizures. However, in a recent report on 84 patients with medically refractory partial epilepsy with secondary generalization undergoing inpatient monitoring, Malow ct al. (2002) noted that acute sleep deprivation did not affect seizure incidence.

Biorhythmic classification of seizures has shown inconsistencies and contradictions. Seizures have been shown to occur predominantly during sleep (nocturnal seizures), predominantly in the daytime (diurnal seizures), or both during sleep at night and daytime (diffuse epilepsy). Taking into consideration different series, the incidence of sleep epilepsy has been quoted to be 22%, but most of these statistics were obtained before the advent of electroencephalography. The most likely figure for nocturnal seizures is aboul 10%. Because of inconsistencies in biorhythmic classification, modern epilcptologists use the International Classification of Epilepsy, which divides seizures into primarily generalized and partial seizures with or without secondary generalization.

Effect of Sleep on Epilepsy, True nocturnal seizures (Malow and Plazzi 2003; Chokroverry and Quinto 1999) may include tonic seizures, benign focal epilepsy of childhood with rolandic spikes or occipital paroxysms, juvenile myoclonic epilepsy, electrical status epilepticus during sleep or continuous spikes and waves during sleep, generalized tonic-clonic seizures on awakening, nocturnal frontal lobe epilepsy including nocturnal paroxysmal dystonia (NPD), and a subset of patients with temporal lobe epilepsy (nocturnal temporal lobe epilepsy). Many patients with generalized tonic-clonic and partial complex seizures also have predominantly nocturnal seizures, Nocturnal seizures may be mistaken for motor and behavioral parasomnias or other movement disorders that persist during sleep or reactivate during stage transition or awakenings in the middle of the night.

Tonic Seizure. Tonic seizures are characteristic of Lcnnox-Gastaut syndrome, which may also include other seizure types, such as myoclonic, generalized tonic-clonic, atonic, and atypical absence. Tonic seizures are typically activated by sleep, occur much more often during NREM sleep than during wakefulness, and are never seen during REM sleep. The typical EEG finding consists of slow spikes and waves intermixed with trains of fast spikes as intcrietal abnormalities during sleep.

Benign Rolandic Seizure. Benign rolandic seizure is a childhood seizure disorder seen mostly during drowsiness and NREM sleep and is characterized by focal clonic facial twitching, often preceded by perioral numbness. Many patients may have secondary generalized tonic-clonic seizures. The characteristic EEG finding consists of centrotemporal or rolandic spikes or sharp waves and sometimes occipital spikes. Seizures generally stop by the 15-20 years of age without any neurological sequela.

Juvenile Myoclonic Epilepsy. Onset of myoclonic epilepsy of Janz usually occurs between 13 and 19 years of age and

is manifested by massive bilaterally synchronous myoclonic jerks. The seizures increase shortly after awakening in the morning and occasionally on awakening in the middle of the night. A typical electroencephalogram shows synchronous and symmetrical polyspikes and spike-and-wave discharges. The intericta) discharges predominate at sleep onset and then on awakening but are virtually nonexistent during the rest of the sleep cycle.

Nocturnal Frontal Lobe Epilepsy. Nocturnal frontal lobe epilepsy includes (Provini et al. 1999; Malow and Plazzi 2003) nocturnal paroxysmal dystonia, paroxysmal arousals and awakenings, episodic nocturnal wanderings, and autosomal dominant nocturnal frontal lobe epilepsy. These disorders all share common features of abnormal paroxysmal motor activities during sleep and respond favorably to anticonvulsants. They most likely represent partial seizures arising from discharging foci in the deeper regions of the brain, particularly the frontal cortex, without any concomitant scalp EEC evidence of epileptiform activities. The relationship to seizures, particularly partial complex seizures of temporal or extratcmporal origin, however, remains controversial. Nonepilepric seizures or pseudoseizures are not common during sleep at night but sometimes can occur and be mistaken for true nocturnal seizures, and it is important to differentiate these from true seizures because of difference in management.

hive patients were originally described who had episodes of abnormal movements that were tonic and often violent during NREM sleep almost every night. Ictal and interictal EEG findings were normal. Later, 12 patients were described with NREM sleep-related choreoathetotic, dystonic, and ballismic movements each night, often occurring many times during the night for many years. The term *nocturnal paroxysmal dystonia {NPD)* was coined for this entity (Table 74.22). The disorder in all patients responded to carbamazepine therapy, and the spells lasted less than 1 minute. It was suggested that these spells were a type of unusual nocturnal seizure. Later, patients with NPD showed IT(. evidence ot epileptiform abnormalities arising from the frontal lobes. A study comparing groups of patients with NPD and those with undisputed frontal lobe seizures supported the contention that patients with NPD may have frontal lobe seizures. Therefore, short-duration NPD attacks may represent a form of frontal lobe seizures (Table 74.23) that arc evoked specifically during sleep at night. Provini and co-workers (1999) gave a comprehensive review of clinical and EEG features of 100 consecutive cases of nocturnal frontal lobe epilepsy.

Table 74.22: Features of nocturnal paroxysmal dystonia

Onset: infancy to fifth decade
Usually sporadic; rarely familial
Sudden onset from non-rapid eye movement sleep
Two clinical types: Common [ype is short-lasting (15 sec to <2 min)
Semiology: ballismic, choreoathetotic, or dystonic movements
Often occurs in clusters
Electroencephalogram: generally normal
Short-duration attacks arc most likely a tvpc of frontal lobe seizure
Treatment: carbamazepine effective in patients with short-lasting attacks

"Table 74.23: Features of frontal lobe seizures

Age of onset: infancy to middle age
Sporadic, occasionally familial (dominant)
lloth diurnal and nocturnal spells, sometimes exclusively nocturnal
Sudden onset in non-rapid eye movement sleep with sudden termination
Duration: mostly less than 1 min, sometimes 1-2 min with short postictal confusion
t Jr'ren occur in clusters
Semiology: tome, clonic, bipedal, bimanual, and bicycling movements; motor and sexual automatisms; contralateral dystonic posturing or arm abduction with or without eye deviation
lctal EEC! may be normal; interictal EEG may show spikes; sometimes depth recording is needed

EEG = electroencephalogram.

Autosomal Dominant Nocturnal Frontal Lobe Epilepsy. An autosomal dominant form of frontal lobe epilepsy usually staffs in childhood and persists throughout adult life. Attacks are characterized by brief motor seizures in clusters during sleep. Neurological examination and ncuroimaging studies are normal. Videotelemetry during the attacks confirms their epileptic nature, and the response to carbamazepine treatment is excellent (Scheffer ct al. 1995).

Effect of Epilepsy on Sleep

Although the usefulness of sleep in the diagnosis of epilepsy has been established, the altered sleep characteristics in epileptic patients are not well known. Most studies have been conducted in patients who have been receiving anticonvulsants, thus adding the confounding factors of the effect of anticonvulsants on sleep architecture. Additionally, there is a dearth of longitudinal studies to determine the effect of epilepsy on sleep in the early stage versus the late stage of illness. A genetal consensus has been reached, however, on the effects of epilepsy on sleep and sleep structure. These effects can be summarized as follows: an increase of sleep-onset latency; an increase in waking aftet sleep onset; a teduction in REM sleep; increased instability of sleep states, such as unclassifiable sleep epochs; an increase in stages I and II NREM sleep; a decrease in stages III and IV NREM sleep; and a reduction in the density of sleep spindles.

Sleep Disorders Associated with Neuromuscular Disorders

Clinicians first became aware of sleep-related respiratory dysrhythmias in patients with neuromuscular diseases by observing hypoventilation in poliomyelitis. Sleep disturbances in neuromuscular diseases arc generally due to respiratory dysrhythmias associated with these diseases (Chokroverty 2001; Guilleminauit and Shergill 2002). In neuromuscular disorders, sleep disturbances are due to involvement of respiratory muscles, phrenic and intercostal nerves, or neuromuscular junctions of the respiratory and oropharyngeal muscles. The most common complaint is EDS resulting from transient nocturnal hypoxemia and hypoventilation, causing repeated arousals and sleep fragmentation. In addition to the sleep-related respiratory dysrhythmias, some patients, particularly those with painful polyneuropathies, muscle pain, muscle cramps, and immobility due to muscle weakness, may complain of insomnia. Patients with neuromuscular diseases often complain of breathlessness, particularly in the supine position.

Respiratory disturbances arc generally noted in the advanced stage of primary muscle disorders or myopathics, but respiratory failure may appear in an early stage. Sleep complaints and sleep-related respiratory dysrhythmias are common in Duchenne's and limb-girdle muscular dystrophies as well as in myopathies associated with acid maltase deficiency. They may also occur in other congenital or acquired myopathies, mitochondrial encephalomyopathy, and polymyositis.

Many patients with myotonic dystrophy have been described with central, mixed, and upper airway OSAS; alveolar hypoventilation; daytime fatigue; and hypersomnolence. Nocturnal oxygen desaturation accompanies alveolar hypoventilation and apneas and becomes worse during REM sleep. EDS in myotonic dystrophy often occurs in the absence of sleep apnea. An entity called *proximal myotonic myopathy* (PROMM) has been described. PROMM, also called DM 2, is a hereditary myotonic disorder that is differentiated from myotonic dystrophy by absence of the chromosome IV CTC trinucleotide repeat that is associated with classic myotonic dystrophy. A brief report (Chokroverty et al. 1997) describes sleep disturbances in two patients consisting of difficulty initiating sleep, EDS, snoring, and frequent awakenings and movement during sleep. An overnight PSG study showed decreased sleep efficiency, increased number of arousals, and sleep architectural abnormalities. One patient had absent REM sleep; the other had dissociated REM sleep characterized by phasic REM bursts associated with EEC patterns showing sleep spindles and alpha intrusions. These sleep abnormalities in PROMM suggested involvement of the REM- and NREM-generating neurons as part of a multisystem membrane disorder.

In polyneuropathies, involvement of the nerves supplying the diaphragm and the intercostal and accessory muscle of respiration may cause breathlessness on exertion and other respiratory dysrhythmias. These may worsen during sleep, causing sleep fragmentation and daytime hypersomnolence, In painful polyneuropathies, patients may have insomnia.

Neuromuscular junctional disorders (e.g., myasthenia gravis, myasthenic syndrome, botulism, and tic paralysis) are characterized by easy fatigability of the muscles, including the bulbar and other respiratory muscles, as a result of nerve impulses of the neuromuscular junctions not being transmitted. Patients with myasthenia gravis may have central, obstructive, and mixed apneas and hypopneas accompanied by oxygen desaturation. A sensation of breathlessness on awakening in the middle oi [he night and early morning hours may indicate respiratory dysfunction. Sleep-related hypoventilation and sleep apnea in neuromuscular junctional disorders may be severe enough to require assisted ventilation (Gonzalez, et al. 2002),

Sleep and Spinal Cord Diseases

Sleep disturbances related to respiratory dysfunction can occur in some patients with high cervical spinal cord lesions. Patients with poliomyelitis, amyotrophic lateral sclerosis (AES) affecting the phrenic and intercostal motor neurons in the spinal cord, spinal cord tumors, spinal trauma, spinal surgery (e.g., cervical cordotomy or anterior spinal surgery), and nonspecific or demyelinating myelitis may all have sleep distutbances. The most common symptom is hypersomnia due to sleep-related respiratory arrhythmias. Occasionally, patients with spinal cord diseases may complain of insomnia as a result of immobility, spasticity associated with flexor spasms, neck pain, and central pain syndrome.

Sleep Disturbances in Poliomyelitis and Postpolio Syndrome

Respiratory disturbances worsening during sleep may occur in many patients during the acute and convalescent stages of poliomyelitis. Some are left with the sequela of sleep-related apnea or hypoventilation requiring ventilatory support, especially at night. Another group of patients develops symptoms decades later that constitute postpolio syndrome, in which sleep disturbances and sleep apnea or hypoventilation have also been noted. Postpolio syndrome is manifested clinically by increasing weakness or wasting <>l UK- prvvioLisly affected muscles and b\ involvement oi previously unaffected regions of the body, fatigue, aches and pains, and sometimes symptoms secondary to sleep-related hypoventilation (e.g., EDS and tiredness).

Sleep and Headache Syndromes

In day-to-day practice, headaches and sleep complaints are common (Jennum and Jensen 2002; Poceta 2002).

Sleep disturbance in OSAS may cause headache, and headache irself may cause sleep disturbance. The *1CSD* (1997) includes cluster headache, chronic paroxysmal hemicrania, and migraine under the heading of sleep-related headaches. PSG recordings in patients with chronic migraine and cluster headaches show a clear relationship between REM sleep and attacks of headache, although sometimes migraine headaches with arousals may occur out of both slow-wave and REM sleep. Cluster headaches are thought to be related to REM, but cluster headaches may sometimes be triggered by NREM sleep. Chronic paroxysmal hemicrania, which is probably a variant of cluster headache, is most commonly associated with REM sleep. Significant sleep disruption in the form of decreased total and REM sleep time, accompanied by an increased number of awakenings during REM sleep, has been described in patients with chronic paroxysmal hemicrania. PSG recordings have documented sleep apnea in some patients with chronic recurring headache syndromes. The relationship between early morning headache and upper airway OSAS has been somewhat controversial, with conttadictory reports. There arc occasion;)I reports of the coexistence of OSAS and cluster headache with improvement of headache following CPAP titration (Zaliek and Cbervin *2000).*

A rare benign headache syndrome, called *bypnic headache syndrome,* is described in patients older than 60 years of age. The patients are awakened from sleep at a constant time each night. Hypnic headache syndrome is differentiated from chronic cluster headache by generalized distribution, age of onset, and lack of autonomic manifestation. This disorder often responds to lithium or indomethacin treatment.

Fxploding head syndrome is an unusual phenomenon that usually occurs in the transition from wake to sleep, abruptly arousing the patient with the sound of an explosion in the head, accompanied by bright light flashes. This is a benign condition and may represent a form of "sleep starts" (sec later).

Kleine-Levin Syndrome

Klcine in 1925 and Levin in 19.16 described an episodic disorder occurring mostly in adolescent boys (but also described later in girls) that was characterized by periodic hypersomnolcnce and bulimia. The episodes usually last for days to weeks. During sleep "attacks," the patient sleeps 16-18 hours a day or more and on awakening eats voraciously. Other behavioral disturbances during the episode may include hypersexuality, confusion, hallucination, inattention, and memory impairment. The condition is generally self-limited and disappears by adulthood. PSG study shows normal sleep cycling, and the MSLT shows pathological sleepiness without SOREMs. The cause of the condition remains undetermined, although a limbic-hypothalamic dysfunction is suspected but not proved. An autoimmune hypothesis has been suggested based on clinical and increased HLA DQBI0201 allele frequency (Dauvilliers et al. 2002). Lithium treatment is effective, and valproic acid may also be useful.

Fatal Familial Insomnia

Fatal familial insomnia (FFI) is a rare and rapidly progressive autosomal dominant prion disease with a missense mutation at codon 178 of the prion protein gene f/V/') (Montagna et al. 2003). FFI was originally described in a family with a progressive neurological illness characterized by insomnia and dysautonomia that terminated in death. Clinical manifestations are impaired control of the sleep-wake cycle, including arcadian rhythms; autonomic and neuroendocrine dysfunction; and somatic neurological, cognitive, and behavioral manifestations. Profound sleep disturbances and, in particular, severe insomnia are noted from the very beginning of the illness. PSG study shows almost total absence of sleep pattern and only short episodes of REM sleep, lasting for a few seconds or minutes, without muscle atonia. This abnormal sleep pattern is associated with dream-enacting behavior in the form of complex gestures and motions and myoclonus. The terminal stage of the illness is characterized by progressive slowing of the electroencephalogram, with the patient drifting into coma, \utonomic function t^rs reveal evidence of sympathetic hyperactivity with preserved parasympathetic activity. Neuroendocrine functions in FFI show a dysfunction of the pituitary-adrenal axis, as manifested by striking elevation of scrum Cortisol but normal adrenocorticotropic hormone, indicating abnormal feedback suppression of adrenocorticottopic hormone. Persistently elevated scrum catecholamine levels associated with abnormal secretory patterns of growth hormone, prolactin, and melatonin are noted. The nocturnal secretory peaks of growth hormone are absent. Plasma melatonin levels progressively decrease, and in the most advanced stage of the illness, there is a complete abolition of melatonin rhythm. Somatic neurological manifestations consist of ataxia, evidence of pyramidal tract dysfunction, myoclonus, tremor, and bizarre astasia-abasia. Neuropsychological studies reveal impairment of attention, vigilance, and memory. The disease progresses rapidly and ends in coma and death.

The neuropathological hallmark of ITl is severe atrophy of the thalamus, particularly the anterior ventral and dorsomedial thalamic nuclei associated with variable involvement of the inferior olive, striatum, and cerebellum. There are no spongiform changes, except in those with the longest duration of symptoms, who show mild-to-moderate spongiform degeneration of the cerebral cortex. Severe hypometaholism of the thalamus and mild hypometabolism of the cingulare cortex arc the main findings on PET study in FFI patients. Based on biochemical, genetic, and

transmission studies, it has been concluded that FFI is a transmissible prion disease resulting from a mutation at codon 178 of *PrP*, associated with substitution of aspartic acid with asparagine along with the presence of methionine codon at position 129 of the mutant allele. All human prion diseases (e.g., Creutzfeldt-Jakob disease and Gerstmann-Straussler-Scheinker disease) should be considered in the differential diagnosis. Approximately 30 unrelated families of patients with FFI have been identified so far. FFI has been transmitted to experimental animals. FFI is thus a transmissible prion disease and represents the third most common hereditary prion disease worldwide. Sporadic instances, however, have also been reported. The study of FFI has rekindled investigation of the role of the thalamus in sleep-wake regulation.

Stroke and Sleep Disturbances

Sleep disruption and sleep complaints resulting from sleep-related breathing dysrhythmias have been reported in many patients with cerebral hemispheric stroke (Bassetti and Chervin 2000). There is. however, a dearth of well-controlled studies establishing a relationship between sleep disorders and cerebrovascular disease. Sleep apnea, snoring, and stroke are intimately related. Sleep apnea may predispose patients to stroke, and stroke may predispose patients to sleep apnea (Shahar et al. 2001). Based on case-controlled, epidemiological, and laboratory studies, there is increasing evidence that snoring and sleep apnea are risk factors for stroke. Several confounding variables are common risk factors for snoring, sleep apnea, and stroke, however, and these should be considered when attempting to establish a relationship between snoring, sleep apnea, and stroke. These variables include hypertension, cardiac disease, age, body mass index, smoking, and alcohol consumption. There is an increased incidence of sleep apnea in patients with both infratentorial and supratentorial strokes (Basserti and Chervin 2000; lranzo et al. 2002). It is important to make a diagnosis of sleep apnea in patients with stroke because this may adversely affect short-term and long-term outcomes in these patients and because there is effective treatment for sleep apnea that can decrease the risk of future sttoke (Wessendorf et al. 2001). Other causes of sleep disruption causing insomnia may include associated depression, spasticity, and immobility.

1 ly per somnolence has been described after bilateral paramedian thalamic infarcts. Several authors have described sleep disturbances in brainstem infarction. PSG findings generally consist of increased wakefulness after sleep onset and decreased REM and SWS in these patients. EEG findings in several reports of patients with locked-in syndrome resulting from ventral pontine infarction generally showed teduced or absent REM sleep and variable changes in NREM sleep, including reduction of SWS and total sleep time (Chokroverty 1999b).

Brainstem infarction may cause the syndrome of primary failure of automatic respiration, or Ondine's curse. Voluntary breathing control is intact, but metabolic control, which is the only respiratory control during sleep, is impaired. Therefore the patients become apneic during sleep. Severinghaus and Mitchell named the condition. The syndrome of Ondine's curse is usually caused by bilateral lesions anywhere caudal to the fifth cranial nerve in the pons down to the upper cervical spinal cord in the ventrolateral region. Occasional patients with unilateral btainstem infarction have been described with loss of automatic respiratory control during sleep.

Traumatic Brain Injury and Sleep Disturbances

Traumatic brain injuries (TBIs) include concussion, contusion, laceration, hemorrhage, and cerebral edema. Insomnia, hypersomnia, and circadian rhythm sleep dysfunction may occur after TBIs, but objective sleep studies in such patients documenting sleep disturbances have not been adequately performed (Rao and Rollings 2002). After a severe TBI, brainstem function is compromised, and the patient becomes comatose. There have been many EFG studies in patients with coma after head trauma. However, no studies have adequately addressed the sleep-wake abnormalities in these patients after recovery from coma as well as in patients after minor brain injuries that did not result in coma. Many of these patients experience so-called postconcussion syndrome, which is characterized by a variety of behavioral disturbances, headache, and sleep-wake abnormalities. A few reports list subjective complaints of sleep disturbance but do not include formal sleep studies. In one report of patients with closed head injury, PSG studies documented sleep-maintenance insomnia with an increased number of awakenings and decreased night sleep. The mechanism of these sleep abnormalities is unknown. Post-traumatic hypersomnolence is listed in the *ICSD* (1997). TBIs may cause central and upper airway OSA by inflicting functional or structural alterations on the brainstem respiratory control system. Many of these patients may, however, have had sleep apnea syndrome

bcfoiv suM:;iiiim: .i 1 1>1. < \\\ adiai! **i"liy(li;n sleep** distill" bances have been described in patients with severe brain damage. There are reports of DSPS after TBIs (Ghokrovcrty 1999b; Smits and Nagtegaal 2000).

Sleep and Multiple Sclerosis

Sleep-related breathing abnormalities and other sleep difficulties, including insomnia, EDS, and depression, have been described in patients with multiple sclerosis. Sleep disturbances in multiple sclerosis are thought to result from immobility, spasticity, urinary bladder sphincter disturbances, and sleep-related respiratory dysrhythmias

due to affected respiratory muscles or impaired central control of breathing.

Sleep Disturbances in Neurodegenerative and Movement 1 >isotdcrs

Neurodegenerative diseases are traditionally defined as a group of heterogeneous diseases of the CNS for which no causal agent can he identified. The disorders generally affect one or more systems symmetrically and run an inexorably progressive course.

Sleep-wake-promoting neurons are involved in the process of diffuse degeneration, causing a variety of sleep disorders in these illnesses (Chokroverry 1996; Hening et al. 1999). Neurodegenerative diseases can he considered under two broad categories: degeneration of the somatic neurons and degeneration of the autonomic neurons. Somatic neuronal degeneration can be predominantly cortical (e.g., Alzheimer's disease), predominantly basal ganglia, or basal ganglia-plus syndromes (e.g., Parkinson's disease, progressive supranuclear palsy, Huntington's chorea, torsion dystonia, and Tourette's syndrome. In contrast to other hyperkinetic movement disorders that are usually suppressed during sleep, motor and phonic tics may persist during all stages of sleep and, additionally, patients with Tourette's syndrome have disturbances of sleep such as increased sleep fragmentation, high co-incidence of arousals, decreased REM sleep, and enuresis (Hanna and Jankovic, 2003). Other neurological disorders with prominent sleep disturbances include cerebellar or cerebellar-plus syndromes (spinocerebellar ataxias (SCAs), such as olivopontocerebellar atrophy (OPCA), or those with degeneration of predominantly motor neurons of the cerebral cortex, brainstem, and spinal cord (ALS or motor neuron disease). Neurodegeneration of the autonomic neurons is responsible for multiple system atrophy (MSA) or Shy-Drager syndrome (Table 74.24) (see also Chapter 77).

Table 74.24: Salient clinical manifestations of multiple system atrophy

- Autonomic features
  - Cardiovascular
    - Orthostatic hypotension
    - Postprandial hypotension
    - Postural syncope
    - Postur'l dizziness, faint feelings, or blurring of vision
    - Orthostatic intolerance

  - Respiratory
    - Sleep apnea-hypopnea
    - Other respiratory dysrhythmias
- Normal mentation
- Normal sensation

Alzheimer's Disease

Alzheimer's disease (AD) is the most common cerebral degenerative disordet causing dementia. Reports of sleep disturbances in AD have been contradictory. Sleep disorders may he related to the severity of dementia as well as to associated PLMS and sleep-telated respiratory dysrhythmias. In addition, the artificial environment of the hospital and laboratory where the sleep disturbance is evaluated may be partly responsible for confusional episodes, including "sundowning" in AD patients. Insomnia, inversion of the sleep rhythm, and in some cases, EDS are the presenting complaints. Sleep disturbances in AD should be differentiated irom ihosc (kvurnn;-, m depression, which is common in elderly subjects. A reduction in the amount of REM sleep and reduced REM density arc quite different from the reduced REM latency and increased REM density often seen in depressed patients. Sleep-related respiratory dysrhythmia has been estimated to be present in *i3-55%* of patients with AD. The questions of whether there is an increased prevalence of sleep apnea in Al) and whether sleep apnea increases with the seventy of the illness or more rapid progression of the disease remain somewhat controversial. Sundowning is a major problem in many patients with AD, causing nocturnal confusional episodes, often accompanied by partial or complete inversion of sleep schedule, with increased wakefulness at night and somnolence in the daytime. The exact relationship between sleep disruption, severe dementia, and sundowning is not clear. Several factors, singly or in combination, may be

responsible for sleep disturbances in AD. They are degeneration of the neurons of the SCN, of cholinergic neurons in the nucleus basalis of Meynert, of the pedunculopontine tegmental and laterodorsal tegmental nuclei, and of noradrenergic neurons of the btainstem, associated depression or PLMS, medication effects, associated general medical diseases, and environmental factors.

Parkinson's Disease

Sleep difficulties have been noted in 70-90% of patients with Parkinson's disease (PD) (Chokroverry 2000). Common complaints include difficulties in initiating and maintaining sleep, inability to turn over during the night or on awakening, and inability to get out of bed unaided. Leg cramps and jerks, dystonic spasms of the limbs or face, back pain, and excessive nocturia are also common. A clear relationship has been noted between sleep disruption and disease progression.

Motor abnormalities during sleep in PD include persistence of tremor in the lighter stages of sleep or its rccmergencc in the transition between sleep and wakefulness and on awakening as well as decreased body movements and positional shifts. Other motor abnormalities in PD during sleep include rapid blinking at sleep onset, blepharospasm during onset of REMs, and intrusion of REMs into NREM sleep. Sleep benefit (early morning improvement of parkinsonian motor features, lasting 1-3 hours) may be noted mostly in mild PD.

Sleep in PD may be secondarily affected because of associated depression, dementia, sleep-related respiratory dysrhythmias, RLS, Pl.MS, RBD, and other parasomnias (sleepwalking and sleep talking) as well as circadian rhythm disturbances. RBD is a common occurrence in I'D, (Gagnon et al. 2002; Ondo et al. 2002), and in some patients, this disorder appears even before parkinsonian symptoms are clinically evident. It is estimated that about 30% of patients with PD may have PLMS, and this proportion increases in elderly patients.

Sleep-related respiratory dysrhythmias may he mote common in patients with PD than in age-matched control subjects. Obstructive, central, or mixed apneas have been described in patients with PD, and such respiratory difficulties have been noted with increasing incidence in patients with autonomic dysfunction. Antiparkinsonian medications may cause respiratory and other dyskinesias, which could be peak-dose dyskinesia (mainly choreiform) or end-of-the-dosc dyskinesia (mostly dystonic). These dyskinesias may cause sleep disruption or fragmentation of sleep. Vivid or frightening dreams (nightmares) can occur after long-standing dopaminergic treatment, causing sleep maintenance problems and EDS.

A report of sudden sleep attacks (Frucht et al. 1999) heightened the awareness of excessive sleepiness and unintended sleep attacks in patients with PD. Excessive daytime sleepiness is very common and often undcrrecognized in PD and probably occurs in 10-50% of patients (Ondo et al. 2001). MSLTs document pathological sleepiness and sleep-onset REMs in many of these patients similar to those noted m patients with classic narcolepsy-cataplexy. Several studies have shown that sleep attacks and sleepiness in PD are class effects (related to all dopaminergic drugs) and are due to the pathology of PD, medications, and eomorbid conditions, e.g., depression, dementia, and OSAS (Homann et al, 2003; Rye 2003; Hobson et al. 2002; Arnulf et al. 2002; Chaudhuri et al. 2002).

Other Basal Ganglia Disorders

A variety of sleep disturbances have been observed in other basal ganglia disorders, such as 1 iuntmgton's chorea, progressive supranuclear palsy, and torsion dystonia, Insomnia with difficulty initiating and maintaining sleep is a common complaint in these conditions. Sleep disturbance is present in almost all patients with progressive supranuclear palsy, A particular L\pe o^{h} iKsioraa, called *hereditary progressive dystonia* with diurnal fluctuation, dopa-responsivc dystonia, or the Segawa variant, presents with parkinsonian-typc masked fades, rigidity, and flexed posture. Patients with this dystonia may obtain significant symptomatic relief from sleep and show dramatic improvement with small doses of L-dopa.

Predominantly Cerebellar or Cerebellar-Phis Syndromes

Sleep disturbances occur in many patients with OPCA and other types of SCAs. Central, obstructive, or mixed sleep apneas have been described in many patients with sporadic OPCA, also categorized as cerebellar form of MSA, but the apneas have occurred less often and have been less intense in this condition than in the parkinsonian variety of MSA. Typical features of RBD have been described in MSA and SCA3/Machado-Joseph disease (Syed et al, 2003). Other complaints in SCAs, particularly in SCA3, consist of sleep initiation and maintenance problems.

Degenerative Disease of the Motor Neurons

The classic example of degenerative disease of motor neurons is ALS, also called *motor neuron disease.* The most common sleep complaint in ALS is daytime hypetsomnolence as a result of repeated sleep-related apneas or hypopneas, hypoxemia, hypercapnia, and sleep fragmentation. Some patients may complain of insomnia. Sleep-related breathing disorders in ALS may result from weakness of upper airway, diaphragmatic, and intercostal muscles due to involvement of the bulbar, phrenic, and intercostal nerve nuclei. In addition, degeneration of the central respiratory neurons may occur, causing both CSA and OSA in this condition.

Sleep Disorders in Autonomic Diseases: Multiple System Atrophy (Sby-Drager Syndrome)

In a consensus statement (Consensus Statement 1996; Gilman et al. 1999), the term *MSA* was suggested to replace the term Shy-Drager syndrome (see Chapter 77). MSA defines a sporadic adult-onset progressive disorder of multiple systems characterized by autonomic dysfunction, parkinsonism, and ataxia in various combinations {see Table 74.24), *Striatonigral degeneration* is the name used when the predominant feature is parkinsonism, whereas *Ol'CA* is used when the cerebellar features are the predominant manifestations. The term *Sby-Drager syndrome* is still used when the autonomic feature is the predominant feature. Some patients complain of insomnia, and many patients manifest RBD, which may occasionally be the presenting feature, but the most common sleep disturbance in patients with MSA results from respiratory dysrhythmias associated with repeated arousals and hypoxemia. Sleep-related respiratory dysrhythmias in MSA may include obstructive, central, or mixed apneas and hypopneas as well as Chcyne-Stokes breathing or a variant oi Cheyne-Stokes breathing. ( )I]KT breathing disorders i:i sleep in MSA consist ni :nie:i.rn.il irispn.uorv stridor, apneustic breathing, inspiratory gasping, or dysrhythmit breathing. Hypersomnia often results from nocturnal sleep disruption. Sudden nocturnal death in patients with MSA, presumably from cardiorespiratory arrest, has been reported.

Both direct and indirect mechanisms are responsible for the pathogenesis of sleep disruption in MSA. These may include one or more of the following: degeneration of the sleep-wake-gene rating neurons in the brainstem and hypothalamus; degeneration of the respiratory neurons in the brainstem or direct involvement of projections from the hypothalamus and central nucleus of amygdala to the respiratory neurons in the nucleus tractus solitarius and nucleus ambiguus, interference with the vagal inputs from the peripheral respiratory receptors to the central respiratory neurons, sympathetic denervation of the nasal mucosa, and alteration of the neurochemical environment.

Sleep in Other Medical Disorders

A number of medical disorders other than neurological illnesses may cause severe disturbances of sleep and breathing that have important practical implications for diagnosis, prognosis, and treatment (Chokroverry 1999c). Sleep disturbances may have adverse effects on the course of a medical illness. A vicious cycle may result from the effect of sleep disturbance on the medical illness and the effect of the medical illness on sleep architecture. Sleep architecture, sleep continuity, and sleep organization may be affected by a variety of medical illnesses. Patients may present with either insomnia or hypersomnolence, but most medical disorders present with insomnia. Some patients may have a mixture of insomnia and hypersomnolence (e.g., those with COPD or nocturnal asthma). The general features of insomnia and medical disorders causing insomnia have been briefly described (see Insomnia, earlier in this chapter). The general features of hypersomnolence and medical conditions presenting with hypersomnolence have been briefly described earlier in this chapter, PSG findings in those presenting with insomnia include prolonged sleep latency, reduction of REM and SWS, more than 10 awakenings per night, frequent stage shifts, early-morning awakening, increased waking after sleep onset, and increased percentage of wakefulness and stage I NRKM sleep. PSG findings in those presenting with hypersomnolence may consist of SDB, repeated arousals with oxygen desatu ration at night, sleep fragmentation, sleep-stage shifts, reduced SWS, shortened sleep-onset latency in MSLTs, and sometimes REM sleep abnormalities. When a patient presents to a sleep specialist with a sleep disturbance, either with a complaint of insomnia or hypersomnia, an important step is to obtain a detailed medical history and other histories, followed by physical examination to uncover the cause of the sleep disturbance.

In an important epidemiological study by Gislason and Alinqvist involving a random sample of 320 I Swedish men, aged 30-69 years, difficulty initiating or maintaining sleep and too little sleep were the major sleep complaints, followed by EDS (Chokroverty 1999c). Sleep-maintenance problems occurred more often with increasing age. The following conditions were associated with sleep complaints: systemic hypertension, bronchitis and bronchial asthma, musculoskeletal disorders, obesity, and diabetes mcllirus. The authors suggested that the reported increased mortality among patients with sleep complaints might be related to the intercurrent somatic diseases.

Cardiovascular Disease and Sleep

Sleep disturbance is very common in patients with ischemic heart disease. Pain may awaken the patient often, thereby reducing sleep efficiency. Nocturnal angina is known to occur during both REM and NREM sleep. Epidemiologically, there is a clear relationship between increased cardiovascular morbidity and mortality and sleep disturbances associated with SDB. Shahar et al. (2001) reported on the cross-sectional data from the sleep Heart Health study cohort showing modest to moderate effects of sleep disordered breathing on various manifestations of cardiovascular disease (e.g., myocardial ischemia, heart failure, or stroke) within a range of apnea-hypopnea index values that are considered normal or mildly elevated. Patients with coronary artery disease and OSA may have an increased cardiac risk due to nocturnal myocardial ischemia triggered by apnea-associatcd oxygen desaturation. An important finding in several reports is circadian susceptibility to myocardial infarction (attacks are most likely between midnight and 6:00 AM).

In patients with CHF, sleep disturbances, periodic breathing, and hypoxemia at night have been described. Multiple factors, including associated SDB and nocturnal oxygen desaturation, are responsible for increased morbidity and mortality in CHF. Cheyne-Stokes respiration, which is commonly associated with CHF. may result in hypoxemia, hypercapnia, sleep disruption due to repeated arousals, daytime somnolence, and impaired cognitive function. Thus Chcyne-Stokes respiration and CHF may present as sleep apnea syndrome. Javaheri et al. (199.5) reported an AHI higher than 20 in 45% of patients with stable heart failure without other comorbid factors. After treatment with nocturnal oxygen administration, CPAP titration, and medications such as theophylline, the patients' conditions improved. However, the role of CPAP in the maintenance treatment of CHF remain's controversial.

A relationship between sleep and atrioventricular arrhythmia has been noted, but the reports are controversial. Contradictory results have also been noted in human studies of the effect of sleep on ventricular arrhythmia, but most studies show an antiarrhythmic effect of sleep on ventricular premature beats due to enhanced parasympathetic lone during sleep. \n .i:i,iK•-,]•-, nl the time of sudden cardiac death in 2023 individuals by Muller and associates revealed high incidence from 7:00 AM to 11:00 AM. Nonfatal myocardial infarction and myocardial ischemic episodes are also more likely to occur in the morning. It is known that sympathetic activity increases in the morning, causing increased myocardial electrical instability; thus sudden cardiac death may result from a primary fatal arrhythmia.

Several studies report an association between OSAS and systemic hypertension and some studies have confirmed that treatment of sleep apnea by nasal CPAP reduces blood pressure. (Sec section on Sleep Apnea Syndrome, earlier in this chapter.!

Sleep and Chronic Obstructive Pulmonary Disease

Disturbances in sleep architecture in patients with COPD have been teported by several authors and may be summari/.ed as follows: a reduction of sleep efficiency, delayed sleep onset, increased wake time after sleep onset, frequent stage shifts, and frequent arousals. Factors that may be responsible for sleep disturbance in COPD include the use of drugs that have a sleep-reducing effect (e.g., methylxanthine), increased nocturnal cough, resulting from accumulated bronchial secretions, and associated hypoxemia and hypercapnia. Severe noctutnal hypoxemia in many patients with COPD may or may not be accompanied by sleep-related apnea, hypopnea, or periodic breathing, and impairment of gas exchange. Repeated or prolonged oxygen desaturation at night may cause cardiac arrhythmias and may lead to pulmonary hypertension and cor pulmonale. Administration of supplemental oxygen at 2 liters per minute by nasal cannula during sleep is found to improve both oxygen saturation at night and sleep architecture by decreasing sleep latency and increasing all stages of sleep, including REM and SWS.

Sleep Disturbances in Bronchial Asthma

A variety of sleep disturbances have been noted in patients with asthma, including early-morning awakenings, difficulty maintaining sleep, and EDS. Sleep disturbances in general consist of a combination of insomnia and hypersomnia. PSG studies may reveal disruption of sleep architecture as well as sleep apnea in some patients. Nocturnal exacerbation of symptoms during sleep is a common finding in asthmatic patients. There is also evidence of progressive bronchoconstriction and hypoxemia during sleep in patients with asthma. Several pathogenic mechanisms, including circadian factors, have been suggested tor sleep disturbances and nocturnal exacerbation of asthma.

Gastrointestinal Diseases and Sleep

Sleep disturbances in peptic ulcer patients characteristically result from episodes of nocturnal epigastric pain. These symptoms cause arousals and repeated awakenings, thereby fragmenting and disturbing sleep considerably. With duodenal ulcers, there is increased nocturnal acid secretion, which can be abolished by vagotomy, thus improving healing of ulcers. Furthermore, patients with duodenal ulcers do not have inhibition of gastric acid secretion during the first 2 hours after sleep onset. In light of evidence about the role of *Helicobacter pylori* infection and nonsteroidal anti-inflammatory drugs in the pathogenesis of gastroduodenal ulcers, the theory of hypersecretion of acid in peptic ulcer patients has been displaced.

Gastroesophageal reflux disease, which is preferable to the term *reflux esophagitis*% characteristically causes heartburn, which is described as retrosternal burning pain. This pain causes difficulty in initiating sleep, frequent awakenings, and fragmentation of sleep. Facilities for all-night PSG study and 24-hour esophageal pH monitoring have contributed to an understanding of the association between sleep and peptic ulcer diseases and esophageal reflux. Sleep adversely affects patients with gastroesophageal reflux disease by increasing the episodes of reflux and prolonging acid clearance time (Orr 2001). Furthermore, repeated spontaneous reflux episodes adversely affect sleep h\ causing arousals, frequent awakenings, and sleep fragmentation.

Sleep and Endocrine Diseases

In patients with myxedema, upper airway OS A and CSA that disappear after thyroxine replacement therapy have

been described. Mechanisms of SDH in this condition include deposition of mucopolysaccharides in the upper airway as well as impaired central respiratory drive, as evidenced by decreased hypercapnic and hypoxic ventilatory responses.

Patients with diabetes mellitus, particularly that associated with autonomic neuropathy, may have upper anway OSA and CSA. These sleep-related respiratory dysrhythmias may cause fragmentation of sleep, resulting in EDS.

CSA has been described in many patients with acromegaly. CSA has been generally associated with increased levels of growth hormone. The relationship between the growth hormone level and sleep apnea, however, has remained somewhat controversial. Octreotide, a long-acting somatostatin analogue, is an effective noninvasive treatment for sleep apnea in acromegaly.

Sleep Disturbances in Chronic Renal Failure

Sleep disturbances are common in patients with chronic renal failure with or without dialysis, particularly in those with end-stage renal disease. Sleep complaints include insomnia, EDS, and day-night reversal or disturbed nocturnal sleep. PSG findings include reduced sleep efficiency, increased sleep fragmentation, frequent awakenings with difficulty maintaining sleep, decreased SWS, and disorganization of sleep cycle. Many patients with chronic renal failure who are and are not receiving dialysis have sleep apnea syndrome, mainly upper airway OSAS, and may have PLMS. A PSG study to establish the diagnosis of OSA should be performed in any patient with a history of FDS mid disturbed night sleep because CPAP titration has been found to be an effective form of treatment in patients undergoing hemodialysis with OSA. Another important finding in patients with chronic renal failure is the presence of a secondary form of RLS. Uremic RLS and idiopathic RLS resemble each other and cannot be distinguished clinically. There has been a report of cure of this form of RLS after successful kidney transplantation.

Fibromyalgia Syndrome

Fibromyalgia syndrome is characterized by diffuse muscle aches and pains not related to diseases of the joints, bones, or connective tissues. Specific diagnostic criteria for fibromyalgia syndrome have been established. Sleep disturbance is very common in fibromyalgia. The characteristic PSG finding is intermirtenr alpha activity during NREM sleep, giving rise to the characteristic alpha-delta or alpha-NREM sleep pattern in the recording. Another important association is the presence of PLMS on PSG examination. Alpha-NREM sleep pattern is not specific for this condition and has been noted in patients with other rheumatic disorders and even in normal individuals, as well as some psychiatric patients. The most common complaints in patients with fibromyalgia include nonrestorative sleep associated with nonspecific PSG abnormalities of sleep fragmentation, increased awakenings, decreased sleep efficiency, and alpha-NREM sleep.

Chronic Fatigue Syndrome

This is an ill-defined medically unexplained heterogeneous condition with multiple causes (Evcngard and Klimas 2002). The condition is characterized by insidious onset of disabling fatigue present for at least 6 months without any causes despite intense laboratory investigations. Arthralgias, myalgias, sore throat, headache, and sleep disturbances are included as minor criteria. Orthostatic hypotension and orthostatic tachycardia syndrome on a tilt-table study may be present in some of these patients (Getrity et al. 2002). Sleep complaints include disturbed night sleep and excessive daytime sleepiness but adequate PSG studies have not been undertaken to characterize the precise sleep disturbance.

Sleep of Intensive Care Unit Patients

Patients in an intensive care unit (ICU) are generally admitted with acute medical, surgical, or neurological illnesses. All these conditions can be associated with sleep disturbances, e.g., insomnia, hypersomnia, and sleep-related respiratory dysrhythmia (Gabor et al. 2001; Richards et al. 2002), The ICU environment itself is deleterious to normal sleep and conducive to sleep deprivation, with attendant complications, such as ICU psychosis. Noise, bright light, and constant activity by ICU personnel for monitoring and drug administration play a significant role in disturbing the sleep of ICU patients. A variety of drugs in the ICU may aggravate sleep and sleep-related respiratory disturbances. ICU syndrome is a characteristic mental state defined as a tcvcrsiblc, confusional state developing 3-7 days after ICU admission; sleep deprivation has been cited as the major cause of ICU syndrome. ICU psychosis is more common in surgical than in medical ICOs. PSG findings to document disruption of sleep structure in the ICU consist of marked diminution of SWS and REM sleep, frequent awakenings, sleep fragmentation, and reduced total sleep time. ICU patients often have EDS because of disturbed night sleep. It is important to be aware of various ICU factors contributing to the problem of sleep disturbances so that correct diagnosis and management of secondary complications can be implemented promptly.

Acquired Immunodeficiency Syndrome

Acquired immunodeficiency syndrome (AIDS) is a multisystem disorder caused by infection with HIV. Sleep disturbances (insomnia, hypersomnia, and circadian dysrhythmia) have been reported in many patients with AIDS, but adequate systematic PSG studies to document sleep

disruption have not heen undertaken. The causes are multifactorial (Phillips *1999).* HIV infection can also cause SDB.

African Sleeping Sickness (Trypanosomiasis)

African sleeping sickness is caused hy T. *gambiense* or T. *rhodesiense* and is transmitted *to* humans by the bite of tsetse flics, CNS involvement is initially characterized by personality changes followed by delusions, hallucinations, and reversal of the sleep-wake rhythm. The patient remains somnolent in the daytime and progresses gradually into the stages of stupor and coma. PSG studies document disruption of the circadian sleep-wake rhythm, which is proportional to the severity of the illness. Circadian disruption of plasma Cortisol, prolactin, and sleep-wake rhyrhms is seen in the patients with the most advanced disease. These findings of circadian disruption suggest selective changes in the SCN. The diagnosis of trypanosomiasis is based on history as well as confirmation that the organism is in blood, bone marrow, cerebrospinal fluid, lymph node, aspirates, or a scraping from the chancre. The treatment of choice for patients in the meningoencephalitic stage is a rsen ica 1 mcl a rs o p r o 1.

Sleep Disturbances in Psychiatric Illness

In psychiatric disorders sleep disturbances are common and insomnia is present more often than hypersomnia (see Insomnia, earlier in this chapter, for a brief review). Specific examples of psychiatric conditions that are associated with insomnia include depression (including bipolar disorder), anxiety disorders, schizophrenia, and post-traumatic stress disorder. Hypersomnia is generally present in patients with seasonal affective disorder and may also be present in some patients with depression. Many patients with eating disorders, some of whom have associated major depression, may also have significant sleep complaints. Finally, antidepressant and neuroleptic drugs used to treat psychiatric illnesses may cause sleep disruption. Assessment of sleep disturbances in psychiatric patients should follow the genetal guidelines discussed earlier in the chapter. The primary treatment should be directed to the psychiatric illnesses causing sleep disruption.

Parasomnias. Parasomnias can be defined as abnormal movements or behavior intruding into sleep during the night intermittently or episodically without disturbing the sleep architecture. The *1CSD* classifies parasomnias into four groups (see Table 74.9): arousal disorders, sleep-wake transition disorders, REM sleep-related parasomnias, and other parasomnias. This classification lists 24 distinct entities, several of which are very rare. Major parasomnias can also be classified into motor and behavioral parasomnias. VI o tor parasomnias arc abnormal movements intruding into sleep and are classified into four categories: NREM sleep parasomnias; REM sleep parasomnias, sleep-wake transition disorders; and diffuse parasomnias (no stage preference). Several parasomnias occurring in NREM and REM sleep may be mistaken for seizures, particularly complex partial seizures. Somnambulism, night terror, confusional arousals, somniloquy, bruxism, head banging, nocturnal enuresis, RBD, and nightmares are some of the parasomnias that may be mistaken for seizures, RBD and nightmares are the only ones associated with REM sleep. Characteristic clinical features combined with EEC and PSG recordings are essential ro differentiate these conditions,

Somnambulism (Sleepwalking). Sleepwalking is common in children between 5 and 12 years of age {Table 74.25). Sometimes, it persists in adulthood or (rarely) begins in adults. Sleepwalking begins with abrupt motor activity arising out of SWS during the first one third of sleep. Episodes generally last less than 10 minutes. There is a high incidence of positive family history in sleepwalking. Injuries and violent actions have been reported during sleepwalking episodes, but generally, individuals can negotiate their way around the room. Sleep deprivation, fatigue, concurrent illness, and sedatives may act as precipitating factors.

Sleep Terrors, Sleep terrors, or pavor nocturnus, also occur during SWS (Table 74.26). Peak onser is between 5 and 7 years of age. As with sleepwalking, there is a high incidence of familial cases of sleep tenor. Episodes of sleep rerrors are characterized by intense autonomic and motor symptoms, including a loud, piercing scream. Patients appear highly confused and fearful. Many patients also have a history of sleepwalking episodes. Precipitating factors are similar to those described with sleepwalking.

Confusional Arousals, Confusional arousals occur mostly before 5 years of age. As in sleepwalking and sleep terrors, these episodes arise our of SWS with confusion. Patients may have some automatic and inappropriate behavior, but the majority of spells are benign, necessitating no treatment.

Hypnic Jerks, Hypnic jerks, or "sleep starts," occur at sleep onset in many normal individuals and are

Table 74.25: Features of sleepwalking (somnambulism)

Onset: common between ages 5 and 12 yr
1 ligh ineidence of positive family history
Abrupt onset of motor activity arising out of slow-wave sleep during the first one third of the night
Duration: less than L0 mm
Injuries and violent activity reported occasion ally
Precipitating factors: sleep deprivation, fatigue, concurrent illness, sedatives
Treatment: precaution, benzodiazepines, lmipramine

Table 74.26: Features of sleep terrors

Onset: peak is between ages 5 and 7 yt
High incidence of familial occurrences
Abrupt arousal from slow-wave sleep during the first one third of the night with a loud, piercing scream
Intense autonomic and motor components
Sleepwalking also seen in many patients
Precipitating factors: stress, sleep deprivation, fever
Treatment: psychotherapy, benzodiazepines, tricyclics

physiological phenomena without any pathological significance. The episodes are associated with sudden brief myoclonic jerks of the limbs or the whole body lasting for a few seconds. Sometimes these are accompanied by sensory phenomena, such as a sensation of falling. These may be triggered by stress, fatigue, or sleep deprivation. Sleep starts may occur in up to 70% of the general population.

Rhythmic Movement Disorder. Rhythmic movement disorder is noted mostly before 18 months of age and is occasionally associated with mental retardation. It is a sleep-wake transition disorder with three characteristic movements: head banging, head rolling, and body rocking. Rhythmic movement disorder is a benign condition, and the patient outgrows the episodes.

Nocturnal Leg Cramps. These are intensely painful sensations accompanied by muscle tightness that occur during sleep. The spasms usually lasl foi ,; lew MVIUVS bui sometimes persist for several minutes. Cramps during sleep are generally associated with awakening. Many normal individuals have nocturnal leg cramps; the cause remains unknown. Local massage or movement of the limbs usually relieves the cramps.

Nightmares (Dream Anxiety Attacks). Nightmares arc fearful, vivid, and often frightening dreams, mostly visual but sometimes auditory, seen during REM sleep. Night mares may accompany sleep ralking and body movements. These most commonly occur during the middle to late part of sleep at night. Nightmares are mostly a normal phenomenon. Up to 50% of children, perhaps even more, have nightmares beginning at age 3-5 years. The incidence of nightmares continues to decrease as the child grows older, and elderly individuals have very few or no nightma res. Very frightening and recurring nightmares (e.g., one or more per week) are not common and may occur in a very small percentage (<1%) of individuals. Nightmares can also occur as side effects of certain medications, such as antiparkinsonian drugs (pcrgolide and i.-dopa), anticholinergics, and antihypertensive drugs, particularly beta blockers. Nightmares are common after sudden withdrawal of REM sleep-suppressant drugs (e.g., tricyclic antidepressants and selective serotonin reuptake inhibitors). Benzodiazepines (e.g., diazepam and clonazepam) often suppress nightmares, but withdrawal from these drugs may precipitate nightmares. Nightmares have also been reported after alcohol ingestion or sudden withdrawal from barbiturates. Nightmares may sometimes be the initial manifestation of schizophreniform psychosis along with severe sleep disturbance. Many people with a certain personality type have nightmares throughout life. Nightmares generally do not require any treatment except reassurance. In patients with recurring and fearful nightmares, however, combined behavioral or psychotherapy and REM sleep-suppressant medications may be helpful.

Rapid Eye Movement Sleep Behavior Disorder. RBD is an important RIM sleep parasomnia commonly seen in elderly persons (Table 74.27). A characteristic feature of RBD is intermittent loss of REM sleep-related muscle hypotonia or atonia and the appearance of various abnormal motor activities during sleep. The patient experiences violent dream-enacting behavior during REM sleep, often causing self-injury or injury to the bed partner (Scheneck and Mahowald 2003; Olson et al. 2000). RBD may be idiopathic or secondary; most cases are now thought to be secondary and associated with neurodegenerative diseases. It is seen with increasing incidence in patients with PD, MSA, corticobasal degeneration, dementia with Lewy bodies disease, OPCA, and PSP. Many patients with narcolepsy, a probable degenerative disease of the hypocrerin-containing neurons in the hypothalamus, may also present with RBD. Some authors (Boeve ct al. 2001) proposed that RBD may he an or-synuclcinopathy disorder because a-synuclein inclusions have been observed in many of the associated neurodegenerative diseases (e.g., PD, MSA, and dementia with Lewy bodies disease). RBD may precede many of these degenerative diseases. RBD may sometimes be drug induced (e.g., sedative-hypnotics, tricyclic antidepressants and anticholingergics) or associated with alcoholism and structural brainstem lesions. RBD has been linked to dopamine cell dysfunction based on PET scan finding of reduced striatal presynaptic dopamine transporter and SPECT scan finding of reduced postsynaptic dopamine D_2 receptors. REM sleep without muscle atonia is the most important polysomnographic

Table 74.27: Features of rapid eye movement sleep behavior disorder

Onset: middle-aged or elderly men
Presents with violent dream-enacting behavior during sleep, causing injury to self ot bed pattner
Often misdiagnosed as a psychiatric disorder or nocturnal seizute (partial complex seizure}
Etiology: 50% idiopathic, 50% causal association with structural central nervous system lesion or related to alcohol or drugs (sedatives-hypnotics, tricyclics, anticholinergics)
Polysomnography: rapid eye movement sleep without muscle atonia
Expetimental model: bilateral peri-locus ceruieus lesions
Treatment: 90% response to clonazepam

finding. Experimentally similar behavior has been noted after bilateral perilocus cemleus lesions in cats.

Bruxism (Tooth Grinding). Bruxism often presents between 10 and 20 years of age, but it may persist throughout life, often leading to secondary problems such as temporomandibular joint syndrome. Both diurnal and nocturnal bruxism may be also associated with various movement and degenerative disorders such as oromandibular dystonia and Huntington's disease. It is also commonly noted in children with mental retardation or cerebral palsy. Nocturnal bruxism is noted most prominently during stages I and II NREM sleep and REM sleep. The episode is characterized by stereotypical tooth grinding and often precipitated by anxiety, stress, and dental disease. Occasionally, familial eases have been described. Local injections into masseter muscles may be used to prevent dental and temporomandibular joint complications (Tan and Jankovie, 2000).

Benign Neonatal Sleep Myoclonus. Benign neonatal sleep myoclonus occurs during the first few weeks of life and is generally seen in NREM sleep but sometimes during REM sleep. Episodes often occur in clusters involving arms, legs, and sometimes the trunk. The movements consist of jerky flexion, extension, abduction, and adduction. The condition is benign, needing no treatment.

Pediatric Sleep Disorders. The field of pediatric sleep disorders remains neglected despite a high incidence of sleep disturbance in children. Several recent surveys found that about 25% of children aged 1-5 years have some kind of sleep problem. Mentally handicapped children and those with attention-deficit/hyperactivity disorder and Tourerte's syndrome have higher rates of sleep disorders than normal children do. The common sleep problems in children include a variety of parasomnias, such as sleepwalking, nightmares, sleep talking, sleep enuresis, bruxism, sleep terrors, and rhythmic movement disorder; sleeplessness due to specific childhood-onset disorder or food allergy; EDS (e.g., narcolepsy or OSA); and DSPS or ASPS. Adjustment sleep disorder, limit-setting sleep disorder, sleep-onset association disorder, and nocturnal eating (or drinking) syndrome are some distinct sleep disorders causing insomnia in infants and children.

1CSD (1997) defines adjustment sleep disorder as a type of sleep disturbance temporally related to acute stress, conflict, or environmental change that causes emotional arousal. The disturbance in most cases is brief. Sleep-onset or maintenance insomnia or daytime sleepiness may be the presenting complaint, but insomnia is more common than sleepiness in children.

Limit-setting sleep disorder is exclusively a childhood sleep disorder eb.iracieii/.cd by the child's stalling or refusing to go to sleep at an appropriate time as a result of inadequate enforcement of bedtime by the caregiver. The condition usually resolves as the child grows older.

Sleep-onset association disorder is a childhood sleep disorder characterized by an impairment of sleep onset because of the absence of a certain object or set of circumstances (e.g., using a bottle, sucking on a pacifier, being rocked, watching television, or listening to the radio). Sleep is normal when the particular association is present.

ICSD (1997) defines nocturnal eating (drinking) syndrome as a condition characterized by recurrent awakenings with the inability to return to sleep without eating or drinking. This condition is common in infancy and early childhood. Treatment involves gradual withdrawal from eating or drinking behavior.

OSAS occurs in children, but there are certain differences from OSAS in adults. Children may present with EDS, but common symptoms include hyperactivity and behavioral problems during the daytime, impaired school performance, intellectual changes, increased motor activity, disturbed sleep at night, and nocturnal snoring for many months or years. An important cause in children is enlargement of tonsils anil adenoids. If OSAS is suspected, an overnight PSG study is indicated for documenting OSA. In contrast to adults, removal of the tonsils and adenoids in children promotes symptomatic improvement. Some occurrences of sudden infant death syndrome are thought to be related to OSA, but the relationship remains unproved and controversial. The most important factor in sudden infant death syndrome is sleeping in the prone position, and every attempt must be made to keep the infant in the supine position.

Primary enuresis is a condition of persistent bed-wetting after 5 years of age in the absence of urological, medical, psychiatric, or neurological disorders. Enuretic episodes occur during all stages of sleep but most commonly occur during the first one third of the night. Enuresis is particularly common in patients with attention deficit disorder and Tourette's syndrome.

Treatment includes behavioral modification and tricyclic antidepressants (e.g., imipraminc) and desmopressin (DDAVP), either as a nasal spray or tablets.

LABORATORY ASSESSMENT OF SLEEP DISORDERS

Laboratory investigation for sleep disorders should be considered an extension of the history and physical examination. First and foremost in the diagnosis of a sleep disorder is a detailed history, including sleep and other conditions, as outlined earlier, under Approach to a Patient with Sleep Complaints. This should be followed by a careful physical examination to uncover any underlying medical, neurological, or other causes of sleep dysfunction, Laboratory tests should include a diagnostic workup for the primary condition causing secondary sleep disturbance and a workup for the sleep disturbance itself. The two most important laboratory tests for diagnosis of sleep disturbance are polysomnography and the MSLT. Various other

rests art' also important lor asscssineiil ot a parienl willi sleep dysfunction.

Polysomnographic Study

An overnight PSG study is the single most important laboratory test for the diagnosis and treatment of patients with sleep disorders, particularly those associated with EDS. An all-night PSG study is required rather than a single-day nap study. A daytime single-nap study generally misses REM sleep, and the most severe apneic episodes are noted during REM sleep. Maximum oxygen desaturation also occurs at this stage; therefore, a daytime study cannot assess severity of symptoms. For CPAP titration, an all-11 iii.li l •deep Stud; is essentia!. In dtici :i nr i'i,- op;i:n.il level of pressure during CPAP titration, both REM and NREM sleep are required. In this section, the PSG study is described under three headings: technical considerations, indications for a PSG study, and characteristic PSG findings in various sleep disorders.

Technical Considerations

A PSG study includes simultaneous recording of various physiological characteristics, which allows assessment of sleep stages and wakefulness, tcspiration, cardiocirculatory functions, and body movements. Sleep staging is based on an electroencephalogram, electro-oculogram, and electromyogram of some skeletal muscles, especially chin muscles. Multiple EEG channels of recordings are preferable to one or two channels for documentation of focal and diffuse neurological lesions, accurately localization of epileptiform discharges in patients with seizure disorders, and more accurate determination of various sleep stages, awakenings, and transient events, such as microarousal episodes. The Reehtschaffen and Kales (1968) technique of sleep scoring, despite limitations, remains the standard for sleep staging. Ideally, sleep scoring should be performed manually; computerized scoring is not reliable. For newborns and infants, the technique recommended by Anders and co-workers is the standard. The following terms arc essential for sleep sraging and scoring (Mitler et al. 1999):

1. Total sleep period: Time from sleep onset to final awakening
2. Total sleep time: Total time spent between sleep onset and final awakening, excluding time spent awake
3. Sleep latency: Time from lights-out to sleep onset
4. REM sleep latency: Tune from sleep onset to the first REM sleep onset
5. Sleep efficiency; Ratio of total sleep time to total time in bed, expressed as a percentage
6. Sleep stages: Stages I to IV of NREM and REM sleep expressed as a percentage of total sleep time
7. Wake aftet sleep onset: Time spent awake during total sleep period
8. Sleep cycles: Number of sleep cycles, including REM cycles, during total sleep period
9. Stage shifts
10. Arousal index (based on guidelines proposed by the American Sleep Disorders Association): Number of arousals per hour of sleep

The PSG study should also include airflow, respiratory effort, an electrocardiogram (ECG), oximetry, and limb muscle activity, particularly EMG recordings of the tibialis anterior muscles bilaterally. It is advantageous to record snoring and body positions. Thermistors or thermocouples are generally used to record oronasai airflow qualitatively, but these are not reliable for accurate determination of hypopnea. Many laboratories, therefore, record nasal pressure using a nasal cannula-pressure transducer, which is more sensitive than a thermocouple or thermistor for detecting airflow limitation (Ayappa et al. 2000). Respiratory efforts can be recorded by use of si rain gauges or inductance plethysmography. Inductance plethysmography and a piezoelectric strain gauge are the **preferred** methods; they can be used in a qualitative or semiquantitative fashion to monitor chest and abdominal movements. Intraesophageal balloon recording, an invasive method, accurately determines intrathoracic pressure swings and is essential for documentation of UARS. EMG recordings of the intercostal muscles using surface electrodes may also be helpful in determining respiratory effort. SDB events are recorded as an AT IT or RDI score, as defined previously. PEMS are recorded from tibialis EMG recordings. The PLMS index is expressed as the number of PEMS per hour of sleep. The upper limit of the normal PLMS index is 5, Details on the technical aspects of PSG recording are beyond the scope of this chapter.

Indications for Polysomnography

Guidelines proposed by the American Sleep Disorders Association (1997) can be summarized as follows:

A PSG study is routinely indicated for the diagnosis of sleep-related breathing disorders.

A PSG study is indicated for **CPAP** titration in patients with sleep-related breathing disorders.

A PSG study is indicated to evaluate for the presence of OS A in patients before they undergo laser-assisted uvulopalatopharyngoplasty (UPP).

A PSG study is indicated for the assessment of treatment results after an oral appliance is used to push mandible and tongue forward and after surgical trearmenr of patienrs with moderately severe OS A, including those whose symptoms reappear despite an initial good response.

A follow-up PSG study is required when the clinical response is inadequate or when symptoms reappear despite a good initial response after treatment with CPAP. It is also necessary after substantial weight loss or weight gain has occurred in patients previously treated successfully with CPAP.

An overnight PSG study followed by MSLT on the next day is routinely indicated in patients suspected of having narcolepsy.

A PSG study is indicared in patients with parasomnias if these are unusual or atypical or the behaviors are violent or otherwise potentially injurious to the patient or others. A PSG study, however, is not routinely indicated in uncomplicated and typical parasomnias.

A PSG study is indicated in patients suspected of having nocturnal seizures,

An overnight PSG study is required in patients with suspected PLMS, but it is not performed routinely to diagnose RES.

A PSG study may be indicated for patients whose insomnia has not responded satisfactorily to a comprehensive behavioral or pharmacological treatment program for the management of insomnia. However, if the presence of a sleep-related breathing disorder or associated PI.MS is strongly suspected in a patient with insomnia, a PSG study is indicated.

Polysomnography Findings in Sleep Disorders

Characteristic PSG findings in OSAS include recurrent episodes of apneas and hypopneas, which are mostly obstructive (Figure 74.7) or mixed, and few episodes of central apneas accompanied by oxygen dcsaturation and followed by arousals with resumption of breathing. An Al II or RD] score of 5 or below is considered normal. An RDI score of more than 5-1 9 may be considered evidence of mild OSAS, 20-49 as evidence of moderate OSAS, and 50 or more as evidence of severe OSAS. Similarly, percentage oxygen saturation of 80-89 may be found in mild OSAS, whereas in moderate OSAS 70-79 is typical, and in severe OSAS, 69 and below is the usual findings. An arousal index of up to 10 is considered normal; 10-15 can be considered borderline. An arousal index above 15 is definitely abnormal. There are some sleep architectural changes in OSAS (reduction of slow-wave and RIM sleep); most of the sleep is spent in stage II NRKM sleep. Other findings include short latency, increased time spent awake after sleep onset, and excessive snoring. In patients with CSA syndrome, the apneas are all central.

Overnight PSG findings in patients with narcolepsy include short sleep latency, excessive disruption of sleep with frequent arousals, reduced total sleep time, excessive body movements, and reduced SWS and SOREMs (seen in 40-50% of patients). Some narcoleptic patients may have associated sleep apneas (Figure 74.8), particularly central apneas. In approximately *9-59%* of patients, PI.MS have been noted, and in about 12% of narcoleptic patients, RBD has been described.

PSG findings in MSA or Shy-Drager syndrome show a reduction of slow-wave, REM, and total sleep time; increased sleep latency; increased number of awakenings during sleep; absence of muscle atonia in REM sleep in those with RBD; and a variety of respiratory dysrhythmias, as described previously. Similar but less intense findings have been reported in patients with OPCA.

In Al), the essential features of sleep architectural alterations are reduced total sleep time, decreased REM and slow-wave sleep, reduction of sleep spindles and

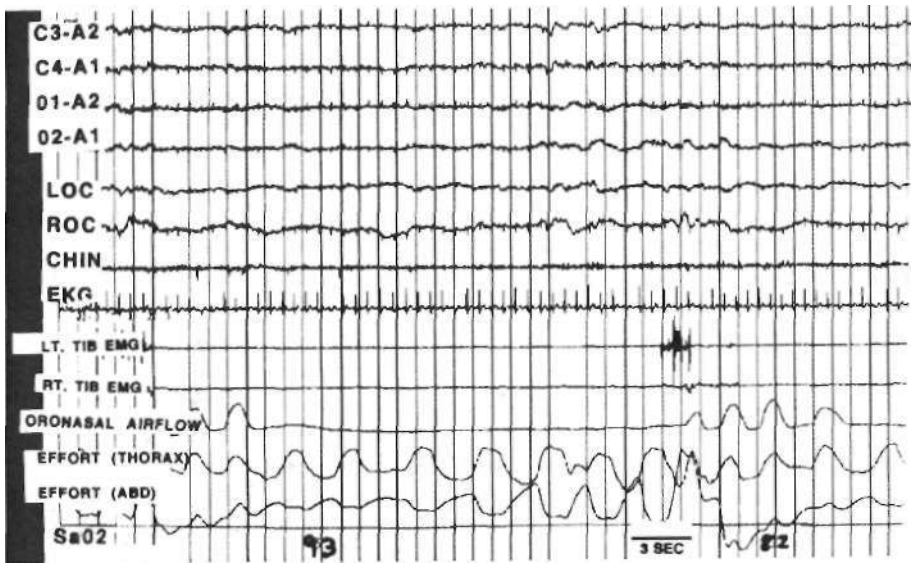

FIGURE 74.7 Polysomnography: recording of a patient with upper airway obstructive sleep apnea syndrome. Note absence of airflow for 23 seconds hut continued effort and oxygen desLituratioil from 93% to 82% in stage II non-rapid eye movement sleep, (Top four channels = electroencephalogram; ABD = abdomen; chin = electromyogram of chin muscle; EKG = electrocardiogram; LOC = lefr electro-oculogram; IT. TIB EMG = left tibialis electromyogram; ROC = right eleetro-oculogram; Sa02 = oxygen saturation; RT. TIB EMG = right tibialis electro myogram.)

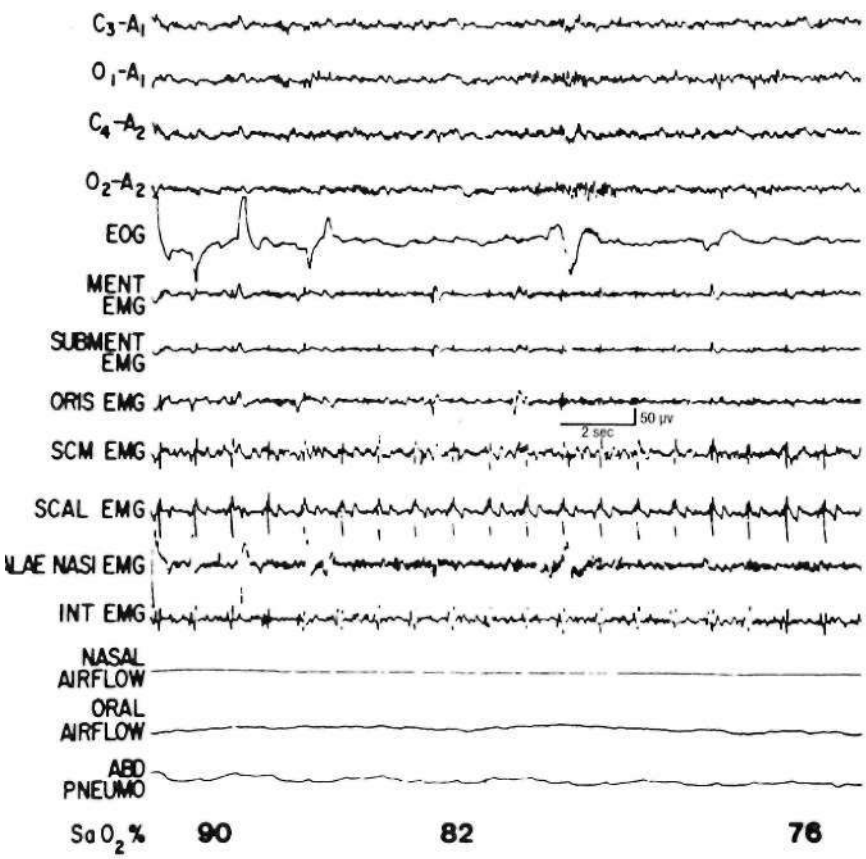

FIGURE 74.8 Polysomnography recording in ,i p;itiri;t with narcolepsy and sleep apnea. (Top four channels = electroencephalogram; EOG = electrooculogram; mentalis [MENT], submental |SUBMENT), orbicularis oris [ORIS], sternocleidomastoid muscle fSCM], scalenus amicus [SCAL], alae nasi, and intercostal [INT] electromyograms [EMG]; abdominal pneumogram [ABD PNEUMO].) Note central apnea during rapid eve movement sleep.

K complexes, increased nighttime awakenings, and sleep fragmentation. There is a high incidence of sleep apnea in those with AD compared with age-matched control subjects.

In PD, a PSG study shows a variety of sleep architectural changes: decreased sleep efficiency, increased awakenings, sleep fragmentation, decreased REM and slow-wave sleep, and sleep spindles, disruption of NREM-REM sleep cycling, absence of muscle atonia, and presence of increasing EMG activities in those presenting with RBD.

The characteristic PSG findings in RBD consist of absence of muscle atonia and presence of increased EMG activities in the upper and lower limbs (Figure 74.9) during REM sleep. It is important to record FMGs from both upper and lower limbs because in some patients with RBD, EMG activities are present in the upper limbs but not in the lower limbs.

In RES, PSG findings document sleep disturbance and PLMS (Figure 74.10), which is found in at least 80% of patients. Diagnosis of PLMD is based on the PLMS index (number of PLMS per hour of sleep); PLMS of up to 5 is considered normal. A high PLMS index with arousal is more significant than the index without arousal.

PSG findings in myopathies, including Duchenne's and other muscular dystrophies as well as myotonic dystrophy, may include sleep fragmentation and disorganization; increased number of awakenings; reduced total sleep time; central, mixed, and upper airway OSAs or hypopneas associated with oxygen desaturation; and nonapneic oxygen desaturation becoming worse during REM sleep. Similar findings may be noted in polyneuropathies or neuromuscular junctional disorders. In addition, in painful polyneuropathies and in neuromuscular conditions associated with muscular pain and cramps, a PSG study may show sleep-onset insomnia and reduced sleep efficiency.

Multiple Sleep Latency Test

The MSLT is an important test for documenting excessive sleepiness objectively. The test has been standardized and is performed after an overnight PSG study. The test consists of four to five daytime EEG, EMG, and electrooculographic recordings at 2-hour intervals with each recording lasting fot a maximum of 20 minutes. The test measures the average sleep-onset latency (timed to the first epoch of any sleep stage for the clinical purpose) and the presence of SOREMs (timed from sleep onset to the first REM sleep). A mean sleep latency of less than 5 minutes is consistent with pathological sleepiness. SOREMs in two or more of the four to five recordings during the MSLT suggest narcolepsy, although abnormalities of REM sleep-regulatory mechanism and circadian rhythm sleep disturbances also may lead to such findings. Pathological sleepiness is noted in all patients complaining of EDS.

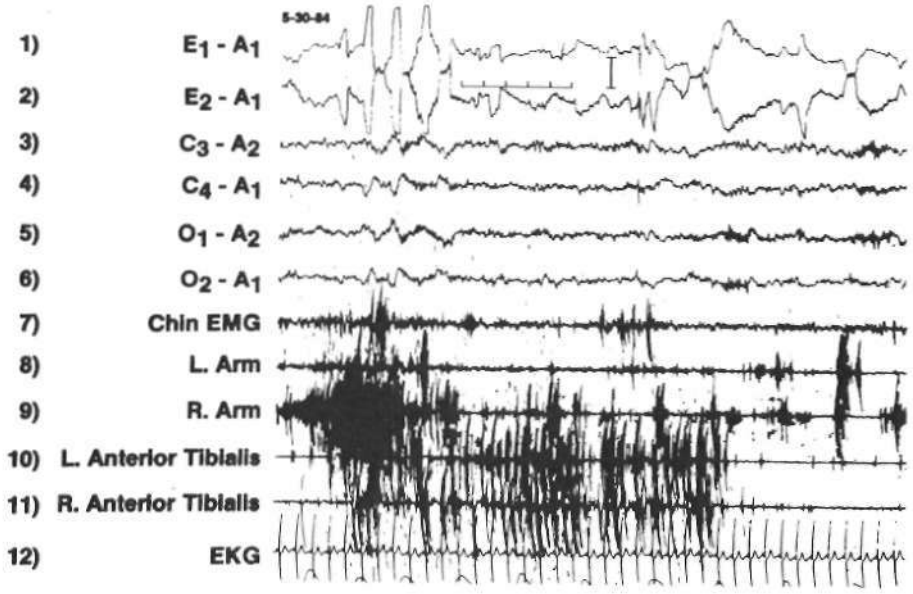

FIGURE 74.9 A portion of polysomnographic tracing in a 64-ycar-old man with rapid eye movement sleep behavior disorder. Electroencephalogram (C3-A2, C4-A1, 01-A2, 02-A1), shows mixed pattern with low-amplitude fast activities and thet.i activities. Chin clcctromyogram (EMG) as well as EMGs from left and right arms, left and right tibialis anterior muscles show tonic inctease in muscle tone with superimposed phasic increase. (EKG — electrocardiogram.) (Reproduced with permission from Broughton, R. "Behavioral parasomnias," in *Sleep Disorders Medicine: Basic Science, Technical Considerations, and Clinical Aspects,* ed S. Chokroverty, Butterworth-Heinemann, Boston Courtesy Drs. Carlos Schenck and Mark Mahowald.)

In approximately 85% of patients with narcolepsy-cataplexy syndrome, a mean sleep latency of less than 5 minutes and two or more SOREMs are both noted. Aldrich and co-workers (1997) documented that both these findings are present in the initial MSLT in only 61% of narcoleptic patients. Occasionally, narcoleptic patients may have normal mean sleep latency with one or more SOREMs. Rarely, MSLT results may be entirely normal, particularly in narcoleptic patients who arc very anxious, A large percentage of patients presenting with EDS and two or more SOREMs have a condition other than narcolepsy.

Maintenance of Wakefulness Test

The maintenance of wakefulness test (MWT) is a variant of the MSLT that measures the patient's ability to stay awake. The MWT is performed at 2-hour intervals in a quiet, dark room; the patient adopts a semireclining position in a chair and is instructed to resist sleep. Four or five such tests are performed, each one lasting for 20 or 40 minutes. The MWT may be important for monitoring the effect of treatment in narcolepsy, but it is not as good as MSLT for measuring daytime sleepiness.

FIGURE 74.10 Polysomnography study of a patient with restless legs syndrome showing periodic limb movements in sleep in the left tibialis electromyogram (ET. TIB EMC). (Top four channels = electroencephalogram [EEG]jABD = abdomen; CHIN = electromyogram of the chin muscle, EKG = electrocardiogram; LOC= left electro-oculogram; RT. TIB FMG = right tibialis. I'kvtromvogmm; l<(>< right electro-oculogram.)

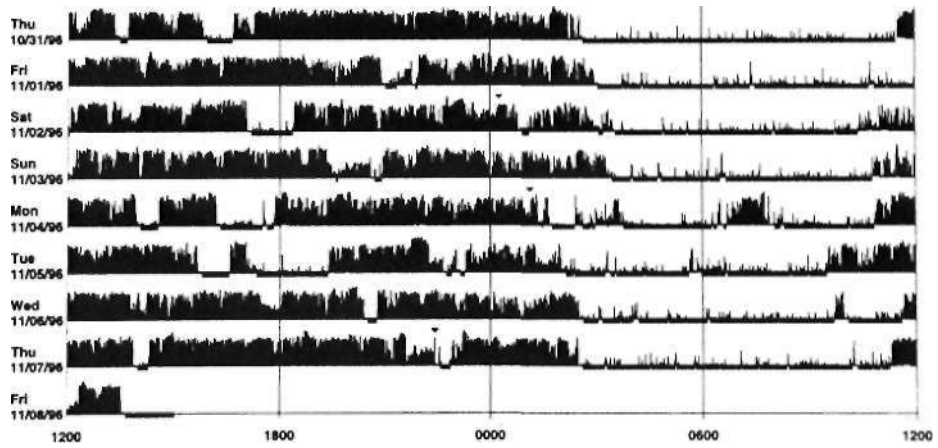

FIGURE 74.11 Acngraphic recording in a 29 year old man with delayed sleep-phase syndrome. The timing of the sleep period is delayed. Sleep typically occurs 3:00 AM to about 10:00-1 1:00 AM *(lighter areas).* The dark a teas represent the periods of activity.

Actigraphy

Actigraphy is a technique of motion detection that records activities during sleep and waking (Saadeh et al. 1995). It complements a sleep diary or sleep log data. The actigraphie instrument is a small device, slightly larger than a wristwatch, worn generally on the wrist but also on the ankle fot 1-2 weeks. It is a cost-effective method for assessing a sleep-wake pattern. Actigraphy is very useful in the diagnosis of circadian rhythm sleep disorders (Figure 74.11), sleep-state mis perception, and other types of insomnia. It can also be used to detect and quantify PLMS. It is not, however, suitable for assessment of SDB events.

Video-Polysomuographic Study

A video-PSG study is important for documenting abnormal movements and behavior during sleep at night in patients with parasomnias, including RBD, nocturnal seizures (Figure 74.12), and other unusual movements occurring during sleep. Parasomnias are generally diagnosed on the basis of the clinical history, but sometimes a video-PSG study is required to document the condition. For nocturnal epilepsy, a video-PSG study using multiple-channel electroencephalograms and multiple montages is required. Ideally, if sleep epilepsy is suspected, the video-PSG recording should be capable of EEG analysis at the standard EEG speed of 30 mm per second to identify epileptiform discharges.

Special Electroencephalographsc Studies in Nocturnal Seizure

In addition to standard EEG recording, 24-hour ambulatory EEG recording and long-term vidco-FEG monitoring may be needed for documentation of seizures. If the results of the EEG recording, including long-term monitoring and neuroimaging, are discordant in localizing the focus, the patient should be referred to a specialized epilepsy center for intracranial recordings.

Neuroimaging Studies

Neuroimaging studies include anatomical and functional (physiological) studies. These studies are essential when a neurological illness is susvvcicd of c.nism;; a sleep disturbance.

Cerebral angiography, including digital subtraction arteriography and magnetic resonance angiography, may be necessary in investigations for strokes in addition to computed tomography (GT) and MRI, which arc important in detection of structural lesions of the CNS (e.g., tumors, infarction, and vascular malformations). CT and MRI are also helpful in patients with demyelinating and degenerative neurological disorders that may be responsible for disturbed sleep and sleep-related breathing dysrhythmias.

A PET study dynamically measures cerebral blood flow, oxygen uptake, and glucose utilization and is helpful in the diagnosis of dementing, degenerative (e.g., PD and MSA), and seizure disorders. SPECT, which dynamically measures regional cerebral blood flow, may be useful for patients with cerebrovascular disease, AD, or seizure disorders. PET and SPEGT can also be performed to investigate dopamine D_2-rcceptor changes in RLS-PLMS as well as narcolepsy, Functional MRI can be useful to study the generators and areas of activation in RLS-PLMS. Doppler ultrasonography is an important test for investigation of stroke due to extracranial vascular disease. Myelography other than CT and MRI is important for diagnosis of spinal cord diseases.

In selected patients, fiberoptic endoscopy may be performed to locate the site of collapse of the upper airway and cephalometric radiographs of the cranial base and facial bones may be obtained to assess posterior airway space or maxillomandibular deficiency. These arc important when

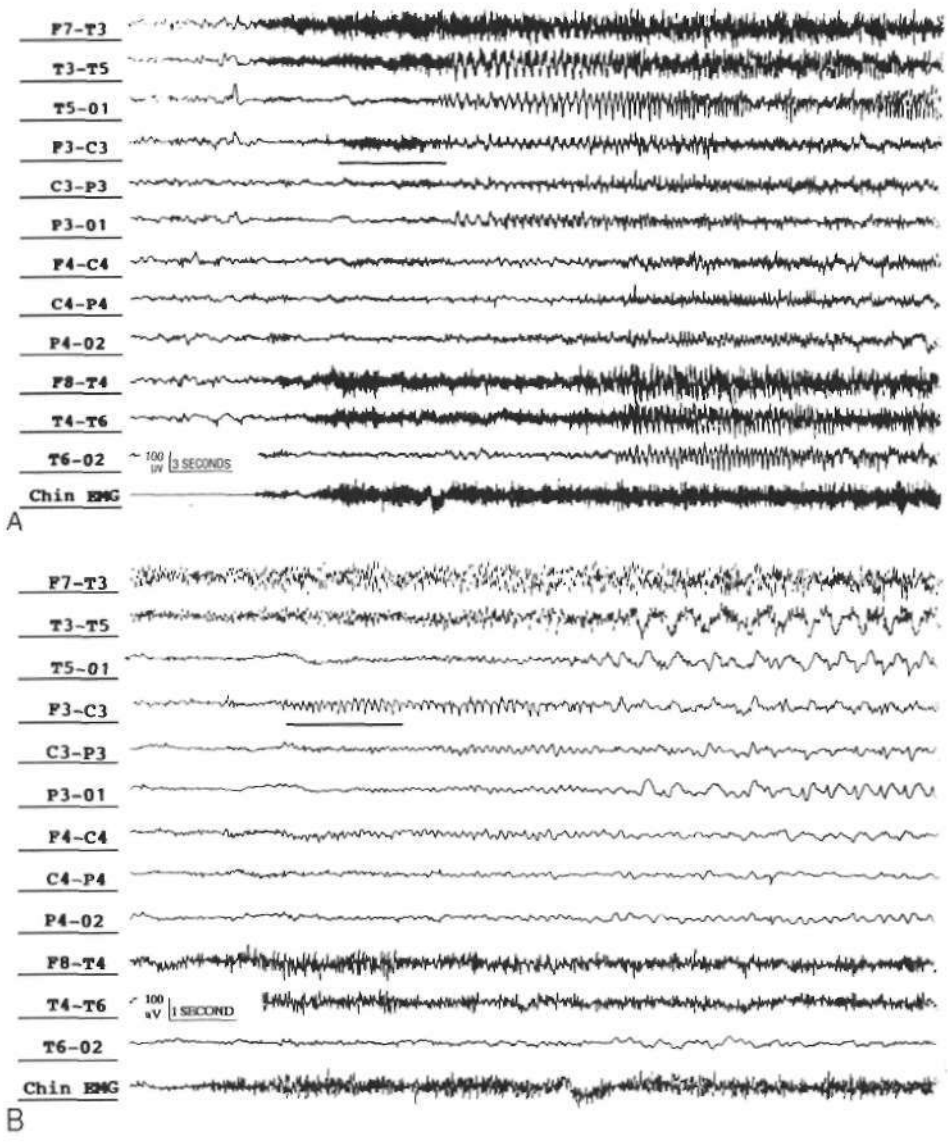

FIGURE 74.12 Portion of polysomnography recording showing the onset of a parrial seizure using (A) 10 mm per second and (B) 30 mm per second paper speed. Twelve channels of electroencephalogram (International Ten-Twenty electrode placement) and chin elccrromyogram arc shown. '. "ndcrlyint: activity represents rhythmic ictal discharges beginning at F3-C3 (left frontocentral) and spreading rapidly to the right hemisphere, and it is accompanied by clinical seizure. The underlying activity superficially resembles muscle artifacts at 10 mm per second paper speed (A) but it is obvious at 30 mm per second paper speed (B) that this activity is the beginning of the rhythmic epileptiform discharges in the electroencephalogram. (Reproduced with permission from Aldrieh, M. & Jahnke, B. 1991, "Diagnostic value of video - EEG po ly s omn ogra p hy," *Neurology,* vol. 41, p.1060.)

surgical treatment is planned. For research investigations, cross-sectional areas of the upper airway during wakefulness may be measured by CT and MRI (Robinson and Guillemmault 1999).

Pulmonary Function Tests

Pulmonary function tests exclude the presence of intrinsic bronchopulmonary disease, which may affect sleep-related lireathing disorders. Pulmonary function tests may include-assessment of ventilatory functions (forced expiratory volume in 1 second |FF.V; |, forced vital capacity [FVC], the FEVi to FVC ratio, peak expiratory flow rate, and forced expiratory flow rate), measurement of lung volumes (total lung capacity, residual volume, and functional residual capacity), gas distribution and gas transfer, and arterial blood gases (Po_2 and Pco>). Respiratory muscle function of individuals with neuromuscular disorders should be specifically assessed, and it is important to measure the maximal static inspiratory and expiratory pressures. Finally, chemical control of breathing (hypercapnic and hypoxic ventilatory responses) may be needed to assess respiratory functions and control systems in patients with various neurological disorders causing dysfunction of the metabolic respiratory controllers as well as in patients with obcsity-hypoventilation {pickwickian) syndrome.

Elcctrodiagnosis of the Respiratory Muscles

FMG recordings of the upper airway and diaphragmatic and intercostal muscles may detect affection of these muscles in various neurological diseases. A laryngeal EMG recording may detect laryngeal paresis in patients

with VISA with laryngeal stridor. A phrenic nerve and intercostal nerve conduction study may detect phrenic and intercostal neuropathy, which may cause diaphragmatic and intercostal muscle affections in some patients with neurological disorders.

Other Laboratory Tests

Appropriate laboratory tests should always be performed to exclude any suspected medical disorders that may be the cause of patients' insomnia or hypersomnia. These tests may include blood analysis and urinalysis, EGG, Holter ECG, chest radiography, and other investigations to rule out gastrointestinal, pulmonary, cardiovascular, endocrine, and renal disorders. In rare patients, when autonomic failure causes a sleep disturbance or sleep-related breathing disorder, autonomic function tests may he required for the diagnosis of the primary condition. In patients with narcolepsy, 1 1LA typing may be performed because most of the patients with narcolepsy show positivity for HLA DR2 DQ1, and DQB1*0602 antigens (Mignot 1998, 1999). Another important test is measurement of cerebrospinal fluid hypocretin 1 levels, which arc found to be low (below 110 pg/mL) in patients with narcolepsy-cataplexy who are HI.A DQBD0602 positive (Mignot et al. 2002). In selected patients suspected of having a psychiatric cause of EDS, neuropsychiatry testing (e.g., the Minnesota Multiphasic Personality Inventory) may be helpful.

In patients with RLS, EMG and nerve conduction studies are important to exclude polyneuropathies or lumbosacral radiculopathies and other lower motor neuron disorders that may be associated with RLS or cause symptoms resembling idiopathic RLS. Other important laboratory tests in patients with RLS include those necessary to exclude diabetes mellitus, uremia, anemia, and other associated conditions. It is particularly important to obtain levels of serum iron (including serum ferritin and transferrin), serum folate, fasting blood glucose, blood urea, and creatinine. The role of nerve biopsy remains controversial. In the vast majority of patients, a nerve biopsy is not necessary, but it may be obtained for research purposes and when there is a strong suspicion of polyneuropathy.

Management of Sleep Disorders

It is important to determine a cause for sleep disturbances so that the primary condition can be adequately treated. Treatment of secondary sleep disturbances is unlikely to be successful unless the primary cause is properly diagnosed and treated. Treatment of an underlying cause may resolve the sleep disturbance. If satisfactory treatment is not available for the primary condition or does not resolve the problem, however, treatment should be focused on specific sleep disturbance. Certain general principles of treatment should apply to treatment of any sleep disorders. It is beyond the scope of this chapter to discuss management of various medical, psychiatric, and neurological disorders. General sleep hygiene measures are listed in Table 74.28.

Steep Apnea Syndrome

The objective of management of sleep apnea syndrome is to improve the quality of life by improving the quality of sleep and to prevent life-threatening cardiac arrhythmias, pulmonary hypertension, CHF, and stroke, which arc related to SDK. Treatment of sleep apnea syndrome includes (Table 74.29) general measures, pharmacological agents, mechanical devices, and surgical treatment (Robinson and Guilleminault 1999).

Genera) measures include avoidance ot sedative-hypnotics and alcohol, which can aggravate sleep-related breathing disorders, and reduction of body weight in obese patients,

Pharmacological Treatment. Pharmacological treatment has not been very helpful in OSAS. The agents that have been partially successful in treatment of mild sleep apnea-hypopnea syndrome are protriptyline and acetazolamidc. There have been isolated reports of the use of selective serotonin reuptake inhibitors, theophylline and medroxyprogesterone acetate, without much benefit as well as topical nasal corticosteroids for OSAS in children with minimal benefit. Acetazolamide, a carbonic anhydrase inhibitor, produces metabolic acidosis, causing a shift in the CO2 apnea threshold, and has been used with some success to treat central apnea at high altitude. In a subset of patients with OSAS who were receiving CPAP treatment, modafinil, a novel wake-promoting agent, has been useful as adjunct treatment for residual daytime sleepiness.

Mechanical Devices. Nasal CPAP is an important therapy for treating OSAS. CPAP opens up the upper airway passage so that obstructive apneas and hypopneas,

Table 74,2H: Sleep hygiene measures

Sleep only as much as you need to feel rested
Keep a regular sleep schedule
Avoid forcing sleep
Exercise regularly for at least 20 min, preferably 4-5 hr before bedtime
Avoid caffeinated beverages after lunch
Avoid alcohol near bedtime: no nightcap
Avoid smoking, especially in the evening
Do not go to bed hungry
Adjust bedroom environment
Deal with your worries before bedtime

Table 74.29: Treatment of sleep apnea syndrome

General measures
Avoid alcohol, particularly in the evening
Avoid sedative-hypnotics
Reduce body weight
Pharmacological treatment (in mild cases)
Protnptyline
Acctazolamide (central apnea at high altitude)
Mechanical devices
Nasal continuous positive airway pressure for OSAS
Bilevel positive airway pressure for OSAS
Intermittent positive pressure ventilation for hypoventilation in neuromuscular disorders
Dental appliances in some mild to moderate OSAS
Tongue-retaining device for OSAS (unpredictable)
Surgical treatment
Uvulopalatopharyngoplasty (UPP), including laser-assisted and radiofrcquency UPP
Major maxillofacial surgical procedures
Tonsillectomy and adenoidectomy
Diaphragm pacing (central sleep apnea)
Tracheostomy (rarely performed nowadays)

OSAS = obstructive sleep apnea syndrome.

hypoxemias, snoring arousals, and sleep fragmentation are eliminated. The optimal (TAP pressure is first determined in the laboratory during overnight an PSG study, and the patient can purchase home units ro use nightly during sleep. Instead of CPAP, some patients may require bilevel positive airway pressure, which delivers a higher pressure during inspiration and a lower pressure during expiration. It is important to follow-up with such patients for the purpose of compliance and to identify patients who did not have adequate benefit and may require repeat titration. All patients do not comply with the CPAP regimen because of various problems, such as difficulty with the mask, claustrophobia, air leaks between the mask and face, and nasal congestion. The compliance vaties from 60% to 70% of patients. Further study is needed to determine the factors for compliance and noncompliance and to understand the long-term effect on the natural history of OSAS. The role of nasal CPAP in CSA syndrome is highly controversial. In a subgroup of patients with CSA who show narrowing or occlusion of the upper airway on fiberoptic scope, nasal CPAP may reverse the apneic episodes.

Surgical Treatment. In a few patients with severe OSAS in which CPAP therapy fails, UPP, including laser-assisted and radiofrequency UPP, and other upper airway surgical procedures have been tried with variable success (Sher 2002). Significant improvement is noted in approximately 50% of patients after UPP, and many of those who show improvement may still need (TAP for elimination of residual apneas. An overnight PSG study must always be performed before UPP is undertaken because it may eliminate snoring without adequately relieving OSAS. Other surgical approaches may be needed in patients with severe disease, including maxillofacial surgery, such as hyoid myotomy and suspension or mandibular osteotomy with genioglossus muscle advancement, although their role remains uncertain (Sher 2002). Tracheostomy may still be needed in an occasional patient as an emergency measure during severe respiratory compromise or severe apnea associated with dangerous cardiac arrhythmias causing a life-threatening situation. Tracheostomy for such severe cases of OSAS appears to be effective and well tolerated in the long term (Thatcher and Maisel 2003). Some patients may later be weaned from the tracheostomy and move to CPAP treatment, which has replaced tracheostomy for obstructive or mixed apneas. In patients with respiratory center involvement with CSA syndrome, diaphragm pacing or electrophrenic respiration has been used successfully, particularly for those who require ventilatory assistance during both day and night.

Other Ventilatory Supports. In patients with neuromuscular disorders, including those with AI.S, poliomyelitis, and postpolio syndrome, ventilatory support is often needed with either negative pressure or positive pressure ventilators ((^hokrovcrty 1999b; Guilleminault and Shergill 2002; Gonzalez et al. 2002). Intermittent positive pressure ventilation (IPPV) can be administered through a nasal mask. Negative pressure ventilation can be delivered from a tank respirator or from a cuirass. With ventilatory support, patients with neuromuscular disorders often obtain relief of daytime hypcrsomnolence and show improvement in sleep architecture. A combination of a nasal mask and positive pressure ventilation may be needed. When OSA complicates sleep hypoventilation, IPPV through a nasal mask during sleep may be a better treatment than negative pressure ventilation and may obviate the need for tracheostomy or diaphragm pacing. Negative-pressure ventilation may improve these patients' nocturnal ventilation during NREM sleep but can produce upper airway obstructive apnea during REM sleep, causing severe hypoxemia and hypercapnia. Patients with respiratory muscle weakness, including diaphragmatic muscle weakness, may require a combination of CPAP, cuirass ventilation, and later IPPV at night. Patients with motor neuron disease and associated sleep-related hypoventilation and apnea have been treated with cuirass ventilators, CPAP, and later IPPV at night with considerable symptomatic relief. Patients with poliomyelitis or postpolio syndrome who require ventilatory support to maintain respiratory homeostasis generally show improvement in sleep architecture and respiratory function after mechanical ventilation via nasal mask. Obstructive or mixed apneas respond to CPAP.

Other Treatment Modalities. Dental appliances can reduce snoring and help patients with mild sleep apnea, but at present, it is not possible to predict which patients will respond to such treatment. A tongue-retaining device is another unpredictable measure for treating sleep apnea.

Narcolepsy

The administration of stimulants, such as modafinil, NKilivlplH-r.ulaU'. pemoline, dextroamphetamine, or mcthamphetamine, is the treatment of choice (Table 74,30) for narcoleptic sleep attacks (Bassetti 2003). In 65-85% of patients, a significant improvement of EDS can be obtained. Modafinil, a novel wake-promoting agent, or methylphenidate is the drug most commonly used initially in patients with newly diagnosed narcolepsy. Because of hepatotoxicity pemoline is rarely used at present. The long-term efficacy and safety of modafinil fot the treatment of excessive sleepiness and sleep attacks associated with narcolepsy have been well established (Moldofsky et al. 2000; Mitlet et al. 2000). The starting dose is 100-200 mg daily and may be increased to 400 nig daily in two divided doses if needed. Methylphenidate treatment may be started with 5-10 mg two to three times daily. To avoid insomnia, the last dose should not be taken aftet 4:00 PM. In patients whose narcolepsy docs not respond to modafinil or methylphenidate, treatment with dextroamphetamine or mcthamphetamine can be administered, starting with 5-10 mg in the morning or twice a day. The maximum acceptable doses of stimulants for treatment of narcolepsy may include up to 50 mg daily (rarely 100 mg) for methylphenidate and 50 mg daily for both dextroamphetamine and methamphetamine. The most common side effects of the stimulants include nervousness, tremor, insomnia, irritability, palpitations, headache, and gastrointestinal symptoms. Another problem is tolerance, which may be noted in many patients, particularly with increasing doses.

The treatment of cataplexy and other auxiliaty symptoms of narcolepsy (see Table 74.30) consists of administration of tricyclic antidepressants, such as protriptyline (starting with 5 mg per day), imipramine (25-200 mg per day), and clomipramine (10-200 mg per day). Specific serotonin reuptake inhibitors, such as fluoxetine (20-80 mg per day), have been used with success. Recently sodium oxybatc (y-hydroxybutyrate) in two divided nightly doses of 3-9 g has been found to be an effective drug for treating cataplexy and narcoleptic sleep attacks (US Xyrctn Multicenter Study Group 2003).

Nonpharmacological treatment of narcolepsy includes general sleep hygiene measures, short daytime naps, and participation in narcolepsy support groups.

Table 74.30: Drug treatment for narcolepsy syndrome

For sleep attacks
- Modafini!: 200 mg/day
- Methylphenidate (Ritalin): 5 mg bid, 30 min before meals to a maximum of 30 mg, rarely 100 mg/day
- IV\m>nmphi'iamine (Dcxcdrine): 5 mg qd or hid, up to 50 mg/day
- YterriampriornmuH' : XI. • -11 L-L 31- i - . - • 5 NIL; qd nr hid, up r<> 50 mg/day
- Mazindol: 2 mg qd or bid, up to 8 mg/day

For cataplexy, sleep paralysis, and hypnagogic hallucinations
- Imipramine: 75-150 mg/day
- Clomipramine: 75-125 mg/day
- Fluoxetine: 20 mg qd, up to 80 mg/day
- Viloxazine: 150-200 mg/day
- Sodium oxybate: 3-9 g nightly

Idiopathic Hypersomnia

The treatment of idiopathic hypersomnia is generally unsatisfactory and is similar to the stimulant treatment for narcolepsy.

Parasomnias

No special treatment is needed for most ot the parasomnias. The subjects with partial arousal disorders (e.g., sleepwalking and sleep terrors) must he protected from injury to self or others by arranging furniture, using a padded mattress, and paying particular attention to doors and windows. If attacks of sleepwalking or sleep terrors are frequent, . realrr.eni v. uli ..u: aniulepirss.im e.g.. imipr.i mule or small doses of a benzodiazepine (e.g., clonazepam) may be tried for a short period.

Most RBDs respond dramatically to small doses of clonazepam (e.g., 1-2 mg at night). Occasional patients may need other drugs {e.g., melatonin).

Circadian Rhythm Sleep Disorders

Orcadian rhythm sleep disorders may be treated by the use of chronotherapy, phototherapy, or both. Chronotherapy refers to the intentional delay of sleep onset by *2-.y* hours on successive days until the desired bedtime has been achieved. After this, the patient strictly enforces the sleep-wake schedule. One study reported a high success rate among patients with DSPS even when the disorder had been present for many years. After several months, however, the patient generally becomes less adherent to the schedule and begins to lapse into his or her original sleep habits.

Exposure to bright light on awakening is effective in altering sleep onset and in synchronizing body temperature rhythm in patients with DSPS. The patient sits in front of a 10.000-lux light for 30^10 minutes on awakening; in addition, room lighting must be markedly reduced in the evening to achieve the desired results, A response is LU.Tiei,;lly (.vide:u Lillet 2-3 weeks- bin maintenance "l the response often requires indefinite treatment. This treatment is still evolving, and no large-scale study with adequate follow-up has been conducted to assess the long-term effect of phototherapy in DSPS. In patients with ASPS, bright light exposure in the evening has been successful in delaying sleep onset.

Melatonin (0,5-7,5 mg/day), taken orally in the evening or at bedtime, has been reported to be effective in some blind people with hypernychthemeral syndrome.

SiToml.m circuliau rhythm disorders (e.g., jet lag and effects of shift work) may be treated with benzodiazepine or /olpidem. Phototherapy has been tried, but its effectiveness has not been determined. Melatonin is being evaluated for treatment of arcadian rhythm disorders.

Restless Legs Syndrome and Periodic Limb Movements in Sleep

hour major groups of drugs have been used to treat RLS and PLMS (Table 74.31): dopaminergic agents, benzodiazepines, gabapentin, and opiates (Hcning et al. 1999). The typical dose for carbidopa/L-dopa (Sinemet) is 25/100 to 100/400 mg taken in divided doses before bedtime and during the night, Pergolide can be started at 0.05 mg and gradually increased to 0.2-0.5 mg taken in divided doses. One dose is taken 1 hour before bedtime and, depending on severity, another dose may be needed earlier in the evening or during the middle of the night on awakening. Another dopamine agonist, bromocriptine, may be tried, beginning with 2.5 mg and gradually increasing to a maximum of 15 mg per day. Bromocriptine has not been found to be as useful as pergolide or carbidopa/i.-dopa. Sometimes, a long-acting drug (e.g., Sincmct-CR) may be combined with short-acting carbidopa/L-dopa for maximum effect. Problems with the use of dopaminergic medications include abdominal pain, nausea, recurrence of RLS symptoms, poor sleep quality during the last part of the night, and the development of rebound or augmentation, consisting of symptoms of RLS-PLMS developing earlier in the day and more severely than before treatment. Nausea, vomiting, and headache also may occur after treatment with carbidopa/L-dopa, whereas nasal stuffiness, hypotension, and nightmares have been reported after treatment with pergolide.

Two new nonergot dopamine agonists, pramipexole and ropinirole, have been available in recent years. The safety and efficacy of these agonists in the treatment of RLS have been proven by several clinical trials. Most physicians now begin treating RLS with one of these agents. Pramipexole should be started at 0.125 mg I hour before bedtime and then gradually increased every 5-7 days as needed. The average dose is about 0.5-0.75 mg and may be increased up to 1.0-1.5 mg a day. Ropinirole should be started at 0.25 mg 1 hour before bedtime and gradually increased to an average dose of 1.5-2.5 mg. Side effects of these two drugs include nausea, sleepiness, dizziness, and peripheral edema. Another long-acting dopamine agonist, cabergolinc, has been used successfully to treat RLS, but this drug is very expensive and generally not used in the United States.

Clonazepam (0.5-2.0 mg per day at bedtime) or temazepam (15-30 mg at bedtime) may be useful in treating RLS-PLMS. Medications should be started with the lowest dose and gradually increased to obtain maximum benefit with minimal side effect. These agents may produce daytime sleepiness or confusional episodes, particularly in elderly patients.

Gabapentin is an anticonvulsant that has been found to be beneficial in mild-to-moderate RLS-PLMS. Divided doses of 300-1800 mg per day may be helpful but can produce somnolence, dizziness, ataxia, or fatigue in more than 10% of patients.

Opiates are effective for treating RLS-PLMS but are a less desirable alternative because of their proclivity to produce constipation and their potential fot addiction. Codeine, propoxyphene, oxycodone, and methadone have all been used for this purpose. Tramadol, a non-narcotic agent with activity at the opiate mu-receptor, also has been used with some success in patients with RLS-PLMS.

For mild RLS-PLMS, the physician may start with gabapentin. In moderate-to-severe conditions, most physicians start with pramipexole or ropinirole. In patients with refractory disease, one may have to use a combination of two to three drugs. In summary, the principle of treatment of RLS-PLMS is to start with the lowest possible dose and then increase by 1 tablet every 5-7 days until a maximum therapeutic benefit is reached or the side effects are noted. The dose can be divided and given 1-2 hours before bedtime. If necessary, for some patients with severe conditions, a daytime dose may be needed.

Other minor drugs (see Table 74,31) that have been helpful in occasional patients with RLS-PLMS include baclofen (10-60 mg daily), carbamazepine {200-600 mg daily), clonidine, an adrenergic agent (0.1-0.9 mg daily), and propranolol (80-120 mg daily).

In secondary RLS, the primary condition should be treated and the deficiency states, including the iron deficiency, should be corrected. The patient should also follow general sleep hygiene measures. Finally, the patients

should avoid certain medication and agents that might aggravate RLS, including neuroleptics, tricyclics, selective serotonin re-uptake inhibitors, other antidepressants, certain antinausea medications, calcium-channel blockers, caffeine, alcohol, and smoking.

Insomnia

Insomnia is a syndrome and not a specific disorder, and therefore treatment depends on the underlying cause of the syndrome. Treatment of secondary insomnia is unlikely to be successful unless the primary cause of the disturbance is diagnosed and properly treated. Both nonpharmacological and pharmacological therapies may be useful in the management of insomnia (Morin ct al. 1999, 2001; Espie ct al. 2001).

Nonpharmacological Treatment. The mainstay of treatment for patients with chronic insomnia is the use of nonpharmacologic.il measures in conjunction with the judicious, intermittent use of hypnotics. Nonpharmacological interventions include relaxation therapy and biofeedback; stimulus-control therapy; sleep restriction; and patient education about sleep hygiene, sleep habits, attitudes toward sleep, and the role of autonomic and cognitive arousals (Table 74.32). Sleep hygiene measures are listed in Table 74.28.

Relaxation therapy involves progressive muscle relaxation and biofeedback to reduce somatic arousal. One small study of several relaxation procedures found a 42% improvement in self-reported sleep complaints after 1 year of relaxation therapy. Stimulus-control therapy may also be useful in patients with chronic insomnia. Bootzin's stimulus-control technique is focused on discouraging the learned association between the bedroom and wakefulness and reestablishing the bedroom as the major stimulus for sleep. These techniques have been reported to lessen complaints of insomnia in approximately 50% of individuals after 1 year. Sleep-restriction therapy may improve sleep efficiency by restricting the total time in bed for sleep. Once this has occurred, gradually increasing the time allocated to sleep may improve the level of daytime functioning and the overall quality of sleep. Roughly one fourth of patients with insomnia may benefit from such a regimen. The relative efficacy of these various nonpharmacological approaches has not been well established. One metaanalysis involving 2102 patients in 59 trials found that sleep-restriction and stimulus-control therapies were more effective than relaxation techniques used alone (Smith et al. 2002). The use of sleep hygiene measures alone was not effective. The extent to which the concomitant use of nonpharmacological therapy augments the performance of pharmacological treatment is also unclear.

  - Benzodiazepines
    - Flurazepam: 15-30 mg
    - Estazolam: 1-2 mg
    - Clonazepam: 0.5-2.0 mg
    - Lorazepam: 1-2 mg
    - Temazepam: 15-30 mg
    - Triazolam: 0.125-0.250 mg
  - Nonbenzodiaiepines
    - Zolpidem: 5-10 mg
    - Zalcplon 5-10 mg
    - Antihistamines
    - Sedative antidepressants
    - Melatonin

Pharmacological Therapy. Hypnotic medications have generally not been the first choice of treatment for chronic insomnia (see Table 74.32). When they are prescribed, they should he used intermittently and always combined with nonpharmacological therapies.

Judicious use of hypnotics may be helpful in treating transient or short-term, idiopathic, and psychophysiological insomnia, but their use should be restricted to less than 4 weeks' duration. Intermittent use of hypnotic medications (e.g., 1-2 nights per week) may be necessary in some patients with chronic idiopathic or psychophysiological insomnia whose insomnia does not respond adequately to nonpharmacological treatment, although the drugs should not be the main component of therapy. Hypnotic medications are contraindicated in pregnancy because of data showing an increased risk of fetal malformations with diazepam or diazoxide if used during the first trimester. The drugs should also he avoided or used judiciously in patients with alcoholism or renal, hepatic, or pulmonary disease. A combination of alcohol and hypnotics is absolutely contraindicated. The drugs should also be avoided in patients with sleep apnea syndrome.

Benzodiazepine drugs (temazepam, flurazepam, triazolam, and estazolam) and two nonbenzodiazepine drugs (/olpidem and zalcplon) are commonly used as hypnotics; two other benzodiazepine drugs (lorazepam and clonazepam) are also often used for this indication (Morin et al. 2001; Walsh and Schweitzer, 1999; Walsh et al. 2000; Danjou et al. 1999). Triazolam is no longer available in Great Britain because of reports of serious side effects, such as amnesia, rebound insomnia, and anxiety. The selection of a specific hypnotic agent should be based primarily on the elimination half-life. Short-acting drugs, such as temazepam, estazolam, triazolam, and Zolpidem, are generally preferable because they produce less residual sleepiness the morning after use. However, these drugs,

particularly triazolam, may have a high incidence of amnesia and rebound insomnia and should be used cautiously in patients with anxiety disorders. Adjustment in dosage may be necessary in patients who have prolonged drug elimination half-lives due to age or impaired renal or hepatic function. Dependence and tolerance arc the major disadvantages of long-term use of hypnotics. The drugs should be discontinued gradually rather than abruptly to avoid precipitating symptoms of withdrawal.

Sedating antidepressants (e.g., amitriptyline and trazodone) are most useful in the management of patients in whom depression and insomnia coexist but are of limited usefulness in nondepressed patients because of rapidly developing tolerance to the sedative effects. Many over-the-counter sleep aids conrain the sedating antihistamine diphenhydramine or doxylaminc. These medications are generally not helpful in the management of chronic insomnia. Melatonin, a normal product of the pineal gland, is sold as a food supplement and an orphan drug in the United States, but over-the-counter sales are banned in the United Kingdom. Data on the efficacy and safety of melatonin are minimal, but the hormone does not appear to be a potent hypnotic for most patients with chronic insomnia. However, a subgroup of elderly patients with low melatonin levels have benefited from melatonin treatment, and it also is useful in some patients with jet lag, DSPS, and hypernychthcmeral syndrome.

Sleep Disturbances in Neurological llhess

Treatment of neurological illnesses causing sleep-related dysrhythmias have been described (see Sleep Apnea Syndrome, earlier in this chapter).

Nocturnal seizures should be treated with standard anticonvulsant medications. Sleep disturbances in these patients often resolve after effective therapy for seizures,

Trearment of acute confusional states associated with dementia should be focused on the precipitating or causal factors for such episodes. Often, episodes are precipitated when the patient is transferred from home to an institution. As much as possible, the home environment of such patients should be preserved. The darkness of night often precipitates episodes, so a night light is helpful. Medication that could have adverse effects on sleep and breathing should be teduced in dose or changed. Associated conditions that could interfere with sleep {e.g., pain due to arthritis and other causes) should be treated with analgesics. Depression is often an important feature in patients with AD, and a sedative antidepressant may be helpful. Frequency of urination in such patients may result from infection or an enlarged prostate gland and may disturb sleep at night. Appropriare treatment should be used for such conditions. Patients should be encouraged to develop good sleep habits. They should be discouraged from taking daytime haps and should be encouraged to exercise (e.g., walking) during the day. They should not drink caffeine in the evening before bedtime. For sleeplessness, a trial with intermediate-acting benzodiazepines, Zolpidem or zaleplon, should be tried for a short period. For extreme agitation, patients should be given small doses of high-potency antipsychotics, such as halopendol or thiothixene, or atypical antipsychotics (e.g., risperidone, olanzapine, quetiapine), which have less side effects than halopcridol or thiothixene. In some patients, appropriately timed exposure to bright light may be helpful.

Treatment of PD improves sleep inconsistently. In patients who have reactivation of parkinsonian symptoms during sleep at night, adjustment in the timing and choice of medication may be helpful. Some patients may benefit from an evening or bedtime dose. Longer-acting preparations of L-dopa also may help when taken near bedtime. Dopamine agonists (e.g., bromocriptine, pergolide, pramipexole, and ropinirole) with their sustained actions may benefit sleep in some patients. Antihistamines such as diphenhydramine may promote sleep in addition to giving a modest antiparkinsonian effect. A small dose of carbidopa/L-dopa, with a second dose later at night if the patient awakens, may sometimes help those with insomnia. In some patients, selegiline may improve sleep. Nocturnal dyskinesias related to i.-dopa and causing insomnia may respond to a reduction in the dose of dopamine agonists or by addition of a small dose of benzodiazepine. In patients with nocturnal hallucinations and nightmares, including nocturnal vocalizations and RBD, clonazepam (0.5-1.0 nag) at bedtime may be beneficial. Nocturnal hallucinations and psychosis in patients with PD have been treated successfully with clozapine or the newer drug olanzapine. During clozapine treatment, the usual precautions of monitoring blood count and testing liver function should be taken. Rivastigmine, a cholinesrerasc inhibitor, has been beneficial in improving sleep disturbance cognition and hallucinations in some patients with PD.

CONCLUSION

There has been an explosion of knowledge in our understanding of sleep and its disorders stretching from the gene to pathophysiology and phenomenology. The field of sleep medicine is beginning to take its rightful place as a distinct subspecialty in medicine. Sleep disorders affect multiple systems and result from dysfunction of almost every system in the body. It is therefore important to have a basic understanding of the physiological changes during sleep and the clinical phenomenology of sleep disorders. In this chapter, I briefly summarize the essential physiological changes during sleep, which are quite different from those during wakefulness as well as circadian rhythms, the function of sleep, and neurobiology of slcep-wakefulness. Clinical manifestations of many primary and secondary sleep disorders, methods of laboratory investigation, and management are also briefly reviewed. Sleep is a function of

the brain and patients with neurological disorders are particularly susceptible to disorders of sleep. Sleep adversely affects neurological illnesses, and neurological disorders in turn adversely affect the quality and quantity of sleep. Therefore, it is incumbent upon neurologists to have a basic understanding of disorders of sleep because sleep dysfunction encroaches on almost every aspect of neurology.

Chapter 75
Headache and Other Craniofacial Pain

Christopher J. Boes, David J. Capobianco, F. Michael Cutrer, David W. Dodick, Eric J. Eross, and Jerry W. Swanson

Headache is one of humanity's most common afflictions. It has been estimated that one person in three experiences severe headaches at sonic stage of life. Most people with a mild recurrent or isolated headache do not consult a physician, and therefore the true prevalence is unknown. The lifetime prevalence for any type of headache as estimated from population-based studies is more than 90% for men and *95%* for women. A survey of a sample of 20,000 households in the United States revealed a prevalence rate of migraine of 18.2% in females and a 6.5% rate among males, resulting in an estimated 27.9 million migraineurs in the United States. Approximately 60% of patients with migraine experience 2 or more attacks per month, and more than 75% of migraineurs report severe or extremely severe pain during attacks. More than 90% of patients report an impaired ability to function during migraine attacks, and 53% report severe disability requiring bedrest. Approximately 31% of patients with migraine missed at least one day from work or school in the preceding 3 months due to migraine (Lipton et al. 2001). Indirect costs of migraine related to decteased productivity and lost days of work have been calculated to be $13 billion per year; it has been estimated that there are the equivalent of 112 million bedridden days per year due to migraine (Hu et al. 1999). Indeed, the World Health Organisation declared migraine to be among the most disabling medical conditions experienced worldwide.

PAIN TRANSMISSION AND MODULATION AS RELATED TO HEADACHE

An understanding of the pathophysiology of headache must first start with a knowledge of which intracranial structures are pain sensitive. Ray and Wolfe reported on the pain-sensitive structures in the head and mapped the pattern of pain referral based on the structure simulated from intracranial surgery performed during local anesthesia in the 1930s. The intracranial pain-sensitive structures include the arteries of the circle of Willis and the first few centimeters of their medium-sized branches, meningeal (dural) arteries, large veins and dural venous sinuses, and portions of the dura near blood vessels. Pain-sensitive structures that are external to the skull cavity include the external carotid artery and its branches, scalp and neck muscles, skin and cutaneous nerves, cervical nerves and nerve roots, mucosa of sinuses, and teeth. Pain from these structures is carried largely by cranial nerves V, VII, IX, and X.

Inflammation, traction, compression, malignant infiltration, and other disturbances of pain-sensitive structures lead to headache. Superficial structures tend to refer pain locally, whereas deeper-seated lesions may refer pain imprecisely to a distant part. A purulent maxillary sinus, for example, causes pain over the involved sinus, whereas within the cranial vault, nociceptive signals reach the central nervous system (CNS) largely by way of the first division of the trigeminal nerve, and therefore an occipital

lobe rumor may refer pain to the frontal head region. Infra tentorial lesions tend to refer pain posteriorly because this compartment is innervated by the second and third cervical nerve roots, which also supply the back of the head. This can change when posterior lesions or cervical spine pathological conditions produce frontal headache, which may occur because the caudal portion of the trigeminal nucleus extends down as far as the dorsal horn at the C3 level. Impulses arriving from C2-C3 converge on neurons within the trigeminal nucleus and may refer pain to the somatic distribution of cranial nerve VI.

Afferent pain impulses into the trigeminal nucleus are modified and modulated by descending facilitatory and inhibitory influences from critical brainstem structures, including the periaqueductal gray, rostral ventromedial medulla, locus ccrulcus, and dorsal raphe nuclei. Opioids diminish the perception of pain by activating the inhibitory systems, whereas fear, anxiety, and overuse of analgesics may activate the facilitatory systems thereby aggravating the pain.

CLASSIFICATION

In 198H, the I leadache Classification Committee of the International Headache Society introduced a detailed classification of headaches, which was revised in 2004. The 14 main headache types are shown in Table 75.1. bach In.\i J ulu- type ;•. furl her dclincd ;ind subclassified according to criteria agreed to by several international subcommittees. Careful definition of the many types of migraine and other primary headache disorders is expected to free future research and clinical publications from the confusing and often poorly defined terminology of earlier work. Until the actual pathogenesis of primary headache syndromes is determined, it will not be possible to develop a unitary classification of head pain.

Tabic 75.1: Classification of headache

The Primary Headaches
1. Migraine
2. Tension-type headache
3. Cluster headache and other trigeminal-autonomic cephalalgias
4. Other primary headache disorders

The Secondary Headaches
5. Headache attribured to head and/or neck trauma
6. Headache attributed to cranial and/or cervical vascular disorder
7. Headache attributed to nonvascular, noninfectious intracranial disorder
8. Headache attributed to a substance or its withdrawal
9. Headache attributed to infection
10. Headache attributed to disturbance of homeostasis
11. Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
12. Headache attributed to psychiatric disorder
13. Cranial neuralgias and central causes of facial pain
14. Other headache, cranial neuralgia, central or primary facial pain

Headache Attributed to Nonvascular, Noninfectious Intracranial Disorders

Intracranial lesions that occupy space, often referred to as *mass lesions,* produce head pain by traction on or compression of pain-sensitive structures. The nature, location, and temporal profile of headache produced by an intracranial mass depend on main [actor-., IIIJ-.KIIIH; tinlocation of the lesion, its rate of growth, its effect on the cerebrospinal fluid (CSF) pathways, and any associated cerebral edema. The intracranial mass lesion may be neoplastic, inflammatory, or cystic. Each type can result in either localized or generalized head pain. The type of headache is characteristic ᵬ(raised iiitracraniaI pressure (sec later) but is not diagnostic of a particular underlying disease.

Intracranial and nil r.iparcrk liyni,;' hematomas ate akn mass lesions and are responsible for traction headaches, but they are classified under vascular disorders causing headache.

Tumors

Approximately 50% of patients with brain rumors report headaches; in one third to one half of these patients headache is considered the primary complaint. The headache can be generalized, but in approximately one third of patients, it overlies the tumor and is referred to the scalp near the lesion. Rapidly growing tumors are more likely to produce headache than are indolent lesions, but slowly enlarging lesions can eventually produce pain by compromising the ventricular system or exerting direct pressure on a pain-sensitive structure, such as the trigeminal nerve. When the CSF circulation is partially obstructed, headache often becomes generalized and worse in the occipitonuchal area. This type of headache, which is a manifestation of raised intracranial pressure, is often worse on awakening, is aggravated by coughing and straining, and is often associated with nausea and vomiting. In children particularly, the vomiting may be precipitate and without nausea. This can lead to projectile vomiting because it occurs without warning. Projectile vomiting rarely occurs in adults.

Large parenchymal tumors and small tumors that interfere with the CSF pathways can be associated with periodic increases in inracranial pressure. Monitoring reveals periods of increased pressure (called the plateau waves of Lundberg), the beginning of which may be associated with increasing severity of headache and the peak of which may

be associated with vomiting or other ictal events, such as decreased consciousness or a change in respiration.

Supratentorial masses generally produce frontal or temporal head pain because of the trigeminal nerve supply to the anterior and middle cranial fossae. The superior surface of the tentorium cerebelli is supplied by the meningeal branches of the first division of the trigeminal cranial nerve, so an occipital lesion can cause pain referred to the fronto-orbital tegion. Mass lesions of the posterior fossa generally cause occipitonuchal pain because the meningeal nerve supply is largely through the upper cervical nerves, which also supply the occipital and cervical dermatomes. Some sensory innervation of the posterior fossa is also carried via cranial nerves VII, IX, and X, and therefore pain referral can be more widespread. Posterior fossa tumors result in headache earlier than their supratentorial counterparts because the greater likelihood of compromise of the ventricular system leads to rapidly developing hydrocephalus and raised intracranial pressure (Forsyth and Posner 1993).

Pituitary tumors and tumors around the optic chiasm commonly cause a frontotcmporal headache, but they can also cause referred pain near the vertex. However, patients with tumors of the sellar and parasellar regions do not often present with headache as the initial symptom because the visual and endocrine symptoms are typically noted first (Edmeads 1997).

Tumors growing in the ventricular system are rare, but they can present dramatically. The classic presentation of a colloid cyst of the third ventricle is a sudden headache of great severity, rapidly accompanied by nausea and vomiting and possibly by loss of consciousness. Intraventricular meningiomas, choroid plexus papillomas, and other intraventricular tumors can present in this manner if they suddenly obstruct the ventricular outflow pathways. A positional change may precipitate such an event; similarly, adoption of a different posture may rapidly relieve the headache and other symptoms. Colloid cysts of the third ventricle generally lead to slowly enlarging hydrocephalus that may result in a generalized, rather constant headache, superimposed on which may be episodes of catastrophic increases in headache. Obstruction of the egress of CSE from the ventricular system rapidly leads to increased intracranial pressure, which can exceed the capillary perfusion pressure of the brain and lead to loss of consciousness due to cerebral ischemia. Headaches that have a rapid onset and are associated with loss of consciousness, amaurosis, or vomiting are serious and should lead the examinet to consider conditions such as subarachnoid hemorrhage, brain tumor, or other mass lesions.

Headache, especially in the occipital region, that is precipitated by sudden Valsalva maneuvers (e.g., coughing, sneezing, ot lifting) or exertion should be taken seriously, A posterior fossa lesion, such as a cerebellar tumor or Chiari malformation, can lead to this clinical picture. In most patients with cough or exertional headache, however, no serious lesion is found.

Infiltrating tumors, such as gliomas, can reach considerable size without causing pain because they may not deform or stretch the pain-sensitive vessels and nerves. Such lesions are more likely to present as focal neurological deficits or with seizures than with headache. Sudden worsening of the neurological state due to hemorrhage into the tumor mass may present with sudden headache. The headache may initially appear in the part of the skull overlying the tumor and then become generalized if intracranial pressure rises. Infarction of a tumor can cause edema and swelling that result in a similar dramatic onset of head pain and neurological deficit.

Tumors that are intracranial but extraparenchymal, such as meningioma, acoustic neuroma, pinealoma, and craniopharyngioma, can all produce headaches, but, as with the parenchymal lesions, there are no specific headache patterns. The headaches can be near the lesion, referred to a more distant site in the cranium, or generalized when intracranial pressure increases. Meningiomas and meningeal sarcomas can invade the skull and can even cause a mass externally by direct tumor spread or by overlying hyperostosis. Such tumors arc often associated with localized head pain. Meningeal carcinomatosis (carcinomatous meningitis) produces a headache in most subjects, but the associated cranial nerve involvement and other neurological symptoms are generally more striking.

The headache associated with other intracranial mass lesions, such as cerebral abscess and intracranial granuloma, is no more specific than that due to a cerebral neoplasm.

In summary, the following features should serve as warnings that a patient's headaches may not be of benign origin and raise the possibility of an intracranial mass lesion (Purdy 2001):

1. Subacute and progressive in nature of headache
2. New onset in adult life (>40 years of age)
3. Change in headache pattern, such as incteascd intensity of pain, increased incidence of attacks, development of new features, or decreased response to treatment
4. Association with any of the following: nausea or vomiting not explained by migraine or systemic illness; nocturnal occurrence or morning awakening; precipitation or worsening by changes in posture or Valsalva maneuver; confusion, seizures, or weakness
5. Abnormalities on neurological examination

Arachnoid Cysts

Cystic spaces bounded by arachnoid membranes found with computed tomography (CT) or magnetic resonance imaging MRI scans IIUMIH-tin investigation ol headaches are rarely responsible for head pain. Uncommonly, an arachnoid cyst has a one-way valvelike structure in its wall, so that arterially induced pulsations of the CSF gradually pressurize

the cyst and cause it to enlarge. Compression of cranial nerves, such as the trigeminal nerve, or distortion of the midline structures causes headaches that may be either generalized or localized. Serial CT or MRI scans reveal the cyst to be increasing in size, and this finding should lead to operative intervention. Enlargement of normal subarachnoid spaces such as the cisterna magna and cisterna ambiens is not a cause for headache and should not lead to shunting or other surgical approaches.

Abnormalities of Cerebrospinal Fluid Circulation

Whether raised intracranial pressure, in the absence of a shift of intracranial structures, results in headache is uncertain. The rate at which the intracranial pressure is increased and the duration of the increase are probably factors that determine whether pain is produced.

Obstruction of the Cerebrospinal ¥luid Pathways

Lesions that prevent free egress of CSF from the ventricular system result in obstructive hydrocephalus. If this occurs before closure of the cranial sutures, enlargement of the skull occurs, usually without producing headache. Ventricular obstruction after closure of the sutures leads to raised intracranial pressure and often to headache. The pain is often worse on awakening, occipital in distribution, and associated with neck stiffness. Vomiting, blurred vision, and transient obscuration of vision due to papilledema may follow as well as failing vision due to optic atrophy.

Rapidly developing obstruction due to a posterior fossa mass lesion or a ball-valve tumor, such as a third ventricular colloid cyst, can lead to a rapidly increasing headache followed by vomiting, impaired consciousness, and iniTi'.isinj.'. nourological deterioration. S'.nwly developing hydrocephalus may result in massively dilated ventricles and may be associated with little or no headache.

Congenital obstruction of the foramina of l.usehk and Magendie—the Dandy-Walker syndrome—can lead to ballooning of the fourth ventricle and deformity of the cerebellum, Minor degrees of this malformation can remain asymptomatic until later in life and then present with obstructive hydrocephalus and headache. Similarly, the Chiari malformation in its various forms can obstruct the free circulation of CSF and lead to hydrocephalus and headache (Taylor and Larkins 2002). This malformation can result in an occipital-suboecipiral headache that is worsened or even initiated by Valsalva's maneuver during lifting, straining, or coughing. Thus, the Chiari malformation is one ol the causes of an exertional 01 Valsalva-induced headache.

In communicating hydrocephalus, there is free communication between the ventricular system and the subarachnoid space bill Mime impairment of CSI' circulation or absorption. Obstruction in the basal cisterns or at the arachnoid granulations may follow subarachnoid hemorrhage and meningitis. Venous sinus occlusion can impair absorption of C5F. Headache may be a prominent symptom of both obstructive and communicating hydrocephalus, except in the case of normal pressure hydrocephalus, which is generally painless (see Chapter 65).

Low Cerebrospinal Fluid Pressure Headache

The headache of lowered CSF pressure characteristically develops with the patient in the upright position and is rapidly relieved by recumbency. It most commonly occurs after a lumbar puncture, especially when this is performed as part of myelography. Loss of CSF volume, due in part to the removal of some CSF for diagnostic purposes and in part to later leakage through the hole in the arachnoid and dural layers, results in a traction headache. The brain normally floats in the intracranial CSF, loss of which allows the brain to sink and thereby exert traction on structures such as bridging veins and sensory nerves. Recumbency removes the effect of gravity, and the traction headache is relieved. The headache that occurs after a spinal tap usually resolves in a few days if the patient remains in bed with good hydration. Occasionally, the syndrome persists for days, weeks, or even months. Relict i.in usually be obtained by the application of a blood patch, in which 10-20 mL of the patient's own blood is injected into the epidural space close to the site of the original spinal tap. This technique prevents further leakage of CSF by exerting increased pressure in the epidural space and by coagulation of the blood, thereby relieving the headache in a few hours. The injection of blood is associated with a small risk of cauda equina compression or subarachnoid hemorrhage, but this is unlikely if the blood volume is small and the blood is injected gently.

An identical syndrome of headache due to low CSF prcssute can occur when there is a leak of fluid through the cribriform plate, through the petrous bones, or through any basal skull defect. CSF rhinorrhea and especially CSF otorrhea may not be obvious to the patient, whose complaint may be postoperative or post-traumatic headache. Leakage of CSF from the skull can occur spontaneously when inttacranial pressure is raised or a tumor erodes through the base of the skull. This occurs most often around the cribriform plate region, where the bone is especially thin. The CSF leak can be identified by radioisotope cisternography. Leakage of CSF through the nasal sinuses can be detected by placing numbered cotton pledgets in the nose next to the various ostia of the sinuses. Contamination of the pledgets by radioactivity enables the sinus, through which the fluid is leaking, to be identified. CSF otorrhea is not easy to identify if the fluid is draining down the eustachian tube when the eardrum is intact. Scanning with a gamma camera after instillation of a radioactive tracer by lumbar puncture may allow the leak

to be identified. Treatment is usually surgical repair of the bony and meningeal defect,

A similar low CSF pressure headache can occur when a tear develops in the spinal theca. This is usually in the midthoracic region and may result from lifting or coughing or, at times, spontaneously. It can also occur with a crush injury to the chest or abdomen and in patients with overdrawing CSF shunts. When it occurs without a significant history of trauma, it can be overlooked as a cause of daily headache. The history of a headache rapidly responding to recumbency should lead one to suspect the condition. However, in some patients whose headaches are longstanding, a persistent headache may be noted and the postural feature of the headache may become less prominent, Nausea or emesis, neck pain, dizziness, horizontal diplopia, changes in hearing, photophobia, upper limb paresthesias, vision blurring, and dysgeusia may also occur, particularly when the headache first develops.

The diagnosis first requires a clinical index of suspicion followed by an MRI scan with gadolinium. MRI has become an invaluable diagnostic tool in this syndrome, with the cardinal features being diffuse pachymeningeal thickening with gadolinium enhancement, subdural collections of fluid, and evidence of brain descent (Figures 75,1 through 75.3). This evidence includes cerebellar tonsillar descent (resembling a Chiari type I malformation); reduction in size or effaccment of the prcpontine, perichiasmatic, and subarachnoid cisterns; inferior displacement of the optic chiasm; and descent of the iter (the opening of the aqueduct of Sylvius as seen on a midsagittal MRI scan).

If the clinical and MRI findings are typical, determination of the CSF opening pressure may not be necessary. Measurement or the opening pressure is warranted in patients with normal MRI scans. However, in only 50% of patients is the CSF pressure less than 40 mm H_20. Because the opening pressure may be normal, the term *CSF volume depletion* identifies best the core of the problem in this disorder (Mokri 2000). These patients may have a variable pleocytosis with up to 40 or more mononuclear cells per ram[1] and a mild-to-modest increase in CSF protein (Mokri 1999).

In patients with the typical clinical and radiographic features of low CSF pressure headache, management may be conservative with bed rest and hydration for 1-2 weeks. If this is either not practical or not effective, options include empirical treatment with a blood patch or further studies to identify the site of the CSF leak. In patients with spontaneous leaks, the leak is often at the level of the thoracic spine or the cervicothoracic junction. Myelography with a CT scan of the spine is more sensitive than radioisotope cisternography or an MRI scan of the spine, but the latter procedures may serve as guides for obtaining multiple CT images at the appropriate levels. Most leaks are stopped with either conservative therapy or blood patches. Although an epidural blood patch is effective in the majority of patients, most requite more than one blood patch (Mokri 1999), and some require as many as four to six blood patches (Mokri 2001). For resistant leaks, surgical intervention with repair of the dural tear may be necessary. Even after a protracted duration, surgical repair of the causative dural tear can be quite effective (Schievink et al. 1998),

Idiopathic Intracranial Hypertension

Headache, transient visual obscuration, pulsatile tinnitus, and diplopia are the most common presenting symptoms of idiopathic intracranial hypertension (pseudotumor cerebri). The headache is rather nonspecific but tends to be worse on awakening and to be aggravated by activity. The blurring and obscuring of vision arc direct results of raised intracranial pressure leading to papilledema. Once it has been determined by MRI scans that there is no intracranial mass, obstruction of the ventricular system, or thrombosis of a dural venous sinus, the high CSF pressure can be confirmed by lumbar puncture manometry. Removal of CSF to achieve a normal closing pressure relieves the headache and temporarily prevents visual obscuration. Long-term management of idiopathic intracranial hypertension is discussed in Chapter 65.

Transient Syndrome of Headache with Neurological Deficits and Cerebrospinal Fluid Lymphocytosis

There is a transient syndrome characterized by recurrent episodes of headache accompanied by reversible neurological deficits and CSF pleocytosis, originally termed *migrainous syndrome with CSF pleocytosis* (Bartlcson ct al, 1981). Several reports of this syndrome used various terms, including headache with neurological deficits and CSF lymphocytosis (Berg and Williams 1995) and pseudomigraine with temporary neurological symptoms and lymphocytic pleocytosis (Gomez-Aranda et al. 1997). This self-limited syndrome consists of one to several episodes of variable neurological deficits accompanied by moderatc-to-severe headache and sometimes fever. Each episode lasts hours, with total duration of the syndrome being from 1-70 days. CSF abnormalities have included a lymphocytic pleocytosis varying from l() to more tha:i ,'UQ CL-lls/inm \ elevation of CSF protein, and in some patients, elevated opening pressure, MRI and CT scans are invariably normal, but an electroencephalogram often shows focal or diffuse slowing. Results of microbiological studies have been negative. The etiology of the syndrome is unclear, although it has been speculated to be due to an immune response to a viral infection. No treatment has been shown to alter the self-limited course of this disorder. In contrast to this syndrome, Mollaret's meningitis is characterized by recurrent episodes of aseptic meningitis with fever (see Chapters 59B and 79). The episodes are separated by months to years and are typically not accompanied by focal neurological symptoms. Classically, the CSF shows a

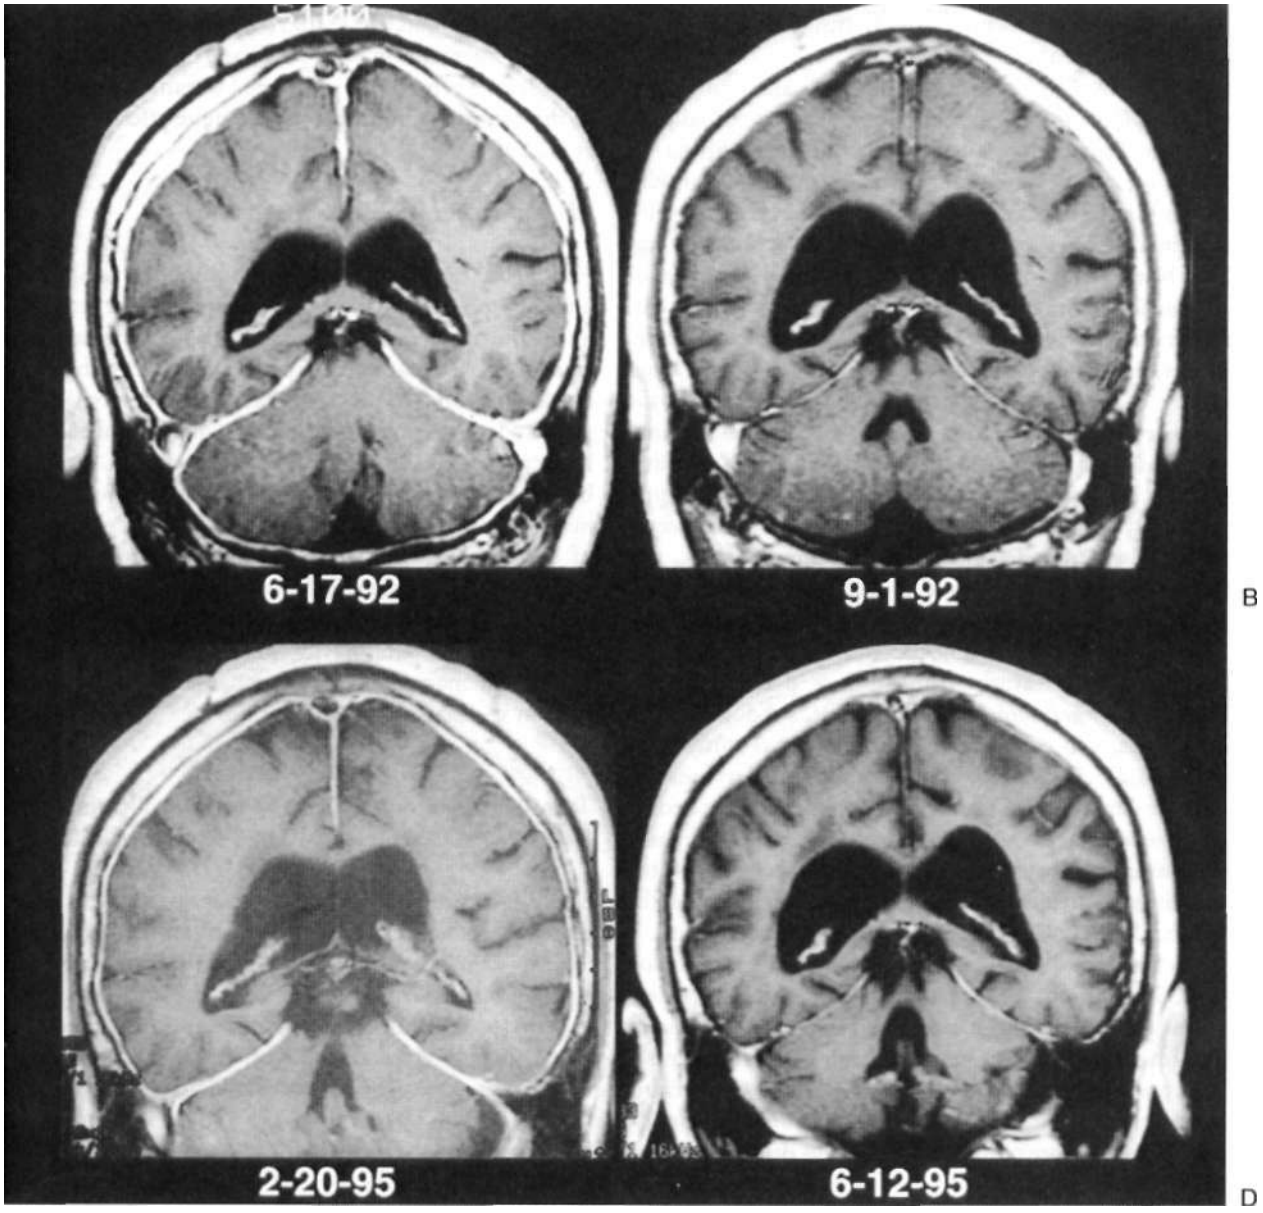

FIGURE 75.1 Coronal Tl-weighted magnetic resonance images with gadolinium in a patient with an overdrawing cerebrospinal fluid shunt and low-pressure headache demonstrate diffuse pachymeningeal thickening and enhancement (A) with resolution after shunt revision and resolution of headaches (B). Patient developed recurrent symptoms and imaging abnormalities after shunt revision (C) followed by resolution after another shunt revision (D). (Reprinted with permission from Mokri, B., Picpgras, D. G., *&C* Miller, G. M. 1997, "Syndrome of orthostatic headaches and diffuse pachvmeningeal gadolinium enhancement," *Maya Clin Proc,* vol. 72, pp. 400-413.)

pleocytosis and in the first 24 hours, neutrophils predominate, and large "endothelial cells" are present; these have been shown to represent monocytes.

Headache Attributed to Infection

Inflammation of any pain-sensitive structures in the cranial caviry can produce headache. Meningitis and meningoencephalitis both have headache as a major symptom. The eharactetistics of the head pain depend on whether the infection is acute or chronic. Acute meningitis produces a severe headache with neck stiffness and other signs of meningism, including photophobia and irritability. Pain is often tetro-orhital and worsened by moving the eyes. Chronic meningitis due to fungal or tuberculous infection can also lead to headache that may be severe and unrelenting. The headache of intracranial infection is nonspecific but

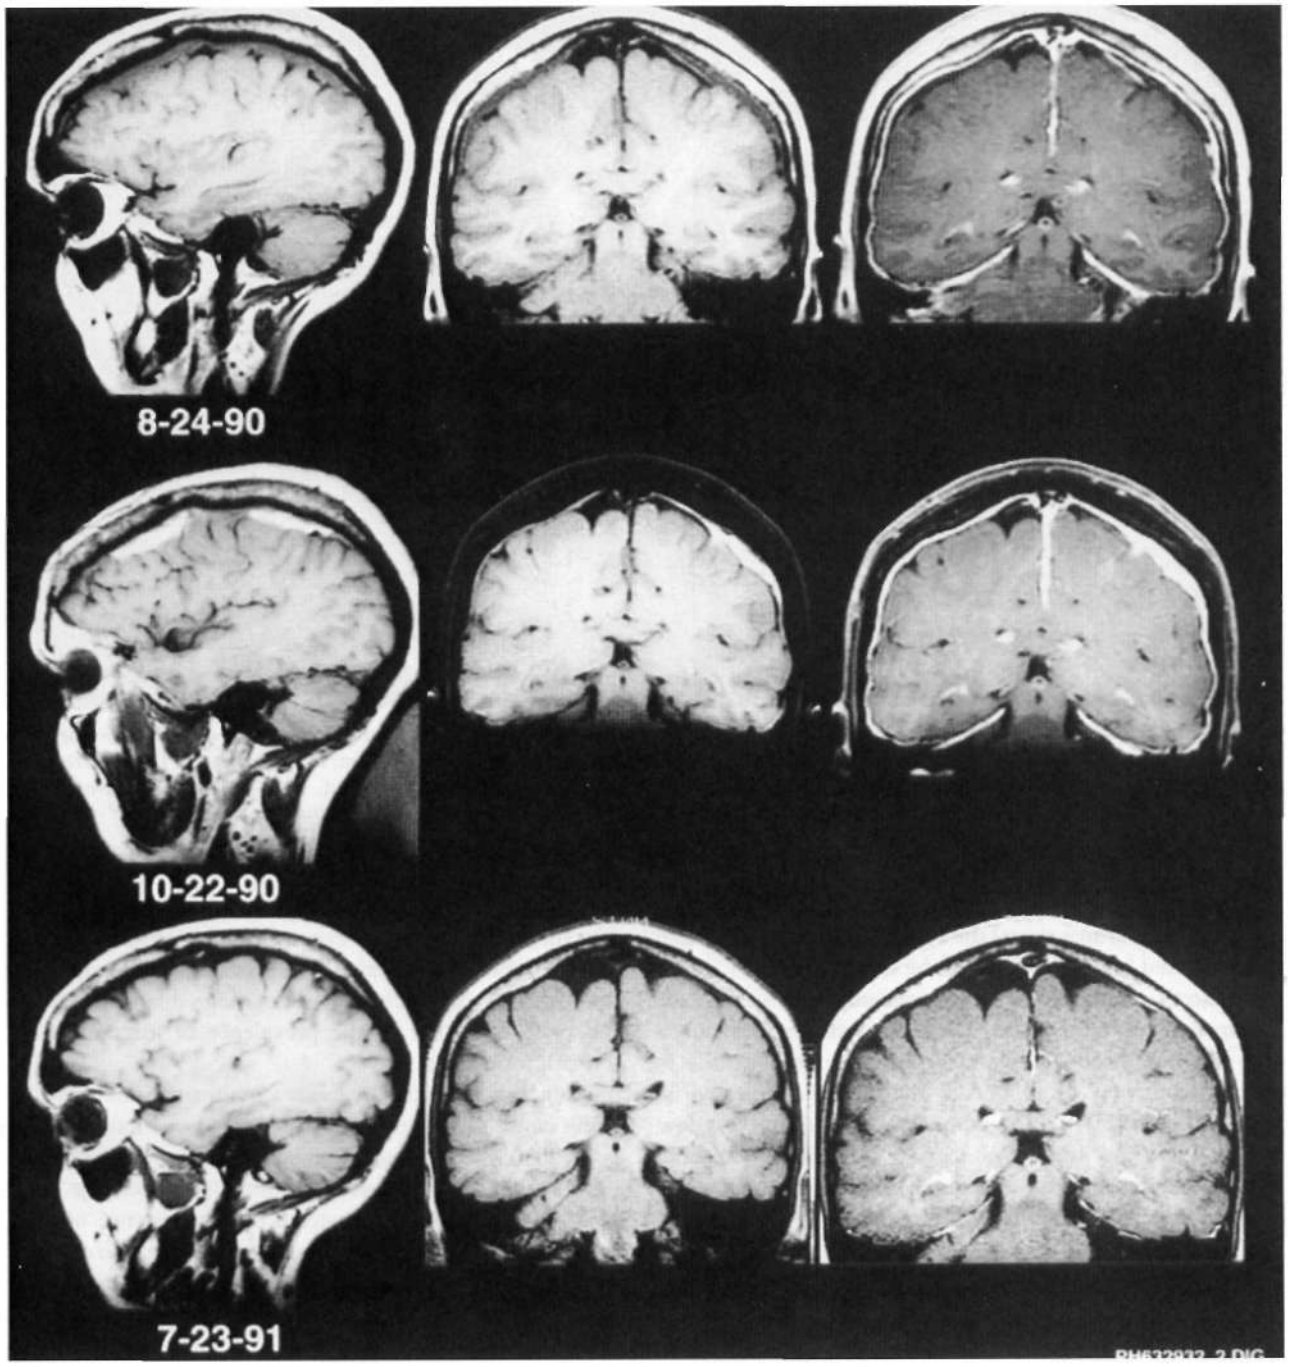

FIGURE 75.2 Sagittal and coronal Tl-weighted magnetic resonance images with gadolinium of a patient with spontaneous low cerebrospinal fluid (CSF)-p res sure headaches demonstrate subdural fluid collections and p achy meningeal enhancement *{top row)* with loculation and progression of subdural fluid collections *(middle row). Bottom row* demonstrates resolution of the fluid collections and meningeal enhancement after correction of the CSF leak and headache resolution. (Reprinted with permission from Mokri, B., Piepgras, D. G., & Miller, G. M. 1997, "Syndrome of orthostatic headaches and diffuse pachymeningeal gadolinium enhancement," *Mayo Clin Proc,* vol. 72, pp. 400-413.)

tinist be considered in the differential diagnosis, especially in patients with a compromised immune system. The diagnosis can be confirmed only by examination of the CSF. The chronic granulomatous meningitis of sarcoid may require biopsy of the basal meninges to confirm the diagnosis. Meningitis is discussed further in Chapter *59.*

Sinusitis, mastoiditis, epidural or intraparcnchymal abscess formation, and osteomyelitis of the skull can all cause focal and generalized headache. The diagnosis is usually suspected from the associated symptoms and signs. After craniotomy, increasing pain and swelling in the operative site may be due to osteomyelitis of the bone flap. Plain

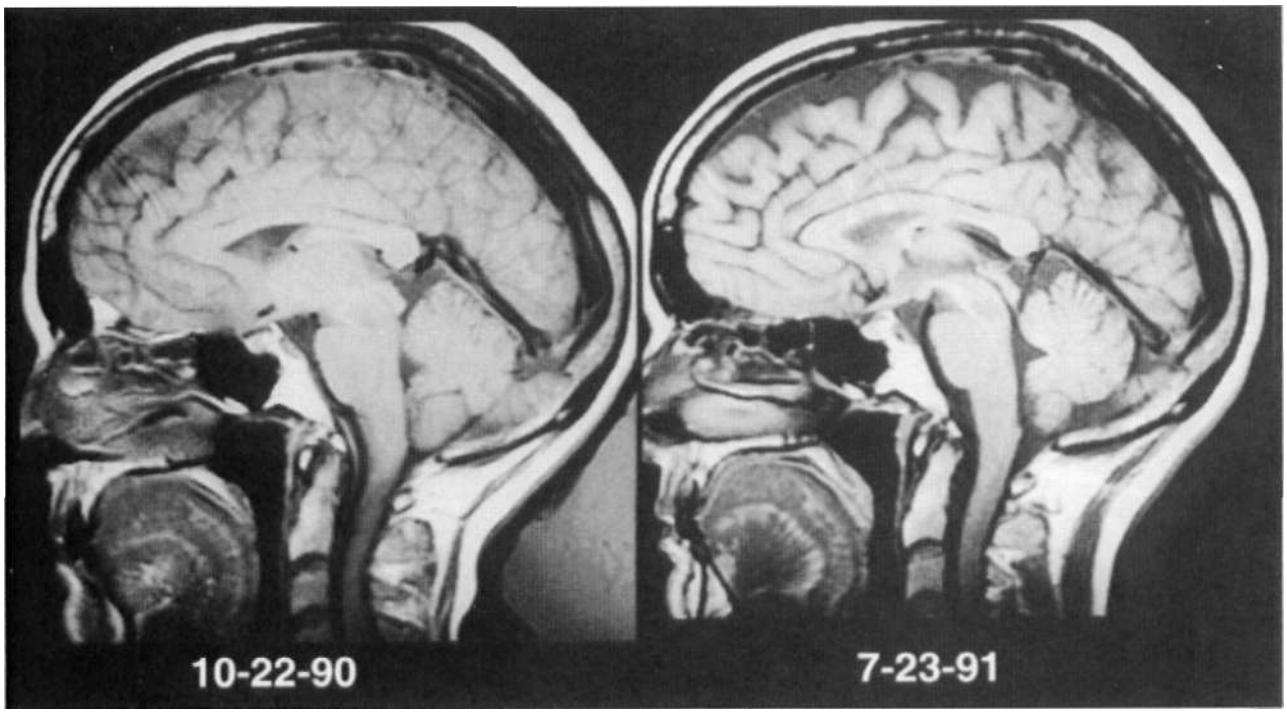

FIGURE 75.3 Sagittal Tl-weighted magnetic resonance images (MRIs) demonstrate cerebellar tonsillar descent and crowding of the posterior fossa in a patient witli spontaneous low-pressure headaches. After symptomatic resolution, the MR] scan of the posterior fossa returns to normal. (Reprinted with permission from Mokri, B., Piepgras, D. G., & Miller, G. M. 1997, "Syndrome of orrhosniric headaches and diffuse pachymeningeal gadolinium enhancement," *Mayo Clin Proc,* vol. 72, pp. 400-413.)

skull roentgenograms reveal the typical mottled appearance of the infected bone. Removal of the flap is necessary.

Mollaret's meningitis is tate, recurrent, and sterile (see Chapters 59B and 79). The CSF cellular response includes large epithelioid cells i Molhret's *a* lis). The pathogenesis is unknown but may be related to the herpes simplex virus (Jensenius et al. 1998). The condition may recur every few days or every few weeks for months or years. Headache, signs of meningism, and low-grade fever accompany each attack. Treatment is mainly symptomatic.

Headache Attributed to Cranial or Cervical Vascular Disorders

Aneurysms and Arteriovenous Malformations and Thunderclap Headache

Intracranial aneurysms are rarely responsible for headache unless the) rupture. K apid enlargement <i .11: aneurysm may produce local pain by pressure on a cranial nerve, especially the oculomotor nerve, or on other pain-sensitive structures. This is most common with aneurysms of the internal carotid and posterior communicating arteries. Enlargement of an aneurysm may occur shortly before rupture, and the local pain is therefore an important clinical sign. Cerebral aneurysms are not a cause of recurrent migraine-like headaches, even when the headache attacks are confined to one side. The prevalence of migraine in patients with subarachnoid hemorrhage due to a ruptured aneurysm is similar to the prevalence of migraine in the general population.

Parenchymal arteriovenous malformations (AVMs) rarely cause pain before rupture. Very large lesions can be associated with ipsilateral or bilateral throbbing cephalalgia, but they rarely cause a migraine-like syndrome. Large AVMs can usually be suspected by the presence of a cranial bruit or of the classic triad of migraine, seizures, and focal neurological deficits. The prevalence of headache in patients harboring AVMs is probably no higher than that in the general population.

The myth has developed that headaches of a migrainous type, if consistently on one side of the head, could be due to an aneurysm or an AVM. In the past, this belief led to many unnecessary arteriograms. The worry expressed by patients and physicians that a recurrent headache might be due to an aneurysm or AVM is now usually easily resolved by obtaining a cranial MRl scan or m.igneric resonance angiogram (MRA). Any aneurysm or AVM responsible tor a recurrent or persistent headache has a very high probability of being seen. Roth aneurysms and AVMs can bleed in a way that produces a less than catastrophic subarachnoid hemorrhage. These small warning leaks can result in one or more sentinel

headaches. 1'acli may be relatively mild Mid short-lived. They usually have a sudden, but not very dramatic, onset. Identification of the sentinel headache is important but is vety difficult.

Patients who do not usually have headaches should be examined whenever they report new onset of headaches or even a single episode if it was described as "the worst **headache** I've ever had" or if it was associated with neck stiffness or pain, transient neurological symptoms (e.g., extraocular nerve palsy), or fever. Patients in whom there is any suspicion of a sentinel bleeding episode or who describe a recent thunderclap headache should be examined with CT scanning to detect blood in the subarachnoid cisterns. If the scan is normal, the continuing suspicion of a warning bleeding episode should lead to an examination of the CSF. If the CSF is blood-stained or xanthochromic or if, despite the absence of positive findings on the lumbar puncture, there is still a suspicion of a sentinel hemorrhage, an MR A or cerebral angiogram may be advisable.

The term *thunderclap headache* describes a severe headache of instantaneous onset (within seconds)—abrupt and without warning like a "clap of thunder." A patient with a sudden, severe headache must be evaluated on an emergency basis for evidence of a subarachnoid hemorrhage as outlined above. Other conditions can present with thunderclap headache including cerebral venous sinus thrombosis, cervicocephalic arterial dissection, pituitary apoplexy, acute hypertensive crisis, and spontaneous intracranial hypotension (Dodick 2002). These entities are associated with significant neurological morbidity and may not be easily seen on the initial CT image, thus undctscoring the need for MRI in this group if results of the initial workup are negative,

The question as to whether an *unruptured* cerebral aneurysm can cause a thunderclap headache has been debated. The weight of evidence, based on several prospective studies of patients with normal neurological, CT, and CSF examinations, indicates that a symptomatic intracranial aneurysm will be rarely found in such patients. The issue of which patients need additional investigations in this setting depends on the clinical suspicion of an underlying disorder (Dodick 2002).

Several follow-up studies of patients with thunderclap headache and negative evaluations for subarachnoid hemorrhage and other underlying disorders have elucidated the often benign natural history of this peculiar headache disorder. Slivka and Philbrook (1995) reported four patients with thunderclap headache without subarachnoid hemorrhage, in three of whom angiography revealed diffuse segmental iir.iaccivlual .irieri.i! vasoconstriction. Resolution of the vasospasm was seen in the one patient in whom angiography was repeated. V/c have seen two similar patients, and through this collective experience, a characteristic profile has begun to emerge (Table 75.2).

Subarachnoid Hemorrhage

Rupture of an intracranial aneurysm or AVM results in a subarachnoid hemorrhage, with or without extension into the parenchyma of the brain. **The** headache of a subarachnoid hemorrhage is characteristically explosive in onset and of overwhelming intensity. Subjects who survive may relate that they thought they had been hit on the head. The headache rapidly generalizes and may quickly be accompanied by neck and back pain. Loss of consciousness may rapidly supervene, but many patients remain alert enough to complain of the excruciating headache. The patient is often vomiting, which aggtavates the head pain. Intraventricular blood, the distortion of the midline structures, and the heavy contamination of the basal cisterns by blood can each contribute to the rapid development of hydrocephalus, which worsens the headache.

Tabic 75.2: Diagnostic criteria for thunderclap headache

Idiopathic thunderclap headache
Very severe pain intensity
Hyperacute onset of pain (<30 sec)
Headache lasts 1 hour to 10 days (may last up to 4 wk)*
Headaches may recur over a 7-day period but do not recur regularly over subsequent weeks or month (may recur over subsequent months to years)*
Thunderclap headache associated with a normal cerebral vasculature or reversible segmental vasoconstriction
May be clinically iiulisiinguishahie from thunderclap head ache associated with intracranial disorder*
May occur spontaneously or be precipitated by Valsalva's maneuver, sexual activity, exercise, or exertion
Thunderclap headache with neurological signs or symptoms
Headache and angiographic features as described above
Neurological signs or symptoms transient or result in minimal residual deficits
Thunderclap headache associated with intracranial disorder
Associated conditions include subarachnoid hemorrhage (cerebral venous sinus thrombosis, pituitary apoplexy)*
May have associated neurological or systemic signs or symptoms, depending on underlying disorder

'"Modifications to diagnostic criteria.

Source; Adapted with permission from Dodick, D. w\. Brown, R. D., Britton, J. \V., & Huston, J, 1999, "Nonaneurysmal thunderclap headache with diffuse, multifocal, segmental, and reversible vasospasm," *Cephalalgia,* vol. 19, pp. 118-123.

The diagnosis is easily suspected and can he confirmed by an unenhanced CT scan that reveals blood in the subarachnoid cisterns or within the parenchyma. Early hydrocephalus may also be seen. When a CT scan unequivocally shows blood in the subarachnoid spaces, it is not necessary or advisable to perform a lumbar puncture because the resultant reduction of CSF pressure may cause herniation of the brain or may remotely induce-further bleeding from the aneurysm. Demonstration of subarachnoid hemorrhage generally indicates the need for cerebral angiography. The timing of this procedure and the subsequent mode of treatment are detailed in Chapter 57C.

Relief of the intense headache of subarachnoid hemorrhage generally requires parenteral administration of analgesics. The need to provide pain relief must be balanced against the need to interfere as little as possible with the level of consciousness, respiration, and physical signs, such as pupil size and reaction. Parenteral codeine is often used, but meperidine is also useful. Sedation with phenobarbital may also be required if the patient is restless because of pain. The headache that occurs after a subarachnoid hemorrhage may be persistent, lasting up to 7-10 days. Rarely, a chronic daily headache may persist for months to years.

The headache of subarachnoid hemorrhage is aggravated by movement and is associated with photophobia and phonophobia. Therefore, it is customary to nurse patients in a dark, quiet room and to disturb them as little as possible. Straining at stool, vomiting, and coughing should be minimized.

The hemorrhage and the headache that can result from a ruptured AVM have qualities and behavior that are essentially identical to those from a ruptured berry aneurysm of the circle of Willis.

Parenchymal Hemorrhage

Until the advent of CT scanning, it was widely believed that a stroke due to a cerebral hemorrhage was associated with severe headache and that an ischemic stroke was generally-painless. However, modern imaging techniques have shown that cerebral infarction is often painful and that cerebral hemorrhaae car v p..'" ;'ss. I best- caveats notwithstanding, a hemorrhage into the cerebral or cerebellar tissue is a potent source of headache of rapid onset and of increasing severity. The intra parenchymal mass causes a traction headache by deforming and shifting the pain-sensitive vascular and meningeal and neural structures. As the hematoma enlarges, it may obstruct the CSF circulation and lead to increases in intracranial pressure. Initially, the pain of a cerebral hemorrhage is often ipsilateral, but it may generalize if hydrocephalus and raised intracranial pressure occur. Rupture of the hematoma into the subarachnoid space or leakage of the blood into the basal cisterns through the CSF pathways causes the headache to intensify and be associated with neck stiffness and other signs of meningeal irritation,

Cerebral and cerebellar hemorrhage can be due to hypertension of any cause; to a bleeding diathesis, including the medical administration of anticoagulants; to an arteritis and amyloid angiopathy; or to an aneurysm or AVM, as discussed earlier (see Chapter 57B), Cerebral infarcts, primary and secondary brain tumors, and areas of cerebritis, such as those that occur in herpes simplex encephalitis, can each be complicated by hemorrhage into the lesion. Headache may signal the presence of the lesion or a worsening of the clinical condition. Almost without exception, the headache of intraparenchymal hemorrhage is ol acute o: subacute ousel and does nol indicate the exacl nature of the underlying disease. Headache associated with focal or generalized cerebral or cerebellar signs demands examination with an unenhanced CT scan.

Cerebellar hemorrhages, which account for about 10% of occurrences of intraparenchymal bleeding, can result in a catastrophic clinical picture. An enlarging hematoma in the cerebellum rapidly compresses vital brainstem structures and obstructs the outflow of CSF from the ventricular system. This leads to occipital headache, which is rapidly followed by vomiting; impaired consciousness; and various combinations of brainstem, cerebellar, and cranial nerve dysfunction. Cerebellar hemorrhage is a neurological and neurosurgical emergency. A CT scan should be obtained as soon as possible. Fvacuation of the hematoma with or without ventricular drainage may be the only chance to save the patient's life.

Treatment options for intracerebral hematomas are discussed in detail in Chapter 57B.

Cerebral Ischemia

Cerebral infarction, whether embolic or thrombotic, may cause head pain (Arboix er al. 1994). The location of the pain is a poor predictor of the vascular territory involved. Some studies indicate that cortical infarction is more likely to be associated with headache than deep cerebral hemisphere infarctions. It may be either steady or throbbing and is not as explosive or as severe as the headache of subarachnoid hemorrhage. The infarct responsible for the pain may be of a moderate size or very extensive. Even small ischemic events that resolve in 24 hours, by definition transient ischemic attacks (TIAs), may be associated with transient head pain in up to 40% of patients; however, the headaches arc rarely prominent. Some reports indicate that carotid distribution ischemia most commonly leads to frontotemporal head pain, whereas vertebrobasilar ischemia tends to lead to occipital headache.

The development of a new or different headache may be noted in about 10% of patients in the weeks and months before onset of ischemic stroke.

If a large cerebral or cerebellar infarct produces a significant mass effect as a result of edema, headache may

worsen. Obstruction of the ventricular system results in increasing hydrocephalus and further aggravation of the pain. The pain may be pulsatile and may be worsened by straining or by the head-low position. As the infarct decreases in size and the phase of hyperemia subsides, headache generally eases. Evolution of a bland infarct into a hemorrhagic infarct may be associated with worsening of headache.

Hashing lights, field defects, and other visual disturbances may represent symptoms ot cerebrovascular disease. Similarly, migraine with aura can produce many different visual symptoms before the headache develops. Hence it is not always possible to differentiate the visual disturbances of migraine from those of more serious cerebrovascular disease. The visual aura of migraine is usually an initially irritative phenomenon producing scintillating, often zigzag, visual hallucinations that can be seen with the eyes open or closed. This is described is .1 posit LM- so num.1. bavin.! tin-effect of spontaneously producing the sensation of light or color. Visual disturbances due to serious visual pathway ischemia or retinal ischemia usually results in vision loss or a negative scotoma, which cannot be recognized 111 the dark or with the eyes closed. Like many rules in medicine, this one is not absolute. An embolus to a retinal artery can result in showers of bright flashes, and calcarine ischemia can occasionally produce scintillating scotoma that resemble those of migraine. The migrainous aura tends to inarch across the visual field over the course of a few minutes and is generally followed by the headache after a latent interval, The headache of cerebrovascular insufficiency or occlusion has a more variable relationship to the visual disturbances.

Carotid and Vertebral Artery Occlusion and Dissection

Occlusion of the cervical portion of the carotid artery can result in headache in several ways. A consequent cerebral infarct may increase the intracranial pressure. Ipsilatcral headache may be due to vasodilatation of collateral vessels in and around the orbit. Headache due to carotid occlusion may be associated with a pattial ipsilatcral Horner's syndrome. The sympathetic hypofunction may be due to interference with the sympathetic fibers around the internal carotid artery as they ascend from the superior cervical ganglion to the intracranial structures. The combination of headache, ipsilatcral Horner's syndrome, and contralateral hcmiparesis is generally due to carotid occlusion.

Cervicocephalic arterial dissections result from penetration of the circulating blood through an intimal tear into the wall of an artery, usually penetrating the media, A variety of results may occur with dissection, including formation of an intramural hematoma that pushes the lumen to one side, resulting in an elongated narrowing of die vessel lumen. Other results arc compression of the lumen to cause an occlusion of the vessel; dissection of the intramural hematoma distally into the true lumen, with creation of two parallel channels; and expansion of the intramural hematoma toward the adventitia, resulting in an aneurysmal dilatation. The condition can result from intrinsic factors that predispose the aneurysm to dissection, including fibromuscular dysplasia, cystic medial necrosis, and association with Marfan's syndrome and Ehlers-Danlos syndrome. Extrinsic factors, such as trivial trauma, may play a pathogenic role when superimposed on structurally abnormal arteries. Severe head and neck trauma may occasionally be the proximate cause of dissection.

In most patients, the initial manifestation of internal carotid dissection is pain {headache, facial pain, or neck pain), which is typically ipsilatcral to the dissection; in a minority of patients, the pain may have a bilateral distribution. Cerebral or retinal ischemic symptoms are the initial manifestations in a lower percentage of patients. 1 lie , iMil 11:;HI el 1-real syndromes with which patients who have carotid dissection present include (I) hemicranial pain plus an ipsilatcral oculosymparbctic palsy, (2) hemicranial pain and delayed focal cerebral ischemic symptoms, or (3) lower cranial nerve palsies, usually with ipsilatcral headache or facial pain.

The most common symptom of vertebral dissection is headache and neck pain. The syndrome seen most often consists of headache, with or without neck pain, followed after a delay by focal CNS ischemic symptoms.

MRI or MRA usually confirms the diagnosis. At the level of involvement, the lumen of the artery appears as a dark circle of flow void of smaller caliber than the original vessel, and the intracranial clot appears as a hyperiutensc and bright crescent or circle (in both T1- and T2-weightcd images) surtounding the flow void (Figure 75.4). Catheter angiography may often be avoided (Mokri 2002).

I he pain .ISM:, ared with ccrvieoccphalk di.ssreiions is ol variable duration and may require treatment with potent analgesics. Patients are usually treated with either anti-platelet agents or, if evidence of distal embolization has occurred, anticoagulation.

Giant Cell Arteritis

tiiant cell arteritis is a vasculitis of elderly persons that has gone by many other names, including temporal arteritis, cranial arteritis, granulomatous arteritis, polymyalgia artcritica, and Horton's syndrome. It is one of the most ominous causes of headache in elderly persons. When unrecognized and untreated, it often leads to permanent blindness. The single most common reason patients with giant cell arteritis are seen by neurologists is headache of an unknown cause. *•

Clinical Symptoms. The clinical manifestations of giant cell arteritis result from inflammation of medium and large arteries. Table 75.3 summarizes clinical symptoms in 166 patients examined at the Mayo Clinic between

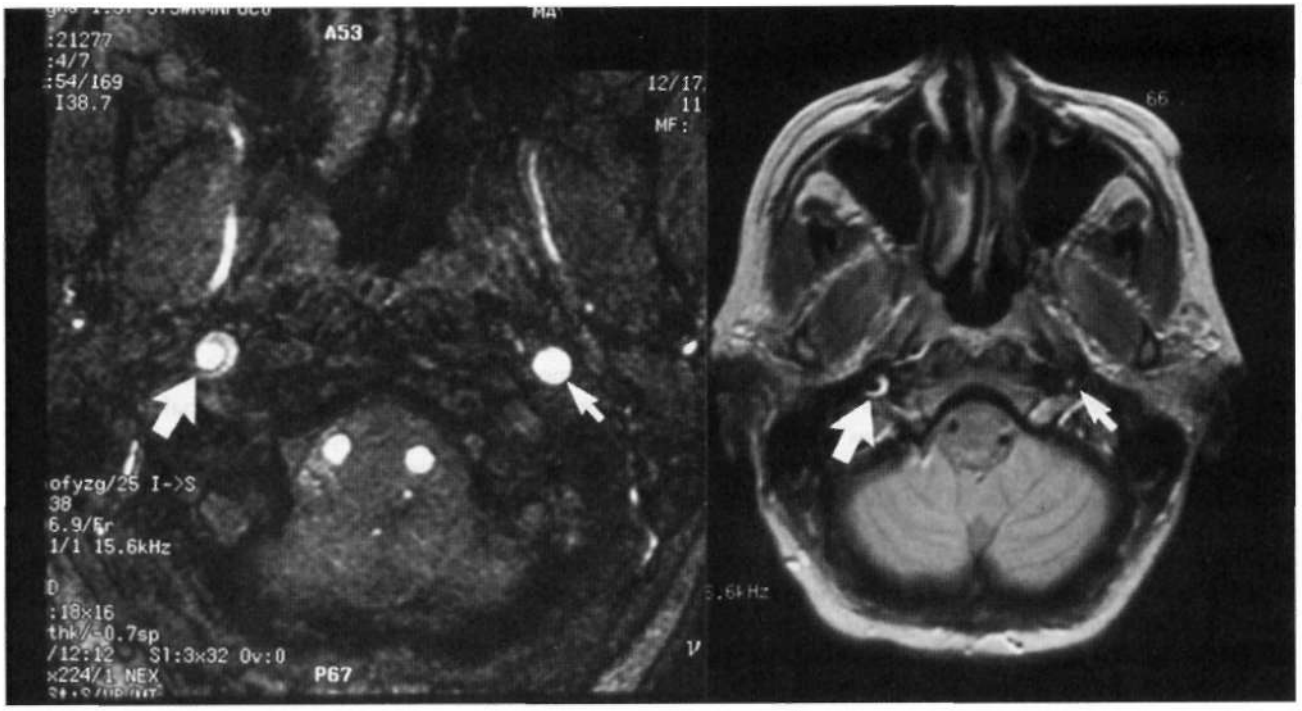

FIGURE 75,4 Magnetic resonance images of a patient with right internal carotid artery dissection. The *large arrow* in each figure points to the right internal carotid artery, which lias ,i smaller flow void than that of the left internal carotid artery *(small arrows),* reflecting the narrowed lumen of the vessel. The region of the flow void is surrounded by a hypcrintense crescent representing the intramural hematoma.

1981 and 1983. Headache was the most common symptom, experienced by 72% of patients at some time, and was the initial symptom in 33%. The headache is most often throbbing, and many patients report scalp tenderness on combing their hair. Headache, although often generalized, is associated with striking focal tenderness of the affected superficial temporal or, less often, occipital artery. One third of patients with headache may have no objective sign of superficial temporal artery inflammation.

More than one half of patients with giant cell arteritis experience polymyalgia rheumatica, and it is the initial symptom in one fourth of patients. Polymyalgia rheumatica consists of aching in proximal and axial joints, proximal myalgias, and often significant morning stiffness. Fatigue, malaise, and a general loss of energy occur in 56% of patients and are the initial symptoms in 20%.

Jaw claudication occurs commonly and is the initial symptom in 4% of patients. Tongue claudication occurs rarely. A nonproductive cough or a sore throat can be present.

One of the most ominous symptoms to occur in giant cell arteritis is amaurosis fugax because if it is untreated, 50% of affected patients subsequently become partially or totally blind. Ten percent of the patients in the Mayo Clinic series experienced amaurosis fugax, which was bilateral in 35%. Blindness occurred in 8% and was monocular in 86% but was preceded by amaurosis fugax in only 14%. In patients with untreated giant cell arteritis, the incidence of permanent vision loss is approximately 40%. Diplopia can occur and may be horizontal or vertical.

Fourteen percent of patients have a neuropathy, which is a peripheral polyneuropathy in 48%, multiple mononcuropathies in 39%, and isolated mononeuropathy in 13%. Limb claudication occurs in 8% of patients and usually involves the upper limbs. TIAs and strokes occur in 7% of patients, and the ratio of carotid to vertebral events is 2 to 1. Vertigo and unilateral hearing loss can occur. An acute myelopathy, acute confusional state, and subacute stepwise cognitive deterioration are rare manifestations.

Physical Findings. Signs on physical examination relate to involvement of various arteries and the end-organ damage-sustained from vasculitis-induced tissue infarction,

Forty-nine percent of patients with histologically verified giant cell arteritis have physical signs of superficial temporal artery inflammation, including erythema, pain on palpation, nodularity, thickening, or reduced pulsation on the affected side. Eighteen percent of patients with signs of superficial temporal artery inflammation do not complain of headache. Although it is rare, ischemic necrosis of the scalp and tongue can occur.

Almost one third of patients have large artery bruits or diminished pulses. The carotid artery is the vessel affected most often. The upper limb arteries are more commonly affected than are those in the lower limbs, and some

*Some patients had coincident onset of more than one symptom.
Source: Data From Casclli, R. J., Hunder, C G. & Whisnant, J. P. 1998, "Neurologic disease in biopsy-proven giant cell (temporal) arteritis," *Neurology,* vol. 38, pp. 352-359.

patients have vasculitic involvement of the aorta or its major branches. Coronary arteritis with consequent myocardial infarction may also occur.

Ocular findings in giant cell arteritis may be striking. During amaurosis fugax, there is visible sludging of blood in the retinal arterioles. With infarction of the optic nerve, vision loss precedes the funduscoptc signs of an anterior ischemic optic neuritis by up to 36 hours. During the acute stage there is papilledema. The disc is pale, and the resulting visual field defect, when subtotal, tends to be altitudinal. Papilledema is followed by the gradual development of optic atrophy.

Extraocular muscle palsies show daily fluctuations in the severity of specific extraocular muscle involvement. Ocuiosympathetic paresis (partial Horner's syndrome) may occasionally occur.

Laboratory Studies. The laboratory abnormality most often recognized in giant cell arteritis is elevation of the erythrocyte sedimentation rate (ESR) (mean, 85 ± 32 mm in 1 hi nit with llu[1] Wcstergren mcthodi, alliouj'.h :l in.v. be normal *(<29* mm in I hour) in 3% of patients, C-reactivc protein levels may be more sensitive than the ESR in some patients and may be used to follow disease activity. Patients are usually anemic (mean hemoglobin **value, 11.7** ± 1.6 g/dL) and show a mild thrombocytosis (mean platelet count, 427 it 116 x IO'VUL). Mild elevation of plasma a_2-globulins, serum aspartate aminotransferase, and alkaline phosphatase concentrations may be present. All these findings are nonspecific, and the diagnosis rests on confirmatory temporal artery biopsy.

An angiogram of the cerebral circulation may fortuitously demonstrate a vasculitis of the superficial temporal, vertebral, or carotid artery, although it is too insensitive to be teliable. The temporal artery shows alternating stenosis and dilatation over several-centimeter segments, often more pronounced distally. An angiogram of the aortic arch vessels may show long segments of smoothly tapered stenosis and occlusions of subclavian, brachial, and axillary arteries,

Physiology. The symptoms and signs of giant cell arteritis result from systemic and local inflammatory processes leading to artetial stenosis and occlusion. End organs, such as the optic nerve, extraocular muscles, spinal cord, peripheral nerves, and brain, may be rendered transiently ischemic or infarcted. In amaurosis fugax, ischemia of the optic nerve and retina results from sludging of blood within the arterioles due to vasculitic involvement of the ophthalmic, posterior ciliary, and (less often) central retinal arteries.

Pathology. The histopathological features of the diagnostic arterial lesion include intimal proliferation with consequent luminal stenosis, disruption of the internal clastic membrane by a mononuclear cell infiltrate, invasion and necrosis of the media progressing to panartcritic involvement by mononuclear cells, giant cell fotmation with granulomata within the mononuclear cell infiltrate, and, variably, intravascular thrombosis (Figure 75.5). Involvement of an affected artery is patchy (skip lesions). Long segments of the notmal unaffected artery are flanked by vasculitic foci. Treatment with oral corticosteroids may change the histopathological findings within days, and a previously vasculitic focus may appear normal or show only intimal fibrosis. For these teasons, biopsy specimens of the superficial temporal artery should be generous (4- to 6-cm-long specimens), multiple histological sections should be taken, and the biopsy may be bilateral if necessary. If the first two conditions are satisfied, 86% of occurrences of giant cell arteritis arc correctly diagnosed by biopsy.

The term *temporal arteritis* can lead to a false sense of security that giant cell arteritis is largely a focal vasculitis affecting the relatively inconsequential superficial tempotal artery. Up to one thitd of patients, however, have clinically significant large artery disease. The most common causes of vasculitis-rclated death are cerebral and myocardial infarction. Rupture of the aorta occurs rarely. In fatal occurrences, vertebral, ophthalmic, and posterior ciliary arteries are involved as often and as severely as the superficial temporal arteries. Peripheral neuropathic syndromes occur, and in patients with acute mono neuropathies, ischemic infarction of peripheral nerves

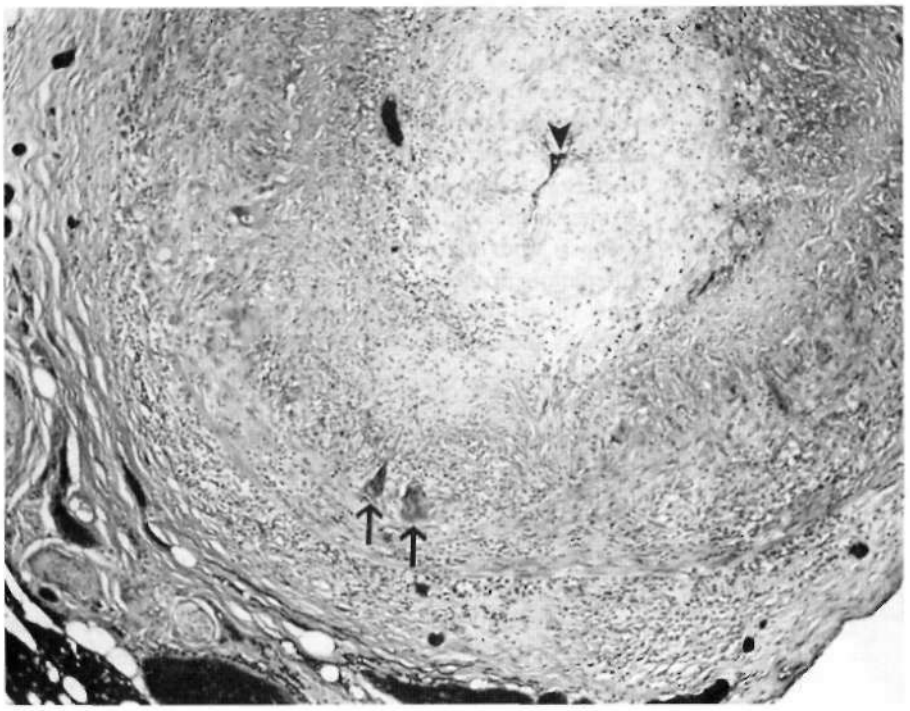

FIGURE 75.5 Transverse section of temporal artery showing narrowed lumen *{arrowhead)* and giant celb *{double arrows)* in relation to the elastic lamina (hematoxylin-cosin stain, xlOO). (Micrograph courtesy of R. jean Campbell, M.B.Ch.B.)

due to vasculitis has been demonstrated. Intracranial vascular involvement has been reported rarely.

Immunology, Etiology, and Pathogenesis. Giant cell arteritis is considered an autoimmune disease of unknown cause. Although it is often a systemic vasculitis, giant cell arteritis usually occurs much more focally than polyarteritis nodosa and is characterized by a mononuclear cell infiltrate with giant cell formation, suggesting differences in immunopathogencsis. No distinctive antigen has been identified to explain the particular tropism of giant cell arteritis, although the possibility that the immune reaction is directed against the internal elastic lamina, which is absent from cerebral vessels shortly after they pierce the dura, presumably explains the paucity of intracranial involvement. Lymphocytes sensitized to the purported antigen infiltrate the internal clastic lamina and release a host of lymphokines, which attract a mononuclear cell infiltrate. Activated macrophages release lysosomal proteases and may transform into epithelioid and multinucleate giant cells. T cells themselves, by antibody-dependent cell-mediated cytotoxicity or natural killer cell actions, may also be involved. Additionally, antibody and complement deposits have been demonstrated at the internal elastic lamina, which suggests that humoral mechanisms are involved.

Epidemiology. In a population-based study of Olmsted County, MN, the incidence of giant cell arteritis was found to increase over a 25-year period from 5,1 to 17.4 cases per 100,000 population per year in people aged 50 or older. This increase was attributed to greater clinical awareness and increased diagnosis. The prevalence was 133 cases per 100,000 population in people aged 50 or older on January 1, 1975. The femalc-to-male ratio was 3.7 to 1. The median age at onset was 75 years (range, 56-92 years).

Course and Prognosis. The clinical onset of giant cell arteritis may be acute (as in patients presenting with sudden transient or permanent vision loss), subacute, or chronic. The median duration of symptoms before diagnosis is I 1lu 'ii(l), Inil exceptional patients nay presenl with a history of up to several years of polymyalgia rheumatica.

On institution of corticosteroid treatment, reversible sympionis and the HSR normalize within days. With tapering doses, relapses may occur and may consist of prior symptoms or new symptoms. Neurological complications, including neuropathies and cerebrovascular events, are not always prevented by corticosteroid administration and have a median onset of 1 month after initiation of treatment. Similarly, large artery involvement can occur up to 7 months after initiation of treatment.

The occurrence of amaurosis fugax often brings a patient with undiagnosed giant cell arteritis to medical attention, but permanent loss of vision after initiation of treatment has been documented in rate instances. In patients with acute and incomplete loss of vision, some visual function may return with the immediate institution of corticosteroid therapy, but this is exceptional.

Treatment and Management. Once the diagnosis is suspected, histological confirmation should be obtained

and treatment started immediately. Treatment should not be withheld pending the result of temporal artery biopsy. Treatment consists of oral corticosteroids given initially in high doses and gradually tapered over months. Prednisone may be initiated at 40-60 mg per day and continued for 1 month, after which time a cautious taper of less than 10% of the daily dose per week may be started, If, at the time of presentation, ischemic complications are imminent or evolving, parenteral high-dose corticosteroids should be given until these complications stabilize. The adjunctive use of anticoagulants for patients with ischemia may be tried, hut their efficacy in this setting is unproved.

Disease activity must be monitored with both clinical assessment and determination of the ESR. A flare of symptoms accompanied by an increase in the ESR mandates increasing the corticosteroid dose at least to the last effective higher dose and, often, boosting it temporarily to a higher level. Relapses generally reflect too rapid a taper, and resumption of a more slowly tapering regimen is indicated after the relapse has stabilized. Some patients may require continuation of low-dose (7.5-10.0 mg per day) ptednisone for several years, although complete withdrawal remains the goal. There is evidence that treatment with methotrexate 10 mg per week may be an effective adjunctive treatment that allows for more rapid tapering of the prednisone dose (Jover et al. 2001).

Finally, the multitude of well-known adverse effects of exogenous corticosteroids necessarily influences management by prompting a more rapid taper and treatment of the side effects themselves. Three particularly alarming treatment complications are symptomatic vertebral body compression fractures (26% of patients), corticosteroid myopathy (11%), and corticostetoid-induced confusional state (3%). All may limit tteatment by necessitating a more aggressive taper thereby exposing the patient to the risks that accompany a relapse of the vasculitis.

Headache Caused by Disorder of the Cranium, Neck, Eyes, Ears, Nose, Sinuses, Teeth, Mouth, or Other Facial or Cranial Structures

Ocular Causes of Headache

In the absence of injection of the conjunctiva or other obvious signs of eye disease, headache and eye pain rarely have an ophthalmic cause. The maxim is that a white eye is not the cause of a monosymptomatie painful eye. Acute angle-closure glaucoma is a rare but often dramatic event, The patient may present with extreme eye and frontal head pain with associated vomiting and may be in the early stage of shock. The sclera is injected, the cornea is cloudy, the pupil is fixed in midposition, and the globe is stony hard. It is a true ophthalmological emergency.

Refractive errors, imbalance of external eye muscles, amblyopia, and (in the terminology used by many patients) eyestrain are not causes of headache in most instances. In children and teenagers, however, refractive errors, especially hyperopia, can produce dull frontal and orbital headaches from straining to achieve accommodation at school. Myopic children are unaffected.

Soon after initiation of miotic preparations such as pilocarpine, some patients with glaucoma complain of eye and frontal discomfort due to ciliary muscle spasm. This subsides with continued use of the drops.

Cluster headaches, migraine, dissection of the carotid artery, and many other varieties of headache cause orbital and retro-orbital pain. Each is discussed elsewhere in this chapter. Of particular interest is SUNCT (short-lasting, unilateral, neuralgiform, headache attacks with conjunctival injection, tearing, rhinorrhca, and forehead sweating) syndrome because of its specific localization to the orbit and associated conjunctival injection and marked tearing. Sharp jabs of pain through the eye lasting 1 second or longer can occur as part of an idiopathic stabbing headache that is considered to be responsive to indomethacin. This condition is of unknown pathogenesis but is most commonly seen in migraineurs. The sharp eye pain, known by various names, including *ophthalmodynia periodica* (or needlc-in-the-eye syndrome), is occasionally felt in the ipsilatcral occipital region simultaneously.

Nasal Causes of Headache and Facial Pain

Acute purulent rhinosinusitis causes local and referred pain. The distribution of the pain depends on the sinuses involved. Maxillary sinusitis causes pain and tenderness over the cheek. Frontal sinus disease produces frontal pain; sphenoid and ethmoidal sinusitis causes pain behind and between the eyes, and the pain may also be referred to the vertex. Acute rhinosinusitis is commonly associated with fever, putulent nasal discharge, and other constitutional symptoms. The pain is worse when the patient bends forward and is often relieved as soon as the infected material drains from the sinus. Currently, there is insufficient evidence to suggest that chrome rhinosinusitis is a cause for headache or facial pain unless associated with a relapse into an acute phase. Ftontal sinusitis that spreads through the posterior wall of the sinus to produce an epidural abscess is a serious cause of local head pain. If neglected, the abscess may pass through the meningeal layers to produce meningitis or a brain abscess. Similarly, an acute infection involving the sphenoid sinus can be particularly dangerous because of its close proximity to the cavernous sinus.

The occurrence of so-called "sinus headaches" without an underlying infection remains unsubstantiated. Commonly migraine headaches are erroneously diagnosed as sinus headaches either because they are associated with cranial autonomic symptoms, have prominent

facial involvement, ot are triggered (i.e., a change in altitude/weather, an exposure to pollens, or a seasonal predilection).

Rarely patients may suffer from mucus.il contact point headaches in which pain is localized to the periorbital, medial canthal, or temporozygomatic regions. Nasal endoscopy or CT imaging must reveal evidence of mucosal contact points to support this diagnosis.

Malignant tumors of the sinuses and nasopharynx can produce deep-seated facial and head pain befote involving ctanial nerves or otherwise becoming obvious. MKI scanning is the optimal technique for the detection of these cryptic lesions. Osteomyelitis, multiple myeloma, and Paget's disease in particular must be considered when bony invasion is present on a scan.

Temporomandibular Joint Disorders

In 1934, Costen first drew attention to the temporomandibular joint {TMJ) as a cause of facial and head pain. Until recently, Costen's syndrome was rarely diagnosed. During the past two decades, however, interest in disorders of the TMJ, the muscles of mastication, and the bite as they relate to headaches has been incteasing. Articles in the popular press and diagnoses by dentists have led many patients to believe that TMJ disorders are the most common cause of headache. Mechanical disorders of the joint, alterations in the way the upper and lower teeth relate, and congenital and acquired deformities of the jaw and mandible can all produce head and facial pain and are very occasionally responsible for the episodic and chronic pain syndromes seen by neurologists.

For the neurologist evaluating head or facial pain, the criteria for identification and localization of **TMJ** disorders listed in Table 75.4 should be helpful.

Bruxism, teeth clenching, and chronic gum chewing are important in the production of pain in the massetcr and temporalis muscles. Arthritis and degenerative changes in the TMJ, loss of teeth, ill-fitting dentures or lack of dentures, and other dental conditions can all lead to the TMJ or myofascial pain dysfunction syndrome that manifests as facial and masticatory muscle pain. Head pain and facial pain, even when associated with the criteria listed in Table 75.4, require full evaluation, which should include a detailed history and examination, appropriate radiographs, and laboratory studies to exclude other more serious causes. If TMJ dysfunction is thought to be the source of the pain, further evaluation and treatment are in the province of the appropriate dental specialist. Even when TMJ dysfunction is believed to be responsible for facial or head pain, conservative management with analgesics, anti-inflammatory agents, application ol local heat, and nonsurgical techniques to adjust the bite generally provide relief. Before surgical modalities are used on the TMJ or mandibles, the diagnosis must be secure and other causes of head and facial pain excluded by appropriate investigations,

Other Dental Causes of Craniofacial Pain

Pulpitis and root abscess generally produce dental pain that a patient can localize. The cracked tooth syndrome results from an incomplete tooth fracture, most commonly involving a lower molar. The initial pain is usually sharp and well localized, but thereafter the pain is often diffuse and hard to locate. After the initial fracture, the tooth is sensitive to cold. Pain may be felt in the head and face ipsilateral to the damaged tooth. With time, infection develops in the pulp, leading to extreme and well-localised pain. Confirmation of the diagnosis and treatment of the cracked tooth require the expertise of a dentist,

Headaches and the Cervical Spine

Degenerative joint disease and cervical disc herniation rarely produce headache in the absence of neck pain. Occipital headache and neck pain on awakening are not uncommon with arthritis of the cervical spine. With activity, the headache and associated stiffness of the neck subside. Similarly, holding the head in one position for hours while driving or working at a desk can cause an increase in neck and head pain in the presence of degenerative changes. The cervical myalgias can spread upward to produce a muscle contraction headache. Rclicl lolkiws rest or sirnpl\ adopt lor. ol ;i different position. For patients with severe degenerative changes in the cervical facet joints, exercise, heat, and the use of simple analgesics can help both the neck and the head pain. Surgical fusion or discccctomy should be performed only if there is bony instability or spinal cord or nerve root compression. A cervical fusion for relief of headache in the absence ot these indications is likely to be ineffective.

Table 75.4: Criteria for identification and localization of temporomandibular joint disorders

Temporomandibular pain	*Temporomandibular dysfu net ion*
Pnin should relate directly to jaw movements and mastication	Interference with mandibular movement (clicking, incoordination, and crepitus)
Tenderness in the masticatory muscles or over temporomandibular joint on palpation	Restriction of mandibular movement
Anesthetic blocking of tender structures should confirm presence and location of pain source	Sudden change in occlusal relationship of the teeth

Ccrvicogenic headache is an entity that is described as consisting of a strictly unilateral migraine-like head and facial pain with associated neck pain and stiffness. Attacks of pain arc often accompanied by ipsilateral autonomic phenomena, such as tearing and even erythema of the face, and can be precipitated by neck maneuvers. Tenderness on the side of the neck ipsilateral to the head pain is sometimes accompanied by triggering of the attacks by pressure over the C2 nerve root, the greater occipital nerve, or the transverse process of C4-C5. At present, the concept of cervicogenic headache remains controversial.

Other Primary Headaches

Cough Headache

Cough headache is a headache of sudden onset that is precipitated by a brief, nonsustained Valsalva's maneuvet, such as coughing, laughing, sneezing, and bending. Because transiently raised intrathoracic pressure is thought to be the trigger in this condition, use of the term *Vahalva-inditced headache* has rapidly gained momentum. The pain is usually described as bursting or explosive, lasting seconds to minutes. As a rule, the patient is free from pain between attacks, but benign cough headache with normal neuroimaging results has rarely been described as lasting up to 24 hours. The headache is usually bilateral and often occipital or suboccipital. The mean age at onset of this headache syndrome is approximately 55 years (range, 19-77 years) with a 4-to-l male predominance. The proportion of patients who have an underlying structural cause is difficult to detetmine because many of them were reported in the era before CT and MRI. However, a recent study suggested that more than 50% of patients have an underlying structural cause (Pascual et al. 1996). Chiari type I malformation is the most common structural abnormality found, but other entities have been described, such as carotid dissection, basilar invagination, platybasia, colloid cysts of the third ventricle, and other space-occupying lesions. All patients therefore require MRI scans before a diagnosis of benign cough headache is made. MRA should be obtained if there are features that raise the possibility of a carotid artery dissection. The treatment of choice is indomethacin, used similarly to the regimen used in the paroxysmal hemicranias. The response to indomethacin is not absolute nor does it confirm a benign etiology. Other reports suggest that benign cough headache may respond to propranolol, dihydroeigotamine, or lumbar puncture.

Exertional Headache

Exertional headache is a bilateral, throbbing headache that is precipitated by sustained physical exercise, such as weight-lifting, dancing, running, howling, and football. The headache is not explosive in onset but rather builds in intensity and lasts between 5 minutes and 24 hours, in contrast to the headache profile seen with cough headache. The headache can be ptevented by avoiding excessive exertion, particularly in hot weather or at high altitude. Similar to cough headache, this disorder can be benign or symptomatic of an underlying cause. Typically benign exertional headaches occur earlier in life compared with benign cough headache. In one series, 12 of 28 patients with exertional headache were found to have underlying causes (Pascual et al. 1996). These patients, however, were older (mean age 42 versus 24), developed acute, severe, bilateral headaches lasting I day to I month, and developed accompanying symptoms of nausea, vomiting, photophobia, or diplopia. Well-described causes of symptomatic exertional headache include subarachnoid hemorrhage, cerebral metastases, pansinusitis, and pheochromocytoma. *Cardiac cephalalgia* refers to a headache brought on by exertion in the setting of underlying coronary artery disease. Exercise-induced cardiac ischemia is thought to refer pain to the head and neck. Appropriate investigations are therefore mandatory in each patient. Indomethacin, either given shortly before exercise or on a regular basis, is effective in the majority of benign exertional headaches. Other medications that may be effective include ergotaminc or methysergide before exercise or the regular administration of a beta blocker, calcium-channel blocker, aceta/olamide, or aspirin.

Headache Associated with Sexual Activity

The onset of a severe headache, usually in the occipitonuchal region, during intercourse or at orgasm is usually benign. There are three types of benign headaches associated with sexual activity. The most common is a bilateral cervical and occipital headache that builds up through intetcourse and is believed to be due to sustained contraction of the cervical and scalp muscles. This headache rapidly resolves with rest. A mote acute and frightening headache develops al the height of orgasm and may be very severe. It usually subsides in minutes, although it may persist for hours and may cause tile subject to seek immediate medical attention. Such acute headaches associated with sexual activity arc typically benign, but careful consideration must be given to the possibility of a subarachnoid hemorrhage. A CT scan of the head should be obtained. If there is no sign of bleeding, a lumbar puncture should be undertaken to examine the CSF for the ptesence of erythrocytes or xanthochromia. If results of these examinations are negative, angiography may be necessary if the history and the physical examination suggest that a small subarachnoid hemorrhage or sentinel bleeding episode may have occurred. A third type of coital headache has been described. This headache type develops after orgasm and has a postural component resembling a low CSF pressure state. Benign coital headaches are more common in men than in women. They more commonly

occur as an isolated event with recurrence generally not the rule. If recurrent orgasmic headaches become problematic, they may be prevented in some patients by the use of indomethacin or ergotamine tartrate taken several hours before intercourse. Several case reports suggest that either daily propranolol or diltiazem may be effective as well.

Migraine

Migraine has afflicted humankind for centuries. Descriptions of acute migraine attacks appear as early as the second century AD in the writings of Aretaeus of Cappadocia. The term *migraine* is derived from the ancient Greek word *hemikranios* which means "half head," underscoring the unilateral distribution of head pain in many sufferers.

Definition and Classification

Because reliable biological markets for migraine currently do not exist, diagnostic classification is based on clinical features of the acute episode. Migraine is now classified according to the scheme devised by the Second Headache Classification Committee of the International Headache Society (Headache Classification Committee 2004), as shown in Table 75.5.

Clinical Aspects

Migraine can begin at almost any age; most commonly, the initial attack occurs during adolescence, and by 40 years of age, 90% of those with the condition have had their first attack. Although migraine can begin in older patients, it should be viewed with suspicion because the incidence of serious intracranial disorders that may mimic primary headaches is greater. After puberty, migraine is more common in females, whereas in children there is a small preponderance of males. A family history of migraine is present in up to 90% of patients. Although there has been some interpopulation variability, several large population-based studies in Europe and United States have shown the prevalence of migraine in women to be approximately 20% and in men approximately 6%. Once migraine has developed, it tends to tecur with varying frequency throughout much of a patient's life. Attacks have a tendency to get milder and occut less often in later yeats although this cerr.unl) is not .i universal finding.

Table 75.S: Migraine

1.1. Migraine without aura
1.2. Probable migraine without aura
1.3. Migraine with aura
1.3.1. Typical aura with migraine headache
1.3.2. Typical aura with non-migraine headache
1.3.3. Typical aura without headache
1.3.4. Familial hemiplegic migraine
1.3.5. Sporadic hemiplegic migraine
1.3.6. Basilar type migraine
1.4. Probable migraine with aura

Although migraine attacks have been separated into those that are and those that are not accompanied by transient focal neurological symptoms known as the aura, the two types are not mutually exclusive, and many patients have separate attacks of the two types. The headache phase of migraine with and without aura is similar and typically consists of episodes of unilateral throbbing head pain of modetate to severe intensity which, if untreated, persists fiom 4 hours up to 3 days and tends to worsen with routine levels of physical exertion. Migraine attacks tend to be accompanied by nausea, vomiting, and light or sound sensitivity although not every patient experiences all of these symptoms. It is important to realize that there is variability in the intensity and details of the headache from patient to patient and from attack to attack.

Migraine without Aura. Migraine without aura occurs episodically and is not preceded or accompanied by any easily identifiable aura due to focal cerebral or brainstem disturbances. Many patients with migraine report that their headaches are preceded by a prodromal phase that may consist of alterations in mood or energy level (either euphoria or depression), excessive yawning, thirst, or food cravings. After these premonitory warnings, the headache may occur within hours or during the next day. The attack may awaken the subject during the night, but more commonly the patient awakens near to the normal time to find that the attack has already started. At this stage, the pain may be unilateral and is usually supraorbital, but it may be holocephalic. An initially unilatetal headache may progress to generalized head pain, or it may switch to the conti a lateral side during the course of the attack. Headache arising frontally can radiate or migrate posteriorly or vice versa. Patients with migraine may have attacks that primarily affect the cheek, ear, nose, or neck. These attacks, sometimes called lower-half headache. should be considered in patients with facial pain accompanied by nausea, vomiting, and photophobia. Pain in the lateral portion of the neck with tenderness over the carotid artery may be found in lower-half headache.

The management of this condition is similar to that of the more common cephalic forms of migraine.

The quality of the pain of migraine is often described as throbbing (pulsatile) although in some patients the throbbing only occurs with more severe attacks. Many patients, however, describe the pain as steady while they remain still. It tends to pulsate or throb at the heart rate with exertion, after Valsalva's maneuver, or during the bead-low position. Strict insistence on obtaining a history of a throbbing pain **sii v/.Mijl.'ir** I'.e.ul.idles ie.uls **lo mum iiTiinmiis conclusions.** In general, during acute attacks migraineurs wish to remain as still as possible and prefer a dark quiet room, although with mild attacks some patients may be able to function at a reduced capacity.

Other symptoms are often associated with the pain of migraine. Photophobia and phonophobia are common and osmophobia (sensitivity to smells) may also occur. The onset of n.uisca and vomiting in migraine can occur almost as soon as the pain develops, but it is more commonly delayed until the attack has been in progress for 1 hour or longer, Anorexia, even intolerance to the smell of food, is even more common than nausea. The gastrointestinal symptoms can include diarrhea. Blurred vision is a common complaint during all types of migraine. Lightheadedness is also common and may progress to syncope in a small percentage. Subconjunctival hemorrhages, orbital ecchymoses, and epistaxis have all been reported to accompany migraine. Fever, tachycardia, and paroxysmal atrial tachycardia are rare migraine-related symptoms, possibly due to associated disturbances of the autonomic nervous system. Sacks' 1392 monograph on migraine has an extensive listing of the symptoms that have been described in migraine.

The pain of an attack of migraine tends to build up to a peak over 30 minutes to several hours. Rarely the onset is desctibed as being more explosive. The attack generally lasts several hours to a full day. Severe episodes can continue for several days and, if associated with vomiting, can lead to prostration and dehydration. Very prolonged attacks or a series of attacks with minimal relief between them is called *status migramosus,* and it often warrants admission to the hospital for pain relief and correction of fluid and electrolyte imbalance. More commonly, the attack subsides within a day or after a night's sleep. The day after the intense pain, the patient feels tired and listless. The head is still heavy and transient pain can occur with sudden movement, bending over, or Valsalva maneuvers.

The frequency and severity of episodes of migraine without aura (common migraine) are extremely variable both from patient to patient and over time within an individual patient. Recurrence of attacks one to four times per month is not uncommon, and attacks in relation to the menstrual cycle are a common pattern in women during the reproductive years. Attacks at less than weekly intervals are common in patients who attend neurology clinics and generally indicate that a chronic daily headache partem is evolving.

Migraine with Aura. In migriiii-e with anr.i. periodic headaches arc preceded or accompanied by an aura consisting of transient visual, sensory, motor, or language disturbance or other focal cerebral or brainstem symptoms. Aura occurs in about 15% of migraineurs and does not occur in every attack. Although each of the aura types may occur alone in a given attack, in some individuals they can occur sequentially. Classically, the visual disturbance is followed by sensory symptoms and then iti-turn by language or motor symptoms. When this occurs, the headache may overlap one or more of the later 'appearing aura symptoms. The head pain is identical to that of migraine without aura but is unilateral in a higher percentage of patients. Alterations in mood and other premonitory symptoms may precede the aura.

The most common aura is the disturbance of vision known as a scintillating scotoma (teichopsia). This generally begins as a shimmering arc of white or colored lights in rhe homonymous part of the left or right visual field. The arc of light gradually enlarges. It may have a definite zigzag pattern. It may be a single band of light or may have a much more complex pattern. It has a shimmering or flickering quality, similar to that seen when a fluorescent light fixture is close to failure or a strobe light is just short of the flicker fusion frequency. Gradually, over the course of a few minutes, the scintillating pattern expands from the point just lateral to the of fixation to involve a quadrant or hcmifield of vision in both eyes. Commonly, the positive scotoma is followed by a spreading zone of vision loss (negative scotoma). Even if there is no identifiable area of vision loss, the disturbance of vision produced by the scintillating scotoma makes it difficult to read or drive. The scotoma is believed to originate in the calcarinc cortex of one cerebral hemisphere and should therefore be an essentially congruent homonymous field defect; however, it is sometimes described as being seen in one eye only or' as being worse on one side than the other. Patients often describe the visual disturbance in vague terms, such as "blurry vision," "double vision," or "jumpy vision." Close questioning ot showing the patient an artist's teprescn-tation of a scintillating scotoma generally clarifies the complaint.

There are many variations of migrainous teichopsia (subjective visual images). The zigzag appearance may be so pronounced to justify the term *fortification spectrum* because of its fanciful resemblance to the ground plan of a fort. Occasionally, the scotoma is less complex and is simply described as a ball of light in the center of the visual fields. It may obscure vision to a significant degree. This type of teichopsia may represent a bilateral calcarine disturbance. The scintillating and positive (bright) scotomata can still be seen with the eyes closed or while in rhe dark. This is not a feature of the negative scotomata (areas of darkness), which disappear in the dark.

The teichopsia of migraine may be more complex and formed than the usual lines and geometric patterns. Rarely,

a complex scene is visible to the migraineur; it may be recognizable as an image from the patient's past experience, or it may be an unknown scene. Disturbances of this complex type may be due to dysfunction in the posterior HTiip-.r-:]l Ic-hc. Changes in the perception of [lie shape or form of viewed objects (mctamorphopsia) can lead to frightening and bizarre visuai hallucinations. The story of *Alice in Wonderland,* in which the heroine perceived herself shrinking, is believed to have been based on Lewis Carroll's own experience of migrainous mctamorphopsia.

Visual disturbances due to retinal dysfunction are relatively uncommon in migraine and nu\ lake the Innn of unilateral flashes of light (photopsia), scattered areas of vision loss, altitudinal defects, or even transient unilateral vision loss. When such monocular visual disturbances are followed by a headache, rhc term *retinal migraine* is appropriate. When the photopsia, teichopsia, and other disturbances are seen in both visual fields simultaneously, they probably originate from the calcarine cortex. A homonymous visual aura is generally followed by a headache on the contralateral side of the head, but exceptions are not uncommon. In such patients, the headache is ipsilateral to the visual disturbance, or it is bilateral.

Sensory aura, the second most common aura type is, like the visual aura, characterized by positive symptoms (paresthesias) followed by negative symptoms (numbness), which slow!\ spread or migrate. Paresthesias can occur, alone or in conjunction with one of the previously described visual symptoms. The numbness or tingling may be felt in almost any distribution, from a hemisensory disturbance to one that involves all four limbs or a much more restricted area, such as the lips, face, and tongue. The paresthesias can last from a few seconds to 20-30 minutes. The paresthesias of migraine aura seem to have a predilection for the face and hands. This may be due to the latge tepresentation of these structures in the sensory cortex or thalamus. The term *cbeiro-oral migraine* is sometimes applied to instances involving a sensoty disturbance of the fingers, lips, and tongue during the aura phase.

The rate of spread of a sensory aura is important to help distinguish it from a sensory seizure and rhe sensory disturbance of a TIA. Just as a visual aura spreads across the visual field slowly, taking as long as 20 minutes to reach maximum, the paresthesias may take 10-20 minutes to spread from the point at which they are first felt to reach their maximal distribution. This is slowet than the spread or march of a sensory seizure and much slower than the spread of sensory symptoms of a TIA. A migrainous sensory aura generally resolves over the course of 20-60 minutes. After the aura there is usually a latent period of a few minutes before the onset of the headache. In some subjects, the aura and the headache merge.

After sensory aura, the next most common type is the language aura. Dysphasia or aphasia can occur as the aura of migraine. The aphasia, which is usually mild and transient, can be either an expressive or a receptive type. Alexia and agraphia can also occur and can be associated with mild confusion and difficulty concentrating. The ensuing headache generally resembles headaches the patient has had in the past and that followed the more typical visual aura. *J*

Weakness of the limbs or facial muscles on one side'of the body occurs only rarely as a motor aura of migraine. Many patients describe a sense of heaviness in the limbs on one side before a headache, but examination during this phase rarely reveals any true weakness. If actual paresis docs occur, it is usually detected in the upper limb and may be accompanied by mild dysphasia if the dominant hemisphere is involved. The weakness genetally lasts 20-30 minutes, although in some patients the weakness may persist fot hours to weeks (see Complications of Migraine, later in this chapter).

A rare occurrence is for the motor aura of migraine apparently to precipitate a focal motor seizure. This may indicate an area of abnormal cortex that has a predisposition to act as a seizure focus. The seiztire appears to be triggered by the cortical abnormality that occurs in the aura of migraine.

Episodes of transient abdominal symptoms, periods of disturbed mentation, deja vu experiences, and other bizarre symptoms have all been thought to be the aura of migraine with aura at various times. The number of patients involved has generally been so small that the true nature of the experiences remains in doubt compared with the more commonly encountered visual, sensory, language, and motor auras already described.

Migraine Aura without Headache or Migraine Equivalents. When a visual, sensory, motor, or psychic disturbance characteristic of migraine aura is not followed by headache, the episode is termed *migraine aura without headache,* a *migraine equivalent,* or *acepkalic migraine.* Most commonly encountered in patients who have a past history of migraine with aura, the episodes can begin *de novo,* usually after 40 years of age, but they can occur at almost any age.

Migtaine equivalents are easily recognized when the attacks occur on a background of migraine with aura. In the absence of such a history, the transient disturbance may be difficult to distinguish from an episode of ttansient cerebral or brainstem ischemia. MRI/MRA, cerebral angiography, echocardiography, and tests of hemostasis may be needed to exclude the more serious causes. The typical scintillating scotoma, with its slow spread and zigzag appearance in both visual fields, is almost invariably migrainous, whether or not it is followed by a headache. Under these circumstances, it is rarely necessary to perform invasive investigations. A conttast-enhanced CT or MRi scan is a reasonable compromise when there is doubt about the migrainous nature of the event.

Acute episodes of confusion can occur with migraine, usually representing the aura stage. Acute confusional or

dysphrenic migraine occurs most often in children or adolescents, but it can occur later in life. In the absence of a long history of migraine with aura, the episodes arc rarely suspected of being migrainous at first. In an elderly patient, the diagnosis is considered only after exclusion of more serious conditions, including transient ischemic events. As a migraine equivalent, the acute confusional state may be unaccompanied by headache. The term *dysphrenic migraine* has been used to describe severe confusional states progressing to partial or generalized seizure activity or coma in young patients. The migrainous nature may be suspected from the past history of more typical migraine with aura.

Basilar Migraine. Basilar migraine is usually first encountered during childhood or the teenage years. It was initially thought to be primarily a disorder of women, but further case reports indicate that it occurs in men almost as commonly (Peatfield and Welch 2000). Basilar migraine is recognized only in the classic form because only the dramatic constellation of brainstem symptoms allows its recognition. The headache is usually occipital and severe. The aura, which lasts 10^45 minutes, usually begins with typical migrainous disturbances of vision, such as teichopsia, graying of vision, or actual temporary blindness. The visual symptoms are bilateral. Numbness and tingling of the lips, bands, and feet often occur bilaterally. Ataxia of gait and ataxic speech, vertigo, dysarthria, and tinnitus are also described in basilar migraine.

Involvement of the brainstem reticular formation can lead to impairment of consciousness, especially in young patients. This often occurs as the other symptoms of the aura are subsiding. The level of coma is never profound and can resemble sleep from which the patient can be temporarily aroused. Recovery usually coincides with onset of the severe throbbing occipital headache. The pain may generalize to the whole head and is often associated with prolonged vomiting. After sleep, the headache is usually gone. A basilar migraine equivalent occurs in which teenagers have the symptoms just described without the headache. This is a clinical picture that can be difficult to recognize. Certain investigations are needed for reassurance. MRI scans and an electroencephalogram usually suffice. Rarely, patients with otherwise typical basilar migraine can have seizures with the attacks of headache. Epileptiform electroencephalographic (EEG) abnormalities have been recorded under these circumstances.

With increasing maturity of the nervous system, attacks of basilar migraine become less common and are generally replaced by migraine without aura. Basilar migraine can occur in later life, but its onset at that age should be viewed with suspicion because arteriosclerotic vertebrobasilar artery insufficiency is more common and can produce almost identical symptoms.

Ophthalmoplegic Migraine. Ophthalmoplegic migraine is a very infrequent condition that almost always has its onset in childhood. Recurrent attacks are the usual pattern. Each episode begins with a unilateral orbital and retro-orbital headache, often accompanied by vomiting, that lasts 1-4 days. Either during the painful stage or occasionally as the headache subsides, ipsilateral ptosis occurs and, within a few hours, progresses to a complete paralysis of cranial nerve III. Rarely, cranial nerves TV or VI may be involved. The neural deficit can last from 1 hour to several months. The focal nature of the deficit has, in the past, often led to major investigations, including angiogtaphy to rule out the presence of an internal carotid or posterior communicating artery aneurysm, but usually no abnormality is found. MRI scans have shown thickening and contrast enhancement of the nerve as it exits the midbrain, which may persist after the third nerve palsy has disappeared (Daroff 2002). It has been speculated that this represents a recurrent demyelinating/inflammatory neuropathy although pathological evidence has not been available for confirmation [.ana and Zagnmi 2001}. In am case, this disordei is probably best considered a cranial neuropathy. The prognosis is favorable for recovery unless attacks occur very often.

Complications of Migraine

Attacks of migraine with associated hemiparesis can occur sporadically or, rarely, as a familial condition. Either form can occur singly or recurrently. The diagnosis can be considered only if the subject has a convincing past history of migraine with aura. The attack usually begins with a motor aura involving the limbs on one side, and facial involvement may be present. Unlike the common aura, however, this motor aura may involve quite profound weakness, which persists throughout the headache phase and for a variable period thereafter. The muscle weakness may last for hours, days, or even weeks in rare patients. Recovery is usually complete, except in patients in whom a dense hemiplegia develops and in whom a CT or MRI scan demonstrates an area of infarction. CSE pleocytosis can occur with hemiplegic migraine. The increased cell count is transient and is believed to occur in response to clinical or subclinical cerebral infarction. 1 he sporadic form of hemiplegic migraine, if it is recurrent, can alternate sides. In the familial form, the involved side tends to be the same with each attack. Inheritance of this condition may be a dominant trait and is discussed further under Migraine Genetics, later in this chapter.

A facioplegic form of complicated migraine with recurrent episodes of upper and lower motor neuron facial palsv also occurs. Whether this state is separate from hemiplegic migraine is unclear.

Usually on a background of migraine with visual aura, an occasional patient reports the persistence of visual symproms for long periods or even indefinitely. Most such patients are found to have a field defect. It can be

congruous and due to a cerebral lesion, or rarely it can be imiocular and due to a retinal abnormality. CT scans have shown small infarcts in the occipital lobes or along the course of the central visual pathways in some patients. In those with retinal involvement, occlusion or spasm of the retinal .lricri;^ has Kvn observed. A IH:L;.W.\ ;• senium.i can persist, and scintillating scotomata can persist for long periods. The association between migraine and stroke is also discussed in Chapter 57A.

Physical Findings

Between attacks, the migraineur generally has a normal physical examination. During an attack of migraine, rhe scalp vessels may be distended and tender. The blood pressure is likely to be raised due to the pain. Many patients are pale and clammy during the attack, especially if nauseated. The patient is likely to object to the lights of the examination room and try to avoid the glare of the ophthalmoscope during the eye examination. Occasionally, there is some inequality of the pupils, with the one ipsilateral in l:ie *ii*\\; .idle **timer .i'l**\ ln-ins; larger. A **lulK** developed "ophthalmoplegic migraine" reveals various degrees of a third cranial nerve deficit, with ptosis, a dilated pupil, and impaired medial and upward movement of the involved eye. Involvement of cranial nerve VI impairs lateral deviation of the globe.

Mild weakness, especially of the upper limbs, may be found during a motor aura, and various degrees of weakness up to hemiplegia may occur in complicated migraine.

Demonstration of impaired vision during the visual aura is difficult. Most often, a patient's visual complaints are purely subjective.

/ *abnnitory Findings*

No special investigation-, are useful for tin- JuiiL.il diagnosis of migraine. EEG, MRI, and CT scan abnormalities may be found during or shortly after an attack, but they are not specific for migraine and simply detect cortical or parenchymal changes that accompany the headache. The EEG changes can range from an area of focal slowing over the hemisphere ipsilateral to the headache to focal spikes, sharp waves, or the more generalized spike-wave discharges seen in idiopathic seizure disorders. Similar findings may be seen in basilar migraine.

Visual evoked potentials are slowed in some subjects with repeated attacks of migraine. This observation, although important for evaluation of the pathophysiology of the condition, is of little use clinically. CT and MRI scans can reveal large areas of decreased attenuation and signal changes over the hemisphere ipsilateral to the headache, especially if it is severe and prolonged. These changes, which are temporary and resolve in a few days, arc believed to represent edema of the affected region. Complicated migraine, especially that leading to a permanent deficit, such as a hemiparesis or a visual field defect, shows an appropriate area of cerebral infarction. The relationship of antiphospholipid antibodies to migrainous infarction is unclear, although the presence of such antibodies is considered a separate risk factor for stroke even in the absence of migraine. Detection of antiphospholipid antibodies in a migtaineur should lead to the administration of anticoagulants or antiplatelet agents.

CT and MRI scans are useful in the investigation of migraine only to the extent that they allow exclusion of other causes of recurrent headaches. If there is a question as to whether a vascular lesion such as an aneurysm or AVM is present, magnetic resonance angiography is often used as a screening tool, although standard angiography may in some instances be necessary when the diagnosis of migraine is doubtful and a vascular lesion is strongly suspected on clinical grounds. Finding a lesion such as an aneurysm does not always mean that the diagnosis of migraine was incorrect. It may simply mean that the patient has migraine and an incidental aneurysm as well. In other circumstances, the angiographic findings may negate the diagnosis of migraine entirely. The risk of angiography in migraineurs is probably no higher than that in other persons of the same age.

Migraine Genetics

The prevalence of a family history of migraine has been recognized since the seventeenth century. Although prior familial migraine studies have shown no clear Mendelian inheritance patterns, recent genetic epidemiological surveys, and a twin study using a polygenic, multifactorial model support the hypothesis of a genetic contribution. Perhaps the most striking evidence of a genetic basis for migraine has come to us over the past decade from investigation of familial hcmiplegic migraine.

Familial hcmiplegic migraine (FHM) is a rare autosomal dominant subtype of migraine with aura in which in the context of otherwise typical migraine attacks, patients experience hemiplegia. The hemiparesis of FHM in many patients is prolonged beyond the customary time limit of 1 hour usually associated with migraine aura. Ataxia, nystagmus, and coma have been described in the context of FHM. In 1993, FHM was mapped to chromosome 19p13 (Joutel 1993) in linkage studies that were inspired by the clinical association with migraine and cerebral autosomal dominant arrcnopathy with subcortical infarcts and leukoencephalopathy. About 50% of tested families have mutations in *C,AC,NA 1 A,* a gene located on chromosome I [L]Jp1 3 which codes for the ct^-subunit of a bra in-specific voltage-gated P/Q-type calcium channel (Ophoff et al. *1996).* Mutations in the same gene have been found in some pedigrees with hereditary paroxysmal cerebellar ataxia, indicating that these two disorders, which share several features, are allelic channelopathies (see Chapter 70). Four years later, Gardner and colleagues (1997) reported another

locus for FHM on chromosome 1 q 31 in a 39-member four-generation pedigree showing a clear FHM phenotype. This region on chromosome 1 is reported to contain a neuronal calcium-channel a_{1E}-subunit gene. Recent reports (Terwindt etal. 2001) indicate that *CACNA1A* is not only implicated in familial hemiplcgic migraine, but is over-represented in patients with migraine without hemiplegia.

Although FHM is a rare genetic subtype of migraine with aura, the clinical similarities (with typical migtaine, with and without aura) suggest at least the possibility of a shared pathophysiology. The discovery of a genetic locus for FHM has generated considerable interest and prompted a large effort in the field of molecular genetics to find the fundamental defect in the more common forms of migraine. However, studies testing the 19pl3 region for linkage to typical migraine have produced conflicting results. One study concluded that chromosome 19 mutations either in the *CACNL1A4* gene or in a closely linked gene are implicated in some pedigrees with familial typical migraine and that the disorder is genetically heterogeneous (Nyholt et al. 1998). Further invesngation will be necessary to determine the extent to which the more common types of migraine in the general population might be influenced by these FHM genes,

A recent study based on a genome-wide screen of 50 multigencrational, clinically well-defined Finnish families showing intergenerational transmission of migraine with visual aura yielded significant evidence of linkage between the migraine with aura phenotype and marker D4S1647 located on chromosome 4q24 (Wessman et al. 2002). The application of new genomic and proteomic techniques to migraine may then lead to the further unraveling of the precise molecular defects that underlie this highly prevalent and disabling condition.

Pathopbys iology

Genesis of the Migraine Syndrome. Clinical and experimental evidence supports the concept that there is abnormal intracranial and extracranial vascular reactivity in migraine and other vascular headaches. Dilatation of the scalp arteries causes incteased scalp blood flow and large-amplitude pulsations during attacks of migraine. Radioactive xenon cerebral blood flow studies show significantly reduced regional flow through the cortex during the aura stage of migraine with aura. At first sight, these studies seem to support the long-held theory of cerebral vasoconstriction during the aura and increased external carotid flow during the headache phase. However, the vasoconstriction-vasodilatation model has several difficulties. First, there is solid evidence from functional MR! studies that the phase of oligemia during the migraine aura is preceded by a phase of focal hyperemia {Hadjikhani et al. 2001). Second, headache may begin while cortical blood flow is still reduced, thereby rendering obsolete the theory that vasodilatation is the sole mechanism of the pain. The oligemia that spreads across the cerebral cortex at a rate of 2-3 mm per minute does not conform to discrete vascular territories, making unlikely the theory that vasospasm of individual cerebral arteries with subsequent cerebral ischemia is the source of the aura. The headache after an aura is often on the inappropriate side. In other words, a right-sided visual field or somatosensory aura can In- followed by an ipsilaieral headache, despite the f.ict thai the cerebral blood flow changes occurred in the opposite hemisphere. Finally, migraine is also associated with a premonitory phase in up to 60% of patients, which would be incompatible with a vascular or ischemic hypothesis. This premonitory phase consists of mood changes, thirst, food cravings, excessive yawning, and drowsiness. The brain location from which a migraine attack is initiated is still unclear, but brainstem and hypothalamic generators have been proposed (Weiller et al. 1995; Zurak 1997).

The observations on spreading oligemia led to a resurgence of the central or neuronal theories of migraine. Briefly, the phase of oligemia demonstrated during the aura of migraine by the tomographic blood flow techniques begins in one occipital pole and spreads forward over the ipsilateral hemisphere at a rate of about 3—4 mm per minute. The area of reduced cerebral blood flow does not correspond to the distribution of any particular cerebral artery but crosses the areas perfused by the middle and posterior cerebral arteries while advancing with a distinct wave front until some major change in cortical cellular architecture is reached (e.g., at the central sulcus). Recently, the description of a patient with migraine without aura who had an attack during positron emission tomography (PET) proved beyond a doubt the phenomenon of spreading oligemia (Woods et al. 1994). This study suggested the possibility that blood flow changes may occur in migraine with and without aura because this patient had only ttansient and mild visual blurring, a ubiquitous symptom in migraineurs. This slow, deliberate march of a wave of oligemia brings to mind two old observations. Lashlcy, in 1941, studying his own scintillating scotoma, postulated on purely theoretical grounds that it must have been due to a change spreading over his occipital cortex at about 3 mm per minute. In 1944, Leao, during his research on epilepsy, observed a wave of cortical electrical depression passing over the exposed brain of lower animals. Activating the posterior cortex of rats started a wave of electrical depression that moved out from the point of initiation at a rate of 3-4 mm per minute.

The spreading depression noted by Leao's and Lashley's observations led to the hypothesis th.it the aura of migraine is primarily a neuronal event that causes the cortical circulation to close down in response to decreased metabolic requirements. Although spreading depression has not been documented to occur in human cortex, functional MRI studies have been strongly supportive. There is also a body of evidence suggesting the presence of a disturbance in energy metabolism in both the brain and extraneural tissues

of patients with migraine. Based on abnormalities identified in the mitochondrial respiratory chain and matrix enzyme activities from the muscle and platelets of patients with migraine, it has been proposed that the defect in brain energy metabolism is due to abnormal mitochondrial oxidative phosphorylation (Welch and Ramadan 1995). In support of these findings, interictal phosphorus-31 magnetic resonance spectroscopy (MRS) studies have shown reduced phosphocreatine levels and phosphorylation potential and increased adenosine diphosphate levels in the occipital lobes of migraineurs. Phosphorus-31 MRS studies done during the ictal phase reveal depletion of high-energy phosphates without an accompanying change in intracellular pH, indicating that the energy failure results from defective aerobic metabolism rather than from vasospasm with ischemia.

In addition, there is increasing evidence to support the presence of both systemic and brain magnesium deficiency in migraineurs, particularly in the occipital lobes (Welch and Ramadan 1995). Magnesium normally maintains a strongly coupled state of mitochondrial oxidative phosphorylation. Magnesium also plays an important role in "gating" N-methyl-D-aspartate (NMDA) receptors. A magnesium deficit can therefore result in an abnormality of mitochondrial oxidative phosphorylation and lead to a gain in NMDA receptor function, thereby causing an instability of neuronal polarization because of a loss of ionic homeostasis, This would then lead to a state of neuronal hypcrcxcitability and a lower threshold for spontaneous depolarization.

Spreading depression might therefore be more aptly described as spreading activation, followed by a wave of spreading depression. This would support the clinical oils,.•!••..ilior nf "prisitiw" visual "scnltilhnnns" followed by a "negative" visual scotoma or by the march of positive sensory (paresthesia) symptoms. This theory may also explain why spreading oligemia may be preceded by focal hyperemia. These findings taken together suggest that the changes in blood vessel caliber and blood flow may be due to a primary neuronal event, triggered by enhanced neuronal excitability and susceptibility to spontaneous depolarization, resulting in prolonged hypometabolism because of an impairment in energy metabolism caused by mitochondrial dysfunction. This hypothesis has also been supported by the finding of increased interictal lactate levels in the occipital cortex of migraineurs using proton MRS (Watanabe et al. 1996).

The theory that the migraine aura is a primary neuronal event was further strengthened by a recent study, which demonstrated no change in the apparent diffusion coefficient on diffusion-weighted MRI despite a reduction of regional cerebral blood flow during spontaneous migraine aura. Because diffusion-weighted MRI is very sensitive to tissue ischemia, the authors concluded that the reduction in cerebral blood flow was not of sufficient magnitude to cause tissue ischemia (Cutrer et al. 1998).

Platelets and Serotonin. Platelets obtained from migraineurs are known to aggregate more readily than normal in response to exposure to several vasoactive amines, including serotonin (5-hydroxytryptamine), adenosine diphosphate, catecholamines, and tyramine. It is also known that platelets contain most of the serotonin normally present in blood and that at the onset of an attack of migraine there is a significant rise in plasma serotonin concentration followed by an increase in the concentration of urinary 5-hydroxyindoIcacetic acid, a breakdown product of the serotonin. Platelet aggregation is necessary for its release. The plarelets of migraineurs, even between attacks of migraine, contain less monoamine oxidase than normal, and a furthct decrease occurs with an attack of headache.

Although the platelet may not have a direct role in the biochemical changes that appear to underlie the basic pathogenesis of migraine, it has been extensively studied because of its similarities to serotonergic nerve terminals.

The role of serotonin in migraine has yet to be fully defined. It constricts large arteries and is a dilator of arterioles and capillaries; also, perhaps of more importance, it is a neurotransmitter. Serotonin-containing neurons are especially concentrated in the brainstem raphe, the projections of which have a widespread distribution to other neuronal centers and cerebral mierovessels. The importance of the brainstem in migraine is still uncertain. Its role is certainly highlighted by the presence of binding sites for specific antimigraine drugs and the demonstration of persistent brainstem activation during and after a migraine attack, as imaged by PET (Weiller et al. 1995). Moreover, recurrent migraine headaches were precipitated in a nonmigraincur after a stereotactic procedure produced a lesion in the dorsal raphe and periaqueductal gray matter, which is part of the endogenous antinociceptive system. Welch et al. (2001) have recently found evidence for simultaneous activation of red nucleus, substantia nigra, and occipital cortex during provoked attacks with a visual irinv.i..-.rior •-unuliizm. This was demonstrated using hood oxygen level-dependent functional MRI, which revealed hyperoxia in these regions. Furthermore, serotonergic circuits are believed to be involved in the modulation of sleep cycles, pain perception, and mood, all of which are important factors in migraine syndrome.

Interest in the role of serotonin in migraine and the recognition of multiple subtypes of serotonin receptors has led to the development of a number of agents having high affinities for specific receptors. This has revolutionized the field of migraine therapeutics (for more details, see Acute Menstrual Migraine Therapy, later in this chapter).

Mechanism of the Headache. Although the aforementioned data strongly suggest that the initiation of a migraine attack is centrally driven, this docs not adequately explain the mechanism of the head pain. Pain-sensitive intracranial structures, including large cerebral blood vessels, pial vessels, dura mater, and large venous sinuses, are

innervated by a plexus of largely unmyelinated fibers that arise from the ophthalmic branch of the trigeminal nerve. Once this trigeminal vascular system is activated, impulses are transmitted centrally toward the fitst synapse within lamina I and ITo of the trigeminal nucleus caudal is (TNC), which extends to the dorsal horn of C2-C3. Activation of neurons in the TNC is reflected in the increased expression of *c-fos* (an immediate early gene) activity. From this point, nerve impulses travel rostrally to the cortex via thalamic relay centers.

In addition to central transmission, there is evidence that neuropeptide transmitters are antidromically released from the widely branching perivascular trigeminal axon nerve terminals. These neuropeptides, including substance P, calcitonin gene-related polypeptide, and neurokinin A, mediate a neurogenic inflammatory process that can activate nociceptive afferents, tesulting in the central transmission of pain impulses. Neurogenic inflammation consists of vasodilatation, vasculat endothelial activation with formation of microvilli and vacuoles, increased leakage of plasma protein from dural vessels into sutrounding tissue, increased platelet aggregation, mast cell degranulation, and activation of the local cellulat immune response, A series of elegant experiments have suggested that the pain of migraine may be due to neurogenic inflammation, which would ako explain the changes in serotonin and platelet serotonin repotted in migraine (Moskowitz and Cutrer 1994).

The importance of neurogenic inflammation in the production of the pain of migraine is supported by the fact thai Il;.V:lL.;I u:is 1:1.11 block neurogenic inflammation and mediate vasoconstriction are successfully used to abort a migraine attack. Neurogenic plasma extravasation can be inhibited by the ergot alkaloids, indomethacin, acetylsalieylic acid, valproic acid, and the new highly selective serotonin (5-HT,) teceptor agonists, which are discussed under Symptomatic Treatment, later in this chapter. However, neurogenic inflammation by itself is probably not the sole mechanism of pain because treatment with selective inhibitors of neurogenic inflammation has uniformly failed in the clinic (May and Goadsby 2001).

Ergotamine compounds and the "triptans" also act centrally to inhibit the activity of neurons within the TNC, which may be important in the termination of an attack. Whether these drugs act on the postsynaptic neuron in the TNC is unclear.

Activation of the trigeminal sensory system is reflected by the development of cutaneous allodynia in most patients during migraine attacks. The underlying mechanism is sensitization of centra! trigeminal neurons (Burstein et al. 2001). Triptans can prevent, but not reverse, cutaneous allodynia in patients and central sensitization in animals, and the presence or absence of cutaneous allodynia can be used as a marker to predict whether triptans would be able to abort a given migraine attack (Burstein et al, 2002). Repeated quantitative sensory testing of patients with migraine was done (1) early in a migraine attack (triptans given before cutaneous allodynia) and (2) late in a migraine attack (triptans administered after cutaneous allodynia). In attacks without allodynia, triptans completely relieved the headache and blocked the development of allodynia. However, in 90% of attacks with established allodynia, triptans provided little or no headache relief and did not suppress allodynia. However, late triptan therapy abolished the throbbing quality of the pain and its worsening upon bending over (peripheral sensitization) in the 90% of attacks in which pain relief was not complete and allodynia was not suppressed.

A link between the migraine aura and headache has now established that cortical spreading depression (CSD), implicated in migraine visual aura, activates trigeminovascular afferents and evokes a series of cortical meningeal and brainstem events consistent with the development of headache (Bolay et al. 2002). By using laser speckle-contrast imaging, CSD was shown to cause long-lasting blood flow enhaiiccniem selective!) within the middle meningeal artery dependent upon trigeminal and parasympathetic activation. CSD has also been shown to lead to plasma protein leakage within the dura mater. This neuroinflammatory response to CSD may be in part due to an upregulation of inducible nitric oxide synthase and inflammation (Reiner et al. 2002). These findings provide a neural mechanism by which extracerebral cephalic blood flow and neurogenic inflammation are coupled to a cortical neuroelectric event.

Summary. A unified hypothesis for the pathogenesis of migraine is as yet unavailable. It appears that the susceptibility[7] to migraine is hereditary and that the migrainous brain is qualitatively and quantitatively different from the nonmigrainous brain. These differences produce a threshold of susceptibility governed by factors that lead to neuronal hyperexcitahility and a tendency for spontaneous depolarization. These laciors may include a deficit in mitochondrial oxidative phosphorylation, an alteration in neuronal voltage-gated calcium-channel function, an intracellular magnesium deficiency, or a combination thereof. Neuronal excitability may be responsible for the phenomena of spreading activation and depression, with subsequent changes in regional cerebral blood flow. In animal models, blockade of IVQ calcium-channel function within the periaqueductal grey leads to burst activity within the TNC. furthermore, spreading cortical depression can directly activate trigeminal vascular nociceptive afferents. These findings provide an anatomic and physiological explanation for how intrinsic brainstem dysfunction or a cortical neuroelectric event can produce trigeminal activation. Once activated, trigeminal nociceptive afferents can generate neurogenic inflammation via the antidromic release of neuropeptides from the axon terminal of nociceptive trigeminal fibers that innervate meningeal blood vessels. The TNC also receives impulses from trigeminal vascular afferents, which are activated by sterile perivascular

neurogenic inflammation. This two-way system could account for migraine that is triggered either from the vascular system by vasodilator substances or arteriography or from die central mechanism of cortical spreading depression or activation of brainstem pain modulatory centers.

Treatment and Management

When a diagnosis of migraine is made, the nature of the disorder should be explained to the patient and reassurance given that it is a painful but generally benign condition that can, in most instances, be controlled or alleviated. The lack ol a cure for migraine should be mentioned, li is important that patients be made to feel that the physician understands that their headaches are a legitimate medical problem and does not consider their headaches to arise from psychological factots. A normal CT or MRI scan offers considerable reassurance. Many patients are more interested in knowing that they do not have a brain tumor or other potentially lethal condition than they are in obtaining relief from the pain.

Avoidance of trigger factors is important in the management of migraine, but -.imply advising a patient to avoid stress and relax more is usually meaningless. Advice to reduce excessive caffeine intake, to stop smoking, and to reduce alcohol intake may be more useful. Current medication use should be reviewed and modified if necessary. The use of drugs known to cause headaches, such as rcserpine, indomethacin, nifedipine, theophylline derivatives, caffeine, vasodilatots (including the long-acting nitrates), and alcohol, should be discontinued or other agents should be substituted if possible. Use of estrogens and oral contraceptives should be discontinued if they are suspected of contributing to the headaches, although in some patients this may not be possible. Exercise programs to promote well-being, correction of dietary excesses, and avoidance of prolonged fasts and irregular sleeping habits can be helpful.

The topic of dietary factors in migraine is difficult. Radical alterations in the diet are rarely justified and seldom effective. Avoidance of foods containing nitrites, such as hot dogs and pteserved cold cuts, and of prepared foods containing monosodium glutamate can be helpful. Avoiding monosodium glutamate can be difficult because it is a constituent of many canned and ptepared foods and is widely used in restaurants, especially in the preparation of Chinese dishes. Ripened cheeses, fermented food items, red wine, chocolate, chicken liver, pork, and many other foods have been suspected of precipitating headaches. These foods mostly contain tyramine, phenylethylamine, and ocltip.iiiiiii;-. All <uY;iM<!ii.il 'VMiriK ulriil ilii's an offending foodstuff, but in our experience, dietary precipitation of migraine is uncommon. Other headache authorities disagree. In some migraineurs attacks are precipitated by strong odors, especially of the perfume or aromatic type. Avoiding the use of strong-smelling soaps, shampoos, perfumes, and other items (e.g., fabric softeners and aftershave lotions! can be helpful for some individuals.

Kveryone is under stress at some time as part of living. People with migraine are not under more stress than any other group of the population, although their responses to stress may differ on the basis of personality and the effectiveness of their defense mechanisms. Many people react to stress by mechanisms that increase the blood pressure, increase the production of gastric acid, or produce symptoms of increased gastrointestinal motility. Others develop various dermatological conditions. The migraincur seems to react with the cerebral and cranial circulations by mechanisms that arc far more complex than this statement would imply.

Helping the patient deal with or avoid stress is difficult. It may be helpful to use a minor tranquilizer or sedative if the response to stress is overwhelming and if the source of the stress is temporary. Long-term stress management requires the help of a psychologist or other appropriately trained professional. Many techniques are used, including biofeedback, relaxation training, and hypnosis. There is evidence that biofeedback, relaxation training, and cognitive behavioral training are useful (Campbell et al. 2000)

Pharmacotherapy. Medical therapy can be administered prophylactically to prevent attacks of migraine or symptomatically to relieve the pain, nausea, and vomiting of an attack. Prophylactic therapy is needed when the frequency or duration of attacks or the dread of attacks seriously interferes with the patient's lifestyle. Other indications for prophylaxis include the occurrence of severe or prolonged neurological symptoms or a lack or response to symptomatic treatment. In general, a prophylactic program should be considered if attacks occur as often as 1 day per week.

Symptomatic Treatment. Symptomatic treatment should usually be started as early in the development of an attack as possible. If an aura is recognized, patients should take most medications during it rather than waiting for the pain to begin. One exception is the subcutaneous form of sumatriptan, which is less effective if taken before the onset of the headache phase. It must be recalled, though, that once the attack is fully developed, otal preparations are almost always less effective because of decreased gastrointestinal motility and poor absorption. If vomiting develops, oral preparations are no longer appropriate.

For many patients, a simple oral analgesic, such as aspirin, acetaminophen, naproxen, or ibuprofen, or an analgesic combination with caffeine may be effective. Caffeine aids absorption, helps to induce vasoconstriction, and may reduce the firing of serotonergic brainstem neurons. However, the use of caffeine-containing combination analgesics more than 2 days per week may lead to increased incidence of headaches. The addition of 10 mg of metoclopramide by mouth may be helpful with any simple analgesic regimen. The patient should rest in a dark, quiet

room with an ice pack on the head, which provides the best situation for the analgesic to relieve the pain. If sleep occurs, the patient often awakens headache free. In some countries, walk-in headache clinics provide a patient with a simple analgesic, an antinausea agent, and a place to sleep for a few hours. In North America, both patients and physicians have come to expect a quick fix; thus, stronger and stronger analgesics and other drugs have been given to those with a headache. Drug addiction is a major problem in some patients who are treated this way. Induction of sleep, control of nausea, simple analgesics, and other non-narcotic agents should be more widely used.

Although increasingly less available, and supplanted in some cases by newer agents, ergot preparations remain important in the symptomatic treatment of migraine. The actions of ergotamine tartrate and other ergot preparations are complex. They are both vasoconstrictors and vasodilators, depending on the dose and the resting tone of the target vessels. Internal and external carotid vessels are believed to read differentl) to therapeutic doses ol these preparations. The external carotid vessels are constricted by ergot preparations. There is no convincing evidence that the internal carotid vessels are similarly affected. The ergot preparations probably exert their effects on migraine via agonist activity at 5-HT receptors. The use of ergotamine tartrate in migraine necessitates intelligent administration by both patient and physician if it is to be effective and if side effects are to be minimized. Oral preparations arc far less effective than those given rectally or parcnterally.

It is important to know the amount of ergotamine in the various preparations and to be familiar with the dose limits and the signs and symptoms of ergotism. Table 75.6 shows the composition and strength of some ergotamine preparations available in the United States. Evidence for the efficacy of these agents in the treatment of migraine is largely based on uncontrolled clinical observations.

When available to the patient, 2 mg of ergotamine tartrate should be administered by mouth as soon as the patient recognizes the symptoms of an acute migraine attack. This dose can be combined with a simple oral analgesic-caffeine combination, and the ergot preparation can be taken again in 1 hour. Possibly a better regimen, but one that is inconvenient and unpleasant to some patients, is to administer ergotamine tartrate by rectal suppository. At the onset of the aura or pain, a 1- or 2-mg rectal suppository of ergotamine tartrate should be inserted and a simple analgesic taken orally. The etgot preparation can be given again in 60 minutes. Expeticnce in the course of several artacks can be used to determine the amount of ergotamine needed to obtain relief. With subsequent attacks, the entire dose can be taken at the onset. If nausea is troublesome, metoclopramide in doses of 10 mg orally aids absorption of the ergotamine tartrate and may prevent vomiting. For patients who are close to vomiting or who are vomiting, an antiemetic suppository, such as chlorpromazine (25-100 mg) or prochlorperazine {25 mg), can be helpful. Analgesics in rectal suppository form include aspirin and acetaminophen, either of which may provide some relief.

With frequent attacks of migraine, care musr be taken to avoid the vicious cycle wherein ergotamine is used so often that the drug-induced vasoconstriction is almost continuous. If this occurs, a lew hours of abstinence from ergotamine leads to relative vasodilatation and results in a withdrawal headache. Such patients often awaken with a vascular headache, obtain relief with a further dose of ergot.inline, arid thus perpetuate the vicious cycle. A sntiil.it-phenomenon can occur with caffeine in people dependent on coffee or caffeine-containing soft drinks. If more than 6 mg of ergotamine is required per week, an alternative preparation should be used.

Ergotamine must be used cautiously in patients with hypertension and in those with peripheral vascular disease. It is contraindicated in patients with coronary artery disease and in women who are pregnant. Administration of ergotamine to patients in whom the aura is particularly prolonged or characterized by a major neurological deficit is also considered unwise. The fear of potentiating the vasospasm to the point of cerebral infarction may be unjustified, but the potential risk can be avoided by withholding potent vasoconstrictors. As an alternative to ergotamine in the symptomatic treatment of migraine, the sympathomimetic agent, isometheptene mucare, is useful. Ir is available in proprietary preparations combined with acetaminophen and dichloralphenazone. It has the advantage of not increasing nausea and of being well tolerated, but it may fail to give relief for severe attacks.

Dihydroergotamine (DHE) has been used for Treatment of migraine since the 1940s. Its poor oral bioavailability limits its administration to the parenteral and intranasal routes (Tables 75.7 and 75.8). Patients can be readily taught to self-administer this drug by each of these routes. This medication should be considered when nausea and vomiting limit the LSL- ol" oral medications or when other medications are ineffective. Although the effect of DHE is slower than that of sumatriptan (see Table 75.8), it does have similar efficacy after 2 hours, and it is associared

with a lower recurrence of headache in 24 hours. It is associated with increased nausea in some patients, and it may need to he comhined with an antiemetic agent. When given intravenously in an acute medical care setting, the use of an antiemetic is mandatory.

IViptans. The developmcni "1 sumatriptan heralded a new class of antimigraine agents that are highly selective at certain 5-HT receptors. These agents, sometimes called *triptans,* together with the less selective ergot preparations, have strong agonist activity at the 5-HT] 15 receptor, which mediates crania! vessel constriction, and at the $5\text{-}HT_m$ receptor, which leads to inhibition of the release of sensory neuropeptides from perivascular trigeminal affcrents. The CNS is largely impermeable to sumatriptan, and hence its action is presumably in the periphery. However, it has hecn shown experimentally that activation of 5-HTm/5-HTn> receptors can also attenuate the excitability of cells in the TNC, which receives input from the trigeminal nerve. According'.v. newer 5 \ \'\\\-*J.*> H'l . .u;(.iri>ts act at central as well as peripheral components of the trigeminal vascular system, and at least part of their clinical action may be centrally mediated.

Sumatriptan can be administered orally, intranasally, and by subcutaneous injection (Table 75.9; see also Tables 75.7 and 75.8). Given as a 6-mg subcutaneous injection, either

self-administered using the manufacturer's auto-injector device or by conventional subcutaneous injection, sumatriptan resulted in significant pain relief at 1- and 2-hour time points after drug administration (see Table 75.8}. For subjects who had no significant pain relief after 1 hour, administration of a second dose of 6 mg provided little further benefit. Zoimattiptan is available as an oral and intranasal preparation.

There are now seven triptans available in the United States. All seem to have a beneficial effect on migraine-associated symptoms, including nausea, photophobia, and phonophobia, which also improves the patient's ability to return to notmal functioning. Table 75.9 provides a comparison of the currently available oral triptans. Side effects of sumatriptan by injection include local reaction at the injection sitc$_v$ usually of mild-to-moderate severity, and a transient tingling or flushed sensation that may be localized or generalized. A more unpleasant sense of heaviness or pressure in the neck or chest has also been described in a small percentage of recipients. It rarely lasts more than a few minutes and is generally not associated with electrocardiogram changes or other evidence of myocardial ischemia. However, because sumatriptan has been shown to produce a minor reduction in coronary artery diameter, it should be used with caution in patients who have significant risk factors for coronary artery disease and should not be given to patients with any history suggestive of coronary insufficiency. It is also contraindicated in patients with untreated hypertension or peripheral vascular disease and in those using ergot preparations. It should not be given to women during pregnancy or lactation or to patients with hemiplegic or basilar migraine.

The potential side effects of all the oral triptans are quite similar. They consist of tingling, flushing, and a feeling of fullness in the head neck or chest.

In general, both the indications and contraindications for these newer 5-HTj agonists are the same as those for sumatriptan. They have not been shown to he safe when administered within 24 hours of ergot preparations or other members of the triptan class.

At this time, there is no evidence to allow accurate prediction of which of these agents will be most effective in a given patient. A few practical guidelines can be given based on the clinical situation and knowledge about available agents. If severe nausea or vomiting occurs early in an attack, the parenteral or intranasal routes should be used. I-'or individuals whose headaches peak rapidly, almotriptan, rizatriptan, and zolmitriptan should be considered, given their early response rates. Some patients may prefer nasal or injectable routes (sumatriptan, DHE, and zolmittiptan). For patients with benign but intolerable side effects from this group of medications, naratriptan, almotriptan, or frovatriptan should be considered, given their favorable side effect profiles. Finally, i! [.here is recurrence of headache after initial relief, DHE, frovatriptan, or naratriptan should be considered. However, it must be remembered that after administration of a triptan, the use of another triptan or any ergotamine derivative within the next 24 hours is contraindicated. If one agent is used and fails, it seems reasonable, barring major side effects, to try another agent in the class.

There is evidence that some of these agents have a lower oral bioavailability when taken during acute migraine attacks than when taken intetictally. Accordingly, it is logical to consider combining these with metoclopramide to improve gastric emptying. Furthermore, experience suggests that coadministration with a nonsteroidal anti-inflammatory drug (NSAID) might be helpful, especially in individuals whose headache responded only partially or who tend to have a headache tceurrence after initial relief (Peroutka 1998).

Symptomatic treatment of migraine with typical aura is essentially the same as that desctibed previously, although subcutaneous sumatriptan is not effective if taken during the aura phase. Modification of the aura is rarely possible or needed.

For many patients, an attack of migraine becomes a harrowing experience. After a variable period, they go to an emergency room or physician's office expecting relief. These patients pose a difficult problem tor the physician. The simplest treatment and generally what the patient wishes or demands is injection of a combination of a opioid, most often meperidine (75-100 mg), and an agent for nausea, such as cblorpromazinc (25-50 mg), promethazine hydrochloride (12.5-25.0 mg), or prochlorperazine (5-10 mg). This is an effective treatment and one that can be used if the physician is sure the patient genuinely has a headache of major proportions. Unfortunately, the complaint of headache is all too easy to simulate as a drug-seeking behavior. The decision to treat with an opioid must be made in each case on the basis of the patient's behavior, the physician's knowledge of the previous history from emergency room records, and the local knowledge of the nursing and emergency room staff. Unfortunately, many patients with headache who report to emergency rooms are given less than adequate relief for fear of indulging drug-seeking behavior. To avoid using opioids, one can use neuroleptic agents acutely, with or without DHE. DHF, 0.5-1.0 mg, with metoclopramide, 10 mg by intravenous injection, is an effective treatment for acute headache and provides an alternative to the use of an opioid. Similarly, prochlorperazine, 10 mg intravenously over 3-4 minutes alone or combined with DHF, can be effective. Sumatriptan, 6 mg subeutaneously, may provide relief of both the headache and the associated symptoms. Some evidence points to the possibility of magnesium deficiency having a role in the pathogenesis of migraine, and intravenous infusion of 1 g of magnesium sulfate results in rapid relief of headache pain in patients with low serum ionized magnesium levels (Bigal et al. 2002). Alternatively, chlorpromazinc, 5 mg injected intravenously every 10 minutes to a maximum of 25 mg,

is also an effective agent when used acutely. The latter agent often produces hypotension, and patients should first receive a bolus of 250-500 mL of *5%* dextrose in one-half normal saline. (Dehydrated patients should always receive appropriate intravenous hydration.) Some patients develop acute extrapyramidal symptoms after treatment with neuroleptic agents. These can be treated with parenteral diphenhydramine, 25-50 mg. The neuroleptic agents do produce sedation, and patients should be advised not to operate a motor vehicle after treatment. Injectable ketorolac, 60 mg given intramuscularly, is another alternative to the narcotic or sedative agents. The use of this NSAID in elderly patients, those who are dehydrated, or those having any history of renal insufficiency should be avoided. A single dose of dexamethasonc combined with other parenteral antimigraine agents has been used for the emergency room treatment of attacks of intractable migraine.

When a migraine lias lasted for many days with little or no relief, the term *status migrainosus* has been used. Dehydration, tiredness due to lack of sleep, and continued pain may necessitate admission to a hospital to terminate the attack. Fluid replacement, correction of electrolyte imbalance, and suppression of vomiting with meto-L-lopi-.iniide. chlorpi'oina/ine, or prochlorperazine generally result in improvement. DHE combined with an antiemetic initially, given intravenous!) every S hours, may aborl migraine status. It is effective, but increased nausea and vomiting may be a reason to switch to an alternative regimen. Corticosteroids, such as dexamethasone or prednisolone, can be administered. A dose of prednisolone of 20 mg every 6 hours initially, followed by a rapidly tapering dose over 2-3 days, may help abort status migrainosus. It is best to avoid narcotic and benzodiazepine agents when treating status migrainosus.

Prophylactic Treatment. When the attacks of migraine occur weekly or several times a month or when they occur less often but arc very prolonged and debilitating, a preventive program is appropriate. Attacks of migraine that occur in a predictable pattern can also respond to prophylactic medication. For example, menstrual migraine can be treated in this way (see Prophylactic Menstrual Migraine Therapy, later in this chapter).

jS-*Adrenergic Blockers*

/J-Adrenergic antagonists are widely used for the prophylaxis of vascular headaches (Silberstein 2000). Propranolol is effective in *55-93%* of patients. These figures do not mean that the migraine attacks stopped but that the patients with responding headaches reported at least a 50% reduction in the frequency and severity of their attacks. In other studies, more than 50% of patients reported having a favorable response to a placebo.

Propranolol should be administered in doses of 80-240 mg per day and, if tolerated, should be given a trial of 2 to 3 months. Compliance is increased with the use of a long-acting form of propranolol that can be given once daily. Side effects are not usually severe. Lethargy or depression may occur and may be a reason for discontinuation of the medication. Hypotension, bradycardia, impotence, insomnia, and nightmares can all occur. As with all ^-adrenergic blocking agents, administration of propranolol should be discontinued slowly to avoid cardiac complications. It is contraindicated in people with a history of asthma and should be used with caution in patients using insulin or oral hypoglycemic agents because it may mask the adrenergic symptoms of hypoglycemia. The benefit of propranolol in migraine may be separate from its action as a /J-adrencrgic blocking agent, but its exact mechanism of action is unknown.

Almost all the available ^-adrenergic blocking agents have been tested for their potential use in migraine. Timolol, nadolol, atenolol, and metoprolol have each been shown to have approximately the same benefit in migraine as propranolol.

A n tidep ressa n ts

Amitriptyline and other tricyclic antidepressants can be helpful in migraine prophylaxis (Silberstein 2000), just as they are useful in the prevention of muscle contraction icnsitei! headaches. The benefit seems to lie independent of their antidepressant action. Blockade of noradrenaline uptake at catecholamine terminals and inhibition of serotonin reuptake may be related, but the action of antidepressants in migraine is unclear at present. Used in doses of 10-150 mg at night, amitriptyline, imipramine, desipramine, or nortriptyline may all provide some reduction in attacks of migraine, although evidence of efficacy in clinical trials is available only for amitriptyline. Side effects can be rather troublesome. Morning drowsiness, dryness of the mouth, weight gain, tachycardia, and constipation are common. The anticholinergic side effects may decrease with time. If tolerated, the tricyclic agents should be given a trial of at least 3 months after a therapeutic dose is reached. The optimal dose for migraine prophylaxis must be determined by titration to the effective or maximum tolerated dose within the therapeutic range (usually 40-150 mg).

The efficacy of newer antidepressants of the selective serotonin reuptake inhibitor type, such as fluoxetine and sertraline, has not been consistently demonstrated in clinical trials, and these drugs have a relatively limited role in the prophylaxis of migraine. Headache is a common side effect of several drugs in this class of antidepressants.

Use of the monoamine oxidase inhibitor (MAOI) phenelzine for migraine prophylaxis is based on the agent's inhibiting the breakdown of serotonin, which would thereby continue to act as a constrictor of cranial vessels. Unfortunately, the dietary restrictions that must be carefully followed if a hypertensive crisis is to be avoided limit

the widespread use of these inhibitors for prevention of migraine, h'or patients with particularly severe and intractable attacks, the MAOIs should be considered. The patient must be given a list of a mine-containing foodstuffs to he avoided, such as strong cheese, red wine, beer, yeast products, cream, broad beans, fermented foods, yogurt, and many others. Dangerous drug interactions can occur with preparations such as sympathomimetic agents, L-dopa, central anticholinergics, tricyclic antidepressants, and opioids, especially meperidine. Side effects of MAOIs include hypotension as well as hypertension, agitation, hallucinations, retention of urine, and inhibition of ejaculation,

Calcium-Channel Blockers

The calcium-channel antagonists prevent spasm of arteries by inhibiting contraction of smooth muscle. Although the relevant mechanism by which they affect migraine is not known, their use in migraine was originally based on their ability to prevent vasoconstriction and on their other actions, including prevention of platelet aggregation and alterations in release and re-uptake of serotonin. Several clinical trials have indicated some benefit for verapamil, nimodipine, and tlimari/.inc in preventing recurrent migraine. Nifedipine seems to cause a generalized headache as a side effect and has little to add to migraine prophylaxis. Verapamil in doses of 80-160 mg three times a day reduces the incidence of migraine with aura, but it is not as useful in migraine without aura. Experience with diltiazem is too limited to permit an assessment of its value at this time.

Anticonvulsants

Over the past several years, anticpileptic drugs have been the fastest expanding class of drugs in the prophylactic arsenal for migraine. Although the mechanism by which the drugs act in migraine prevention is not known, they are all modulators of the y-aminobutyric acid system.

In the early 1990s sodium valproate was shown in several blinded, placebo-controlled studies to have a beneficial effect in the prophylactic treatment of migraine (Silberstein 2000). Fifty percent of patients showed a response with a 50% or better reduction in migraine incidence. Valproic acid is usually given in the form of divalproex sodium and is generally effective at a range of 500-1750 mg per day taken in divided doses. Side effects include sedation, dizziness, increased appetite, increased bleeding time, increased fragility of hair, and an asymptomatic increase in liver function test values. Valproate should not be used in women who are at risk of becoming pregnant because it is associated with an increased risk of neural tube defects in the infants of women taking it during the first trimester. Gabapentin has been shown to be effective in the reduction of migraine incidence (Mathew ct al. 2001), It also has beneficial effects in somatic pain and may be a good choice if a patient has neck pain, back pain, or painful peripheral neuropathy as well as migraine. It appears to be relatively well tolerated although dizziness and sedation may limit its use in some patients. The therapeutic dose range for gabapentin is 600-2400 mg per day. Topiramatc is the most recent addition to the antimigraine armamentarium. Its efficacy for migraine has been demonstrated in several small blinded series (Storey et al. 2001). Topiramate has effects not only on y-aminobutyric acid but also on non-NMDA glutamate and carbonic anhydrase activity. It may have prominent sedating and cognitive side effects, making a slow gradual titration of the drug (15 mg per week initially) to the therapeutic range of 70-200 mg per day the most successful strategy. Other side effects include paresthesia and weight loss, the latter making topiramate a particularly attractive choice for many patients. It is also associated with a mildly increased risk nl kidney stones.

Serotonergic Agents

Methysergidc may be an effective prophylactic agent for all types of vascular headache. At this time, though, its manufacturer has ceased its production in the United States, and whether it will reappear is uncertain. Historically it has been a very useful agent despite its potential for producing serious complications, such as retroperitoneal, pulmonary, and heart valve fibrosis, which seriously limit its use as a long-term prophylactic agent. It should be reserved for the most intractable migraine and should be given for periods of only 6 months at a time. Between such courses, methysergide should be discontinued for 4 weeks. A clinical examination, urinalysis, and serum creatinine determination may be undertaken to detect any evidence of the fibrotic complications. Some authorities also advise obtaining a chest roentgenogram, scrum creatinine level, and an abdominal CT or MRI scan. If there are no signs of side effects, treatment with the drug can be restarted and continued for another 6 months. The incidence of fibrotic complications is low, perhaps 1 in 1000 patients. If fibrosis does develop, it may resolve if methyscrgide is immediately and permanently withdrawn, but this is not always the case.

Whenever methysergidc is prescribed, it must be started very slowly. A fraction of a 2-mg tablet is the initial dose, followed by a gradual increase ovet 7-10 days to the minimal effective dose, generally in the range of 6-8 mg in three or four divided doses per day. Rapid introduction of the drug leads to nausea, abdominal cramps, pain in the legs (possibly due to venospasm), hallucinations, and agitation. Methysergide is a derivative of lysergic acid *" diethylamide. It can act as a serotonin antagonist peripherally and as a serotonin agonist centrally, but its mode of action in vascular headaches is incompletely understood.

Cyproheptadine is also a peripheral serotonin antagonist. It also has weak antibradykiuin activity and prevents platelet aggregation. In adults, it has a minor role in the

prevention of migraine, but it is more effective in children. At all ages, it causes drowsiness and may cause significant weight gain.

Other Prophylactic Agents

Riboflavin administered orally in a dose of 400 mg per day has been shown to be effective in migraine prophylaxis in a prospective, randomized, controlled study that enrolled a relatively small number of subjects. The effect on the frequency of attacks was not statistically significant until the third month of the trial (Schocncn et al. 199S). There are minimal side effects associated with this treatment.

Oral magnesium supplementation has also been shown in double-blinded, placebo-controlled, randomized studies to be effective in migraine prophylaxis. Oral magnesium supplementation with 600 mg of a chelated or slow-release preparation is recommended. Magnesium-induced diarrhea and gastric irritation are the most common side effects (Mauskop and Altura 1998).

Aspirin, 325 mg taken every other day for the prevention of cardiovascular disease, reduces the incidence of migraine slightly. The NSAIDs have been tried for migraine prophyl.iM-„ wiili some bcnchl. 1 hoy arc, however, helpful for providing analgesia during the acute attack.

Botulinum toxin A injection in the treatment of migraine is supported by an increasing body of anecdotal evidence from small MTICS .iiul n conirulled •.iin.U ^i I bets: cm ci al. 2000b). The treatment may exert its effect by reducing the release of proinflammatory and vasodilating neuropeptides from nociceptive terminals. Botulinum toxin blocks the release of glutamate from nociceptive terminals and therefore may reduce or inhibit the development of peripheral and central trigeminal sensitization. Doses of up to 100 units ate injected in muscles of the forehead, as well as temporalis, splemus capitis, and trapezius. The effect, when it occurs, appears within 7-10 days and persists for up to 3 months. Side effects are minimal when lateral forehead injection is avoided. For patients who do not tolerate or do not comply with daily drug usage or who may prefer an injectable agent rather than chronic oral therapy, botulinum toxin may be a viable option.

Hormones and Migraine

Migraine occurs equally in both sexes before puberty, but it becomes three times more common in women after menarehe. Approximately 25% of women have migraine during their reproductive yeats. The changing hormonal environment throughout a woman's life cycle, including menarehe, menstruation, oral contraceptive LLSC, pregnancy, menopause, and hormonal replacement therapy (HRT), can have a profound effect on the course of migraine.

Menstrual Migraine. Migraine attacks are associated with menses in one of three ways. The attacks may occur exclusively during menstruation and at no other time during the cycle. This association is referred to as *true menstrual migraine* (TMM), and it has recently been proposed that TMM be defined as attacks that occur between days —2 and +3 of the menstrual cycle (MacGregor 1996). The incidence of TMM according to this definition is approximately 7%. Mote commonly, migraine attacks occur throughout the cycle but increase in frequency or intensity at the time of menstruation. This association occurs in up to 60% of female migraineurs. Finally, premenstrual migraine can occur between days —7 and —3 before menstruation as part of premenstrual syndrome or late-luteal phase dysphoric disorder. This disorder is characterized by a cluster of symptoms in the luteal phase, including depression, irritability, fatigue, appetite changes, bloating, backache, breast tenderness, and nausea. These different relationships between migraine and the menstrual cycle can reliably be determined by reviewing headache diaries, and their distinction is important because pathophysiology may differ as would the therapeutic approach.

Numerous mechanisms have been proposed to explain the pathogenesis of menstrual migraine. There is abundant clinical and experimental evidence to support the theory that estrogen withdrawal before menstruation is a trigger tor migraine in some women. Estrogen withdrawal may modulate hypothalamic /t-endorphin, dopamine, ^-adrenergic, and serotonin receptors. This complex relationship causes significant downstream effects, such as a reduction in central opioid tone, dopamine receptor hypersensitivity, increased trigeminal mechanorcceptor receptor fields, and increased cerebrovascular reactivity to serotonin, These changes, which occur during the luteal phase of the cycle, may be germane to the pathogenesis of menstrua] migraine,

Several lines of investigation have implicated both prostaglandins and melatonin in the pathogenesis of menstrual migraine. Prostaglandins and melatonin are important mediators of nociception and analgesia, respectively, in the CNS. The concenttation of prostaglandin F_2 and nocturnal melatonin secretion increase and decrease, respectively, during menstruation in female migraineurs. These observations are the basis for the clinical use of NSAIDs and melatonin for the prophylaxis of mensttual migraine.

Management of Menstrual Migraine, A direct link between menstruation and headache attacks must be established by asking the patient to keep a diary card of migraine attacks and menstrual periods for at least 3 consecutive months. The nature of this relationship determines subsequent therapy. For example, for patients who have both menstrual and nonmenstrual attacks (menstrua I-associated migraine), a standard prophylactic medication might be used throughout the cycle rather than the perimenstrual use of a prophylactic agent. The goals of therapy should be clearly outlined in addition to the

dosages, benefits, and side effect profile of each recommended medication. A headache dian should ideally be started by the patient in an effort to identify other nonhormonal triggers. Biofeedback and relaxation therapy can be helpful in selected patients and should be used whenever possible. Lifestyle factors, such as regular meals, sufficient sleep, and regular aerobic exercise, are important items to emphasize. These simple efforts can have a significant impact on the patient's headache burden and may limit the incidence of attacks that require pharmacological intervention.

Acute Menstrual Migraine Therapy. The goal of acute menstrual migraine therapy is to decrease the severity and duration of pain as well as the associated symptoms of an individual migraine attack, including nausea, vomiting, photophobia, and phonophobia. Some women may control attacks of menstrual migraine quite adequately with abortive therapy only (Figure 75.fi).

The acute management of menstrual migraine does not differ from the treatment of migraine unassociated with menstruation. Mild attacks (which are relatively rare) can hr managed with acetaminophen or NSAIDs. Moderatc-to-severe attacks can be treated by using an oral triptan. If there is significant nausea and vomiting, however, an alternate route of administration is necessary. In this setting, parenteral therapy with sumatriptan, DHE, ketorolac, or a neuroleptic, such as prochlorperazine, is appropriate. Alternatively, both sumatriptan and DHE are available in a nasal formulation and can he helpful in patients with significant gastrointestinal upset. The combination of an antiemetic with any of these medications may not only alleviate nausea and vomiting but may also potentiate the efficacy of these compounds.

Prophylactic Menstrual Migraine Therapy. Prophylaxis may either be perimenstrual (cyclic) or continuous (noncyclic) (Table 75.10). Many of the regimens suggested for perimenstrual migraine prophylaxis depend on regular menstruation. Perimenstrual prophylaxis commences a few days before the period is expected and is continued until the end of menstruation. In women whose cycles are difficult to predict, continuous prophylaxis with standard migraine prophylactic agents, such as tricyclic antidepressants and beta blockers, can be quite effective if taken continuously.

NSAIDs arc considered to be a first-line agent for both acute and prophylactic therapy in patients with either

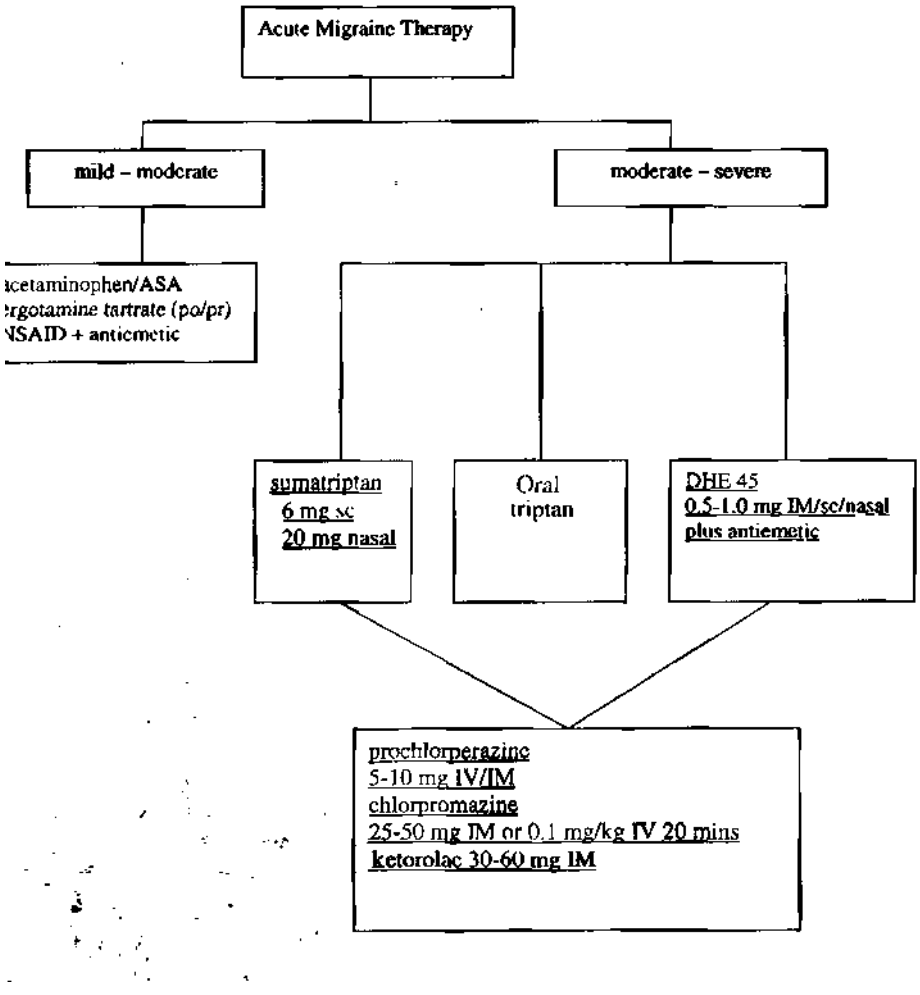

FIGURE 75.6 Algorithm for acute treatment of menstrual migraine. (ASA = acerylsalicylic acid: 1)1 II-. • dihydroergotamine; NSAID = nonsteroidal anti-inflammatory drug.)

Table 75.10; Nonhormonal prophylaxis for menstrual migraine

Cyclic (perimenstrual) days —3 through +3
- Nonsteroidal anti-inflammatory drugs
  - Naproxen sodium 5.50 nig hid
  - Mefenamic acid 250 mg tid
  - Ketoprofen *IS* mg tid
- Triptans and ergots
  - Sumatriptan 25 mg tid
  - Narairiptan 1.0 mg tid or 2.5 mg bid
  - Frovatriptan 2.5 mg once daily
  - Zolmitriptan 2.5 mg bid
  - Ergotamine tartrate + caffeine (Wigraine) 1 mg qhs or bid
  - Dihydroergotamuie 0.5-1.0 mg (SC, 1M, or intranasal) bid

Noncyclic (throughout cycle)
- Tricyclic antidepressants
  - Nortriptyline or amitriptyline 10-150 mg qhs
- Beta blocker
  - Propranolol or nadolol 40-240 mg daily
- Calcium-channel blocker
  - Verapamil 240-480 mg daily
- Anticonvulsant
  - Divalproex 250-500 mg bid
- Dopamine agonists
  - Bromocriprine 2.5-5.0 mg tid
- Oilier
  - Magnesium 360-600 mg daily

menstrua I-associated migraine or TMM when the timing of menstruation is predictable. Different classes of NSAlDs should be tried because response may vary in a given individual. Ergot derivatives in the form of ergotamine tartrate, etgonovine maleate, and DHE can also be effective when used as a symptomatic or prophylactic drug around the time of menstruation. Concerns about habituation or rebound headaches are minimal given the limited duration of treatment when used drugs are used perimenstrually.

For those with TMM, attacks can also be prevented by stabilizing estrogen levels during the late luteal phase of the cycle. Estrogen levels can be stabilized by maintaining high levels with estrogen supplements or by maintaining low levels that result from a natural or medically induced menopause (Table 75.11).

Estradiol implants, percutaneous estradiol gel, and estrogen patches produce reasonably stable levels of estrogen and rhcit use can be an effective preventive strategy. If periods are less predictable, suppression of the ovulatory cycle with high, static estrogen levels can be accomplished with either a low-dose combined estrogen-progestin oral contraceptive pill taken continuously for 3-4 months or with two 100-ug patches replaced every 3 days in combination with cyclic progestogens. Treatments that suppress the cycle by reducing estrogen levels (danazol), inducing a medical menopause (goserclin [Zoladexj), or modifying the effect of estrogen (tamoxifen) have also been anecdotally reported to be successful in the treatment of resistant menstrual migraine. They are not commonly used in clinical practice, howevct, because the menopausal side effects of these medications can be unpleasant. Theit use should be reserved for patients with recalcitrant migraine. Progesterone atone is ineffective in the treatment of menstrual migraine.

Table 75.11: Hormonal prophylaxis for menstrual migraine

Static high-maintenance levels
Transdermal estradiol (1 x 100 ug days —3/—1/+2)
Combined oral contraceptive or transdermal patch !.i 4 mosl
Percuraneous esrradiol (1.5 mg daily days —3 ro +6)
Static low-maintenance levels
Danazol 200-600 mg/day
Tamoxifen 5-15 mg/day (days 7-14 luteal cycle)
Goserclin (treatment limited to 6 mo)

Bromocriptine, a dopamine (D_2) receptor agonist, may decrease perimenstrual symptoms of breast engorgement, irritability, and headache when administered during the luteal phase of the cycle. Efficacy is enhanced, however, when the medication is used continuously throughout the cycle rather than perimenstrually (Herzog 1997).

The use of magnesium for the acute and prophylactic treatment of migraine and menstrual migraine has received considerable attention over the past few years. Low levels of systemic magnesium have been found in women with menstrual migraine, and MRS studies have demonstrated reduced lewis <1 mlI.KVIIUI.U magnesium in the cerebral cortex of migrameurs. Low levels of intracellular magnesium may lead to neuronal hypei excitability and spontaneous depolarization, which may be the central process by which a migraine attack is initiated. This has led some investigators to study the effect of magnesium on both the acute and prophylactic management of menstrual migraine (Mauskop and Altura 1998).

Some physicians still advocate the use of hysterectomy and oophorectomy in women with intractable PMS and menstrua] migraine whose headaches tespond to medical ovariectomy. There ;iu- no loiigicrni tulUm -up ur controlled studies to conclusively substantiate this position. Because no study has been placebo controlled, the positive results seen in some studies may reflect the daily postoperative use of estrogen. Although two thirds of women who have physiological menopause experience migraine relief, the opposite effect may occur with surgical menopause with bilateral oophorectomy. A retrospective study of 1300 women also demonstrated the unfavorable effects of surgical menopause on migraine (Granclla ct al. 1993). Therefore, until convincing evidence demonstrates otherwise, hysterectomy with or without oophorectomy is *not* currently recommended for women with menstrual migraine.

Oral Contraception in Female Migraineurs. Migraine prevalence is highest in women during their reproductive years, the very population who use oral contraceptive therapy. Oral contraceptives have a variable effect on migraine. Migtainc may begin *dc novo* after a woman starts taking oral contraceptives, pre-existing migraine may

worsen in severity or frequency, or the characteristics of the migraine attack may change. For example, aura symptoms may develop in a woman who for years may have had migraine without aura. On the other hand, migraine attacks may lessen after an oral contraceptive is started, particularly in women whose migraine attacks had a very close relationship to menstruation. In the majority of women, however, the pattern of migraine does not change appreciably alter ney a/irt raking .111 oral conrau'prive, particularly with the lower doses of estrogen and progestin now found in most oral contraceptives.

The concern ahout the use of synthetic estrogen in women with migraine pertains to the increased risk of ischemic stroke in this population, relative to age-matched women without migraine. There is now convincing evidence that female migraineurs have a greater risk of experiencing ischemic stroke. Tzourio and colleagues (19951 found migraine to be strongly associated with the risk of ischemic stroke in young women (odds ratio 3.5), and this association was independent of other vascular risk factors. The risk of ischemic stroke was particularly increased in women with migraine who were using oral contraceptives (odds ratio 13.9), were heavy smokers (odds ratio 10.2}, or who had migraine with aura (odds ratio 6.2). It has been estimated that the incidence of ischemic stroke in young women with migraine with aura who use oral contraceptives is 28 and 78 per 100,000 women aged 25-34 and 35-44, respectively. This is in contrast to the incidence of ischemic stroke of approximately 4 and 11 per 100,000 women in the general population in the same respective age groups. Although the relative risk of ischemic stroke is increased in this group, it is important to hear in mind that the absolute risks are still small.

The International Headache Society Task Force developed evidence-based recommendations for the use of oral contraceptives and hormone replacement therapy in migraineurs (Bousser et al. 2000). When prescribing combination oral contraceptives (COCs) in women with migraine, their recommendations were the following:

- Identify and evaluate risk factors.
- Diagnose migraine type, particularly the presence of aura.
- Recommend that women with migraine should stop smoking before starting COCs.
- Treat other conditions, such as hypertension and hyperlipidemia.
- Consider non-ethinylestradiol methods in women who are at increased risk of ischemic stroke, particularly in those who have multiple risk factors. Some of these contraceptives are as or more effective in preventing pregnancy than COCs and include progestogcn-only hormonal contraception. Observational studies suggest that progestogen-only hormonal contraceptive use is not associated with an increased risk of ischemic stroke, although quantifiable data are limited.
- High-dose COCs (>50 pg cthinylestradiol), particularly those containing first-generation progestogens, are no longer recommended for routine use.
- Low-dose formulations (<50 pg ethinylestradiol) containing either second- or third-generation progestogens should be used when possible. Second-generation progestogens include ethynodiol diacetate, levonorgestrel. and norethisteronc. Third-generation progestogens include desogestrel, gestodene, and norgestimate.

Migraine symptoms that may necessitate further evaluation or cessation of COC include the following:

- New pei sisting headache
- New onset of migraine aura
- Increased headache frequency or intensity
- Development of unusual aura symptoms, particularly prolonged aura

With respect to contraindications for the use of HRT, the Task Force concluded that there was no evidence proving that migtaine is a risk factor for ischemic stroke m women older than age 45. In addition, there are insufficient data to support an increased risk of ischemic stroke in women with any type of migraine who are using HRT. Consequently, the usual indications and contraindications for HRT should be applied.

Migraine and Pregnancy. Pregnancy has a variable effect on migraine. Although approximately 70% of women experience improvement or remission of migraine symptoms during pregnancy, the attacks can either remain unchanged or worsen. Moreover, migraine may even begin for the first time during pregnancy. Remission or improvement occurs more often in women with pre-existing menstrual migraine, whereas worsening is more common in those with a history of migraine with aura. The majority of women who develop migraine during pregnancy have migraine with aura. Although there is a trend for improvement in the second and third trimesters, there is no significant correlation between improvement or worsening of migraine and a specific trimester.

If remission occurs during pregnancy, migraine often recurs in the postpartum period, particularly 111 those with a history of menstrual migraine or migraine associated with estrogen withdrawal. Postpartum migraine occurs most often 3-6 days after delivery. As with pregnancy itself, migraine may first begin in the postpartum period, although this is a very rare occurrence.

The use of medication to treat migraine during pregnancy should be limited. For most tnild-to-moderate attacks, nonpharmacological treatment, including biofeedback, rest, and relaxation therapy, should be used. Acetaminophen may be combined with codeine, but the indiscriminate use of codeine may present a risk to the fetus during the first or second trimester.

For patients with severe attacks or status migrainosus, the risk to the developing fetus may be greater than the judicious of medications. The intravenous use of neuroleptics, supplemented with eithet intravenous opioids or corticosteroids, is an effective strategy for these patients. Either chlorpromazine or prochlorperazine (10 mg) delivered in 4 mL of crystalloid or 50 mL of normal saline as a bolus over 10-15 minutes can be effective for both the headache as well as the nausea and vomiting associated with a severe attack. Mcthylprednisolone (50-250 mg) delivered intravenously can also be an effective method to terminate a severe acute migraine attack or status migrainosus during pregnancy. Methylprednisolone is preferred over dexamcthasonc because the latter more readily crosses the placenta.

Migraine in Menopause. Just as with pregnancy, the effect of menopause on the course of migraine is somewhat unpredictable. Although in two thirds of women with a previous history, migraine decreases with a physiological menopause, migraine can either regress or worsen at menopause (Silberstein 2001), and in a minority of women, migraine or its functional equivalents may begin after menopause.

Women with menopausal symptoms resulting from erratic or diminished estrogen secretion may benefit from HRT. Few published studies have assessed the effects of HRT on migraine in perimenopausal women, but the evidence available appears to highlight the importance of both route and method of administration. With any preparation of estrogen, the lowest effective dose should be used. In general, parenteral or transdermal preparations provide a more physiological ratio of estradiol to estrone and a steady-state concentration of estrogen. They are also more suitable delivery systems for women with migraine or for those whose headaches are worsened by oral estrogen replacement therapy (Silberstein 2001). Also, continuous rather than interrupted HRT may be more effective in female migraineurs, particularly if their headaches had been associated with estrogen withdrawal.

Migraine may be worsened by the use of cyclic progestins. Tor women who require combined estrogen and progesterone therapy after hysterectomy, use of a transdermal progestin patch usually circumvents this problem.

Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster Headache

Among the many painful conditions that affect the head and face, the one known by the most names is also unique in several other respects. Cluster headache, Horton's headache, histaminic cephalalgia, or migrainous neuralgia, as the condition is variously known, is without doubt the most painful recurrent headache and the one that produces the most stereotyped attacks. Despite its readily recognizable features, the syndrome continues to be misdiagnosed as trigeminal neuralgia or sinus or dental disease and therefore is ineffectually treated.

Classification and Terminology

In episodic cluster headache, attacks of pain occur daily for days, weeks, or months before an attack-free period of remission occurs. This respite may last from weeks to years before another cluster of attacks develops. In *chronic* cluster headache, attacks of pain occur for more than 1 year without a remission longer than 2 weeks (ICD 10 Guide for Headache 1997). This chronic form of the disease may develop *de novo* or may evolve from episodic cluster headache. Chronic cluster headache can therefore be divided into primary and secondary chronic types.

Clinical Features

Cluster headache is predominantly a disease of men. Onset typically begins in the third decade of life although its onset has been described as early as 1 year of age and as late as the seventh decade.

Periodicity is a cardinal feature of cluster headache. In most patients, the first cluster of attacks, the cluster period, persists, on average, 6-12 weeks, and is followed by a remission lasting for months or even years. The duration of the cluster period is often strikingly consistent for a given patient. A common pattern is one or two cluster periods per year. With time, however, the clusters may become seasonal and then occur more often and last longer. During a cluster, the patient may experience from one to three or more attacks in 24 hours, and the attacks commonly occur at similar times throughout the 24 hours for many days. Onset during the night or 1-2 hours after falling asleep is common. In some patients, this may correspond to the onset of REM sleep. At times, several attacks per night can result in sleep deprivation in patients with chronic cluster headache, particularly when they avoid sleep fot fear of inducing a further attack. With increasing age, the distinct clustering pattern may be less recognizable. In some patients, perhaps as many as 10%, periods of relief become less common, and the condition enters the chronic phase in which attacks may occur daily for months or years. In these patients, the condition may persist into old age, but in nearly 50% the attacks eventually cease.

Whether the patient is in the episodic or the chronic phase of headache, the attacks of pain are identical for all individuals. The pain is strictly unilateral and almost always temains on the same side of the head from cluster to cluster; rarely, it may switch to the opposite side in a subsequent cluster. The pain is generally felt in the retro-orbital and temporal regions but may be maximal in the cheek or jaw (lower syndrome). It is usually described as

steady or boring and of terrible intensity (so-called suicide headache). Graphic descriptions of feeling the eye being pushed out, or an auger or hot poker going through the eye are very common.

Onset is usually abrupt or preceded by a brief sensation of pressure in the soon-to-be-painful area. An occasional patient may describe tension and discomfort in the limbs and neck ipsilateral to the pain, either during the attack or just preceding it. Aura symptoms (as seen in migraine) have been reported to precede cluster attacks (Silberstein et al. 2000a). The pain intensifies very rapidly, peaking in 5-10 minutes and usually persisting for 45 minutes to 2 hours. Toward the end of this time, brief periods of relief may be followed by several transient peaks of pain before the attack subsides over a few minutes. Occasionally, attacks last twice as long, or, even less commonly, the attacks may seem to merge together, producing 12 or more hours of pain. After the attack, the patient is then completely free from pain, but exhausted; however, the respite may be transient because another attack may occur shortly.

During the pain, patients almost invariably avoid the recumbent position because doing so increases the intensity of the pain. Unlike patients with migraine, they are restless and prefer to pace or sit during an attack. Some remain outdoors, even in freezing weather, for the duration of the attack. Otherwise rational persons may strike their heads against a wall or hurt themselves in some other way as a distraction from the intense head pain. Most patients prefer to be alone during [he attack. Some appl\ ice to the painful region, others prefer hot applications; almost all press on the scalp or the eye to try to obtain temporary relief. During the pain, many patients consider suicide; a few attempt it.

During the pain of cluster headache, the nostril on the side of the pain is generally blocked; this blockage in turn leads to ipsilateral overflow of tears caused by blockage of the nasolacrimal duct. The conjunctiva may be injected ipsilaterally, and the superficial temporal artery may be visibly distended. Profuse sweating and facial flushing on the side of the headache have been described but are rare. Nasal drainage usually signals the end of the attack. Ptosis and miosis on the side of the pain are common. This partial Horner's syndrome may persist between the attacks and is believed to be due to compression of the sympathetic plexus secondary to vasodilatation or other changes in the region of the carotid siphon. Photophobia during the painful stage is less common than in migraine, but it may occur and may be accompanied by phonophobia. Gastrointestinal symptoms are not usual features of cluster headache attacks. Although nausea occurs in up to 50% of patients, vomiting is rare (Bahra et al. 2002). In some patients, nausea may be due to the medication ingested. Facial swelling, most often periorbital, may develop with repeated attacks. Rarely transient localized swellings of the palate ipsilateral to the pain can be observed. More commonly, the patient complains that the palate feels swollen, but no abnormality can be detected by the examiner, even during an attack.

Patients with cluster headaches have a high incidence of duodenal ulceration and elevated gastric acid levels that may approach those found in the Zollinger-Ellison syndrome. They also tend to have coarse facial skin of the *peau d'oratvge* type, deep nasolabial folds, and an increased incidence of hazel eye color. Many of the patients are heavy cigarette smokers and tend to use more alcohol than age- and sex-matched control subjects.

Investigations

In most patients, the diagnosis is so certain on clinical grounds that special neurological investigations are unnecessary. However, imaging studies are warranted in any patient presenting with an atypical episodic cluster headache or for patients with headache in the chronic phase. As part of the management, however, it may be advisable to obtain a contrast-enhanced MRI scan to help reassure the patient and the relatives that the extremely painful attacks are not due to some major intracranial abnormality. On occasion, examination of the eyes should include measurement of the ocular tension to detect glaucoma. Tests of a general nature are needed to determine any conttaindications to the use of various medications.

Pathop bysiolog)'

The pathogenesis of cluster headache is not entirely understood. Any explanation for the etiology of cluster headache must account for the cyclically occurring attack-susceptible periods, The periodicity of cluster headache is probably related to hypothalamic dysfunction. Changes have been shown in the levels of melatonin, Cortisol, prolactin, ^-endorphin, and testosterone between cluster periods and remissions.

The most direct evidence in support for a role of the hypothalamus in cluster headache comes from neuroimaging. PET imaging studies showing activation in the ipsilateral ventral hypothalamic gray matter during nitroglycerin-induced cluster attacks (May et al. 1998). In addition, a morphometry study of MR] scanning technology has shown an increase in volume in the diencephalon corresponding to the inferior hypothalamus (May et al. 1999).

Although vasodilatation has been generally believed to be responsible for the pain. PET studies of experimental pain and cluster headache have shown that carotid artery dilation is not specific for cluster headache but is seen with other types of ophthalmic division pain; it appears ro he an epiphenomenon of a primary neural process (May et al. 1999). *

Moskowitz in 1993 emphasized the role of the trigeminovascular connections and substance P in the pathogenesis of vascular head pain. Further evidence suggested activation of the trigcminovascular system as manifested by increased levels of calcitonin gene-related peptide in blood

sampled from the external jugular vein ipsilateral to an acute spontaneous attack of cluster headache. Vasoactive intestinal polypeptide levels were similarly elevated in the cranial venous blood during a cluster attack, demonstrating activation of the cranial parasympathetic nervous system (Goadsby and Edvinsson 1994).

Several observations suggest that histamine may play a role in causing this condition. During painful attacks, increased histamine levels have been detected in the blood and urine, but whether this increase is a primary or secondary phenomenon remains unknown. Morphological studies of the increased number and abnormal distribution of mast cells in the forehead skin of patients with cluster headache support the ihcon thai local release ol histamine is involved in some way in this condition, F.vidence to the contrary, however, comes from the observation that blockade of H_r and H2-histamine receptors by antihistamine drugs has no effect on the painful attacks.

Epidemiology

Compared will: tension headache and migraine, the syndrome of cluster headaches is uncommon. In many headache clinic populations, migraine is 10-50 times more common than cluster headache. In the general population, the comparative percentages vary somewhat because people with migraine do not always seek help, whereas the intensity of cluster headache can rarely be endured in silence. Data from the Republic of San Marino showed a prevalence rate of cluster headache of S6 per 100,000 (prevalence rate for men of 115.3 per 100,000) with an incidence rate of 2.5 per 100,000 per year (Tonon et al. 2002).

The diagnosis of cluster headache is essentially clinical and depends on obtaining an accurate history from the patient. It is helpful to have confirmation from the spouse or relatives of the periodicity, rapidity of onset and resolution, and presence of conjunctival injection, rhinorrhea, ptosis, and altered behavior during the attack. Despite the stereotyped nature of the attacks from episode to episode and from patient to patient, the diagnosis is often missed for several years. Conditions that cause episodic, unilateral head and facial pain should be considered, but they are easy to exclude. Trigeminal neuralgia, sinusitis, dental disease, and glaucoma may superficially mimic the pain of cluster headache; however, in each, the temporal profile, lack of associated autonomic features, and past history allow easy differentiation. Similarly, migraine, temporal arteritis, and the headache of intracranial space-occupying lesions should not be difficult to differentiate from cluster headache. Episodic headache due to phcochroinocyronia or hypoglycemia produced by endogenous or exogenous insulin is likely to be bilateral and unaccompanied by tearing, nasal stuffiness, or ptosis. Orbital, retro-orbital, and frontal pain associated with incomplete Horner's syndrome can result from ipsilateral dissection of the carotid artery; unlike the pain of cluster headache, however, it is not episodic and does not produce the restlessness so characteristic of this condition. The pain associated with Tolosa-Hunt syndrome and Raeder's paratrigeminal syndrome is accompanied by oculomotor or trigeminal nerve dysfunction, a feature that should easily prevent confusion with cluster headache. Similarly, pain from compression of the third cranial nerve by an aneurysm should be easy to distinguish from cluster headache pain, especially when partial or complete third cranial nerve palsy is detected.

A number of primary headache syndromes collectively referred to as the *trigeminal-autonomic cephalalgias* may resemble cluster headache (Goadsby and Lip ton 1997). The trigeminal-autonomic cephalalgias are characterized by discrete, short-lasting, episodic attacks of intense, unilateral, orbital-temporal region pain with prominent ipsilateral autonomic features. These disorders differ mainly in the shorter duration and higher incidence of individual attacks. Interestingly, as attack incidence increases, attack duration tends to decrease. The differentiation between cluster headache and other paroxysmal hemicranias has important therapeutic implications. The paroxysmal hemi- i inm,is rypically respond dramaticall; to iiuloitie:l:aeiri therapy.

Treatment and Management

Care should be taken to reassure the patient that the syndrome, even though unbearably painful, is benign and not life threatening. Pain reduction but not cure should be promised.

The frequency, severity, and brevity of individual attacks of cluster headache and their lack of response to many symptomatic measures necessitate the use of a prophylactic program to-- most paiienls. 1'iie :ivaliucr:! plaa is dcier mined by several factors, including whether the phase of the disorder is episodic or chronic and whether other disease states, such as hypertension and coronary or peripheral vascular insufficiency, arc present.

Pharmacological Management

Acute (Symptomatic) Therapy. Given the rapid onset and short time to peak intensity of the pain of cluster attacks, fast-acting symptomatic treatment is imperative. Oxygen, subcutaneous sumatriptan, and subcutaneous or intramuscular DHE provide the most rapid, effective, and consistent relief for cluster headache attacks,

Oxygen delivered at a flow rate of 8-10 liters per minute via a nontebreathing face mask can he dramatically effective for aborting a cluster attack. Oxygen is believed to help because of its vasoconstrictor properties. Although portable regulators arc available, the major drawbacks to the use of oxygen are the inconvenience, lack of accessibility, and the need to have the regulator and cannister available at all times.

Administration of sumatriptan by subcutaneous injection in a dose of 6 mg is an effective means of aborting an individual cluster attack. However, preemptive treatment before the anticipated onset of an attack does not prevent the attack and, thus, the drug is not used for cluster headache prophylaxis. Sumatriptan nasal spray is less effective than the subcutaneous formulation.

DHE is available in injectable and intranasal formulations. DHE-45 administered intravenously provides prompt and effective relief of a cluster attack. The intramuscular and subcutaneous routes of administration provide slower relief. The potential role of intranasal DHE (2 mg) has not been validated in a controlled fashion.

Other potential symptomatic options include zolmitriptan and intranasal lidocainc administered by dripping 4% viscous lidocainc into the nostril ipsilateral to the pain.

Preventative Pharmacotherapy. Use of an effective preventative regimen cannot be overemphasized. The goals of preventative therapy are to produce a rapid suppression of attacks and to maintain a remission over the expected duration of the cluster period. Preventative therapy in cluster headache can be divided into transitional and maintenance prophylaxis.

Transitional Prophylaxis. Transitional prophylaxis involves the short-term use of corticosteroids, ergotamine, or DHE. This typically induces a rapid suppression of attacks while one of the maintenance agents can rake effect.

During the initial cluster, or when the patient's past history suggests that a cluster will be of limited duration, relief can usually be obtained by administering a short course of corticosteroids. Several regimens are effective, such as 60 mg of prednisone as a single daily dose for 3-4 days followed by a 10-mg reduction after every third or fourth day to thereby taper the dose to zero ovet IS or 24 days. Alternatively, an intramuscular injection of triamcinolone (80 mg) or methylprednisolone (80-120 mg) can be used to give a tapering corticosteroid blood level. Whichever program is used, the patient usually obtains relief from the headaches until the lower doses or blood levels of corticosteroids arc approached. The course can be repeated several times, but thereafter the risk of side effects suggests that an alternative prophylactic regimen should be used if the cluster has not tun its course.

Ergotamine tartrate can be given orally or by rectal suppository on retiring to prevent nocturnal attacks of headache. This approach may only postpone the attack until morning, when it may be more troublesome if it occurs when the patient is at work. Prophylactic use of ergotamine tartrate can nevertheless be valuable, but great care must be taken to regulate the dose if chronic ergotism is to be avoided. Most patients with cluster headache can be given 2 mg of ergotamine tartrate daily for several weeks withonl adverse effects. X.iii-i .i and peripheral paresthesias are common side effects of ergot regardless of the route of administration. DHE is a well-tolerated ergot derivative that can be given in a dose of 0.5-1.0 mg every 6-8 hours in an attempt to prevent headaches, but this dose should be continued for only a few days to avoid ergotism.

In addition, an occipital nerve block ipsilateral to the cluster headache may be useful as a transitional measure in some patients. This can provide temporary relief when the use of other medications may be contraindicated or poorly tolerated.

Maintenance Prophylaxis. Maintenance prophylaxis refers to the use of preventative medications throughout the anticipated duration of the cluster period. The preventative medication is started at the onset of the cluster period in conjunction with either corticosteroids or ergotamine derivatives, but these are continued after these initial suppressive medications arc discontinued.

The calcium-channel blockers, particularly verapamil, are considered first-line preventative therapy for both episodic and chronic cluster headache. They are generally well tolerated and can be used safely in conjunction with ergotamine, sumatriptan, corticosteroids, and other preventative agents. Doses in the range of 80-160 mg three times a day often result in a dramatic decrease in the frequency and intensity of attacks. Subsequent reduction in benefit can be overcome by an increase in dose or by a drug holiday, followed by reinrroduction of the agent. The favorable side effect profiles of the calcium-channel blockers make them a logical choice over the more toxic and troublesome agents, such as methysergide and lithium.

Methysergide in a dose ranging from 4 to 10 mg per day is effective for reducing or preventing cluster headache in about 60% of patients. The side effects, which include leg cramps, nausea, and fluid retention, are usually minor, and the drug seems to be better tolerated in patients with cluster headache than in those with migraine. The risk of retroperitoneal and other types of fibrosis is important only when methysergide must be taken for months or longer, For the episodic phase ol cluster headache. this drug nay be needed for only a few weeks; therefore, the risk of serious side effects is low. If methysergide gives relief, the lowest effective dose should be determined and the use of the preparation continued for 2^4 weeks after the last attack. It can be restarted if the headaches return after discontinuation. If the cluster period is very long or if the patient has chronic cluster headaches, methysergide can be taken for *2-6* months. It should be discontinued for 4 weeks, during which time an abdominal CT or MR1 scan, chest roentgenogram, and determination of serum creatinine level are recommended by some authorities. If the patient has no signs of fibrosis, treatment with methysergide can be continued for an additional 3-6 months, after which the drug should again be temporarily stopped. Unfortunately, as mentioned earlier, its manufacturer has ceased its production in the United States.

For patients who have chronic clustet headache with attacks that occur daily for years, relief may be obtained with lithium. Lithium carbonate, 300 mg three times a day,

can be given initially and the dose adjusted at 2 weeks to obtain a serum lithium level of about 1.0 mliq/liter. Side effects at this level include a mild tremor of the limbs, gasttointestinal distress, and increased thirst. The therapeutic range is very narrow, and blood levels of more than 1.5 mEq/liter are to he avoided. Nephrotoxicity, goiter formation, and a permanent diabetes insipidus-like state have been reported after lithium treatment. In chronic cluster headache, lithium may have a beneficial effect within 1 week; however, the response is typically delayed for several weeks. Although attacks may recur after some months, a renewed response to lithium may occur if the drug is withdrawn and then reintroduced after a few weeks. In patients whose headaches respond to lithium, use of the drug should be discontinued every few months to determine whether the cluster headaches have subsided. While lithium is being given, it is necessary to monitor the blood level at regular intervals to avoid the development of serious side effects. Thiazide diuretics should not be used concurrently because they can cause a rapid elevation of blood levels of lithium.

Despite the available treatments, management of patients wit!) chronic differ headache car, be extreme^ difficult because many of their headaches do not respond or respond only briefly to the programs already described. In such patients, a combination of several meditations may give relief. On the basis of clinical experience, the combination of verapamil and topiramatc or verapamil and lithium can prove quite effective. For particularly resistant headaches, triple therapy may be necessary, consisting of verapamil with methysergide or either topiramate or valproate plus lithium. Corticosteroids can be useful in chronic cluster headache to provide brief remissions for fixed periods. Nonetheless, long-term use of corticosteroids in patients with chronic cluster must be resisted.

In patients for whom conventional, first-line therapy is ineffective, poorly tolerated, or contraindicated, one may consider adjunctive therapy with a number of potential agents including intranasal capsaicin, indomethaeui, c hi or promazine, and clonidine (Dodick and Campbell 2001).

Surgical Treatment. Thirty to 50 years ago, injection of alcohol into the gassenan ganglion and trigeminal root section was used in the treatment of chronic migrainous neuralgia (cluster headache). These procedures did nor gain widespread acceptance and were gradually abandoned because of the high incidence of complications, including neuroparalytic keratitis, postoperative herpes keratitis, and anesthesia dolorosa of the denervated area.

Recently, interest has been renewed in the surgical relief of this condition. Onofrio and Campbell reported their results in a series of 26 patients with intractable chronic cluster headaches treated surgically. Their patients had radio frequency thermocoagulation of the gassenan ganglion or sensory root section of the trigeminal nerve through a posterior fossa approach. Approximately two thirds of the patients obtained excellent-to-good relief of pain. In most of the remaining patients pain was not relieved because of the production of incomplete first-division anesthesia, and in several subjects, pain persisted despite dense trigeminal sensory loss in all three divisions of the nerve. Keratitis and anesthesia dolorosa are serious complications of any procedure causing destruction of the trigeminal nerve. Thermocoagulation of the gasserian ganglion and injection of glycerol into Meckel's cave have been effective fot providing pain relief in this condition. More recently, stereotactic radiosurgery with the gamma knife under local anesthesia has been used to treat patients with chronic cluster headache refractory to medical therapy (Ford et al. 1998); unfortunately, this technique does have a significant failure rate. More recently, Frazini et al. (2003) reported a complete response in five patients with medically refractory chronic cluster headache after stereotactic implantation of a stimulating electrode into the periventricular hypothalami]",. The r.ttioiia!c tor ".his procedure is based on the activation of the periventricular hypothalamus seen on PET scanning of patients during attacks of cluster headache. The morbidity and adverse events of this procedure thus far appear to be minimal, but the long-term safety and durability of this procedure await long-term prospective follow-up data on these and other patients,

Indomethacin-Responsive Headache Syndromes

lndomethacin-responsive headache syndromes (IRHSs) represent a unique group of primary headache disorders that are characterized by a prompt, absolute, and often permanent response to indomethaein. IRHSs can easily be confused with cluster headache because of the facial autonomic features associated with individual headaches. In addition, attacks may occur during sleep and can be triggered by alcohol, features that also characterize cluster headache. However, IRHSs can be distinguished from cluster headache by their short duration, with the exception of hemicrania continua, and by the high frequency of attacks. Several other primary short-lasting headache syndromes respond either partially or entirely to indomethaein. although with less consistency. These include idiopathic stabbing headache and benign cough, exertional, and sexual headache, which arc described elsewhere in this chapter.

Paroxysmal Hemicrawas

The paroxysmal hemicramas are primarily disorders of young adults, with typical onset in the second and third decades. The female-to-male ratio is approximately 2 to 1, which in addition to the differences in attack profile (frequency and duration), contrasts with cluster headache for which there is an overwhelming male predominance.

Chronic and episodic paroxysmal hemicranias differ predominantly in their temporal profile. Chronic paroxysmal hemicrania, as the name implies, occurs daily, with multiple discrete attacks occurring throughout a 24-hour period. Episodic paroxysmal hemicrania is characrerized by bouts of attacks sepatated by remission periods. The headache bouts can range from 2 weeks to 5 months, and remission periods can last 1-36 months. Both disorders are associated with daily attacks of severe, short-lived, unilateral pain, which is often maximally felt in the orbital-periorbital or temporal region, although extratrigeminal pain in the ear or occiput can occur. The characteristic attack frequency is more than or equal to 5 per day (range, 1-40/day) (Boes and Dodick 2002). Each attack lasts approximately 20 minutes (range, 2-120 minutes). Similar to cluster headache, each paroxysm is accompanied by at least one robust ipsilateral autonomic feature, which may include lacrimation, ptosis, eyelid edema, conjunctival injection, nasal congestion, or rhinotrhea (Goadsby and Lipton 1997).

Hemicrania Continua

As the name implies, hemicrania continua is characterized by a continuous unilateral headache of moderate intensity that may involve the entire hemicranium or simply be confined to a focal area. The female-to-malc ratio is approximately 2 to 1, and the average age of onset is 28 years (range 5-67 years) (Peres et al. 2001). Although invariably continuous, this disorder may sometimes resemble a prolonged unilateral migraine attack lasting several days to weeks, with headache-frcc remissions. The continuous headache is often punctuated by painful unilateral exacerbations lasting 20 minutes to several days. Attacks may alternate sides, and unilateral attacks may rarely become bilateral. These periods of increasing pain intensity are often but not invariably accompanied by one or more autonomic features, which arc usually more subtle than that seen in the paroxysmal hemictanias or cluster headache. Stabbing head pains ("ice-picks") are often a feature of this disorder, usually on the ipsilateral side, and usually during a period of exacerbation. Because of its daily persistence, hemicrania continua may be seen in the context of medication overuse, which may alter the clinical features and affect the response to treatment. Therefore, a higher index of suspicion may be required in these cases.

Treatment

The response of IRHSs to indomethacin is often quite striking, although the mechanism is not yet understood. Despite this dramatic response, all patients require neuroimaging to exclude a structural cause because organic condirions that mimic IRHS have been desctibed. Indomethacin is effective in doses ranging from 25 to 300 mg daily. The usual starting dose is 25 mg three times daily with meals. The dose is titrated according to the patient's response and the side effect profile. A slow-release preparation is available for patients with nocturnal breakthrough headaches. A treatment response is usually seen within 48 hours. Tachyphylaxis is not a feature, but medication withdrawal is often met with recurrence of the headaches. Nevertheless, once an effective dose is achieved and maintained for several weeks, a tapering schedule is recommended in an effort to find the lowest effective dose possible, which often varies from patient to patient. If indomethacin is contra indicated or in the rare circumstance in which it is ineffective in treating paroxysmal hemicrania or hemicrania connnua, other medications, with anecdotal reports of success, may be tried. In paroxysmal hemicrania, these include celecoxib, NSAIDs (ibuprofen, ketoprofen, aspirin, piroxicam, naproxen, diclofenac, and phenylbutazone), calcium-channel blockers (verapamil, nicardipine, and flunari/.inc), corticosteroids, acetazolamide, crgotamine, and lithium. In hemicrania continua, there is anecdotal evidence for the effectiveness of rofecoxib, celecoxib, NSAIDs (aspirin, naproxen, ibuprofen, diclofenac, and piroxicam), acetaminophen with caffeine, DHF, methysergide, corticosteroids, lamotrigine, gabapentin, and lithium. The natural history of these disorders is not known, but long-term treatment appears to be required in the majority of patients.

SUNCT

SUNCT is a moderately severe unilateral cephalalgia characterized by neuralgiform pain of very short duration (15-120 seconds). These painful paroxysms are usually felt in or around the eye and can sometimes be triggered by cutaneous stimuli or neck movements. Their incidence ranges from 1 or 2 per day to up to 30 per hour, but patients are typically free from pain between paroxysms. The ipsilateral conjunctival injection and lacrimation are very prominent. Unlike trigeminal neuralgia, the pain occurs exclusively in a cranial nerve V_L distribution, whereas the brevity and high frequency of attacks in SUNCT should make the distinction with cluster headache quite clear. Treatment with carbamazepine has been reported to be partially effective in several patients. I.amorngine has been effective in several patients when given in an open fashion (D'Andrca ct al. 2001). There is anecdotal evidence for the effectiveness of gabapentin, and one patient has had a response to topiramare. The role of neurosurgical intervention in the treatment of SUNCT is uncleat, and it should only be considered as a last resort,

Primary Stabbing Headache

Persons subject to migraine may describe brief, extremely sharp twinges of pain that occur without warning and that can be felt anywhere in the head, including the orbit. The pains are graphically described as being like a spike being

driven into the skull, hence the term *ice-pick headache* (idiopathic stabbing, jabbing headache), but similar pains have been described under different terms by other authors. Similar jabbing pains may occur spontaneously (50%) or in association with another underlying headache disorder, such as cluster headache, chronic paroxysmal hemicrania, and tension-type headache (Pareja et al. 1996). Ice-pick-like head pain has also been described in patients with giant cell arteritis. Some patients report precipitants for this type of pain, including sudden postural changes, physical exertion, and transition from darkness to light. Because of the brevity of the pain, the sporadic nature of attacks, and the common occurrence of spontaneous remissions, treatment is not usually required and reassurance generally suffices. However, in patients with "ice-pick status," in whom stabs of pain occur often, the treatment of choice is indomethacin, administered in a regimen similar to that described for the paroxysmal hemicranias.

Other Types of Headache and Facial Pain

Headache Associated with Metabolic Abnormalities

Carbon dioxide retention and exposure to carbon monoxide can both lead to a vascular headache. The presumed mechanism is vasodilatation. Chronic hypcrcapnia from chronic obstructive pulmonary disease can lead to chronic-headaches and eventually to raised intracranial pressure with papilledema. Carbon dioxide retention and oxygen desaturation due to sleep apnea of both the primary and the obstructive type can result in nocturnal and early morning headaches that diminish with activity. Tissue anoxia due to anemia or lack of oxygen, as occurs at high altitude, can each produce a throbbing vascular headache. Hypoglycemia can cause a headache that has vascular features.

Hypertension is rarely the cause of headaches unless there is a rapid and major increase in blood pressure. The headache of a pheochromocytoma characteristically occurs with dramatic suddenness and is associated with a significant elevation in blood pressure. Occasionally, early-morning headache is a sign of sustained hypertension. Preeclampsia with the accompanying high blood pressure can lead to headaches during pregnancy. The onset of severe headache around the time oi delivery ma) indicate the onset of eclampsia.

Tension-Type or Muscle Contraction Headache

Almost everyone has a headache at some rime when stressed, overworked, or angry. Such headaches, which can also result from muscular strain due to working in a physiologically unsound position, rapidly subside with relaxation, sleep, or ingestion of simple analgesics. The prevalence of this type of headache is unknown because medical help is sought only when the condition becomes sufficiently frequent or chronic to interfere with the patient's lifestyle.

Chronic headaches that are not associated with focal neurological symptoms and do not have the gastrointestinal features of migraine are often diagnosed as tension headaches and have historically been ascribed to persistent contraction of the scalp, neck, and jaw muscles. The term *tension* has been tacitly taken to mean both emotional tension and muscle tension, thus implying both pathogenesis and pain mechanism. The International Headache Society classification ot headache has instituted a small but important change in the terminology of tension or muscle contraction headache. The word *type* has been added after tension, thus the term *tension-type headache* is now used to bring attention to the fact that actual muscle tension or sustained contraction may not be a key factor in the pathophysiology of this common head pain (ICD 10 Guide for Headaches 1997).

The concept of muscle contraction causing headache has been questioned in recent times, and the distinction between vascular headaches and tension-type headaches has become much less certain. liMG studies of neck and scalp muscles during headache do not show a difference between people with migraine and those with the clinical diagnosis of muscle contraction headache. Pericranial muscle spasm and tenderness are as common in migraine as in muscle contraction headache. Provocation of headache by alcohol and nitroglycerin is almost as common in subjects with a history of tension-type headaches as in those with a history of migraine. Similarly, patients thought to have tension-type headaches may report throbbing pain. The platelet serotonin concentration is low in patients prone to frequent tension-type headaches. Similar findings have been noted in patients with migraine. Autogenic training and relaxation therapy are as helpful in migraine as in muscle contraction headaches. These observations and many others have led to the concept that muscle contraction headache and migraine may not be entirely different disorders but are the extreme ends of a continuum or spectrum of headache. However, evidence in favor of tension-type headache and migraine being separate conditions comes from Schocncn and Bendtsen (2000). They showed tliat exteroceptive suppression of voluntary contraction of the jaw muscles in response to electrical stimulation of the labial commissure is abnormal in subjects with tension-type headaches but not in those with migraine or other types of headache.

Many patients with chronic daily headaches have a history of episodic headaches of the common migraine type. The evolution or transformation of one type of headache to another may be associated with overuse of analgesics and ergot preparations. Depression may also be an important factor.

Clinical Symptoms. Tension-type headaches, which can begin at any age, are generally bilateral (commonly

occipitonuehal, bitemporal, or bifrontal). They are often described as being like a tight hand around the head, a sense of pressure, or a bursting sensation. The pain may wax and wane throughout the course of a day or may be described as being present and steady for days, weeks, or even years at a time. Despite the complaint of a constant headache, sleep may be undisturbed. In general, tension-type headaches are not associated with nausea and vomiting and are much less commonly associated with light and sound sensitivity than migraine.

Physical Findings and Laboratory Studies. Physical examination in acute tension-type headache is generally unrevealing. Chronic tension-type headache may be associated with tenderness in the cervical paraspinal muscles, restricted neck motion, and tenderness over the temporalis muscles and in scattered areas over the scalp. Laboratory studies are unhelpful, except to rule out other conditions. The FSR should be determined in elderly patients with headache to help exclude temporal arteritis. The recent onset of headaches in any patient older than age 40, even when the symptoms are clearly those of muscle contraction headache, warrants a CT or MRI scan of the head to look for intracranial disease. Many serious structural intracranial diseases can cause symptoms that mimic benign muscle contraction headache. Cervical spine films may be needed to detect bony and joint disease that can trigger sustained contraction of the cervical and scalp muscles, leading to secondary tension headache.

Psycho logical Factors. Anxiety, depression, repressed resentment, anger, and hostility have all been identified as factors contributing to the production of tension-type headaches, but the prevalence of these emotions in the population without headaches is unknown. Although psychosocial stress, anxiety, and depression are important in patients with chronic headaches, it is uncertain whether they are always causative factors or are due to the chronic pain.

The somatoform disorders, including hypochondriasis, somatization disorder (previously called *hysteria),* and the somatoform pain disorder, can have headache as part of the clinical picture. Together with headaches as a manifestation ot somatic delusions, these are now classified under tension-type headaches, with the recognition that scalp and neck muscle contraction is not a primary factor in the pathogenesis.

Pathogenesis. The long-held belief that emotional tension leads to muscle tension and hence to headache is too simplistic. A growing number of authorities suspect that a far more complex central mechanism is responsible for the pain. Disturbances originating in the hypothalamus and spreading by way of the mamillothalamic tract to the upper brainstem and influencing the antinociceptive mechanisms have been suggested. Alterations in central pain modulation and changes in serotonin and endorphin levels are also likely to be important in chronic ten si on-type headache. The role of the descending tract and nucleus of the trigeminal nerve and its relationship to noxious input from the cervical spine via the upper cervical roots is currently being studied.

Course and Prognosis. Chronic tension-type headache, especially when it becomes a daily event, can persist for years, ft is difficult to manage and rarely responds completely to any therapeutic regimen. Spontaneous remissions may occur, and in some patients the condition subsides with age. Secondary depression, drug addiction, and chronic pain behavior are often the result of chronic headaches.

Treatment and Management. An understanding, sympathetic physician who communicates an interest in the patient's headache will achieve far better results than one who dismisses the patient with the exhortation to relax more or the statement that the headache is all due to "nerves," Many patients arc more interested in knowing that the headache is not due to a serious intracranial pathological condition than in obtaining relief of pain. Reassurance that the headache is not serious can be given only after a thorough examination and after appropriate investigations, including neuroimaging. Such reassurance may considerably relieve the patient's anxieties and thereby relieve the headaches.

Techniques to promote relaxation of the scalp and neck muscles can be helpful; these methods include stretching exercises, the application of heat and massage to the neck, biofeedback conditioning, and relaxation training. Although short-term results confirm the efficacy of these techniques, long-term beneficial effects are nor so obvious. Many patients revert to their muscle-contracting habits unless the relaxation techniques are frequently reinforced.

For occasional mild tension-type headache, aspirin or acetaminophen may be sufficient treatment. More severe headaches usually require a prescription analgesic, but no specific preparation has been shown to be better than another. Aspirin or acetaminophen in combination with propoxyphene or butabarbital and caffeine is often effective for temporary relief but should be avoided for repeated, long-term use because of the risk of paradoxical worsening of the headache related to analgesic rebound. NSAIDs, such as naproxen or lbuprofen, are often helpful. Preparations containing codeine or dihydrocodeine are often avoided because of the risk of dependency; however, these preparations are occasionally useful to carry patients through brief, difficult periods when headaches occur more often than usual. Muscle relaxants and the major and minor tranquilizers arc generally ineffective for long-term management of tension-type headache but are useful for short-term relief.

The most effective prophylactic drug is amitriptyline. Controlled trials have shown an improvement of more than 50% in more than *65%* of patients. The usual dose is

50-150 mg per day, but higher doses may be needed. The drug is better tolerated if given as a single bedtime dose. Side effects include those listed for this agent under Migraine, earlier in this chapter. Elderly patients may also he troubled by confusion and orthostatic faintness, but the latter side effect is minimized by the bedtime dose regimen. A satisfactory response does not depend on the presence of underlying depression.

Chronic tension-type headache can be the most difficult headache to treat. Transient improvement often follows introduction of any treatment, hut most patients continue to complain until the headaches lessen or subside spontaneously. This improvement usually occurs with some change for the better in the subject's life or when a reaction to stress diminishes.

Headache Attributed to Head or Neck Trauma

Subdural Hematoma. Bleeding into the subdural space is generally due to tearing of one or more of the bridging veins that cross the space to reach the venous sinuses, particularly the sagittal sinus. Most subdural hematomas occur over the convexity of the cerebral hemispheres, but they can occur in the posterior fossa or adjacent to the tentorium. In 50-80% of patients there is a history of head trauma. Chronic subdural hematomas may cause headache via enlargement of the lesion without serious neurological signs for a considerable time. Changes in personality, alterations in cognitive abilities, a subacute dementia, and nonspecific symptoms, such as dizziness and excessive sleepiness, may be present for weeks or months. Focal seizures, focal weakness, or sensory changes, and, ultimately, decreasing levels of consciousness may occur. Symptoms of chronic subdural hematoma, including headache, may fluctuate and occur intermittently. Episodic cerebral manifestations may mimic transient ischemic attacks. Headache is the single most common symptom and often is a severe bitemporal pain. Headache due to subdural hematoma is more common in young people, who have less cerebral atrophy than elderly patients. In the presence of atrophy, a larger hematoma can accumulate before it stretches and deforms pain-sensitive structures. Subdural hematoma should be considered in an elderly person with recent onset of headaches. Once suspected, a subdural hematoma should be sought with a CT scan or MRI. Treatment of subdural hematomas is discussed in Chapter 56B. Once the lesion is drained or when it is spontaneously absorbed, headaches tend to resolve.

Headaches, dizziness, difficulty concentrating, irritability, decreased libido, and fatigue are common complaints after **lieail** injur) **Kenitl** ami li.ini.ui.in .!'i'H)'i. Vrinus **lead** trauma, resulting in major brain damage, causes post-traumatic headaches less often than seemingly minor head injuries. This difference may be more apparent than real because the seriously injured patient may have so many symptoms that headache is of less importance than other complaints. Headache is far more common after industrial and traffic accidents than after trauma sustained in sporting activities or in circumstances in which litigation is not a factor. Despite this, few still hold to the postulates claiming that post-traumatic syndrome is a neurosis that persists until there is a compensation settlement and that it is not seen in professional and managerial people or after serious head trauma.

The headache that occurs as part of the post-traumatic (or postconcussive) syndrome can be generalized and resemble a tension-type headache, localized to the site of the head injury, or hemicranial and resemble migraine. The physical examination is often unrevealing, although scalp tenderness and decreased motion of the cervical spine are often found. Examination by CT scan rarely reveals any abnormalities, although unexpected subdural hematomas are occasionally found. Examination of patients with head injuries with MRI has revealed a higher than expected incidence of previously undetected small extracerebral hematomas, cortical contusions, and indeterminate changes in the cerebral parenchyma. Other observations to support the organic basis for the post-traumatic syndrome arc that EEG findings are frequently abnormal and there are transient or long-lasting abnormalities in the visual evoked responses and brainstem evoked responses in some subjects.

Treatment of post-traumatic syndrome and post-traumatic headache is difficult. Encouragement, reassurance, and a sympathetic attitude on the part of the physician are essential. All the treatments useful for tension-type headaches, migraine, occipital neuralgia, and neck sprains may be needed. Physical therapy, biofeedback, and psychotherapy each have a place in treatment. Drug treatment may include analgesics (nonopioid), NSAIDs, and antidepressants. The tricyclic antidepressants and gabapentin can be particularly helpful.

Recovery from post-traumatic syndrome, including the headache, may be significantly delayed. Most patients who continue to have headaches for more than 2 months after the trauma continue to have them for 1-2 years (Ramadan and Keidcl 2000). Treatment can be difficult and the results disappointing.

Post-traumatic syndrome may develop more commonly when patients believe that the evaluation shortly after the injury has been incomplete. Their initial fear and that of their relatives is that a skull fracture or brain injury has been overlooked. Physicians know that a skull fracture is generally unimportant unless it is depressed or results in a CSF leak, but any head injur)- or skull fracture has serious implications to the patient. Emergency room physicians and others caring for patients with a bead injury should therefore conduct a thorough examination, obtain whatever radiological investigations seem indicated, and then, if appropriate, reassure the patient that no serious damage has been caused. If the history included a period of unconsciousness or if there is a simple skull fracture, a limited period of bed rest followed by a graduated return

to full activity should be advised. Cervical spine injuries should not be overlooked in the patient with a head injury.

Post-traumatic dysautonomic cephalalgia usually follows a neck injury, often from blunt trauma. The patient develops a throbbing unilateral headache, ipsilateral mydriasis, and facial sweating. Overactivity of the cervical sympathetic system seems to be induced by the neck injury. This rare syndrome responds to treatment with propranolol. Minor head trauma, such as that occurring when a soccer ball is hit with the head, may be rapidly followed by a headache indistinguishable from migraine. This syndrome may occur repetitively with minor head trauma. A head injury can also be followed by recurring attacks of migraine, even in the absence of a history of similar headaches.

Cold-Stimulus Headache. "Ice cream" headache is a common experience. It occurs when an extremely cold substance comes into contact with the roof of the mouth and the upper incisors. The pain, which is most often felt midfrontally, begins within seconds of the cold stimulus, peaks in 20-60 seconds, and subsides in about the same time. It is less commonly felt bitemporally or even in the occipital region. The complaint is more common in migraineurs than in the general population. Migraineurs may feel an ice cream headache on the side where their migraine is located. The pathogenesis is not completely understood, but reflex vasoconstriction may be involved. Accompanying the pain is a decrease in the skin temperature of the forehead of 1°C. There is evidence to suggest that active migraine facilitates perception of forehead pain induced by a cold palatal stimulus. The pain can be prevented by avoiding ice-cold food and drink.

Neck-Tongue Syndrome. The neck-tongue syndrome was initially described by Cyriax in 1962. Paroxysmal pain and paresthesias in one half of the tongue precipitated by neck movement are the cardinal features of the neck-tongue syndrome. The tongue discomfort has been accompanied by a varied constellation of other symptoms. Occipital pain, discomfort in the trapezius region, ipsilateral hand paresthesias, and neck pain have been described. All can be precipitated by neck movement. The exact mechanism remains speculative. Atlantoaxial subluxation, cervical spondylosis, and lesions of the upper cervical cord and the emerging cervical nerves have been suggested. Neural anastomosis between the glossopharyngeal nerve and the hypoglossal nerve via the pharyngeal plexus may explain the unusual syndrome. The condition is generally considered benign. In rhe absence of any structural abnormality management is conservative. Treatment includes the use of anti-inflammatory agents and temporary immobilization of the neck in a cervical collar (Chedrawi et al. 2000).

Atypical Facial Pain. *Atypical facial pain* is a term far too readily applied to any obscure pain in the face. A more preferable term is *facial pain of unknown cause.* It is not appropriate to attribute all causes of idiopathic facial pain to psychogenic mechanisms.

The diagnosis of atypical facial pain should be considered only when all facial pains due to disturbances of anatomy and pathophysiology have been excluded. Exhaustive radiographic and other imaging techniques may be necessary to exclude conditions such as nasopharyngeal and sinus neoplasms, bony abnormalities of the base of the skull, and dental conditions, such as cryptic mandibular and maxillary abscesses. The evaluation may also require a chest roentgenogram or chest CT scan if referred pain from lung cancer is suggested by the history (smoker) or examination (digital clubbing).

Patients in whom atypical facial pain is eventually diagnosed are usually middle-aged and predominantly female. They complain of deep, poorly localized pain. Generally unilateral, but occasionally bilateral, the pain may be described in graphic terms, such as tearing, ripping, or crushing, or often as aching and boring. The pain is usually present all day and every day and gradually worsens with time. It is not influenced by factors such as alcohol consumption, heat, or cold or by factors that trigger trigeminal neuralgia. Local anesthetic blocks of the trigeminal nerve do not relieve the pain. Many patients have already undergone extensive dental, nasal, or sinus operations, to no avail. Depression may be present; most patients are preoccupied with the pain, yet there is no convincing evidence that the pain is due to the depression, When no symptomatic etiology is identified, treatment centers around the use of tricyclic medications, often combined with other antimigraine or antineuralgic medications.

Cranial and Facial Neuralgias

Trigeminal Neuralgia. One of the most severe pains known, trigeminal neuralgia, was first desctibed by John Fothergill in 1775.

Clinical Symptoms, The pain of trigeminal neuralgia is paroxysmal. It is felt within the distribution of one or more divisions of the trigeminal nerve. The pain is often •r:s',i\dvd by a sensory stimulus to the skin, mucosa, 01 teeth innervated by the ipsilateral trigeminal nerve. The pain is described as electric shocklike, shooting, or lancinating. Each attack lasts only seconds, but the pain may he repetitive ,u short intervals MI that the individual attacks blur into one another. After many attacks within a few hours, the subject may describe a residual lingering facial pain. Attacks of trigeminal neuralgia are most common in the second and third divisions of the nerve. Pain confined to the ophthalmic division is extremely rare. Although the tongue is supplied by the mandibular division of the nerve, it is uncommon for the pain to spread into the tongue, even when the lower lip and mandible are involved.

Physical Findings. In primary trigeminal neuralgia, there is no sensor;. impairment and the motor division of the nerve is intact. Examination of the face may be difficult because the patient is reluctant to let the examiner stimulate the skin for fear of triggering an attack. Male patients occasionally present with one portion of the face, the trigger zone, unshaven. Initiation of the pain by chewing, brushing the teeth, and talking and even by cold drafts striking the face is commonly reported. Attacks of pain during sleep are tare. Weight loss, dehydration, and secondary depression can occur if the attacks occur often.

When trigeminal neuralgia occurs as a result of a lesion involving the gasserian ganglion, main sensory root, or root entry zone in the pons (secondary trigeminal neuralgia), there may be associated physical signs. These include sensory loss in the fifth cranial nerve distribution, weakness and atrophy of the muscles of mastication, and involvement of ad|acent cranial nerves. When trigeminal neuralgia occurs bilaterally, it is often due to multiple sclerosis,

Laboratory and Radiological Findings. In classic trigeminal neuralgia, there are no accompanying laboratory or radiogtaphie abnormalities, EMG and nerve stimulation techniques, such as blink reflex studies, reveal normal responses. Trigeminal neuralgia due to structural lesions, such as a meningioma or schwannoma of the posterior fossa or compressing the gasserian ganglion or malignant infiltration of the skull base, is associated with the expected abnormalities on studies such as CT scans and MRI.

Pathology, Histological changes are seen within the gasserian ganglion in patients with trigeminal neuralgia. Vacuolated neurons, segmental demyelinarion, vascular changes, and other abnormalities were more common in ganglia from patients with a history of trigeminal neuralgia than in control specimens. Demyelination of the axons in the main sensory root may be associated with compression by vascular loops.

Pathogenesis and Etiology. The cause of trigeminal neuralgia is probably multifactorial. Multiple sclerosis, cerebellopontine angle tumors, schwannomas, and other local lesions account for a very small proportion of cases and most cases have long been called idiopathic. The work of Jannetta has revitalized Dandy's vascular loop-nerve compression theory. Jannetta found arterial compression of the posterior root in *59%* of patients and venous compression in 25%. Vaseulat compression is believed to increase with age and to result in changes in the trigeminal sensory root and root entry zone that results in prolongation of electrical impulses within the nerve and re-excitement of the axons, leading to repetitive neuronal discharges. The vascular compression theory has, however, not found universal support.

Epidemiology. Trigeminal neuralgia begins after the age of 40 years in 90% of patients. It is slightly more common in women.

Course and Prognosis. Once trigeminal neuralgia has developed, it is likely to have an exacerbating and remitting course over many years. During exacerbations, the painful attacks may occur many times a day for weeks or months at a time. A spontaneous remission may occur at any time and last for months or years. The reasons for these fluctuations are unknown.

Treatment and Management. Treatment of trigeminal neuralgia due to a focal lesion compressing the sensory root of the trigeminal nerve is surgical exploration and decompression of the nerve. Management of primary trigeminal neuralgia can be either medical or surgical.

Carbamazepineis the most effective drug for the treatment of trigeminal neuralgia, and the condition responds in approximately 75% of patients. Administration of the drug must be initiated with small doses of 50-100 mg and increased slowly as tolerated. Vertigo, drowsiness, and ataxia are common side effects, especially in elderly patients, if the preparation is introduced too quickly. Therapeutic doses generally range from 600-1200 mg per day. Once the pain is controlled completely, the dose can be tapered every few weeks to determine whether a remission has developed. Regular blood counts should be obtained for the first few months and thereafter, generally once a year while carbamazepine is administered, in view of the earlier reports of agranulocytosis with this preparation.

Second-line options for the management of trigeminal neuralgia include phenytoin, baclofen, and valproate. Other drugs that have been used include gabapentin, clonazepam, lamotrigine, oxcarbazepine, and topiramate (Sindrup and Jensen 2002). The above drugs should be considered for trial, alone or in combination, when carbamazepine is either not helpful or not tolerated. Nonetheless, given the beneficial effects of gabapentin in other neuropathic conditions and its benign side-effect profile, an initial trial with this drug may be an alternative option to carbamazepine.

On occasion, one may encounter a patient in the midst of a severe attack. A useful technique in this situation is the administration of intravenous fosphenytoin at a dose of 250 mg. Anesthetizing the ipsilatcral conjunctival sac with the local ophthalmic anesthetic proparacaine has also proved most effective in providing relief from pain for several hours to days.

The simplest nonmedical therapy is an alcohol block of the peripheral branch of the division of the trigeminal nerve that is painful. The mental or mandibular nerve can be blocked with 0.50-0.75 mL of absolute alcohol to control mandibular division trigeminal neuralgia. The infraorbital and supraorbital nerves can also be injected for pain involving the second and first divisions. Relief of pain occurs in a high proportion of patients so treated, but relapse is likely in most after 6-18 months. The procedure can be repeated once or twice, but thereafter it is prudent to perform a more proximal and lasting procedure because the further injection of alcohol is likely to be ineffective.

The advantages of a peripheral alcohol injection include the lack of morbidity and the temporary nature of the sensory loss. Preservation of corneal sensation is also an advantage. Avulsion or section of the peripheral branches has been used for control of pain but is now rarely used.

For many patients, especially those who are elderly or who have complicating medical conditions, percutaneous radiofj-eqiu'ncy thermocoagulation ol the trigeminal nerve sensory root as it leaves the gasserian ganglion is the procedure of choice. Authors have reported pain relief in up to 93% of patients. Recurrence rates vary with the period of follow-up. The procedure can be repeated when relapse occurs. Complications include damage to the carotid artery, the adjacent cranial nerves, and the trigeminal nerve motor root. Corneal sensory loss can lead to serious eye complications. *Anesthesia dolorosa,* a distressingly painful sensation in the numb area, occurs occasionally. Troublesome dysesthesias of the face are more commonly encountered.

Section of the sensory root of the trigeminal nerve via a middle fossa or posterior fossa approach is used for the treatment of trigeminal neuralgia less often than previously. This decline has largely been due to the increasing use of the technique of microvascular decompression advocated by Jannetta. In his 1991 series of 1185 patients, 70% had excellent relief of pain continuing 10 years after the trigeminal nerve and the compressing vessel were separated (Barker et al. 1996). Relief of pain without the production of anesthesia is the major advantage of the procedure. The disadvantages include the need for a posterior fossa exploration, with a reported mortality of between 1 and *2%* and the risk of injury to other cranial nerves, most commonly IV, VII, and VIII. Despite the inherent risks of a retromastoid craniectomy, microvascular decompression is associated with the longest duration of pain relief, preserves facial sensation, and remains the only surgical treatment that directly addresses the presumed mechanism (Elias and Burchiel 2002). When no vascular loop is found at the time of operation, the options include performing a partial or complete sensory root section or subsequently performing a radiofrequency procedure.

For a young patient whose condition does not respond to medical treatment, posterior fossa microvascular decompression should be considered. For an elderly patient or a patient with other medical complications, however, radiofrequency thermocoagulation is the procedure of choice because of its case of performance, possibly preceded by an alcohol block so that the sensation of facial numbness can be experienced before the more permanent procedure.

More recently, several new procedures have shown promise in patients with trigeminal neuralgia refractory to medical management and have added to the surgical armamentarium. Percutaneous balloon compression of the trigeminal ganglion has been shown to be an effective and technically simple treatment. However, the early recurrence rate is higher than reported for radiofrequency thermocoagulation. Stereotactic radiosurgery with the gamma knife has also been shown to be an effective therapy for trigeminal neuralgia and is the least invasive surgical option (Kond/iolka et al. 2002). Dogmatic recommendations relating to the particular interventional or surgical procedure cannot he made. Patients offered such treatment need to be informed of the track record of the surgeon performing the procedure.

Glossopharyngeal Neuralgia

The pain associated with neuralgia of the ninth cranial nerve is similar in quality and periodicity to that of trigeminal neuralgia. The pain is lancinating and episodic and may be severe. It is felt in the distribution of the glossopharyngeal nerve and the sensory distribution of the upper fibers of the vagus nerve. Pain in the throat, the tonsillar region, the posterior third of the tongue, the larynx, the nasopharynx, and the pinna of the ear is often described by patients with this rare neuralgia. The pain is usually triggered by swallowing, chewing, speaking, laughing, or coughing. The pain is unilateral in most patients. Bilateral involvement does occur, but it is very rare. The age group involved is generally older than 40 years of age. Bradycardia and syncope can occur when the painful attack strikes.

Secondary glossopharyngeal neuralgia may be due to oropharyngeal malignancies, peritonsillar infections, and other lesions at the base of the skull. Most occurrences have been thought to be idiopathic, but vascular compression of the ninth cranial nerve has been described.

Carbamazepine and phenytom have been administered with mixed success in glossopharyngeal neuralgia. Intracranial section of the glossopharyngeal and upper rootlets of the vagus nerve almost always produces complete pain relief.

Geniculate Neuralgia (Nervus Inter me dius Neuralgia of Hunt)

The sensory root of the geniculate ganglion, the nervus intermedins of Wrisberg, innervates the inner ear, the middle car, the mastoid cells, the eustachian tube, and part of the pinna of the ear. A syndrome of pain in the ear, pinna, and auditory canal has been ascribed to neuralgia of the geniculate ganglion and nervus intermedins. There is no known pathological condition. Clinical features of this syndrome are not well defined. If one were to characterize geniculate neuralgia by paroxysmal pain of great intensity but short duration in the ear, pinna, or auditory canal, this syndrome must be exceedingly rare. Some would argue that geniculate neuralgia, unlike the neuralgias already described, need not be lancinating and episodic but tends to be more prolonged. It may be sharp or burning. It occurs in middle-aged adults and more often in women than in men.

Treatment with carbamazepine is appropriate, **but** the rarity of the condition has prevented accumulation of any meaningful results. Excision of the nervus intermedins and the geniculate ganglion via a middle fossa approach has provided relief (Pulec 2002).

Geniculate Herpes Zoster or Ramsay Hunt Syndrome

Presumed infection of the geniculate ganglion with herpes zoster virus results in ear pain with radiation to the tonsillar region ipsilaterally. Vesicles are found in the external auditory canal and on the pinna. Less often, they are also seen on the anterior pillar of the fauces. "The infection may affect the chorda tympam, leading to loss of taste on the anterior two-thirds of the tongue. In almost all patients, the main trunk of the facial nerve is involved, causing facial paralysis. Adjacent nerves may also become involved, most commonly the eighth, which leads to hearing loss and vertigo. The exact site of the herpes infection is debated and may be within the brainstem rather than confined to the geniculate ganglion. Treatment is symptomatic. Recovery of facial nerve function tends to be less complete than after idiopathic Bell's palsy.

Occipital Neuralgia

A headache in the occipital region may be due to entrapment of the greater or lesser occipital nerves on one or both sides. The patient may have a histoty of trauma to the back of the head, but more commonly the condition develops spontaneously. Chronic contraction of the neck and posterior scalp muscles may be responsible for entrapment of the occipital nerves.

The pain is described as shooting from the nuchal region up to the vertex. In addition to the lancinating pains, dull occipital discomfort may be present. Percussion over the occipital nerves should reproduce the symptoms, and discrete tenderness should be evident in the area of the nerve low in the occipital region. Local anesthetic and corticosteroid can he infiltrated around the nerve as a diagnostic procedure. While the area remains anesthetized, the spontaneous pain should be relieved, and pain should not be triggered by percussion over the nerve. In many instances, this treatment results in long-term relief. Avulsion or nerve section should be avoided because these procedures often do not give complete relief and may lead to formation of a neuroma.

Postherpetic Neuralgia

Herpes zoster infection of the trigeminal nerve almost always involves the ophthalmic division. The typical eruption is strictly unilateral and involves the forehead and upper part of the eyelid. It may be accompanied by a keratitis that can permanently scar the cornea. Pain during the acute phase is severe and may require opioid analgesics. Antiviral drugs and prednisone can decrease the pain during this stage. In elderly patients, the acute phase may be followed by a terribly distressing, long-lasting, painful dysesthctic stage. Postherpetic neuralgia can be defined as persistent pain occurring I month after the healing of the herpetic rash. Postherpetic neuralgia occurs in about 10% of patients with herpes zoster ophthalmicus.

The pain of the acute attack may merge into the postherpetic stage. The pain is constant, with superimposed lancinating pains. Terms such as *burning, stabbing,* and *tearing* are used to describe the pain. The site of the previous eruption may be either hypoesthctic or hypercsthetic.

Inflammatory changes and the results of such inflammation have been found throughout the peripheral and central trigeminal pathways and even as far caudal as the lower portion of the descending trigeminal tract in the cervical cord. Thus, the pain is a central phenomenon, which explains why peripheral surgical procedures to relieve postherpetic neuralgia are generally ineffective.

Once developed, postherpetic neuralgia may persist indefinitely, although with time it may become less severe. Many elderly patients with this distressing pain become depressed, lose weight, and become withdtawu. Treatment of established postherpetic neuralgia is difficult and in many instances ineffective. Randomized, controlled trials have supported the use of tricyclic antidepressants, gabapentin, and oxycodone.

The use of topical capsaicin is nor practical in trigeminal disttibution postherpetic neuralgia, and the use of lidocaine patches is not recommended in this circumstance. Intrathecal methyl prednisolone has been reported to be efficacious in intractable postherpetic neuralgia, but this study did not enroll patients with painful regions innervated by the trigeminal nerve (Kotani et al. 2000). Procedures to denervate the affected area of skin, trigeminal destructive procedures, and trigeminal tractotomy have been used for control of pain, but they arc rarely used at present.

Other Neuralgias

Vanna-, painful syndromes ol the head and neck have Ivrn described as neuralgias. Specific nerves have been incriminated with little to suppott the claim. Many of the syndromes have features resembling those of cluster headache. Similar temporal profiles, similar accompanying autonomic features, and similar responses to treatment indicate that the mechanisms underlying these syndromes may be identical to those responsible for cluster headache. Examples include Sludcr's sphenopalatine neuralgia, Vail's vidian neuralgia, Gharlin's ciliary neuralgia, and Gardner's petrosal neuralgia. With the possible exception of the condition described by Sluder, there is little to be gained by adhering to the belief that specific painful syndromes are due to disturbances of these nerves.

Headache in Children and Adolescents

Headaches are very common in children and their prevalence increases in adolescence. Data from multiple studies have shown the prevalence of headache of any type to be in the range of 37-51% in 7 year olds, growing steadily to 57-82% in 15 year olds. Prepubertal boys arc more often afflicted than girls whereas after puberty, headaches occur more often in girls {Lewis et al. 2002).

Obtaining the child's history of head pain can be challenging because most subjects younger than 10 years of age are unable to give clear details about the temporal profile of the headache, its frequency, and its characteristics. The examiner is very dependent on the observations of the parents. It is important to recognize the effect of the headache on the child's behavior. Does the youngster continue to play, want to go to bed, refuse food, refuse to go to school, and then appear to recover? It is also important to determine whether the headache is episodic and separated by periods of welt-being, as occuts with migraine; chronic and progressive, as might occur with a brain tumor; or chronic and nonprogressive, as might occur with a psychogenic headache or depressive equivalent,

The neurological examination in a child should evaluate the same factors as in an older patient, including careful assessment of the fundus. In addition, the head size should be measured, the fontanclles examined, and the developmental markers checked.

Investigations are undertaken after a thorough history and physical examination of the child. Neuroimaging is not done routinely. Features that are associated w'ith a the presence of a space-occupying lesion include (1) headache onset of less than 1 month, (2) absent family history of migraine, (3) abnormal neurological findings on examination (including gait abnormalities), and (4) the presence of seizures (Lewis et al. 2002). The child with a constant, nonprogressive headache may need a psychological evaluation, and the family dynamics may require full evaluation. Reports from teachers are of value in assessing the child's performance.

Migraine

Migraine is the most common cause of headaches in children referred to a neurologist. Although migraine can manifest all the features seen in older patients, migraine attacks in children arc often shorter and occur less often than those in adults, and unilateral location is not a specific feature of juvenile migraine. It can be triggered by similar factors at all ages, including stress, fever, head trauma, and sleep and eating pattern changes In girls, the onset of migraine may coincide with menarche.

Nonpharmacological approaches to treatment include elimination of known triggers and training in biofeedback and relaxation techniques. Biofeedback and relaxation training may be of benefit in patients older than 9 years of age,

Pharmacological treatment of migraine in children includes many of the agents used in adults, but the details depend on the age of the child. In children younger than 6 years of age, acetaminophen (10-15 mg/kg per dose) or ibuprofen (10 mg/kg per dose) combined with rest in a dark quiet room works well. In older children, medications such as a variety of the NSAIDs and butalbital-containing analgesic compounds may be used. The potential for analgesic-induced rebound headaches can be avoided if repeated long-term use is not undertaken. Opioid medication should be avoided.

The results of treatment with preparations of 5-HTT agonists have been mixed in older children and adolescents. In some studies, the efficacy has not been as great as has been demonstrated in adults probabh as a function of the shorter average duration of attacks. Nevertheless, sumatriptan in doses ol 2\~ nig orally and greater, tizatriptan at 5-10 mg orally, and zolmitriptan at 2.5-5 mg have been useful in some patients with moderate-to-severe attacks (Lewis 2002). Ergotamine is now rarely used given its higher rate of side effects and lower efficacy.

Both suppository and oral forms of antiemetics are helpful in patients when migraine attacks are accompanied by significant nausea and vomiting. Promethazine in a dose of 0.25-0.5 mg/kg per dose up to three times daily, ttimethobenzamide 100-200 mg up to three times daily, prochlorperazine 0.25-0.5 mg/kg every 4-6 hours, and metodopramide 1-2 mg/kg (<10 mg) every 6-8 hours can be useful. Antiemetics should be used with caution in children because of the potential for dystonic reactions (Lewis 2002).

For acute incapacitating headaches, parenteral DHE and sumatriptan have been effective. The intravenous form of DHL in a dose of 0.1-0.2 mg with 2 mg of metodopramide has been an effective acute treatment. Subcutaneous injection of sumatriptan with a dose adjustment of 0.06 mg/kg to a maximum of 6 mg can be efficacious (Lewis 2002).

For children and adolescents with repeated migraine attacks (one a week or several prolonged attacks per month), prophylactic treatment should be considered. Unfortunately, data from controlled trials for preventative agents are lacking in these age groups. Propranolol in an initial dose of 0.5-1.0 mg/kg in two daily divided doses (to a maximum of 10 mg twice daily) can be gradually increased until a therapeutic response occurs or side effects preclude further increases. As in adults, a clinical response may not occur for several weeks. If use of a jfj-adrenergic blocking agent is ineffective or contra indicated, one of the calcium-channel antagonists may be tried, such as verapamil. Cyproheptadine, long known to he an antihistamine and antiserotonin agent, is also a calcium-channel

antagonist and may be helpful in migraine prophylaxis. It is effective in less than 50% of patients, though, and drowsiness and weight gain arc common side effects. Tricyclic antidepressants, such as notttiptyline and amitriptylinc, are sometimes effective prophylactic agents. Their side effect profile (particularly cardiac) limits their use in children. Sodium valproate and gabapemin, useful prophylactic agents for migraine in adults, are sometimes helpful in children and adolescents.

Migraine Variants of Childhood

There are some periodic syndromes that occur in childhood that appear to be variants or precursors of migraine. *Cyclical vomiting* is characterized by episodic attacks of repeated vomiting (at least 4 emeses per hour) and severe nausea, pallor and lethargy; they typically last 1 to 72 hours. The episodes usually begin between 1 and 3 years of age. They are associated with pallot and lethargy. *Abdominal migraine* is typified by attacks of abdominal pain lasting I to 72 hours. The pain is typically of midline location, of dull quality, and of modetate or severe intensity. Anorexia, nausea, vomiting, and pallor are common accompanying features. Cyclical vomiting and abdominal migraine usually begin between 4 and 10 years of age. In *benign paroxysmal vertigo of childhood,* brief attacks of vertigo lasting minutes to hours occur suddenly and may be associated with nystagmus, vomiting, and pulsatile headache. *Benign paroxysmal torticollis* is manifested by tecurrent episodes of head tilt to one side, usually lasting 4 hours to 4 days (not always to the same side) and stops spontaneously. Pallot, irritability, malaise, and vomiting usually accompany the attacks, which begin in infancy. Ataxia may occur in older children. Many individuals with these symptoms develop more typical migraine at some time (Al-Twaijri and Shevell 2002). *Alternating hemiplegia of childhood* consists of episodes of alternating hemiplegia beginning before 18 months of age and may be associated with other paroxysmal phenomena including tonic spells, dystonic posturing, chorcoathetoid movements, and oculat motor abnormalities. In all of these syndromes, no evidence of othet etiologies is present on examination or investigations.

Tension-Type Headache

Chronic tension-type headaches in children are similar to the same condition in adults. Life stresses are often the underlying cause. Depression and anxiety may result from peer pressure, excessive parental expectations, conflict with teachers, and physical or sexual abuse. The headache is often diffuse, present to some degree almost continuously, and unaccompanied by any physical signs. Refusal to go to school and other secondary gain mechanisms may be obvious. Treatment is difficult and may require psychotherapy and family counseling.

Chapter 76
Cranial Neuropathies

Patrick J. Sweeney and Maurice R. Hanson

This chapter covers the cranial nerve (CN) disorders, with the exception of the olfactory (CN I) (see Chapter 20), optic (CN II) (see Chapters 14, 15, and 40), and cochlcovestihular (CN VIII) (see Chapters 18, 19, and 41) nerves. Because of their complexity, we devote more attention to the neuroanatomy of the lower CNs (VII, IX, X, XI, and XII) than to the upper CNs.

OLFACTORY NERVE (CRANIAL NERVE I)

See Chapter 20.

OPTIC NERVE (CRANIAL NERVE II)

See Chapters 14, 15, and 40.

OCULOMOTOR NERVE (CRANIAL NERVE III)

Neuroanatomy

Arising from paired nuclei in the dorsal midbrain, beneath the superior colliculus, the oculomotor CN components derive from individual cell groups that include parasympathetic fibers from the Edinger-Westphal nucleus. The fibers pursue a curved course through the tegmentum and cerebral peduncles of the midbrain, some traversing the red nucleus itself. Emerging from the side of the interpeduncular fossa, they pass forward through the lateral wall of rhe cavernous sinus into the orbit through the superior orbital fissure. Markinovic and Gibo (1994) provide an extensive review of rhe vascular supply of the oculomotor nerve (CN III).

Brainstem Syndromes

Dysfunction of the third CN can occur anywhere from its nuclear origins in the midbrain to its final terminations in the orbit. As the fascicles pass through the midbrain and exit from anteromedial aspects of the cerebral peduncles, well-defined syndromes can result, allowing anatomical localization of the problem. Thus it is possible for a strategically located lesion to involve selectively both of the third CNs or even just a portion of their nuclear origins. Current neurology and ncuro-ophthalmology texts differ somewhat in their descriptions of these named midbrain syndromes (Table 76.1).

Posterior circulation disturbances with infarction or hemorrhage are common causes of these rare syndromes. Less commonly, demyelinating disease and neoplasia, primary or metastatic, may be etiological factors. Symmetrical pu>M- *uv.v,* hi- :i sign ol caudal midline nuclear involvement of the third CN. Silverman, Lui, and Galetta (1995) provide a comprehensive teview of brainstem syndromes and crossed paralysis. (See also Chapter 22 for a discussion of brainstem syndromes affecting the third CN.)

Aneurysmal Involvement of the Oculomotor Nerve

After the fascicles of the oculomotor nerve exit the brainstem, they fuse in the interpeduncular fossa. Any extra-axial mass in this subarachnoid area could involve one or both oculomotor nerves. Aneurysms of both the posterior communicating artery and the basilar bifurcation may produce internal ophthalmoplegia, with a dilated and relatively fixed pupil as its initial manifestation. Oculomotor dysfunction is also relatively common as a complication of surgery on a basilar bifurcation aneurysm. The palsy is likely due to retraction of the nerve during surgery. When it occurs in isolation, the prognosis for recovery is good, with resolution occurring over several months. On the other hand, when the third CN dysfunction is accompanied by a hemiparesis, recovery is often incomplete.

In the past the dictum that compressive third nerve etiologies invariably produce pupillary paralysis and microscopic vascular etiologies spare the pupil has been widely believed. However, because of the ftequency of overlapping factors such as aging and vascular risk factors, this clinical guideline is less reliable in plotting a course of action (Trobe 1998).

Raised inttactanial pressure, from whatever cause, may produce transtentorial uncal herniation with extrinsic compression of the third CN on the margin of the tentorium. Because of the peripheral location of the pupilloconstrjctot fibers, or theit vulnerability to compression, a unilateral pupillary enlargement on the side of the lesion may be the earliest sign of increased intracranial pressure (Hutchinson's pupil).

Table 76.1: Terminology for midbrain syndromes

Syndrome	*Milter and Newman (Walsh and Hoyt)*	*CLisrr*	*I i-ifii- • ':ii /••'*	*Original description*
Benedict's (1889)	Oculomotor palsy	Oculomotor palsy	Oculomotor palsy	Oculomotor palsy
	Contra la [era 1 chorea, tremor, ballismus, or aril cms is	Contralateral ataxia and intention tremor	>	Contralateral hemiparesis
	LS: rhird nF, RN	LS: third nF, RN	LS: third nF, RN, CP	Contralateral involuntary movements or tremor LS: third nF, CP, SN?, RN?
Claude's (1912)	Oculomotor palsy Contralateral asyncrgia, ataxia, dysmctria, dysdiadocliokinesia LS: third nF, RN, BC	Not mentioned	Oculomotor palsy l .13111 i. L :. t Hi : ll . U . I M . I , and slow rubral tremor LS: third nF, RN	Oculomotor palsy Contralateral ataxia asynergy, dysdiadocliokinesia
Nothnagel's (1879)	Oculomotor palsy Ipsilateral ataxia LS: third nF, BC	Not mentioned	Oculomotor palsy with vertical gaze palsy LS: third nF and ?	±Trochlear palsy, iscnsory loss LS: third nF, RN, SCP (ifourth nerve, ML, MLF) Bilateral oculomotor palsies of varying degree and usually as) mmetrical ±Nysragmus Gait ataxia LS: superior and inferior colliculi

BC = brachium conjunctivum; CP = cerebral peduncle; LS = lesion site; ML = medial lemniscus; MLF = medial longitudinal fasciculus; RN = red nucleus; SCP = superior cerebellar peduncle; SN — substantia nigra; third nF = third cranial nerve fascicle.
Source: Used with permission from Liu, L C. T., Crenner, C. W., Logigian, E. L., et al. 1992, "Midbrain syndromes of Benedikt, Claude and Nothnagel: Setting the record straight," *Neurology,* vol. 42, pp. 1820-1822.

Trauma

The third CN in the subarachnoid space can be injured in head trauma. Even minor head trauma may produce a third nerve palsy as the initial sign of parasellar or clival tumor, presumably because the oculomotor nerves are already stretched over the rumor or are partially encased and fixed by the tumor and hence vulnerable to sudden mechanical stress. A third nerve palsy triggered by mild head injury should prompt investigation for a basal tumor.

Cavernous Sinus Syndromes

As the third CN enters the cavernous sinus, it courses forward in the upper aspects of the lateral sinus wall, above the trochlear and trigeminal nerves. In this location, it is prone to compromise by a variety of pathological processes that may simultaneously compromise other cavernous sinus structures, t impression *A\\d* dysfunction of the third, fourth, or sixth CNs in the cavernous sinus may be i..iu^J by .1 i-:i!'!>;id arury enlarged by diswiinn, bin tinmore likely cause of ocular motor palsies in spontaneous carotid dissection is interruption of the nutrient arteries supplying the nerves.

Thrombophlebitis of the cavernous sinus is a potentially life-threatening condition secondary to contiguous infection in the surrounding sinuses, eye, or nose. Involvement of the third CN, along with any other CNs or vascular structures traversing this cavity, can result in a clinical picture of a sick and septic patient with headache, with varying degrees of ophthalmoplegia, chemosis, and proptosis. If the condition is untreated, the initial unilateral picture may become bilateral via spread through the circular sinus. In the immunosuppressed or poorly controlled diabetic in acidosis, mucormycosis must be considered in the diffetential diagnosis. This fungal infection, caused by either *Rhizopus* or *Mucor* species, often produces nasal turbinate necrosis and a serosanguineous nasal discharge. Surgical debridement of the area and intravenous amphotericin B may save the patient from otherwise certain death. Other fungal infections, such as *Aspergillus,* may produce similar manifestations.

Aneurysms of the carorid artery in the cavernous sinus, as well as primary and metastatic neoplasia, are important causes of third or sixth nerve dysfunction. A coexisting involvement of both parasympathetic and sympathetic pupillary function suggests localization to this area.

Infarction of the third CN in the cavernous sinus involves the central cote of the nerve, sparing peripheral pupilloconstrictor fibers, producing a characteristic painful pupil-sparing palsy of CN III. In the past, this was offered as a reliable sign of noncompressive disease that obviated the need for invasive studies, such as angiography. Vascular versus compressive etiologies can often be predicted from how the iridoplcgia and ophthalmoplegia evolve during the first 7 days of the illness.

Superior Orbital Fissure and Orbit

The third CN passes through the superior orbital fissure in its passage from the cavernous sinus into the orbit. It is often difficult to distinguish lesions of CN III in the orbit from those of the superior orbital fissure and those in the proximal orbit. Coexisting optic nerve dysfunction suggests orbital involvement. Involvement of maxillary division facial sensation suggests that the lesion extends at least as far back as the midcavcrnous sinus. Although the superior :irbiral :issi;re ma\ be bivolved ir almost an\ or the conditions mentioned previously, the Tolosa-Hunt syndrome merits special comment. Usually appearing in the fourth through sixth decades of life, this syndrome manifests over several weeks as a steady, boring, unilateral orbital pain. Palsies of the third, fourth, or sixth CNs, in any combination, are possible. Optic nerve involvement is unusual. Although first-division trigeminal sensory involvement may occur, involvement of the maxillary division is uncommon. Both sexes are affected equally, and spontaneous remissions are reported. The entity is diagnosed by exclusion of other space-occupying lesions in the area of the superior orbiral fissure and its contiguous parts. Corticosteroid responsiveness is the rule. Pathological examination reveals nonspecific inflammatory granulation tissue filling the cavernous sinus.

Distal Branch Syndromes

As the oculomotor nerve enters the orbit, it subdivides into superior and inferior branches. The former, passing lateral to the optic nerve, supplies the superior rectus and levator palpcbrae superioris muscle. The inferior branch, the larger of the two, supplies the inferior and medial rectus muscles and inferior oblique muscle. A twig of nerve passing to the inferior oblique also supplies, through the short ciliary nerves, the sphincter of the pupil and ciliary body. Selective paralysis of these terminal branches has multiple causes, including orbital trauma, but may be idiopathic.

Isolated superior branch oculomotor palsies produce a characteristic picture of unilateral ptosis, with weakness of the superior rectus and preserved pupillary, medial, and inferior rectus muscle function. The cause is often idiopathic and presumed in lv viral, bin internal carotid artery aneurysms, located either in the intracavernous portion or on the posterior communicating artery, may damage nerve fibers in the oculomotor nerve before division into its terminal superior and inferior branches. Myasthenia gravis may occasionally cause a similar picture.

Aberrant Regeneration Phenomena

Aberrant regeneration phenomena are oculomotor synkinesias that encompass a variety of signs, the most classic of

which is lid retraction on adduction or depression (pseudo-Graefe's sign) of the ipsilatcral eye.

TROCHLEAR NERVE

Neuroanatomy

The trochlear nerve, or fourth CN, is unique among the CNs m several ways. It originates from cells beneath the inferior colliculus just above the medial longitudinal fasciculus and caudal to the third CN complex. It is the only CN to exit on the dorsal aspect of the brainstem and is [lie only CN thai is completely crossed. Thus fibers from the right fourth CN nucleus cross in the anterior medullary velum to reach the left orbit, and vice versa. It is also the smallest of the CNs to the extraocular muscles and has only approximately 2100 axons as compared with the oculomotor nerve, which has 15,000, and the abducens nerve, which has 3500. The fourth CN travels forward in the lateral wall of the cavernous sinus beneath the third CN and above the trigeminal nerve to reach the orbit and ultimately the superior oblique muscle.

Congenital Versus Acquired Palsies

The diplopia in traumatic fourth nerve palsies usually subsides in less than 1 year. When trauma is excluded, a small number of patients are found with congenital fourth nerve palsies. Im.ie.e rilnne, vr>inbiiH\l with vertical diplopia occurs only in acquired cases of recent onset, not in congenital fourth nerve paralysis.

Etiology

Trauma is the most common cause of trochlear nerve palsy in adults. Twenty percent of traumatic cases are bilateral, Head impact at the time of trauma may produce disruption of the crossing fibers in the anterior medullary velum, perhaps by distention of the fourth ventricle. Transient ipsilatcral trochlear nerve paresis may occur after anterior temporal lobectomy for intractable seizures (Jacobsen, Warner, and Ruggles 1995).

The etiology of a large number of palsies of CN IV remain undetermined. Vascular ischemic disease from hypertension, diabetes, and atherosclerosis accounts for approximately one fifth of eases. On very rare occasions, aneurysm in such disparate locations as the cavernous sinus and the posterior fossa may produce a fourth nerve paralysis. Myasthenia gravis must always be considered in the differential diagnosis of any ocular muscle palsy of nontraumatic origin. On rare occasions, fourth nerve palsy may follow an attack of herpes zoster ophthalmicus, but its onset may be delayed up to 4 weeks after the rash.

In a child, fourth nerve palsy prompts consideration of congenital origin, with head trauma being the second most common cause.

TRIGEMINAL NERVE

Neuroanatomy

The trigeminal nerve, or fifth CN, is a mixed motor and sensory nerve. The larger lateral portion of the fifth CN transmits sensation from sharply defined cutaneous fields on the face, oral cavity, and nasal passages. The smaller motor branch provides motor function to the muscles of mastication and travels with the third division.

The ophthalmic, maxillary, and mandibular nerves enter the cranial cavity through the superior orbital fissure, foramen rotundum, and foramen ovale, respectively, to unite in the gasserian (semilunar) ganglion situated on the cerebral surface of the petrous bone.

Atrophy and fatty replacement of muscle mass can be visualized with magnetic resonance imaging (MRI) when the mandibular division of CN V has undergone motor denervation (Russo, Smoker, and Weissman 1997).

Trigeminal Sensory Neuropathy

Trigeminal sensory neuropathy presents with sensory disturbance in one or more divisions of the nerve. Patients with a benign form have no associated neurological defects and have preservation of the corneal reflex. The paresthesias may resolve completely in a matter of months, with only a small percentage of patients developing other conditions, such as trigeminal neuralgia. Sinister etiologies include infiltrating neoplasms or vasculitis. In this population, patients usually have other neurological signs associated with the facial numbness. If intraoral sensation is impaired sufficiently, there may be difficulty in chewing and swallowing. Perineural spread of facial skin cancer and nasopharyngeal carcinoma may occur months or years after excision of the malignancy (Catalano, Sen, and Btller 1995; Su and Lui 1996).

Trigeminal sensory neuropathy may be associated with scleroderma and other connective tissue disease. Distinguishing features of connective tissue disease are bilaterality, associated pain, and paresthesias that are not confined to individual nerve territories. Typically, the trigeminal motor pathway is spared. The site of involvement may be the cisternal portion of the nerve or gasserian ganglion, where motor and proprioceptive fibers bypass the sensory root (Forster et al. 1996).

Interferon-ty, used in the treatment of a variety of malignancies, may produce intermittent or continuous sensory disturbance in the trigeminal distribution (Read, Crawford, and Pender 1995).

In controlling the paresthesias ami neuropathic pain associated with these disorders, a literature review by McCleanc (2000) points to the effectiveness of lamotngine in these situations.

Numb Ciiin and Cheek Syndromes

Numbness of the lower lip may be the initial manifestation of metastatic disease to the lower jaw, affecting primarily the inferior alveolar nerve. Metastatic lung and breast cancers are the most common primary tumors.

There are also neoplastic causes of numbness in the malar region. History of basal or squamous cell carcinomas of the face should be sought. There may he a spread of this type of tumor along regional nerves to the skull base and into the intracranial space, with meningeal involvement. As a result of mandibular bone atrophy from aging, the elderly may develop stenosis at the mental nerve foramen with paresthesias in the ipsilateral chin. A similar phenomenon has been reported with scleroderma (Fischoff and Sirois 2000).

Trigeminal Nctjralgia

See Chapter 75 for a discussion of trigeminal neuralgia.

Traumatic Neuropathies

Both cranial and facial trauma may affect the peripheral infraorbital and supraorbital branches of the trigeminal nerve. Cavernous sinus tumors may also involve the trigeminal nerve, but often there is associated contiguous CN involvement that localizes the site of the disease. Trigeminal nerve branch injury can rarely result from dental anesthetic injections.

Lingual nerve (a branch of the mandibular division of CN V) injury may occur after surgery on the third molar and after laryngeal mask airway placement (Laxton and Kipling 1996). These patients present with complaints of paresthesias on the ipsilateral tongue surface.

Herpes Virus Infections

Viral infection with herpes simplex and herpes zoster may occur. The recurring herpes simplex mucous membrane lesions that occur throughout an individual's lifetime are associated with lifelong residence of that virus in the trigeminal ganglia. Herpes zoster, which is the result of lifelong varicella zoster virus residence in the ganglion, produces a much more fulminating infection, with disabling pain. Preherpetic neuralgia may precede the rash by several days and is followed by postherpetic neuralgia in about one third of the patients. The ophthalmic division of the trigeminal nerve is most commonly affected.

ABDUCENS NERVE

Neutoan atomy

Of all the motor nuclei of the extraocular nerves, those of the abducens nuclei lie farthest from rheir muscles of termination and originate at the lowest level in the brainstem. They lie just below the floor of the fourth ventricle, close to the midline, in the caudal pons. In contrast to the trochlear nerve, but in common with the oculomotor fibers, the abducens or sixth CN fibers have a considerable intramedullary extent. The axons course ventrally and in a somewhat caudal direction through the brainstem parenchyma to emerge at the pontomedullary junction.

The nerve then makes a right-angle turn to pass upward along the face of the clivus; it turns anteriorly at Dorello's canal and passes into the medial aspect of the cavernous sinus, where it lies just beneath the internal carotid artery, The abducens nerve supplies the lateral rectus muscle.

Brainstem Syndromes

As with the other CNs, lesions at different foci in the brainstem produce distinct syndromes. This anatomy explains the rare combinations of ipsilateral sixth nerve palsy, gaze palsy, and peripheral seventh CN weakness (Millard-Cubler syndrome) and of sixth nerve palsy and contralateral hemiplegia (Foville's syndrome). Infarction in the territory of anteroinferior cerebellar artery is probably the most common cause of these syndromes. Foville's syndrome is often combined with varying degrees of ipsilateral Horner's syndrome, facial hypesthesia, and hearing loss. A characteristic disorder, referred to as *one-and-a-half syndrome,* consists of preservation of abduction in only one eye, which also exhibits jerk nystagmus in the abducted position, while the other eye lies fixed in midline for all attempts at lateral movement.

See Chapter 22 for a discussion of brainstem syndromes affecting the abducens nerve.

Extra-Axial Posterior Fossa Syndromes

It is possible for any cerebellopontine angle tumor to cause varying combinations of trigeminal, facial, and auditory nerve dysfunction. Chordomas of the clivus may selectively involve the sixth nerve in its climb along the clivus. In the preantibiotic era, medial extension of middle ear infection or mastoiditis resulted in osteitis of the petrous pyramid and paralysis of CN VI as it approached Dorello's canal

and the petroclinoid ligament (Gradenigo's syndrome). Metastatic disease to the same area or primary neoplasia, such as cholesteatoma, may produce a similar painful sixth nerve palsy. In the middle-aged to elderly adult with abducens nerve palsy and a combination of cervical [ymphadenopathy, serous otitis media, and blood-tinged nasal discharge, evaluation must exclude a nasopharyngeal carcinoma. Both unilateral and bilateral abducens paresis may occur in the syndrome of spontaneous intracranial hypotension (Berlit, Berg-Dammer, and Kuchne 1994).

For a discussion of cavernous sinus syndromes, see Oculomotor Nerve, earlier in this chapter.

Pathophysiology

Of all the oculomotor palsies, abducens nerve paresis is the one most frequently reported and at the same time most often indeterminate in cause. In the middle-aged to elderly adult population, especially if there is a history of hypertension or diabetes, small-vessel ischemic infarction of the nerve is the most likely cause. The microscopic neuroanatomy of the abducens nerve, as well as of rhe oculomotor and trochlear nerves, reveals rhat they are penetrated by small nutrient vessels, occlusion of which produces infarction. If the sixth nerve palsy is bilateral, however, ischemia is seldom the cause, and neoplasia, demyelinating disease, subarachnoid hemorrhage, meningeal infection, and increased intracranial pressure must be considered.

Unilateral or bilateral abducens weakness is also encounteted as part of Wernicke's disease in the nutritionally deprived alcoholic population. Myasthenia gravis may produce isolated weakness of ahduction, mimicking abducens nerve palsy.

Abducens. Nerve Palsy in Childhood

In children, abducens nerve palsies are most frequently due to neoplasia (13%) and trauma (40%). Often the neoplasm is a primary brainstem glioma, and abducens weakness may be the first sign of disease. In the newborn period, abducens nerve paresis may be a transitory and benign finding. Amblyopia may be a complication of sixth nerve paresis in children, and close monitoring to prevent this complication is warranted (Aroichane and Rcpka 1995).

FACIAL NERVE (CRANIAL NERVE VII)

Neuroanatomy

The facial nerve is the most complex of the CNs because of its multiple motor, sensory, and autonomic components, and its long, tortuous intracranial and extracranial course. The nerve is the motor nerve to the mimetic muscles of the face. It also contains secretory fibers to the salivary and lacrimal glands, and the mucous membranes of the oral and nasal cavities. There are also somatic pain fibers from the external auditory canal and a small strip between the mastoid and the pinna, as well as taste fibers from the ipsilateral two thirds of the tongue.

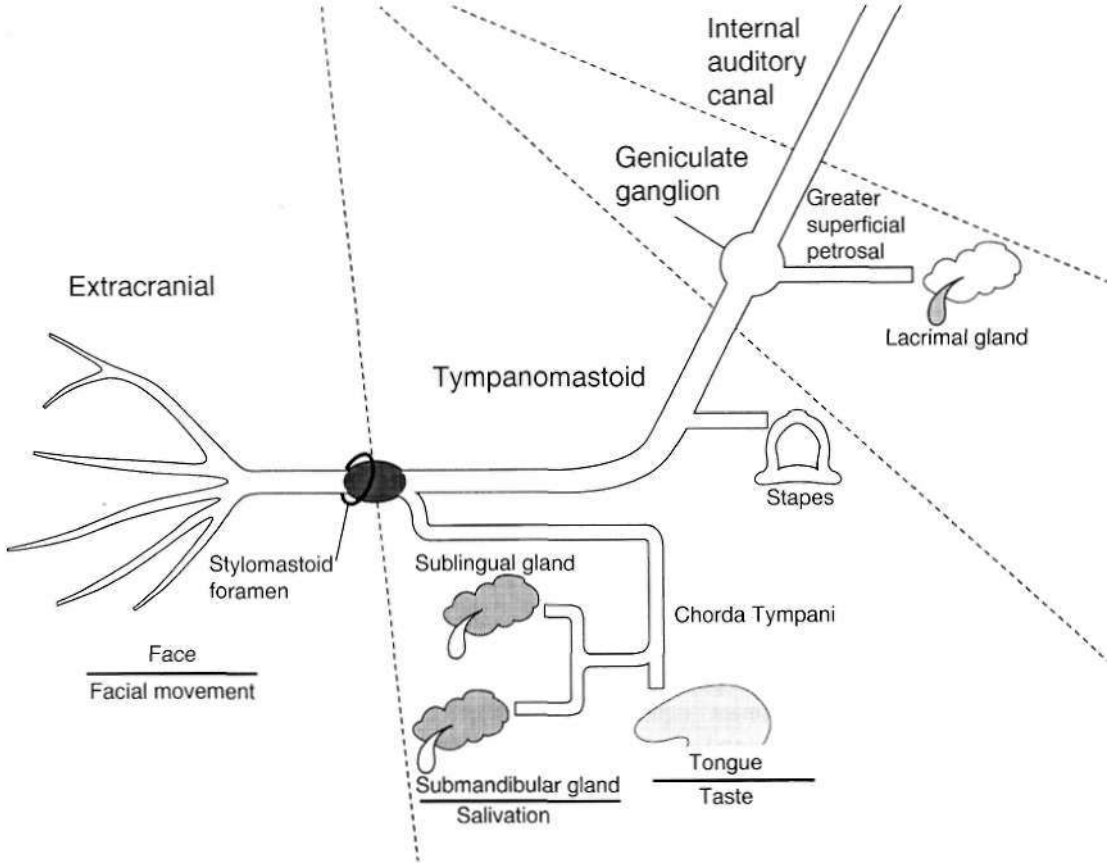
The facial nerve has two principal roots. Seventy percent of the nerve fibers arise from motor neurons of the facial nucleus; thirty percent are mixed sensory and autonomic fibers, forming the nervus intermedius of Wrisberg. The facial motor nucleus is located in the ventrolateral portion of the caudal pons. Its fibers coutse from the dorsal aspect of the nucleus to the medial side of the sixth CN nucleus, at which point they curve laterally around the dorsal surface of the sixth CN nucleus, forming the facial colliculus in tlu- t'liior ni tlu- fourth uiiii:.lf. The fibers then pursue a ventrolateral course through the pontine tegmentum to exit from the lower body of the pons between the olive and restiform body. Fibers for voluntary and reflexive facial movements are anatomically separate rostral to the lowei pons (Urban et al. 1998).

The sensory root of the facial nerve (the nervus intermedius) is a combination of sensory and parasympathetic nerve fibers that include special visceral afferent fibers arising from the bipolar neurons within the geniculate ganglion, which supply taste fibers to the anterior two thirds of the tongue by way of the chorda tympani. The centra) portions of these branches traverse the nervus intermedins and terminate in the nucleus solitarius. Visceral efferent fillers arisir.s', fruir. the superior salivatorv nuclei course in the nervus intermedius and travel with the greater superficial petrosal nerve to the synapse in the sphenopalatine ganglion, yielding postganglionic fibers to the lacrimal and palatine glands. Still other preganglionic efferents continue in the chorda tympani to the submandibular glands. After leaving the pons, the motor and sensory roots of the facial nerve course through the cerebellopontine angle cistern for approximately 24 mm before entering the internal auditory canal. Within the canal, CN VII occupies a position anterior and superior to CN VIII.

From the internal auditory canal to the stylomastoid foramen, CN VII traverses a torruous course of approximately 33 mm.

The facial nerve is the longest and most complex of the CNs (Figure 76.1), consisting of six segments: intracranial, internal auditory canal, labyrinthine or petrous, tympanic, mastoid, and intraparotid. The labyrinthine, tympanic, and mastoid segments are in the fallopian canal.

After the facial nerve (with the nervus intermedius) leaves the internal auditory canal, it begins its long course through the fallopian canal, beginning with the labyrinthine segment, which is approximately 3—4 mm long. The nerve enters the fallopian canal at the petrous bone and runs at a right angle to the petrous pyramid. The geniculate ganglion is included in this segment, giving rise to the greater superficial petrosal nerve. This is the narrowest portion of the fallopian canal, and the nerve occupies up to 80% of



HCiURI- 7h. I J In, schematic ol the facial nerve shows the- major subdivision- .nu! ILUMI.IU-. die |nioci]ial functions thai mighi he impaired at the level of a lesion and distal to it. For example, a lesion at the level of the geniculate might produce impaired taste and glandular secretions, as well as hyperaeusis (in addition to facial paralysis).

the available diameter. In addition, the labyrinthine portion is the only segment without anastomosing atterial arcades, making it vulnerable to ischemia and compression. The labyrinth and tympanic segments of the fallopian canal form an acute angle of approximately 75 degrees, predisposing the nerve to vascular lesions and traumatic injury. I'he tympanic portion 12-13 mm) courses behind the cochlea and semicircular canal, ending with the beginning of the mastoid segment (15-20 mm) that continues along the anterior wall of the mastoid process. It is the longest segment of the nerve and has two major branches. The first branch goes to the stapedius muscle. The second branch is the chorda tympani, the terminal branch ol the ncrvus intermedins. This branch courses anteriorly and superiorly over the incus and under the malleolus, crossing the tympanic cavity to exit the temporal bone through the petrotympanic fissure, joining the lingual nerve to innervate the submandibular and sublingual glands. The chorda tympani also contains the taste fibers from the anterior two thirds of the tongue.

CN VII ends its course in the fallopian canal by exiting through the stylomastoid foramen, giving off several branches, which include an inferior branch to the posterior belly of the digastric and stylohyoid muscles. The main trunk of the facial nerve entets the parotid gland, dividing into upper and lower parts. The upper division gives rise to frontal, zygomatic, and buccal branches; the lower trunk gives rise to the mandibular and cervical branches. Approximately 17 paired muscles of facial expression are innervated by these various branches. An upper group of muscles raises the eyebrows, moves the forehead, and is involved in frowning. An intermediate group is involved in closing the eyelids and wrinkling the nose, and an inferior group is involved in smiling, laughing, whistling, wrinkling the chin, and raising the upper lip. The only facial muscle that is not innervated by CN VII is the levator palpebra superioris, which is innervated by the oculomotor nerve.

Supranuclear lesions produce a different pattern of facial paralysis than do infranuclear and nuclear lesions (Table 76.2). The traditional explanation is that the lower face has primarily a contralateral innervation, whereas the upper face has both ipsilateral and contralateral innervation. However, a contributing factot is that the conical representation of the upper face is in the anterior cingulate gytus, and not the motot cortex (Morecraft et al. 2001).

There is a disparity between emotional facial mimetic expression and voluntary facial movement that is best

Table 76.2: Clinical differential features of upper motor neuron versus lower motor neuron facial weakness

Upper motor neuron lesions	*Lower motor neuron lesions*
Unilateral paresis of voluntary movements of lower face with sparing of the frontalis muscle	Unilateral paresis of all mimetic muscles, including the frontalis muscle
Facial muscle weakness less apparent with emotional than with voluntary action	Degree of facial weakness similar with emotional and voluntary movements
Preservation or accentuation of facial reflexes	Suppression of facial reflexes
Preserved taste, anterior two thirds of tongue	Possible impairment of taste
Normal lacrimarion	Possible abnormality of lacrimation

explained by different pathways subserving these functions {Holstege 2002).

Clinical Evaluation

The symptoms of facial nerve disease depend on several factors, including size of lesion, severity of the disorder, acuteness of onset, and whether the lesion or lesions are bilateral or unilateral. A sudden severe unilateral infranuclear paralysis, as seen in Bell's palsy, produces (in addition to an obvious cosmetic embarrassment) significant dysarthria, pooling of saliva, drooling, and decreased tearing; it also allows food to collect between the gum and the cheek as a tesult of buccinator weakness. Depending on the size of the lesion, there may also be perversion of taste and hyperacusis. On the other hand, a moderate degtcc of weakness of the lower face, as seen with a unilateral corticobulbar lesion, may produce few complaints relative to the face, particularly if attention is distracted by ipsilateral limb weakness or if language dysfunction is present because of a dominant hemisphere lesion. Bilateral corticobulbar disease, as with multiple lacunae, is much more devastating to speech and swallowing functions. Unilatetal facial weakness of slow evolution, as seen with a pontine glioma, may go unnoticed by a patient, although it is obvious to the examinet. This is consistent with the general clinical observation that objective neutological deficits more apparent to the examiner than to the patient are usually of gradual evolution.

Facial reflexes may aid in establishing or localizing lesions of the facial nerve. Some arc true myotatic reflexes, and others represent associated movements. A variety of stimuli, such as noise, sudden light, and pain, can elicit a blink reflex that uncovers unilatetal facial weakness.

The bilateral orbicularis oculi (blink or glabellar) reflex is elicited by tapping over the supraorbital ridge or root of the nose. It should be elicited by holding a hand over the top of the forehead, to avoid a visual blink response. With early, mild, or resolving unilateral facial paresis, the ipsilateral glabellar reflex is diminished. The afferent pathway is via the first division of CN V, with a rapid unilateral monosynaptic component and a delayed bilatetal polysynaptic component. A variation of this reflex is the orbicularis oculi stretch teflex, elicited by gtasping the lateral orbital skin between the thumb and index finger and tapping the thumb with a reflex hammer. A similar bilateral blink response is present. The afferent impulses, howevet, atisc from stretch receptors in the muscle.

Anothct stretch reflex is the orbicularis oris reflex, elicited by percussing the uppet lip and producing elevation of the lip and angle of the mouth. Like most othet myotatic responses, these reflexes are diminished or abolished by segmental dysfunction and preserved or heightened with bilateral corticobulbar lesions.

Bell's phenomenon is a true associated movement. With attempted closure of the eyes against resistance, the globes move up and out. This normal movement can be observed with the incomplete eyelid closure in Bell's palsy.

The stapedial reflex is particularly helpful in diagnosis. Stapedius muscle contraction, activated by strong acoustic stimuli, pulls the stapes out of the round window, attenuating intense sound waves. Reduction ot absence of this reflex results in hyperacusis or phono phobia. It can be quantified by measuring acoustic impedance (see Chaptet 41) but can be tested at the bedside using the stethoscope loudness imbalance test. A stethoscope is placed in the patient's ears, and a gently vibrating tuning fork is placed on the bell. With notmal hearing, the perception of sound is symmetrical. With greater activation, the sound laterali7.es to the side of the facial paresis (in some cases) because the attenuating effect of the stapedius muscle is reduced or absent.

The sensory functions of CN VII are not easily tested, arc rather cumbersome, and are not always reliable. Testing taste sensation is desctibed in Chapter 20.

With any facial paresis, it must first be determined whether the lesion is affecting the upper motor neuron or the lower motor neuron. In most instances, it is obvious, but when it is less clear, cettain critical observations can usually settle the issue.

Upper motor neuron disorders with unilateral facial paresis affect the voluntary movements of the lower face with relative sparing of the orbicularis oculi, frontalis, and corrugator supercilii muscles. There are certain circumstances in which this rule is violated:

- During recovery from Bell's palsy, if the upper facial groups recover before the lower groups, and if recovery is incomplete, as may occasionally occur in incomplete acute lesions

If nuclear lesions are restricted to the caudal portions of the nucleus, as in polio, and at some stages of motor neuron disease

If an extracranial lesion involves only the lower division of the facial nerve, as sometimes happens after radical neck dissection or with parotid tumors

In upper motor neuron lesions, there is preservation of the blink and stapedial reflexes; lacrimal and taste sensibilities also remain unimpaired. This may also be true for lower motor neuron lesions. If reflex functions are involved, however, this is strong evidence that the lesion is not upper motor neuron.

In lower motor neuron lesions, the degree of weakness is the same with voluntary and emotional movements. With upper motot neuron involvement, particularly of the prefrontal cortex, the face is relatively symmetrical, with a normal emotional smile, and the movement of the involved side may actually be exaggerated, despite the unilateral weakness on voluntary contraction. The latter observation is probably the only one that consistently separates upper motor neuron from lower motor neuron lesions.

A large number of congenital and acquired disease states may damage the facial nerve anywhere along its course, from its brainstem nuclear origin to its peripheral terminations in the face.

Congenital Disorders

Congenital disotders of the facial nerve must be distinguished from traumatic damage to the facial nerve as a result of birth injury. Difficult forceps delivery, periauricular ecchymosis, hemotympanum, and swelling often provide clues to a traumatic cause, but many patients seem to have an uncomplicated birth history,

In contrast to infants with traumatic facial paralysis, newborns with congenital disorders of facial palsy have a poor prognosis for improvement in facial nerve function. Clues pointing to a congenital cause may be other birth defect stigmata, especially microtia and external auditory canal atresia. Congenital malformations elsewhere in the body, such as limb deformity or hypoplasia of the pectoral muscle, also suggest a congenital cause for the facial palsy. There are a number of well-recognized syndromes of congenital facial palsy, including cardiofacial syndrome and Mobius' syndrome. Cardiofacial syndrome comprises facial asymmetry when crying but not at rest and may result from isolated weakness of the depressor anguli oris and depressor labii inferioris muscles of the lower lip. It does not interfere with smiling or sucking and does not result in drooling, but it may be associated with congenital heart defects and other anomalies.

Mobius' syndrome consists of a spectrum of abnormalities; most cases occur on a sporadic or familial basis. The mutation in one large family with dominantly inherited Mobius' syndrome was mapped to the long arm of chromosome 3. The most consistent features arc congenital paresis of CNs VII and V1I1 with variable orofacial and limb malformation. Necropsy has shown defects ranging from hypoplasia to agenesis of the respective CN nuclei.

Toxins

Peripheral facial paralysis may occur in thalidomide embryopathy. Medical and occupational exposure to the antiseptic solution chlorocreso), used in electrode paste and various dcrmatological skin ctcams, may produce transient facial paralysis. Ingestion of the antifreeze component ethylene glycol, eithet in a suicide attempt or for inebriation, may also cause bilateral peripheral facial weakness, either permanent ot temporary.

Traumatic Facial Palsy

A peripheral facial paralysis occurring in the context of head trauma should always raise the possibility of basilar skull fracture. Basilar temporal bone fractures are generally categorized as eithet longitudinal (extending medially along the bony external canal) or transverse (crossing the long axis of the pettous pyramid). Both types of fracture may be accompanied by facial nerve palsy.

Transient facial palsy may oivur 1:1 up in *?.(.)%* or patients undergoing sphenoidal electrode insertion for prolonged video electroencephalographic monitoring. The mechanism is likely related to the effect of local anesthesia on the peripheral branches of the facial nerve.

Pregnancy

Cohen et al. (2000) reviewed the occutrcncc of Bell's palsy in pregnancy. They concluded that (1) women of reproductive age are affected two to four times more often than men of the same age, (2) pregnant women are affected three times more often than nonpregnant patients, and (3) most cases occur in the third trimester or in the puerperium. The authors concluded neonatal outcome is unaffected, recovery is good, and treatment of the palsy with corticosteroids is conttoversial. In women developing Bell's palsy while pregnant, there is an increased risk of hypertensive disorders of pregnancy such as preeclampsia (Shmorgun, Chan, and Ray 2002)

Bilateral Facial Palsy

Bilateral simultaneous peripheral facial weakness can be part of the clinical spectrum in several syndromes.

Best known is the facial diplegia of varying intensity that accompanies the Guillain-Barre syndrome. Bilateral facial weakness in the presence of aseptic meningitis or with a slightly erythematous indurated face resembling painless cellulitis should raise the possibility of Lyme disease. The conjunction of Lyme aseptic meningitis and facial weakness is sometimes referred to as *Banmuarth's syndrome.* Recurrent bilateral facial palsy is also sometimes seen in sarcoidosis and at the time of seroconversion in human immunodeficiency virus infection.

Keane (1994) provided an authoritative review on the topic of bilateral facial palsy. In his extensive series, 22 of the 44 patients reported had self-limited causes, including Bell's palsy and Guillain-Barre syndrome.

Schattner et al. (2001) revisited the topic adding acute lymphoblastic leukemia to the differential diagnosis.

Tumor involvement of the facial nerve itself is not common, but it remains an important consideration in the differential diagnosis, particularly with slowly progressive (over many days to several weeks) peripheral facia! weakness. Metastatic invasion of the temporal bone is the most common type. Breast, lung, and prostate are the most common primary tumors. Direct extension of regional tumors and primary schwannomas of the facial nerve also occur. In all these cases, the onset and course are slow and progressive. Parotid gland cysts and tumors, both benign and malignant, may involve terminal branches of the facial nerve that produce varying degrees of peripheral weakness. Obtaining a history of facial skin cancer in a patient presenting with a partial facial palsy or facial paresthesia is important because perineural spread of tumor can present long after "complete" excision of a skin malignancy (Catalano, Sen, and Biller 1995).

Bell's Palsy

The appearance of a severe, unilateral, intranuclear facial palsy is one of the most distinctive in clinical medicine. The most common cause of an acute, acquired, nontraumatic lesion is Bell's palsy, in which there is a flaccid paresis of all mimetic muscles on the involved side. In a severe case, the affected side is smooth and the brow droops, but the palpebral fissure is widened. The angle of the mouth is depressed, and the cheek balloons on expitation. The lid remains open (lagophthalmos), and on attempted closure, the globe turns up and out (Bell's phenomenon). The lower lid is everted with excessive tearing (epiphora). Facial movements arc paralyzed to voluntary and involuntary contractions, and various facial reflexes are lost. Traditional teaching posits discrete anatomical localization along the various segments of CN VII in Bell's palsy based on the test results of taste, the stapedial reflex, lacrimation, and mandibular deviation. Although there may be some validity to these observations in early lesions, the localization is much less precise in practice. As a general rule, proximal lesions at or before the geniculate ganglion may affect taste and lacrimation, as well as the stapedial reflex, whereas those distal to the geniculate ganglion produce only muscle weakness. The incidence of Bell's palsy in the general population is approximately 20 cases per 100,000, with a peak incidence in the third decade. The typical patient complains of an acute onset of facial palsy, which may evolve over 24-48 hours, often accompanied by retroauncular pain. This disorder affects males and females of all ages and is believed to be of viral origin (most often herpes simplex). It often begins with pain in or behind the ipsilatcral car, suggesting an ear infection. Unilateral weakness invariably follows within several days and usually achieves maximal paralysis within 48-72 hours. Patients may report tingling paresthesias on the involved side of the face early in the course, but this symptom is seldom prominent. Impairment of taste and hyperacusis (due to weakness of the stapedius muscle) is present in many cases. The oral phase of swallowing was found to be disturbed in 79% of patients with Bell's palsy (Scc-il, Aydogdu, and Ertekin 2002) due primarily to weakness of the orbicularis oris and buccinator muscles, resulting in the accumulation of food in the mouth. MRI shows contrast enhancement of the involved nerve (Sartoretti-Schcfer ct al. 1998).

Eighty to eighty-five percent of patients recover completely within 3 months of onset. Incomplete paralysis at the onset is perhaps the most favorable prognostic sign. Electrophysiological demonstration of lack of excitability of the facial nerve to electrical stimulation and electromyographic evidence of denervation of the involved facial muscles after 2-3 weeks establish severe axon loss. This implies a more prolonged and probably incomplete recovery, with risk of aberrant regeneration of the facial nerve fibers. Har-El and McPhee (2000) have successfully employed transcranial magnetic stimulation in the laboratory to determine the integrity of the facia! nerve immediately after trauma, bypassing the time limitations imposed by wallerian degeneration.

The prognosis is less favorable in the syndrome of facial nerve palsy with geniculate herpes (Ramsay Hunt syndrome), which involves pain and vesicles in the external auditory canal or soft palate. Scvcdia-Cayabyab and Spaeey (2002) have documented recurring Bell's palsy secondary to herpes zoster infection; acyclovir treatment produced cessation of the episodes. This report adds herpes zoster to the differential diagnosis of recurrent Bell's palsy along with sarcoid and Lyme disease. Recurrent Bell's palsy may be associated with a deeply furrowed tongue (lingua plicata) and recurrent facial edema in Melkersson's syndrome; the prognosis is initially good, but permanent paralysis may eventually result after many recurrences.

Aberrant regeneration may have several variations, rhe most prominent being involuntary tearing of the eye on the involved side when eating ("crocodile tears") or synkinesis of the facial musculature when chewing. This often takes the form of a jaw-winking phenomenon, wherein the lid

closes on the involved side when the jaw opens (Marin-Amat syndrome). The onset of Bell's palsy in an elderly person should prompt the physician to consider the possibility of diabetes or hypertension before the administration of prednisone, which is an often prescribed but controversial treatment.

Infections

Infection of the central nervous system by *Borrelia burgdorferi* (Lyme meningitis) is an increasingly recognized cause of peripheral nerve weakness in endemic areas. Leprosy also affects the facial nerve (see Chapter 59A).

Hemifacial Spasm

In hemifacial spasm, there are recurring episodes of involuntary unilateral spasms of the facial musculature invariably beginning about the lateral canthus of the eye on the involved side and gradually spreading downward, over many months to several years to involve the remainder of the facial musculature. Although mass lesions such as meningioma are rarely encountered as the etiology, Janetta has documented the common cause to be neurovasculature compression from a redundant vascular loop. Hypertension appears to be a predisposing factor if the hemifacial spasm occurs on the left but not the right side of the face (DeFazio ct al. 2000).

COCHLEAR-VESTIBULAR NERVE (CRANIAL NERVE Vm)

See Chapters 18, 19, and 41.

GLOSSOPHARYNGEAL NERVE (CRANIAL NERVE DC)

Neuroanatomy

Fibers of the glossopharyngeal nerve, or CN IX, originate from several nuclear complexes (tractus solitarius [gustatory nucleus], nucleus ambiguus, and inferior salivatory nucleus) in the brainstem. They pass outward as several distinct subsets of fibers, to emerge from the medulla between the inferior olive and the inferior cerebellar peduncle, caudal to the seventh CN and rostral to the U'lidi (:N. UN IX exits the skull through the jugular foramen along with CN X and CN XI and comes to lie between the internal jugular vein and the internal carotid artery (Remley and Latchaw 1993). It ultimately reaches the lateral wall of the pharynx by tracking along the inferior border of the srylopharyngeus muscle.

Clinical Features

Isolated lesions of the glossopharyngeal nerve are extremely uncommon. Almost invariably, involvement of this nerve occurs in conjunction with that of the vagus, accessory, and hypoglossal nerves. Isolated paralysis of the glossopharyngeal nerve produces slight and usually transient difficulty in swallowing, due to involvement of the stylopharyngeus muscle, and temporary decrease in parotid gland secretions.

Peripheral dysfunction of the nerve may be due to blunt neck trauma, such as nonfatal suicidal hanging, diseases of the middle ear, and pharyngeal abscesses.

Glossopharyngeal Neuralgia

See Chapter 75.

VAGUS NERVE (CRANIAL NERVE X)

Neuroanatomy

The vagus nerve is the longest of all the CNs. In many respects, its origins and functions are similar to those of the glossopharyngeal nerve.

The motor fibers of the vagus arise from the nucleus ambiguus and the dorsal motor nucleus of the vagus. The sensory portions have cell bodies of origin in the jugular and nodose ganglia. Exiting the skull through the jugular foramen, the vagus travels within the carotid sheath between the internal jugular vein and the carotid artery, giving off pharyngeal branches and superior and inferior (recurrent) laryngeal nerves (Remley and Latchaw 1993), Spontaneous dissection of the internal carotid artery may present with an isolated vagal neuropathy (Moussouttas andTuhnm 1998).

Brainstem Lesions

Supranuclear involvement of the vagus nerve is significant only when it is bilateral, producing a pseudobulbar-type syndrome with dysphagia and dysarthria. Nuclear involvement of the vagus nerve may be encountered as part of motor neuron disease in patients with progressive bulbar palsy. Poliomyelitis and primary brainstem neoplasms may also produce dysfunction at a nuclear level. (See Chapter 22 for a fuller discussion of brainstem lesions affecting the vagus nerve.)

Vascular lesions within the medulla may involve the vagus nerve. Wallenberg's syndrome is the most common presentation, with the acute onset ni v.r.;'.ul:i -> (lineup), vertigo, and ataxia. On examination, an ipsilateral Horner's syndrome, crossed (ipsilateral face and contralateral body) loss of pain and temperature sensation,

ipsilateral cerebellar tremor, and weakness of the ipsilateral oral pharynx constitute the clinical picture.

Systemic Disorders

Vagal nerve dysfunction with vocal cord paresis is sometimes the initial manifestation of multiple system atrophy (see Chapters 77 and 83). The recurrent laryngeal branches of the vagus nerve may be damaged as a result of primary thoracic disease, the left more often than the right because it is longer. Of clinical value in localizing lesion sites in vagal disease is that the pharyngeal branches depart the vagus high in the neck; therefore the absence of sensory changes in the pharynx suggests that the lesion is below this level. Tumors of the mediastinum and lung are the most common causes of an isolated vocal cord palsy. Cytomegalovirus infection of the laryngeal nerves with hoarseness may occur in patients with acquired immunodeficiency syndrome.

Sl'INAL ACCESSORY NERVE (CRANIAL NERVE XI)

Neuroanatomy

The spinal accessory nerve is entirely motor in function and composed of two portions: a smaller cranial part ("accessory" to the vagus) and the larger spinal portion (arising from the upper five cervical cord segments). The cranial portion, with the vagus and glossopharyngeal nerves, supplies the musculature of the pharynx and larynx, whereas the spinal portion innervates the sternocleidomastoid and upper portions of the trapezius musculature.

The spinal portion emerges as a series of rootlets between the dentate ligament and the dorsal horns of rhe spinal cord. Merging, they ascend and pass through the foramen magnum. Here they join the accessory rootlet originating from the nucleus ambiguus in the caudal medulla oblongata. These fused components then pass through the jugular foramen with CN TX and CN X. After exiting the skull, a branch travels with the vagus, and the spinal accessory nerve proper continues, supplying the sternocleidomastoid and trapezius muscles (Figure 76.2).

The principal action of the sternocleidomastoid draws the occiput toward the side of the contraction, rotating the face to the opposite side. Contracting together, the sternocleidomastoid muscles flex the cervical spine. The upper trapezius retracts the head and elevates, retracts, and rotates the scapula; it also elevates the abducted arm above the horizontal. With bilateral contraction, the head draws back and the face up. The trapezius is also innervated by branches of the cervical plexus. The supranuclear innervation is complex. Corticobulhar fibers to the trapezius are principally crossed, but fibers destined for the sternocleidomastoid terminate predominantly in the ipsilateral nuclei (De Toledo and Dow 1998),

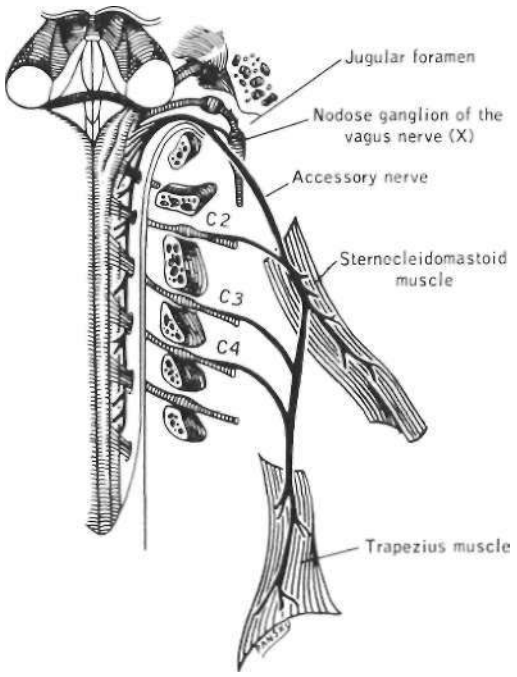


FIGURE 76.2 Course and distribution of the spinal accessory nerve. (Reprinted with permission from House, E. L. &: Pansky, R. 1967, *A Functional Approach to Neuroanatomy*, 2nd ed, McGraw-Hill, New York.)

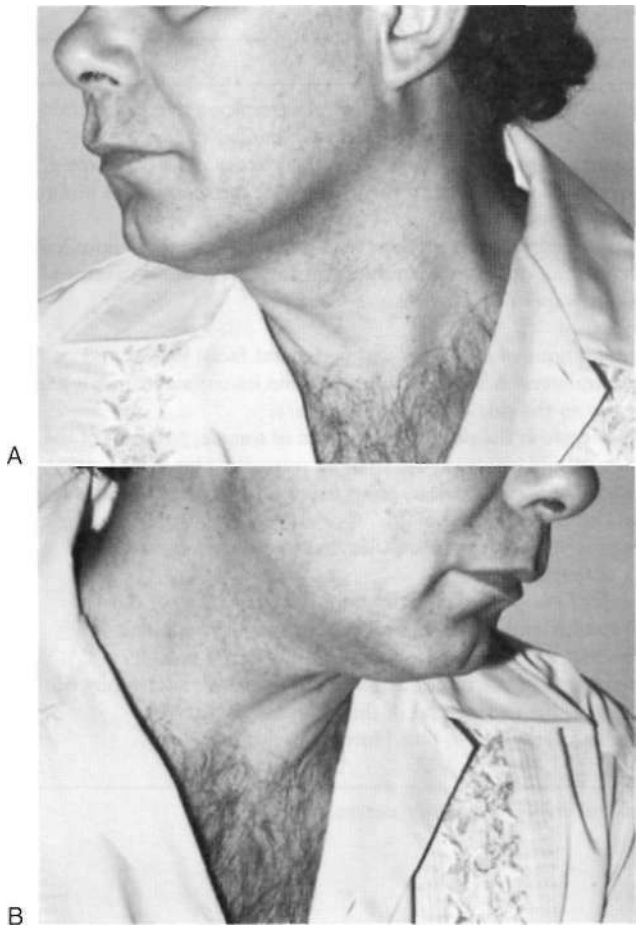
Although the spinal accessory nerve is regarded as purely a motor nerve, the symptoms of its dysfunction are both motor and sensory, the latter being predominantly pam. In acute lesions, traumatic or inflammatory, the pain is steady, severe, and localized to the neck and top of the shoulder. Pain, however, may be delayed until the patient starts to use the arm. Paresthesias arc common and often diffuse, taking the form of pins and needles, coldness, and throbbing sensations. When the sternocleidomastoid muscle is involved unilaterally, there is loss of bulk, which is best demonstrated by turning the chin against resistance (Figure 76.3).

The findings with a unilateral lesion include an obvious drooping of the affected shoulder. With the arms hanging loosely at the sides, the fingertips touch the thigh at a lower level on the affected side. Winging of the scapula is due to paresis of the middle trapezius muscle, whereas loss of abduction more than 90 degrees is due to weakness of the upper trapezius. Winging due to trapezius palsy is more prominent with abduction of the arm; the superior angle of the scapula moves farther from the midline (Figure 76,4),

Wirh a long thoracic nerve lesion, the winging is increased with forward flexion of the arm.

Evaluating supranuclear lesions may be confusing because of the ipsilateral innervation of the sternocleidomastoid muscle. In hemispheric lesions, the weakness of the sternocleidomastoid is on the same side as the lesion (De Toledo and Dow 1998). If this is not recognized, the signs



1'IGURE 76.3 (A) Normal left sternocleidomastoid muscle with forceful thrust of chin to the right. Note the prominent left sternocleidomastoid muscle. (B) The same maneuver as that shown in A, but to the left, showing loss of bulk of the right sternocleidomastoid muscle.

may indicate that the patient with a left hemiparesis has a right accessory nerve lesion and therefore a lower brainstem problem rather than a more rostral lesion. Cortical, capsular, and high brainstem lesions affecting the corticobulbar fibers may result in decreased strength on turning the head away from the side of the lesion. Dissociated weakness may also cause confusion when the sternocleidomastoid muscle is involved and the trapezius is not.

Etiology and Management

The most common cause of eleventh nerve palsies are iatrogenic, secondary to nerve injury during surgery involving the posterior triangle, particularly lymph node biopsies. The symptoms are often delayed for 1-2 weeks, followed by pain and weakness. If hiss ol function is complete or the extent of the lesion is unknown, exploration with reanastomosis of the nerve is probably the best approach. Electrodiagnosis with nerve conduction studies

FIGURE 76.4 Spinal accessory lesion on attempted abduction of the left arm, demonstrating scapular winging.

and needle examination done after the third week postinjury may assist in determining whether the lesion is partial or complete. Traumatic lesions other than those with iatrogenic causes include shoulder injuries, bites, stretching of the nerve, and radiation.

Supranuclear involvement, as from stroke, usually causes only modest dysfunction of CN XI, manifested by contralateral drooping of the shoulder and weakness of the upper portions of the trapezius muscle, as well as weakness of head turning away from the side of the hemispheric lesion. Nuclear involvement of CN XI occurs in motor neuron disease, syringobulbia, and syringomyelia and is associated with muscle paresis, atrophy, and fasciculations,

A large group of named syndromes (Table 76.3) occurs with involvement of this nerve and other medullary structures. Isolated peripheral involvement is uncommon and, as with central involvement, is usually attended by evidence of involvement of other structures. Causes include internal jugulai \ cm C.UIIHII.IILOII. biting injures n> the neck, shoulder dislocation, unsuccessful attempts at suicidal hanging, and radical neck dissection. Selective trapezius involvement has occurred in patients undergoing carotid endartcrectomy; traction on the sternocleidomastoid muscle during surgery may produce stretch injury to the branch to die trapezius. In myotonic dystrophy, atrophy of the sternocleidomastoid muscle, simulating selective spinal accessory nerve involvement, is prominent.

A benign self-limited isolated paralysis of the eleventh CN may be analogous to other types of spontaneous and restricted neuropathies, such as Bell's palsy or long thoracic nerve palsy. An abrupt onset of sharp pain localized to the posterior sternocleidomastoid region is followed by resolution of the pain and the typical features of an accessory nerve lesion, with winging of the scapula and drooping of the affected shoulder.

Matz and Barbara (1996) and London, London, and Kay (1996) provide excellent reviews of the diagnosis and treatment of iatrogenic spinal accessory nerve injury.

Table 76.3: Syndromes of the upper, middle, and lower cranial nerves

Syndromes	*Cranial nerve involvement*	*Clinical abnormalities*
Weber's	III	Oculomotor palsy with contralateral hemiplegia due to pyramidal tract involvement at the base of the midbrain
Benedikt's	III	Oculomotor palsy with contralateral corticospinal signs, tremor, and cerebellar ataxia due to involvement of the red nucleus and the corticospinal tract
Tolosa-Hunt	Varying combinations of III, IV, V (ophthalmic or maxillary) and VI	Multiple designated cranial nerve palsies with cavernous sinus lesions; coexisting optic nerve dysfunction suggests a distal cavernous sinus, superior orbital fissure locus
Millard-Gubler and Fovilie's	VI and Vll	Combinations of ahducens and peripheral facial palsies and contralateral hemiplegia from pontine lesion; sometimes a gaze palsy to the side of a lesion (Foville's)
Verntt's (jugular foramen)	IX, X, and XI	Loss of taste at the posterior one third of tongue; paralysis of the VC, palate, and pharynx; paralysis of trapezius plus SCM
Schmidt's	X and XI	Paralysis oi the -. • H IL p.il.iK', pli.ir yu\. ,nnl MIVIU; i — i I. i L . i .il u i/akncss of the trapezius and SCM
Tapia's	X and XII	Paralysis of the pharynx and larynx; paralysis and atrophy of die tongue
Jackson's	X, XI, and XII	Patesis of the palate, pharynx, and larynx; paresis of the trapezius and SCM; paresis and atrophy of the tongue
Collet-Sicard	IX, X, XI, and XII	Anesthesia of the palate; paresis of the VC and palate; weakness of the trapezius and SCM; paresis and atrophy of the tongue; hemianesthesia of the pharynx and larynx
Villaret's	IX, X, XI, XII, and cervical sympathetic	Same as Collet-Sicard, plus Horner's syndrome

Note: Unless otherwise noted, the clinical abnormality is ipsilateral to the involved nerve or nerves.
SCM = sternocleidomastoid; VC = vocal cord.

HYPOGLOSSAL NERVE (CRANIAL NERVE XII)

Neuroanatomy

A purely motor nerve, the hypoglossal nerve (CN XII) supplies innervation to the extrinsic and intrinsic muscles of the tongue. Arising from the hypoglossal nucleus beneath the floor of the fourth ventricle in the caudal medulla, it courses ventrally through the brainstem to exit between the pyramidal tract and the olivary eminence. The rootlets coalesce and pass through the hypoglossal canal to exit the skull. The nerve travels briefly with the ninth, tenth, and eleventh CNs before it separates at approximately the mastoid level and passes on to the tongue musculature (Figure 76.5).

A lesion of the hypoglossal nerve causes ipsilateral weakness and wasting of the tongue, which deviates to the weak side when protruded.

Clinical Syndromes

Isolated involvement is rare but occasionally occurs in the context of inadvertent nerve trauma incurred at the time of carotid endarterectomy because of the proximity of CN XII to the carotid bifurcation; the dysfunction is usually temporary.

The review by Keane (1996) of 100 cases of twelfth nerve palsy provides an overview of common etiologies for dysfunction in CN XII. Tumors, predominantly malignant, produced nearly one half of the palsies (49 cases). Gunshot wounds made trauma the second most common cause (12 cases), and stroke (6 cases) the third. Aneurysms or dissection of the carotid artery may selectively compress the twelfth CN (Lemmerling et al. 1996). Primary bony disease and malformations affecting the base of the skull (as seen with platyhasia and Pager's disease) may produce mechanical damage to the nerve. Giuffrida et al. (2000) emphasized that after appropriate exclusionary studies, a transient twelfth nerve palsy can be encountered that is analogous to the more common and invariably benign seventh nerve Bell's palsy.

Keane (2000) also reviewed his extensive experience with combined twelfth and sixth nerve palsies. He confirmed the observation made in 1947 by Godtfrcdsen that combined dysfunction of these two CNs (Godtfredsen's syndrome) suggests the presence of an aggressive tumor. In Kcane's experience, a metastatic lesion to the clivus was the most common etiology, followed by nasopharyngeal carcinoma that was infiltrating posteriorly.

Vertebrobasilar vascular disease may produce an ipsilateral hypoglossal paralysis (medial medullary syndrome) (see Chapter 22). In medial medullary syndrome, as a result of occlusion of cither the vertebral arterv or the anterior

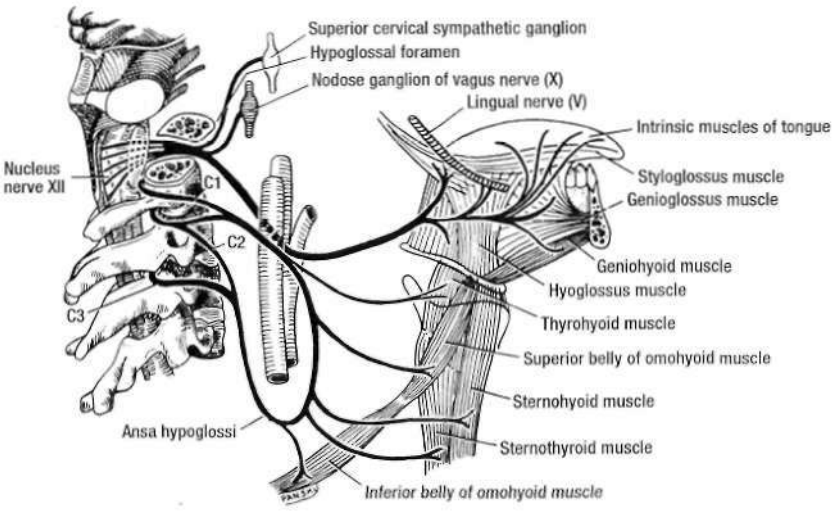


FIGURE 76.5 Origin, course, and distribution of the hypoglossal nerve. (Reprinted with permission from Mouse, E. L. & Pansky, B. 1967, *A Functional Approach to Neuroanatomy,* 2nd ed, McGraw-Hill, New York.)

spinal artery high in the neck, there is ipsilateral paralysis of the tongue (nucleus or root fibers), with a contralateral corticospinal tract lesion causing paresis of the arm and leg. The syndrome also involves diminished proprioceptive and tactile sense caused by medial lemniscus involvement.

Motor neuron disease and poliomyelitis may involve the hypoglossal nuclei, causing progressive tongue atrophy with fasciculations.

JUGULAR FORAMEN SYNDROME

This section covers the lower CN syndromes when they are affected as a group.

Neuroanatomy

The jugular foramen is located between the lateral portion of the occipital bone and the petrous portion of the temporal hone. It is a canal coursing anteriorly, inferiorly, and laterally in an intracranial-to-extracranial projection. Two compartments of the foramen are recognized. The anteromedial compartment (the *pan nervosa)* contains the inferior petrosal sinus and the glossopharyngeal nerve. The pars venosa contains the vagus and accessory nerves, as well as a portion of the jugular bulb. There are many variations on this theme, and there is no agreement on position of the nerves in the jugular foramen or on the constancy of the separation of these compartments.

After exiting the cranial base, CN IX is anterolateral and CN XI medial and next to the carotid sheath. CN X runs deeper between the internal jugular vein and internal carotid artery (Lustig and Jacklcr 1996). Upon leaving the jugular foramen, the three CNs enter the posterior retropharyngeal space, along with CN XII. This space is bordered posteriorly by the cervical spine, medially by the pharynx, anteriorly by the parotid gland and muscles attached to the styloid process, and superiorly by the base of the skull and the jugular foramen. The space contains the last four CNs, the internal jugular vein, the carotid artery, and the cervical sympathetic nerves. After exiting this space, the nerves separate and follow their individual courses.

Clinical Features and Etiology

The most common causes of the jugular foramen and allied syndromes are primary and metastatic tumors, vascular lesions, trauma, inflammatory, and iatrogenic lesions.

The most common primary tumors are schwannomas, glomus tumors, and meningiomas. Schwannomas constitute approximately 25% of all tumors in the head and neck, but schwannomas of nerves IX, X, and XI, in the absence of neurofibromatosis, arc decidedly rare, constituting approximately 3% of all intracranial schwannomas.

A neuroirnaging review of the appearance of schwannomas of the jugular foramen (Eldevjk, Gabrielson, and Jacobsen 2000) emphasized a characteristic picture with a sharply demarcated, contrast-enhancing lesion enlarging the jugular foramen with rounded bony borders and a sclerotic rim. Schwannomas are more common in women, with the average age at diagnosis in the fourth decade. The symptoms generally manifest when the tumor is large and are determined by both origin and size of the tumor. Most cases present with hearing loss and dizziness indistinguishable from acoustic neuroma. Other presentations are the jugular foramen syndrome or a neck mass. The clinical signs indicate dysfunction of CNs IX, X, and XI in 80%, hearing loss in 70%, and facial palsy in 25%. Contemporary diagnosis of these tumors involves both computed tomographic scan and MR],

Glomus jugulare tumor is a highly vascular tumor that may involve the glossopharyngeal nerve, as well as the other nerves (vagus and accessory) traversing the jugular foramen, and can enlarge sufficiently to damage the facial

and hypoglossal nerves. The patient usually presents with pulsatile tinnitus followed by conductive hearing loss, Because the tumor partially or completely occludes the intravascular portion of the jugular vein, the patient may also present with increased intracranial pressure. Other symptoms encompass a spectrum of nonspecific dizziness, he.ill lehe, .nil c.iMehe. Otolo:'jcal evimin.inor ~omerimes reveals the pulsating dark red lesion behind the eardrum. Biopsy of these tumors is contraindicated because of their hypervascularity. Treatment often consists of initial radiotherapy, followed if necessary by surgical removal of the tumor en bloc with the jugular bulb.

The most common neoplastic causes of jugular foramen syndrome are either primary nasopharyngeal tumors that spread locally to the cranial base or distant metastases from breast, Ling, prostate, and Kmph tissue.

Villarer's syndrome consists of unilateral lesions of the last four CNs (IX-XII) and I lorner's syndrome (see Tabic *763).* The syndrome results from lesions occupying the posterior retropharyngeal space, such as parotid tumors, enlarged lymph nodes, nasopharyngeal carcinomas, pharyngeal abscesses, carotid artery aneurysms, giant cell arteritis, and penetrating wound trauma (Tiliket et al. 1996).

Chapter 77
Movement Disorders

Kathleen M. Shannon

MOVEMENT DISORDERS AND THE BASAL GANGLIA

Neurologists often equate movement disorders with disease or dysfunction of the basal ganglia, and no chapter on inn: emcnl disorders would be complete without .: dis cussion of basal ganglia anatomy, physiology, and patho-physiology. The implied connection is a natural one. In some movement disorders, such as parkinsonism, chorea, and ballism, the link to the basal ganglia is supported by climcopathological, biochemical, functional neuroimaging, and electrophysiological data, whereas in other movement disorders, such as tremor, dystonia, and tics, dysfunction of the basal ganglia is implied but not proven. Clinico-pathologica! studies relate' [he ^gns ol P.irkinson's disease (PD) to deficient dopaminergic neurotransmission in the striatum consequent to the death of dopaminergic neurons in the substantia nigra pars compacta (SNc). Choreic movements in Huntington's disease (HD) are linked to the death of medium spiny neurons in the caudate and putamen. I Icmiballism is typically associated with structural lesions in the contralateral subthalamic nucleus (STN) or its afferent

or efferent connections. Changes in basal ganglia neurotransmission are well described in many movement disorders, and deepening understanding of basal ganglia neurotransmission has yielded promising symptomatic therapies in many such conditions. Functional ncuroimaging studies with specific radiopharmaceutical agents demonstrate abnormal function of basal ganglia structures, and intraoperative electrophysiology studies demonstrate abnormalities in neuronal firing rates and patterns in the STN and globus pallidus (GP) in parkinsonism and chorea. Animal models, including the l-methyl-4-phenyl-1,2,3,6-tetrahydropyridinc (MPTP) model of PD, excitotoxic and transgenic models of HD, and the STN lesion model of hemiballismus (HIS) confirm the central role of disordered basal ganglia function in these conditions. In other movement disorders, such as dystonia, the link with basal ganglia function is more complex. For example, although secondary dystonias may result from structural lesions in the contralateral putamen, other sites of pathology include the thalamus, rostral brainstem, and cerebellum. Functional ncuroimaging studies in patients with dystonia show abnormal activation of the lenticular nucleus, but also the cortex, brainstem, and cerebellum. In other movement disorders, such as essential tremor (ET), stiff person syndrome (SPS), and hemifacial spasm, we now know the dysfunction lies outside of the basal ganglia, often in the brainstem, cerebellum, spinal cord, or even in the peripheral nervous system.

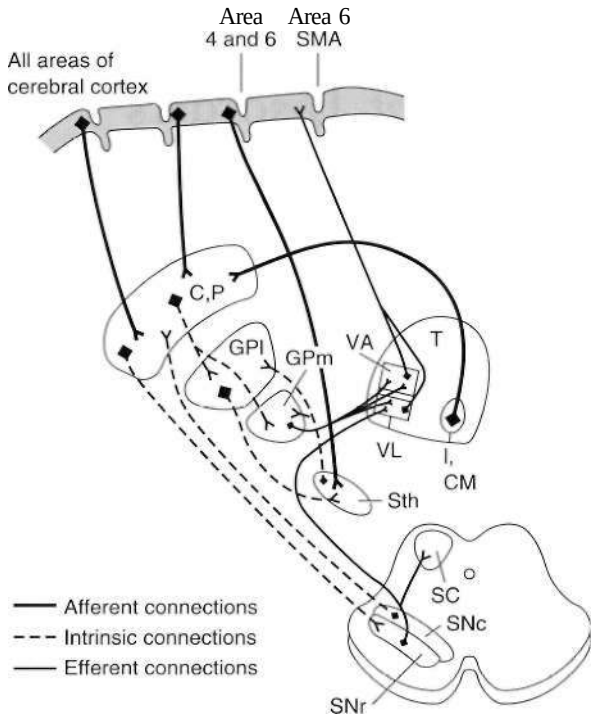

FIGURE 77.1 Schematic tint wing of the interconnections between the basal ganglia and its afferent and efferent connections. C, P — caudate putamen; GPI = lateral (external) globus pallidus; GPm = medial (internal) globus pallidus; Sth = subthalamic nucleus; SNc = substantia nigra pars compacta; SNr = substantia nigra pars reticulata; SC = superior eolliculus; T = thalamus; VA = ventral anterior; VL = ventrolateral; CM = centromedian nucleus of the thalamus.

Basal Ganglia Anatomy

There is no clear consensus on which structures should be included in the basal ganglia. For the purposes of this discussion, we consider those structures in the striatopallidal circuits involved in modulation of the thalamocortical projection—the caudate nucleus, the putamen, the external segment of the GP (GPe), and the internal segment of the GP {GPi). In addition, we consider related structures, the two divisions of the SN (the pars compacta [SNc] and the pars reticulata [SNrP, and the STN.

The *caudate nucleus* is a curved structute that traverses the deep hemisphere at the lateral edge of each lateral ventricle. Its diameter is largest at its head, tapering to a small tail. It is continuous with the *putamen* at the head and tail. The caudate and putamen together arc called the *striatum,* and they form the major target for projections from the cerebral cortex and the SN. The putamen and the GP together form a wedge-shaped structure called the *lenticular nucleus.* The GP is divided into two parts, the GPe and the GPL The GPi is structurally and functionally homologous with the SNr. The SNr and SNc extend the length of the midbrain ventral to the red nucleus and dorsal to the cerebral peduncles. The STN is a small lens-shaped structure at the border of the brainstem and cerebrum. The basal ganglia and its relation to the thalamus and overlying cortex are illustrated in Figure 77.1.

Functional Organization of the Basal Ganglia and Other Pathways

Afferent projections to the striatum arise from all areas of the cerebral cortex, the intralaminar nuclei of the thalamus, mesencephalic SN, and ftom the locus ceruleus and raphe nuclei. There is also a projection from the cerebral cortex to the STN. The major efferent projections are from the GPi and SNr to the thalamus and brainstem nuclei such as the pedunculopontine nucleus. The GPi and SNr project to ventral anterior and ventrolateral thalamic nuclei. The GPi also projects to the centromedian thalamic nuclei and the SNr projects to the mcdiodorsai thalamic nuclei and superior eolliculus. The ventral anterior and ventrolateral thalamic nuclei then project to the motor and premotor cortex. Throughout, these projections are somatotopically organized (Yelnik 2002).

The basal ganglia has dense internuclear connections exemplified by the box and line circuit diagrams that have become entrenched in the literature. Five parallel and separate closed circuits through the basal ganglia have been proposed. These are the *motor, oculomotor, dorsolateral prefrontal, lateral orbitofrontal,* and *limbic* loops. It is now

Table 77.1: Divisions of the striatum

Division	*Origin of striatal afferents*	*Striatal nucleus*	*Termination of basal ganglia efferents*	*Function*
Sensorimotor	Motor cortex	[illegible]	[illegible] Primary motor cortex Supplementary motor area	Movcmnii
Associative	Fronral cortex Parietal cortex Temporal cortex Occipital cortex	Dorsal caudate	Prefrontal cortex	Cognition
I iinlii.	Hippocampus Amygdala Cingulate cortex Temporal cortex Orbitofrontal cortex	Ventral striatum	Anterior dngukue Medial orbitofrontal	Emotion Motivation

generally agreed that these loops form three major divisions, *sensorimotor, associative,* and *limbic,* that are related to *motor, cognitive,* and *emotional* functions, respectively (Table 77.1), The functions of the *sensorimotor* striatum are subserved mainly by the putamen, which derives its afferent cortical inputs from both motor cortices. Sensorimotor pathways arc somatotopically organized and the pathway ultimately terminates in the premotor and primary motor cortices and the supplementary motor area. Cognitive functions are managed by the *associative striatum.* In this pathway, the dorsal caudate nucleus receives afferent input from the homolateral frontal, parietal, temporal, and occipital cortices. Projections from this pathway ultimately terminate in the prefrontal cortex. The *limbic striatum* subserves emotional and motivational functions. Its input derives from the cingulate, temporal, and orbitofrontal cortices, the hippocampus, and the amygdala. It comprises mainly the ventral striatum with ultimate projections to the anterior cingulate and medial orbitofrontal cortices (Yclnik 2002). Whether these divisions are interconnected or organized in parallel remains a topic of debate.

Within each basal ganglia circuit lies an additional level of complexity. Each circuit contains two pathways by which striatal activity is translated into pallidal output. These two pathways, named the *direct* and *indirect* pathways, depending on whether striatal outflow connects directly with the GPi or first traverses the GPe and STN. The direct and indirect pathways have opposite effects on outflow neurons of the GPi and SNr. A closer look at the motor circuit illustrates this principle (Figure 77.2A).

In the motor *direct pathway,* excitatory neurons from the cerebral cortex synapse on putaminal neurons, which in turn scud inhibitory projections to the GPi and its homologue, the SNr. The GPi/SNr sends an inhibitory outflow to the thalamus (Figure 77.2B). Activity in the direct pathway disinhibits the thalamus, facilitating the excitatory thalamocortical pathway and enhancing activity in its target, the motor cortices. Thus the direct pathway constitutes part of an excitatory cortical-cortical circuit that likely functions to maintain ongoing motor activity. In the *indirect pathway,* excitatory axons from the cerebral cortex synapse on putaminal neurons. These neurons send inhibitory projections to the GPe. The GPc sends an inhibitory projection to the STN. The net effect of these projections is disinhibition of the STN. The STN in turn has an excitatory projection to the GPi (see Figure 77.2C). Activity in the indirect pathway thus excites the GPi/SNr, which in turn inhibits the thalamocortical pathway.

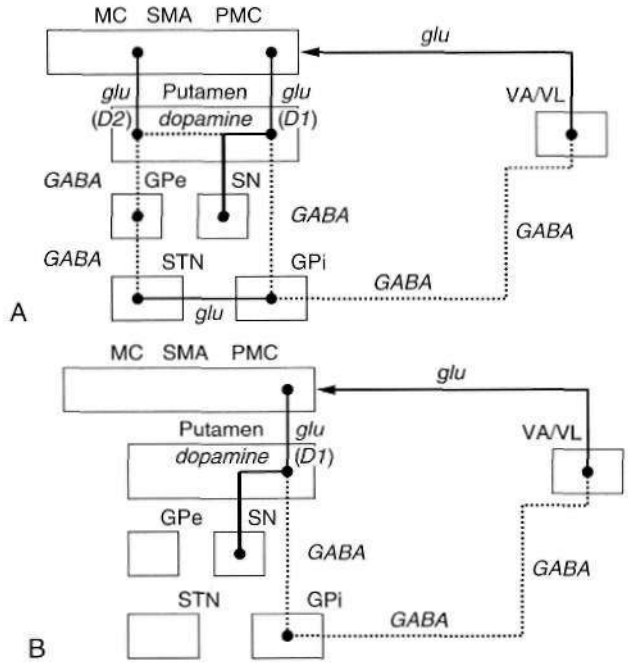

FIGURE 77.2 Schematic drawing of the internuclear connections of the basal ganglia, including (A) direcr and indirect pathways and depicting (B) the direcr pathway. (See Figure 77.3 for a depiction of the indirect pathway.) Excitatory pathways in solid lines, inhibitory pathways in dotted lines. MC = motor cortex; SMA = supplementary motor area; PMC = premotor cortex; GPe = external segment of the globus pallidus; SN = substantia nigra; STN = subthalamic nucleus; GPi = internal segment of the globus pallidus; VA/VL = ventral anterior/vcntrolateral thalamic nuclei; glu = glutamate; GARA = y-amiuobutyric acid; D^ = dopamine D2 receptor; D_t — dopamine D] receptor. *Continued*

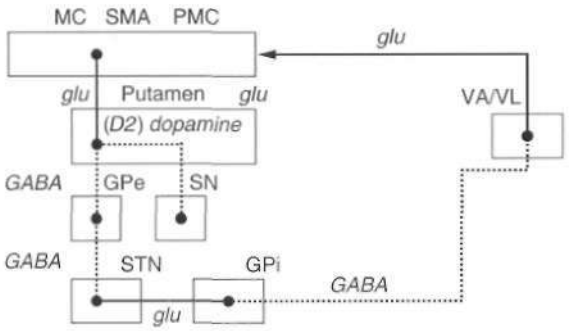
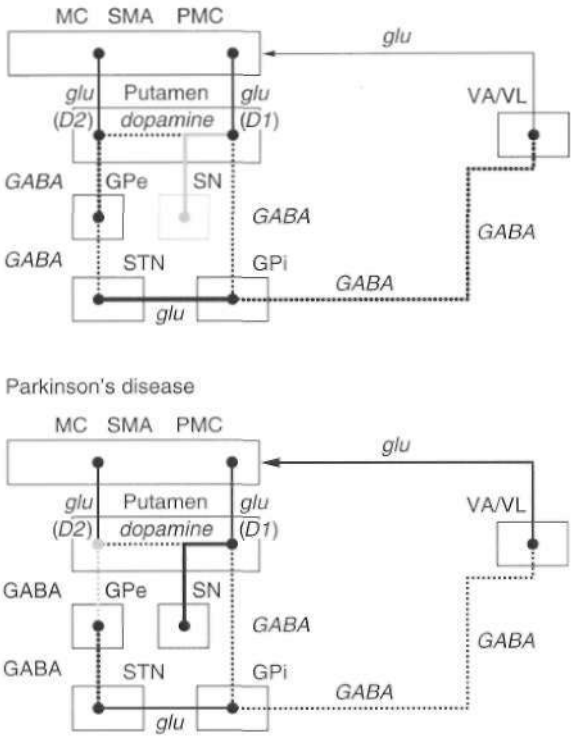


F1CURE 77.2, cont'd.

Thus the net effect of increased activity in the indirect pathway is cortical inhibition.

The striatum also receives robust afferent input from the SNc. This projection from the SNc, an important modifier of striatal activity, facilitates activity in the direct pathway and inhibits activity in the indirect pathway, thus promoting cortical excitation through both pathways (see Figure 77.2A).

Disorders ol the basal ganglia result in prominent motoi dysfunction, though not generally in frank weakness. The absence of direct primary or secondary sensory input and the lack of a major descending pathway below the level of the brainstem suggest that the basal ganglia moderates rather than controls movement. In the simplest sense, the direct and indirect pathways have opposite effects on the cerebral cortex. The direct pathway is important in initiation and maintenance of movement and the indirect pathway helps with suppression of extraneous movement. From this model of basal ganglia connectivity, hypotheses about the motor function of the basal ganglia have been proposed. One hypothesis is that the relative activities of the direct and indirect pathways serve to balance the facilitation and inhibition of the same population of thalamocortical neurons, thus controlling the scale ol movement. A second hypothesis proposes that direct pathway-mediated facilitation and indirect pathway-mediated inhibition of different populations of thalamocortical neurons serve to focus movement in an organization reminiscent of center-surround inhibition. These hypotheses relate activity in the direct and indirect pathways mainly to rates of firing in the STN and GPi. Thus death of neurons in the SNc decreases activity in the direct pathway and increases activity in the indirect pathway. These changes cause an increased rate of tiring of subthalamic and GPi neurons with excessive inhibition of thalamocortical pathways and produce the behavioral manifestations of bradykinesia in PD (Figure 77.3A). On the other hand, selective loss of indirect pathway neurons, as in HD, interferes with supptession of involuntary movements. Choreic involuntary movements arc the usual result (see Figure 77.3B). Direct electrophysiological recordings of the STN and GP during stereotactic functional neurosurgical procedures confirm that the GPi and STN arc overly active



B Huntington's disease

in patients with PD. The activity of these nuclei returns toward normal with effective pharmacotherapy, and chorea is associated with lower firing rates of neurons in these nuclei. Unfortunately, this model does not completely explain some important features of movement disorders. For example, bradykinesia and chorea coexist in HD and in treated PD. Thalamic lesions that might be expected to wotsen parkinsonism by reducing excitatory thalamocortical activity do not do so. Pallidal lesions that might be expected to worsen chorea by decreasing inhibition of thalamocortical pathways instead are dramatically effective at reducing chorea. The model is even more problematic when applied to dystonia. It has been suggested that in dystonia, there is overactivity of both the direct and indirect pathways. Yet, intraoperative recordings in dystonia have shown low rates and abnormal patterns of neuronal firing in the GPi. A simple change in firing rate of the STN or GPi is thus insufficient to explain the underlying physiology of dystonia. It is likely that disordered patterns and synchrony of pallidal firing as well as changes in sensorimotor

integration and the control of spinal and brainstem reflexes are important. These factors are under investigation, but current models remain useful for understanding the rationale of pharmacological and ablative surgical procedures for certain movement disorders.

Although much of the emphasis has been on GPi and SNr effercnts to the thalamocortical system, there is growing evidence that descending pathways, particularly to the zona incerta and pedimculopontine nucleus, are important in movement disorders. The pedunculopontine nucleus appears to play a role in the genesis of akinesia. A number of other pathways also seem particularly relevant to myoclonus, including a corticolemni seal thalamocortical circuit and a spinobulbar-spinal circuit that primarily involves the spinoreticular tracts, nucleus reticularis gigantocellularis of the medullary reticular formation, and the reticulospinal tracts. The Guillain-Mollart triangle is a network connecting the red nucleus, dentate nucleus, and inferior olive, which has been implicated in palatal tremor (formerly known .is *j-.djtdi mytn limns),* [he propnospinal pathways and segmental spinospinal loops are important in the genesis of propriospinal and spinal segmental myoclonus, respectively.

Biochemistry

Our understanding of basal ganglia pharmacology is growing rapidly. Along with this growth is an expanding spectrum of practical applications for pathology, neuroimaging, and therapeutics. For example, catecholamine and amino acid neurotransmitters coexist with peptides. This co-localization may allow histopathological differentiation among medium spiny striatal projection neurons that secrete K-aminobutyric acid (GABAergic), further elucidating the specific nature and progress of striatal neu rode generation. Neuroimaging technology has been aided by the development of radiopharmaceutical ligands with such discrete targets as the dopamine transporter on the presynaptic dopamine neuron and subpopulations of dopamine receptors on the postsynaptic neuron. The pharmaceutical industry is searching for ways to provide better targeted and more physiological stimulation of neurotransmitter receptors and is expanding its investigations from the primary targets themselves to approaches that may modify responsiveness of the primary targets.

The major neurotransmitters of the basal ganglia arc outlined in Table 77.2 (see also Figure 77.2). Most excitatory synapses of the basal ganglia and its connections, including those from the cerebral cortex to the striatum, the STN to the Gl'i, and the thalamocortical projections, use *glutamate.* Projections from the striatum to the GPe and Gl'i and from the GPe to the STN and from the GPi to the thalamus arc inhibitory and employ *GABA.* Medium spiny GABAergic neurons in the direct pathway colocalize substance P and dynorphin. GABAergic neurons in the indirect pathway colocalize enkephalin. *Dopamine* is the major neurotransmitter in the nigrostriatal dopamine system; it has excitatory or inhibitory actions depending on the properties of the stimulated receptor. *Acetylcholine* is found in large aspiny striatal interneurons. *Norepinephrine* is important in the autonomic nervous system, lateral tegmentum, and locus ceruleus. *Serotonin* is found in the dorsal raphe nucleus of the brainstem, the hippocampus, cerebellum, and spinal cord.

For each of rhese neurotransmitters, multiple types of receptors may exist. Glutamate is active at a number of types of ligand-gatcd ion channel receptors named for their selective agonists: N-methyl-D-aspartate (NMDA); a-amino-3-hydroxy-5-methy]-4-isoxazole propionic acid (AMPA); and k a mate. The NMDA receptor has been the focus of particular attention because of its potential role in excitotoxic neuronal injury. There arc also mctaborropic glutamate receptors. There are two classes of GABA receptors, named GABA,\ and GABA^. $GABA_A$ receptors are ligand-gated chloride channels. There are many subtypes of this receptor. The GABAu receptor is a mctaborropic receptor. Five types (D[through D_5) and two families (D] and D2) of dopamine receptors have been identified. The D_5 family of receptor is adenylate cyclase dependent and contains subtypes Di and D5. D] receptors reside primarily in the direct pathway, cerebral cortex, and limbic system, D^ receptors arc located primarily in the indirect pathway, cerebral cortex and limbic system,

as well as the pituitary gland. There are two families of *acetylcholine* receptors, nicotinic and muscarinic. There are two subtypes of nicotinic and five subtypes of muscarinic receptors. Most striatal cholinergic receptors are muscarinic. In the *norepinephrine* system, there are two primary receptor systems, *a* and *fi.* There are 14 distinct receptor subtypes of *serotonin* receptors including G protein-coupled receptors in the 5-HTj, 5-HT_2, 5-HT_4, 5-HT_5, 5-HT_6, and 5-HT_7 families and the 5-HT_3 type ligand-gated ion channels. Drugs targeting specific subpopulations of receptors are in use or under development for movement disorders, but there remains a knowledge deficit about the relative clinical utility of specific rcccpror agonists and antagonists,

NEURODEGENERATION AND "TOXIC PROTEINS"

Many of the neutodegenerative movement disorders share the property of neuronal damage caused by the accumulation of aggregation-prone proteins that have toxic effects (Table 77.3). In order for a protein to function normally, it must be properly synthesized and folded into its normal three-dimensional structure. Nascent proteins are aided in folding by molecular chaperones. Proteins that are not properly folded arc otherwise damaged, or beyond their useful lives are degraded by the ubiquitin-dependent proteasome protein degradation system (Taylor ct al. 2002). In the ubiquitin-dependent proteasome system, proteins are first iabeled for degradation by attachment of a polyubiquitin chain (Figure 77,4). Ibis three-step process involves activation, conjugation, and ligation, steps catalyzed by three types of enzymes, $E_{1;}$ E_2, and E_3, respectively. Polyubiquinated protein enters the 26S proteasome, a cylindrical complex of peptidases. The end products of proteasome action are protein fragments and polyubiquitin. The polyubiquitin is then degraded and recycled to the cellular ubiquitin pool, a process requiring enzymatic action by ubiquitin carboxy terminal hydrolase 1 (McNaught and Olanow 2003).

Recent ultrastructural work has elucidated that many degenerative movement disorders can be linked to abnormal synthesis, folding or degradation of specific proteins or protein families. Thus, a number of akinetic-tigid disorders involve the alpba-synuelein or tau proteins. Certain other disorders are linked to abnormalities in pathways involving proteins with expanded polyglutaminc tracts (poh/Q). Among these disorders, clinical and pathological differences depend on the distribution of protein aggregates or in the abnormal configuration they assume when they aggregate. The *synudeinopathies* include PD, diffuse Lcwy body disease, and multiple system atrophy (MSA). The *tauopathies* include progressive supranuclear palsy (PSl'i, corticobasal degeneration (CBD), familial frontotemporal dementia with parkinsonism (FTDP), postencephalitic parkinsonism (PEP), post-traumatic parkinsonism, and amyotrophic lateral sclerosis (ALS) PD of Guam. The *poiyQ* disorders include HD, dentalin'iibr.d-pallidoluysian atrophy (DRPLA), and spinocerebellar ataxias.

The cascade of pathogenic events linking abnormal protein aggtegation to cell death is the subject of intense investigation. AliJituirJ'. .is>,s.\ivj.'.,iu-s arc the nn^: striking physical change in surviving cells, the actual role of the aggregate remains a mystery. Indeed, many now believe that the formation of aggregates may be a protective mechanism sequestering the wayward protein from vulnerable cell processes. Misfolded proteins may produce the most mischief as they form protofibrils. A number of mechanisms have been described. In some cases, these are specifically related to the type of protein, but in many other cases, they are nonspecific mechanisms shared by all the misfolded protein diseases. Some potential mechanisms of ncuro degeneration related to misfolded protein stress arc listed in Table 77.4. The mutant protein may be unable to perform a vital function or may interfere with the function of the wild type protein. Mutant protein, protofibrils, or aggregates might intetfere with other proteins. Interference with transcription factors may be particularly important in this regard. Mutant proteins may activate caspases or in other ways activate the apoptotic cascade. They may interfere with intracellular transport or other vital processes. They may suppress activity of the proteasome, enhancing protein aggregation. They may interfere with mitochondrial function, making cells more vulnerable to excitotoxicity. Oxidative stress may be enhanced and there may be microglial activation (Taylor et al. 2002).

Despite that most of these abnormal proteins are widely expressed in neuronal and non-neuronal tissues,

these diseases wreak their particular havoc within the nervous system, suggesting that nervous system cells are especially vulnerable to misfolded protein stress. Within nervous tissue itself, certain neuronal populations seem selectively vulnerable to the effects of certain aberrant proteins. This preferential degeneration of specific neuronal populations ultimately determines the phenotypc of the disorder. The key to successful neuroprotection will lie in careful reconstruction of the intracellular crime scene. Potential therapeutic interventions might include reducing translation of the aberrant protein, upregulating molecular chaperoncs, or facilitating protein ubiquination or proteasomal function. Other options include reducing oxidative stress, improving mitochondrial function, and blocking proapoptotic processes. Many of these interventions might be suitable for any of the candidate diseases, although others might be disease specific. A single intervention might produce a benefit of small magnitude and significant neuroprotection might be achieved only with a combination of treatment interventions. Animal studies hint that neuroprotective interventions early enough in the protein aggregation neurodegeneration might actually be able to partially reverse extant neurodegenerative changes. For example, in a conditional transgenic HD model that allows the transcription of the mutant gene to be turned off, reversal of behavioral and pathological changes may be seen {Yamamoto ct ah 2000).

PARKINSONIAN SYNDROMES

Parkinson's Disease (Idiopathic Parkinson's Disease, Paralysis Agitans)

Although described by others before him, James Parkinson is attributed with rendering the first cogent description of PD. In his monograph, *The Shaking Palsy* (1817), he identified the hallmark features of the illness through descriptions of cases observed in the streets of London. Over time, the specific terms *PD* and *idiopathic PD* have come to be reserved for the clinical syndrome of asymmetrical parkinsonism, usually with rest tremor, in association with the specific pathological findings of loss of dopaminergic SN neurons with eosinophilic cytoplasmic inclusions (Lewy bodies). Dopamine deficiency in parkinsonian brain homogenates was described by Horny kiewicz in 1959, a discovery that ultimately led to highly effective pharmacotherapy with L-dopa and direct-acting dopamine agonists (DAs). Recently, a genetic form of parkinsonism that is clinically indistinguishable from PD has been linked to missense mutations in the alpha-synuclein gene. This discovery undermined the concept that PD represents a homogeneous disease but also revealed the importance of disordered protein handling in the genesis of PD. In its present context, PD is best considetcd a syndrome with genetic and environmental etiologies.

Epidemiology and Clinical Features

In community-based series, PD accounts for more than 80% of all parkinsonism, with a prevalence of about 360 per 100,000 and an incidence of 18 per 100,000 per year. I'D is a disease of aging, showing a gradual increase in prevalence beginning after the age of 50 years and a steep increase in prevalence after age 60 years. Disease before the age of 30 years is very rare and often suggests a hereditary form of parkinsonism. Prevalence rates in the United States are higher than those in Africa and China, but the role of race remains unclear. Within the United States, race-specific prevalence rates vary, with some studies suggesting a similar prevalence among whites and American blacks. Unfortunately, blacks make up only a small fraction of most specialty clinic populations, thus .ire under-represented in clinic-based studies and clinical trials.

Typically the onset and progression of PD are gradual. The most common presentation is with rest tremor in one hand, often associated with decreased arm swing and shoulder pain. Hradykinesia and rigidity are often detectable on the symptomatic side, and midline signs such as reduced facial expression or mild contralateral bradykinesia and rigidity may already be present. The presentation may be delayed if hradykinesia is the earliest symptom, particularly when the onset is on the nondominant side. The disorder usually remains asymmetrical throughout much of its course. With progression of the illness, generalized hradykinesia may cause difficulty with arising from a chair or turning in bed. The gait and balance arc progressively affected and falls may occur. Sudden arrests in movement, also called *freezing* or *motor blocks,* soon follow, first with gait initiation, turning and traversing narrow or crowded environments, and then during walking. Bulbar functions deteriorate, impairing communication and nutrition. The Hoehn and Yahr stage, first described before effective dopaminergic treatment became available, accurately outlines the milestones in progression of the illness from mild unilateral symptoms through the end-stage nonambulatory state (Table 77.5).

Nonmotor symptoms are universal in PD and contribute prominently to declining quality of life. *Autonomic symptoms* include reduced gastrointestinal transit time with postprandial bloating and constipation, urinary frequency and urgency sometimes with urge incontinence, impotence, disordered sweating, and orthostatic hypotension. *Cognitive and behavioral changes* are universal as well. Attention and concentration wane. Executive dysfunction with diminished working memory, planning, and organization is common. Global dementia occurs in about 30% of patients, increasing in frequency with the age of the patient. Those with prominent early executive dysfunction and more severe motor signs seem particularly at risk (Levy et al. 2002). *Anxiety* and *mood disorders* are common in PD. Each is seen in as many as 40% of patients with PD, with considerable overlap (Walsh and Bennett 2001). *Sleep disturbance* is nearly universal in PD and is multifactorial. Disordered sleep onset and maintenance lead to fragmentation of nocturnal sleep. A variety of motor movements including restless legs and periodic leg movements of sleep may be seen and many patients have rapid eye movement (REM) sleep behavior disorder (RBD) with active motor movements during REM sleep. Some patients have sleep apnea. Vivid dreams and nightmares are very common, particularly in treated patients. Sleep disorders in PD variably relate to pathological changes of the disease itself, arousals due ro immobility, comorbid primary sleep disorders, and side effects of antiparkinsonian medications. Many patients with PD are excessively sleepy during the day, sometimes with serious consequences such as unintended sleep episodes while driving. In most cases, this excessive daytime drowsiness is related to dopaminergic drugs (Ondo et al. 2001). *Fatigue* is a common and complex symptom of PD. The differentiation of fatigue from excessive daytime sleepiness, depression, apathy, and other conditions can be difficult, and there is not yet a useful body of literature on its assessment and treatment.

Table 77.5: Hoehn and Yahr stage

Stage	
I	Unilateral involvement only, minimal or no functional impairment
II	Bilateral or midline involvement, without impairment of balance
III	First sign of impaired righting reflex, mild to moderate disability
IV	Fully (ic\ eloped, severe]; disabling disease; [Utiem Mill able to walk and stand unassisted
V	Confinement to bed or wheelchair unless aided

PD is a clinical diagnosis, and it is not usually difficult to diagnose a patient with unilateral or asymmetrical rest tremor, hradykinesia, and rigidity. Clinicopathological studies have found that the syndrome that best reflects the typical pathological changes of PD is an asymmetrical illness with rest tremor along with rigidity or hradykinesia, and significant improvement with i.-dopa supplementation, in the absence of other diagnoses known to cause parkinsonism. The presence of this syndrome carries a positive predictive value of 92%, with a sensitivity of 90%. Misdiagnosed cases generally are found to have MSA, PSP, or subcortical vascular disease. When making the diagnosis of early PD, the clinician should be aware of a number of "red flags" (Table 77.6). Cognitive impairment within the first year should raise the possibility of Alzheimer's disease, dementia with Lewy bodies (DLB), CBD, PSP, or ETDP. Symmetrical or prominent midline or bulbar signs suggest MSA or PSP. Early gait disorder with falls points to the diagnosis of PSP or to subcortical vascular disease. Dependence on a wheelchair within 5 years of onset is suggestive of PSP, MSA, or vascular parkinsonism. Early orthostatic hypotension or incontinence points to the

autonomic dysfunction of MSA. Severe sleep apnea or sighing or gasping respirations also suggest MSA. Apraxia, alien limb, or cortical sensory loss may be seen in CRD.

Routine laboratory studies are not helpful in the diagnosis of PD, and their use should be directed by other clinical indications. Neuroimaging studies such as computed tomography (CT) and magnetic resonance imaging (MRI) are also not helpful in making a diagnosis of PD, because they are generally normal or show only incidental abnormalities. Sometimes, neutoimaging abnormalities can be useful in suggesting alternative diagnoses such as PSP or MSA, The radiopharmaceutical 6-[^{18}FJ-fluorodopa (F-dopa) is taken up by dopaminergic neurons in the SN and metabolized to 6-[^{11t}Fl-fluorodopaminc. Positron emission tomography (PET) scans using this radiopharmaceutical agent show reduced E-dopa uptake in dopaminergic nerve terminals in the putamen and caudate proportional to the severity of degeneration in the ipsilateral SN and symptoms in the conttalateral hemibody (Plate 77.1). Although these tests make useful contributions to PD research, they are not clinically available at this time. Single-photon emission CT* (SPECT) with radioligands that label the dopamine transportet on nerve terminals in the striatum is another research tool, and its clinical relevance is now being studied. There is no role for routine electrophysiological testing in the diagnosis of PD. Because identified genetic causes are rare, there is as yet no role for routine genetic testing in PD.

Pathology

The most striking pathological changes in PD occur in the SNr. The SN appears pale to the naked eye. Microscopic chanties include nciuncal loss, gliosis, and the presence of extracellular pigment. Surviving neurons may show characteristic cytoplasmic inclusions (Plate 77.11). The inclusions, called *Lewy bodies*, have a dense eosinophilic core and a pale halo. They contain hyperphosphorylatcd neurofilament proteins, lipids, iron, ubiquitin, and alpha-synuclein (Jellinger 2002). Pigmented nuclei elsewhere in the brainstem, including the locus ceruleus, dorsal motor nucleus of the vagus, and others, may also show Lewy bodies and characteristic degenetative changes. The substantia innominata and intermediolateral cell column in the spinal cord also are affected. Patients with PD and dementia show more diffuse Lewy body pathology of comorbid Alzheimer's disease (Apaydin et al. 2002).

Etiology

Studies of large numbers of patients with PD have suggested that PD is a multifactorial illness with likely genetic and environmental determinants. Although strongly hereditary PD is rare, there is a tendency for familial aggregation of I'D. Twin studies suggest that hctcdity plays a relatively small role in the population at large, but the hereditary component is greater if one twin has disease onset at younger than 50 years of age (Tanner et al. 1999). Moreover, PPT studies of twins suggest that most monozygotic co-twins of patients with PD show subclinical declines in dopamine innervation, strengthening the evidence for a significant hereditary contribution irrespective of age at onset.

Families whose pedigrees suggest dominant!y inherited PD are rare, making up no more than 5% of the PD population at latge. Most of these families show no identified genetic mutation. However, linkage studies have suggested genetic susceptibility factors on chromosomes 5, 6, 8, 9, 10, 16, and 17. Association studies point to genes for monoamine oxidase B (MAO-B), N-acetyltransferase-2 detoxification enzyme, tau, and glutathione transferase detoxification enzyme, but the relevance of these associations is not yet known {Tan et al. 2000).

Evidence for environmental causes of PD comes primarily from two sources—the fortuitous discovery of parkinsonism in parenteral drug users exposed to the contaminant MPTP and epidemiological associations of sporadic PD or other parkinsonisms with certain lifestyle ot occupational exposures. More than two decades ago, the discovery that a handful of drug addict-, had developed ; \CUTI i.-dup.i-responsive form of parkinsonism following parenteral administration of a meperidine analogue contaminated with the mitochondrial protoxin MPTP suggested that environmental toxins might cause PD, The discovery of MPTP-induccd parkinsonism in humans was a sentinel event in our understanding of the disease because it pointed to a class of environmental toxins that might be important in sporadic disease. Although MPTP spawned the development of reproducible models of disease in many kinds of animals, its role in human disease is limited to the cluster of cases in drug addicts and a few others. Intriguing studies have confirmed that certain pesticides such as paraquat and rotcnone can reproduce the pathology of PD in animals, but their role in human disease remains undefined (Grcenamyre et al. 1999).

Epidemiological studies suggest that exposure to environmental metals or organic toxins may be associated

with an increased risk of PD or an earlier age at onser of PD (Tsai et al. 2002). Case-control studies have suggested that the risk of PD is increased in persons who have worked in the agricultural industry, who have been exposed to pesticides, or who have sustained significant head injury, Exposure to welding seems to predispose to earlier onset L-dopa-rcsponsive PD, possibly as a result of manganese poisoning. On the other hand, the risk of PD seems less in those with a high dietary intake of antioxidant-rich foods, as well as caffeine drinkers and those who have smoked cigarettes (Ross and Petrovitch 2001), These epidemiological studies have failed to find a "smoking gun" in the etiopathogenesis of PD.

Irrespective of genetic or environmental influences, the central feature of ncurodegeneration in PD is aggregation of alpha-synuclein. In PD, the natural tendency of alpha-synuclein to aggregate is likely enhanced by genetic factors controlling the protein synthesis, secondary processing or degradation and environmental factors such as aging, oxidative stress, and toxic exposures. Misfoldcd alpha-synuclein triggers mechanisms in the cell (see previous discussion) that ultimately lead to its demise.

Trent meat

A preclinical period lasting years to decades and a slow progression rate make PD an ideal candidate for *neuroprotection.* The increased understanding of disease etiopathogenesis suggests many candidate neuroprotective agents (Table 77.7). Neuroprotective trials to this point have been somewhat disappointing. Pie lirsi and larr.iM iuuro protective trial, DATATOP, randomized patients with early PD to treatment with placebo, tocopherol, selegiline (deprenyl), or both, using the time until patients needed potent symptomatic dopaminergic therapy, L-dopa, as a proxy endpoint for disease progression. The selective MAO-B inhibitor selegiline successfully delayed this endpoint, but interpretation of the study was contaminated by its mild antiparkinsonian and antidepressant properties, as well as potential effects of its amphetamine metabolites. A similar magnitude effect was shown in a latge randomized placebo-controlled study of another MAO-B inhibitor, lazabemide, but this drug is no being actively developed. A third MAO-B inhibitor, rasagiline, has been shown to have modest symptomatic benefit. Its effect on disease progression is under study. A recent randomized placebo-controlled study of three doses of coenzyme Q_{J0} suggested a slowing of decline in function in the 1200-mg-per-day group. This finding warrants *w* litional study in a larger group of research subjects (Siiults et al. 2002). Two intriguing studies comparing the effects of carbidopa-L-dopa (CD-LD) and DAs (pramipexole and ropinirole) on decline in functional ncuroimaging markers of presynaptic dopaminergic function in early DD suggested a slower loss of dopamine neurons in patients tteated with DAs than with CD-LD (Marek ct al. 2002). Although these studies are thought provoking, they require independent confirmation using clinical measures.

Tabic 77.7: Candidate neuroprotective approaches in Parkinson's disease

Mechanism	*Potential neuroprotective approaches.*
Oxidative stress	Antioxidants, for example, monoamine oxidase inhihitors, coenzyme Qm
Mitochondrial dysfunction	Coenzyme QKJ, creatine
Excitotoxicity	Glutamate antagonists, for example, riluzole
(iaspase ;li iw.UKiii	Caspasc inhibitors, for example, minocycline
Apoptosis	Antiapoptotic agents, for example, mixed lineage kinase inhibitors
Inflammation	Anti-inflammatory drugs
Trophin deficiency	Neil rotropfi ins

Symptomatic Treatment of Parkinson's Disease. Six types of medications arc available for the symptomatic treatment of PD: anticholinergics, amantadine, L-dopa, monoamine oxidase inhibitors (MAOIs), catcchol-O-methyltransferase (COMT) inhibitors, and DAs (Tabic 77.8). *Anticholinergics* such as trihexyphenidyl and benztropine antagonize the effects of acetylcholine at muscarinic receptors postsynaptic to striatal intcrneurons. They reduce tremor and rigidity but have no effects on bradykinesia. Toxicity relates to antagonism of acetylcholine at central receptors, causing confusion, and peripheral receptors, causing blurred vision, dry mouth, constipation, and utinary retention. Although *amantadine* has been available for nearly four decades

Table 77.8: Commonly used antiparkinsonian drugs

Drug	*Usual starting dose*	*Usual daily dose*
Anticholinergics		
Trihexyphenidyl	1 mg	2-12 mg
Benztropine	0.5 mg	0.5-6.0 mg
Bipendin	1 mg	2-16 mg
Amantadine	100 mg	100-300 mg
L-DOPA (with carbidopa)		
Immediate release	100 mg	150-800 mg
Controlled release	100 mg	200-1000 mg
Dopamine agonists		
Bromocriptine	1.25 mg	15-40 mg
Pergolide	0.05 mg	2-4 mg
Pramipexole	0.375 mg	1.5^4.5 mg
Ropinirole	0.75 mg	8-24 mg
C-alx'rgoline	0.25 mg	0.25^1.0 mg
Catcchol-O-methyl transferase inhibitors		
Entacapone	200 mg with each dose	200 mg with each dose
Toleapone	300 mg	600 mg

(it was originally marketed as an antiviral agenr), irs antiparkinsonian mechanisms have been poorly understood. It has been thought to stimulate release of endogenous dopamine stones, to block reuptake of dopamine from the synaptic cleft, and to have anticholinctgic properties. However, recently, it has been found to have antiglutamatergic properties and as such is the only antiparkinsonian drug that improves L-do pa-induced dyskinesia. *CD-LD* combines L-dopa, the immediate precursor of dopamine *w h* carbidopa, an aromatic acid decarboxylase inhibitor thrit prevents its peripheral metabolism, Its global antiparkinsonian efficacy is so dramatic and predictable that a positive therapeutic response is used to define the disease its*If. Advetse effects of CD-ID include nausea and von ;i ting, orthostatic hypotension, sedation, confusion, sleep disturbance, altera nous of dream phenomena, hallucinations, and dyskinesias, A number of direct-acting DAs are available including bromocriptine, pergolide, pramipexole, and ropinirole. Cabergoline is available in the United States, but it does not have Food and Drug Administration (FDA) approval for the treatment of PD and is prohibitively priced. Lisuride, piribedil, and apomorphine are not available in the United States. DAs cause side effects similar to those of L-dopa, although orthostatic hypotension, sleepiness, and hallucinations are more common or severe. DA monotherapy is associated with a very low incidence of dyskinesia. Agents that interact with the metabolism of L-dopa or dopamine are also available for the treatment of PD (Figure 77.5). *Selegiline* blocks MAO-B-dcpcndent dopamine degradation and has modest effects in potentiating the action of L-dopa. COMT inhibitors block peripheral degradation of peripheral levodopa *(entacapone* and *tolcapone)* and central degradation of L-dopa and dopamine (tolcapone), increasing central L-dopa and dopamine levels. Hcpatotoxicity associated with tolcapone has limited its use. Triple-combination therapy containing L-dopa, carbidopa, and entacapone became recently available for pancms with modcralcb advanced I'D,

Symptomatic treatment should begin when the patient is noticing functional, occupational, or social disability related to PD symptoms. Prospective studies have suggested that about 70% of patients with PD will require symptomatic therapy within 2 years of disease onset. Less potent therapies such as selegiline and amantadine may be useful for initial therapy, but CD-LD or DAs arc the choices when more potent therapy is indicated. The choice between CD-LD and DA for initial therapy remains controversial. There is universal agreement that CD-LD is the most potent and best tolerated drug in the modern PD arsenal, but there are concerns that it might be toxic to dopaminergic neurons and that it promotes the development of motor fluctuations.

The argument that L-dopa might be toxic to dopaminergic neurons is based on the recognition that dopamine metabolism increases oxidative stress and the observation that i.-dopa is toxic to cultures of mesencephalic neurons in vivo. There is no in vivo evidence in laboratory animals that i.-dopa accelerates disease progression, and it is difficult to reconcile the potential of dopamine toxicity with the obvious fact that the drug prolongs life in patients with PD. A 9-month study, called *ELLDOPA*, compared different doses of L-dopa with placebo and found no evidence of L-dopa toxicity.

Clinical experience with CD-LD treatment of PD suggests that there is a progressive increase in the

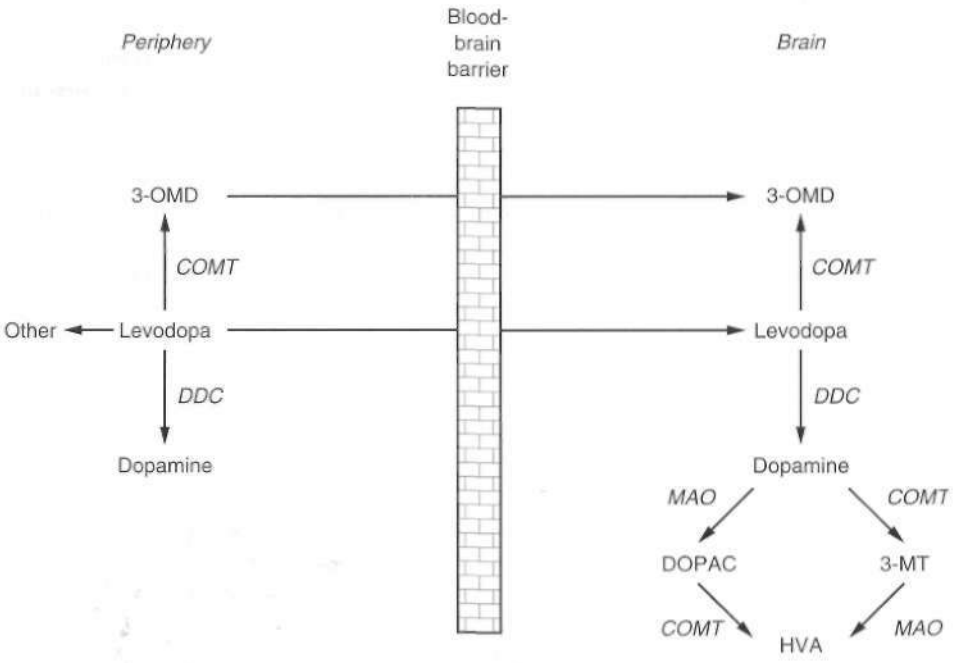

FIGURE 77.5 Peripheral and central L-dopa and dopamine Meta holism. COMT = catechol-O-methyl transferase; DDC = dopa decarboxylase; DOl'AC = dihydroxyphenylacetic acid; HVA = homovanillic acid; MAO = monoamine oxidase; 3-MT = 3-methyttyrosine; 3-OMD = 3-O-methyldopa.

prevalence of drug-related motor fluctuations (wearing off, dyskinesia) over time that relates mainly to the seventy of the underlying PD. Wearing off results from loss of continuous receptor stimulation. Experimentation in animal models relates the development of dyskinesia to changes in striatal glutamate receptor sensitivity consequent to pulsatile stimulation of striatal dopamine receptors. Continuous dopamine receptor stimulation with L-dopa or with long-acting dopamine receptor agonists prevents or reverses this phenomenon. Two pivotal clinical trials studied whether more sustained dopamine receptor stimulation afforded by DA (pramipexole and ropinirole) therapy was less likely to induce motor fluctuations and dyskinesia than therapy with the shorter half-life agent CD-LD. In both studies, the efficacy of CD-LD for the primary symptoms of PD was superior to that of DA, even though open-label supplementation with CD-LD was allowed during the study. CD-LD was better tolerated than DA, which caused more edema, sleepiness, and hallucinations than CD-LD (Table 77.9). In both studies, the risk of development of dyskinesia or motor fluctuations was substantially reduced in the DA monotherapy group and even in subjects who ended the study on CD-LD and DA (Parkinson Study Group 2000; Rascol et al. 2000). At this time, it remains unclear whether the delay in development of early dyskinesias and fluctuations is worth the poorer efficacy and tolerability and greater expense of agonists. Clearly, by the second decade of therapy, all patients arc on L-dopa, often in combination with DA, and it is not yet clear whether initial treatment will influence overall function or quality of life at this point in the disease. In many specialty centers, otherwise healthy and cognitively intact patients younger than 70 years are usually treated first with DAs and less healthy, cognitively impaired, and elderly patients are started on L-dopa.

Irrespective of initial treatment, virtually all patients with PD experience an evolution of their response to L-dopa that includes wearing off and other motor fluctuations. The middle years of PD treatment can best be characterized as the years of optimizing drug delivery. The first step in rational pharmacotherapy of PD at this stage is characterizing the pattern of response to the therapeutic agents, a step wholly reliant on the patient history. The patient should be asked to describe the severity of symptoms in the morning on arising and the magnitude and duration of benefit from incremental doses of antiparkinsonian drugs. The usefulness of historical information may be augmented by careful patient education on symptom recognition and the development of a shared vocabulary. Completing motor diaries (Figure 77.6) helps both the patient and the treating physician recognize the patterns ot motor response and adjust the medications accordingly.

Table 77.9: Frequency of common side effects in comparative trials of dopamine agonists and L-dopa

Side effect	*Ropinirole* (%)	*Pramipexole* (%)	*L-Dopa (%)*
Nausea	**48.6**	**36.4**	**43.1**
Somnolence	27.4	**32.4**	**18.2**

Constipation	**9.5**	**20.5**	**12.6**

Wearing off is the most common type of motor fluctuation. It is the predictable return of parkinsonism in advance of the next scheduled antiparkinsonian dose. *On off is* the unpredictable reappearance of parkinsonism at a lime when central levels <-l Linlip.irkinsnninn drugs **are** expected to be within the target therapeutic range. *Delayed on* is a prolongation of the time required for the central antiparkinsonian drug effect to appear. Dose *failure* is the completed failure to develop a favorable response to an incremental dopaminergic dose. *Protein-related offs* occur when the transport of L-dopa across the intestinal wall is impeded by competition for facilitated transport by large amounts of neutral amino acids. A variety of dyskinesias can further complicate the picture of midstage PD. *Peak-dose dyskinesias* are usually choreiform or stereotypical movements present at the peak of the therapeutic response; dystonic movements are seen less commonly. *Off-period dystonia* usually appears in the more severely affected foot in the morning before the first daily doses, sometimes reappearing during wearing off. *Diphasic dyskinesias* arc usually large-amplitude dyskinetic movements of the lower body during the time of increasing and decreasing L-dopa levels.

Armed with a few basic principles and a commonsense approach, the clinician can usually smooth out fluctuations for most patients (Table 77.10). Delay to onset of therapeutic benefit can be hastened by avoiding or reducing protein ingestion or by crushing the L-dopa tablet and mixing it with a carbonated beverage. The duration of benefit increases when the incremental dose is increased or dopamine metabolism is blocked with an MAO inhibitor or COMT inhibitor. The brittle patient with motor fluctuations and dyskinesia may do better on smaller, more frequent L-dopa doses. A homemade solution of liquid L-dopa allows very tight titration of the resulting 1-mg/mL of i.-dopa solution and is particularly useful in young fluctuators (Table 77.11).

In addition to the fluctuating response typical of moderate PD, patients with advanced disease may have acquired j,-dopa-resistant motor symptoms such as freezing, progressive gait dysfunction, dysarthria and dysphagia, and recurrent falling. Other features of the advanced illness, including cognitive impairment, autonomic dysfunction,

FIGURE 77.6 Sample diary in Parkinson's or her disease. For each hour, the patient indicates whethet and which antipatkinsonian drugs he or she has taken then places a mark to indicate his or her motor state for most of the hour.

Table 77.10: Management of drug-related motor fluctuations in Parkinson's disease

Wearing off
Adjust L-dopa dose and interdose interval
Shorter interval
Smaller increment, especially if dyskinesia is a problem
liquid carbidopa/L-dopa
Add catechol-O-methyl transferase inhibitor
Entacapone
Tolcapone
Add dopamine agonist
Add amantadine
Add selegiline
Dyskinesia
Adjust L-dopa dose and interdose interval
Smaller increment
Shorter interval, if needed
Add dopamine agonist and reduce L.-dopa dose
Add amantadine
Add atypical antipsychotic
Morning dystonia
Chew or crush first dose, take with carbonated beverage
Add dopamine agonist
Add baclofen
Add anticholinergic
On-off fluctuations
Careful identification/management of predictable fluctuations
Add dopamine agonist

and psychiatric complications, may limit the types and dose of tolerated medications. *Freezing,* sudden immobility of the feet while walking, often with falls, may be seen in the off period or in the on period. Although off-period freezing docs improve with optimization of medications, on-period freezing may be resistant to treatment. Behavioral strategies such as sensory cues may be helpful. Dysarthria and dysphagia are often treated by speech therapists, although documentation of improvement from these techniques is scant. *Cognitive impairment* increases mainly with the age of the patient and with disease severity. Pteliminary reports suggest that cholinesterasc inhibitors might be useful in PD-associatcd dementia, but these studies require confirmation in carefully controlled trials. *Autonomic dysfunction* can be managed conservatively, with salt supplementation, fludrocortisone, midodrinc for orthostatic hypotension, urological medications for bladder dysfunction, and dietary changes for constipation. *Hallucinations* occur in about 30% of treated patients; a loss of insight that the visions are not real or the appearance of psychotic thinking signals a particularly disabling complication. Hallucinations often improve with atypical antipsychotics such as quetiapine and clozapine. Cholinesterase inhibitors may reduce hallucinations in some patients. Sleep disorders may respond to hypnosedatives, tricyclic antidepressants, or nighttime dopaminergic therapy. Excessive daytime sleepiness may respond to methylphenidate or modafinil.

Table 77,11: Liquid L-dopa

Recipe
10 tablets of car hi do pa/Ldo pa
1 liter of water
500 mg of ascorbic acid
Powdered drink mix for taste
Calculating the dose
Divide rhe total daily dose into 13 increments
Increase the first morning dose increment by 10-20%
Give 13 hourly doses from 7:00 AM through 7:00 PM
Give one dose of Sinemet CR at 8:00 PM
i itriite .is needed using motor fluctuation diaries as a guide

Surgical Treatment of Parkinson's Disease. Despite decades of experience with the medical treatment of PD, many patients with moderate to advanced disease have a poor quality of life because of fluctuating medication response, troublesome dyskinesia, or i.-dopa-unresponsive symptoms. For these reasons, there has been a resurgence of interest in surgical approaches to motor dysfunction in PD. Palliative surgical approaches include stereotactic destruction of physiologically defined overactive brain nuclei (thalamotomy, pallidotomy), deep brain stimulation (DBS) using implanted pulse generators, and the implantation of cellular sources of dopamine. Surgical approaches aimed more at the degenerative process itself include delivery of trophic factors using implanted pumps or by gene therapy and cellular transplantation.

Stereotactic *thalamotomy* reduces or eliminates contralateral rest tremor and reduces rigidity in 75-85% of patients, but there is no effect on bradykinesia, and bilateral procedures can harm speech and cognition. *Thalamic DBS* is similarly efficacious {Rehncrona et al. 2003) but is better tolerated and can be performed bilaterally without serious effects on speech and cognition. Stereotactic *posteroventral pallidotomy* effectively reduces contralateral L-dopa-induced dyskinesia and modestly improves akinesia in the off state. Overall, about 70% of patients improve. Contralateral dyskinesia improves most of the time, about 90%, Off-period motor disability improves by about 30%, although most studies show[T] no substantial improvement over that produced by L-dopa m the on state. There is a 1.2% risk of death and about a 3.8% risk of intracerebral hemorrhage or infarction from pallidotomy (de Bic et al. 2002). *Pallida! DBS* has had limited study, but its efficacy seems equivalent to structural pallidal lesions. In a large multiccnter study, 38 patients with bilateral pallidal DBS showed significant reductions in off time and in the severity of disability in the off period, dyskinesias were improved, but l.-dopa dose could not be reduced {Deep-Brain Stimulation for Parkinson's Disease Study Group 2001). *Subthalamic DBS* has become the preferred surgical procedure for patients with advanced PD, despite the lack of a well-designed randomized efficacy trial, STN stimulation is associated with 44-52% improvement in

motor severity in the off state and a smaller improvement in the on state. Unlike other surgical procedures, STN DBS allows reductions in antiparkinsonian drug dose (Deep-Brain Stimulation for Patkinson's Disease Study Group 2001). Pharmacological suppression of excessive STN firing may be possible with a gene therapy approach that uses adc no-associated viral vector delivery of glutamic acid decarboxylase, the enzyme that synthesizes GABA. This technique is now in preliminary human trials.

PD is a condition that seems ideally suited for neurotransplantation. Most symptoms relate to degeneration of a single cell type in a ncuro.inatrimically small defined region, and dramatic improvements can be obtained by replacing the product of the degenerating cells. Animal experimentation supports the concept that human fetal SN cells implanted into the striatum survive and establish functional connections with target neurons there. Early trials of *adrenal medullary autografts* showed disappointing results and unacceptable morbidity. *Xenografts* appear poorly efficacious and are haunted by concerns about cross-species mtivuon. Open trials ol bilateral human fetal SN transplants into the putamen suggested substantial improvements in the primary symptoms of PD, significant improvements in PET scan measures of dopaminergic function, and robust survival of engrafted cells. The first randomi/.ed, sham surgery-controlled study of human fetal transplantation involved 40 patients with advanced PD. These patients were randomly assigned to sham surgery (bilateral burr holes without dura! penetration) or implantation of tissue obtained from two fetal brains per side. Despite changes in PET scans that confirmed increases in dopaminergic innervation and autopsy evidence of cell survival, there was no improvement in the primary endpoint, a global measure of improvement. There were significant improvements (18-34%) in objective rating scales, particularly in the subgroup of transplant recipients who were 60 years old or younger. However, some patients developed dyskinesias or dystonia, even in the absence of exogenous dopaminergic stimulation. In some cases, subsequent surgeries were required to control these dyskinesias (Freed et al. 2001). for the present, it is clear that without major refinements, human feral transplantation is not likely to be a useful intervention for PD.

Delivery of trophins or other substances directly to the brain parenchyma has been a recent focus of investigation. *Glial-derived neurotrophic factor* (GDNF) is a neuropeptide with neurotrophic properties for dopaminergic neurons. In rat models of PD, intracerebral administration has both protective and restorative effects. A phase II trial of monthly intracerebroventricular bolus injections of GDNF in 85 patients with moderately advanced PD showed the treatment was poorly tolerated. No efficacy was demonstrated, likely because the compound did not penetrate into the target tissue area (Nutt et al. 2003). Early clinical trials of intrastriatal GDNF pumps are in progress. Delivery of GDNF to the striatum using lentiviral or other vectors has shown some promise in animal models of PD, but clinical trials have not begun.

Irrespective of the type of surgical approach, neurosurgery for PD should be performed only by experienced functional neurosurgeons in centers with multidisciplinary teams including movement disorders neurologists, physiologists, and other support personnel. Patient selection is very important. The best surgical results arc achieved in younger, cognitively unimpaired patients with a robust response to dopaminergic therapy and good function in the on state. Many surgeons will not operate on patients who arc older than 75 years, because of an increased risk of morbidity in the elderly. Other common reasons to exclude patients include cognitive or psychiatric impairment, insufficient clinical severity, neurounaging abnormalities, and poor motivation or comorbid systemic illness. It is important to recognize that long-term outcomes have not been established for most surgical procedures.

Genetic Parkinsonisms

A number of genetic parkinsonisms have been described (Table 77.12). These discoveries have helped elucidate the ways in which single-gene abnormalities might predispose to a degenerative disease and have helped shed light on the cellular processes that underlie sporadic PD as well. Two missense mutations in the ;tlpha->yiniclcin gene on the fourth chromosome *(PARK1)* have been described in two Mediterranean pedigrees with highly penetrant asymmetrical I.ewy body parkinsonism (Polymeropoulos 1998), The onset of parkinsonism is often before age 45 years and affective disturbance is more common and prominent than in sporadic PD. However, clinical overlap with sporadic PD is considerable and individual cases of PARK1 are indistinguishable from sporadic PD. Both described mutations accelerate the production of alpha-synuclein protofibrils. High levels of oxidative stress in dopaminergic neurons and catecholamine-induccd inhibition of the conversion of toxic to stable alpha-synuclein may explain the selective vulnerability of dopaminergic neurons to the alpha-synuclein mutation.

A much more common inherited parkinsonism is *PARK1. PARK2* is a recessively inherited early onset parkinsonism linked to mutations on the sixth chromosome. *PARK2* is an early onset parkinsonism with mean onset near 30 years of age. *PARK2* is often a symmetrical parkinsonism, with prominent dystonia at onset. There is a robust response to antiparkinsonian therapy, although these patients are plagued by early and ultimately severe motor fluctuations. Dozens of causative mutations have been discovered. Homozygous mutations result in the absence or truncation of the parkin protein, a ubiquitin ligasc involved in the ubiquitin proteasome protein degradation system. The substrates for parkin have not

Table 77.12: Genetic forms of parkinsonism

Variant (chromosome)	*Pattern*	*Onset (yr)*	*Dementia*	*Asymmetry*	*Tremor*	*Dopa response*	*Other signs*	*Pathology*	
								Nigral degeneration?	*Lewy bodies?*

PARK2 (6)	AR	20-50		±	±	+++	Dystonia	Yes	Rarely
PARK3 {4}	AD	50s	±	1.	+++	1-		Yes	Yes
PARK4 (4)	AD	Early	++	+++	+++	+++	Tremor	Yes	Yes
PARK5 (4)	AD?	50s		+++	+++	+++		Yes	Yes
PARKS (1)	AR	30s		+++	+++	+++		?	?
PARK7(1)	AR	30s		+++	++	+++	Dystonia	?	?
PARKS (12)	AD	40-60	-	+++	+++-	+++		Yes	No
PARK 10(1)	?	Eate	?	?	f	?		?	?

been conclusively demonstrated, but rau and alpha-synuclein may be among them. Because the proteins are not ubiquinated, Lewy bodies do not generally form. Parkin mutations are thought to cause up to 77% of parkinsonism with onset before age 20 years, but only 3% of parkinsonism between 30 and 45 years (Lucking et al, 1998).

A mutation in the ubiquitin carboxy-terminal hydrolase (UCH-L1) gene *(PARKS)* has been described in a German sibling pair with parkinsonism. This enzyme is important in dissociation of monomeric ubiquitin from the polyubiquirin chain after proteolysis, thus in tecycling ubiquitin. The pathology of this hereditary parkinsonism is not known.

Two consanguineous pedigrees from the Netherlands and Italy *(PARK?)* have been found to have homozygous mutations in the DJ-1 gene on chromosome 1, with resulting loss of function of the highly conserved **DJ-1** protein, believed to be involved in cellular protection against oxidative stress (Bonifati er al. 2002).

Point mutations in the noncoding region of NR4A2 (Nl'RKl) gene on chromosome 2 have been described m some patients with otherwise typical idiopathic PD (Le et al. 2003). NR4A2 is a member of the nuclear receptor superfamily of proteins. It is thought to be essential for differentiation and maintenance of nigral dopaminergic neurons.

In other forms of familial parkinsonism, linkage to various regions of the genome has been described, although the causative genes remain unknown. In some northern European families, parkinsonism is linked to the second chromosome *(PARK3).* Onset, presentation, and course are similar to idiopathic PD. A kindred from Iowa has an autosomal dominant parkinsonism with reduced penetrance that is linked to the fourth chromosome *(PARK4).* These patients show early onset, slowly progressive L-dopa-responsivc parkinsonism with behavioral and psychiatric distutbances and blepharospasm. A genetic locus on chromosome 1 is responsible for *PARK6* and a locus on chromosome 12 is responsible for *PARKS,* a Iow-penetrance autosomal dominant parkinsonism seen in a Japanese family. One family with maternal inheritance and a mitochondrial DNA mutation has been reported, but the relative importance of mitochondrial DNA abnormalities remains unknown in the PD population at latge.

Dementia with Lewy Bodies

1)1.B is the second most prevalent degcnenur, e dementia after Alzheimer's disease. It is a progressive dementia characterized especially by fluctuating cognitive impairment, prominent disruption of attention and visuospatial abilities, visual hallucinations, and parkinsonism. RBD and depression are also very common. Patients with DLB arc extremely sensitive to dopamine receptor antagonists and experience severe parkinsonism when treated with neuroleptics. Characteristic pathological changes include cortical and brainstem Lewy bodies. Spongiform changes, neurofibrillary tangles, and dystrophic Lewy neuritis may also be seen, and overlap with Alzheimer's disease is considerable. Treatment of DLB is difficult. Although antiparkinsonian agents are used to treat parkinsonian signs, the degree of sensitivity of parkinsonian signs to dopaminergic therapy has not been well defined. Psychiatric and behavioral changes may improve with atypical antipsychotics. An open-label study found improvements in delusions, apathy, agitation, and hallucinations with rivastigmine treatment, but these findings should be corroborated in controlled clinical trials.

Multiple System Atrophy

MSA is a relatively new diagnostic designation that includes disorders with various combinations of pyramidal, extrapyramidal, cerebellar, and autonomic features. Within this category are subtypes named for their predominant clinical manifestations. **The** more purely parkinsonian MSA *{MSA-P)* replaces the term *striatonigral degeneration.* Cerebellar MSA *{MSA-Q* replaces the term *olivopontocerebellar atrophy. Autonomic MSA [MSA-A)* replaces the term *Shy-Drager syndrome.*

MSA is considerably more rare than PD, with a prevalence of 4-5 per 100,000. It is a disease of adulthood

affecting men and women, with a mean age at onset of 54 years. The clinical distinction between I'D and MSA can be difficult and misdiagnosis is common. The most common signs in pathologically confirmed cases are parkinsonism (87%), autonomic dysfunction (74%), cerebellar ataxia (54%), and pyramidal signs (49%). MSA-P usually presents with symmetrical parkinsonism, often without tremor. Although there may be a positive response to L-dopa, this is generally relatively short lived. Many patients develop midline dystonia, especially antecolic head posture and stridor, and dystonia that is induced or worsened by L-dopa is common (Plate 77.111). Patients often have involuntary gasping or deep sighing when awake and apnea during sleep. Autonomic signs include orthostatic hypotension, incontinence, and impotence. Patients with MSA-C have parkinsonism with prominent cerebellar signs, especially wide-based ataxic gait. Autonomic signs are variably present. Patients with MSA-A generally present with autonomic failure. Early signs are incontinence in women and impotence in men. Orthostatic hypotension is the rule. There seems to be substantial residual sympathetic tone in MSA, so orthostatic hypotension is generally accompanied by supine hypertension, making treatment difficult.

Clinical tests of autonomic dysfunction may be helpful in diagnosis or treatment. Testing of cardiovascular reflexes such as heart rate variability- at rest and during forced respiration, as well as blood pressure changes during head-up tilt, may help establish a clinical diagnosis of MSA. A lack of responsiveness of growth hormone to clonidine challenges and denervation on rectal sphincter electromyography (EMG) are also characteristic findings. T2-weighted MRI brain scans may show a hyperintense rim at the lateral edge of the dorsolateral putamcn, with decreased signal within the putamcn. Cruciform hyperintensity within the pons, the "hot cross **bun**" sign, may also be a helpful sign. Although MRI brain scans differentiate MSA from PD, they do not adequately distinguish among the subtypes of MSA (Bhattacharya et al. 2002).

At autopsy, MSA brains show neuronal loss and gliosis in the striatum, SN, locus ceruleus, inferior olive, pontine nuclei, Purkinje's cells, intermediolateral cell column, and Onuf's nucleus in the sacral spinal cord. There are characteristic cytoplasmic inclusions in the glia, especially the oligodendroglia. These glial cytoplasmic inclusions contain alpha-synuclcin (Plate 77.1V). There is a severe depletion of cholinergic neurons in the pedunculopontine nucleus and laterodorsal tegmental nucleus. The etiology of MSA remains unknown. There are no known genetic forms of the illness and no known risk factors.

Treatment of MSA is very difficult. There arc no specific interventions, and symptomatic therapies provide only partial relief of disability. Parkinsonism may respond to i.-dopa, particularly early in the disease course, but the results are not dramatic or sustained. DAs are not helpful and may be poorly tolerated because of orthostatic hypotension. There is no effective treatment for the cerebellar signs. Orthostatic hypotension may improve with nonpharmacological measures such as liberal salt and water intake, compressive stockings, and sleeping with the head up, but most people require pharmacotherapy with fludrocortisone, midodrinc, or other agents. Treatment of orthostatic hypotension often worsens supine hypertension. Even in the best hands, MSA has a poor prognosis, with a mean survival of 7-9 years.

Progressive Supranuclear Palsy

In 1964, Steele, Richardson, and Olszewski described a progressive illness characterized by vertical supranuclear ophthalmoplegia, axial rigidity, pseudobulbar palsy, and mild dementia. P.uholn^ical findings inckided neuronal loss, gliosis, neurofibrillary tangles, and granulovacuolar degeneration in neurons of the brainstem. PSP is a rare disease; prevalence estimates range from 1.39-6,4 per 100,000, Men are affected more often than women. PSP typically begins in the sixth to seventh decades of life with gait disorder and falling. Patients develop an akinetic-rigid state with symmetrical signs and prominent axial rigidity. In contrast to the flexed posture of patients with PD, those with PSP may have an extended trunk or retrocolic neck posture. A characteristic facial appearance with a wide-eyed stare, furrowing of the forehead, and deepening of other facial creases allows experienced clinicians to make an instant diagnosis (Plate 77,V). Pseudobulbar palsy with dysarthria and dysphagia lend the patient a characteristic dysarthria with spasticity, hypokinesia, and ataxia, and often "silent" aspiration. Frontal lobe features are common. There is striking executive dysfunction early in the disease course and concrete thought, difficulty shifting set, decreased verbal fluency, and personality changes such as impulsiviry and poor judgment are nearly universal, Apraxia is often seen. A progressive apathetic dementia ensues. Supranuclear vertical gaze palsy may not appear until later in the disease course, and some patients may never develop gaze palsy. Atypical presentations are often seen, especially pure dementia, PSP is rapidly progressive. By the fourth year of illness, half of patients need assistance for walking and have dysarthria and visual symptoms, Dysphagia becomes prominent shortly thereafter. The median interval from onset to wheelchair dependence is 8.2 years. The diagnosis of PSP is usually made by clinical criteria. Electro-oculographic recordings in PSP show decreased amplitude and normal latency of horizontal saccadic eye movements. Typical MRI signs of PSP include midbrain atrophy, increased signal in the midbrain and GP, atrophy or increased signal in the red nucleus, third ventricle dilatation, and atrophy of the frontal or temporal lobes (Schrag et al. 2000a)

At autopsy, the midbrain in PSP is atrophied and the sylvian aqueduct is dilatated. The SN is depigmented and appears orange and shrunken. The locus ceruleus may also

show some depigmentation, but this is less prominent than in idiopathic PD. Other structures may also show atrophy, most notably the frontal lobe, STN, and superior cerebellar peduncle. Histopathologically, the degenerative process involves mainly the basal ganglia, dicncephalons, and brainstem. There are tufted astrocytes in the motor cortex and the striatum, and the typical neuronal lesion is the globose neurofibrillary tangle, made up of hypcrphosphorylated four-repeat tau protein filaments (Plate 77.VI).

PSP almost always occurs sporadically, yet an increasing number of familial cases suggest a genetic etiology in some cases. Pedigrees with apparent dominant and recessive inheritance have been described. Affected families may show phenotypical heterogeneity, with some affected persons showing dementia, dystonia, gait disorder, or tics. Mutations in the tau gene have been reported in patients with a familial PSP-like illness, but these have been quite rare and mutations are not believed responsible for most PSP cases. However, patients with PSP are homozygous for a common haplotype that contains a normally occutring polymorphism in the tau intron immediately preceding exon 10 (Morris et al. 2002). No toxic, viral, or other environmental risk factors have been described.

According to retrospective reviews of response to various treatments, dopaminergic agents, particularly i.-dopa, aid about 40% of patients. A few patients improve with amitriptylinc, imipramine, methysergidc, or 5-hydroxytryptophan, DAs have not shown efficacy in small clinical trials. A randomized placebo-controlled trial of donepezil showed modest cognitive improvements but poor tolerability (Litvan et al. 2001). Botulinum toxin injections may be useful to treat blepharospasm or retrocollic neck posture in PSP (Muller et al. 2002). The prognosis of PSP is poor with a median duration of survival of 10 years.

Corticobasat Degeneration

In 1967, Rebeiz et al. described three patients with akinetic rigidity, apraxia, dystonia, tremor, and aphasia, who at autopsy had pale achromatic ballooned neurons similar to those seen in Pick's disease. The condition was named *corticodentatomgral degeneration with neuronal acbromasia* in 1989 but has since become known as *CBD.* Although CBD generally brings to mind a particulat motor syndrome of asymmetrical rigidity, apraxia, and cortical sensory dysfunction, its underlying pathological features may be seen in other clinical syndromes including progressive aphasia and frontal lobe dementia (Dickson et al. 2002).

CBD is exttcmely rare. The mean age at onset is 60-64 years. In its most recognizable form, it is predominantly a motot disease, but it is a clinically heterogeneous disorder. Motor signs include parkinsonism with strikingly asymmetrical rigidity, asymmetrical dystonia, myoclonus, apraxia, alien limb, and cortical sensory loss. Cognitive signs range from subfluent aphasia in patients with predominantly right-sided motor signs to a generalized dementia.

Patients with CBD have cortical atrophy on MRI, with widening of the sylvian and interhemisphcric fissures and dilatation of frontal, parietal, and temporal sulci. In about half, atrophy is asymmetrical {Schrag et al. 2000a). Fluorodeoxyglucosc (FDG) PET scans show hypomcrabolism in the thalamus and motor cortex contralateral to the more involved arm {Luttc et al. 2000), SPKCT scans show significant asymmetry of cortical blood flow in CBD (Zhang et al. 2001). One study found elevated levels of tau protein in cerebrospinal fluid (CSF) in CBD patients, but this test is not clinically available.

At autopsy, patients with a clinical syndrome consistent with CBD have gross brain atrophy. Typical microscopic changes arc tau-positive neuronal and glial lesions, especially gray and white matter astrocytic plaques and threadlike lesions, and neuronal loss in the cortex and SN. The inclusions are formed of hypcrphosphorylated four-repeat tau (Forman et al. 2002). Overlap with other conditions including Alzheimer's disease, l'SP. I'D, progressive aphasia, frontotemporal dementia (FTD), and hippocampal sclerosis is common.

As with other tauopathies, the etiology of CBD is unknown. There are no familial forms of the illness and no mutations in the tau gene have been identified. There is clinical and pathological overlap with other tauopathies, and patients with CBD share a similar tau haplotype with patients with PSP.

There is no treatment for the degenerative process. Parkinsonian features are not dramatically responsive to dopaminergic drugs, but about 20% of patients have some improvement in parkinsonism with L-dopa. Benzodiazepines, particularly clonazepam, may help myoclonus. Botulinum toxin injections may improve function in dystonic limbs early in the disease and help relieve pain and facilitate care in advanced disease. The prognosis is poor, with a reported median survival after onset of about 7 years.

Lrontotempnr.il Degeneration **Willi 1'arkiiiMiiiism Linked** to Chromosome 17

FTD is a group of illnesses characterized by behavioral changes and neuropsychological evidence of frontal lobe dysfunction. They include Pick's disease, pallidopontonigral degeneration, disinhibition-dementia-parkinsonism-amyotropby, familial multiple system tauopathy with presenile dementia, familial subcortical gliosis, FTD, FTD with ALS, FTD with inclusion body myopathy, and FTDP-17. In up to 60% of patients with FTD, there is a positive family history. Genetic loci on chromosomes 17 (FTDP-17), 9 {FTD with ALS, and FTD with inclusion body myositis), and 3 (FTD) have been described.

There is considerable phenotypical and genotypical heterogeneity in FTDP-17. The disorder most often begins

in the fifties or sixties with personality and behavioral changes, including disinhibition and aggressiveness, and frontal executive dysfunction. Other common signs include social misconduct, stereotyped verbalizations, impaired recent memory, and parkinsonism. Some families present with early parkinsonism. Many mutations have been reported in the tau gene. They comprise mainly three groups: mutations in the coding region for a microtubule-binding domain, resulting in a dysfunctional protein; mutations outside the microtubule-binding domains; and mutations that alter the ratio of three- to four-repeat tau isoforms. Pathological findings include tau-positive neuronal and glial inclusions distributed variably throughout the brain (Lantos et al. 2002). In patients with prominent parkinsonism, there is severe neuronal loss in the SN. The response of parkinsonism to symptomatic treatment is not known. The prognosis is poor, with death occurring within 10 years.

Bilateral S tri at op a Hid o dentate Calcification (Fahr's disease)

Calcification of the basal ganglia has many causes. It is an incidental finding in up to 1% of all CT brain scans. Basal ganglia calcifications can also be seen in infectious, metabolic, and genetic disorders affecting this brain region. There are familial and sporadic forms. When symptoms occur, they usually begin in adulthood, between age 30 and 60 years. Cognitive dysfunction, cerebellar signs, dysarthria, pyramidal signs, psychiatric illness, gait disorder, and sensory impairment are common. About half of symptomatic patients have movement disorders. Among these, parkinsonism and chorea are most common. Fewer than 10% of patients have tremor, dystonia, athetosis, or orofacial dyskinesia. The presence of symptoms correlates with the amount of calcification (Manyam et al. 2001). Calcification is most often seen in the GP but may also occur in the caudate, putamen, dentate, thalamus, and cerebral white matter, as well as internal capsules. Calcium is deposited in the perivascular extracellular space. Dominant and recessive inheritance patterns have been described. No specific information is available about treatment.

Parkinsonism-Demenria Complex of Guam

A high incidence of an ALS-likc illness among the Chamorros, indigenous people of Guam, was noticed more than 50 years ago. In the same population, a smaller number of people had a syndrome of parkinsonism with dementia, the parkinsonism-dementia complex (PDC). Some people had both motor neuron disease and PDC. Early in its course, PDC appears variably, like PD, atypical parkinsonism, or PSP; however, in rhe end stages, it most resembles PSP. Familial aggregation of cases has been noted, but prior attempts to elucidate a hereditary basis to the illness proved fruitless. A similar constellation of ALS and PDC has been reported on the Kii peninsula of Japan.

Pathologically, the disorder is characterized by neuronal degeneration and abundant neurofibrillary tangles in the brain and spinal cord. A recent reanalysis of a patient registry suggests that both the spouses and the offspring of persons with PDC have a significantly higher risk of themselves developing ALS-PDC, suggesting both environmental and genetic risk factors (Plato et al. 2002). The critical age for exposure to the environmental factor was adolescence or early adulthood. Despite extensive analysis of the diet and other environmental factors, the etiology of PDC Guam remains unknown, although neurotoxic damage from the cycad nut has been implicated.

Guadeloupean Parkinsonism

Over the past .5 years, a focus of atypical parkinsonism has been described in the French West Indies. So-called *Guadeloupean parkinsonism* shows clinical features of L-dopa-unresponsive parkinsonism, postural instability with early falls, and pseudobulbar palsy. More than 25% of these patients have a phenotype like PSP (Caparros-Lefebvre et al. 2002). The etiology of this form of parkinsonism is unknown, but exposure to dietary or other environmental toxins is suspected.

Vascular Parkinsonism (Lower Half Parkinsonism)

As many as 3-6% of patients with parkinsonism have a vascular etiology, but the true frequency is unknown. Vascular changes are common, but the cause and effect arc not always clearly established. Among stroke patients, parkinsonism is more common in patients with lacunar stroke. Vascular parkinsonism usually presents as a gait disorder with prominent start and terminal hesitation, as well as freezing. Postural instability and a history of falls are common. Many patients have dementia and cortico-spinal findings of incontinence. The pathology includes subcortical vascular disease with preservation of dopaminergic cells in the SN,

The symptoms of vascular parkinsonism are unlikely to show a significant response to L-dopa, but a therapeutic trial is worth pursuing because as many as half of the patients improve somewhat. Amantadine may help some patients. Physical therapy may also be useful.

Postencephalitic Parkinsonism

Between 1916 and 1927, there was a worldwide epidemic of encephalitis lethargica, which killed about 250,000

persons and left an additional 250,000 with chronic disability. These survivors of the acute illness developed parkinsonism, usually within 10 years of the infection. PEP resembles PD, although more prominent behavioral and sleep abnormalities occur early in the disease course, extraocular movements are often abnormal, and oculogyric crises are common. Other common movement disorders include chorea, dystonia, tics, and myoclonus. Pyramidal tract signs are common. The pathological appearance of PEP includes degeneration of SN neurons with neurofibrillary tangles in surviving neurons. Although the etiology is presumed to be a virus, none has ever been identified. There have been no subsequent epidemics of encephalitis lethargica, although sporadic cases of PEP are occasionally reported. The symptoms of PEP tend to be L-dopa responsive, but behavioral complications such as hallucinations and delusions are common, limiting therapy.

Drug-Induced Parkinsonism

Dopamine receptor-blocking drugs reproduce the major clinical features of PD, although signs arc usually symmetrica! and the tremor is more often present during posture holding than at rest. The most common causes of drug-induce parkinsonism (DIP) are the typical neuroleptic antipsychotic drugs, antidopaminergic antiemetics, and drugs that deplete presynaptic nerve terminals of dopamine, such as reserpme and tetrabenazine. Among the newer or "atypical" antipsychotics, the relative propensity to cause DIP is as follows: risperidone > ziprasidone > olanzapine > quetiapine > clozapine. This ranking reflects their respective affinity for the D_2 receptor. A number of other drugs have been associated with DIP, including selective serotonin reuptake inhibitors, lithium, phenytoin, of-methyldopa, valproic acid, and the calcium-channel antagonists flunarizine and cinnarizinc, which are not marketed in the United States. DIP generally appears subacutely, after weeks to months of therapy. Although it is reversible, DIP may resolve very slowly, over a period of up to 6 months, and symptomatic treatment with anticholinergics, amantadine, or L-dopa may be required. Occasionally, parkinsonism docs not resolve, suggesting the offending drug likely has unmasked an underlying parkinsonism.

Toxin-Induced Parkinsonism

In 1982, a number of young California drug addicts developed acute and severe parkinsonism after intravenous injection of a synthetic heroin contaminated by MPTP. Subsequent study showed that the offending toxin was the metabolic product of MPTP produced by monoamine oxidase, 1-methyl-4-phenyl-propion-oxypiperidine (MPP^+). Postmortem examination in patients 10 years after the original exposure showed severe loss of SN neurons without Lewy body formation. Interestingly, despite the 10-year interval between exposure to the toxin and death, there was evidence of an active neurodegenerative process, including extracellular melanin and active neuronophagy. This suggests that intracellular mechanisms may promote neurodegeneration after a distant environmental insult (Langston et al. *1999).* MPTP-induced parkinsonism is L-dopa responsive, but the response is complicated by the early development of motor fluctuations and dyskinesias, which may become severe, and psychiatric complications such as hallucinations. Cognitive function usually remains intact.

Acute *carbon monoxide* poisoning is associated with parkinsonism, MRI scans show high-intensity white matter lesions and necrosis of the GP bilaterally. Cognitive signs including decreased short-term memory, attention, and concentration are common. Patients with neurological sequelae of carbon monoxide intoxication may experience gradual clinical and radiological improvement over months to years.

Manganese toxicity is associated with L-do pa-unresponsive symmetrical parkinsonism with dystonic features such as oculogyric crisis. The disorder may progress for years following cessation of exposure. Striatal MRI T2-weighted hyperintensity may be present during the acute phase of the poisoning. F-dopa **]'TT** -;c;uis in subjects with manganism show normal presynaptic dopamine function, suggesting postsynaptic pathology. The fungicide maneb (manganese cthylene-bis-dithiocarbamate) has also been shown to induce a toxic parkinsonism.

TREMOR

Physiological Tremor

A fine rremor of the outstretched limbs is a universal finding. Physiological tremor appears to originate in the heartbeat, mechanical properties of the limbs, firing of motoneurons, and synchronization of spindle feedback. Its frequency ranges from 7-12 Hz. It is usually not noticeable except with electrophysiological recording, but its amplitude is accentuated by fatigue, anxiety, fear, excitement, stimulant use, and medical conditions such as hyperthyroidism (Tabic 77.13).

Essential Tremor

Epidemiology and Clinical Features

ET is one of the most common movement disorders. In population-based studies, the prevalence increases steadily with age, occurring in up to 5% of patients older than 60 years. The prevalence is higher in men than in women and in whites than in nonwhites. In its purest form, FT is a

  Evidence for psychogenic origin
  Primary orthostatic tremor
  Isolated voice tremor
  Isolated posirion- or task-specific tremor
  Tsolarcd tongue or chin tremor
  Isolated leg tremor

monosymptom.!tic illness characterized by gradually increasing amplitude postural and kinetic tremor of the forearms and hands (with or without other body parts), in the absence of endogenous or exogenous triggers or other neurological signs. In clinic-based scries, as many as 50% of patients exhibiting ET do not conform to this clinical picture, suggesting substantial heterogeneity (Jankovic 2002). The clinical definition of ET is problematic, because there are no pathological, biochemical, genetic, or other established and validated diagnostic criteria.

The median age at onset is 15 years, but there is a bimodal distribution and virtually all patients are symptomatic by the age of 65 years. The typical patient becomes aware of a barely perceptible postural or action tremor, usually in the distal arms and hands. The head and lower limbs are less commonly affected. Head tremor (titubation) is milder than limb tremor and is predominantly of a sidc-to-side "no-no" type. Tremor of the face, trunk, and voice are rarely seen. The kinetic tremor is higher in amplitude than the postural tremor and is the major determinant of disability. Handwriting is particularly troublesome (Plate 77.VII). A striking improvement following ingestion of a small amount of ethanol is seen in 50% of patients and may be helpful in diagnosis. Over time, the tremor worsens, causing increasing functional disability. Only a fraction of affected persons seek medical attention and there is often a long latency from onset to presentation for care. At the time of diagnosis, nearly all patients with ET have^ significant social, functional, or occupational disability, an'd as many as 25% must make occupational adjustments as a result of tremor-related disability. ET is thought to be a monosymptomatic illness without changes in cognition, strength, coordination, or muscle tone, and the neurological examination is usually normal. However, detailed studies of patients with ET have demonstrated frontostriatal cognitive deficits, changes in tandem gait, and other, albeit subtle, evidence of cerebellar dysfunction (Stolze et al. 2001). The worsening of ET over time likely relates to two phenomena. First, the frequency of tremor in ET decreases over time, and its amplitude increases. This results from decreased attenuation of lower frequency tremor secondary to age-related changes in the mechanical properties of limbs and muscle. A second possible contributor is true progression of the underlying disorder. According to recent studies, the severity of ET relates to disease duration independent of aging and age-related changes in mechanical properties of the muscles and limbs.

The diagnosis of ET is made by history and physical examination. Diagnostic criteria for ET are listed in Table 77.14. The tremor of ET has a frequency between that of PD and physiological tremor. Although EMG recordings of tremor may demonstrate both simultaneous contraction of agonist and antagonist muscles and the typical frequency tremor, such findings are not pivotal to the diagnosis.

Etiology

As many as two thirds of patients give a positive family history of tremor, and first-degree relatives of patients with ET are 5-10 times more likely to have ET than first-degree relatives of control subjects. Direct questioning or examination of first-degree relatives increases the yield of family history to as high as *96%,* In some families, pedigree analysis suggests ET is an autosomal dominant trait, with virtually complete penetrance by the age of 50 years. Hereditary ET is genetically heterogeneous, with several described loci including FFTl (ETM1) on chromosome 3, and HTM2 on chromosome 2, and a candidate locus on chromosome 4 (Higgins et a I. 1998). Twin studies suggest both hereditary and environmental factors are important in JiM-n-r c\p: i^sion.

The mechanism of disease production in these genetic disorders remains unknown and no consistent pathological structural changes have been found in postmortem brain or nervous tissue. F7T is believed to relate to the action of a central generator (see Table 77.13). A number of lines of evidence point to cerebellar dysfunction in ET; abnormal tandem gait is one example. The tremor may resolve following ipsilateral cerebellar lesions. Motor control studies show evidence of abnormal production of ballistic

movements in a partem that suggests abnormalities in cerebellar timing. PET scans have shown evidence of bilaterally increased cerebellar activity at rest and during tremor. The demonstration of reduced N-acety I-[.-aspartate (NAA) relative to total creatine in the cerebellar cortex by-magnetic resonance spectroscopy (MRS) suggests that the cerebellar disorder may be degenerative. Patients with ET may have higher blood levels of £i-carbolinc alkaloids. These endogenous compounds, also found in plant-derived foods, increase the synchrony of neuronal firing in the inferior olive and cause tremor in experimental animals and humans.

Treatment

Patients with mild ET whose main source of disability is tremor during meals and whose tremors respond to ethanol often benefit from a cocktail before meals. The two most commonly used pharmacological treatments are ^-adrener-gic blockers and primidone. Placebo-controlled studies have shown that /S-adrcnergic blockers such as 120-320 mg of propranolol per day reduce tremor amplitude in 40-50% of patients. Common side effects of these beta-blocker drugs include bradycardia, fatigue, nausea, diarrhea, rash, impotence, and depression. Beta blockers are contra-indicated in patients with congestive heart failure, asthma, third-degree atrioventricular block, and diabetes. Primidone improves ET about 50% in short-term con-trolled trials and has been suggested to be more effective for head tremor than other agents. Because of the risk of acute side effects such as vertigo, nausea, and unsteadiness, primidone is usually started at a dose of 25 mg at bedtime and then titrated as tolerated to its effective dose range of 50-350 mg daily. It can be given as a single nighttime dose or in divided dose increments. Long-term primidone therapy is usually well tolerated. Propranolol and primi-done combination therapy may be more effective than cither agent alone. Double-blind crossover studies have suggested topiramarc, alprazolam, or gabapentin may reduce ET, but these results require confirmation (Connor 2002). Other drugs, such as clonazepam, acetazolamide, methazolamide, flunarizine (not available in the United States), nimodipinc, and theophylline have not conclusively been shown to be effective in ET. Botulinum toxin may be helpful, particularly in patients with prominent head tremor. Botulinum toxin treatment of hand tremor improves tremor amplitude, but function may not improve, presumably because of secondary hand weakness.

Stereotactic thalamotomy has been reported to suppress contralateral tremor as much as 75% in up to 90% of cases. The effect appears to be long lasting. Side effects of this procedure are relatively common, although most are transient, and bilateral thalamotomy may cause speech difficulty, so it should be avoided (Pahwa et al. 2000). Thalamic DBS has shown very good efficacy in controlling ET. Tremor improves as much as 80% contralateral to the implantation, and bilateral stimulation can be performed safely. Long-term follow-up shows that efficacy remains good for 6-7 years (Rehncrona et al. 2003). Adverse effects of the surgery and subsequent stimulation include a low incidence of intracranial hematoma, postoperative seizures, dysarthria, paresthesia, dyscquilibrium, headaches, dys-praxia, and word-finding difficulty. Problems with the stimulator use It are relatively uncommon but include lead fracture or migration, and failure of the impulse generator. Reoperation may be necessary ro correct device-related adverse effects {Pahwa et al. 2000). In a prospective randomized single-blind comparison of thalamotomy and thalamic stimulation in severe tremor, the procedures were equally efficacious, although thalamic stimulation was better tolerated (Schuutman et al. 2000). DBS should be considered for cognitively intact, otherwise healthy patients wall disabling medicatioii-resisraiii tremor.

Dystonic Tremor

Three types of tremor are associated with dystonia. Some family members of persons with hereditary dystonia may have isolated tremor *{dystonia-gene-associated tremor),* suggesting the conditions may be allelic or that tremor in these cases may be a forme fruste of dystonia. In other cases, a person with dystonia of one or more body parts may have pure tremor in other body parts, for example, cervical dystonia may be accompanied by postural hand tremor *[tremor associated with dystonia).* Lastly, tremor may he part of the dystonia, sharing body distribution and directional preponderance with the dystonic movement *{dystonic tremor).* Dystonia-gene-associated tremor and tremor associated with dystonia are treated the same way as ET, whereas dystonic tremor is treated as part of the underlying dystonia (sec latet discussion).

Primary Writing Tremor

Primary writing tremor is a rare condition characterized by a 4-7 Hz tremor in the hand during the assumption of a writing posture or during the writing task itself. Most patients are men. About one third have a positive family history of writing tremor and a similar number give a history of improvement after ethanol ingestion. Surface EMG shows isolated extensor tremor, alternating tremor in flexors and extensors, or co-contraction of flexors and extensors. Writing tremor may he difficult to distinguish clinically from ET and from task-specific or writing dystonia. Phcuomenologically, it does not show the phe-nomenon of overflow usually seen in dystonia, and electrophysiological studies suggest it is distinct from both conditions. Accelerometry suggests that the primary writing tremor reflects the normal rhythmic movement of writing, but the amplitude of the movements is enhanced.

The tremor may respond to /^-adrenergic blockade or primidone or anticholinergic medications, but botulinum toxin injections provide the most consistent relief. Thalamic DBS has also been reported effective in some cases.

Orthostatic Tremor

Orthostatic tremor is high-frequency (14-18 Hz) isometric tremor that presents with tremor in the legs during quiet standing. Patients may not be aware of the tremor, but complain of unsteadiness and sensory complaints in the legs that are relieved by leaning against a stationary object or by walking. Leaning on the arms may precipitate a similar frequency tremor in the arms, and a tremor of the closed jaw has also been reported. Orthostatic tremor may he visible or palpable and can be confirmed by the appearance on EMG of high-frequency tremor when standing. Unlike parkinsonian tremors and ETs, orthostatic tremor shows significant side-to-side coherence, suggesting a central generator, PET scans have shown increases in resting cerebellar activity similar to those seen in ET. A recent study has suggested that coherent high-frequency tremor in the legs may be a normal response to perceived unsteadiness when standing still, and that orthostatic tremor may be an exaggeration of this response (Sharott ct al. 2003), Clonazepam is thought to be the most effective pharmacological treatment, although there are reports of benefit from L-dopa and gabapentin.

Neuropathic Tremor

Tremors associated with neuropath} arc usually postural and kinetic tremors with a frequency between three and six cycles per second. Demyelinating neuropathies have a particular association with tremor. The diagnosis is made when a typical tremor affects a person with neuropathy in the absence of other tremorogenic neurological disorders. The pathophysiology of neuropathic tremor is believed to be disordered feedback control related to abnormal peripheral sensory input. Some patients develop tremor after a peripheral injury, sometimes associated with abnormal posture as well as reflex sympathetic dystrophy or complex regional pain syndrome (Jaukovie 2001). The mechanism of this peripherally induced movement disorder is not understood. Pharmacological treatment is usually disappointing, but some patients respond to beta blockers or clonazepam.

Cerebellar Tremor

The tremor typically associated with cerebellar disease is a slow tremor that is absent during rest but appears and progressively increases in amplitude with movement, particularly with fine adjustments in movement required for a precise movement. Sitting or standing unsupported may induce a tremor of the trunk and head (titubation). A variant of cerebellar tremor is known as *Holmes' tremor*, or *rubral tremor.* Rubral tremor is present during rest, posture holding, and action. At rest, it is slower and less rhythmic than parkinsonian rest tremor. Rubral tremor results from acquired structural lesions in the ipsilateral cerebellar dentate nucleus and superior cerebellar peduncle. The usual causes are multiple sclerosis, stroke, and head injury. Pharmacological treatment of Holmes* tremor is difficult, although some patients respond to i.-dopa. Thalamotomy or thalamic DBS may be useful in some cases.

Fragile X Premutation

Male carriers of the fragile X premutation have been found to have a neurodegenerative syndrome characterized by the onset after age 50 years of intention tremor, gait ataxia, and executive cognitive dysfunction (Leehcy ct al. 2003). Bilateral cerebellar hypenntensities have been reported on T2-weightcd MRI studies in some cases, No information is yet available about pathology, pathophysiology, or treatment.

Palatal Tremor

PT is the term now applied to the condition also known as *palatal myoclonus* characterized by rhythmic movements of the soft palate. Although it is rhythmic, like tremors, the movement consists of repetitive, rather than oscillatory, contractions of agonists only, so it shares similarities with segmental myoclonus (see later discussion). There are two types of PT depending on the presence or absence of a structural lesion of the brainstem or cerebellum. Patients without an underlying structural lesion are considered to have essential PT, and those with underlying structural lesions arc considered to have symptomatic PT. Essential and symptomatic PT can be distinguished by clinical features and neuroimaging (Table 77.15).

Essential PT is very rare. It affects men and women equally. Patients with essential PT complain of audible ear

Tabic 77.15: Features ot essential and symptomatic palatal tren

	Gender	*Muscle*	*Ear clicks*	*Regional tremor*	A i *K I Imttini*^
Essential palatal tremor	M = F	Tensor veli palatini	Yes	No	None
Symptomatic palatal tremor	M > F	Levator veli palatini	No	Yes	Olivary hypertrophy

clicks. The movements usually disappear during sleep. In essential FT, the palatal movements are produced by rhythmic movement of the tensor veli palatini muscle. *Symptomatic PT* is more common than essential PT and affects men more often than women. Symptomatic or secondary PT is not associated with ear clicks, because the levator veli palatini rather than the tensor veli palatini is involved. Simultaneous tremor of other regional structures with cranial nerve innervation may be seen. Some patients have oscillopsia from pendular nystagmus. Laryngeal involvement may interrupt speech or may cause rhythmic involuntary vocalizations. Rhythmic limb tremor may be seen. In patients with symptomatic PT, hypertrophy of the superior olive is demonstrable on MRI brain scans. Causative structural lesions are found in the brainstem or cerebellum within the Guillaiu-Mollaret triangle, which connects the dentate nucleus with contralateral red nucleus and inferior olive (Deuschl and Wilms 2002), Many underlying etiologies have been reported, including neurodegenerative, infectious, inflammatory, dcinye I mating, traumatic, ischemic, and other disorders. Characteristic pathological changes include enlargement of olivary neurons with vacuolation of the cytoplasm. Astrocytic proliferation with aggregates of argyrophilie fibers may also be seen.

The pathophysiology of PT is incompletely understood, but it is believed that in symptomatic PT, damage to the dentato-olivary tract induces synchronization of cells in the inferior olive. The firing rhythm appears to be determined by membrane properties of the olivary neurons. This rhythm is then propagated through the inferior cerebellar peduncle to the contralateral cerebellar hemisphere, where it interferes with oculomotor, cerebelloreticular, and cerebellospinal system*. [Vii^thl and Wiims 200.V:.

Treatment of PT is difficult. Because of the rarity of the condition, there ate no randomized controlled clinical trials of therapeutic agents. Phenytoin, carbamazcpinc, clonazepam, diazepam, trihexyphenidyl, and baclofen are considered first-line agents in the treatment of PT, Second-line drugs include 5-HTP, and presynaptic amidopaminergic drugs such as tetrabenazine. Sumatriptan has been reported to aid a single patient. Injections of hotulinum toxin into the tensor veli palatini muscle have been reported beneficial in essential PT.

CHOREA

Huntington's Disease

The first complete description of I 11) is attributed to George Huntington, in 1872. He accurately reported the salient clinical features of the disease, its pattern of transmission from parent to child, and its dismal prognosis, HD is a highly penetrant autosomal dominant disease characterized by a progressive movement disorder associated with psychiatric and cognitive decline, culminating in a terminal state of dementia and immobility.

Epidemiology and Clinical Features

Prevalence figures for HD vary depending on the geographical area, but the best estimate is 10 per 100,000. The disorder is reported in all races, although it is much more common in Scotland and Venezuela and less common in Hnland, China, Japan, and black South Africans. HD usually begins between the ages of 30 and 55 years, although it has been reported to begin as early as age 2 years and as late as age 92 years. About *5%* of cases begin in patients younger than 21 years; the juvenile phenotype differs from the adult phenotype, and patients are often misdiagnosed. HD is a progressive degenerative disease that affects movement, behavior, and cognitive function (Kirkwood et al. 2001). Common symptoms of the early, middle, and advanced stages of the illness are outlined in Table 77. Id.

When clinical illness begins, it does so gradually and it is best to define a "zone," rather than a time of onset. Patients with HD may present with motor signs (about 60%), with behavioral signs (about 15%), or with both motor and behavioral signs (about 25%). Patients themselves may be unaware or unconcerned about early cognitive and motor changes. Concerned family members often bring them to medical attention. A change in the ability to generate saccadic eye movements and their speed is often the earliest sign. A blink or head thrust may be required to initiate saccadic eye movements. The motor disorder usually begins with clumsiness and fidgetiness that evolves into chorea. The presence and severity of chorea vary markedly from subject to subject and over time. In addition to chorea, patients with HD have hradykmesia and motor impersistence, with difficulty sustaining ongoing movement. They may be unable to maintain forced eye closure, hold the mouth open, or protrude the tongue for long periods. With advancing disease, there is progression of bradykinesia and dystonic movements appear. The chorea may become

somewhat less prominent or may continue to worsen. The gait disorder of HD is complex, with chorea, parkinsonism, lapses in tone of antigravity muscles, and ataxia. The walking patient with HD resembles a marionette, lurching, swaying, dipping, and bobbing. Tandem walking becomes difficult, then impossible. Ultimately, intractable falls lead to the wheelchair- or bed-bound state. Dysarthria and dysphagia progressively impair communication and nutrition, Most patients spend the last several years of their lives in nursing home settings and die of complications including pneumonia and head injury. Mean survival is 17 years, but the natural history varies and is influenced by genetic and environmental factors. Generally, patients with onset at a younger age have the largest number of CAG repeats and tend to progress more rapidly than patients with onset at an older age (see later discussion). The juvenile phenotype differs from the adult phenotype, with prominent parkinsonism and dystonia, even early in the course, and with myoclonus and seizures.

Behavioral changes contribute mightily to disability in HD. Ninety-eight percent of patients show one or more behavioral symptoms (Paulsen et al. 2001) (Table 77.17). The most common changes in early disease are irritability, anxiety, and mood disturbance, irritability may be accompanied by verbal or physical aggression. Patients with HD often have a low threshold for anger and react to minimal provocation with an explosive response. Depressed mood is very common and 30% of patients meet criteria for major depressive disorder. Mania and hypomania are seen less commonly than depression. The risk of suicide is increased as much as sixfold over the general population. Unmarried and childless persons living alone, those who are depressed, and those with a family history of suicide are particularly at risk. Fear of the disease leads to an increased risk of suicide, even in first-degree relatives of affected individuals who are at autopsy found not to have inherited the mutant gene. Psychosis is rare and it may be difficult to treat. Obsessive-compulsive disorder has been reported but can be difficult to differentiate from frontal lobe personality with perseveration. Apathy increases in concert with disease severity and is a nearly universal feature of advanced disease. Behavioral and psychiatric disorders may predate the onset of overt HD by as long as a decade, reflecting early pathological changes in the nonmotor areas of the striatum. Because some behavioral signs may be episodic and respond to pharmacotherapy, their severity does not progress in a linear fashion with cognitive and motor cl!;in;:cs. Ik'h.u ior.il signs seem to ntiprow :n ilu KTIIUM.II stages of the illness, but ascertainment may be hindered by the severe physical disability of such patients.

Cognitive changes are universal in HD. The dementia of HD tits the description of subcortical dementia with disordered attention, concentration, motivation, insight, judgment, and problem solving rather than traditional cortical signs such as aphasia and apraxia. Executive dysfunction renders affected persons unable to work, drive, and manage family finances relatively early in the disease course, but prominent global dementia occurs later.

The diagnosis of HD in a patient with a typical clinical picture and a confirmed family history is straightforward. Unfortunately, the family history may be vague or it may be negative because of competitive mortality, misdiagnosis, denial, inaccurate parental information, or obfuscation. In addition, there is a small but definite new mutation rate as expansion occurs with transmission of a premutation. Although there is a broad differential diagnosis of chorea, there are few alternative causes of the fully developed syndrome. When the clinical suspicion of HD is high, the most cost-effective diagnostic procedure is genetic testing. Neuroimaging studies can show generalized or preferential striatal atrophy, but these findings are not specific for the disorder. Although volumetric analysis of the striatum shows declining volume even in presymptomatic gene carriers, many obviously symptomatic patients do not have clinically apparent striatal atrophy. Somatosensory evoked potentials are abnormal in 94% of patients with HD and abnormalities correlate with clinical signs of the illness. However, the use of these and other electrophysiological studies for diagnosis or measuring illness progression remains unproven. The direct DNA test for the CAG repeat expansion in the huntingtin gene is highly sensitive and specific.

The availability of the HD genetic test makes possible the identification of mutant gene carriers long before they become symptomatic. However, because of concerns about the potential for occupational, insurance, and social discrimination and the lack of neuroprotective treatment interventions, only 3-5% of eligible at-risk subjects pursue testing. Those who pursue testing do so either to help with reproductive choices or because their uncertainty about the future is unbearable. Women are more likely to request presymptomatic resting than men at equal risk. Although prenatal testing is also available, relatively few prenatal

tests have been performed. Interested researchers, working in concert with lay organizations, have outlined principles that guide clinicians in the preparation of potential gene carriers for predictive genetic testing. These guidelines discourage genetic testing in asymptomatic minors and recommend genetic and psychological counseling before and after testing. One obvious concern is the risk that once given a positive genetic test result, the patient may have a major depression or other psycho pathology or may attempt suicide. When carefully managed, presymptomatic test programs are safe. In studies of life events after gene-carrier detection, less than 1% of patients have a potentially severe adverse outcome such as attempted or completed suicide or hospitalization for psychiatric illness (Almqvist et al. 1999). Adverse outcomes may be seen in patients whose predictive test suggests they are not gene carriers, the "survivor guilt" phenomenon. Depressive symptoms in such patients tends to become apparent several months after the testing process is completed, A premorbid history of depression increases the risk of an adverse outcome of testing, irrespective of test result, confirming the need for careful screening and counseling in genetic testing programs.

Pathology

The pathology of HL) includes prominent neuronal loss and gliosis in the caudate nucleus and putamen along with regional and more diffuse atrophy (Plate 77.VIII). At autopsy, only 20% of the loss of total brain weight is explained by the striatal atrophy, suggesting a very widespread degenerative process. Large cortical neurons in layer VI are also involved, as are neurons in the thalamus, SNr, superior olive, lateral tuberal nucleus of the hypothalamus, and deep cerebellar nuclei. Within the striatum, GABAergic medium spiny neurons bear the brunt of the degenerative process. Early, there is preferential loss of GABAergic neurons that co-localize enkephalin, dynorphin, and substance P. These neurons are thought to predominate in the indirect pathway, accounting for difficulties suppressing adventitious movement early in the disease course. With disease progression, all GABAergic medium spiny neurons are affected, including those in the direct pathway, explaining the emergence of parkinsonism in later disease. Juvenile-onset disease, more severe from the beginning, resembles late-stage HD with degeneration of GABAergic neurons in both pathways.

Etiology

HD is a dominantly inherited condition caused by an unstable expanded GAG trinucleotide repeat in exon 1 of the huntingtin gene on the tip of the short arm of chromosome 4. Normal alleles have fewer than 30 GAG repeats in this region. Alleles with 30-35 repeats do not cause clinical disease but may become unstable, particularly when transmitted by a man. Alleles with 36-39 repeats may cause disease, but the penetrance is reduced. Everyone with 40 or more CAG repeats in the huntingtin gene will develop the clinical illness unless there is early mortality due to another cause. Because of the inherent instability of the huntingtin gene, there may be expansion of the mutation with an increase *u:* repeat number during inrergenerational transmission. Because repeat instability of this mutation is much more common in spermatogenesis than in oogenesis, the offspring of men may have substantially greater CAG repeat lengths than their fathers. This feature accounts for the phenomenon of anticipation in HD. In large studies, there is an inverse correlation between the CAG repeat **length** and **the** age at disease onset. The extreme manifestation of this relationship is the association of juvenile-onset illness with repeat lengths of 60 or greater and onset within the ri:-,r decide with repeat k-iiiuhs o: 80 or greater. About 5% of patients present before the age of 21 years; in nearly all cases of juvenile-onset disease, the mutant allele is inherited from the father. Likewise, very late disease presentations often are associated with repeat lengths between 36 and 41. The correlation between repeat length and age at onset is driven by a very tight relationship of these two factors at the two ends of the mutation spectrum. Indeed, although one can construct tables of median age at onset versus CAG repeat length (Table 77.18), the repeat length accounts for only abour 70% of the variance in age at disease onset, suggesting that other genetic or environmental factors ate important. For this reason, the CAG repeat length is not a particularly useful tool for making predictions about disease onset and severity in individual patients.

HD is a true dominant condition. Homozygotes do not have an earlier onset or more severe form of the illness, suggesting the disorder results from a toxic effect of the mutant protein, a so-called "gain of function." The huntingtin gene controls the synthesis of huntingtin,

a widely expressed protein of uncertain function. Huntingtin is a cytoplasmic protein, hut ubiquinated, mutant, proteolytic N-terminal huntingtin fragments form protein aggregates in the cytoplasm and nucleus of neurons. Mutant huntingtin causes misfolded protein stress. Huntingtin interacts with huntingtin-associated protein, a protein selectively exptesscd in the striatum, and glyceraldehyde-3-phosphate, an enzyme essential for glycolysis, and other proteins (huntingtin-interacting proteins 1 and 2), A number of lines of evidence point to impaired mitochondrial function in HD, including abnormalities in complex I, II, III, and IV in caudate nuclei of affected brains. PET studies show reductions in striatal glucose metabolism and loss of dopamine Dj-receptor-bearing neurons in the striatum (Plate 77.IX) and MRS studies have suggested increased brain lactate levels. Systemic administration of the mitochondrial toxin 3-nitroproprionic acid models the disease in animals. Intrastnatal administration of the excitotoxins kainate and qurnolinic acid also reproduce the striatal lesions of HD. One theory that tics these animal models together is that of indirect excitotoxicity. Mitochondrial energy failure increases the vulnerability of the cell to excitotoxic injury because the resulting change in cell membrane potcnii.il result in '.oss ol thr magnesium ion ftom the KMDA-receptor-associated ion channel, allowing ligand-associated depolarization of the post-synaptic receptor and excitotoxic-mediated damage. Huntingtin may also interfere with the function of |n>-a-,vjiap:it density proum-95, a scaffolding protein associated with NMDA and kainate receptors, rendering these gluramate receptors hypersensitive. Mutant huntingtin also interferes with gene transcription, leading to an alteration in cell phenotypc and disrupting many cell functions. Mutant huntingtin may block the normal function of huntingtin to upregulate brain-derived neurotrophic factor. Mutant huntingtin likely also triggers apoptotic cell death (Evert et al. 2000).

Treatment

As in all other neurodegenerative disorders, no treatment is yet proven to favorably influence disease progression. [.ike other neurodegencrations, many potential types of interventions might prove useful, such as blocking transcription of the mutant gene, enhancing chaperonc function, interfering with association and aggregation of the protein, improving cell biocnergctics and mitochondrial integrity, and interfering with the triggers of and the ultimate steps in the process of apoptosis. Clinical trials of antioxidants designed to slow down the progression of the disease have been disappointing. One large-scale study assessed the potential neuroprotective effects of the mitochondrial complex I booster coenzyme Q_{10} (600 mg per day) or the antiexcitotoxic agent remacemide (600 mg per day) on the decline of the total functional capacity score over 30 months. The study demonstrated a trend toward slowing the decline in this measure of disability in the coenzyme Q]o treatment arm, but this did not achieve statistical significance. Remacemide showed no evidence of neuroprotection. A number of other potential strategies have shown promise in transgenic disease models, although they have not been studied in human safer)' and efficacy trials. These include the caspase inhibitor minocycline, creatine, lithium, ethyl eicosapentaenoic acid, cystaminc, bile acids, inhibitors of transglutaminase, and others. Like other neurodegenerative disease, there is no gold standard for determining disease severity or its rate of change over time. Studies relying on clinical rating scales must be quite large. For example, if one were to design a study of a neuroprotective agent that would slow HD progression 20%, it would require 940 subjects per treatment arm and a 30-month study duration to achieve 80% power to detect the protective effect (Marder et al. 2000). Because the number of potential subjects is relatively small (35,000), prioritizing agents for clinical testing are important,

One intriguing discovery in HD is that in ttansgenic models, turning off the huntingtin gene not only stops progression of the experimental illness but also teverses pathological findings, including aggregates, and is associated with clinical improvement (Yamamoto et al. 2000). Apparently, continued production of the mutant protein is required for maintenance of cell dysfunction and ultimately for cell death. This argues for a period of cellular dysfunction before death and raises the possibility that neuroprotection might have the potential to at least partially reverse extant clinical features of the disease.

Appropriate symptomatic treatment of HD begins with an assessment of the nature of the patient's complaint. Patients with chorea are often unaware of or untroubled by their involuntaty movements. Although typical neuroleptics represent the conventional approach to chorea, they have been shown not to improve function in HD and arc not used as much as in the past. Preliminary study suggests the glutamate antagonist amantadine may improve chorea in HD and is well tolerated in doses up to 400 mg (Verhagen Metman et al. 2002). Antidopaminergic drugs, particularly tetrabenazine, have been found effective in reducing chorea in patients with HD (Ondo et al. 2002). Tetrabenazine is available in many European countries and Canada and is currently studied in multiple centers in the United States. Atypical antipsychotics such as olanzapine may also be useful and may be preferable to typical neuroleptics because of lower risk of tardive dyskinesia (TD) with long-term use. Some patients * with prominent bradykinesia improve on dopaminergic therapy. Although psychiatric symptoms are ubiquitous in HD, there is little literature on the classification and appropriate treatment of these symptoms. Selective serotonin reuptake antagonis seem to improve irritability. aggression, depression, and obsessive-compulsive symptoms.

Irritability may respond to carbamazepine or valproic acid. Olanzapine has been reported to be useful in patients with irritability and aggression.

Dentatorubral-Pallidoluysian Atrophy (Haw River Syndrome)

DRPLA is an inherited neurodegenerative disease that appears to be rare outside Japan. Typical symptoms of DRPLA include chorea, ataxia, myoclonic epilepsy, dystonia, parkinsonism, psychosis, and dementia. Onset is usually in the twenties with death about 20 years later. Anticipation occurs with paternal transmission of the gene. The pathology of DRPLA includes degeneration of the dentate and red nuclei, the GP, and the STN. Ncurodegeneration may also be found in the cerebral white matter, putamen, medulla oblongata, and spinal cord (Oyanagi 2000). Neuronal nuclear inclusions stain for uliKjuitin and atrophin-1. There is also evidence for aberrant phosphorylation of the DRPLA protein complex and the nuclear membrane (Yazawa 2000). DRPLA is associated with an expansion of CAG trinucleotide repeat, in a gene on chromosome 12. In this region of the genome, the normal trinucleotide repeat length is 7-23. In DRPLA, the CAG repeat length is between 49 and 75. Because of the polyglutamine stretch in the mutant protein, neurodegeneration likely relates to interactions between the protein, other cellular components, and cellular proteins. The *Haw River syndrome,* described in a multigenerational African American family, is caused by the same repeat expansion as DRPLA. Clinical differences include lack of myoclonic epilepsy and the presence of subcortical white matter demy el i nation, basal ganglia calcifications, and neuroaxonal dystrophy. No information is available about the treatment of DRPLA, but as in HD, the clinician should be guided by the nature and severity of symptoms.

Neuroacanthocytosis and the McLcod Syndrome

The term *acantbocyte* is derived from the Greek word for "thorn." Acamhocytes arc contracted erythrocytes with unevenly distributed thorny projections, often with terminal bulbs. Acamhocytes are seen in peripheral blood smears in patients with three neurological syndromes: *abetalipoproteinemia neuroacanthocytosis* and the *McLeod syndrome* (Rampoldi ct al, 2002). A broad spectrum of movement disorders is seen in neuroacanthocytosis and the McLeod syndrome.

Epidemiology and Clinical Features

All forms ⋈ iicuroacanthocyrosis are rare disorders. Autosomal recessive *neuroacanthocytosis* is characterized by onset at around age .35 years of a progressive syndrome that includes a movement disorder and behavioral and cognitive changes. The movement disorder predominantly consists of chorea, dystonia, and tics; parkinsonism may occur in more advanced stages. There is also prominent orofacial dystonia with dystonic tongue protrusion interfering with eating. In addition, many patients exhibit lip and tongue biting and prominent dysarthria and dysphagia. Behavioral changes resemble those seen in HD with anxiety, depression, obsessive-compulsive disorder, and emotional lability. Subcortical dementia is a late feature. Seizures develop in about 50% of patients. There may he myopathy or axonal neuropathy, and the creatine kinase level is elevated. In patients with neuroacanthocytosis, acamhocytes usually make up 5-20% of peripheral blood erythrocytes. Autopsy changes include atrophy of the caudate, putamen, GP, and SN with marked neuronal loss and gliosis. The cerebral cortex is relatively spared. Mutations in the *CHAC* gene on chromosome 9 that lead to the production of a truncated protein, chorein, of unknown function have been found in this syndrome. Homologous proteins in animals seem important in intracellular trafficking.

McLeod's syndrome is an X-linked recessive disorder linked to a number of mutations in the *XK* gene, a gene for the Kell group of erythrocyte membrane glycoprotein antigens on the X chromosome. McLeod's syndrome usually begins around 50 years of age and has a slowly progressive course. The most common clinical feature is an axonal peripheral neuropathy. Some patients have evidence of myopathy as well, and all have elevations in serum creatine kinase level. The central nervous system illness is characterized by limb chorea. Oral movements and lip and tongue biting are less common than in neuroacanthocytosis. Facial tics are common, and some patients have dystonia. Seizures may be seen. Subcortical dementia and behavioral changes occur later in the disease course in about 50% of patients. Cardiomyopathy and hemolytic anemia are other common manifestations. Neuroimaging studies may show caudate atrophy with secondarily enlarged lateral ventricles. Increased T2-weighted signals in the lateral putamen may be seen on MRI scans. Pathological changes include intense caudate atrophy, loss of small cells, and gliosis in the dorsolateral putamen with less severe changes in the GP. Milder changes may be present in the thalamus, SN, and anterior horns of rhe spinal cord. Neurons in the cerebral cortex, STN, and cerebellum are spared. The reported mutations in the *XK* gene result in absence or truncation of the protein product. Kell is an endothelin processing enzyme. Endothelins arc important in proliferation and development of neural crest-derived cells and arc thought to be important in neurotransmitter release in dopaminergic neurons. No information is available about treatment of neuroacanthocytosis, but the physician should be guided by the clinical manifestations.

Benign Hereditary Chorea

Benign hereditary chorea (BHC) has been defined as a nonprogressive syndrome of inherited childhood-onset chorea wirh a good outcome in the absence of an underlying degenerative disease. Chorea is presenr from early childhood, usually from the first decade of life. It is nonprogressive and often associated with mild cognitive impairment (Brccdvcld et al. 2002). Some patients have dysarthria and dystonia. In many cases, the chorea improves during adolescence and young adulthood. The diagnostic rubric has been applied somewhat sloppily. Review of cases in the literature suggests that many cases so classified are more consistent with alternative diagnoses such as HD, myoclonic or other dystonias, ataxia-telangiectasia, or myoclonus. BHC is genetically heterogenous, but some families have a mutation in a region on chromosome 14 that harbors the 7777-'J gene, a transcription factor essential for lung, thyroid, and basal ganglia organogenesis (Breedveld et al. 2002). Symptomatic therapy of chorea with dopa mine-receptor blockers or dopainme-depleting drugs may be necessary.

Sydenham's Chorea

Sydenham's chorea (SC) is one of the major manifestations of rheumatic fever, but it typically appears months after the index infection. Because of the widespread availability of antistreptococcal therapy, SC is extremely rare in developed conn tries. It is a disorder of children, mainly girls, between the ages of 5 and 75 years, with a mean age at onset of 8.4 years. The chorea begins insidiously but progresses over a period of weeks, and it generally resolves within about 6 months. Choreic movements arc usually generalized, but hemichorea may also be seen. Behavioral accompaniments such as restlessness, irritability, and obsessive-compulsive traits are common. It is a self-limited disorder, usually lasting up to *6* months. About 20% of cases recur and multiple recurrences occur rarely. Knlargemeni oi the basal ganglia may hi- seen on MRI brain scan. Pathologically, SC is characterized by inflammation of the cortex and basal ganglia. Ann -basal ganglia antibodies can be detected by enzyme-linked immunosorbent assay and Western immu nob lotting and have a high sensitivity and specificity (Church et al. 2002). The mechanism of basal ganglia damage is likely molecular mimicry with cross-reaction between antibodies directed againsr streptococcal antigens and striatal antigens. Because it is often self-limited, the decision to treat SC depends on the magnitude of each patient's disability. A recent comparative trial suggested that valproic acid is the most effective treatment, followed by carbamazepinc and haloperidol. Because SC tends to be self-limited, periodic attempts should he made to wean therapy. Later in life, people who have survived SC may have a recrudescence of chorea in the presence of hormonal stress such as during pregnancy or estrogen treatment.

Ballismus (Hemiballismus, Hemichorea)

Ballismus is a dramatic proximal, ballistic, flinging movement. Ballism most commonly affects the limbs on one side of the body (HB), but involvement in both legs (paraballismus) and both sides of the body (biballismus) has been reported. Ballism is usually classified with the choreas for a number of reasons: Ballistic and choreic movements typically coexist, over time ballistic movements arc often replaced by choreic ones, and animal models employing subthalamic lesions result in a mixture of choreic and ballistic movements. HB is relatively rare, but its true prevalence in an at-risk population, such as patients with acute strokes, is unknown. The mean age at onset is 48-75 years. The tempo of development of the movements varies with its underlying etiology. HB related to stroke appears suddenly or emerges more slowly in a recovering plegic limb. HB related to inflammation or tumor arises gradually. HB usually results from a relatively small lesion in the contralateral STN or in its afferent or efferent connections. Rarely, lesions in other locations, including even ipsilateral cerebral cortex and striatum have been linked to HB. Although the underlying lesion is usually cerebrovascular disease in the elderly and infectious or inflammatory disease in younger patients, any type of structural lesion, appropriately placed, can produce the characteristic movement. Metabolic disorders such as nonketotic hyperglycemia and drug exposure may also cause HB (Table 77.19). Loss of subthalamic excitation of the GPi results in a loss of inhibitory drive to the thalamus, thus excessive motor activity. Low firing frequency of the STN has been confirmed in a few cases using intraoperative recording.

In the past, HB was thought to have a uniformly grave prognosis, with death resulting from exhaustion or cardiovascular collapse. In parr, this is related to a literature that was heavily based on clinicopatbological material. Better symptomatic and supportive care doubtless has improved survival and quality of life for patients with HB. More recent literature suggests that survival closely relates to the mortality of the underlying etiology, for example, survival rates following vascular HB mirror those of vascular disease, with only 32% survival and 27% stroke-free survival 150 months following the onset of the movciiK-111 disnrdi-v iRisfic ct al. 2i'^2;. The movements often regress or become more choreic over several months. However, they can be quite exhausting or disabling when present, and treatment is usually indicated acutely and in patients whose movements do not resolve spontaneously. Drugs with antidopaminergic properties arc expected to reduce this excessive thalamocortical drive, and thus benefit patients with HB. Although the rarity of the condition has

precluded controlled clinical trials, there is ample evidence from case series and reports that dopamine antagonists and dopamine depletcrs effectively decrease choreic movements. Beneficial results have also been obtained using gabapentin and valproic acid. Periodic efforts should be made to taper or discontinue these therapies when possible. Stereotactic thalamotomy or pallidotomy may be considered in patients who prove refractory to medications (Suarez et al. 1997).

Senile Chorea

Senile chorea is an idiopathic disorder characterized by the development in old age of continuous mouthing, chewing, or tongue movements. Prevalence estimates vary, but as many as one third of some populations may be affected. The diagnosis of senile chorea should be made with caution, because extensive investigation often reveals an alternative diagnosis, For example, among 12 senile patients with chorea, 11 were found to have HD, antiphospholipid antibody syndrome, hypocalcemia, TD, or Fahr's disease. Pharmacological therapy should be considered for patients with disabling movements. Antidopaminergic drugs are the most effective, but their use should be accompanied by close surveillance for the development **of TD.**

TARDIVE DYSKINESIA

TD is a movement disorder that develops in the context of chronic dopamine-receptor blockade, usually in patients who arc chronically treated with neuroleptic drugs or antiemetics. The prevalence of TD is as high as 20% of patients treated with typical neuroleptics. TD usually requires a minimum of 6 weeks or more of dopamine-receptor blockade, but onset as soon as after the first dose has been reported. Reported risk factors include age, female gender, affective disorder, and edentulousness. Although the stereotypical form of TD is most common, other movement disorders, such as chorea, akathisia, dystonia, tics, and myoclonus, may be seen as part of TD. Tardive parkinsonism has also been reported, but some of the patients with parkinsonism persisting years following withdrawal of the offending neuroleptic have been found to have pathological evidence of PD. The classic appearance of TD is repetitive, stereotypical (e.g., chewing) movements of the mouth, tongue, and lower face {oral-buccolingtial dyskinesias). In contrast to HD, the upper face tends to be spared (sec Chapter 24). Choreic movements may also affect the trunk and pelvis, causing respiratory dyskinesia and pelvic thrusting. Limb chorea and restlessness (akathisia) may also be seen.

The pathophysiology of TD is incompletely understood. Denetvation supersensitivity of the dopamine receptor is the most likely cause. PET studies document upregulation of D_2 receptors in neuroleptic-treated patients (Silvestri et al. 2000). There are other theories including oxidative stress and insufficiency of GABA. Genetic susceptibility factors that might be involved in increased risk of TD include polymorphisms of the dopamine D_3 receptor gene and the 5-HTc serotonin receptor gene (Scgman et al. 2000).

The most important intervention in TD is to prevent its occurrence. For example, in prospective studies, high-risk subjects treated with atypical rather than typical antipsychotics appear to have a reduced risk of TD compared with historical controls. Because patients may not complain about early or mild movements, the clinician must carefully examine neurolep tic-treated patients for early signs of TD, Neuroleptics should be discontinued, if possible, or an atypical antipsychotic drug should be substituted. Some studies suggest tocopherol might improve TD symptoms. Mild TD may improve with benzodiazepines or baclofen, Catecholamine-depleting drugs, particularly tetrabenazine, are often very useful in the treatment of severe TD (Jankovic and Beach *1997).*

DYSTONIA

Childhood-Onset Generalized Primary Dystonia

Epidemiology and Clinical Features

Most cases of primary generalized dystonia are inherited and begin in childhood (Nemeth 2002). Generalized dystonia is quite rare, with an estimated prevalence of about 1.4 per 100,000. The most common form of childhood-onset primary generalized dystonia, also referred to as DYT7 or *Oppenbeirri's dystonia* and previously called *dystonia musculorum deformans* is an autosomal dominant disorder with relatively low penetrance. Particularly common in persons of Ashkcnn/i Jewish descent, the reported prevalence of DYT1 dystonia is as high as 20-30 per 100,000. Half of patients are affected by age 9 years and onset in patients older than 40 years is extremely rare. The earliest symptom is usually an action-induced dystonia in the leg or arm. Onset in the cervical, facial, laryngeal, or pharyngeal region is rare. In about 70% of patients, dystonic movements spread to the trunk and other limbs, and the condition generalizes over about 5 years. Patients with earlier onset and onset in the leg are more likely to develop generalized dystonia than those presenting later or with arm dystonia. Generalized dystonia produces severe disability, and most patients with this severe form of the illness are nonambulatory. Even in generalized disease, however, laryngeal and pharyngeal dystonia remains rare. The diagnosis of childhood-onset primary generalized dystonia is made clinically in a patient with onset after the age of 26 years of limb dystonia, with subsequent spread, the absence of other movement disorders with the exception of tremor, normal intellect and neurological examination, and absence of a pronounced response to L-dopa.

A number of other childhood-onset generalized dystonias have been described, but none accounts for large numbers of cases. *DYT2* has been assigned to recessively inherited limb-onset dystonia in gypsies. However, there have been no families in whom recessive inheritance can be eon tinned, so the existence of this syndrome is tentative. The designation *DYT4* applies to an Australian family with dominantly inherited laryngeal and cervical dystonia that often generalizes over time. The disorder begins between adolescence and 40 years. Its genetic locus is unknown. DYT6" is a dystonia seen in Mennonite families that localizes to the chromosome 8. This autosomal dominant dystonia begins during the late second decade of life with a DYTI-like phenotype or with cranioccrvical or focal dystonia. *DYT13* mapped to chromosome 1 presents as cranioeervical or arm dystonia with some tendency to generalize.

Routine laboratories and neuroimaging studies do not contribute to the diagnosis. Simultaneous recording of EMG activity from antagonist muscles often reveals simultaneous contraction of antagonistic muscles and spread or overflow of activity to muscles not involved in the intended action. Such studies are not required for the diagnosis. DNA testing is available for DYT1 dystonia, but the low penetrance of the disease limits the usefulness of this test for prenatal or presymptomatic diagnosis.

Pathology

Pathological studies in childhood-onset primary generalized dystonia arc limited. No consistent structural or pharmacological changes have been detected in postmortem brain.

Etiology and Pathogenesis

The low penetrance of DYT1 dystonia, combined with variable expression that may range from an asymptomatic state to severe life-threatening dystonia (dystonic storm), may obscure its hereditary nature in many families {Opal et al. 2002). The disorder is genetically homogeneous in Ashkenazi Jews, 90% of whom are found to have the *DYT1* mutation. Non-Jewish patients are genetically more heterogeneous. The DYT1 mutation is a GAG deletion in the torsin A gene on chromosome *9* with an estimated frequency of 1 per 2000 to 1 per 6000 in Ashkenazi Jews and about 1 per 20,000 to 1 per 30,000 in non-Jewish populations. The high prevalence of DYT1 in Ashkenazi jews is related to a founder mutation estimated to have originated about 350 years ago in Lithuania or Byelorussia and the subsequent large increase in the population from a limited number of ancestors.

The pathogenesis of generalized dystonia remains poorly understood. Torsin A is a protein of unknown function that is homologous to the adenosine triphosphatases and heat-shock proteins. Its structure suggests a role in endoplasmic reticulum function, intracellular trafficking, or vesicular release. Mutant torsin A may interfere with these functions or may contribute to misfolded protein stress. There is experimental, clinical, neuroimaging, and electrophysiological evidence of dysfunction at the cortical, subcortical, brainstem, cerebellar, and spinal levels. Dystonia produced in nonhuman primates by repetitive hand movements is associated with inappropriate spread of the cortical representation of the affected hand. There is disordered sensory function in human dystonics and certain sensory inputs influence motor output in these patients. Deep brain recordings support abnormally low firing rates in the GPi with an abnormal pattern of firing as well. During sustained dystonia, there is increased metabolic activity in the midbrain, cerebellum, and thalamus. Functional neuroimaging of the dopamine system suggests decreased dopamine neurotransmission in the striatum, but decreased striatal dopamine has not been confirmed in postmortem tissue {Hurukawa et al. 2000b), Because dystonia may respond to pallidal lesions or stimulation, a central role of the GPi has been proposed. It is likely, however, that

the pathophysiology of dystonia involves many factors including changes in the rate and pattern of neuronal firing, the degree of synchronization of firing, and aberrant focusing of sensory input (Vitek 2002).

Treatment

Rather limited information is available on the medical treatment of child hood-onset primary generalized dystonia. Absent an obvious neurotransmitter deficiency or excess, there is no compelling rationale for the use of any particular pharmacotherapy, and no drug has been found to be universally effective for symptom control (Table 77.20). In the absence of genetic confirmation of the DYT1 mutation, a trial of dopaminergic therapy should be considered, because patients with dopa-responsive dystonia {see later discussion) have such a gratifying response. In patients younger than 20 years, about 50% will respond well to high-dose anticholinergic therapy. The response rate is better in patients treated within 5 years of onset. Baclofen, clonazepam, benzodiazepines, and dopamine-depleting medications may be useful in some patients. The treatment of childhood-onset primary generalized dystonia is a trial-and-crror process. Treatment should be initiated with very small doses and the dose should be increased slowly and gradually. Botulinum toxin injections may be considered to treat one or a few particularly problematic body areas in patients with generalized dystonia. Chronic intrathecal baclofen has been reported to help some patients with dystonia, especially those with concomitant spasticity, Stereotactic thalamotomy is said to benefit about 66% of patients who have been operated on, but some patients worsened and side effects were common. Thalamotomy may he most useful for patients with dystonia of the distal limb. More recent reports suggest that axial symptoms might improve after bilateral pallidotomy or pallidal DBS. Patients with the DYT1 mutation seem most likely to improve (Coubes et al. 2000).

Adult-Onset Primary Focal and Segmental Dystonia

Epidemiology and Clinical Features

A community-based postal survey of primary dystonia suggested the prevalence of adult-onset primary focal or segmental dystonia was 12.9 per 100,000. Cervical dystonia and blepharospasm were most commonly represented. The focal and segmental primary dystonias generally begin in adulthood with dystonic movements in the band and arm, neck, or face. When spread occurs, the ultimate distribution tends to maintain a segmental pattern. For most such dystonias, the women are somewhat over-represented, *Cervical dystonia* is the most frequently diagnosed form of focal dystonia, accounting for about half of focal dystonia cases. Patients with cervical dystonia present with neck pain, difficulty maintaining a normal head position, and sometimes tremor. Although across patient populations, the movements may occur in any single plane, or commonly in several planes, there is a directional preponderance to the movements. Sensory tricks are common (see Chapter 24) and include resring the head against a wall or high-backed chair or touching the chin or back of the head lightly with one hand. Spontaneous remissions may be seen in as many as 20% of patients, although recurrence is very common. About 20% of patients with focal dystonia have dystonic movements of the eyelids, *blepharospasm.* Symptoms of blepharospasm are often preceded by a gritty or otherwise abnormal sensation in the eye. Increased blinking may follow, or frank spasms of eyelid closure m.n begin. Symptoms of blepharospasm are typically worse with driving, reading, or watching television. Improvement induced by placing a finger alongside the eye is a common finding. Blepharospasm may be accompanied by *oromandibular dystonia* (cranial dystonia), or the latter may occur in isolation. Otomandibular dystonia typically causes involuntary jaw opening or closure, tongue prorrusion, dysarthria, and dysphagia. Because the actions of eating and speaking activate the dystonia, these tasks are particularly affected. Sensory tricks in oromandibular dystonia include touching the face or inserting something, such as candy or the tip of a pencil, into the mouth. Vocal cord involvement with *adductor* or *abductor dysphonta* affects pdonation, resulting in a harsh and sttanglcd, or breathy voice, respectively. Whispering and singing are often relatively unaffected in such patients. The *occupational* or *task-specific dystonias* are those that arise in the context of

repetitive or skilled use of a body part. The most common task-specific dystonia is *writer's, cramp,* in which action dystonia of the arm and hand develop during writing. Hair stylists, musicians, court reporters, and others who work repetitively with the hands may find these specific skills similarly affected. Players of wind instruments may develop dystonia of embouchure, with difficulty maintaining the proper mouth and lip posture. Occasionally, an adult patient will present with a pure *truncal* dystonia, with flexion, extension, or lateral bending. Isolated *foot dystonia* in an adult is very rare and suggests an underlying structural lesion, a parkinsonian disorder, or 5PS. The diagnosis of adult-onset primary focal or segmental dystonia is made clinically. Ncuroimaging studies are useful if an underlying cause is suspected (see Secondary Dystonia, later in this chapter) but arc generally normal. Simultaneous recording of agonist and antagonist muscles may show inappropriate co-contraction, but this is not required for diagnosis.

Etiology and Pathogenesis

Many studies have suggested that focal and segmental dystonia might have a genetic basis. About 25% of adult-onset focal or segmental dystonia patients have a positive family history of dystonia, which would be consistent with an autosomal dominant condition with low penetrance. Some families with clear dominant inheritance have been reported and there is already one identified locus of focal dystonia, *DYT7,* in a large German family. This family-shows an autosomal dominant pattern of inheritance with reduced penetrance and adult onset of cervical dystonia, dysphoria, or hand tremor. The locus has been mapped to chromosome IS.

The pathogenesis of adult-onset primary focal or segmental dystonia is unclear, but similar mechanisms to childhood-onset primary generalized dystonia are proposed. Studies suggest that there is reduced inttacortical inhibition in dystonia, believed related to impaired cortical and striatal GABA levels (Levy and Hallett 2002). Several lines of evidence suggest that abnormal central somatosensory processing may lead to insufficient sensorimotor integration in dystonia. PET scans suggest an abnormal pattern of regional glucose metabolism with hypermetabolism of the basal ganglia, cerebellum, and supplementary motor area (Trost et al. 2002). Recent studies have suggested disordered copper metabolism with increased lenticular concentrations of copper and manganese. Changes in trace minerals may affect cellular function or lead to cellular death (Becker et al. 1999).

Treatment

Medical treatment of adult-onset primary focal and segmental dystonia is difficull and employs those agents typically used in generalized dystonia. Adults are less able to tolerate effective doses of these agents, so the response to therapy is somewhat more disappointing than that seen in children. Botulinum toxin injections, on the other hand, are very helpful in the treatment of focal and segmental dystonia. Botulinum toxin is injected subcutaneously over the facial muscles or directly into larger deeper muscles that underlie pain and inappropriate movement in other focal dystonias. Many, though not all, clinicians use EMG to help guide toxin injection. Botulinum toxin injections have been proven effective in the treatment of blepharospasm and other facial dystonias, as well as cervical dystonia. Clinical experience suggests they are very useful in the treatment of oromandibular, laryngeal, truncal, and limb dystonia. Overall, more than 75% of treated patients report moderate to marked improvement in dystonic pain or posture. The procedure is generally well tolerated, with excessive weakness of injected muscles or occasionally neighboring muscles (he most often reported side effect. The mechanism of action of botulinum toxin appears complex. Botulinum toxin not only blocks neuromuscular transmission, producing weakness in the injected muscles, but also normalizes intracortieal reciprocal inhibition, possible by an effect on muscle spindle input. Botulinum toxin injections have a brief duration of action, requiring repeated injections every 3-6 months. Secondary resistance occurs in some chronically treated patients, especially those injected frequently with higher doses of the toxin (Jankovic, Vuong, and Ahsan 2003).

Patients who fail to respond to botulinum toxin injections may be offered surgical interventions. Blepharospasm can be tteated by orbital myectomy. Good results are obtained in some patients with cervical dystonia following selective peripheral denervation of the muscles participating in the production of abnormal head movement. A prospective open study of selective peripheral denervation for patients with cervical dystonia with botulinum toxin resistance showed 68% of patients wetc functionally improved after surgery. Pain control was less sustained than control of movement, and posterior cervical dysesthesias were a common side effect. Pallidal DBS has been tried in some patients with refractory cervical dystonia with good results. More study is required to determine the utility of the technique in this diagnosis (Volkmann and Benecke 2002).

X-Linked Dystonia-Parkinsonism (DYT3; Lubag's Syndrome)

DYT3 or Lubag's syndrome is an X-linkcd condition with progressive dystonia and parkinsonism affecting Filipino adult men descended from maternal lines from the Panay Island. The disorder is heterogeneous, and affected men may show dystonia, parkinsonism, tremor, chorea, or myoclonus. This phenotypical heterogeneity is evident in colorful descriptions of the disorder in the local dialect.

"Lubag" means intermittent and "Wa-eg" sustained twisting or posturing, suggesting the predominantly dystonic form of the illness. "Sud-Sud" refers to shuffling gait, suggesting the parkinsonian form of the illness. Lubag affects men in the fourth or fifth decades, although much earlier onset cases have been described. Symptoms predominantly relate to dystonia, although parkinsonism is present in more than 30% of patients. A nearly pure parkinsonian phenotype is thought to predict a more benign prognosis.

PET studies have shown both postsynaptic and presynaptic dopaminergic changes. In some patients, parkinsonian symptoms are r-dopa-responsive, although there are reports rh.it t.-dopa worsens symptoms in some predominantly dystonic patients.

D op a-Responsive Dystonia (DYT5)

Dopa-responsive dystonia (DRD) is an uncommon condition, with a prevalence of 0.5-1.0 per 1,000,000. Girls are preferentially affected. DRD is a childhood-onset generalized dystonia with a dramatic, sustained and uncomplicated response to low doses of i.-dopa. The disorder begins in the first decade of life with an action dystonia in the foot. The condition then progresses to the fully formed illness that ranges in severity' from mild focal to disabling generalized dysronia. Early onset cases may be mistakenly diagnosed as cerebral palsy. The most characteristic historical feature is prominent diurnal fluctuation. Affected patients may be almost normal in the morning, becoming progressively more disabled over the course of the day with peak disability late in the evening. Parkinsonian symptoms become part of the clinical picture over time. DRD is usually dominantly inherited with incomplete penetrance (DYT5). DYT5 results from mutations in the guanosine triphosphate cyclohydrolase-l *(GTPCH1)* gene on chromosome 14. (Eurukawa et al. 2000a). More than 50 mutations of the gene have been discovered, and therefore DMA testing is currently not feasible. *GTPCH1* is an enzyme involved in the synthesis of tetrahydrobiopterin, a cofactor for tyrosine hydroxylase. Other mutations affecting enzymes involved in tetrahydrobiopterin synthesis have also been i in plica red in DRD. A recess ively inherited DRD relates to mutations in the gene for tyrosine hydroxylase, the rate-limiting enzyme in the synthesis of i.-dopa. Patients with the DRD have low levels of tyrosine hydroxylase, and therefore low levels of dopamine. F-dopa PET and postmortem studies confirm normal numbers of dopaminergic neurons. DRD responds very well to low[r] doses of L-dopa (100-300 mg daily) in combination with carbidopa. Patients with DRD do not develop the motor fluctuations and dyskinesias associated with chronic L-dopa therapy in PD. Anticholinergic drugs may also be useful.

Another childhood-onset dystonia related to deficient dopaminergic neurotransmission is *aromatic acid decarboxylase deficiency.* This disorder is recessively inherited. Dystonia, parkinsonism, oculogyric crises, autonomic symptoms, and progressive neurological impairment begin in childhood. There are deficiencies in central biogenic amines including dopamine, norepinephrine, epinephrine, and serotonin. i'>ce.uise llie enzyme deficiency is distal to l. dopa in the dopamine synthetic pathway, the symptoms are not L-dopa responsive. However, direct-acting DAs and MAOIs may be useful (Swoboda et al. 1999).

Myoclonus Dystonia (DYT11)

In myoclonus dystonia (MD), dystonia is the predominant symptom, but tremor and myoclonus are present as well. Some patients have pure myoclonus. Symptoms usually begin before the teenage years and predominantly affect the head, arms, and upper body. Ehe involuntary movements may be exquisitely sensitivity to ethanol. Psychiatric features including affective disorder, obsessive-compulsive disorder, substance abuse, anxiety, phobic or panic disorders. and psychosis have been described. Cognitive decline has also been reported (Dohcny et al. 2002). No other neurological deficits are seen and the course is usually benign. Ehe pathology is unknown. A number of heterozygous mutations in the E-sarcoglycan gene on chromosome 7 have been reported in families with MD. Another suggested locus is on chromosome 18. Mutations in the torsin A *{DYT1)* gene and the D_2 dopamine receptor gene have also been described, but e-sarcoglycan mutations were subsequently described in these families as well. There is likely another locus on chromosome 18 (Furukawa and Rajput 2002). MD responds poorly to medical therapy, but beneficial responses to valproic acid and trihexyphenidyl have been reported. VIM stimulation has been reported to be beneficial in MD in a single case (Trottenberg et al. 2001).

Rapid-Onset Dystonia Parkinsonism (DYT12)

Rapid-onset dystonia parkinsonism (RDP) is a very rare disorder in which signs of parkinsonism and upper body dystonia develop subacutely. Onset ranges from childhood ro adulthood. Dystonia preferentially affects bulbar muscles and progresses over a period of days to weeks but then remains stable. Although sporadic cases have been reported, most cases belong to a small number of families showing dominant inheritance with incomplete penetrance. A genetic locus on chromosome 19 has been discovered. Eow levels ot homovanillic acid (IIVA) have been detected in the spinal fluid, but PET scans using presynaptic markers fail to demonstrate a loss of dopaminergic neurons (Brashear et al, 1999), There is no evidence of

neurodegeneration and RDP symptoms do not improve with administration of L-dopa, suggesting a functional deficit (Nemeth 2002).

Wilson's Disease (Hepatolenticular Degeneration)

Epidemiology and Clinical features

Wilson's disease (WD) is a rare heredodegenerative disorder thought to affect 1-2 per 100,000 persons. It is related to abnormal copper disposition. In childhood, the liver progressively accumulates copper. Many patients present in childhood wiE 1 I •.ympmniN and signs ol liver disease, ranging from cirrhosis to fulminant liver failure. Once cirrhosis has deyelopcd, extrahepatic copper deposits begin to form, especially in the brain, eyes, and kidneys. Some patients present with hemolytic anemia, hypersplenism, or renal failure. Nearly half of all patients with WD present with central nervous system symptoms and signs (l'andit et al. 2002). Neurological signs usually present during adolescence or early adulthood, but presentations up to the age of 51 years have been reported. Neurological presentations include parkinsonism, postural and kinetic tremor, ataxia, titubation chorea, seizures, dysarthria, or dystonia. A fixed stare with a smiling exptcssion and drooling are classic features of the illness but are not seen in all cases. Dystonia is a common sign, ptescnt in 37% at presentation in one series. Dystonia may he focal, segmental, or generalized (Svetel et al. 2001). Sensation is spatcd. Dementia, if present, is mild. Psychiatric signs are very common and may be quite disabling. Mood and personality disorders, behavioral changes, and psychosis are reported. In the ptesence of neurological signs, ophthalmological examination, including slit-lamp examination essentially always demonstrates copper deposition in Descemet's membrane (Kayser-Fleischer rings) (sec Chapter 24). Many patients with WD also have sunflower cataracts. Laboratory studies often show abnormalities in hepatic enzymes, aminoaciduria, low uric acid, and demineralization of bone. MRI scan usually shows decreased signal intensity (hypodensity) in the striatum and supetior colliculi and increased signal intensity in the midbrain tegmentum {except for red nucleus) and in the lateral SNr giving the appearance of "face of the giant panda" on T2-weighted images. Low serum ceruloplasmin, elevated 24-hour copper excretion, and the presence of Kayser-Fleischer rings are useful in making the diagnosis, which is confirmed by demonstrating elevated hepatic copper (Pandit et al. 2002).

Pathology

Gross inspection of the brain often reveals cerebral atrophy and shrunken, discolored putamen and GP. Microscopically, WD brains show both preferential striatal and generalized neuronal loss. There is diffuse gliosis with Alzheimer's types I and 11 astrocytes, as well as Opalski's cells, cells of microglial origin.

Etiology and Pathogenesis

WD is an autosomal recessive disorder of copper metabolism related to mutations in the *ATP7B* gene on chromosome 13 (Pandit et al. 2002). riecause there are so many different mutations, genetic testing is not clinically available. This gene regulates a copper-transporting adenosine triphosphatase. Although the neurological disorder clearly relates to harmful effects of intracellular copper, the precise mechanisms of cell dysfuncrion and death are not well understood.

Treatment

The goal of treatment of WD is to reduce the body burden of copper and to prevent its reaccumulation. Traditionally, acute chelation began with n-pcnicillamine, but more recent treatment strategics stress somewhat less toxic therapies such as tticntine and zinc or tetrathiomolybdate. The effectiveness of initial de-coppering is monitored by serially measuring urine copper excretion and plasma copper levels. Although there may be an acute deterioration associated with the mobilization of copper stores, most patients improve over time. Long-term therapy must be maintained, usually with tricntine and zinc. D-Penicillaminc is associated with a number of systemic toxicities including dermatopathy, neuromuscular junction disorders, thrombocytopenia, and Goodpasture's syndrome. Asymptomatic siblings should be tested for the disease, because timely treatment prevents the illness. Orthotopic liver ttansplantation is curative but has been used largely in patients with luhuinaiit hepatic failure who have not yet devel oped significant neurological signs (Emre et al. 2001), The response of neurological symptoms to liver transplantation is not completely understood.

Neurodegeneration with brain iron accumulation (pan tothenate kinase-associated neurodegeneration [PKAN], Hallervorden-Spatz disease; hypoprebetalipoptotcinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration [HARP]).

A number of disorders cause neurodegeneration with brain iron accumulation (Hayflick et al. 2003). The classic form of neurodegeneration with brain iron accumulation is *PKAN* formerly known as I lallcrvorden-Spatz disease. It is an autosomal recessive neurodegenerative disorder presenting in childhood with the insidious onset of dystonia and gait disorder. Rigidity, dysarthria, spasticity, dementia, retinitis pigmentosa, and optic atrophy develop and progress relentlessly until death in early childhood. "12-weighted MRI brain scans show areas of reduced attenuation in the GP surrounding an area of hyperintensity, the "eye of the tiger" sign. Autopsy studies show a brown discoloration of the GPi and SNr, reflecting pathological

accumulation of iron. Microscopic changes include neuronal loss, gliosis, loss of myelinated fibers, and axonal swellings (spheroids). Virtually all families with typical PKAN have mutations in the pantothenate kinase gene *(PANK2)* on chromosome 20. Pantothenate kinase is an important regulatory enzyme in coenzyme A synthesis. There are atypical forms of the illness that begin later and are more slowly progressive. These cases often present with early speech disorder and often have personality changes suggesting FTD. Although the Mill scan shows evidence of iron accumulation, the "eye of the tiger" sign is not seen, and these patients do not have mutations in the *PANK2* gene. *HARP syndrome,* a constellation including hypoprebetalipoproteincmia, acanthoeytosis, retinitis pigmentosa, and pallidal degeneration, has also been linked to mutations in this gene (Ching ct al. 2002). The precise mechanism of neurodegeneration is unknown (Zhou et al. 2001).

Post-Traumatic Dystonia

Dystonia resulting from brain trauma most often presents as hemidystonia, but cervical, segmental, axial, or spasmodic dysphonia can also be seen (Krauss and Jankovic 2002). Most reported post-traumatic dystonias occur in men, reflecting a male preponderance among patients with head injury. Most cases have occurred in children or adolescents who have survived severe head injury. Often, the dystonia emerges as a traumatic hemiparesis improves or resolves. There may be a latent period between the trauma and the development of the dystonia from 1 day to 6 years, followed by slow progression of dystonic symptoms. Younger patients tend to have longer latencies than those who are older at the time of the head injury. Focal lesions in the caudate, putamen, or thalamus contralatetal to the affected side arc usually found on neuroimaging studies. Lesions of the mesencephalon or dentatothalamic pathways have also been found. The prognosis of this form of post-traumatic dystonia is poor, with a low rate of spontaneous improvement. Most cases arc refractory to medical therapy, although some may respond to anticholinergic drugs. Botulinum toxin injections may be helpful. DBS or stereotactic thalamotomy, or pallidotomy may be helpful, although the magnitude of response is much less than that seen in patients with primary dystonia.

Dystonia may also occur after peripheral injury (Jankovic 2002). For example, oromandibular dystonia may follow dental surgery or facial and jaw trauma. Limb dystonia has also been reported to occur after peripheral trauma, often in the context of causalgia or reflex sympathetic dystniphy. TJii-ic .i:e no ..Kveptcd clniic.il criteria for this diagnosis, and differentiation from psychogenic disease may be difficult. The response of this condition to medical or other therapies is disappointing.

Tardive Dystonia

Tardive dystonia (TDy) should be differentiated from transient acute dystonic reaction and from the more typical TD. In a review of 11 studies of psychiatric patients chronically exposed to neuroleptics, 2.7% developed TDy. Men are more likely to develop TDy, and they develop it at a younger age than women. All of the typical antipsychotics, as well as antiemetics with dopamine-receptor-blocking properties, have been associated with the development of TDy (Kiriakakis et al. 1998). Symptoms of TDy begin insidiously after days to decades of neuroleptic therapy, Although rare cases have been re ported after a <hori deration ot therapy, the median duration of exposure to neuroleptics at the time of onset is 5.1 years. TDy usually presents as focal or segmental dystonia, such as blepharospasm, oromandibular, or cervical dystonia, but the most typical presentation is a truncal dystonia in a young man associated with pronating movements of arms and extension of the elbows. There is a relationship between age at onset and distribution of the dystonic movements with trunk and leg symptoms in younger persons and face, jaw, and neck involvement in older persons. The extent of spread is determined in part by age, with more generalized movements in younger patients, but it usually remains segmental, In comparison with primary focal or segmental dystonia, there is more rctrocollis and anrecollis. Dystonic symptoms may improve over a period of 5 years if the offending neuroleptic agent is withdrawn, although recovery is less common than in patients with choreic TD. Young patients with a shorter duration of neuroleptic exposure have the gteatest likelihood of remission (Kiriakakis et al. 1998).

Like TD, TDy has been thought to relate to changes in the postsynaptic dopamine receptors. However, evidence is accumulating that suggests that neuroleptics arc toxic to the striatum. Apoptotic cell death has been described in animals chronically exposed to neuroleptics (Galili et al. 2000). Oxidative stress and excitotoxicity have been implicated in this process. The brains of TDy patients show basal ganglia cell loss and gliosis.

As with TD, the primary treatment of TDy is prevention. Once TDy has developed, every attempt should be made to rid the patient of the offending neuroleptic. Neuroleptic-dependent patients should be managed with atypical antipsychotics, if possible. Tetrabenazine, anticholinergics, benzodiazepines, and baclofen have all been reported to help p.it lent>, will; I I)\ KiriaLikis ci al. I '"JSi. Botulinum toxin injections can be particularly helpful in patients having disability from blepharospasm or with cervical or truncal dystonic movements.

Paroxysmal Kinesigenic Dyskinesia (DYT10)

Paroxysmal kinesigenic dyskinesia (PKD) is a disorder of childhood onset characterized by attacks of involuntary

movements that include prominent dystonia, chorea, or other hyperkinesias. Because the attacks are often nor witnessed and therefore appropriate phenomenological categorization is not possible, the less specific term *paroxysmal dyskinesia* is preferred to the alternative term, *paroxysmal kinesigenic epilepsy* (Jaiikovic and Deinirkiran 2002). Boys make up 80% of cases. There is often a family history. Patients typically recount that episodes are triggered by rapid movement, often in response to an unexpected stimulus such as the telephone ringing. There may be a premonitory sensation in an affected limb. The movements may be unilateral or bilateral. The spells last less than 1 minute and occur up to 100 times daily (Houser et al. *J999).* There is a tendency for spells to decrease in adulthood. Diagnosis depends on careful history taking, because the examination usually shows no abnormalities, typical spells may not be elicited in the examination setting, and neuroimaging and electrophysiological studies are usually normal. Two loci for PKD (DYT10) have been localized to chromosome 16, suggesting a family of genes on that chromosome that might be important in producing the syndrome, although causative genes have not yet been discovered. PKD is usually very responsive to anticonvulsant medications. Carbamazepine and phenytoin are most frequently used, but there have been recent reports that levctiracctam is effective and well tolerated.

Paroxysmal Nonkinesigenic Dyskinesia (DYT8)

Paroxysmal nonkinesigenic dyskinesia (PNKD) usually licgiiis in ir.tiiik;-. .iii!: .itlciis boys more than girls. I he spells of PNKD occur less often but are more prolonged than those in PKD. Their frequency ranges from several episodes per month to several episodes per day and their duration is generally between 10 minutes and several hours. They are not precipitated by action but may be triggered by ethanol, caffeine, fatigue, or stress (Jankovic and Deinirkiran 2002). Genetic loci for PNKD (DYT8) have been discovered on chromosomes 1 and 2. CSF monoamine metabolites have been reported to decrease during an attack (Jarman et al. 2000). MRS and PET scans using the D2-selective radioligand raclopridc do not show any significant abnormalities in these patients. Unlike PKD, PNKD does not show a dramatic response to anticonvulsants. Some patients respond to clonazepam, other benzodiazepines, carbamazepine, gabapentin, anticholinergics, L-dopa, acetazolamide, and neuroleptics.

Secondary Paroxysmal Dyskinesia

Secondary paroxysmal dyskinesia has been thought to be rare. However, in one series, 26% of paroxysmal dyskinesia cases occurred in the context of another nervous svstem disease (Blakeley and Jankovic 2002). Underlying etiologies include cerebrovascular disease, trauma, infection, and metabolic encephalopathy. The clinical manifestations of secondary paroxysmal dyskinesia are heterogeneous. Some are kinesigenic and some are not. Some are associated with premonitory sensations and others have no warning signs. Treatment of the underlying cause may improve the dyskinesia.

TICS

Tourette's Syndrome

Epidemiology and Clinical Features

Prevalence estimates for Tourette's syndrome (TS) vary from 10-700 per 100,000, depending on the population studied and the study methods used. Although the prevalence is greater among children in special schools and those with disorders in the autism spectrum, the vast majority of patients with TS have normal intelligence. Boys are more commonly affected than girls. TS begins in childhood or during early adolescence, but most often begins between the ages of 2 and 10 years. Typical early signs of TS are cranial motor tics including eye blinks, stretching of the lower face, and shaking the head (see Chapter 24). Vocal tics include sniffing, throat clearing, grunting, whistling, chirping, and words, including profane words (coprolalia). Over time, the tics wax and wane and new tics enter and leave the repertoire. Tics may be simple or complex and can resemble any voluntary or involuntary movement. Patients with TS have both motor and vocal tics. Symptoms tend to increase throughout childhood, with peak expression in adolescence, and become somewhat less troublesome in adulthood. Behavioral changes arc very common in TS, especially attcntion-deficit/hyperactivity disorder (ADHD), conduct disorder, or obsessive-compulsive disorder. The latter association is particularly intriguing, because girls in families with a history of TS may have pure obsessive-compulsive disorder without tics. Obsessions in TS predominantly concern symmetry and counting. The diagnosis of TS rests entirely on the history and physical examination. The neurological examination is usually normal, as are neuroimaging and electrophysiological study results. No pathological changes have been described in patients with TS, but limited study of postmortem brains has suggested reduced levels of brainstem serotonin, pallidal glutamate, and cortical cyclic adenosine monophosphate.

Etiology and Pathogenesis

Clinical evidence strongly suggests that TS is a hereditary disease {Jankovic 1991:. The concordance of i'S among monozygotic twins is 86%, and segregation analyses are consistent with an autosomal dominant, sex-influenced

trait. However, despite this evidence, definite mendelian inheritance has not been established and no genetic locus has yet been identified. Because there is a robust response to dopa mine-receptor-bloc king medications, altered central neurotransmission has been proposed to underlie TS. PET studies suggest increased dopaminergic innervation of the ventral striatum, and abnormal regulation of dopamine release and reuptake,

Treatment

The first step in the treatment of TS is the definition of the sources of disability. Treatment should be reserved for patients who arc experiencing interference from tics in the educational, social, or family spheres. Disabling tics are most effectively suppressed by neuroleptic medications such as haloperidol and pimozide. In a double-blind controlled comparison, pimozide was more efficacious and better tolerated than haloperidol. Sulpiride and tiapride, which are not available in the United States, may also be helpful in the treatment of tics. Risperidone and olanzapine have been shown to be effective' in small uncontrolled trials, and ziprasidone has shown preliminary efficacy, although clozapine has not. Fluphenazine and tetrabenazine are also very effective in the treatment of tics with minimal side effects. Very-low-dose pergolidc (0.15-0.3 mg daily) has also shown some preliminary efficacy for tics (Gilbert et al. 2000). It is thought to work by selective action at presynaptic dopamine autoreccptors. Baclofen has been said to effectively decrease tic-related impairment, though not tics themselves in a small placebo-controlled trial (Singer et al. 2001). Other treatments suggested to be effective in small or uncontrolled studies include cannabinoids, nicotine, donepezil, antiandrogenic agents, kctanserin, ondansetron, and selective serotonin reuptake inhibitors. Obsessive-compulsive disorder responds to selective serotonin reuptake inhibitors. Comorbid ADHD can be safely treated with clonidine, methylphenidate alone, and in combination (Tourcttc Syndrome Study Group 2002). Guanfacine, tomoxetine, desipramine, deprenyl, and nortriptyline have also been proposed to treat ADHD inTS.

Adult-Onset Tics

Adult-onset tics are much rarer than childhood-onset tics and usually represent recurrences of child hood-onset tics. .Many affected patients have childhood histories of obsessive-compulsive tendencies and family histories of tic disorders. Adult-onset tic disorders often develop after a triggering event and are more severe and socially disabling than the more typical early onset disease. Tics in adulthood are relatively resistant to pharmacotherapy (Eapen et al. 2002). Other causes of adult-onset tics, such as the use of cocaine or other central nervous system stimulants, tardive tics, and neuroacanthocytosis, should be considered in the differential diagnosis.

POSTINFECTIOUS AUTOIMMUNE NEUROPSYCHIATRY DISORDERS ASSOCIATED WITH STREPTOCOCCAL EXPOSURE

Postinfectious autoimmune neu to psychiatric disorders associated with streptococci (PANDAS) is a controversial entity that has been recently linked to TS. Children with PANDAS have explosive onset of obsessive-compulsive disorder, tics, hyperactivity, and choreiform movements in the prepubertal years. There is an association with prior group A beta-hemolytic streptococcal infection, although the syndrome is distinct from rheumatic fever and Sydenham's chorea (Garvey et al. 1998). Affected children have enlargement of the caudate, putamen, and GP by volumetric MRI. Antineuronal antibodies against putaminal antigens have been detected in the plasma of patients with TS. An autoimmune molecular-mimicry mechanism has been proposed. A double-blind placebo-controlled crossover study of penicillin in patients with PANDAS failed to show that penicillin prevented symptom recurrences, but adequate prevention of streptococcal infection was not achieved. Intravenous immune globulin and plasmapheresis reduced obsessive-compulsive symptoms, but tic scores were improved only in the plasmapheresis group. These improvements were sustained for 1 year. PANDAS is not a universally accepted syndrome and additional research is required to better define its role in TS (Garvey et al. 1998).

MYOCLONUS

Essential Myoclonus

Essential myoclonus (EM) is diagnosed when myoclonus is present as an isolated neurological sign or is accompanied only by tremor or dystonia. EM can be sporadic or inherited. Dominantly inherited EM usually presents before the age of 20 years. EM is usually multifocal myoclonus with upper body predominance. Although spontaneous jerks are seen, they are exacerbated by action. Alcohol may dramatically suppress the myoclonus. Sporadic forms of this illness are also described. (MD is discussed earlier in this chapter.) MD and EM are allelic disorders linked to the e-sarcoglycan gene on chromosome 7.

Hereditary Gcniospasm (Chin Tremor)

Hereditary geniospasm is characterized by involuntary vertical movement of the tip of the chin with quivering and mouth movements. Geniospasm may be spontaneous

or stress induced. Trembling becomes apparent in infancy or early life. Trembling episodes last minutes. The attacks become somewhat less frequent with age. The disorder is genetically heterogeneous, with linkage to chromosome 9q 13-21 in some, but not all families (Grimes et al. 2002). Geniospasm has been suggested to be a form of hereditaty EM.

Posthypoxic Myoclonus (Lance-Adams Syndrome)

The first cases of posthypoxic myoclonus (PHM) were described in 1963 by Lance and Adams. PHM is a generalized myoclonus that occurs with recovery from the acute effects of severe brain hypoxia. The most common etiologies of the hypoxia are respiratory arrest (especially asthmatic), anesthetic and surgical accidents, cardiac disease, and drug overdose. The typical patient is in coma for several days to 2 weeks. Myoclonus and seizures may be present during the comatose phase. After recovery from coma, myoclonic jerks become apparent, especially with voluntary movements, which trigger volleys of high-amplitude jerks and intermittent pauses in the activated body part. The myoclonic movements typically flow to body parts not directly involved in the voluntary movements. The ampliunle ni the myoclonus is directly proportional to the delicacy of the attempted task, producing extreme disability in the performance of activities of daily living. Gait is disturbed not only by positive myoclonic jerks, but also by negative myoclonus, resulting in falls. Other neurological signs are always present and include seizures, dysarthria, dysmerria, ataxia, and cognitive impairment.

CSF studies have shown low levels of 5-hydroxyindoleacetic acid (5-HIAA), the main metabolite of serotonin. A role for GABA in this disorder is suggested by the production of myoclonus by injecting GABA antagonists into the rat thalamus. Autopsies in patients with PHM show changes lelated to hypoxic brain damage but do not reveal any specific structural changes in brainstem raphe nuclei. Myoclonus in posthypoxic rats responds to serotonin agonists that stimulate particular subtypes of serotonin receptors (5-HT_{1B}, .S-HT_{2A}/2is> arid possibly 5-HTto) (Pappert et al, 1999). Other studies in rat models have suggested that basal serotonin levels are normal, but there is an abnormality in release of serotonin by potassium chloride and NMDA.

There is some tendency for improvement in myoclonus over time, but most patients have significant disability related to the movements. GABAergic drugs such as valproic acid and clonazepam are usually used in the treatment of PHM. Each is associated with improvement in about 50% of treated patients. Levctiracetam has been recently reported to he effective in an open-label trial in chronic myoclonus (Genton and Gelisse 2001). Other GABAergic drugs such as vigabatrin and gabapentin have not shown promise. Piracetam improves PHAN by an imperfectly understood mechanism that does not involve serotonin or GABA. It is available in Europe and Canada, though not in the United States. L-5-HTP administered with carbidopa may be useful, but this investigational agent has limited access and gastrointestinal side effects limit its tolerability. The effects of L-5-HTP may be enhanced by concomitant use of a selective serotonin reuptake inhibitot.

Startle and Hyperekplcxia

Hypetekplexia is a startle syndrome, characterized by muscle jerks in response to unexpected stimuli. Two forms of startle have been described. Families with autosomal dominant and recessive inheritance have been described. The major form of the illness is characterized by continuous stiffness beginning in infancy, and exaggerated startle culminating in tails. Some patients have seizures and low intelligence. In the minor form, there is only excessive startle, with hypnic myoclonic jetks. Startle in patients with hyperekplcxia differs from normal startle because it has a lower threshold, is more generalized, and fails to normally habituate with tepeated stimuli. Electrophysiological studies in well-characterized cases suggest the origin of the pathological startle in the lower brainstem, possibly the medial bulbopontine reticular formation. The disorder is genetically heterogeneous, with most mutations occurring in patients with the major form of the illness. Most defined mutations involve the «i-subunit of the inhibitory glycine receptor. Symptomatic hyperekplexia has been reported to result from infarct, hemorrhage, or encephalitis. Clonazepam is the treatment of choice (Brown 2002).

Spinal Myoclonus and Propriospinal Myoclonus

Spinal myoclonus (SM) is a syndrome of involuntary-rhythmic or semirhythmic myoclonic jerks in a muscle or group of muscles. The myoclonic jerks may be unilateral or bilateral. In some cases, they are stimulus sensitive. The jerks relate to spontaneous motoneuron discharge in a limited area, often a single segment of the spinal cord. Propriospinal myoclonus is a more widespread disorder in which myoclonic jerks are propagated up and down the spinal cord from a central generator. Most patients with propriospinal myoclonus have had minor spinal cord trauma with normal MRI findings, but the disorder has been reported in severe spinal eord injury, multiple sclerosis, human immunodeficiency virus, or Lyme infection, syringomyelia, spinal cord tumors, and spinal cord infarction (Nogues et al. 2000). Propriospinal myoclonus has been reported to affect particularly the transition from wake to sleep.

Toxin- and Drug-Induced Myoclonus

A number of drugs and environmental agent with central nervous system toxicity have been shown to cause myoclonus (Table 77.21). Criteria for drug- or toxin-induced myoclonus include verified exposure, temporal association, and exclusion of genetic or other causes. The myoclonus produced by drugs and toxins is often multifocal or generalized, stimulus sensitive and action sensitive, and accompanied by other suggestive nervous system signs, particularly by encephalopathy signs. Metrizamide and diclofenac may cause segmental myoclonus. Treatment requires withdrawal of the causative drug and symptomatic treatment, if required with clonazepam, valproic acid, or levetiracetam.

MISCELLANEOUS MOVEMENT DISORDERS

Hemifacial Spasm

Data from Olmsted Comity, Minnesota, suggest that the prevalence of hemifacial spasm is 14.5 per 100,000 in women and 7.4 per 100,000 in men. Hemifacial spasm is characterized by twitching of the muscles supplied by the facial nerve. The disorder usually begins in adulthood, with an average age at onset of 45-52 yeats. Although there are some familial cases, most are sporadic. In typical cases, twitching first affects the periorbital muscles but spreads to other ipsilateral facial muscles over a period of months to years. The spasms arc synchronous in all affected muscles. In about 5% of patients, the opposite side of the face becomes affected, but when bilateral, the spasms are never synchronous on the two sides. The spasms of hemifacial spasm may be clonic or tonic, and often, a paroxysm of clonic movements culminates in a sustained tonic contraction. Although the spasms occur spontaneously, they may be precipitated or exacerbated by facial movements or by anxiety, stress, or fatigue. The affected muscles may be weaker than their contralateral counterparts. Some patients have evidence of regional cranial neuropathy such as altered hearing or trigeminal function. Detailed neuroradiological workups using routine and specialized MRI techniques may demonstrate compressing vascular structures in most, if not all, patients with hemifacial spasm. Mm,' advanced ^canning techniques Mich as high-resolution T1- and T2-weighred spin-echo or gradient-echo imaging with gadolinium provides maximum visualization of the root entry zone (Port 2002). Yet, serious underlying causes are rare, and many clinicians do not toutinely image patients with typical hemifacial spasm unless the clinical picture is atypical or the patient is being considered for surgery.

Tabic 77.21: Drugs associated with myoclonus

Anesthetics
LtonmLitc, chlonilose
Antibiotics, antihelminthics, antiviral drugs
Penicillin, Imlpencm, quinolones, piperazinc, acyclovir
Anticonvulsants
Phenytoin, phenobarbital, primidone, valproic acid, carbamazepine, gabapentin, lamotngine, vigabatrin
Antihistamines
Sodium bicarbonate (baking soda)
Benzodiazepine withdrawal
Psychotropic medications
Tricyclic antidepressants, selective serotonin reuptake inhibitors, monoamine oxidase inhibitor, lithium, buspirone, neuroleptics
Antineoplastic drugs
Chlorambucil, p red nimustine, ifosfamide
Narcotics
Morphine, meperidine, hydromorphone, fentanyl, sufentanil, diamorphine

In cases of hemifacial spasm, the facial nerve root entry zone generally shows axonal demyehnation or nerve degeneration. Hemifacial spasm is thought to result from compression of the facial nerve at the root exit zone, usually by vascular structures. Tumors or other space-occupying lesions are found in about 5% of patients. Vessels commonly implicated are the posterior inferior cerebellar artery, the anterior inferior cerebellar artery, or the vertebral artery. When tumors are present, they are most commonly epidermoid, neuroma, meningioma, astrocytoma, and parotid tumors.

There are two main theories of pathogenesis. The first proposes that in the area of compression-induced demyelination, an "ephapse," or false synapse, forms. Mechanical irritation or other regional changes induce ectopic activity in the region, which is then conducted antidromically within the nerve fiber. The main competing theory proposes that the aberrant signals arise from the facial nerve nucleus, which reorganized as a result of deranged afferent information.

Traditionally, patients with hemifacial spasm have been treated with anticonvulsants, typically carbamazepine, and more recently gabapentin. Other agents said to be useful include baclofen, anticholinergics, halopcridol, and clonazepam. The clinical availability of borulinum toxin injections revolutionized the treatment of hemifacial spasm. Botulinum toxin injected into the periorbital subcutaneous tissue produces clinically meaningful improvement in ilmost 100% of patients and side effects are mild and transient, Botulinum toxin injections must be administered every 3-6 months. Follow-up of chronically treated patients shows the injections retain their efficacy at least 10 yeats (Defazio et al. 2002).

A number of surgical techniques have been used in hemifacial spasm. These include removal of the orbicularis oris or other affected muscles, selective destruction of parts of the facial nerve, decompression of the facia) canal, or radiofrequency thermocoagulation of the netve. Intracranial microvascular decompression of the nerve is

successful in relieving spasms in up to 90% of patients, but complications such as facial nerve injury and hearing loss occur in up to 15% of patients (Samii et al. 2002).

Painful Legs-Moving Toes Syndrome

Painful legs-moving toes syndrome (PLMTS) is a very rare condition characterized by pain in the legs and spontaneous movements of the foot and toes. The pain usually precedes the onset of involuntary movements and varies in constancy and intensity. In some cases, the condition is painless. The toe and foot movements arc complex, combining flexion, extension, abduction, and adduction in various sequences, at frequencies of 1-2 Hz. The movements may be precipitated or aborted by moving or repositioning the foot or toes, but they cannot be simulated voluntarily. Similar movements have been described in the arms, with or without accompanying pain. In most cases, there is an underlying cause, although there is little consistency from case to case. PLMTS has been associated with injuries to the spinal cord and cauda equina, spinal nerve roots, peripheral neuropathy, and soft tissue or bony limb trauma. EMG studies show that the movements are produced by long bursts of normal motor unit firing with normal recruitment patterns. PLMTS doubtless has a central origin. Central reorganization consequent to altered afferent information from the periphery has been proposed, but a precise location and mechanism of these changes remain unknown.

Treatment of PLMTS is very difficult. Many medications have been tried, including baclofen, benzodiazepines, anticonvulsants, and antidepressants, but none has emerged as effective. Lumbar sympathetic block or epidural stimulation may give transient relief. Spontaneous resolution is very unusual.

Stiff Person Syndrome

SPS is rare and no information is available about its epidemiology. SPS is a syndrome of progressive rigidity of axial and proximal appendicular muscles with muscle hypettrophy and extreme lumbar lordosis. Intense spasms are superimposed on a background of continuous symptoms. Gait is slow and stiff legged. Some authors divide SPS into three syndromes: stiff trunk syndrome, stiff limb syndrome, and rapidly progressive encephalomyelitis with rigidity (Barker el al. I99K). l'.MC! examination shows continuous firing of normal motor units.

SPS is associated with autoimmune disorders, such as type I diabetes, thyroiditis, myasthenia gravis, pernicious anemia, and vitiligo. High titers of antibodies to the 65-kd fraction of GAD are present. It is thought that SPS results from dysfunction of descending suprascgmcntal pathways possibly secondary to immune-mediated inhibition of GABA synthesis. Paraneoplastic SPS has been reported with breast and other cancers.

Untreated, SPS progresses to extteme disability. Diazepam at doses of 20-400 nig per day is the most effective symptomatic treatment. Clonazepam, baclofen, valproic acid, clomdine, vigabatrin, and tiagabine have also been reported to be effective. Plasmapheresis and immunosuppression have been reported to have variable effects on the condition. In a recent placebo-controlled crossover study of nilr.lv Pilous inininne j-'Juhtiliii, active [rr;i! mm! v,as uwk/i ated with clinical improvement and decreases in anti-GAD antibody titers (Dalakas ct al. 2001). Intrathecal baclofen and local intramuscular injections of botulinum toxin have been lielpti:) :n Mime cases.

Psychogenic Movement Disorders

Psychogenic movement disorders (PMDs) make up a small part of any clinical movement disorders practice. The most common PMD is tremor, but dystonia, myoclonus, and parkinsonism are also seen. In many cases, the symptoms are abrupt in onset and associated with a specific trigger. Clinically, distractibiliry is common, as ate stimulus sensitivity and entrainment with voluntary activities. Other psychogenic symptoms are often present. About 25% of patients have a comorbid organic movement disorder. About half have an Axis 1 psychiatric disorder, most often depression. The long-term outcome of patients with PMDs is unknown. In a series of 88 subjects with documented PMD, interviews were conducted an average of 3 years after diagnosis; 52.5% of survivors were interviewed, and 95% had active or remote primary psychiatric illness (major depression and anxiery or both). Nearly half had personality disorders. In only 10% had the PMD remitted, but half of these patients had new psychogenic symptoms. Patients with PMD did not acknowledge the psychiatric origin of their PMD (Feinstein et al. 2001). No specific information is available about treatment.

Chapter 78
Disorders of the Cerebellum, Including the Degenerative Ataxias

S. H. Subramony

Cerebellar ataxia can he the result of a variety of insults to the cerebellum and its connecting pathways. The cerebellum can be the seat of pathology in many well-recognized diseases of the central nervous system (CNS) and may be involved in such processes in isolation or in combination with other structures. Thus ataxia can he either the major feature of the disease or one of its various clinical signs. In addition, progressive degeneration of the cerebellum and its connections resulting in ataxia can result from a number of genetic abnormalities. Finally, the term *sporadic ataxia* or *idiopathic ataxia* is used for those diseases in which ataxia related to cerebellar degeneration occurs in the absence of a definite genetic or acquired etiology (Ahclc ct al. 2002). In this chapter, I briefly discuss some of the well-defined acquired causes of ataxia, summarize the current understanding of the inherited ataxias, and address the issue of sporadic ataxia.

ACQUIRED ATAXIAS

In many patients, progressive ataxia results from environmental insults and other well-recognized disorders involving the nervous system. In any patient presenting with cerebellar ataxia, such disorders as ischemic or hemorrhagic stroke involving the cerebellum, previous episodes of cerebral hypoxia, primary or metastatic tumors, and demyelinating diseases such as multiple sclerosis can be diagnosed by appropriate imaging studies and other investigations. Many of these diseases tend to have an acute or subacute evolution, rather than the chronic course associated with degenerative ataxias. However, other diseases can present with ataxia in which the major imaging abnormality may be an atrophic cerebellum akin to the finding in degenerative ataxias. Some of these are briefly discussed. Table 78.1 lists acquired causes of ataxia.

1 lypothyroidism

Occasional patients with hypothyroidism develop a mild gait ataxia in conjunction with their systemic symptoms. Thyroid functions need to be tested in patients with progressive ataxia. Thyroid replacement can improve the neurological symptoms.

Toxic

Alcohol

Alcohol remains the major exogenous agent causing ataxia. A significant proportion of alcoholics have midline cerebellar degeneration at autopsy. Clinically, this disease is characterized by a progressive gait disturbance of a cerebellar type with little in the way of upper limb ataxia, speech difficulties, or eye movement abnormalities. This may reflect the relative sparing of the cerebellar hemispheres. Imaging studies typically reveal vermian atrophy, Chronic alcoholism can also produce significant cerebellar atrophy in the absence of major clinical deficits (Hillborn etal. 1986).

Chemotherapy

Some cancer chemotherapcutic agents may produce ataxia as an adverse effect. 5-Fluorouracil (5-FU), a fluorinated pyrimidine that acts by incorporating into RNA and interfering with RNA function, has been used to treat

Tabic 78.1: Acquired causes of ataxia

Disorder	*Diagnostic process*
Vascular disease	History of strokes, imaging
Hypoxic encephalopathy sequel	History of hypoxic episode
Demyelinating disease	Remitting and relapsing episodes, imaging
Posterior fossa tumor	Imaging
Craniovertebra 1 junction anomaly	Imaging
Hypothyroidism	Thyroid studies
Toxic disorders	History
Alcohol, chemotherapy, metals Solvents, anticonvulsants	
Infections (see text)	Imaging, CSF, serology
Acute cerehellitis, postinfectious, BickcrstafPs encephalitis, HIV, CJD	
Autoimmune disease	
Paraneoplastic	Anti-Hu, anti-Yo, anti-Ri, others
Gluten ataxia	Anti-gliadin, anti-endomysial
Ann GAD ataxia	Anti-GAD

CJD — Creutzfeldt-Jakoh disease; CSF = cerebrospinal fluid; GAD = glutamate decarboxylase; HIV = human immunodeficiency virus.

breast and gastrointestinal cancer. Conventional doses of 5-FU may cause cerebellar ataxia if there is an abnormality of pyrimidine metabolism in the form of dihydropyrimidinc dehydrogenase deficiency. Higher doses of 5-FU can cause* a panccrcbcllar syndrome that has an acute to subacute evolution.

When cytosine arabinoside is given in high doses (3 g/m for 8-12 doses as opposed to the conventional 100-200 mg/m for 5—7 days), a significant number of patients develop a cerebellar syndrome. Pathologically, this is characterized by loss of Purkinje cells, gliosis, loss of dentate neurons, and spongiform changes.

Metals

Organic mercury poisoning has occurred in epidemic form as a result of contamination from mercury-containing fungicides. Mercury appears to be particularly toxic to cerebellar granule cells and visual cortex and causes a syndrome that includes paresthesias, ataxia, and restricted visual fields. Manganese may cause not only parkinsonism but also ataxia. Gait ataxia associated with other signs such as confusion and myoclonus has also been described with bismuth toxicity resulting from excessive intake of bismuth subsalicylate (Pepto-Bismol).

So bents

Chronic solvent abuse, especially of toluene, can cause persistent neurological deficits including ataxia. Spray paint and paint thinners are the usual sources. Cognitive deficits and pyramidal tract signs often accompany the ataxia and dysarthria.

Anticonvulsants

The issue of cerebellar atrophy and anticonvulsant use, especially phenytoin, is controversial. Ttansient cerebellar signs associated with supratherapeutic levels of drugs have been seen with many anticonvulsants. More persistent ataxia and documented Purkinje cell loss has been primarily seen in epileptics treated with phenytoin for prolonged periods of time. Cerebellar atrophy occurs in phenytoin-treated patients but may not always be associated with overt ataxia. The pathogenesis of this syndrome remains unclear. The various hypotheses include a direct toxic effect of phenytoin, a result of repeated hypoxia related to seizures, the effect of the seizure-related electrical discharge on cerebellar Purkinje cells, and the possibility that both the seizures and the cerebellar pathology are secondary to a unifying underlying pathology such as prenatal injuries. Another intriguing possibility is that both the sei/.ures and the progressive cerebellar syndrome could result from a single underlying gene mutation. It is probably best to avoid phenytoin in an epileptic patient if either ataxia or cerebellar atrophy is present.

Infectious

Ataxia can be one of the features of postinfectious encephalomyelitis but usually accompanies a more diffuse cerebral process (Coyle 2000). A more restricted cerebellar syndrome has been seen in children after viral infections. Connolly et al. (1994} have proposed that this diagnosis be considered when children develop an acute ataxic disorder that is not associated with a more diffuse process reflected by seizutes, meningismus, or obtundation. In most children, LIIIS condition is preceded b\ a nonspeeifk viral syndrome or varicella with a peak incidence at the age of 5-6 years. A similar syndrome following Epstein-Barr virus infection or vaccinations occurs in the teenage years. Cerebrospinal fluid (CSF) analysis may show some elevation of protein and a modest mononuclear pleocytosis and magnetic resonance imaging (MRI) scans often reveal signal density changes in the cerebellum (Figure 78.1). Such a disorder may occur in adults as well (Klockgether et al. 1993). Prognosis for recovery is excellent with residual dysfunction seen in a distinct minority.

Similarly a combination of ataxia, ophthalmoplegia, and other lower cranial nerve palsies can occur as a result of brainstem encephalitis (Bickerstaff's encephalitis). Clinically, this disorder resembles the Miller Fisher variant of Guillain-Barre syndrome from which it is distinguished by the presence of high-signal lesions in the brainstem on MRI scans (Fargas et al, 1998).

FIGURE 78.1 Signal density change in the cerebellum io a child with acute cerebellar ataxia of childhood. (Courtesy Dr. V. Vedanarayanan, Department of Pediatries, University of Mississippi Medical Center.)

Human immunodeficiency virus (HIV) infection can result in many neurological syndromes, including ataxia. Most patients with ataxia in the presence of HIV infection have discrete, well-recognized lesions such as lymphomas, chronic meningeal infection, progressive multifocal leukoencephalopathy, or toxoplasmosis. Also, approximately 30% of patients with HFV dementia have an ataxic syndrome at the onset of their illness before cognitive decline begins. Other authors have described isolated progressive cerebellar ataxia that does not evolve into HIV dementia in a small number of patients (Tagliatti et al, 1998). These patients had a rapid evolution of their ataxia leading to a chair-bound status in less than a year; MRI revealed cerebellar atrophy. Pathological examination in a small number of patients has revealed marked granule cell loss.

The relationship between possible human T-lymphotropic virus type II (HTLV-1I) infection and ataxia has been raised by some anecdotal experience but remains to be proven.

Creutzfeldt-Jakob disease (CJD) should also be considered in the differential diagnosis of patients presenting with progressive ataxia. CJD is typically a rapidly progressive dementing illness related to the accumulation of mutant prion protein, which results from post-translational modification of the normal prion protein. Among patients with classic CJD, close to 17% have early ataxia and more than 60% have cerebellar pathology at death. Jellinger, Heiss, and Dcisenhammer (1974) noted that the ataxic variant of CJD began with minor behavior symptoms followed by ataxia. Upper motor neuron signs were common; myoclonus occurred only in 25% and dementia evolved late. Survival among these patients was slightly longer than in typical CJD with a mean time to death of 16 months and a range of 7 weeks to 8 years. Pathologically, the cerebellum shows striking granule cell loss. Patients suspected of having CJD can be tested for the presence of the 14-3-3 protein in the CSF and for codon 129 homozygosity in the prion gene. CSF tau protein assay by enzyme-linked immunosorbent assay, already readily available in routine laboratories, has been found to have a 92% positive predictive value in diagnosing CJD; 74 of 77 patients with probable CJD had tau protein levels of more than 1300 pg/mL, whereas only 2 of 28 patients with Alzheimer's disease had such high levels, and even lower percentage in other dementias (Otto et al. 2002).

Interestingly, both Gerstmann-Straussler-Scheinker (CSS), an autosomal dominant form of CJD associated with codon 102 mutation, and growth hormone-related CJD have a cerebellar presentation. The new variant CJD also may have a cerebellar presentation (Will et al. 1996).

Autoimmune Causes of Ataxia

Paraneoplastic Cerebellar Degeneration

This is a rapidly progressive pancerebellar syndrome that reaches its nadir within a few months of onset. It produces a severe ataxic disease associated with dysarthria and oscillopsia. Diplopia and vertigo may also occur. Many patients also develop other neurological signs including dementia, extrapyramidal signs, hearing loss, and dysphagia. MRI typically shows atrophy of the cerebellum, although some high-signal density changes may occur in the deep white matter. CSF usually shows a mononuclear pleocytosis and oligoclonal bands may be present. It is believed that in many cases the syndrome results from an autoimmune process triggered by the cancer. The anti-Yo antibody is usually seen in ovarian cancer and primarily causes a cerebellar syndrome. The anti-Hu antibody is seen with small cell cancer of the lung and typically causes a multifocal disorder, the most common of which is a sensory ganglionopathy. Purkinjc cell degeneration has been noted in about 25% of patients with anti-Hu antibody. The anti-Ri antibody has been seen in patients with truncal ataxia and opsoclonus in the setting of breast cancer. Patients who exhibit a combination of ataxia and Lambert-Raton syndrome against a background of small cell cancer of the lung usually have no demonstrable antibodies. The nomenclature of these antibodies is under debate. Thus the

anti-Yo, anti-Hu, and anti-Ri antibodies may he equated with the Purkinje cell antibody type 1 (PCA-1), the antiiicuronal antibody type 1 (ANNA-1), and the anti-neuronal antibody type 2 {ANNA-2), respectively. Other antibodies that have been related to paraneoplastic cerebellar ataxia include the anti-Ta, anti-Ma, anti-CV2, and antiglutamate antibodies (Henzen-Logmans et al. 2000; Posner and Dalmau 2000).

Ataxia with Gluten Sensitivity

Following the observation that cerebellar ataxia can often be a neurological complication of celiac disease, Hadjivassiliou et al. (1998) looked for gluten sensitivity among a group of patients with sporadic ataxia. Sixty-eight percent of these patients had antigliadin antibodies, contrary to 5% of neurological controls. Malabsorption did not appear to be the cause of the ataxia. Other studies have noted a lower prevalence of gliadin antibodies in patients with idiopathic ataxia or none at all (Pellechia et al. 1999; Combaross et al. 2000; Burk el al. 200] . Busharactal. (20:11) have reported that patients with idiopathic ataxia and those with a definite genetic form of ataxia had a similar occurrence of gluten sensitivity, taising doubts about the significance of the gliadin antibodies. Recent immunocytochemical studies, however, have supported the idea that these antibodies do indeed bind to Purkinje cells of the cerebellum (Hadjivassiliou et al. 2002). Patients with gluten sensitivity usually have slowly progressive ataxia associated with brisk tendon reflexes, peripheral neuropathy, and often, mild cognitive changes. Myoclonus and eye movement abnormalities have been desctibed as well. Nervous system pathology has been characterized by cerebellar Purkinje cell loss, infiltration by T lymphocytes, and posterior column degeneration. A variable proportion of patients have typical celiac disease on duodenal biopsy, even when there are only minor gastrointestinal symptoms; some have either normal biopsies or simply lymphocytic infiltrates. Whether a gluten-free diet or other irnmuno-modutation will improve gliadin antibody-associated ataxia is unclear.

Ataxia and Antiglutamate Decarboxylase Antibodies

Recently, a number of reports have noted the presence of antibodies to glutamate decarboxylase (GAD) among a small number of patients with progressive ataxia (Honnorat et al, 1995; Said et al. 1997). The patients have been usually middle-aged women. Ataxia was occasionally associated with petipheral neuropathy, slow saccades, and in some cases stiff person syndrome. Many patients had multiple organ-specific antibodies including those directed against thyroid cells, parietal cells, and pancreatic islet cells, and insulin-dependent diabetes was an invariable accompaniment. The antibodies occut in higher titers than those found in adult-onset diabetes, and there is evidence that they bind to presynaptic nerve terminals around cerebellar Purkinje cells. GAD is the enzyme that synthesizes y-aminobutyric acid (GABA) from glutamate and it is believed that the antibodies may be pathogenic because of their binding to GABA terminals. Intravenous immune globulin may cause partial remission of symptoms.

Nutritional

Acquired vitamin E deficiency occurring in the setting of fat malabsorption can cause ataxia. Examples include cystic fibrosis and cholestatic liver disease.

INHERITED ATAXIAS

The initial recognition that progressive balance difficulties related to pathology in the cerebellum and its connecting pathways could have a genetic basis is attributed to Nicholas Friedreich, who published a series of papers describing siblings with such a disease, now known as *Friedreich's ataxia* (FA). As early as 1893, Pierre Marie noted the clinical and genetic heterogeneity among the inherited ataxias. During much of the twentieth century, inherited ataxias that did not quite fit the Friedreich mold were often labeled *Marie's ataxia.* Also, many patients have progressive ataxia of a degenerative nature, clinically and pathologically resembling the inherited ataxias and yet having no discernible genetic basis. Much of the last 100 years saw the detailed clinical and pathological descriptions of these patients and attempts to understand them on a clinicopathological basis. Nevertheless, the clinical, neuro-pathological, and genetic heterogeneity of the disorders did not allow a universally acceptable classification. Based on an extensive clinical study of many families, Harding wrote a clinical genetic classification that served as a prelude to an increasingly gene-based listing of the inherited ataxias. A classification that is based on the recent understanding of phenotype-genorype correlations is still needed. This section summarizes the current information regarding the inherited forms of ataxia.

Autosomal Recessive Ataxias

Table 78.2 lists various autosomal recessive ataxias based on specific gene loci. Most of these diseases begin in childhood or early adult life; however, onset late in life is possible. Singleton patients may occur in many families. Typically, parents do not manifest any symptoms because they are heterozygous for the mutation. If the sibship size is large or when extended pedigrees are obtained, other involved persons may be found; the disotders affect both males and females. Consanguinity among the parents may be found but is not essential.

Table 78.2: Autosomal recessive ataxias with known gene loci

Disease	*Gene locus*	*Gene*	*Mutation*
Friedreich's ataxia	9ql3-21.l	X2.5	GAA expansion
Ataxia-telangiectasia*	llq22-23	ATM	Point mutations/deletions
Ataxia with oculomotor apraxia"	9pl3	Aprataxin	Point mtirations/deletions/insertions
A [TU-	llq21	MRE11	I'oint mutations
SCAN-1*	I4q31	II >!' I	Point mutations/deletions/insertions
AVI D	***H***	aTTP	Point mutations
ARSACS	13qll	SACS	Point mutations
Ataxia, neuropathy, high ar-femprotein	9q33-34	Unknown	Unknown
IOSC A	10q24	Unknown	Unknown
Ataxia, deafness, optic atrophy	6p21-23	Unknown	Unknown
Unverricht-Lundborg disease	21q	Cystatin B	Repeat expansion

These all involve mutations in DNA repair genes. Xeroderma pigmentosum and Cockayne's syndrome are other multiple system DNA repair detects in which one may see ataxia.
ARSACS = autosomal recessive spastic ataxia of Charlevoix-Saguenay; ATLD = ataxia-tclangiectasia-like disorder; AVED = ataxia with isolated vitamin E deficiency; IOSC A = infantile onset spinocerebellar ataxia; SCAN-1 = spinocerebellar ataxia with axonal neuropathy 1; TDP = tyrosyl DNA phosphodiesterase; TTP — tocopherol transfet protein.

Friedreich '$ Ataxia

Clinical Features. The prevalence of FA has been estimated to be 2 x 10^{-5} (Pandolfo 1999). Classic descriptions of the disease include an age at onset of younger than 25 years, typically early in adolescence (Harding 1981). Onset is with increasing gait difficulties and neurological examination reveals gait ataxia, loss of proprioceptive sense in the lower limbs, and absence of deep tendon reflexes, cither generalized or in the lower limbs. These findings are related to the early pathology in the dorsal root ganglion cells and the occasional patient may have symptoms that can be mistaken for a hereditary neuropathy. However, most patients exhibit signs indicating involvement of the CNS, including dysarthria, upper motor neuron findings such as extensor plantar responses and eye movement abnormalities such as square wave jerks. Rarely, patients may present with cardiac disease or .: spinal deformity and later develop neurological disease. Patients tend to lose ambulation about 9-15 years after onset. At this stage, patients have increasing ataxia of both upper and lower limbs, profound proprioceptive loss, areflexia, weakness of lower limb muscles, dystonia, flexor spasms, and increasing dysarthria and dysphagia (Hou and Jankovic 2003). Optic atrophy and hearing loss may occur in many patients.

Systemic abnormalities that occut include abnormal electrocardiogram recordings, hypertrophic cardiomyopathy in about 50% of the patients, and diabetes in 10%. Skeletal abnormalities such as spinal deformities and foot deformities are common. The mean age at death among patients with FA has been reported to be late in the fourth decade; however, this information comes from studies performed before the availability of FA mutation analysis. Cause of death is usually cardiac, but the respiratory compromise related to spine deformiry may also contribute.

Nerve conduction studies show early absence or reduction of sensory nerve potentials in a diffuse fashion, reflecting the loss of large sensory axons in peripheral nerves. This is correlated with loss of myelinated fibers in sural nerve biopsies. Central motor conduction studies show evolving abnormalities and may reflect the progression of the disease. MRI scans of the brain reveal no abnormalities in the cerebellum; rather, the upper cervical cord shows atrophy. Pathologically. iluTc is loss ni dorsal root ganglion cells, resultant degeneration of the dorsal columns, degeneration of spinocerebellar and corticospinal tracts, and loss of cells in the cerebellar dentate nucleus,

The Friedreich's Ataxia Mutation. The mutation in FA is an unstable expansion of a repeated trinucleotide (GAA) sequence within the first intron of the gene X 25 on chromosome 9ql3-21.1 (Campuzano et al. 1996) (Figure 78,2). More than 80% of the normal alleles have fewer than 10 GAA repeats. Long normal alleles with 12-40 repeats are believed to serve as a reservoir for expansion into mutations that appear restricted to Indo-Caucasian populations (Pandolfo 1999). Expanded alleles have 66-1000 repeats. Because the disease is recessively inherited, both copies of the gene have to be mutated to produce disease. In nearly 95% of the affected persons, the GAA expansion occurs in both alleles (homozygous expansion), although the size of the expansion can be different in the two alleles. Patients with clinical findings compatible with FA but with only a heterozygous expansion of the GAA repeats constitute the remaining 5%; such patients are found to have point mutations in the unexpanded allele. Commercially available FA mutation analysis cannot distinguish between such compound heterozygotcs and unaffected carriers of the disease. Homozygous point

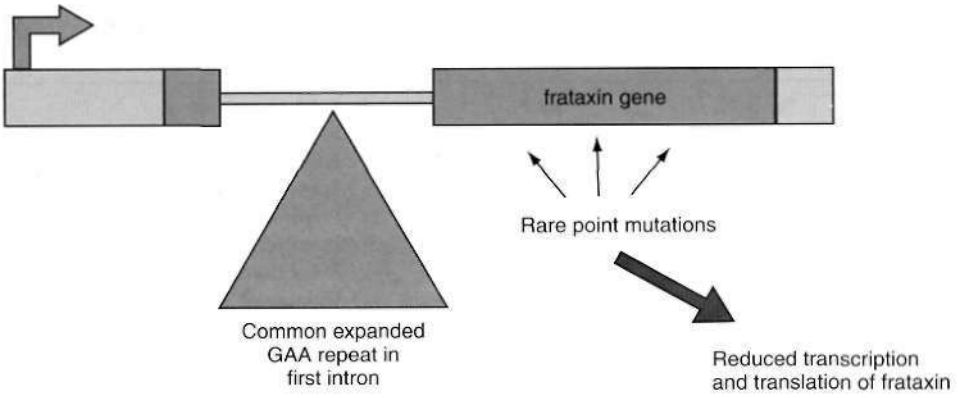

FIGURE 78.2 Schematic representation of the GAA expansion in the first intron of the gene X 25 on chromosome 9 in Friedreich's ataxia. (Courtesy Dr. H. Paulson, University of Iowa.)

mutations have not been found in patients with the diagnosis of FA.

Since the identification of the FA mutation, wc have realized that many patients with a phenotype very atypical for classic FA carry the FA mutation (Durr et al. 1996; Filla et al. 1996; Montcrmini et al. 1997). Approximately 15% of patients with homozygous GAA expansion have neurological signs that are identical to those of classic FA hut have an age at onset of later than 25 years (late-onset FA). Other patients with the GAA expansion have the typical age at onset hut retain their tendon reflexes or even have exaggerated reflexes (FA with retained reflexes). There are patients who combine a later onset with retained reflexes ;-, well; in addition, vcr\ Life unset ol mild gail ataxia, spastic paraparesis, and even chorea has been rarely associated with the FA GAA expansion (Hon and Jankovic 2003). As with other trinucleotide repeat diseases, there is an inverse correlation between the size of the GAA repeat and the age at onset; this correlation is better with the smaller of the two expanded alleles. Cardiomyopathy and diabetes also tend to occur in patients with larger (>700) GAA repeats. However, not all of the variation in age at onset and severity of disease can be cortelated with the GAA size alone. Other genetic and possibly environmental factors may contribute to this variation. We already know that the size of the GAA expansion exhibits somatic mosaicism, so the severity of pathology in a particular tissue may depend to some extent on the repeat size in that tissue.

Point Mutations. Approximately 5% of patients with FA have heterozygous GAA expansion in one copy of the gene and a point mutation m the second copy. Both missense and truncating mutations located in the carboxy terminal half of the frataxin gene appear to be associated with typical FA phenotype (Cossee et al. 1999). Missense mutations in the amino terminal half such as the G130V mutation appear to result in a milder phenotype with less ataxia, greater spasticity, and absence of d\ sartbria.

Pathogenesis. The presence of the expanded GAA sequence in the first intron of the gene results in reduced transcriptional and translations) efficiency, leading to a partial deficienc) ol the protein frataxin (I'uccio and Koenig 2000; Lodi, Taylor, and Schapira 2001; Pandolfo 2001). The lack of documented homozygous point mutations causing FA suggests that the complete absence of frataxin may be incompatible with life, and this has been further supported by the inability to create transgenic animal models of the disease by complete knockout of the gene. The reduced transcriptional efficiency of the mutated gene has been attributed to an unusual "sticky DNA" configuration of the expanded repeat (Sakamoto et al. 1999). The exact role of frataxin in normal biology is still not clear, but many studies suggest that it is a mitochondrial protein. Knockout of the frataxin homologue in yeast leads to accumulation of iron in the mitochondria, a finding of interest in view of the presence of iron in the cardiac muscle in human disease. Rotig et al. (1997) have shown that activity of enzymes that contain iron-sulfur clusters is impaired in cardiac muscle biopsies of patients with FA, It has been hypothesized that this impairment is related to oxidative stress induced by the presence of excess iron that can induce such stress via the Fenton reaction. However, it is also possible that the deficiency of iron-sulfur cluster enzymes may he directly related to the reduced amounts of frataxin. Recent conditional knockout mouse models of FA, in which frataxin deficiency confined to cardiac and neural tissue has been achieved, appear to support this concept. Frataxin appears to be important in making mitochondrial iron available to such processes as synthesis of Fe-S cluster enzymes and heme synthesis. MRI has suggested excess iron in the dentate nucleus of patients with FA and there is magnetic resonance spectroscopy evidence of impaired respiratory capacity of skeletal muscle in FA. Thus FA is an example of a nuclear-encoded mitochondrial disease related to impaired respiratory activity of mitochondria.

Treatment of Friedreich's Ataxia. Based on the ability of the coenzyme Q analogue idebenone to suppress iron induced oxidative damage, early studies have shown a reproducible response of the hypertrophic cardiomyopathy of FA to idebenone treatment (Rustin et al. 1999;

Hausse et al. 2002). Improved bioencrgetics of cardiac and skeletal muscle have been shown to occur in response to coenzyme Q and vitamin F. (Lodi ct al. 2001).

In addition, many attempts have been made at symptomatic therapy for patients with FA with possible neurotransmitter replacements such as cholinergic, scrotoninergic, and GABAergic drugs, which have shown variable and usually less than optimal results.

The supportive care of patients with FA includes adequate rehabilitation efforts aimed at mobility, using appropriate devices. Monitoring and caring for the systemic complications are also important. This includes skeletal deformities, cardiomyopathy, and diabetes.

A tax ia-Telangiectasia

Ataxia-telangiectasia (AT) occurs with a frequency of three per million. Typically, the disease has its onset in the first decade. Children develop progressive ataxia associated with hypotonia, areflexia, peripheral neuropathy, and choreoarhetosis. Also, they exhibit a characteristic oculomotor apraxia, requiring head thrusts for saccadic eye movements. Telangiectasias develop over the conjunctivae (Figure 78.3), ear lobes, and other areas during the second half of the first decade. MRI scan of the brain shows atrophy of the cerebellum. AT is associated with increased risk of malignancies, especially hematological and infections related to immune deficiency. Increased susceptibility to radiation damage has been shown to cause chromosomal translocations and has been used in a fibroblast survival assay as a diagnostic test. Many patients have decreased immunoglobulin A (IgA) levels; decreased immunoglobulin E and immunoglobulin M levels, lymphocytopenia, and skin anergy may also occur. In addition, elevation of *a*-fetoprotein in the serum is a consistent finding in AT.

AT is caused by truncating mutations of the gene ATM on chromosome I 1 (Savitsky et al. 1995; Halazoncitis and Shiloh 1999). More than 300 mutations of this gene have been associated with AT, and mutation detection may not be the best way to make a definitive diagnosis. The protein product of ATM has sequence similarities to phosphatidyl-3-kinase and may be involved in checkpoint responses to DNA damage, explaining many of the systemic features of the illness. The neurological illness itself is still not directly treatable; however, children with AT requite supportive rehabilitation efforts, as well as monitoring and management of the various systemic features.

Ataxia with Isolated Vitamin E Deficiency

The occurrence of a childhood-onset recessive ataxia associated with isolated vitamin E deficiency {AVED} is related to mutations in the gene encoding the a-tocopherol transfer protein (a-TTP) on chromosome 8 (Ouahchi et al. 1995). a-TTP is a hepatic protein involved in the processing of vitamin H for transport in the chylomicrons. The severity of the phenotype associated with a-TTP mutations depends on residual protein activity; the childhood-onset disease has considerable resemblance to FA, causing ataxia, areflexia, proprioceptive loss, and dysarthria. A recent report of 43 patients with AVED noted age at onset from 2-52 years; patients with AVED had a lower incidence of

EIGURE 78.3 Conjunctival telangiectasia in a patient with ataxia-telangiectasia.

cardiomyopathy and more frequent head titubation, compared with patients with FA (C Cavalier et a I. 1998). vitamin F levels should be obtained in all persons with sporadic ataxia of childhood or young adult onset. Patients with AVED have typically less than 1.8 mg/L of vitamin E in serum. Treatment with large doses of vitamin E will elevate the levels and perhaps slow progression of the disease.

A beta tip op ro teinem ia

Mutations in the microsomal triglyceride transfer protein cause this rare disease (Sharp et al. 1993). The diagnosis can be established by the presence of retinopathy, malabsorption including that of vitamin E, low serum cholesterol levels, and the presence of acanthocytes. Serum lipoprotein electrophoresis can also establish the diagnosis.

Autosomal Recessive Ataxia of Charlevoix-Saguenay

Autosomal recessive spastic ataxia of Charlevoix-Saguenay is a childhood-onset disease that has been described from a population isolate in the Canadian province of Charlevoix-Saguenay and is characterized by spastic ataxia. Onset is in early childhood; neurological findings include spasticity, cerebellar eye movement abnormalities, and limb ataxia. Progression is vow and MHM:I a;;;' .11 dr.ilh is in the late fifties. The mutation causing this has been shown to involve a gene on chromosome 13, The protein product of this gene has similarities to chaperone proteins and has been named *sacsin* (Engert et al. 2000). Families from other parts of the wotld have been linked to the same locus. Thus the true prevalence of this disorder among childhood ataxias remains to be determined.

Autosomal Recessive Ataxia with Oculomotor Apraxia

Autosomal recessive ataxia with oculomotor apraxia is characterized by early onset of ataxia, autosomal recessive inheritance, and some features resembling AT such as oculomotor apraxia, loss of deep tendon reflexes, and cerebellar atrophy. Setum albumin level is decreased and total cholesterol level is elevated. Other systemic features of AT such as malignancies are not seen. Two groups have identified the gene mutation involving the aprataxin gene. Aprataxin is widely expressed and shares homologies with histidine-tnad (HIT) proteins and with DNA binding C2H2 zinc-finger proteins. It may be involved in DNA repair as well (Date et al. 2001; Moreira et al. 2001).

Other DNA Repair Defects Causing Ataxia

An AT-like disorder (ATLD) has been recently linked to mutations in another DNA repair gene known as MRE11 {Stewart et al. 1999). Similarly, mutations in tyrosyl-DNA phosphodiesterase 1 (TDP-1), another DNA repair enzyme, causes spinocerebellar ataxia (SCA) with axonal neuropathy (SCAN-1). These patients do not have any systemic features that characterize AT and ATLD (Takashima et al. 2002). Cockayne's syndrome and xeroderma pigmentosum are diseases caused by DNA repair defects in which systemic disease predominates the phenotype, but CNS features including ataxia are often present. Mutations in genes encoding components of the nucleotide excision repair pathway occur in these diseases (Chu and Maync 1996).

Infantile-Onset Olivopontocerebellar Atrophy

Infantile-on set olivopontocerebellar atrophy has been reported from a population isolate in Finland. The disorder begins with clumsiness soon after children begin walking. Neurological signs include ataxia, peripheral neuropathy, areflexia, athetosis, and extensor plantar reflexes. Speech is impaired and hearing loss occurs. Ophthalmoplegia, optic atrophy, seizures, learning deficits, and skeletal deformities are other features. The gene has been mapped to 10q24 (Nikahet al. 1997).

Other Genetically Defined Autosomal Recessive Ataxias

Other recessive ataxias have been genotyped in a limited number of families. These include an FA2 locus on 9p, ataxia, neuropathy, and high w-fetoprotein (9q), ataxia, deafness, and optic atrophy (6p), and ataxia with increased saccadic speed (lp) (Bemontet al. 2000; Christodoulu et al. 2001; Swartz et al. 2002).

Ataxias with Defined Biochemical Errors

Many childhood-onset and young adult-onset ataxias are related to metabolic errors that can be diagnosed by specific laboratory tests, rather than by gene-based tests. In many of these diseases, ataxia forms only a parr of the phenotype. Table 78.3 lists some of these diseases. Some of these are amenable to various forms of therapy including dietary manipulations.

Clinically Defined but (Likely) Genetically Heterogeneous Syndromes

Many children and young adults with progressive ataxia still have undefined genotypes. The term *early onset ataxia with retained reflexes* was originally used to describe a syndrome of ataxia with onset in childhood with some resemblance to FA except for the preservation of deep tendon reflexes. We now know that many of these patients carry the FA mutation; in others, however, the genotype remains unknown. Similarly, Cordon Holmes originally described the syndrome of recessive ataxia associated with hypogonadism in 1907. This may also be genetically hetetogeneous, although in some patients with such a disorder, mitochondrial mutations have been described.

Tabic 783: Ataxias in which specific biochemical abnormalities may confirm or point to the diagnosis (some also appear in Table 78.2}

Disorder	*Laboratory tests*
WHL>	Low vitamin H levels
Abetalipoproteinemia	Low vitamin K levels, high cholesterol, abnormal lipoprotein electrophoresis
AOA	Low albumin, high cholesterol
V!	High a-fetoprotein, low IgA
Cercbrotendinous xanthomatosis	High serum eholestanol
Ad ren o I e u k od y str o p h y	Serum long chain fatty acids
Ataxia with CoQ deficiency	Low CoQ in muscle biopsy
Vanishing white matter disease	MRI, MRS
Late onset GMj gangliosidoses	Hexosaminidase in fibroblasts
CDG syndromes	Transferrin isoelectric focusing
Mitochondrial diseases	Lactic acid levels, RRF in muscle
Sialidosis	Neuraminidase
Maple syrup urine disease	Urine amino adds
Organic acidurias	Urine organic acids, ketone bodies
Urea cycle defects	Plasma ammonia
Pyruvate dehydrogenase deficiency	Lactate levels

AOA = ataxia with oculomotor apraxia; AT = ataxia-telangiectasia; AVED = ataxia with isolated vitamin E deficiency; CDG = carbohydrate-deficient glycoprotein; CoQ = coenzyme Q; M!U = magnetic resonance imaging; MRS = magnetic resonance spectroscopy; RRF = ragged red fibers.

The term *Ramsay Hunt syndrome* is used for the association of ataxia and myoclonus or myoclonic epilepsy. One form of this, Unverricht-Lundborg syndrome, is related to mutations in the cystatin P> gene (Pennachio et al. 1996). Others have mitochondrial DNA mutations or other disorders of intermediary metabolism such as ceroid lipofuscinosis or sialidosis (Table 78.4).

Mitochondrial Diseases and Ataxia

Progtessive ataxia is often an intrinsic feature of many mitochondrial cytopathies related to mutations in the mitochondrial DNA (mtDNA). The association of ataxia with myopathy, external ophthalmoplegia, or other features of mitochondriopathies such as short stature, endocrine deficiencies, elevated CSF protein, and retinal pigmentary degeneration may suggest a mitochondrial disease. Some mtDNA mutations have been specifically associated with ataxia, including the nt8344 mutation tclatcd to myoclonic epilepsy with ragged red fibers (MF.RRF) and the nt8993 mutation in the adenosine triphosphatase gene associated with neurogenic weakness, ataxia, and retinitis pigmentosa. Other classic mtDNA syndromes such as progressive external ophthalmoplegia, Kcarns-Sayre syndrome, and mitochondrial, encephalopathy, lactic acidosis, and strokclike episodes can also be associated with ataxia in a variable proportion of patients. Because mtDNA mutation may give rise to complex tissue distribution of symptomatology related to replicative segregation of the mutant mtDNA and to variable tissue susceptibility to oxidative deficiency, it is possible that isolated CNS symptomatology telated to such mutations may be difficult to define by studies of peripheral tissues.

Autosomal Douiiiiani Ataxias

Autosomal dominant ataxias have onset usually in the third to fifth decade of life, although there is wide variability in age at onset. The disease occurs in each generation of the pedigree; the offspring of affected parents have a 50% risk of inheriting the disease in general. Male-to-malc transmission of the disease is definite evidence for autosomal dominant inheritance. Since the 1990s, the genetic heterogeneity among the dominant ataxias has been more than amply documented (Subramony and Filla 2001) (Table 78.5). Progressive dominant ataxias are labeled *SCA,* followed by

Table 78.4: Young-onset ataxias with some distinctive clinical features but as yet poorly understood at a genetic level

Disorder	*Comments*
Early onset ataxia with retained reflexes	Some have FA or ARSACS mutation; others are genetically undefined

a number to denote the chromosomal locus. Dominant ataxias that are named differently include Machado-Joseph disease (MJD) (earlier known as SCA-3) and dentatorubral-pallidoluysian atrophy (DRPI A), In addition, at least two gene loci are known for episodic ataxia (EA-1 and EA-2) syndromes. The absence of symptomatic disease in cither of the affected parent with autosomal dominant ataxia is rare but can occur for a number of reasons. Examples include reduced penetrance of the disease, onset of disease in a child before onset of symptoms in the affected parent because of anticipation, death of the involved parent before onset of symptoms, and wrong paternity. De novo mutations and expansion from an intermediate si/.e allele to a pathogenic allele in disorders related to repetitive nucleotide sequences may be oilier explanations.

Clinical Features of Dominant Ataxias

Overall, progressive dominant ataxias related to different gene mutations have ovetlapping clinical features (Subramony 1999). Gradually progressive ataxia associated with an array of cerebellar signs forms the core feature of most of these diseases. Patients exhibit progressive ataxia of gait associated with clinical signs of limb ataxia such as dysmettia and adiadokokinesia. Speech is dysarthric, often with spastic components. Eye movement abnormalities related to cerebellar dysfunction are common and include abnormal pursuit and inaccurate saccades in addition to nystagmus. Many, but not all, of the disotdcrs are also associated with clinical signs referable to pathology in CNS structures other than cerebellum and its connections (Diaz et .-.'.. $I^{1})$"!); Seijuims and tioulinho P'^{1}' >; Goldfarb et al. 1996; Schols et al. 1996; Gomez et al. 1997), Oculomotor abnormalities unrelated to cerebellar dysfunction include gaze palsy, ptosis, blepharospasm, and an "ocular stare," Many patients have additional bulbar deficits such as facial atrophy, facial fasciculations, tongue atrophy and fasciculations, and poor ability to cough. Upper motor neuron signs such as brisk reflexes with or without spasticity, and Babinski's signs occur early in many dominant ataxias. Extrapyramidal signs including akinetic-rii',id syndromes, hypomimic fades, chorea, athetosis, and dystonia (Figure 78.4) tend to occur variably in dominant ataxia in different stages of the illness. Evidence of peripheral nerve disease occurs often and includes distal sensory loss and loss of deep tendon reflexes, as well as amyotrophy, (n selected dominant ataxias, there can be associated cerebral signs such as cognitive decline or seizures; in others, there is evidence of retinal disease with visual loss (Figure 78.5).

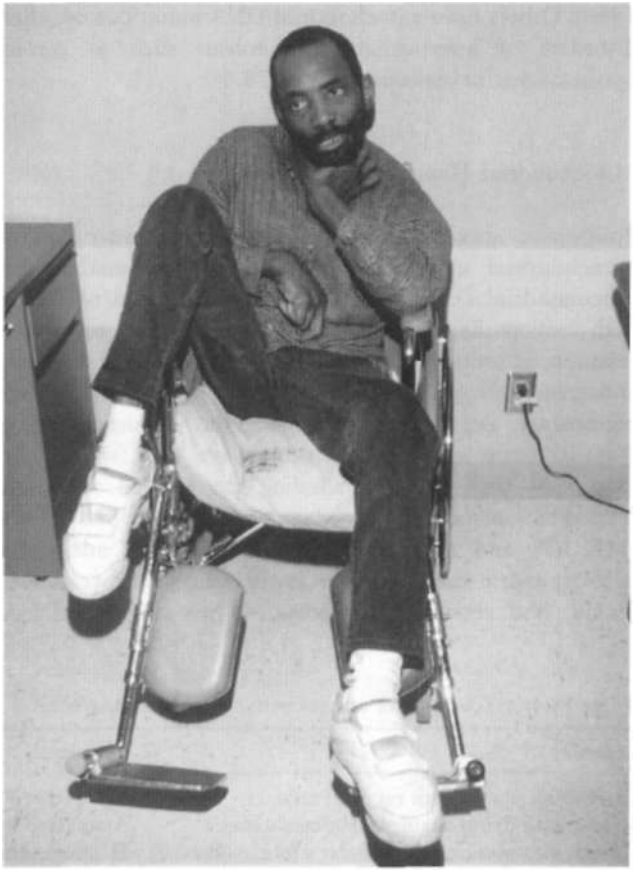

FIGURE 78.4 Dystonia in a patient with Machado-Joseph diseasi.

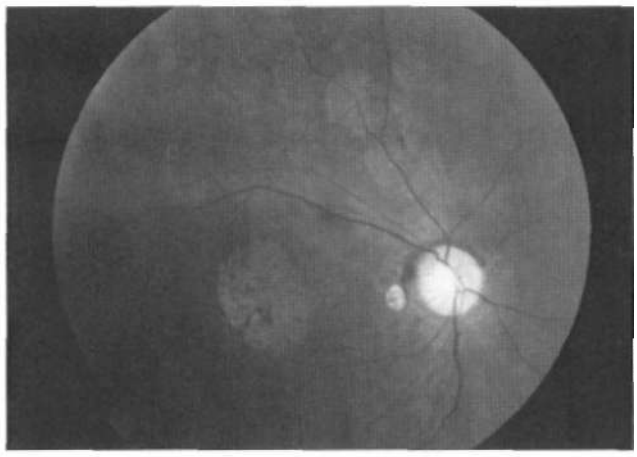

FIGURE 78.S Maculoparhy in a patient with spinocerebellar ataxia type 7.

The motor syndrome is inexorably progressive with loss of ambulation over 10-15 years. A faster rate of progression is correlated with earlier onset of disease.

Individual gene mutations often exhibit considerable phenotypical heterogeneity. Some of the clinical heterogeneity within members of the same family is related to duration of the disease; for example, previously present nystagmus may disappear as the saccadic system gets involved or brisk deep tendon reflexes may disappear because of increasing peripheral nerve pathology. Other differences in clinical signs are related to the severity of the gene mutation itself and other intrinsic and extrinsic factors.

The underlying gene mutation docs affect the clinical picture to some degree, but clinical differences between the various genotypes are not sufficient to permit confident clinical diagnosis of the genotype without the appropriate mutation analysis. Table 78.6 summarizes some clinical features that may help in the clinical differentiation of various progressive dominant ataxias.

The EA syndromes cause intermittent episodes of imbalance, dysarthria, vertigo, and abnormal eye movements that last from minutes to hours. At least two different gene mutations give rise to EA. EA-1 is associated with brief episodes of ataxia and no interictal cerebellar abnormalities; however, many patients have skeletal muscle myokymia interictally. In EA-2, the ataxic episodes arc longer and may be associated with some interictal abnormalities such as nystagmus. Some patients with EA-2 also develop progressive ataxia.

Imaging and Other Laboratory Studies in Dominant Ataxias

MRI and computed tomographic scans of the brain are useful to exclude many disorders causing ataxia other than the inherited causes such as strokes, tumors, and multiple sclerosis. The dominant ataxias arc associated with progressive atrophy of the cerebellum; in addition, there may also be atrophy of the pons, medulla, middle cerebellar peduncles, and upper cervical cord (Klockgether et al. 1998) (Figure 78.6). There can be some hyperintensity of the middle cerebellar peduncles on T2-weighted images. Imaging studies alone are insufficient to differentiate the various genotypes. SCA-1, SCA-2, and SCA-3 are usually associated with pontocerebellar atrophy, and SCA-6 with isolated cerebellar atrophy. Experience with other disorders is limited. Many of the dominant ataxias arc also associated with evidence of an axonal polyneuropathy on nerve conduction studies *:\nii* abnormal hrainstem-evoked responses.

Table 78.6: Distinctive phenotypical features of some dominant ataxias; in general, the various genotypes resemble each other closely

Phenotypical feature	*Disorders*
Age at onset	Young adult: SCA-1, SCA-2, MJD; older adult: SCA-6; childhood onset frequent in SCA-7/DRPLA
Degree of anticipation	More in SCA-7, DRPLA
Benign course	SCA-6
Upper motor neuron signs	SCA-1, -7, -8, MJD; rare in SCA-2
Akinetic-rigid/ Parkinson's signs	MJD, SCA-2, SCA-17
Chorea	Prominent in DRPI.A; late in SCA-2, -1, MJD
Action tremor	SCA-12, 16
Very slow saccades	Early in SCA-2, -7; late in SCA-1, MJD; never in SCA-6
Downbeat nystagmus	SCA-6, EA-2
Generalized a reflex ia	SCA-2, SCA-4, older adult-onset MJD
Visual loss	SCA-7
Vi/.UIYS	SCA-10, early onset DRPLA, SCA-7

DRPI.A = dcntatorubral-pallidoluysian atrophy; EA = episodic ataxia; MJD = Machado-Joseph disease; SCA = spinocerebellar ataxia.

Neuropathology

SCA-1, SCA-2, and SCA-7 are usually associated with fairly widespread pathology in the nervous system including loss of Purkinjc cells in the cerebellum, pontine neurons, and olivary neurons (Figure 78.7). In addition, other structures such as dorsal root ganglion cells, Clarke's column cells, and cranial and lower motor neurons may be affected, together with their tracts. In MJD, cerebellar Purkinje cells are relatively spared, but there is severe involvement of pontine neurons, Clarke's column cells, and nigral cells. Spinal motoneurons and vestibular nuclei arc also involved. SCA-6 is characterized by isolated involvement of the Purkinje cells and olivary neurons (Robitailic- et al. *1997)* (Figure 78.8).

FIGURE 78.6 Magnetic resonance imaging scan of the brain in a patient with spinocerebellar ataxia type 1, showing ponto-cerebellar atrophy.

FIGURE 78.8 Isolated cerebellar atrophy in a patient dying with spinocerebellar ataxia type 6.

Gene Mutations and Phenotype—Genotype Correlations in Dominant Ataxias

Both unstable expansions of repeated nucleotide sequences {Figure 78.9) and point mutations have been related to dominant ataxias. At least eight dominant ataxias arc related to unstable expansions of CAG repeats inherited in a heterozygous fashion (Orr ct al. 1993; Kawaguchi et al. 1994; Nagafuchi ct al. 1994; Pulst et al. 1996; Zuchenko et al. 1997; David et al. 1998; Holmes et al. 1999; Zuhlke et al. 2001); all are progressive diseases. Because CAG codes for glutamine and the protein product of the mutated gene contains excess number of gluta mines, many such diseases are examples of polyglutamine disorders. All the CAG expansion diseases are characterized bv an inverse correlation between the number of repeats in the expanded alleh and thi' age ;i(u:iscl. 1 argcr repeal sizes are also associated with more rapid progression of the disease and with more rapid atrophy of posterior fossa structures. Thus the phenotypical heterogeneity within single genotypes is related to a complex interaction between the size of the repeats in a particular individual, the duration of the disease, and additional environmental and genetic factors of unknown nature. The unstable nature of these expansions causes a change in the size of the repeats from one generation to the next, accounting for the variability in age at onset and some of the phenotypical heterogeneity. The observed anticipation in age at onset of many dominant ataxias can be at least partly explained by the expansion of these unstable repeats. Typically, paternal transmission of the disease is associated with a greater tendency for expansion. The SCA-6 CAG expansion, which involves

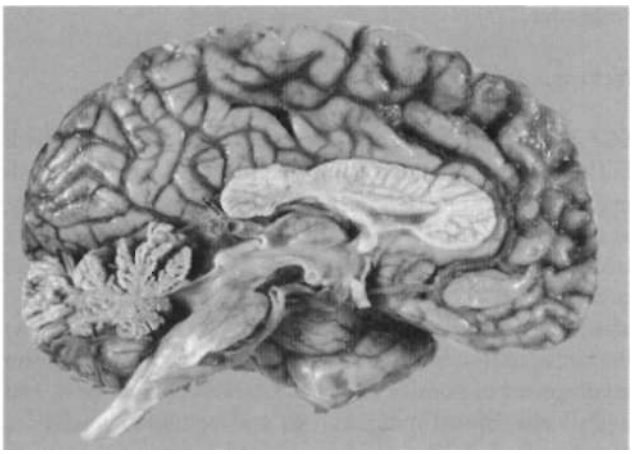

FIGURE 78.7 Gross features showing cerebellar and brainstem atrophy in a patient dying with spinocerebellar ataxia type 1.

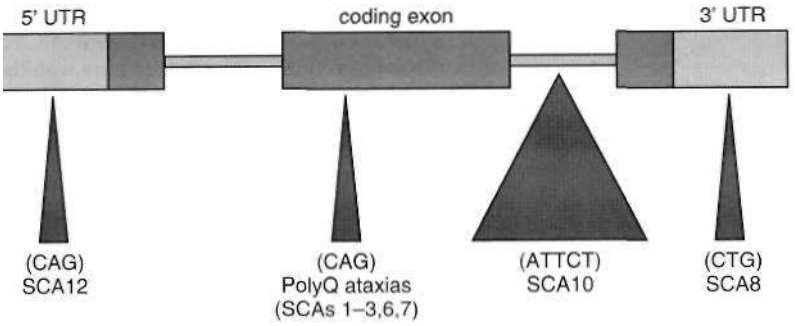

FIGURE 78.9 Schematic representation of various repetitive nucleotide expansions in dominant ataxias. (Courtesy Dr. H. Paulson, University of Iowa.)

the wi-SLibiinit of the neuronal calcium channel gene, is exceptional in that it is transmitted in a stable fashion for the most part.

The recently described SCA-8 has been related to an unstable expansion of a CTG tract in the V untranslated region of the gene on chromosome 13 (Koob et al. 1999). The primary roie of this expansion in causing ataxia has been controversial because the same CTG expansion has also been found in patients with other disorders such as stroke and Parkinson's disease and even in general population samples (Stevanin et al. 2000; Worth et al, 2000). The vertical transmission of the expansion has been extensively studied in only one family by Koob et al. (1999), in which a significant lod score was calculated; even in this family, there were several nonpenetrant individuals who had expansions of the repeat into a larger than normal but presumably nonpathogenic range. Thus the interpretation of an expanded SCA-8 CTG repeat in an individual with ataxia remains controversial, and the possibility exists that either the expansion is not fully penetrant or the real mutation is somewhere else but in linkage dysequilibrium with the expansion. The CTG tract in the SCA-8 gene is transcribed to a messenger RNA (mRNA) but not translated into a protein.

Still another form of repeat expansion occurs in SCA-10, a disorder typified by progressive ataxia and epilepsy. The mutation is a large unstable expansion of a pentanucleotide repeat (A'lTCT) on chromosome 22 (Matsuura et al. 2000).

The CAG expansion in the recently reported SCA-17 involves the TATA binding protein (TBP) gene (Zuhlke et al, 2001). This is of interest because TBP is a critical player in transcription, and transcriptional dysregulation may occur in many of the other polyglutamine diseases as well.

The EA syndromes are related to point mutations. In EA-1, the mutation involves a potassium channel gene (KCNA1) on chromosome 12 (Browne et al, 1994). EA-2 has been related to both nonsense and missense mutations in the ai-subunit of the calcium-channel gene (CACNA1) (Ophoff et a I. 1996). Poor penetrance and phenotypical variability have been well documented in EA-2 (Danier et al, 1999).

A number of dominant ataxias have been localized to specific chromosomes, but the mutations are as yet undefined. These include SCA-4 (chromosome I6q), SCA-5 (chromosome lip), SCA-11 (chromosome 15q), SCA-13 (chromosome I9q), SCA-14 (chromosome 19q), and SCA-16 (chromosome 8q), SCATS (chromosome 7q), SCA-21 (chromosome 7), and SCA-23 (chromosome 20p) (Ranum et al, 1994; Flanigan et al. 1996; Worth et al, 1999; Herman-Bert et al. 2000; Miyoshi et al. 2001; Yamashita et al. 2000; Takashima et al. 2002; Brkanac et al. 2002; Verbcck et al, 2002; Vuillaumc et al. 2002). Still others are known to be in as yet unknown loci and these include SCA-9, SCA-15, and SCA-22 (Storey et al. 2001; HUGO Web site).

Pathogenesis

The pathogenesis of the dominant ataxias has been the subject of intense research since the mid-1990s (Paulson 1999; Zoghbi and Orr 2000; Or 2001). The CAG expansion disorders have been particularly scrutinized by many workers. The SCA-1, SCA-2, SCA-3, and SCA-7 proteins, as well as the DRPLA protein, have all been novel proteins of unknown function and have been named ataxins 1, 2, 3, and 7, and atrophin, respectively. In all these diseases, evidence has accumulated for the gain-of-function hypothesis (Figure 78.10). This states that the disease is caused by the acquisition of a novel toxic function by the protein product of the mutated gene, rather than by the deficiency of the protein, which is typical of many recessive diseases. This idea is consistent with the fact that disease occurs from a single copy of the mutated allele. In all these diseases, the mutated allele is transcribed and translated into its respective protein product in a widespread fashion. Because CAG codes for glutamine, the mutant protein has a longer stretch of glutamines than wild type protein; thus the CAG expansion diseases have also been called *polyglutamine disorders.* The distribution of the protein has also been shown to be different in diseased brain. Normally, most of the proteins have a diffuse cytoplasmic localization with some additional nuclear presence. However, in diseased brain tissue, the protein has been shown to accumulate as aggregates within the nucleus in SCA-1, SCA-3, and SCA-7, as well as in DRPI.A (Orr 2001). In SCA-2,

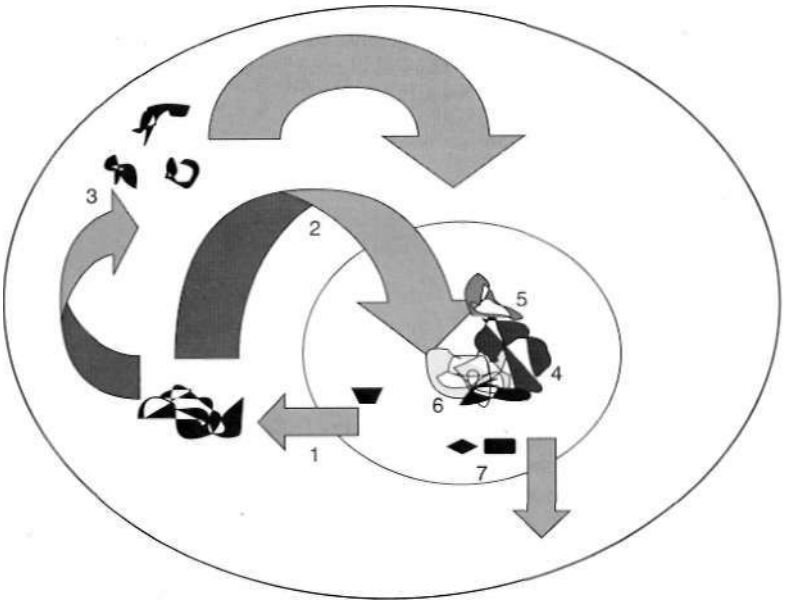

FIGURE 78.10 Diagrammatic representation of some current ideas about the pathogenesis of CAG expansion disorders. 1. The mutant gene with the CAG expansion is transcribed and translated to *a* mutant protein with an excess number of glutamines. 2. The mutant protein enters the nucleus where it forms aggregates (4). 3. In some situations, truncation of the mutant protein by caspases or similar enzymes might possibly create fragments of the protein containing the polyglutamine tract and such fragments may then enter the nucleus. 4. Formation of nuclear inclusions (Nls). In selected situations, aggregates may occur in the cytoplasm ;is well. 5,fi. Nls recruit a variety of other nuclear proreins including the ubiquitin-proteasome system, the heat shock protein system, and transcription factors. The list of proteins associated with NI is slowly growing. 7. Secondary events may include r ra user i prion a 1 dysregulation of other critical genes or as yet unknown pathways such as depletion of critical nuclear proteins.

aggregation of the protein appears to he predominantly in the cytoplasm. Nuclear inclusions (Nls) have heen shown to contain the mutated protein in each instance, and the expanded ghitamine tract is important in the formation of the NI. The Nls also have heen shown to recruit a variety of other proteins such as members of the heat shock protein (hsp) chaperone system and the ubiquitin-proteasome pathway. These findings support the idea that the mutated protein assumes a misfolded configuration (Paulson 1999). The presence of Nl has been reproduced in many transgenic and transfection models of the CAG expansion disorders. Genetic engineering of the hsp and ubiquitin-proteasome pathway has been shown to modify the intensity of NI formation in these model systems and to alter the toxicity of the mutant protein. Also, in some model systems, such as those for MJD and DRPLA, truncated construct[1]; of the gene containing the CAG expansion have been more efficient in causing pathology. Whether truncation of the mutant protein occurs in human tissue in the case of the ataxias is not yet established, although many of the proteins do have caspase sites. In addition, the essential role of NI in the pathogenesis of neuronal death has been questioned. In fact, in SCA-1 transgenic mouse, genetic manipulation has been able to disassociate the NI from neuronal loss; the deletion of a self-association domain from the ataxia-1 gene prevented the formation of NI, but the pathology was not diminished. On the other hand, deletion of a nuclear localization signal preventing nuclear entry of the mutated protein was enough to prevent neurological disease, establishing the importance of nuclear entry. This has given rise to the idea that interference in essential nuclear functions by the mutated protein may be an important mechanism of disease. Such secondary events may include binding to essential nuclear proteins including transcription factors and downregulation of other essential genes.

The SCA-6 CAG expansion may cause disease by a mechanism different from the aforementioned scenario, although aggregation of the calcium-channel protein in the cytoplasm has been reported (Ishikawa et al. 1999). Expression studies of the mutated channel protein also have suggested that altered calcium-channel function may play a role (Restituito et al. 2000). This may also he true for the point mutations in the calcium-channel gene associated with EA-2.

SI'OH UMC ATAXIAS

The occurrence of progressive cerebellar ataxia clinically resembling inherited ataxias but with no definite genetic etiology has been recognized for more than 100 years. The term *sporadic ataxia* has been used for such a process when other well-established causes of cerebellar ataxia have been excluded. Some of the common causes of ataxia such as multiple sclerosis, strokes, and tumors can be easily excluded by imaging studies. Other causes of ataxia such as alcohol and hypothyroidism have nonspecific imaging findings and can be diagnosed only by appropriate history and laboratory studies. There is little understanding of the etiopathogenesis of truly sporadic cases of ataxia. Sporadic ataxia with childhood or young adult onset may still have undefined single-gene mutations as the underlying cause. When sporadic ataxia has onset in older adults (idiopathic late-onset ataxia), it may be the result of a complex interplay of genetic and environmental factors. It should be noted that among patients with a diagnosis of sporadic

ataxia, a very small percentage test positive for one of the known gene mutations. It is difficult to make specific recommendations regarding the gene tests that need to he obtained in a patient with sporadic ataxia (Tan and Ashizawa 2001). The FA GAA expansion and the SCA-6 CAC, expansion may be the most likely to yield a positive result (Abele et al. 2002). One should consider some of the mutation analyses in patients with sporadic ataxia if the family history is not very clear or the clinical picture is more typical for one of the genetically determined ataxias. Among patients with idiopathic late-onset ataxia, some have added noneerebellar signs and some do not (Klockgcther et al. 1990).

Sporadic Cortical Cerebellar Atrophy

Sporadic cortical cerebellar atrophy usually has onset in patients older than 50 years and results in a progressive ataxia not associated with other neurological deficits even many years after onset. MRI scans and pathological examination usually show isolated cerebellar atrophy, but this correlation is not absolute. The disease has a slow progression with a median life span of more than 20 years after onset.

Sporadic Ataxia with Added Noncerebellar Deficits

Patients with sporadic ataxia with added noncerebellar deficits initially have slowly progressive ataxia bur soon develop additional signs such as upper motor neuron signs, ophthalmoplegia, parkinsonian features, and autonomic failure. In keeping with this, both MRI and pathological examination show cerebellar and brainstem degeneration; the autonomic structures may be affected as well. Thus the L1UIIL.I1 picture of this disorder merges with that of the olivopontocerebellar atrophy form of multiple system atrophy (MSA). Among patients with idiopathic progressive ataxia, 25-35% will transition to probable MSA over 5-10 years (Gilman et al. 2000). The clinical evidence for this in most will be added parkinsonian and autonomic deficits, but in a few, only autonomic failure develops. Such signs include orthostatic hypotension, incontinence, erectile dysfunction, rigidity, and facial hypomimia. Older age at onset and a more rapid progression to a disabled state suggest a higher risk of such transmission. Median survival after such transition was only *3.5* years. Sphincter electromyography and cardiovascular autonomic testing may be useful to confirm the diagnosis of MSA. Signs of autonomic failure are uncommon in the inherited ataxias, although bladder dysfunction is not uncommon in late stages.

CIJNTCAL APPROACH TO PATIENTS WITH DEGENERATIVE ATAXIAS

A careful clinical approach to patients presenting with progressive ataxia allows accurate diagnosis and appropriate management (Figure 78.11). The age at onset, the tempo of progression, associated neurological and systemic signs, and the availability of family history all can be considered in making a diagnosis. Imaging studies, especially MRI ol the brain, allow diagnosis of those disorders in which characteristic morphological abnormalities underlie ataxia, such as infarcts, mass lesions, or dcmyclinating plaques. Other laboratory studies of value include thyroid function, vitamin E and P;_ levels, serology for syphilis, gliadin and antt-GAD antibodies, antibodies associated with paraneoplastic syndtomes, and possibly CSF examination for pleocytosis, oligoclonal bands, and malignant cells. In young adults and children, specialized biochemical tests, as indicated in Table 78.3, may be indicated.

Tabic 7S.7: Normal and pathogenic range of repeat expansions associated with inherited ataxias

Disease	*Repeat*	*Norma!*	*Intermediate*	*Expanded*
FA	. .\ : ı	*h* 40		66 to >1000
SCA-1	CAG	6-44		39-82
SCA-2	CAG	14-31	32-33	33-64
V1Jl.)	CAG	12-40		54-86
SCA-6	CAG	4-18		19-30
SCA-7	CAG	4-27	28-36	37-200
SCA-8	CTG	16-91		107-127[2]
SCA-10	ATTCT	10-22		1000-4500
SCA-12	CAG	*<29*		66-78
SCA-17	CAG	25-44		50-63
(TBP)DRPLA	CAG	7-35		44 SS

Note: In SCA-1, the normal and pathogenic ranges overlap. However, the pathogenic-ally expanded repeat can be distinguished from the normal repeat by the absence of CAT interruptions.
DRPLA = dentatorubral-pallidoluysian atrophy; FA = Friedreich's ataxia; M)D = Machado-Joseph disease; TBP = TATA-hinding protein.

Table 78.8: Geographical variation in the prevalence of various genotypes among autosomal dominant ataxias

Source: Data summarized with permission from Storey, E., du San, D., Shaw, J, H,, et al. 2000, "Frequency of spinocerebellar ataxia types 1, 2, 3, 6 and *7* in Australian patients with spinocerebellar ataxia," *Am] Med Genet,* vol. 95, pp. 351-357,

DNA testing is now available for EA, SCA-1, SCA-2, MJD, SCA-6, SCA-7, SCA-8, **SCA-10,** SCA-12, SCA-17, and DRPI.A (Table 78.7). Gene testing is possible for AT, autosomal recessive ataxia of Charlevoix-Saguenay, AVED, ataxia with oculomotor apraxia type 1, and EA syndromes but is not readily available. Patients with features compatible with specific inherited ataxias, as discussed earlier in this chapter, are candidates for such DNA testing. Such testing is very accurate and relatively inexpensive. However, the genetic heterogeneity of the

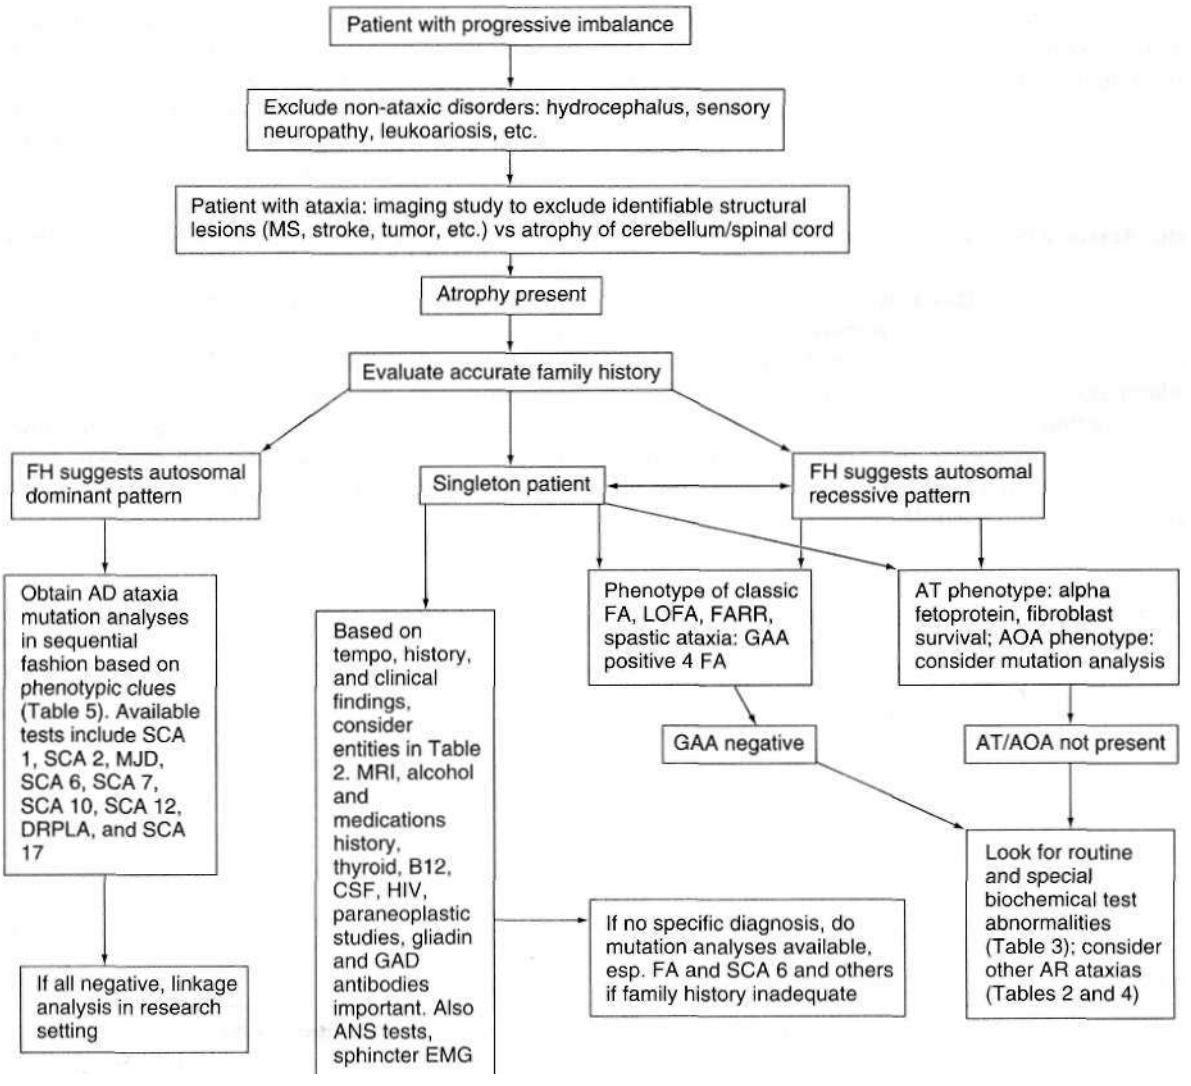

FIGURE 78.11 An algorithm for a diagnostic approach to patients with progressive ataxia.

ataxias, the overlapping phenotypes, and the fact tliat there arc unknown genotypes all make such tests less than optimal. Some of the phenotypical features discussed earlier can serve as guidelines to select appropriate mutation analyses. In addition, information regarding ethnic predilections among the ataxias may also guide the selection of tests (Tahle 78.8). Thus FA is restricted to European, Indian, and Middle I'.astem populations. Ataxia with oculomotor apraxia is the most common recessive ataxia in Japan and second only to FA in Portugal. Among dominant ataxias, MJD is the most common in Germany, |ap,tn, China, and most South American countries. SCA-2 appears co he more prevalent in the United Kingdom, Italy, and India. SCA-6 is common in Japan, DRPI.A constitutes close to 20"o oi dominant ataxias in some parts ol Japan but is uncommon elsewhere. Lastly, certain population isolates have a high incidence of certain ataxias, such as SCA-1 among the Iakut in Siberia, SCA-2 in eastern Cuba, and MJD in the Azorean islands.

Chapter 79
Disorders of Bones, Joints, Ligaments, and Meninges

Richard B. Rosenbaum and David P. Ciaverella

Because of their proximity to the nervous system, disorders of the bones, joints, ligaments, and meninges can cause several myelopathic and radiculopathy syndromes and can affect the cranial nerves and intracranial contents. This chapter considers many of these disotders, both congenital and acquired. Chapters of overlapping interest include Chapters 27, 56C, 57b, and 66.

CONGENITAL AND INHERITED SPINAL DISORDERS

Disorders of the craniocervical junction include bony abnormalities of the occiput and foramen magnum, dysfunction of connecting ligaments, hindbrain malformations, upper cervical skeletal deformities, and syringomyelia or syringobulbia (Mcnzes 1997). Many of these are congenital; their embryogenesis is discussed in Chapter 66, Magnetic resonance imaging (MRI) and computed tomogtaphic (CT) scanning have improved the detection, understanding, and treatment of these anomalies.

Craniocervical Deformities

Occipitalization of the Atlas

Occipitalization ot assimilation of the atlas refers to congenital partial or complete fusion of the atlas (first cervical vertebra) to the occiput (Figute 79.1). The anterior arch of the atlas may fuse to the lower end of the clivus or the posterior arch of the atlas may fuse to the occiput. The anomaly is often asymptomatic until early adult life and may become symptomatic after trauma. Unilateral occipitalization of the atlas is one cause of torticollis in young children. The loss of movement between the occiput and atlas increases the stresses at the atlantoaxial joint, predisposing it to gradual degeneration or traumatic dislocation. Patients with occipitalization of the atlas may have associated anomalies, such as the Klippel-Feil anomaly, basilar impression, or Chiari malformation.

Basilar Impression

Basilar impression or *invagination* refers to abnormal cephalad position of the fotamen magnum (Goel et al. 1998).

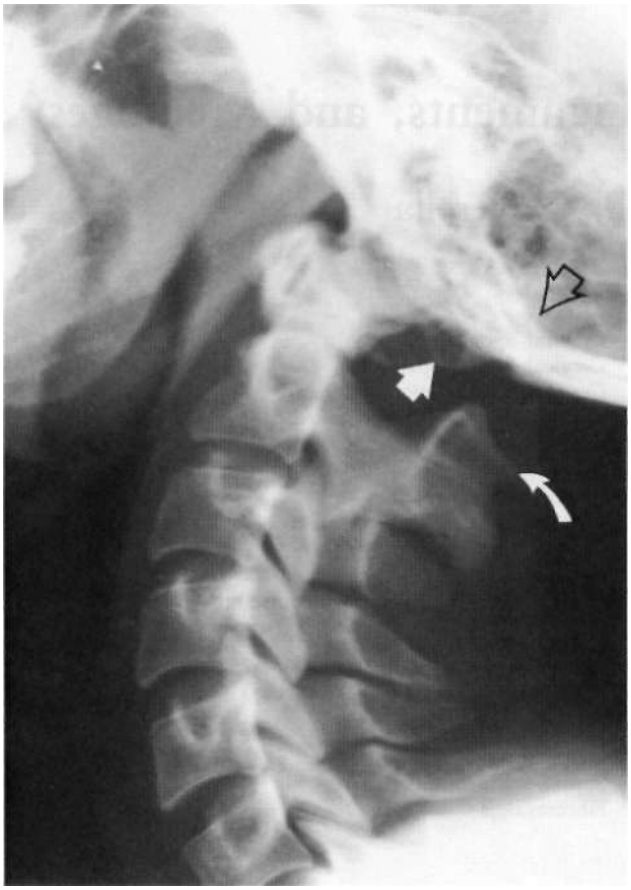

FIGURE 79.1 Occipitalization of the atlas. Radiograph shows fusion of the lamina of the atlas to the occiput *(open arrow).* The lamina contains the circular arcuate foramina *[arrow),* through which the vertebral arteries pass. The spinous process of the atlas *{curved arroiv)* has fused with C2, making this a partial incorporation of CI into the skull base. There is a broad spectrum of variations in this congenital anomaly. (Courtesy Erik Gaensler.)

Several radiological lines (Chamberlain's, McGregor's, McRae's, digastric) (Figure 79.2) and measurements can be used to make the diagnosis. Congenital basilar impression may occur in isolarion or may be associated with conditions such as achondroplasia, occipital dysplasia, Down syndrome, Hurler's syndrome, Klippel-Feil anomaly, and cleidocranial dysplasia. Some instances of basilar impression are familial. The skeletal anomaly is often accompanied by anomalies of the neuraxis, including Chiari 1 or II malformation and syringomyelia. Basilar impression can cause compression of the brainstem (Figure 79.3) or cerebellum, or rarely vertebral artery compression, leading to vertebrobasilar ischemia. It is often asymptomatic, particularly when mild and unaccompanied by other anomalies.

Platybasia or *flattening of the skull* refers to straightening of the angle between the clivus and the floor of the anterior fossa. It infrequently accompanies basilar impression; it can occur also as an isolated radiographic finding without any adverse neurological consequences.

Klippel-Feil Anomaly

Patients with the Klippel-Feil anomaly (congenital synostosis of the cervical vertebrae) (Figure 79.4) have short necks, low haitlines, and limitation of cervical motion. The diagnosis is confirmed by radiographic demonstration of fused cervical vertebrae. The condition is congenital, caused by failure of normal segmentation of the cetvical vettebrae between the third and eighth weeks of fetal development. Although familial instances oecut, most cases ate isolated and idiopathic. The anomaly can cause direct nerve root, cetvical spinal cord, or vcrrebtal or spinal artety compression, Neck pain is common. Hearing loss is the most common symptom of cranial neuropathy. Mitror

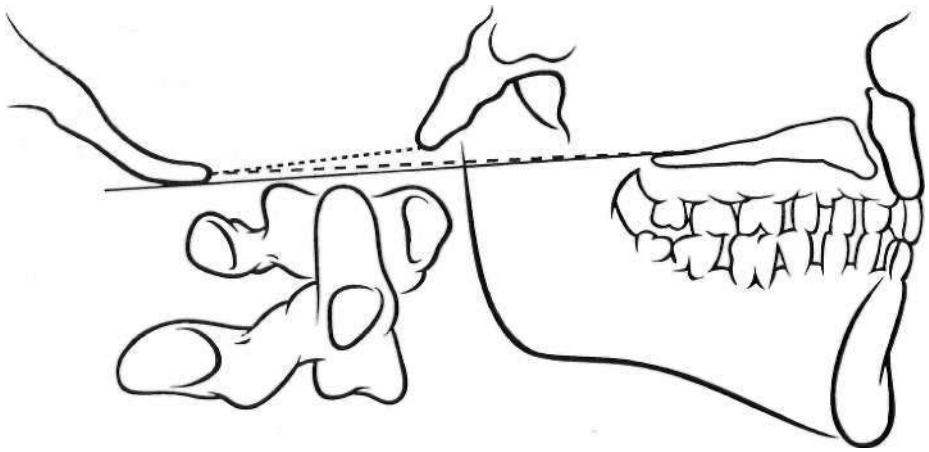

FIGURE 79.2 Chamberlain's line *(dashes)* extends from the roof of the hard palate to the posterior lip of the foramen magnum; McGregor's line *(solid)* extends from the roof of the hard palate to the most caudal portion of the occipital bone; McRae's line *[dots]* extends from the anterior lip of the foramen magnum ro the posterior lip of the foramen magnum. The tip of the odoiitoid is normally not more than 5 mm above McGregor's line and not above Chamberlain's or McRae's line. (Modified with permission from Roscnhaum, R. B, Campbell, S. M., *&c* Roscnhaum, J. T. 1996, *Clinical Neurology of Rheumatic Diseases,* Burtcrworth-Heinemann, Boston.)

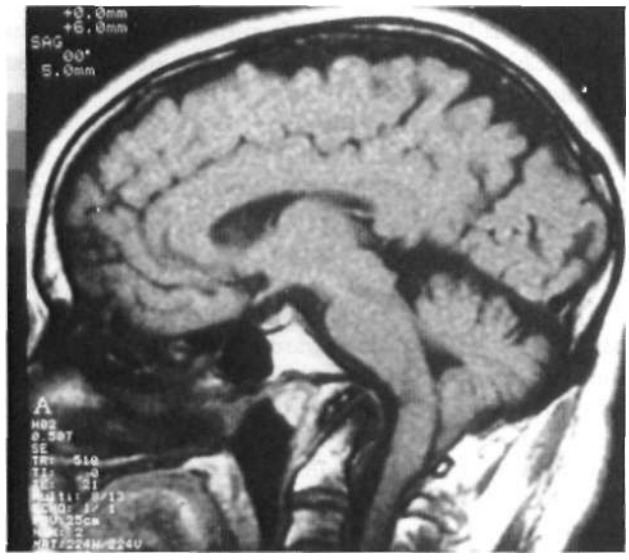

FIGURE 79.3 Magnetic resonance image of a patient with basilar impression showing angulation of the brainstem.

movements of the hands may occur in children with Klippel-Feil anomaly and are attributed to incomplete decussation of the pyramidal tracts. Patients with Klippel-Feil anomaly can have a wide variety of associated abnormalities of brain, spinal cord, or skeletal development, especially congenital scoliosis ot Sprengel's deformity with unilateral shoulder elevation. Patients may develop hydrocephalus, syringomyelia, or syringobulbia. However, most patients with Klippel-Feil anomaly have no neurological symptoms or signs.

FIGURE 79.4 Patient with Klippel-Feil syndrome showing short neck,

Atlantoaxial Dislocation

Various congenital or acquired conditions can disrupt the integrity of the atlantoaxial joint, leading to its dislocation (Table 79.1). In horizontal subluxation, CI usually moves anteriorly to C2. The movement can be assessed by measuring the separation between the dens and the anterior arch of CI on flexion radiographs; in adults, the separation should not exceed *3.5* mm. Patients with horizontal atlantoaxial joint subluxation are likely to compress their spinal cords if the diameter of the spinal canal at the level of the dens is less than 14 mm, and they are unlikely to if the diameter is more than 17 mm. The actual relationship between the cord and the subluxing bones is best imaged wiili MRI or CI myelography, which should include I iix i< >n and extension views. In some patients, particularly those with acquired inflammatory disease, such as rheumatoid arthritis (RA), inflamed adjacent soft tissue contributing to cord compression is best characterized by MRI.

Patients with congenital atlantoaxial dislocation may have associated abnormalities such as Chiari I malformation or diastcmatomyelia. They can develop secondary syringomyelia. Atlantoaxial subluxation in patients with long-standing RA is a prime example of acquired

Table 79.1: Mechanisms of atlantoaxial dislocation

[. Congenital
- A. Os odontoideum (failure of the odontoid to fuse with the body of the axis)
  - 1. Isolated
  - 2, With connective tissue dysplasias (e.g., Down syndrome, pscudoacbondroplasia, multiple epiphyseal dysplasia, spondyloepiphyseal dysplasia, Morquio's disease, Klippel-Feil anomaly, Conradi's syndrome)
- B. Hypoplastic dens
  - 1. With connective tissue dysplasia
  - 2. With incomplete segmentation (e.g., occipital assimilation of atlas, basilar invagination, incomplete segmentation of C2, C3, and so forth)
- C. Other anomalies of C2 (e.g., bifid dens, tripartite dens with os apieale, agenesis of all or part of dens)
- D. Laxity of the transverse arlantal ligament (e.g., Down syndrome)

II. Acquired
- E. Traumatic, acute or chronic un-united dens fracture
- F. Infectious
- G. Neoplastic (e.g., neurofibroma)
- H. Arthritic (e.g., in rheumatoid arthritis, ankylosing spondylitis, renal amyloidosis)
- I. Bone disease (e.g., vitamin D-resistant rickets and others associated with basilar invagination)

abnormality of the atlantoaxial joint and is discussed in more detail later in this chapter. Patients with atlantoaxial subluxation may be asymptomatic, particularly if their spinal canal diameter is generous. However, they are vulnerable to spinal cord trauma during intubation or other neck motion under anesthesia, or in relation to a whiplash injury. Patients at risk of atlantoaxial dislocation, such as those with Down syndrome or chronic RA, should have lateral flexion and extension cervical spine radiography performed before general anesthesia so the anesthesiologist can plan appropriate care during intubation.

Arnold-Chiari Malformation and Syringomyelia

Arnold-Cbiari Mai format ion

Chiari (1891, 1896) described four types of malformations with cerebellar tonsillar displacement. Cleland (1883) had previously written about them. Arnold (1894) reported a case of Chiari II malformation. In current usage, the terms *Arnold-Cbiari* and *Chiari malformation* are often used interchangeably for all four types.

Chiari 1 malformation (Figure 79.5) is characterized by abnormal extension of the cerebellar tonsils below the foramen magnum and is sometimes accompanied by rostral displacement or extension of the medulla. Slight extension of the tonsils below the foramen is normal in childhood, and normal values decrease with increasing age (Table 79.2). Cerebellar tonsillar displacement below the foramen magnum results from downward herniation of the brain caused by mass lesions or sagging of the brain in patients with low intracranial pressure. Patients with Chiari malformations of all types often have hydrocephalus, syringomyelia, or syringobulbia. Patients may have associated bony abnormalities such as basilar impression, occipitalization of the atlas, or CI-level spina bifida.

Chiari I malformations can be asymptomatic (Meadows et al. 2000). Clinical manifestations, which typically begin in young adulthood, can include headaches, visual

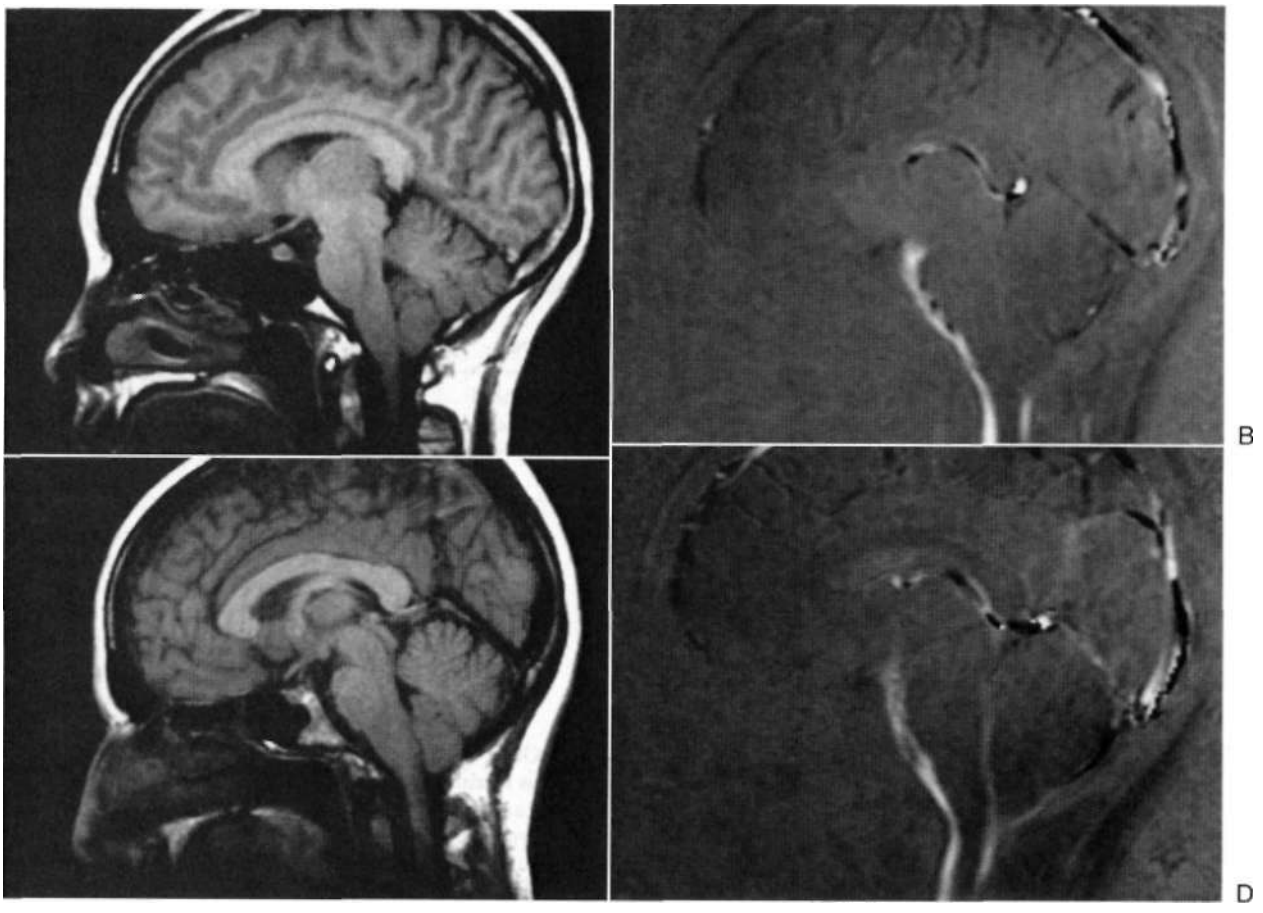

FIGURE 79.5 (A) Sagittal magnetic resonance imaging (MRI) scan of a patient with an Arnold-Chiari type I malformation. This midline Tl-wcighted image demonstrates low cerebellar tonsils, 8 mm below the foramen magnum. (Id VI RI ferebrospirial fluid (CSF) flow study of the same patient demonstrates diminished flow signal at the cerebellar tonsils, indicative of CSF flow propagation abnormality. Notice the normal CSF flow signal below the tonsils and anterior to the brainstem. (C) Sagittal MRI of a patient with low-lying cerebellar tonsils at 6 mm below the foramen magnum, and (D) CSF flow study demonstrating normal flow signal ar the level of the cerebellar tonsils. This is indicative of normal propagation of CSF flow through the foramen magnum.

disturbances, neurootologica! complaints, cranial nerve dysfunction, and sleep apnea (Milhorat et al. *1999).* Motor, sensory, sphincter, and reflex disturbances suggestive of myelopathy can occur whether or not a syrinx is present. Despite speculation and public interest, there is no scientific confirmation of an association between Chiari I malformation and fibromyalgia or chronic fatigue syndrome (Garland and Robertson 2001).

The malformation is best seen on sagittal MRI scans of the brain and cervical spine, which allows assessment of the shape of the posterior fossa, search for any accompanying syrinx, and extent, if any, of brainstem compression. Magnetic resonance cerebrospinal fluid (CSF) flow imaging of CS! pulsation at tin.' for .inu-n magnum in both systole and diastole may provide further information about the significance of tonsillar ectopia, the potential for development of syringohydromyelia, and value of decompressive surgery.

Surgical treatment of Chiari I malformation is aimed at brainstem decompression; any associated syrinx will often improve after improvement in CSF flow.

Chiari II malformation combines the features of Chiari I with caudal displacement of the medulla and fourth ventricle. The brainstem is elongated and distorted at the foramen magnum. Usually, patients have a lumbar myelomeningocele.

In Chiari III malformation, the displaced cerebellar and brainstem tissue extends into an infra tentorial meningocneephalocele.

Chiari IV malformation is characterized by cerebellar and brainstem 1npi>pl;w:i i.i;kr ih.in dn-p aivneni and is probably a variant of the Dandy-Walker malformation.

Hydromyelia, Syringomyelia, and Syringobulbia

Hydromyelia is an abnormal dilatation of the central spinal canal, which almost always communicates with the fourth ventricle. A syrinx is a cavity in the spinal cord (syringomyelia) or brainstem (syringobulbia) (Figures 79.6 through 79.8). The cavity may be connected with a dilatated central spinal canal or may be separate from the central canal. There are several causes of syringomyelia.

Clinical Presentation. The prototypical presentation of a syrinx is the combination of lower motor neuron signs at the level of the lesion (usually in the arms or lower cranial nerves), a dissociated suspended sensory loss (impaired pain and temperature sensation but preserved light touch, vibration, and position sense in a cape or hem i-cape distribution on the arms and upper trunk), and spinal long tract dysfunction below the level of the lesion. However, few patients show this total picture, and the clinical features vary with the size, location, and shape of the cavity and with associated neurological conditions.

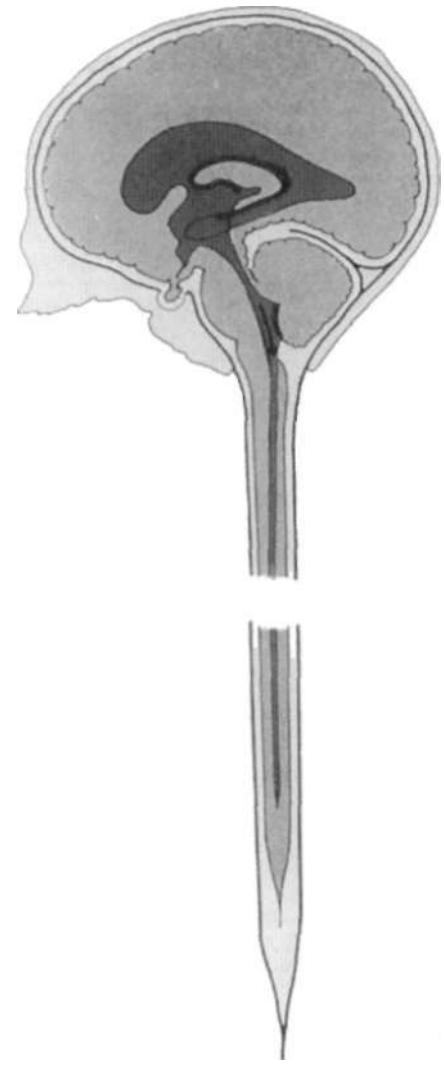

FIGURE 79.6 Diagrammatic representation of persistent central i anal extending throughout the length of the spinal cord.

Fain is a prominent symptom in most patients with syringomyelia. Common complaints include neck ache, headache, back pain, radicular pain, and areas of segmental dysesthesia. Some patients have trophic changes corresponding to the segmental dysesthesia. Sytingomyelia can cause neuropathic monoarthritis (Charcot's joints), most commonly in a shoulder or elbow.

Most syringes are in the cervical spinal cord. Those developing from hydromyelia of the central canal are usually associated with Chiari I or II malformations,

FIGURE 79.7 (A) Sagittal T2-weighted magnetic resonance imaging demonstrates intramedullary signal abnormality posterior to the T1-T3 level of rhe spinal cord. Possible causes include edema, myelomalacia, or syringohydromyelia. (B) Axial computed tomographic myelogram performed at a 3-hour delay demonstrates filling of the area of signal abnormality with myelography contrast that had been injected into the lumbar subarachnoid space. The filling of the cavity with contrast is consistent with syringohydromydia but would not be expected in cases of cord edema or myelomalacia.

FIGURE 79.8 Magnetic resonance image demonstrates a large syringomyelic cavity in the cervical cord.

communicating hydrocephalus, or abnormalities at the craniocerebral junction. Hydromyelia and these associated syringes may be noted as asymptomatic abnormalities on MRI scans obtained to study the cranial problems. When the syrinx enlarges as an asymmetrical localized paracentral outpouching from the hydromyelia, particularly at its cranial or caudal ends or at its level of greatest axial cross section, the paracentral extensions often lead to local segmental signs such as cranial nerve dysfunction in patients with syringobulbia, as well as segmental lower motor neuron signs and dissociated sensory changes at the level of spinal involvement. Patients with eccentric cavities have some combination of long tract and segmental signs depending on the location of the cavity and of any associated cord pathology such as tumor, ischemia, or contusion. A syrinx associated with a spinal cord tumor can occur at any level of the spinal cord.

Although either CT or MRI can demonstrate a syrinx, MRI is more sensitive for complete evaluation of the cord and surrounding soft tissues. CT myelography can be useful in discerning syringohydromyelia, which will commonly fill with contrast on delayed images, because of communication with the CSF through the central canal of the spinal cord (see Figure *79.7A* and B}.

Causes

Communicating and Noncommunicating Syringes. The terms *communicating* and *noncommunicating syringes* indicate whether the syrinx is in communication with the CSF pathways. However, it is often difficult to determine this, even at autopsy, and hence these terms are mainly of use in discussions of etiology. It is better to classify syringomyelia according to its associations.

Abnormalities of the Cervicomedullary Junction

The exact mechanism of production of the syrinx m patients with abnormalities of the cervicomedullary junction and posterior fossa is controversial (Oldfield 2001). The central canal of the spinal cord is normally widely open during embryonic life and becomes atretic after birth. It can be found occasionally to be patent in the adult (see Figure 79,6). It is more commonly dilatated (hydromyelia) when associated with abnormalities of the cervicomedullary junction, including Chiari anomalies types I and 11 and the Dandy-Walker malformation. Syringes often arise in association with hydromyelia and are formed as out-pouchings of the dilatated central canal (see Figures 79.7 and 79.8). One hypothesis is that the posterior fossa abnormalities interfere with the passage of CSF from the fourth ventricle through the foramina of Luschka and Magendic into the subarachnoid space. The consequence is transmission of bulk flow and the various pressure waves of the CSF (arterial, venous, respiratory, and so forth) down the central canal of the spinal cord, leading to dissection of a syrinx into the substance of the spinal cord. Noncongenital abnormalities at the cervicomedullary junction that sometimes cause syringomyelia include arachnoiditis and meningiomas.

Syrinx Associated with Spinal Cord Tumors

Syringomyelia accompanies 25-60% of intramedullary spinal tumors; conversely, 8-16% of syringes are caused by tumors (Figure 79.9). Intramedullary tumors in von Hippel-Lindau syndrome or neurofibromatosis are particularly likely to be accompanied by syringes. The syrinx extends from **the** tumor, more often rostrally than caudally.

Syrinx Associated with Spinal Cord Trauma

Syringes develop as late sequelae in perhaps 3% of cases of serious spinal cord trauma. Symptoms of usually ascending long tract or segmental spinal cord dysfunction develop months or years after the acute traumatic myelopathy has stabilized, improved, or even become asymptomatic. Pain is often a prominent symptom. Findings usually evolve gradually but occasionally worsen suddenly after events such as *a* cough or Valsalva maneuver. The cavity is usually eccentric, arising from an area of post-traumatic myelomalacia, then spreading rostrally or caudally.

Syrinx Associated with Other Focal Spinal Cord Pathologies

Any illness causing arachnoid inflammation can lead to formation of a noncommiinicating syrinx. Reported causes include meningitis, subarachnoid hemorrhage, spinal trauma, epidural infections, epidural anesthesia, myelography with oil-based dyes, and spinal surgery, but many cases of focal arachnoiditis are idiopathic. Syringes can develop as a complication of various intramedullary pathologies including trauma and tumors (see previous discussion), spinal ischemic or hemorrhagic strokes, radiation necrosis, or transverse myelitis.

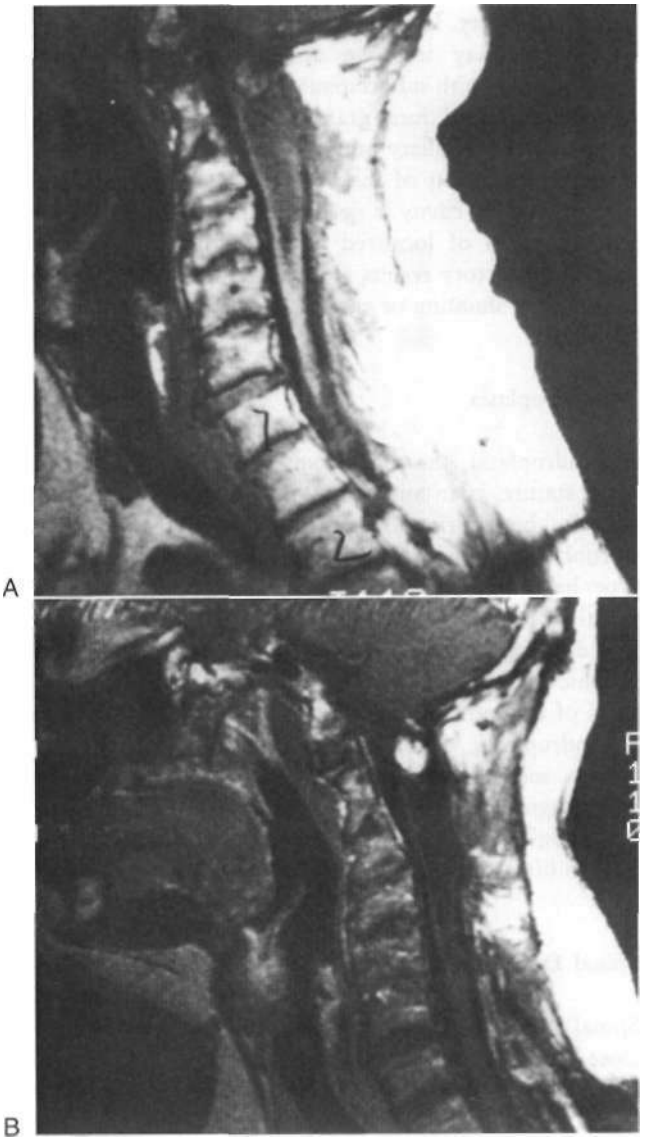

FIGURE 79.9 Magnetic resonance image demonstrates syrinx associated wirh spinal cord tumor (hcmangioblastoma). (A) Tl-weighted image shows enlargement has a nodule on the upper cervical cord caused by a low-signal central mass suggestive of a cyst. The upper border of the cyst has a nodular component. (B) Postgadolimum image shows that the nodule intensely enhances, which is classic for hcmangioblastoma. (Courtesy Erik Ciaensler.)

Treatment. Indications for and approaches to surgical therapy for syringes are far from standardized (Goel and Desai 2000). The cavity may be drained by simple myelotomy or by shunting to the subarachnoid, peritoneal,

or pleural cavity. In patients with Chiari I malformations, the syrinx may improve after decompression of the malformation with suboccipital craniectomy, tipper cervical laminectomy, and dural grafting. When the syrinx extends from an intramedullary tumor, resection of the tumor often leads to regression of the syrinx, so no specific surgical drainage of the cavity is needed. When the syrinx extends from an area of localized arachnoiditis, some surgeons report satisfactory results after resection of the arachnoiditis without shunting or entering the cavity.

Achondroplasia

Achondroplasia, the most common cause of abnormally sin in stature, is ,*m* autosomal dominant disorder of endochondral bone formation caused by a specific mutation of a fibroblast growth factor receptor gene. The mutant genotype has complete penetrance, and approximately three fourths of cases occur because of spontaneous mutation. The diagnosis can be confirmed by pathognomonic radiographic changes or by DNA testing. Neurological complications of achondroplasia are common (Table 79.3). Young achondroplasia children should be observed for complications such as hydrocephalus, compression at the foramen magnum, thoracolumbar kyphosis, and sleep apnea. Neurological complications of spinal stenosis tend to occur later in life.

Spinal Dysraphism

Spinal dysraphism is congenital failure of the neural tube to close during fetal development (Botto et al. 1999). In spina bifida occulta the vertebral elements fail to fuse, but the thecal and neural elements remain within the spinal canal. In spina bifida cystica {also called *spina bifida aperta),* the meninges protrude out of the spinal canal through the bony defect; neural elements may be contained within the protruding sac.

Spina Bifida Occulta

Spinal bifida occulta is usually asymptomatic. It is most common at posterior elements of L5-S1 and is usually noted as an incidental finding on spinal plain radiography (Figure 79.10). Cutaneous abnormalities may be associated (Table 79.4). Orthopedic foot deformities, urinary or rectal sphincter dysfunction, or focal neurological abnormalities can indicate that the spina bifida occulta is associated with compression or malformation of neural tissues or with spinal cord tethering.

Myelomeningocele

Myelomeningocele and meningocele (spina bifida cystica) are congenital defects of spinal closure that when present are often visible on examination of the back of the newborn (Figures 79.12 and 79.13). When the skin and vertebral canal are unclosed, a sac of meninges is directly visible. The defect is most common in the lumbar region. If it contains nerve roots or spinal cord, it is a myelomeningocele; if neural elements are absent from the sac, it is a meningocele. It is often accompanied by hydrocephalus and may be accompanied by cerebellar tonsillar herniation (Chiari II malformation), syringomyelia, or cerebral malformations such as poly microgyria. Initial surgical treatment in utero or in the neonatal period can provide cosmetic repair and decrease the risk of infection; hydrocephalus can be shunted. Any existing myelopathic or radiculopathic neurological deficit is likely to persist after surgery. The infants are at risk for later development of tethered cord syndrome (sec Tethered Cord Syndromes, later in this chapter) or of spinal dermoid or epidermoid inclusion cysts.

Myelomeningocele is the most common major birth defect. An impottant cause is maternal folate deficiency, and most cases would be prevented if women with childbearing potential routinely took 0.4 tng of folic acid daily. Other risk factors include family history of neural closure defects, and maternal treatment with antiepilcptic drugs such as valproic acid. Pregnant women can be screened for serum cr-fetoprotein levels, which are elevated when the fetus has neural closure defects. The defects also can iv delected by fetal ultrasound.

Tethered Cord Syndromes

Congenital abnormalities of the spinal cord or cauda equina can prevent normal cephaiad movement of the conus mcdullaris during early life (McLone and La Marca 1997) (Table 79.5). A child or even an adult with these abnormalities can develop progressive neurological dysfunction due to traction on the cord or nerve roots. The most common neurological finding is unilateral lower motor neuron dysfunction in one leg, but patients can also have sensory, upper motor neuron, or sphincter dysfunction. Children also may present with orthopedic foot deformities or scoliosis.

FIGURE 79.11 Sagittal T]-weighted magnetic resonance image demonstrates several findings. The conus medullaris is low lying; there are lipomas of the filum terminale (bright signals within the central canal); and there is spina bifida with protruding lipomyelomeningocele through the defect *(arrowheads).*

Diastematomyelia (Figure 79,14) is a congenital malformation of the spinal cord characterized by sagittal division of a portion of the cord into two hemicords. In most instances, the division is located in the lower thoracic or lumbar regions. Diastematomyelia is often accompanied by skin abnormalities, such as a tuft of hair at the level of the lesion. If each hemicord is enclosed in its own arachnoid sheath, the sheaths are usually separated by a bony, cartilaginous, or fibrous spur and by dura in the cleft between the two portions of the cord. The spinal cord is usually tethered by the spur, leading to progressive neurological dysfunction as the spinal cord attempts to move upwards upon the spur during growth. The diagnosis can often be suspected on plain radiography, which shows widening of the interpeduncular distance and a posterior bony bridge at the level of the lesion. MRI scans or CT myelography can confirm the diagnosis (see Figure 79.14), Surgical therapy consists of attempts to free all structures tethering the cotd by removing the spurs and dura in the cleft and cutting the filum terminale if abnormal.

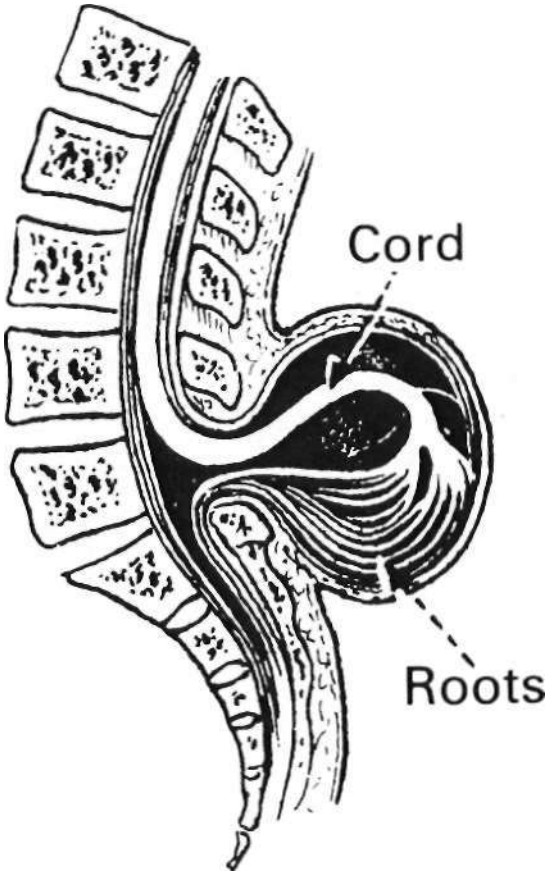

FIGURE 79.12 Diagrammatical representation of myelomeningocele.

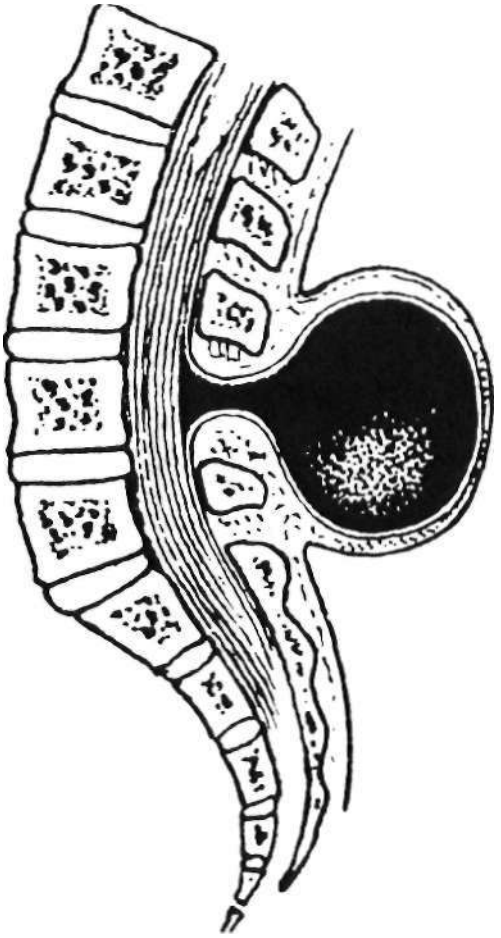

FIGURE 79.13 Diagrammatical representation of meningocele.

Clinical Correlations. A single patient often has more than one of the conditions discussed {Figure 79.15). Thus a patient with one of the Chiari hindbrain malformations also may have some combination of bony abnormalities of the foramen magnum or cervical spine, syringomyelia, and meningomyelocele.

The clinical manifestations of craniocervical deformities are protean depending on which neural structures and associated anomalies are involved. When a patient has these problems, diagnosis and treatment starts by analyzing each component. MRI and CT scans have greatly eased the analytical ptocess. Many patients arc asymptomatic or first present with neurological complaints in adult life. Patients may have short necks or abnormal neck posture or movement, particularly if there is an element of skeletal deformity (e.g., Klippel-Fcil anomaly and occipitalization of the atlas). Findings attributable to the brainstem or cerebellum may occur with Chiari malformations, compression of the brainstem (e.g., basilar impression or vertical displacement of the dens), or syringobulbia. Uncommonly, atlantoaxial disease or basilar invagination can cause compromise of vertebrobasilar circulation, causing posterior circulation strokes or transient ischemic attacks. Specific findings suggestive of disease at the foramen magnum include downbeat nystagmus or the combination of long tract signs with lowet motor neuron dysfunction in the lower cervical spinal cord; the lower

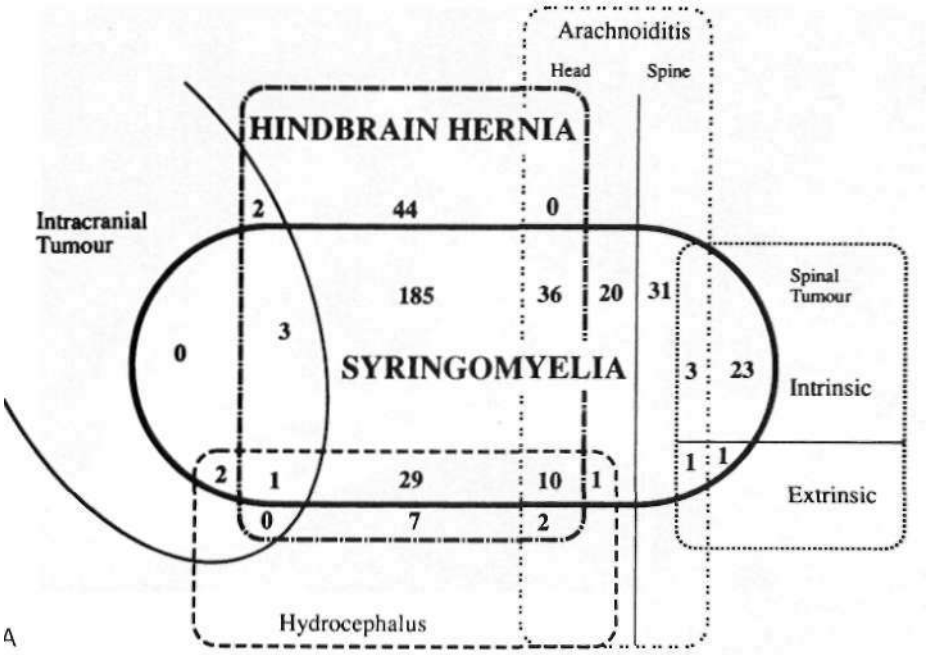
motor neuron dysfunction has been attributed to impaired spinal venous drainage at the foramen magnum.

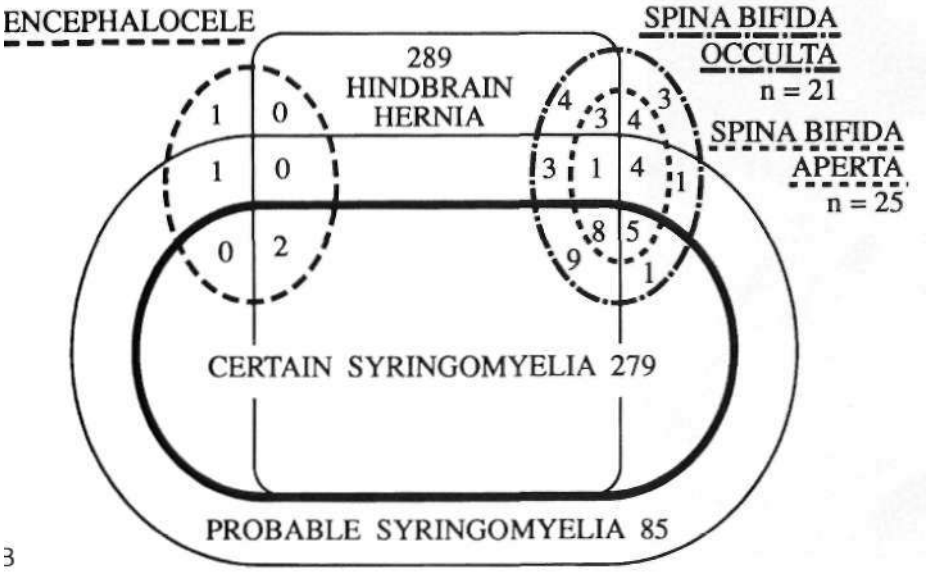
Spinal cord syndromes can be caused by syringomyelia or by extramedullar}' cord compression (e.g., by the dens with atlantoaxial dislocation or by spinal stenosis in Klippel-Eeil anomaly). Additional neurological dysfunction can occur when the anomalies form part of more widespread developmental failure (e.g., lumbar effects of myelomeningocele in Chiari II malformation or accompanying cerebral malformations in Klippel-Feil anomaly).

SPINAL DEFORMITIES AND METABOLIC BONE DISEASE

Osteoporosis

Osteoporotic vertebral compression fractutes occur most commonly in the thoracic and thoracolumbar spine (Figure 79.16). Most occur in postmenopausal women. By age 75 years, nearly one fourth of women have vertebral compression fractures; although these may lead to kyphosis and loss of body height, most are painless. In younget men and





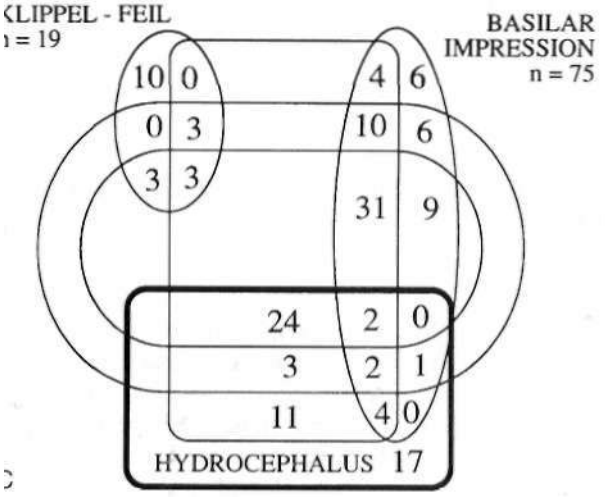


FIGURE 79.15 Venn diagrams show the overlap of various craniospinal abnormalities from patients seen at a center specializing in syringomyelia. The bright appearance of the vertebra indicates preservation of the fat within the marrow compartment, which would be dark if replaced by tumor. (t .on: ley I r.k (..ICII-.IIT. •

women, acute post-traumatic compression fractures arc more likely to be painful. The pain usually is centered at **the level** of the compression and is accompanied by loss of spinal range of motion. Pain increases with activity, decreases with bed rest, and resolves slowly, sometimes incompletely. Percutaneous vertebroplasty with poly-iru-t/iyliiiciii.kTyl.iir c.i:i decrease the duration "I pain (Mathis et al. 2001). Transient radiculopathic pain or spinal cord compression are uncommon complications of this procedure.

Compression fractures not due to metastases infrequently lead to spinal cord or nerve root compression, so if a compression fracture is accompanied by a focal neurological compression syndrome, the possibility of a metastatic vertebral lesion should be considered. MRI features that favor a malignant cause of the compression fracture include decreased Tl-weighted and increased T2-weighted signal in the vertebral body, pedicle involvement, and associated epidural or paravertebral mass (Do 2000}.

Osteogenesis Imperfecta

The various types of osteogenesis imperfecta are inherited connective tissue disorders manifested by brittle osteopenic bones and recurrent fractures. Four types are known, with variations in severity and in associated findings such as short stature, blue sclera, bearing loss, scoliosis, and skeletal abnormalities. Potential neurological complications of osteogenesis imperfecta include communicating hydrocephalus, basilar invagination, macrocephaly, skull fractures, and seizure disorder. The basilar invagination can lead to brainstem compression (Hayes et al. *1999).* Spinal cord compression, syringomyelia, Chiari I malformation, Dandy-Walker cysts, leptomeningeal cysts, microcephalus, or central nervous system tumors are rarer associations.

Osteomalacia and Rickets

Osteomalacia and rickets are conditions of deficient bone mineralization. Usually long bones arc more involved than the spine. Spinal pain, kyphosis, and compression fractures can occur in osteomalacia, bui compression ot -.pina. cord or nerve roots is rare. Basilar impression can occur in patients with osteomalacia. The neuromuscular complications of osteomalacia are discussed in Chapter H5.

Osteopetrosis

Osteopetrosis is a rare disease characterized by increased bone density caused by impaired bone resorption (Figure 79.17). It may be inherited as an autosomal dominant or

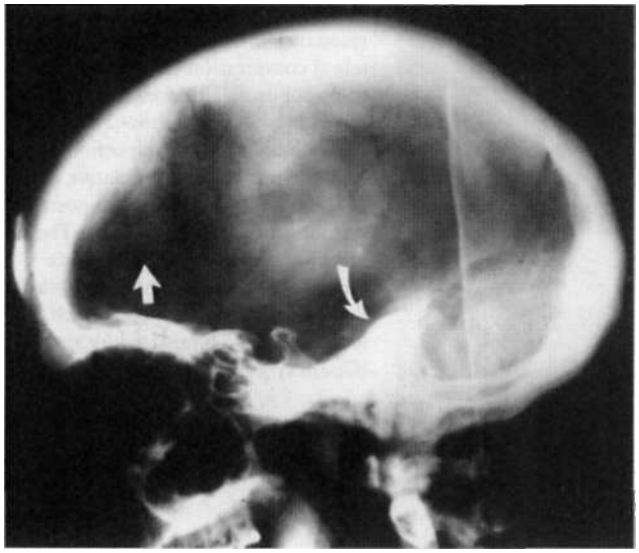

FIGURE 79.17 Radiograph of patient with osteopetrosis. The skull is extremely dense. The radiograph is slightly overexposed; note the darkness of the central areas *{arrow).* The bone of the petrous apex *{curvedarrow)* is particularly dense. (Courtesy Erik Gaensler.)

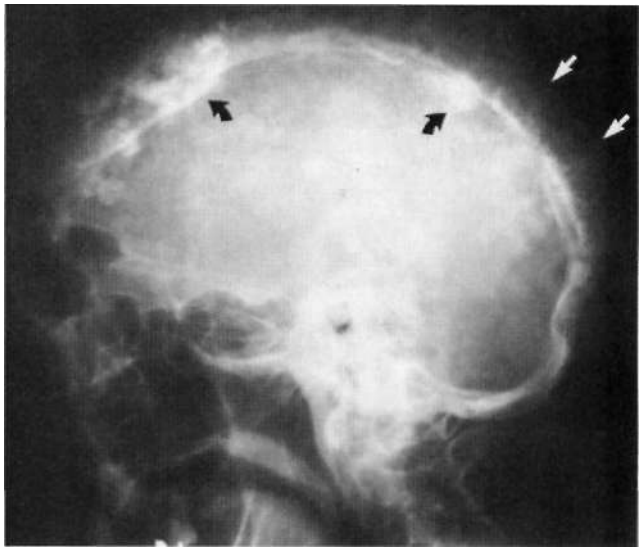

FIGURE 79.18 Radiograph of patient with Paget's disease of the skull. (Courtesy Erik Gaensler.)

recessive disorder. Osteopetrosis of the skull can cause cranial neuropathies, basilar impression, hydrocephalus, or syringomyelia. Osteopetrosis of the spine can contribute to spinal canal stenosis with secondary compressive myelopathy.

Pager's Disease

Paget's disease is a focal metabolic bone disease of excessive osteoclastic bony destruction coupled with reactive osteoblastic activity (Poncelet 1999) (Figure 79.18). The incidence increases with age and varies among ethnic groups, with a high incidence (nearly 5%) in elderly whites of Northern European descent. Men are slightly more commonly affected. The current leading pathogenic hypothesis is that a chronic viral infection of osteoclasts causes the illness and genetic factors affect susceptibility. The condition is usually asymptomatic and discovered only because of laboratory or radiographic abnormalities. However, it may cause symptoms by bone or joint distortion, fractures, compression of neurological tissue by calcification, hemorrhage, or focal ischemia caused by a vascular steal by the metabolically hyperactive bony tissue. It may also cause hypercalcemia, especially if the patient becomes bed bound. Uncommonly, neoplasms, especially osteogenic sarcoma, can develop in pagetic bone.

Diagnosis

Pager's disease usually can be diagnosed by characteristic findings on radiography. Osteolytic activity can cause well-demarcated round patches of low bone density. Osteoblastic activity can lead to thickening of cortical bone and then to a general increase in bone density, often with distortion of normal organization. Osteolytic and nsicnNastic findings arc often present together,

Although most patients with Paget's disease have elevation of serum bone alkaline phosphatase and of markers of bone resorption, focal skeletal disease with neurological complications may occur in patients without laboratory abnormalities. Alkaline phosphatase levels, when elevated, are helpful not only in making the diagnosis but also in following response to treatment.

Cranial Neurological Complications

Paget's disease of the skull can lead to head enlargement, Patients often complain of headache. The most common focal neurological manifestation is hearing loss. Paget's disease of the cribriform plate can disrupt olfaction. Other cranial mononeuropathies, including optic neuropathy, trigeminal neuralgia, and hemifacial spasm, can occur. Distortion of the posterior fossa or basilar invagination can lead to brainstem or cerebellar compression, hydrocephalus, or syringomyelia. Patients with Paget's disease of the skull occasionally develop seizures. The pagetic skull is more • Li 11 IL- : ,i 1>I L t;> b k n L i u ; l i o i n :i 1:01 I: • i mi, ; , which can lead to epidural hematoma.

Spinal Neurological Complications

Symptomatic Paget's disease of the spine occurs most often in the lumbar region, where it can cause monoradiculopathies or a cauda equina syndrome. The disease may

involve adjacent vertebra) bodies and the intervening disc-space or may cause root compression by extension from a single vertebral body. The differential diagnosis in patients with Paget's disease and neurological dysfunction in a single limb includes peripheral nerve entrapment by pagetic bone.

Paget's disease of the spine leading to myelopathy is more often thoracic than cervical. A variety of mechanisms arc reported, including extradural extension of pagetic bone, distortion of the spinal canal by vertebral compression fractures, spinal epidural hematoma, or sarcomatous degeneration leading to epidural tumor. In a few cases of myelopathy, imaging shows no evident cord compression, and vascular steal from the cord by hypermetabolie bone in the vertebral body is suggested. In support of this hypothesis, drug treatment of Paget's disease in these patients can lead- to improved spinal cord *t*unction.

Treatment. The potent bisphosphonates are the drugs of first choice for treatment of Paget's disease. Other treatment options include calcitonin, plicamycin, ipriflavone, or gallium nitrate. Within 1-2 weeks of treatment, bone pain may improve, and serum alkaline phosphatase levels may decrease. Some patients experience significant neurological improvement after treatment, but improvement is often delayed 1-3 months. In cases with severe cord compression, surgical decompression is indicated, but drug treatment before surgery decreases the risk of operative bone hemorrhage. Patients with cranial neuropathy have less impressive responses to drug therapy. Patients with hydrocephalus may benefit from ventricular shunting.

Juvenile Kyphosis

Juvenile kyphosis (Scheuermann's disease) manifests as thoracic or thoracolumbar 1-. •-•hnM-. m .idolcM-i-nK. Spinal pain is more likely to accompany lumbar than thoracic disease. Spinal radiography shows anterior vertebral wedging. Neurological abnormalities are uncommon, but spinal cord compression can occur from thoracic disc herniation or direct effects of severe kyphosis.

Scoliosis

Scoliosis, with or without kyphosis, which develops as an idiopathic painless condition in childhood and adolescence, is usually not accompanied by neurological abnormalities. Most cases are idiopathic, but a minority have an accompanying tumor, spondylolisthesis, syrinx, or Chiari I malformation. Indications for spinal MRI include pain, progression suddenly or after spinal maturity, thoracic curvature to the right, or abnormal neurological examination (Oestreich, Young, Young Poussaint 1998). Spinal cord compression is a rare complication of idiopathic scoliosis and is particularly rare if no kyphosis is present. In each patient presenting with scoliosis and myelopathy, an important consideration is whether the myelopathy caused, rather than resulted from, the scoliosis.

Patients with congenital scoliosis, unlike those with idiopathic scoliosis, usually have anomalous vertebrae and may have other associated developmental problems such as Klippel-Feil anomaly or diastematomyelia. Scoliosis caused by skeletal disease, such as achondroplasia, is more likely than idiopathic scoliosis to lead to spinal cord compromise. Myelopathy can result also from spinal cord distraction during treatment of scoliosis with traction or surgery.

Scoliosis can be caused by various neurological diseases including cerebral palsy, spinocerebellar degenerations (e.g., Friedreich's ataxia), inherited neuropathies (e.g., Charcot-Marie-Tooth disease), myelopathies (e.g., syringomyelia), paralytic poliomyelitis, spinal muscular atrophy, dysautonomia (e.g., Riley-Day syndrome), and myopathies (e.g., Duchcnne's muscular dystrophy). Scoliosis is the most common skeletal complication of neurofibromatosis type 1. Scoliosis that develops in adulthood can often be traced to an underlying cause such as trauma, osteoporotic fracture, degenerative spondylosis, or ankylosing spondylitis; it can result in local back pain, nerve root compression, or spinal canal stenosis.

Diffuse Idiopathic Skeletal Hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) (Forestier disease, ankylosing hyperostosis) is a syndrome of excessive calcification that develops with aging, more often in men than in women. The diagnosis is made by spinal radiographs that show "flowing" calcifications along the anterior and lateral portion of at least four contiguous vertebral bodies without loss of disc height and without typical radiographic findings of ankylosing spondylitis (Figure 79.19). Patients are often asymptomatic but may have spinal pain or limited spinal motion. Large anterior cervical calcifications can contribute to dysphagia, hoarseness, sleep apnea, or difficulty with intubation. A rare complication is myelopathy caused by spinal stenosis if the calcifications are present also within the spinal canal. Like patients with ankylosing spondylitis, patients with diffuse idiopathic skeletal hyperostosis can develop spinal fractures after relatively minor trauma.

Ossification of the Posterior Longitudinal Ligaments or Ligamcntum I'lavum

Ossification of the posterior longitudinal ligament anterior to the spinal canal (Figure 79.20) and ossification of the ligamcntum flavum posterior to the spinal canal are uncommon syndromes of acquired calcification. The posterior longitudinal ligament extends the length of the spine, scpatating the posterior aspects of the discs and

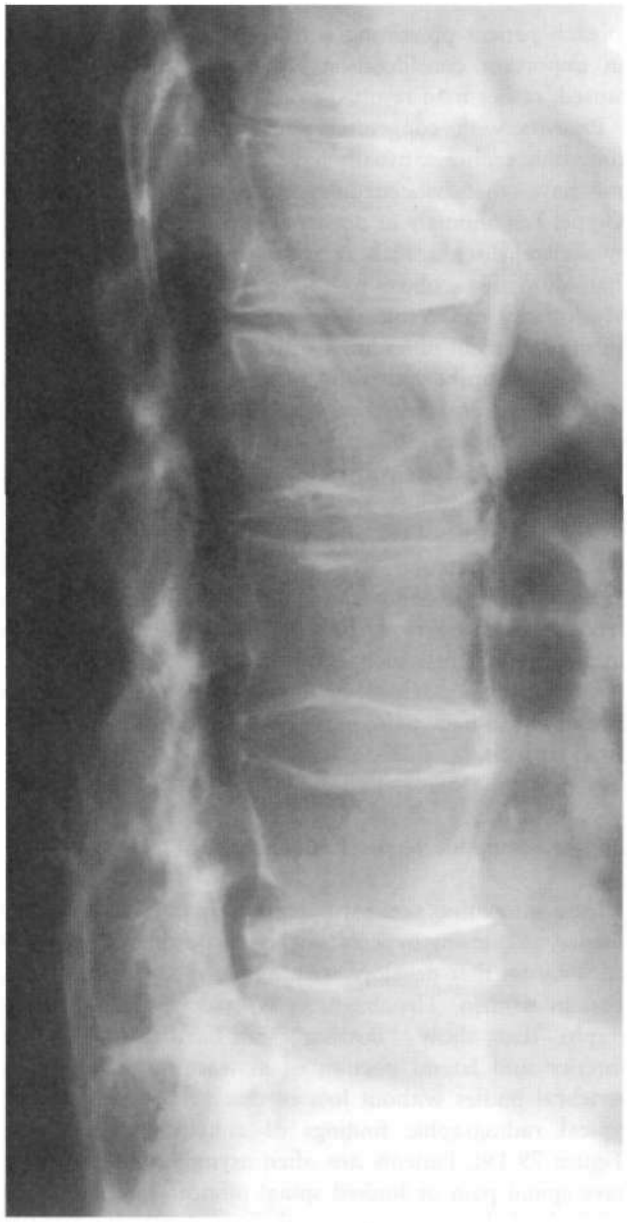

FIGURE 79.19 Lateral thoracic spinal radiograph shows diffuse idiopathic skeletal hyperostosis. Note the flowing calcification of the anterior osteophytes with preservation of disc heights. (Reprinted with permission from Roscnbaum, R. B., Campbell, S. M., & Rosenbaum, J. T. 1996, *Clinical Neurology of Rheumatic Disease,* Butterworth-1 ieineinann, Boston.)

vertebral bodies from the thecal sac. The ligamentum flavum is in the dorsal portion of the spinal canal, attaching the laminae and extending to the capsules of the facet joints and the posterior aspects of the neural foramina. Either ligament can ossify in later life, apparently independently of the usual processes of spondylosis and degenerative arthritis. Ossification of the posterior longitudinal ligament occurs more commonly in Orientals than in non-Orientals. It may be visible on lateral spinal radiography but is usually asymptomatic. It is better seen by CT scan, in which it is distinguished from osteophytes by favoring the middle of the vertebral bodies rather than concentrating at the endplates. Thickness of the calcification can range from 3-15 mm. Ossification of the posterior longitudinal ligament is most likely to be symptomatic in the cervical spine where it can contribute to cord compression if it is rhiek or it the canal is lunbr- narrowed K congenital md degenerative changes.

The ligamentum flavum can contribute by hypertrophy or ossification to spinal stenosis, most often in the lower thoracic or lumbar spine, affecting the cord or cauda equina. Risk factors for development ot ossification of the ligamentum flavum include trauma, hemochromatosis, calcium pyrophosphate deposition disease, diffuse idiopathic skeletal hyperostosis, ankylosing spondylitis, or ossification of the posterior longitudinal ligament.

DEGENERATIVE DISEASE OF THE SPINE

Spinal Osteoarthritis and Spondylosis

Osteoarthritis of the spinal facet joints manifests radiographically as joint narrowing, sclerosis, and osteophyte formation. Spondylosis refers to degenerative disease of the intervertebral discs, visible on radiography as disc space narrowing, vertebral endplate sclerosis, and osteophyte development. Spinal osteoarthritis and spondylosis are inevitable consequences of aging that are visible on routine spinal radiography in more than 90% of people by age 60 years. They are usually asymptomatic but cause compression of the spinal cord or nerve roots in a minority of people. Nonetheless, they are the most common cause of compressive myelopathy or radiculopathy, accounting for far more neurological disease than all the other conditions discussed in this chapter combined,

In youth, the intervertebral discs consist of a gelatinous central nucleus pulposus and a firm collagenous annulus fibrosus. The disc herniation syndromes occur when the nucleus pulposus bursts through a tear in the annulus fibrosus. This herniation can compress the nerve roots or spinal cord, depending on the spinal level involved. Rarely, disc material breaks into the thecal sac or a fragment ruptures into an epidural vein. Disc herniation is most likely to occur in young adults.

By age 40 years, most adults have some disc degeneration with dehydration and shrinkage of the nucleus pulposus, necrosis and fibrosis of the annulus fibrosus, and sclerosis and microfractures of the subchondral bone at the vertebral endplate. Compression of neurological tissue can develop from a combination of disc herniation, osteophyte formation, ligament hypertrophy, congenital stenosis of the spinal canal, low-grade synovitis, and deformity and misalignment of the spine.

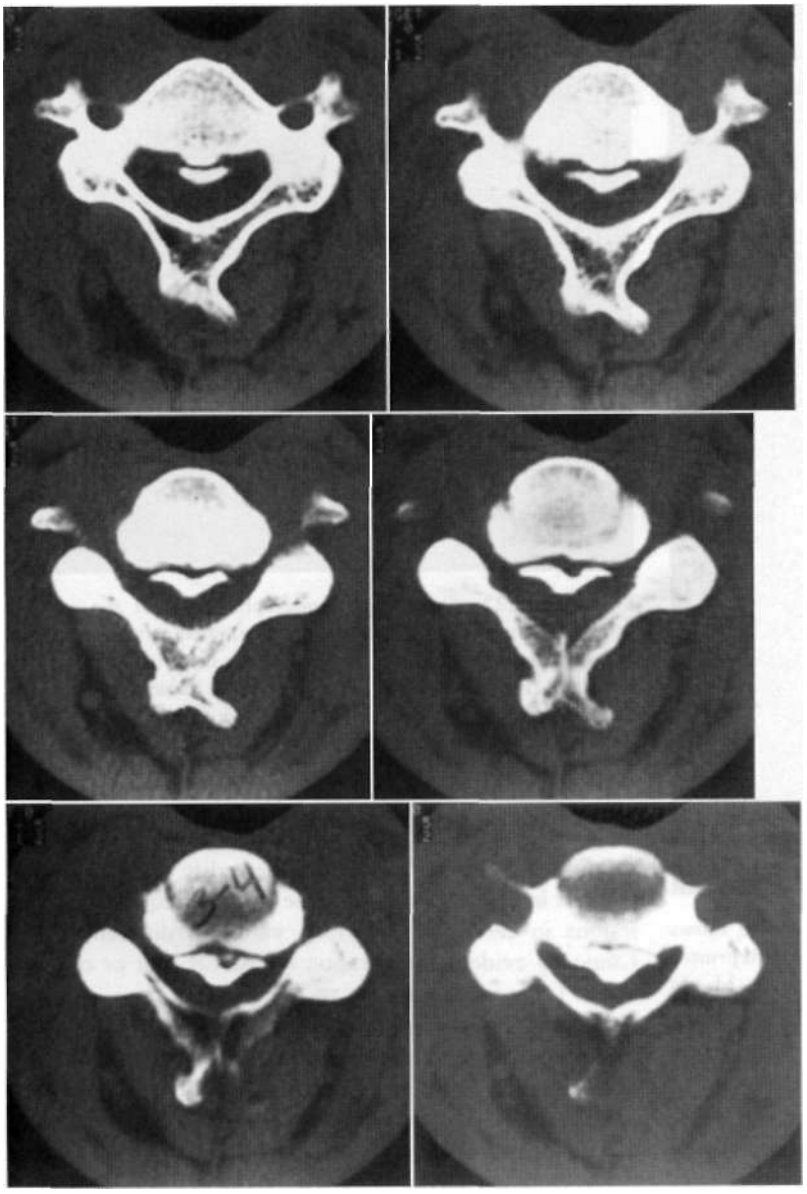

FIGURE 79.20 Computed tomographic scan of a patient with ossification of the posterior longitudinal ligament. Note the continuous bony ridge that is present at every level, nor just at the disc space. In contrast to calcified degenerative spurs, these ligamentous calcifications are not connected to the vertebral bodies. (Courtesy Erik Gaensler.)

Cervical Spondylosis

The cervical spinal column includes 37 joints that are continually in motion throughout life. Cervical osteoarthritis and spondylosis are ubiquitous with increasing age (Figure 79,21), These disorders can be attributed only rarely to specific activities or injuries. Patients with dystonia and other cervical movement disorders may be predisposed to premature cervical spinal degeneration. Because cervical osteoarthritis and spondylosis are so commonplace, it is usually difficult to ascertain their role in contributing to the pathogenesis of chronic neck pain or headache. Cervical spine surgery is rarely, if ever, indicated for treatment of headache or neck ache in the absence of cervical radiculopathy or myelopathy.

Cervical Radiculopathy

Clinical Presentation

The symptoms of cervical radiculopathy often appear suddenly. Although disc herniation or nerve root contusion can be caused by acute trauma, many cases become symptomatic without an identifiable preceding traumatic event. Disc herniation is more likely to be the cause in patients younger than 45 years; neural foraminal stenosis by degenerative changes becomes more likely with increasing age. Pain is usually in the neck with radiation to an arm; patients may also have headache. Radiculopathic arm pain may increase with coughing or with the Valsalva maneuver. Arm pain may increase with neck rotation and flexion or extension to the side of the pain (Spurliug's sign).

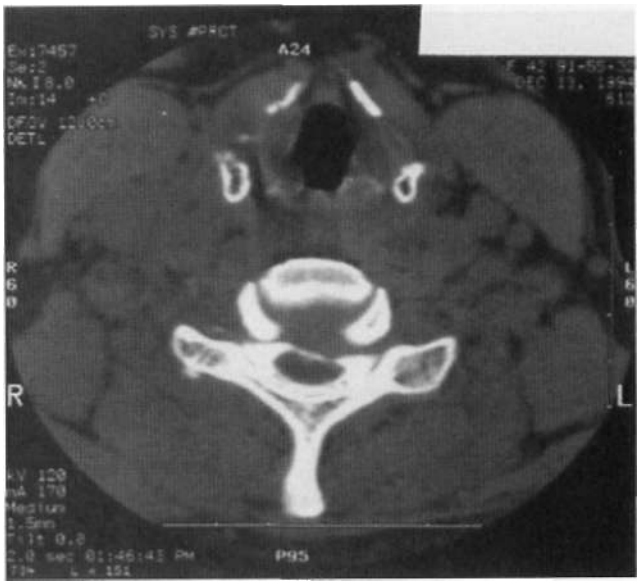

FIGURE 79.22 Computed tomographic scan of the cervical spine with intrathecal contrast shows herniated cervical disc. The spinal cord *{gray)* and thecal sac *(white)* arc distorted on the left by the disc. (Reprinted with permission from Rosenbaum, R. B,, Campbell, S. M., & Rosenbaum, J. T. 1996, *Clinical Neurology of Rheumatic Disease,* Buttcrworth-Heinemann, Boston.)

Spondylosis, osteophytes, and disc herniations at the C4-C5 level can affect the C5 root, causing pain, paresthesias, and sometimes loss of sensation over the shoulder, with weakness of the deltoid, biceps, and brachioradialis muscles. The biceps and supinator reflexes may be lost. Spread of the biceps reflex to the finger flexors, an increased triceps reflex, or an inverted biceps reflex (absent or reduced biceps reflex with reflex contraction of the finger flexors, or rarely the triceps) suggest the presence of a myelopathy at the C6 level. Spondylotic lesions at the *C5-C6* level can affect the C6 cervical root and cause paresthesias in the thumb or lateral distal forearm and weakness in the brachioradialis, biceps, or triceps. The biceps and brachioradialis reflexes may be diminished or inverted. Lesions at the C6-C7 level, compressing the C7 root, cause paresthesias, usually in the index, middle, or ring fingers, and weakness in C7-inncrvated muscles, such as the triceps and pronators. The triceps tendon reflex may be diminished.

The C5, C6j and C7 roots are the ones most commonly involved in cervical spondylosis, because they are at the level of greatest mobility, where disc degeneration is greatest in the cervical spine. The relative frequency of root lesions in cervical spondylosis varies in different series. Clinically evident compression of the C8 root or of roots above *CS* is more rare.

Cervical radiography is of little value in diagnosing or excluding cervical radiculopathy. MRI scanning of the cervical spine is usually helpful in identifying nerve root compression in patients with cervical radiculopathy. Cervical myelography followed by CT scanning is sometimes more sensitive than MRI (Figure 79.22). However, MRI may show nerve root compression, particularly in the neural foramina, which is invisible by CT. CT myelography is also better than MRI for distinguishing disc herniation from osteophytes. However, cervical MRI or CT myelography must be interpreted with caution because degenerative abnormalities are so commonly seen in the asymptomatic spine. Electromyography and nerve conduction studies can be useful in difficult diagnostic cases, both by identifying an affected motor nerve root and myotome and by helping to exclude other diagnoses, such as brachial plexopathy or peripheral neuropathy (Nardin et al. 1999).

Treatment

Most instances of cervical radiculopathy improve significantly over 4-8 weeks, regardless of treatment. Various treatments such as nonsteroidal anti-inflammatory drugs, use of a soft cervical collar, physical therapy, or cervical

traction give similar results. Patients with a typical clinical presentation and little or no neurological deficit usually can he managed with these noninvasive approaches without radiography or electrodiagnostic studies. When patients have intractahlc weakness or pain or have not improved with nonoperative therapy, surgical nerve root decompression is usually successful; however, there is little randomized, controlled comparison of nonoperative therapy and surgery (Fouyas, Statham, and Sandercock 2002). Anterior cervical discectomy is used more widely than posterior cervical laminectomy.

Cervical Spondylotic Myelopathy

Myelopathy caused by compression of the cervical spinal cord by the changes of spondylosis and osteoarthritis usually develops insidiously, but it may be precipitated by trauma or progress in stepwise fashion. Typical findings are a combination of leg spasticity, upper extremity weakness or clumsiness, and sensory changes in the arms, legs, or trunk. Either spinothalamic tract-mediated or posterior column-mediated sensory modalities may be impaired. Sphincter dysfunction, if it occurs, usually is preceded by motor or sensory findings. Neck pain is often not a prominent symptom, and neck range of motion may or may not be impaired. Some patients experience leg or trunk paresthesia induced by neck flexion (Lhermitte's sign).

The anterior-posterior diameter of the cervical spinal cord is usually 10 mm or less. Patients rarely develop cervical spondylotic myelopathy if the congenital diameter of their spinal canal exceeds 16 mm. In congenitally narrow canals, disc protrusion, osteophytes, hypertrophy of the ligamentum flavum, ossification of the posterior longitudinal ligament, and vertebral body subluxations can combine to compress the spinal cord. The relation between the spinal canal and the spinal cord can be imaged by MRI or CT myelography (Figure 79.23). MR1 provides more intramedullary detail such as secondary cord edema or gliosis. CT provides better images of calcified tissues. Even with excellent cross-sectional imaging of the spinal canal, the clinical correlation between neurological deficit and cord compression is imperfect; dynamic changes in cord compression and vascular perfusion undoubtedly contribute to the pathogenesis of cervical spondylotic myelopathy.

The natural history ot cervical spondylotic myelopathy is variable. Some patients may have stable neurological deficit for many years without specific therapy, whereas other patients may have gradual or stepwise deterioration. Some patients improve with treatments such as bed rest, soft collars, or immobilizing collars, but these treatments have not been assessed in controlled trials. Many patients with cervical spondylotic myelopathy are treated by surgical decompression with variable surgical results (Figure 79,24). Surgical and nonsurgical treatment results are best when the neurological deficit is mild and present less than *6* months and when the patient is younger than 70 years. Anterior cervical discectomies are generally performed for spondylotic lesions at a limited number of levels, whereas posterior laminectomy, sometimes with an expanding laminoplasty, is generally performed for congenital spinal canal stenosis.

Vertebral Artery Stroke Caused by Cervical Osteoarthritis

Compression of a vertebral artery by an osteophyte is a rare cause of stroke in the vertebrobasilar circulation. The vertebral arteries pass through the foramina in the transverse processes from C6-C2. Osteophytes from the uncinate joints can compress the arteries. The compression may occur only with head turning. However, the turning usually leaves the contralateral vertebral artery uncompressed, so ischemic symptoms are usually limited to those patients who have both osteophyte arterial compression on one side and a contralateral hypoplastic, absent, or occluded artery,

Thoracic Spondylosis

Degenerative changes are less common in the thoracic than in the lumbar or cervical spines (Vanichkachorn and Vaccaro 2000). Thoracic osteophytes are more likely to develop on the anterior or lateral aspects of the vertebral bodies and infrequently cause clinical radiculopathy. Thoracic disc herniations arc visible on MRI in many-asymptomatic individuals. Thoracic disc herniations occur most often in the lower thoracic spine. These rarely cause cord or root compression and may regress spontaneously.

Thoracic myelopathy caused by disc herniation probably has an annual incidence of approximately I case per i million. Most cases occur between ages 30 and 60 years. Symptoms often develop insidiously, without identifiable preceding trauma. Back pain may or may not be present. Patients have some combination of motor and sensory findings of myelopathy; sphincter dysfunction is present in more severe cases. Thoracic MRI, CT, or myelography can confirm the diagnosis (Figure 79.25). The treatment is surgical decompression.

Lumbar Spondylosis

Low Back Pain

Approximately 80% of people experience episodes of acute low back pain, which usually resolve within a few days. These episodes often recur, and approximately 4% of people report chronic low back pain. Pain-sensitive structures in the lumbar region include the nerve roots,

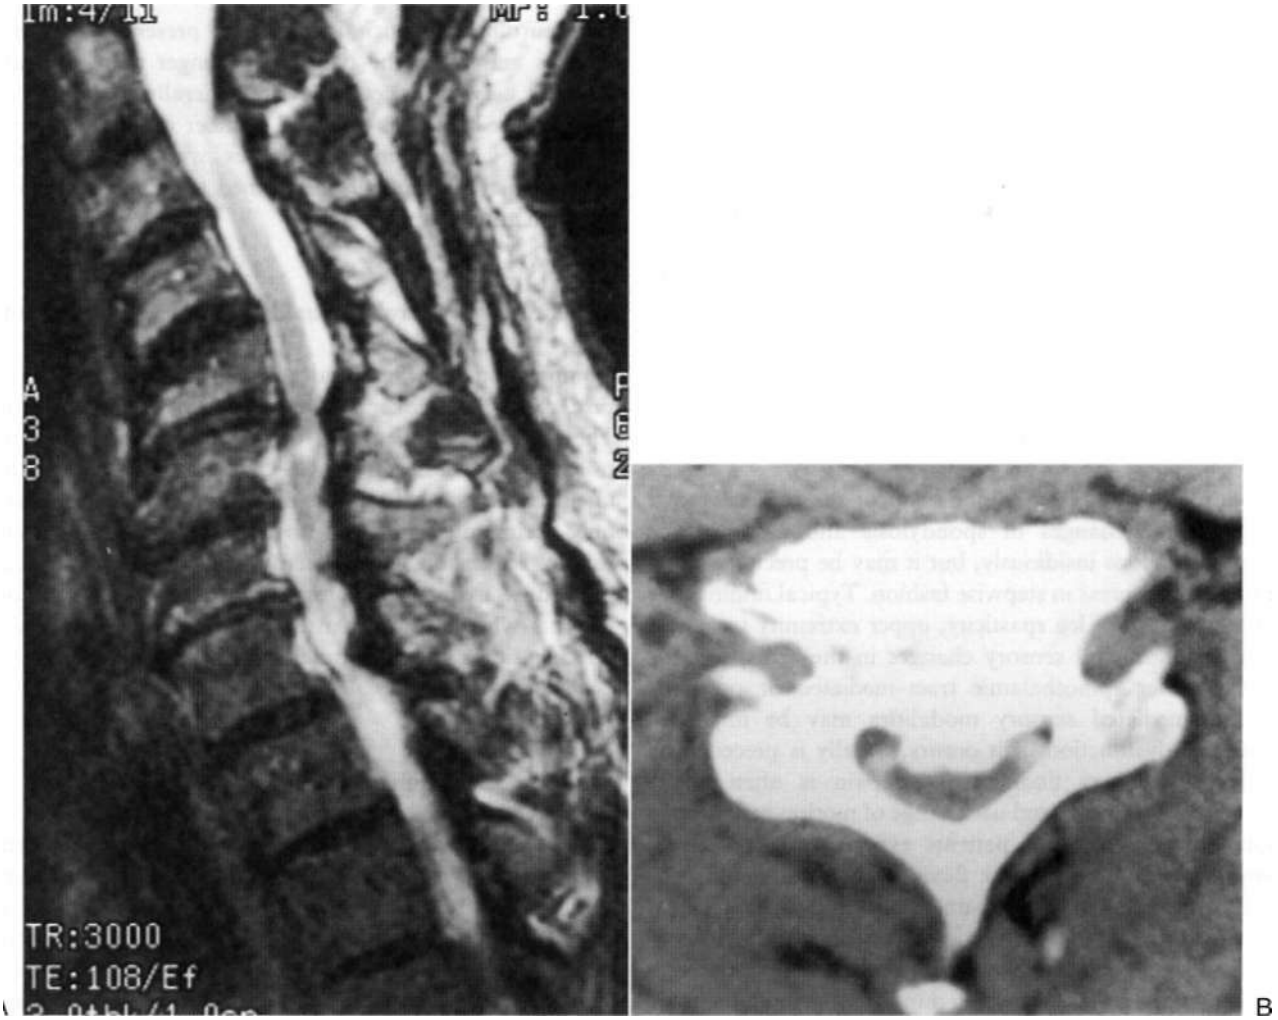

FIGURE 79.23 Cervical spondylotic myelopathy. (A) The sagittal T2-weighted magnetic resonance imaging scan shows maximal compression of the thecal sac and spinal cord at C5-C6. (B) The axial computed tomographic scan with intrathecal contrast at this level shows a large osteophyte arising from the posterior aspect of the vertebral hody; the spinal cord at this level is compressed, and the thecal sac is so compressed that little of the white intrathecal contrast is visible. (Reprinted with permission from Rosenbaum, R. B., Campbell, S. M., & Rosenbaum, J. T. 1996, *Clinical Neurology of Rheumatic Disease*, Burterworth-Heinemann, Boston.)

zygapophyseal joints, sacroiliac joints, intervertebral ligaments, muscles, fascia, annulus fibrosis and circumferential portions of the discs, and vertebral periosteum. Controlled local anesthetic injection studies suggest that in some patients, the cause of low back pain can be localized to specific zygapophyseal joints or sacroiliac joints. In other patients, injection of contrast media into lumbar discs reproduces pain, suggesting that the lumbar disc is the source of pain in these patients. However, this localization cannot be achieved reliably by history or physical examination, and with current therapeutic techniques, invasive testing for localization is not valuable in planning therapy. Furthermore, localization of the source of pain is unsuccessful in many patients. Thus in clinical practice, "nonspecific lm\ h,;c \ pain" i- .1 i< minimi ly made diagnosis.

The findings of osteoarthritis and lumbar spondylosis on radiography (osteophytes, endplate sclerosis, disc space narrowing) appear gradually with increasing age and are rarely absent by age 60 years (Figure 79.26). The presence or absence of these findings does not correlate with symptoms and demonstrating them is of no diagnostic or therapeutic value. Therefore radiography of the lumbar spine is indicated only when alternative diagnoses such as compression fractures, neoplasia, or infections are being seriously considered. The Agency for Health Care Policy and Research has recommended that spinal radiography be reserved for patients with "red flags" for trauma, tumor, or infection (Table 79.6). Kven limiting radiography to patients meeting these guidelines results in many needless radiographs. For example, hack pain in a patient older than 50 years need not be an indication for imaging studies, unless other findings suggest a condition more serious than nonspecific low back pain.

Lumbar disc disease has multifactorial etiologies, including body habitus, type and amount of physical activity,

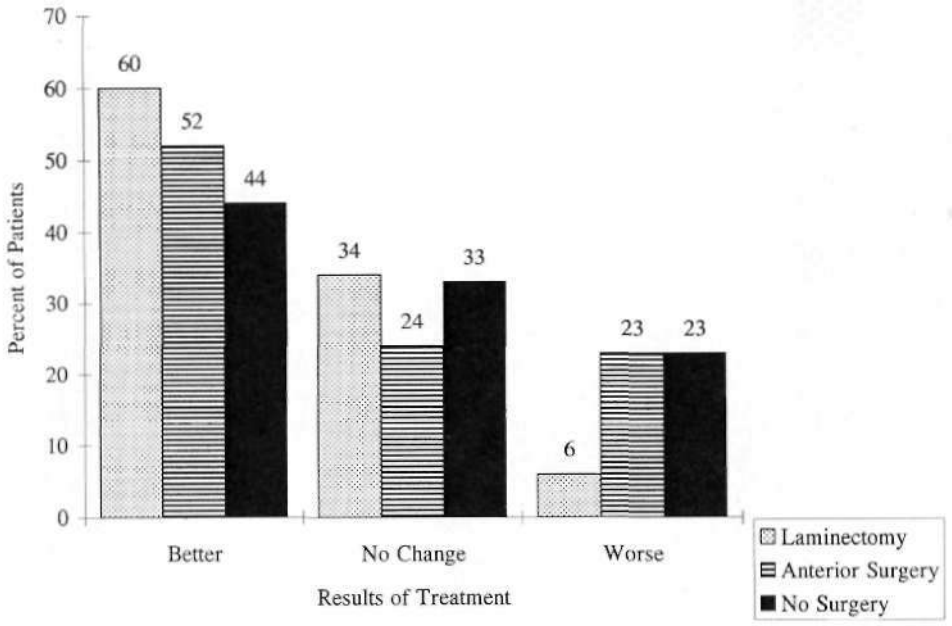

FIGURE 79.24 Results of treatment of cervical spondylotic myelopathy. (Reprinted with permission from Rosenbaum, R. B., Campbell, S. M., £c Rosenbaum, J. T. 1996, *Clinical Neurol*V>*gy of Rheumatic Disease,* B u tter wort h -H c ine ma nn, Boston.)

acute injury, and genetic predisposition. The genetic factor is illustrated by the tendency for lumbar disc herniations to occur in families (Marini 2001). Allelic differences in collagen IX, a component of the annulus fibrosus, nucleus pulposus, and endplates, appear to affect the risk of developing symptomatic disc herniations (Paassilta et al. 2001).

Spondylolysis and Spondylolisthesis. Spondylolisthesis is displacement of one lumbar vertebral body relative to an adjacent vertebral body. Some cases are caused by spondylolysis, a discontinuity in the vertebral pars interarticularis, which disrupts the normal stabilizing effect of the facet joints. Other causes of spondylolisthesis include congenital vertebral anomalies, degenerative spondylosis,

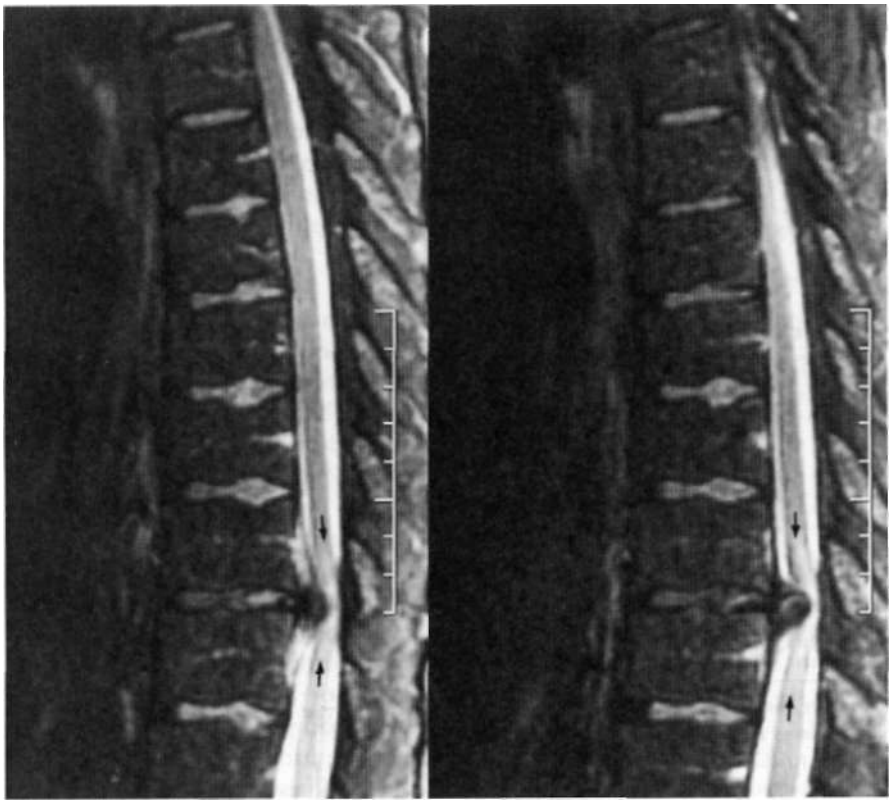

FIGURE 79.25 Thoracic magnetic resonance image of a patient with thoracic disc herniation. This large acute disc herniation at T10-T11 consists of extrusion of most of the nucleus pulposus into the spinal canal. There is secondary narrowing of the disc space. There is spinal cord edema *(arrows)* above and below the level of spinal cord compression. (Courtesy Erik Gaensler.)

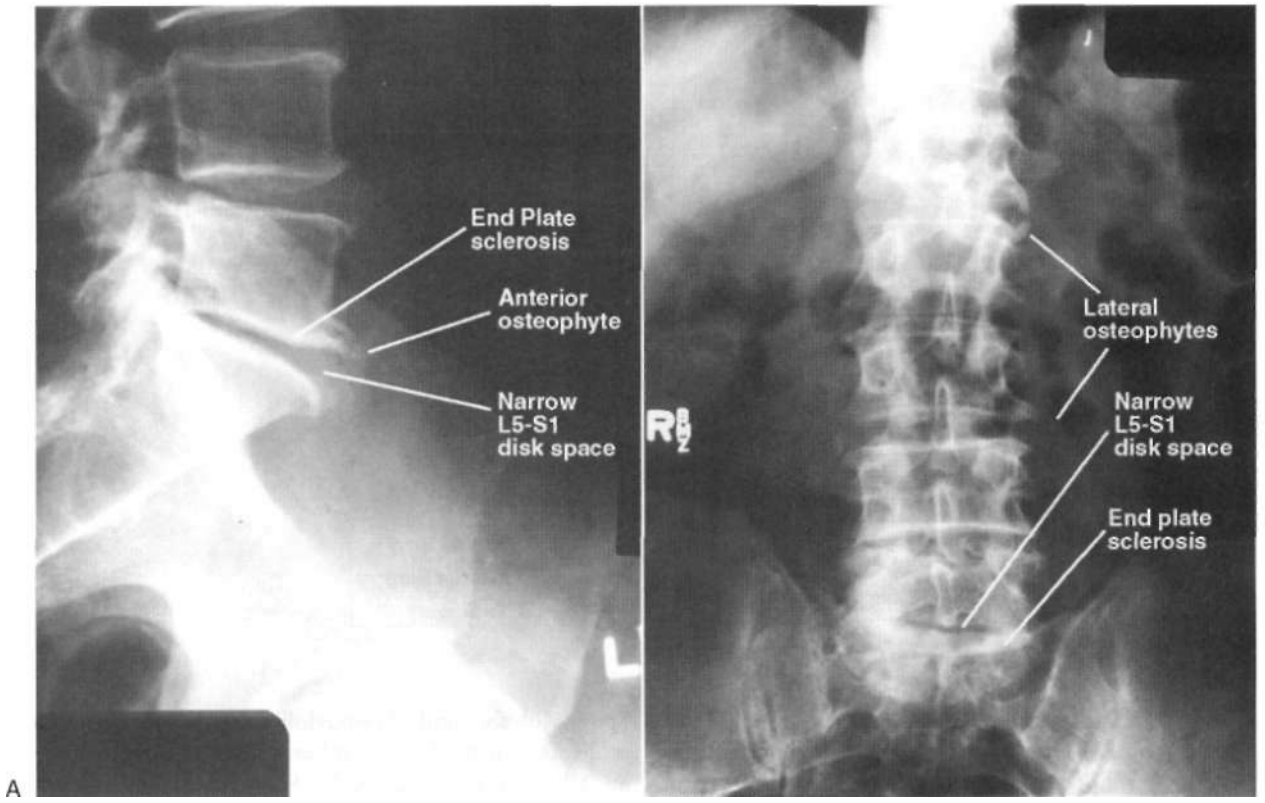

FIGURE 79.26 (A) Anteroposterior and (B) lateral radiographs of the lumbar spine showing osteophytes, disc space narrowing, and sclerosis of the vertebral body articular plates, (Reprinted with permission from Rosenbaum, R. B., Campbell, S. M., &c Rosenbaum, J. T. 1996, *Clinical Neurology of Rheumatic Disease,* ftuttcrworth-Heinemann, Boston.)

and vertebral trauma. Spondylolysis occurs in 5-7% of the population and is usually asymptomatic. Spondylolisthesis is often painless or may cause low back pain that sometimes radiates to the buttocks. Spondylolytic spondylolisthesis is a common cause of back pain in adolescents. Occasionally, spondylolisthesis can advance to the point of compressing nerve roots in the neural foramina or causing lumbar canal stenosis.

Table 79.6: Indications for lumbar spine radiography in patients with acute low hack pain

Red flags for trauma
Major trauma (e.g., motor vehicle accident, fall from height)
Minor trauma or even strenuous lifting in older or potentially osteoporotic patient
Prolonged corticosteroid use
Osteoporosis
Age older than 70 years
Red flags for tumor or infection
Age older than 50 years or younger than 20 years
History of cancer
Constitiition.il symptoms (e.g., fever, chills, weight loss)
Risk factors for spinal infection (e.g., recent bacterial infection, intravenous drug use, immunosuppression!
Pain that is worse when supine or is severe at night

Lumbar Radiculopathies. The back and leg neurological examination is key to decision making in patients with low back pain. Perhaps 1-2% of patients with acute low back pain have significant lumbar nerve root compression. Three syndromes merit specific diagnostic consideration.

Monoradiculopathy

Clinical Fresentatio?!. Patients with an acute lower lumbar or lumbosacral monoradiculopathy caused by nerve root compression present with unilateral leg pain (sciatica) radiating into the buttock, lateropostetior thigh, and distally, sometimes with paresthesia. Patients usually also have low back pain. Pain may increase with movement, coughing, sneezing, or Valsalva maneuver and decrease with rest. Pain often increases when the straightened ipsilateral leg is raised while the patient is supine (straight-leg-raising test, Laseguc's sign) or when the leg is straightened at the knee while the patient is seated. The most commonly compressed nerve roots are 1.5, usually by L4-L5 disc herniation, or SI, usually by L5-S1 disc herniation. For L5 radiculopathy, the findings are typically medial foot and hallux pain; paresthesia, especially on the medial dorsal foot; and weakness in the extensor hallucis

Iongus muscle, ankle dorsiflexors, and peroneal muscles. SI nerve root compression can lead to Literal foot pain and paresthesia, depressed ankle jerk, and weakness of peroneal muscles and less frequently of ankle plantar flexors. When the radiculopathy is mild, the patient may have no objective neurological deficit.

Diagnostic Studies. Disc herniations, osteophytes, spondylolysis and spondylolisthesis, facet joint hypertrophy, and hypertrophy or calcification of intraspinal ligaments can compress nerve roots of the cauda equina within the spinal canal ot in the lateral recesses and neural foramina through which the roots exit the spinal canal. The anatomical relations between the nerve roots and the surrounding tissues are well visualized by lumbar MRI or CT myelography figure 79.27). Each technique has high sensitivity for demonstrating causes of nerve root compression. On occasion when a patient has strong clinical evidence of lumbar radiculopathy but initial imaging studies do not show the cause of the compression, a second complementary imaging study is indicated. For example, imaging with a lumbar MRI usually is sufficient for most clinical purposes, but occasionally a patient

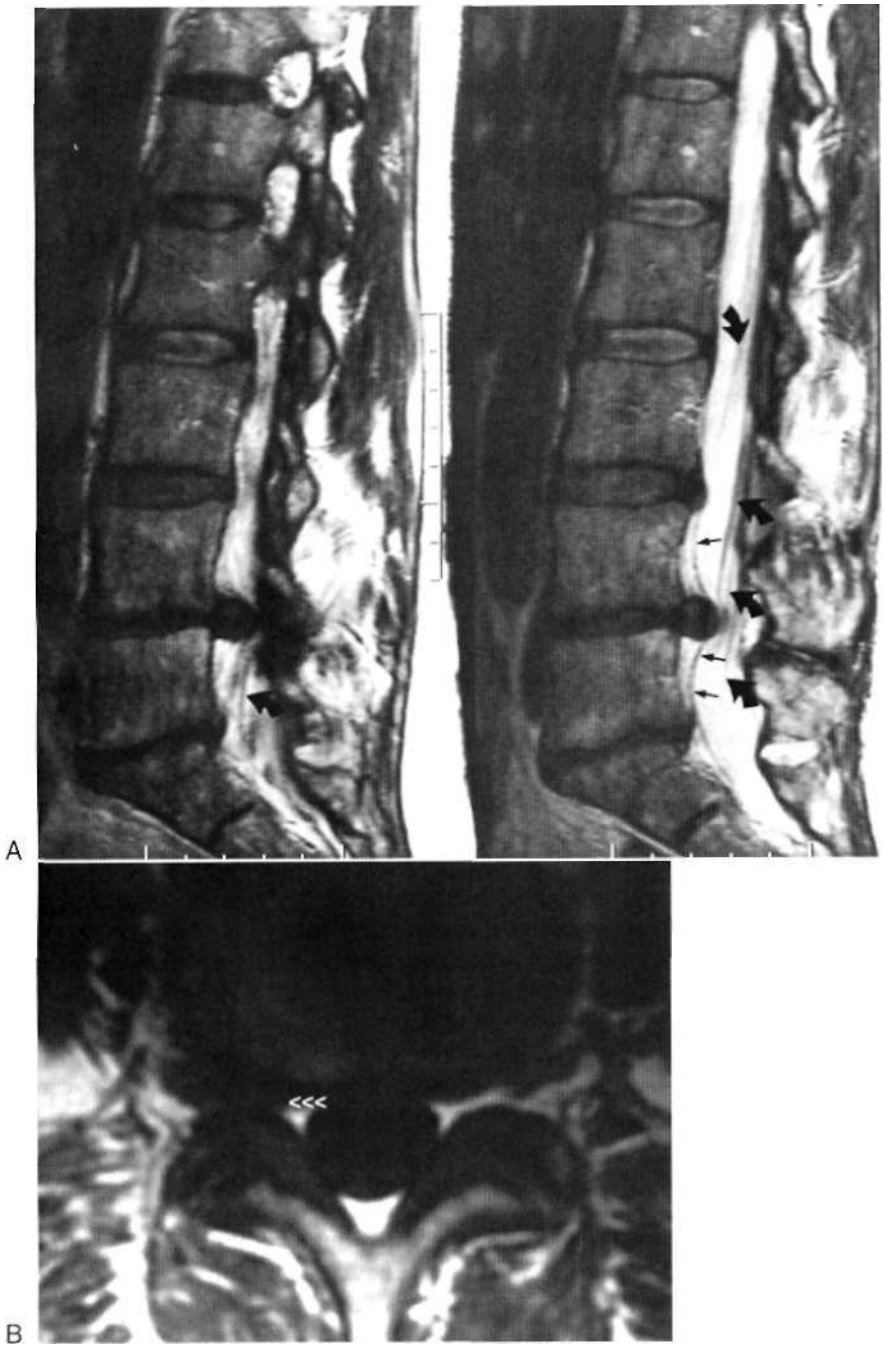

FIGURE 79.27 (A) Lumbar magnetic resonance image (MRI) of a patient with lumbar disc herniation at L4-L5. The ventral dura is displaced *{straight arrows)* posteriorly. The roots of the cauda equina are compressed *(curved arrows). (B)* Axial Tl-weighted MRI demonstrates an intraforaminal focal disc protrusion (herniation) within the right neural foramen *(arrowheads).* This is well delineated because of the thin images angled to the disc space and the contrast of bright fat within the neural foramen. Notice the nerve roots as the oval structures exiting each neural foramen. (A, Courtesy Fj-ik Gacnslcr.)

also needs CT myelography to clarify the anatomy. I nli i!iui:.;klv a I spinal imaging modalities frequently show anatomical abnormalities that are not the cause of symptomatic nerve root dysfunction; all imaging results must be interpreted carefully in clinical context.

Electromyography can aid in neurological localization by demonstrating neuropathic abnormalities in specific myotomes, It is relatively insensitive because it detects only compression affecting motor roots severely enough to cause axonal interruption. However, in complex cases, it is particularly helpful in separating monoradiculopathy from other conditions such as dvsfunction ot multiple roots, plexopathies, or peripheral neuropathy.

Treatment. Most sufferers of low back pain and sciatica recover within 6 weeks using simple, nonoperative therapies such as brief periods of bed rest, activity limitations as required by pain, simple analgesics, and physical or manipulative therapies. Evidence indicates that prolonged immobilization is detrimental and that early mobilization results in more rapid recovery. Many patients with acute low back pain and sciatica can be managed at this stage based on clinical examination without spinal imaging studies. Patients who have progressive weakness or sensory loss or who have severe pain that fails to improve after 6 weeks of nonoperative therapy can be considered tor surgical nerve root decompression. The patients least likely to benefit from lumbar nerve root surgery are those who lack objective neurological signs of nerve root dysfunction or who lack corresponding imaging evidence of nerve root compression.

A few patients develop a chronic low back pain syndrome or have repeated exacerbations of acute low back pain. Back-strengthening exercises and the avoidance of maneuvers that put strain on the lower back, together with the judicious use of nonsteroidal anti-inflammatory drugs, generally improve such patients' pain. Workers who are off work with low back pain for longer than 6 months have a guarded prognosis for return to work. Physicians caring for patients with low back pain lasting longer than 4 weeks need, whenever possible, to emphasize exercise to avoid deconditioning and early return to graded work.

When surgery is performed for lumbar nerve root compression, the surgical technique depends on the clinical details such as the cause of compression and the number of nerve roots compressed. In patients with sciatica caused by disc herniation, the most common surgical approach is microsurgical discectomy with minimal removal of the lamina. Perhaps 90% of patients reporr excellent relief of neuropathic pain after surgery. Many are able to return to physically strenuous work. However, a small proportion of patients postoperatively develop more severe chronic pain problems *(failed back syndrome),* which particularly occurs when patients selected for surgery have neither clinical evidence of radiculopathy nor corresponding neuroimaging evidence of nerve root compression. Patients with chronic pnMopiTa'.ive p./ I iiv.ii'v careful neurological evaluation to consider such problems as surgery done at the wrong level, incomplete removal of extruded disc fragment or other matter compressing the nerve root, progression of spinal degeneration, postoperative arachnoiditis, and psychosocial issues interfering with recovery.

Acute Cauda Equina Syndrome

Acute cauda equina syndrome presents as low back and leg pain caused by compression of multiple lumbosacral nerve roots. Patients may have bilateral leg pain and neurological deficits in the distribution of multiple nerve roots. Particularly worrisome findings are sacral sensory loss or impaired function of the rectal and urinary sphincters. Acute Cauda equina compression occurs in fewer than 1% of all patients who have lumbar or lumbosacral disc prolapses. The cause is usually a large midline disc herniation, most often at L4-L.5 or I.5-S1. When an acute cauda equina compression occurs, the patient needs urgent spinal imaging and decompressive surgery, because the window of opportunity for restoration of neurological function is limited to perhaps 48 hours.

Lumbar Canal Stenosis

Lumbar canal stenosis results from various anatomical changes that decrease the normal cross-sectional area of the spinal canal including congenitally small canal size, degenerative osteophytes, spondylolisthesis, facet joint hypertrophy, thickening of the ligamentum flavum, and disc herniation. It usually develops insidiously with aging and rarely becomes symptomatic before age 40 years. Men are more often affected than women. Stenosis is often asymptomatic. Patients often have some low back pain. The classic symptom of lumbar canal stenosis is neurogenic intermittent claudication: leg discomfort elicited by walking or by certain postures such as standing straight, which is relieved within minutes by stopping walking or changing posture. This is to be contrasted with the relief within seconds of stopping walking m vascular claudication. The pain may be anywhere in the legs or buttocks and may include numbness or paresthesia.

Patients sometimes can decrease their discomfort by bending forward while they walk and may be able to bicycle without difficulty. They may develop leg symptoms with sustained erect posture or after lying with their back straight. In contrast, vasogenic intermittent claudication may be elicited by almost any leg exercise and is not elicited or relieved by any specific postures.

Most patients with neurogenic intermittent claudication do not have objective signs of nerve root dysfunction. However, occasionally a patient manifests progressive neurological deficits from chronic cauda equina compression. Some patients develop leg weakness or other abnormal neurological signs following exercise, and neurological

examination before and after precipitation of the pain is a helpful part of the evaluation of neurogenic claudication. Patients with congenital lumbar canal stenosis are more likely to have congenital stenosis of the cervical canal and may have signs of a cervical myeloradiculopathy.

Diagnostic Studies

Spinal canal stenosis can be studied by MRI, CT, and myelography (Figure 79.28). MRI is best at demonstrating sagittal relationships, such as the role of spondylolisthesis in narrowing the canal. CT is best at studying calcified tissues and distinguishing disc from osteophyte, especially within the neural foramina. No imaging modality quantifies the extent of nerve root comptession, and clinical correlations between symptoms and apparent reduction in size of the spinal canal are imperfect. In choosing which patients would benefit from decompressive surgery, one should rely more heavily on clinical findings than on the appearance of the canal in imaging studies.

Treatment

Patients who have neurogenic intermittent claudication may have stable symptoms for many years without developing progressive neurological deficit. Some even note regression of symptoms aftct months of recurrent claudication. These patients may be managed with mild analgesics. Some describe decreased discomfort if they walk with a slight stoop or using a cane. Those patients with intractable leg pain or progressive neurological deficit can be treated with wide laminectomy of the stenosed spinal canal, which usually improves claudication. Back pain is much less likely TO improve after surgery. Those with severe or multilevel stenosis ate least likely to benefit from surgery.

INFECTIOUS DISEASES OF THE SPINE

Pyogenic Vertebral Osteomyelitis and Epidural Abscess

Vertebral osteomyelitis and spinal epidural abscess (see Chapter 59) are uncommon conditions that present with focal spinal pain and tenderness. Epidural abscesses in the anterior spinal canal are more likely than those in the posterior canal to be associated with osteomyelitis; in cither location, they can cause radiculopathic pain, compromise of nerve root function, or spinal cord compression. Some patients with spinal epidural abscess or with vertebral osteomyelitis are afebrile at presentation, but nearly all have an elevated sedimentation rate. Early in the infection, routine spinal radiography may be norma). If the diagnosis is being considered, an MRI scan (Figure 79.29) of the involved area is sensitive for detecting vertebral body abnormalities and is particularly helpful to assess for epidural or paravertebral infection. Spinal CT is useful if MRI is unavailable or contraindicated. Osteomyelitis may involve any vertebral body but is least common in the cervical vertebrae. Often in pyogenic, but infrequently in granulomatous, osteomyelitis, the MRI shows involvement of the adjacent disc space. The most common causative

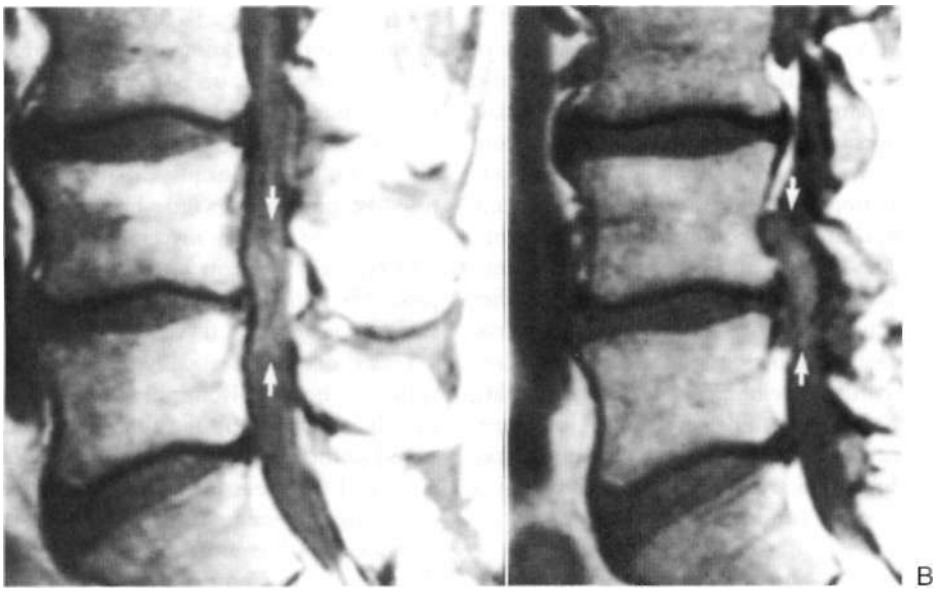

FIGURE 79.28 Magnetic resonance image of patient with lumbar spinal stenosis. (A) Midline and (B) parasagittal images of the lumbar spine show narrow anteroposterior dimensions of the spinal canal consistent with spinal canal stenosis (see normal dimensions in Figure 79.27). The 1.4-1,5 disc herniation *(arrows)* that fills the entire spinal canal is actually much smaller than the herniation shown in Figure 79.27. (Courtesy Erik Gaensler.)

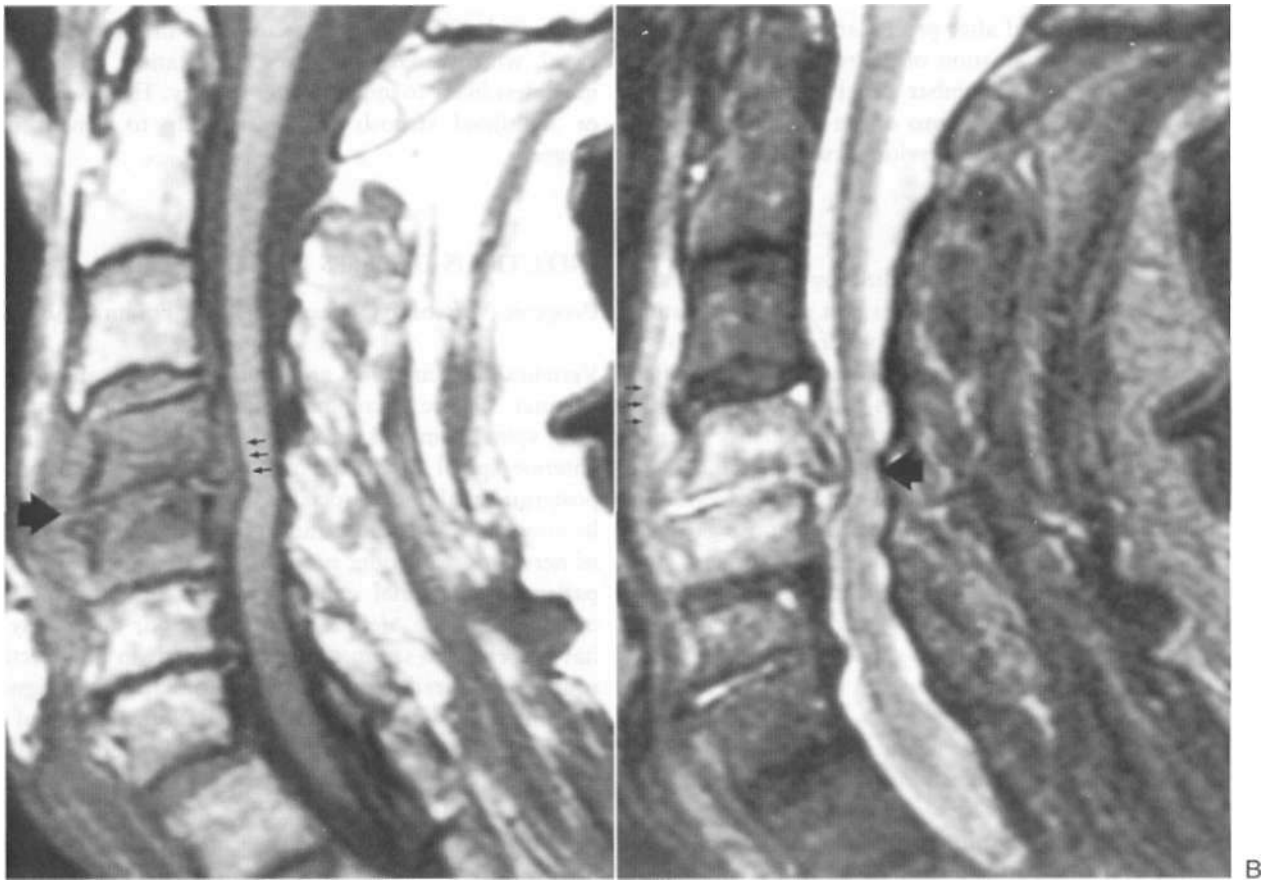

FIGURE 79.29 Magnetic resonance image of a patient with pyogenic vertebral osteomyelitis. (A) Tl-weighted sagittal image shows replacement of the normal marrow fat of the C4 and C5 vertebrae with low-signal intensity edema, with narrowing of the disc space *{arrow)* and thickening of the epidural soft tissue *(small arrows).* (B) T2-weighted image shows mild spinal cord compression *[arrow]* and hype nn ten sin- of the anterior longitudinal ligament, consistent with superior extension of the infectious process *(small arrows).* (Courtesy Erik Gaensler.)

organism is *Staphylococcus aureus,* but a wide variety of other bacteria can be responsible. Polymicrobial infection is uncommon after hematogenous infection but can occur when the source is open trauma or contiguous spread from other tissues. Osteomyelitis and spinal epidural abscess usually occur by hematogenous spread and arc more likely following septicemia. Diabetes, alcoholism, acquired immunodeficiency syndrome (AIDS), and other forms of immunosuppression increase the risk of its development. Other risk factors are intravenous drug use or spinal trauma. Cases may be iatrogenic following spinal surgery. When cases are diagnosed before development of spinal instability or compression of the spinal cord or nerve roots, long-term antibiotic therapy can be curative. Spinal instability may require surgical stabilization. Neurological compression is an indication for emergent surgical decompression.

Granulomatous Vertebral Osteomyelitis

Tuberculosis (TB) of the spine (Pott's disease) is one of the more common forms of nonpulmonary TB and by far the most common gtanulomatous spinal infection. The risk is highest in regions or populations where TB is endemic. In the United States high-risk factors are immigration from an endemic area, AIDS, homelessness, and drug or alcohol abuse. Other organisms capable of causing granulomatous osteomyelitis include brucellosis, a variety of fungi, *Nocardia,* and Actinomyces. Granulomatous spinal infection typically presents with insidious progression of back pain. The patient often has symptoms of systemic infection such as weight loss, fever, night sweats, or malaise.

Pott's disease classically presents with destruction of vertebral bodies. Routine spine radiography results are usually abnormal by the time the diagnosis is made, and spinal deformity is a common complication. MRI or CT is needed to assess for contiguous abscess in the epidural or paraspinal spaces and to evaluate possible nerve root or spinal cord compression when the spine is deformed (higure 79.30). Compression of spinal cord or nerve roots can occur in vertebral TB by vertebral deformity or collapse, epidural abscess, granulation tissue, or bony sequestrum. Patients may develop delayed neurological complications after apparently successful treatment of the infection.

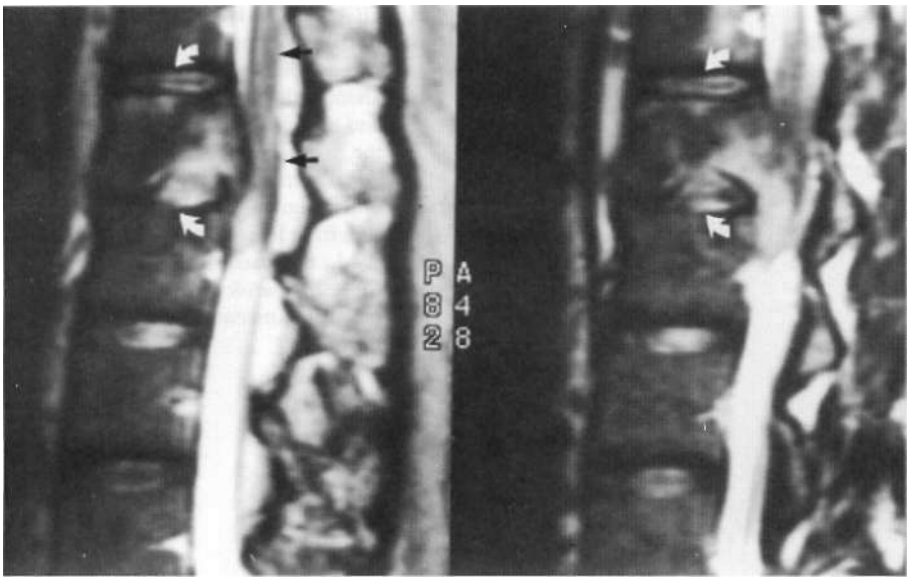

FIGURE 79.30 Magnetic resonance image of a patient with tuberculous vertebral osteomyelitis. T2-weighted images show destruction of rhe posterior inferior portion of the TI2 vertebra, with a soft tissue mass projecting posteriorly into the spinal canal, compressing the conus medullars *{arrows).* Note that the T12 and LI discs *(curved arrows)* are relatively well preserved, which is a distinguishing feature of spinal tuberculosis. (Courtesy Erik Gaensler.)

This may be caused by infarction from endarteritis obliterans, delayed degenerative bony changes, or reactivation of infection. Neurological compression is most common with thoracic vertebral disease, hence the eponym *Pott's paraplegia-* cauda equina compression is uncommon in TB. Treatment of vertebral TE requires long-term multiple-drug antituberculous therapy. Spinal surgery may be needed depending on the degree of spinal destruction or deformity and is often required in cases of neurological compression.

Inflammatory Joint Disease

Rheumatoid Arthritis

Systemic Presentation. RA is a chtonic, inflammatory, symmetrical destructive immune-mediated polyarthritis. In population studies, 0.2-2.0% of the population is affected, women twice as often as men. The cause of RA is unknown, but genetic factors are evident in familial cases and susceptibility is linked to some human leukocyte antigen-DR (HLA-DR) types. The most commonly affected joints are the small joints of the hands and feet. The diagnosis is based primarily on characteristic clinical findings. Serological testing for rheumatoid factor can support the diagnosis. However, many patients have seronegative RA, and, conversely, there are numerous other causes for elevation of rheumatoid factor. Radiography shows juxta-articular demitieralization or characteristic joint erosions in advanced cases.

Pathogenesis. The immimopathogenesis of RA includes T- and B-cell activation, angiogencsis and cellular proliferation in the synovium, inflammation in soft tissue, and eventual destruction of cartilage and bone. Cytokine release, immune complex deposition, and vasculitis can all contribute to the inflammatory process. The inflamed proliferative rheumatoid synovium is called *pannus.* In the spine, pannus can disrupt stabilizing ligaments, particularly of the atlantoaxial joint, and thick pannus can add to compression of nervous tissue. Rheumatoid inflammatory tissue can form nodules in soft tissue; on the rare occasions that these nodules form in the dura, they can conttibutc to rheumatoid pachymeningitis.

Neurological Manifestations. Common neurological complications of RA are carpal tunnel syndrome and other nerve en trap men ts, peripheral neuropathy, and myopathy; these are discussed in Chapters 55, 82, 84, and 85. RA can evolve to a rheumatoid vasculitis that like other medium-sized vessel vasculitides has the potential to cause ischemic mononeuritis, mononeuritis multiplex, or, rarely, stroke.

Headache and neck ache are common in patients with RA. These are often caused by rheumatoid disease of rhe cervical spine. Focal neurological dysfunction is a rarer and later manifestation of spinal RA. Patients with RA, of course, develop the ubiquitous changes of spinal osteoarthritis and spondylosis. In addition, early in RA, cervical radiography may show rheumatoid changes such as erosions and sclerosis at vertebral endplates and apophyseal joints. Patients may have cervical subluxations. Disc space narrowing may occur at upper cervical discs, without associated osteophytosis.

Patients with progressive RA can develop subluxation at the atlantoaxial joint. Lateral atlantoaxial joint subluxation rarely causes focal neurological dysfunction but can contribute to neck ache and headache. Horizontal atlantoaxial joint subluxation, often combined with adjoining soft tissue pannus, can cause myelopathy, especially in patients with a smaller congenital canal diameter (Figure 79.31). The earliest neurological sign is usually hyperreflexia; assessment of gait and strength in patients with advanced RA is often difficult because of their peripheral

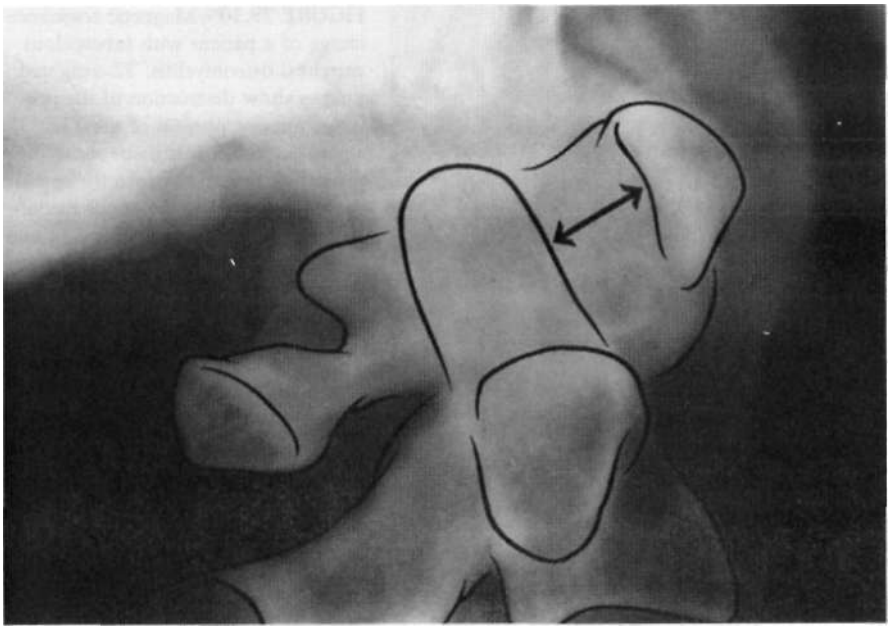

FIGURE 79.31 Lateral radiographs of the flexed neck of a patient with rheumatoid arthritis and anterior atlantoaxial subluxation. The odontoid and pedicle of C2 and the elements of the ring of CI are outlined. The atlantoaxial separation *{double arrow)* is also shown. (Reprinted with permission from Rosenbaum, R. B., Campbell, S. M., & Rosenbaum, J. T. 1996, *Clinical Neurology of Rheumatic Disease,* Bultcrworth-Heinemann, Boston.)

joint pain and deformity. Vertical subluxation can lead to spinal cord or brainstem compression or rarely to vertebral artery compression or injury.

Choosing which patients will benefit from surgical stabilization of the subluxed joint is a clinical challenge. Findings of progressive myelopathy or brainstem dysfunction are usually indications for surgery if the general health of the patient permits. Neurological dysfunction caused by atlantoaxial subluxation usually occurs in patients who are already severely debilitated by their disease. Many patients do not regain neurological function after surgical stabilization of the subluxation; goals arc limited to preventing deterioration. The 5-year survival of patients at this late stage of RA is perhaps 50%.

Patients with RA may also develop spinal subluxations, usually in the cervical spine, at levels caudal to the atlantoaxial joint. These subluxations can lead to spinal cord compression. Subaxial subluxations may progress after surgical stabilization of the atlantoaxial joint. A rare late manifestation of RA is rheumatoid pachymeningitis. The dura may develop either focal rheumatoid nodules or diffuse infiltration by inflammatory cells. In rare instances, toed ilin.il disease can lead to spinal cord, cauda equina, or cranial nerve compression or to focal cerebral complications such as seizures.

I}iflammatory Spondyloarthropathies

Clinical Presentation. The inflammatory spondyloarthropathies include ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and the arthritis of inflammatory bowel disease. Ankylosing spondylitis is characterized by inflammatory low back pain, loss of spinal range of motion, sacroiliitis, and, as it advances, radiographic evidence of sacroiliitis and spondylitis (Figure 79.32). The clinical symptoms of inflammatory lumbosacral spine disease are insidious onset of low back (and sometimes buttock) pain, lasting more than 3 months, prominent morning stiffness, and improvement with activity. Most patients become symptomatic before age 40 years, and men are affected more commonly than women. Other organ systems are affected commonly in patients with inflammatory spondyloarthropathies; manifestations include uveitis, mucocutaneous lesions, peripheral arthritis, gastrointestinal disease, cardiac disease, and enthesopathy (entheses are sites of

FIGURE 79,32 The anteroposterior radiograph of the sacroiliac joint shows sacroiliitis with some preservation of the left sacroiliac joint. (Reprinted with permission from Rosenbaum, R. B., Campbell, S. M., & Rosenbaum, J. T. 1996, *Clinical Neurology of Rheumatic Disease,* Butte r worth-He in emaun, Boston.

insertion of ligament or tendon to bone). The syndesmophytes that form where spinal ligaments join vertebral bodies arc one form of enthesopathy. Examples of other sites of enthesopathy are the foor (Achilles tendinitis, plantar fasciitis, heel pain}, fingers or toes (dactylitis or sausage digits), and symphysis pubis, clavicle, and ribs.

Reactive arthritis (formerly called *Reiter's syndrome)* is classically preceded by venereal or gastrointestinal tract infection. The triad of reactive arthritis is arthritis, conjunctivitis, and urethritis, but many patients do not have all thtee manifestations. Inflammatory low back pain is common in patients with reactive arthritis, and up to one fourth of patients develop radiological evidence of sacroiliitis ot spondylitis.

Pathogenesis. The inflammatory spondyloarthropathies are generated by" a combination of genetic and environmental factors. In ankylosing spondylitis, the genetic factor is clearest, with perhaps 90% of patients expressing the gene fot HLA-B27. However, only approximately 5% of people expressing this gene develop ankylosing spondylitis. In the other spondyloarthropathies, the prevalence of HI.A-1127 positiviiy is lower. In reactive arthritis, the environmental factors arc clearest, with many patients experiencing a preceding gastrointestinal or genitourinary tract infection with organisms such as *Shigella, Salmonella, Yersinia, Campylobacter,* or *Chlamydia.* The inflammatory process is presumably mediated by autoimmune T cells with tissue specificity leading to inflammation at such sites as joints, entheses, and the eye.

Spinal Neurological Complications. The neurological complications of the inflammatory spondyloarthropathies generally do not occur until spinal disease is clinically advanced with loss of spinal range of motion and kyphosis and radiologieally evident with vertebral body squaring and syndesmophytes. Spinal complications include atlantoaxial joint subluxation, spinal fractures and pseudoarthroses, disco vertebral destruction, spinal canal stenosis, and cauda equina syndrome caused by lumbar arachnoid diverticula (Table 79.7).

P., et a). 1982, "Spinal injury, spinal fracture, and spinal stenosis in ankylosing spondylitis," *J Ncurosurg,* vol. 37, pp. 609-616. (Reprinted from Roscnbaum, R. B., Campbell, S. M., &r Rosenbaum, J. T. 1996, *Clinical Neurology of Rheumatic Disease,* Butterworth-Heinemann, Boston.)

Subluxation of the atlantoaxial joint is a late and uncommon complication of inflammatory spondyloarthropathy. Diagnosis and management issues are the same as those for patients who develop atlantoaxial disease as part of RA. The fused spondylitic spine is particularly susceptible to fracture, especially in the midecrvical region. The most common fracture site is C6, followed by C5 and C7. After even minor trauma, the patient with advanced spondylitis needs radiographic assessment of the cervical spine to detect fractures if possible before myelopathic complications. Much more rarely, patients with spondylitic rigid spines develop post-traumatic myelopathy caused by epidural hematomas or cord contusions.

Destruction of a disc, particularly in the low lumbar or high thoracic region, is a late complication of spondylitis (Figure 79.33). The adjacent vertebral bodies also may be involved. An initiating trauma is not always identified. The destruction may be asymptomatic or painful. The pain increases with movement and decreases at rest, in contrast to typical inflammatory low back pain. An epidural inflammatory response leading to cord compression can occur.

Cauda equina syndrome with insidious evolution of leg pain, sensory loss, leg weakness, and sphincter dysfunction is a late complication of inflammatory spondyloarthropathy. Imaging studies (MRI, CT, myelogtaphy) show posterior lumbosacral arachnoid diverticula (Figure 79.34). Although arachnoiditis may play a role in development of this syndrome, the presence of the diverticula distinguishes it from most cases of chtonic adhesive arachnoiditis.

Other unusual complications of spondyloarthropathy include lumbar monoradiculopathy secondary to disc herniation or osteophytes, spinal canal stenosis, and from the era when spinal radiation was used to treat spondylitis, radiation-induced cauda equina sarcoma.

Nonspinal Neurological Complications. Rare nonspinal complications of inflammatory spondyloarthropathies include brachial plexopathy or tarsal tunnel syndrome. Proximal weakness and atrophy, sometimes with mild elevations of serum creatine kinase level, often occur in advanced cases of spondylitis, suggesting an inflammatory myopathy. In patients with psoriatic arthritis, the myopathy is occasionally painful. A number of case reports detail unusual neurological sequelae in patients with reactive arthritis (Table 79.8).

Laboratory Abnormalities. Patients with inflammatory spondyloarthropathies sometimes have mild elevations of CSF protein levels with normal glucose and cell counts. They can have unexplained abnormalities of visual, auditory, and somatosensory evoked responses.

Possible Associations with Multiple Sclerosis. Case reports and small series link the occurrence of multiple sclerosis and ankylosing spondylitis in the same patient,

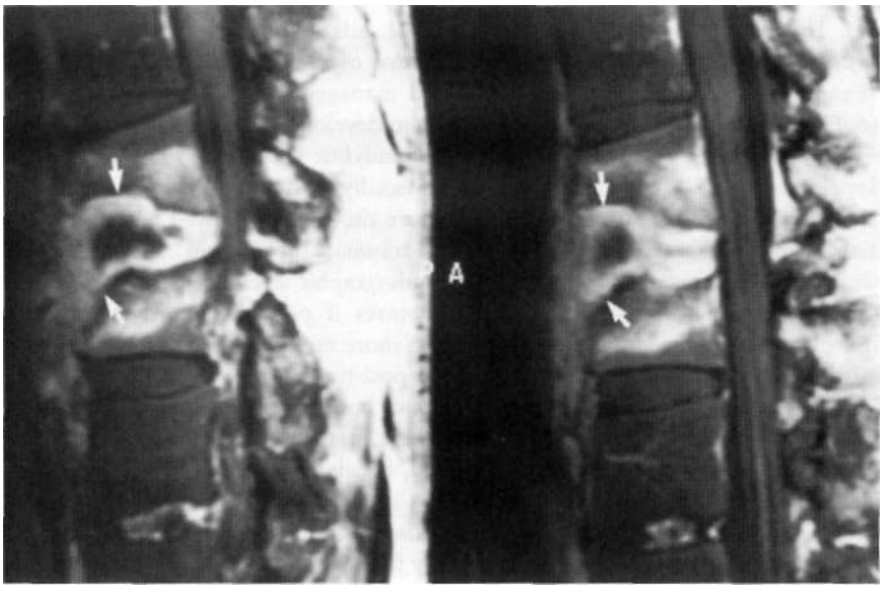

FIGURE 79.33 Magnetic resonance image shows disco vertebra I destruction *{arrows)* in a patient with ankylosing spondylitis. There is a chronic fracture in the lower thoracic spine, which is otherwise rigid because of bony fusion. Chronic hypcrmobility at this single nonfused segment has occurred, leading to exuberant fibrous tissue development. The fibrous tissue enhances on this post-gadolinium-enhanced Tl -weighted image. This appearance can be mistaken for infectious spondylitis (see Figure 79.29) if the presence of a bamboo spine on plain films is overlooked. (Courtesy Erik Gaensler.)

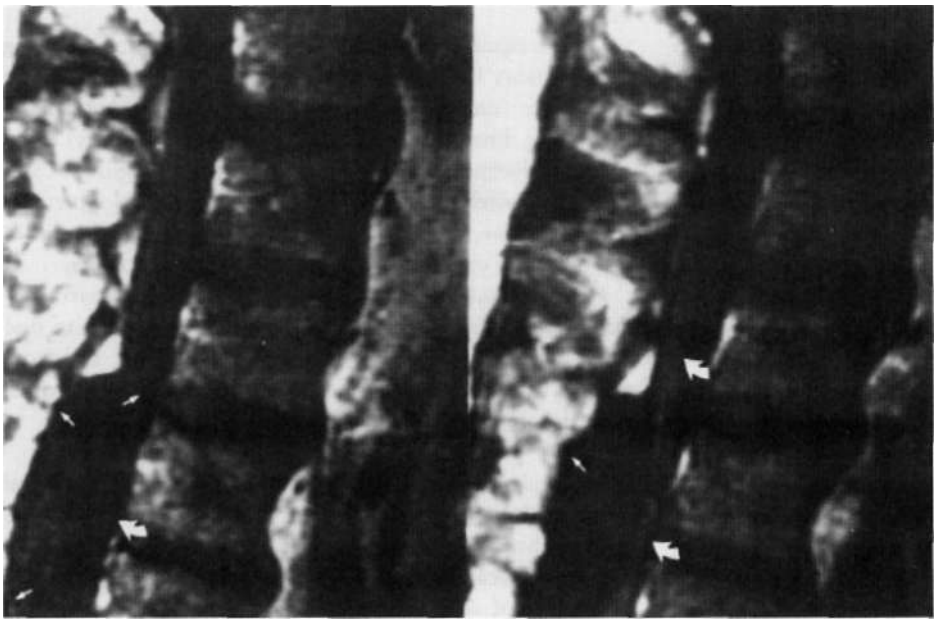

FIGURE 79.34 Magnetic resonance image of the lumbar spine shows a posterior lumbar arachnoid diverticulum in a patient with ankylosing spondylitis. The spinal canal is expanded at T12T.1 by a mass that shows signal intensity equivalent to cerebrospinal fluid on these Tl-weighted images. Isointensity to cerebrospinal fluid suggests an arachnoid cyst, and the small arrows outline the internal margins of the cyst. The curved arrows show the nerves of the cauda equina, which have been displaced anteriorly. (Courtesy Erik Gaensler.)

but insufficient data exist to determine whether a true association exists between the two illnesses. Evaluation is complicated because either condition might cause a myelopathy, transient vision loss (iritis versus optic neuritis), or evoked response abnormalities.

Epidural Lipomatosis

Epidural lipomatosis is a non-neoplastic accumulation of fatty tissue in the thoracic or lumbar epidural space that can occur idiopathically but is more commonly a

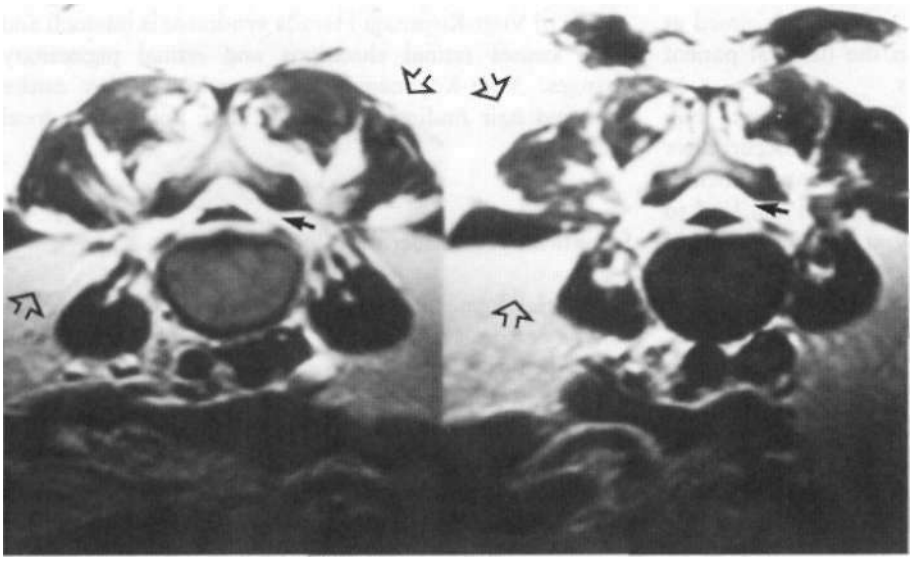

FIGURE 79.35 Magnetic resonance image shows epidural lipomatosis. T1-weighted axial images show markedly increased fat *{arrows)* within the spinal canal compressing the thecal sac, which is quite small. Note that the patient is quite obese, with large amounts of fat in the retroperitoneutn and posterior paraspinous tissues *[open arrows).* (Courtesy Erik Gaensler.)

complication of chronic corticosteroid excess, obesity, or hypothyroidism (Koch et al. 2000). A typical patient has been on corticosteroids for more than 6 months and is obese and cushingoid; spinal radiography typically shows diffuse osteoporosis. Criteria for the diagnosis include (1) history consistent with segmental spinal cord compression or nerve root compression, (2) epidural fat thickness of more than 7 mm in the region of compression, and (3) a body mass index of more than 27.5 kg/m^2 (Figure 79.35), The compressive tissue can regress when corticosteroid doses are decreased, but the compression of neurological tissue may be severe enough to require laminectomy.

Chronic Meningitis

Most cases of chronic meningitis arc caused by infection (see Chaptet 59), neoplasia (see Chapter 58), or sarcoidosis (see Chapter 55). Behcet's syndrome, isolated central nervous system angiitis (sec Chapter 57), systemic lupus erythematosus, Sjogren's syndrome, or Wegener's granulomatosis are included in a comprehensive differential diagnosis. Some other chronic or recurring meningitic syndromes merit discussion.

Chronic Adhesive Arachnoiditis

Chronic focal or diffuse inflammation of the spinal theca can cause neurological symptoms caused by inflammation, adhesion, and distortion of nerve roots or spinal cord. This condition is termed *chronic spinal arachnoiditis* or *chronic adhesive arachnoiditis.* However, the process usually involves all layers of the meninges and in its chronic stages may be fibrotic rather than inflammatory. Calcification of the meninges (arachnoiditis ossificans) is an occasional late finding. The clinical manifestations are of a gradually ascending painful cauda equina syndrome, followed by an ascending myelopathy as the arachnoiditis spreads up the **spinal** cord. Death may result in 3-10 years from decubiti, urosepsis, and other complications of severe paraplegia.

Adhesive arachnoiditis occasionally complicates a variety of surgical or medical violations of the thecal sac {Table 79.9). Focal arachnoiditis is most common in the cauda equina following lumbar disc surgery or myelography, particularly if oil-based contrast has been used for the latter. The symptoms can include local or radicular pain, radicular paresthesia, and less commonly more severe findings of oligoradiculopathy such as motor loss or sphincter dysfunction. The diagnosis can usually be made by spinal MRI, which may show clumping of nerve roots, nodules in the subarachnoid space, loculation of spinal fluid, and local areas of enhancement. The nerve roots may clump at the periphery of the thecal sac, usually adjacent to an area of previous surgery, or in the center of the sac, usually in areas of spinal stenosis. The extent of the MRI findings correlates poorly with the severity of the clinical nerve root dysfunction. Spinal fluid may show increased CSF protein levels and mild to moderate mononuclear pleocytosis. Surgical debridement of the arachnoiditis is sometimes attempted but is usually unsuccessful and may lead to increased neurological deficit. Epidural or intrathecal corticosteroids arc sometimes tried, but there is no proof of their efficacy, and there are reports of arachnoiditis

caused by their use. Therefore most treatment is aimed at symptomatic pain control, except in the unusual patient with progressive neurological deficits.

Arachnoiditis of the spinal cord is less common than arachnoiditis of the cauda equina. It can occur after apparently successful treatment of granulomatous meningitis or of epidural or vertebral infection and can lead to myelopathy. Arachnoiditis, especially at the craniocervical junction, can cause syringomyelia.

Recurrent Meningitis

Patients with recurrent attacks of acute bacterial meningitis need to be screened for dural CSF leaks or fistulas, parameningcal infections, and immunodeficiency (see Chaptet *59).* Recurrent meningitis also can be caused by chemical irritation from leaking dermoid tumors or craniopharyngiomas. Drug-induced meningitis, most common as an idiosv ncralii reaction to noiiMcniidn .inii inflammatory drugs, can recur with repeated drug exposures. Rarely, recurrent meningitis can complicate systemic inflammatory diseases such as systemic lupus erythematosus, Sjogren's syndrome, Behcet's disease, Lyme disease, familial Mediterranean fever, or sarcoidosis.

Mollaret's meningitis is another form of recurrent aseptic meningitis. Attacks are self-limited, lasting a few days. The spinal fluid shows a mixed pleocytosis; sometimes large macrophagc-like cells (Mollaret's cells) arc present as well. Some cases are caused by herpes virus infections, but a causative organism is not always identified.

Uveomeningitis Syndromes

The combination of chronic or recurrent meningitis and uveitis has a specific differential diagnosis (Table 79.10). Often ophthahnological chatacterization of the uveitis can further limit the differential diagnosis. For example, the uveitis of Vogt-Koyanagi-Harada syndrome is bilateral and often causes retinal elevations and retinal pigmentary changes. Vogt-Koyanagi-Harada syndrome also causes skin and hair findings such as vitiligo, poliosis, or focal alopecia.

Superficial Hemosiderosis

Superficial hemosiderosis is a rare disorder that causes slowly progressive cerebellar ataxia, mainly of gait, and sensorineural deafness, often combined with manifestations of myelopathy, such as spasticity, brisk reflexes, and extensor plantar responses, bladder disturbance, or sensory signs. Less common features include dementia, anosmia, or anisocoria, and more rarely extraocular motor palsies, neck or backache, bilateral sciatica, or lower motor neuron signs (5-10% each). Men are more often affected than women (3:1). The diagnosis may not be suspected clinically, but the neuroraetiological abnormalities arc striking. MR1 shows a black rim around the posterior fossa structures and spinal cord and less often the cerebral hemispheres on T2-weighted images (Figure 79.36). These paramagnetic signal changes represent encrustation of the brain surfaces with hemosiderin. The adjacent neural tissue atrophies, with accumulation of ferritin in microglia and Rergmami's cells in the cerebellum. Superficial siderosis is presumably secondary to chronic or recurrent blood leakage into the subarachnoid space. It has been described after hemispherectomy, head or spine trauma, and in association with chronically or recurrently bleeding intracranial aneurysms, arteriovenous malformations, and spinal tumors. However, the CSF analysis may be normal, and not all patients have an identifiable source of bleeding. Treatment relies on identifying and arresting the source of bleeding; chelation therapy does not appear to be effective.

Fibromyalgia

Fibromyalgia, a syndrome defined by widespread musculoskeletal or soft tissue pain and multiple tender points, is part of the differential diagnosis of many patients with spinal pain. The American College of Rheumatology classification criteria for the diagnosis define pain as *widespread* when it is bilateral, above and below the waist, and axial. To meet the classification criteria, a patient must have tenderness to palpation at 11 or more of 18 specific points (Figure 79.37), but the validity of these tender points as diagnostic criteria has been cogently questioned. Typically, patients have multiple symptoms including fatigue, stiffness, nonrcstorative sleep, headaches, and mood disorders. Patients may have many symptoms of neurological import such as weakness, paresthesia, and dizziness. Nonetheless, theit neurological examinations ate normal, unless they have a separate neurological Illness.

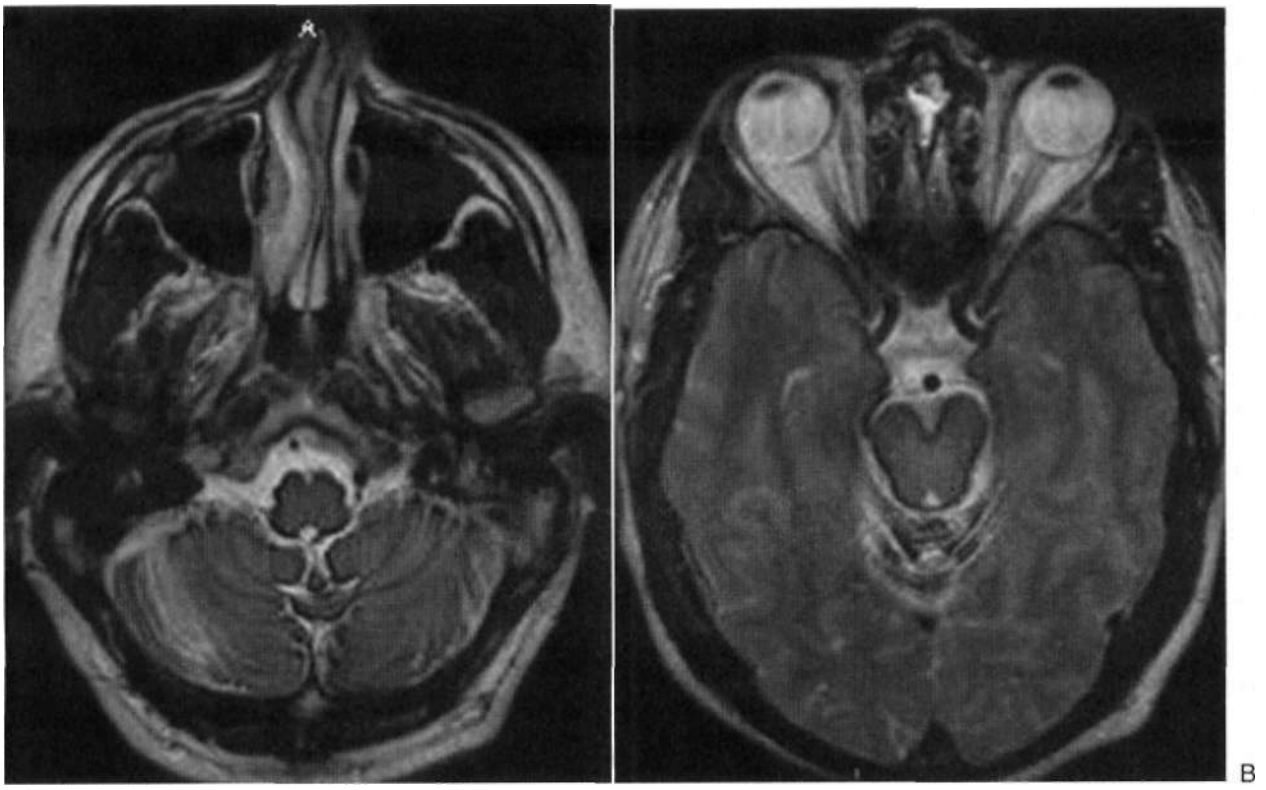

FIGURE 79.36 (A, B) Axial T2-weighted magnetic resonance images demonstrate a thin ring of hypointensity surrounding the medulla and midbrain, indicating hemosiderin deposition along the leptomeninges. (Courtesy Jim Anderson, Oregon Health Sciences University, Portland, Oregon.)

FIGURE 79.37 The tender point location of fibromyalgia. The nine paired tender points recommended by the 1990 American College of Rheumatology Criteria Committee for establishing a diagnosis of fibromyalgia are (1} insertion of the nuchal muscles into occiput; (2) upper border of the trapezius, midportion; (3) muscle attachments to upper medial border of scapula; (4) anterior aspects of the C5, C7 intenransverse spaces; (5) second rib space approximately 3 cm lateral to the sternal border; (6) muscle attachments to lateral epicondyle, approximately 2 cm below the bony prominence; (7) upper outer quadrant of gluteal muscles; (8) muscle attachments just posterior to the greater trochanter; and (9) medial fat pad of knee proximal to joint line. A total of 11 or more tender points in conjunction with a history of widespread pain is characteristic of the fibromyalgia syndrome. (Reprinted with permission from Bennett, K, M, 1997, "The fibromyalgia syndrome: Myofascial pain and the chronic fatigue syndrome," in *Textbook of Rheumatology,* 5th ed, eds W. N. Kelley, E. D. Harris, Jr., S. Ruddy, et al., WB Saunders, Philadelphia.)

Diagnostic neurological investigations, such as brain imaging, muscle biopsy, or electrodiagnostic studies, are norma! or show minor nonspecific abnormalities.

The cause of most cases of fibromyalgia is unknown. Behavioral and biological factors both contribute to the clinical presentation of the syndrome (Oof ford and Clauw 2002). Neuroscientific research on the pathogenesis of fibromyalgia has examined muscle, sleep, neuroendocrine function, and central pain processing, including studies using functional brain imaging (Bradley et al. 2002). Symptoms and signs of fibromyalgia can occur in association with an autoimmune disease, such as systemic lupus erythematosus, or other systemic illness, such as hypothyroidism. Focal trauma can cause localized, self-limited soft tissue myofascial pain. The pathogenic role of trauma, on-the-job injury, or workplace stress is controversial. Treatment includes a supportive doctor-patient relationship, tricyclic antidepressants, aerobic exercise, and avoiding inactivity.

Chapter 80
Disorders of Upper and Lower Motor Neurons

Brian Murray and Hiroshi Mitsumoto

The marriage of clinical nenroscience and molecular biology has greatly advanced our understanding of motor neuron disorders over the last decade. Through cellular, animal, and Inn nan research, there has been a veritable explosion in new information relating to the pathogenesis of both hereditary and acquired disorders of the motor system as it extends from the brain to the anterior horn cell. In addition, a host of prospective, controlled trials are yielding new treatment options for several disorders that were hitherto unbeatable. In this chapter, we review the causes, diagnosis, and treatment of the motor neuron diseases according to whether the disorder affects upper motor neurons (UMNs), the lower motor neurons (LMNs}, or both UMNs and LMNs.

DISORDERS Ol UPPER MOTOR NEURONS

Neuroanatomy of Upper Motor Neurons

The UMN is the motor neuron, the cell of which lies within the motor cortex of the cerebrum, and the axon of which forms the corticobulhar and corticospinal tracts. It is distinguished from the LMNs lying in the brainstem motor nuclei and the anterior horns of the spinal cord that directly innervate skeletal museles. The UMNs are rostral to the LMNs and exert direct or indirect supra-nuclear control over the LMNs (Mitsumoto, Chad, and Pioro 1997) (Table 80.1).

Motor Cortex

In the cerebral cortex, UMNs are located in the *prtmary motor cortex* (Brodmann's area 4) and the *premotor areas* (brodmann's area 6), which are subdivided into the *supplementary motor area* (sometimes called the *secondary motor cortex)* and the *premotor cortex,* respectively. The somarotopic organization and topographic specificity of the corticospinal projection appear to be far more complex and broader than was previously thought, *Betz's cells* (giant pyramidal neurons) are a distinct group of large motor neurons in layer 5 of the primary motor cortex and represent only a small portion of all primary motor neurons

Table 80.1: Upper motor neurons and their descending tracts

The motor areas
The primary motor neurons (Betz's giant pyramidal cells and surrounding motor neurons)

Limbic motor control

with axons in the corticospinal tracts. Individual motor neurons in the primary motot cortex initiate and control the contraction of small groups of skeletal muscles subserving individual movements. The entire motot area of the cerebral cortex controls the highest levels of voluntary muscle movement, including motor planning and programming of muscle movement.

Corticospinal and Corticobulbar Tracts. Axons from the motor areas form the corticospinal and corticobulbar tracts. Axons arising from neurons in the primary motor cortex constitute only one third of all the corticospinal and corticobulbar tracts. Among these, Betz's cell axons make up 3-5% of the tract, and the remaining fibers from the primary motor cortex arise from other neurons in layer 5 of :1K- pnman mom:- concx. Another one iln:\: ol the axons in these tracts arc detived from Brodmann's area 6, which includes the supplementary motor and the lateral premoror cortex. The remaining third is derived from the somatic sensory cortex (areas 1, 2, and 3) and the adjacent temporal lobe region. The corticobulbar tract projects bilaterally to the motot neurons of cranial nerves V, VII, IX, X, and XII. Most corticospinal fibers (75-90%) decussate in the lower medulla (pyramidal decussation) and form the lateral corticospinal tract in the spinal cord (the pyramidal tracts). The remaining fibers descend in the ipsilateral ventral corticospinal tract. The lateral corticospinal tract projects to ipsilateral motor neurons and their interneurons that control extremity muscle contraction, whereas the anterior corticospinal tract ends bilaterally on ventromedial motor neurons and interneurons, which control the axial and postural muscles. These corticospinal axons provide direct glutamatergic excitatory input to alpha motoneurons.

Brainstem Control. In a broad sense, several brainstem nuclei can be considered part of the UMN system because they exert supranuclear influence on the LMN population in the spinal cord. The projections from the brainstem to spinal cord LMNs are highly complex. The fibers originating in the medial and inferior vestibular nuclei in the medulla descend in the medial vestibulospinal tract and terminate both on medial cervical and thoracic motor neurons and on interneurons. They excite ipsilateral motor neurons but inhibit contralateral neurons. The lateral vestibulospinal tracts originating in the lateral vestibular nucleus (Dciter's nucleus) activate the extensor motor neurons and inhibit the flexor motor neurons in both the upper and the lower extremity.

The brainstem reticular formation also sttongly influences the spinal motor neurons, exerting widespread polysynaptic inhibitory input on extensor motor neurons and excitatory input on flexor motor neurons. The reticulospinal tracts modulate various reflex actions during ongoing movements. The brainstem reticular formation receives supranuclear control from the motor cortex via the cortical reticulospinal pathway, to act as a major inhibitot of spinal reflexes and activity. Therefore a lesion of the corticoreticular pathway can disinhibit reticulospinal control of the LMNs. The tectospinal tract originates in the superior colliculus and controls eye and head movement. Muscle tone is altered by variations in the balance between inhibitory input (mediated by the dorsal reticulospinal tract) and faeilitatory input (mediated by the medial reticulospinal tract and to some extent by the vestibulospinal tract) upon muscle stretch receptors.

Limbic Motor Control. The limbic system is involved in emotional experience and expression and is associated with a wide variety of autonomic, viscetal, and endocrine functions. It strongly influences the somatic motor neurons: The emotional status and experience of an individual determines overall spinal cord activity and the limbic motor system also influences respiration, vomiting, swallowing, chewing, and licking (at least in animal studies). Furthermore, the generation of pseudobulbar signs in amyotrophic latctal scletosis (ALS) is closely related to an abnormal limbic motor control, particularly in the periaqueductal gray and nucleus retroambiguus. The latter nuclei project to the somatic motor neurons that innervate pharyngeal, soft paiatal, intercostal, diaphragmatic, abdominal, and probably laryngeal muscles. Pseudobulbar symptoms may appear when UMN control over these motor nuclei is impaired, and thus limbic motot control is disinhibited. There appears to be some degree of emotional regulation by the cerebellum: The recently described "cerebellar cognitive affective syndrome" can arise when stroke, tumor, or infection interrupts connections between the cerebellum and cerebral association and paralimbic regions (Schmahmann and Sherman 1998).

Signs and Symptoms of Upper Motor Neuron Involvement

Loss of Dexterity

Loss of dexterity is one of the most characteristic signs of UMN impairment. Voluntary skillful movements require

Table 80.2: Signs and symptoms of upper motor neuron

Loss -.i tk-xii -MI-
LOSS of muscle strength (weakness!
Spasticity
Pathological hyper-reflexia
Pathological reflexes
Increased redeyes in an atrophic limb
Pseudobulbar (spastic bulbar) palsy

the integrated activation of many interneuron circuits in the spinal cord; such integration is ultimately controlled by the corticospinal tract and thus by UMNs. Loss of dexterity may be expressed as stiffness, slowness, and clumsiness in performing any skillful motor actions; in particular, rapid repetitive motions, such as foot or finger tapping, are impaired (Table 80.2).

Loss of Muscle Strength (Weakness)

Although muscle strength is reduced, the degree *n*\ muscle-weakness resulting from UMN dysfunction is generally mild. Extensor muscles of the upper extremities and flexor muscles of lower extremities may become weaker than their antagonist muscles because the UMN lesion disinhibits brainstem control of the vestibulospinal and reticulospinal tracts.

Spasticity

Spasticity is the hallmatk of UMN disease. The pathophysiology of spasticity is complex and controversial: It seems to reflect altered firing of alpha motoneurons and interneurons within the spinal cord, together with increased activity of group II nerve fibers derived from muscle spindles. There is an excess level of excitatory input to gamma motoneutons via excess synaptic levels of excitatory neurotransmitters such as serotonin, noradrenaline, and glutamate. In addition, there is reduced inhibitory glycinergic and y-aminobutyric acid (GABAergic) neurotransmission. The result is a state of sustained increase in muscle tension when the muscle is lengthened. Clinically, muscles exhibit a sudden resistive "catch," midway during passive movement of the limb. However, when a sustained passive stretch is continued, spastic muscles quickly release the tension and relax, an event often described as the "clasp-knife phenomenon." In muscles that are severely spastic, passive movement becomes more difficult and even impossible. Sustained increases in muscle tone lead to a slowing in motor activities, which may be clinically demonstrated by asking a patient with spasticity to carry out rapid repetitive motor activities such as finger or foot tapping. In some patients with UMN degenerations, the increase in tone may be minimal.

Pathological Hyper-reflexia and Pathological Reflexes

Pathological hyper-reflexia is another crucial manifestation of UMN disease. The Babinski sign (extensor plantar response) is the most important sign in the clinical neurological examination and is characterized by extension of the great toe (often accompanied by fanning of the other toes) in response to stroking the outer edge of the ipsilatcral sole upward from the heel with a blunt object.

Pseudobulbar (Spastic Bulbar) Palsy

Pseudobulbar palsy (or spastic bulbar palsy) develops when there is disease involvement of the corticobulbar tracts that exert supranuclear control over those motor nuclei that control speech, mastication, and deglutition. The prefix "pseudo-" is used to distinguish this condition from "true" bulbar palsy that results from pure I.MN involvement in brainstem motor nuclei. Articulation, mastication, and deglutition are affected in both pseudobulbar and bulbar palsies, but the degree of impairment in pseudobulbar palsy is generally milder. Spontaneous or unmotivated ctyiug and laughter uniquely characterize pseudobulbar palsy. This is also termed *emotional lability,* labile affect, or *emotional incontinence* and is often a source of great embarrassment to the patient.

Laboratory Evidence of Upper Motor Neuron Involvement

Nettroimagmg

Brain magnetic resonance imaging (MRI) sometimes shows abnormal signal intensity in the corticospinal and corticobulbar tracts as they descend from the motor strip via the internal capsules to the cerebral peduncles. In AI.S, a disorder of UMNs (and LMNs), these signal changes are best appreciated on T2-weighted (increased signal in the internal capsules) and proton density (low signal in the preccntral cortex) images and probably represent wallerian degeneration. However, theses changes do not appear to be sufficiently sensitive or specific, and efforts continue to evaluate other potential MRI techniques, such as diffusion tensor and volumetric MRI, which may serve as markers of UMN disease (Ellis et al. 2001; Smith 2002).

Magnetic Resonance Spectroscopy Imaging

Proton density magnetic resonance spectroscopy ('H-MRS) is a noninvasive nuclear magnetic resonance technique that combines the advantages of MRI with in vivo biochemical information. N-acery(aspartate, a neuronal marker, is significantly reduced relative to creatine:phosphocreatine level (used as an internal standard because all cells, including glial cells, contain creatine and phosphocreatine),

Table 80.3: Disorders of upper motor neurons and their key characteristics

Disorders	*Key characteristics*
Primary lateral sclerosis	A diagnosis ɨ4 exclusion
Hereditary spastic paraplegia	Heredity, usually autosomal dominant, spastin gene mutation, other mutations (see text)
HTLV-1-associated myelopathy	Slowly progressive myelopathy, endemic, and positive HTLV-1
HTLV-2-associated myelopathy	Amerindian, IV drug abuser
Adrenomyeloneuropathy	X-linked recessive inheritance may have adrenal dysfunction myelopathy, very long chain fatty acid
Lathyrism	History of consumption of chickling peas
Konzo	Eastern African, cassava root consumption

HTLV = human T-lymphotropic virus; IV = intravenous.

in the sensorimotor cortices of patients with ALS who have UMN signs. Alterations in the measured levels of these metabolites using 'H-MRS can be used in the detection of UMN dysfunction early in the evolution of ALS and be used to monitor progression over time (Kaufmann and Mitsumoto 2002; Suhy ei al. 2(102;.

Transcranial Magnetic Stimulation

Another technique is transcranial magnetic stimulation (TMS), which electro physiologically evaluates UMN function. TMS over the scalp at the region of the motor cortex induces motor evoked potentials thai are recorded at the skeletal muscle and variations in the response pattern of the motor evoked potential have been correlated with UMN involvement (Auer-Grumbach et al. 2000).

Primary Lateral Sclerosis

Primary lateral sclerosis (PLS), first described by Frb in 1875, is a rare motor neuron disease variant that accounts for 2-4% of all cases of ALS and has traditionally been distinguished by a lack of LMN involvement. This has led some to argue that PLS is not a variant of ALS but is an entirely distinct entity. However, a recent prospective study tevealed several features that indicate not only some degree of LMN involvement but also disease extension beyond the motor system (Le Forestier, Maisonobe, Piquard 2001}. It typically presents in patients in their early fifties as a slowly evolving, spastic paraparesis that spreads to the upper extremities and eventually causes pseudobulbar palsy. Othet features include cramps, fasciculations, and sometimes urinary urgency, but such complaints arc neither prominent nor universal. Although muscle weakness is present, the main deficits are in dexterity and gait due to spasticity. The rate of progression can be exceedingly slow, often progressing over many years to the point where the patient manifests a robotic gait, debilitating generalized spasticity, and prominent pseudobulbar palsy. Muscle atrophy is a very late feature, if it occurs at all. There are no clinically detectable sensory changes, but derailed somatosensory evoked potential studies may be abnormal. Neuropsychology test batteries may define subtle cognitive deficits due to frontal cortical involvement, but dementia is not a prominent feature. A few patients may exhibit abnormal voluntary eye movements.

The underlying pathogenesis of PLS remains undefined. Pathological changes appear to be restricted to a striking loss of layer 5 Betz's cells in the frontal and prefrontal motor cortex (and other smaller pyramidal cells) and laminar gliosis of layers 5 and 5 with degeneration of the corticospinal tracts. Spinal anterior horn cells are spared. A recent study of a patient using serial MRI identified extensive involvement not just of the motor and premotor cortex but also extension of atrophy into sensory cortex suggesting possible selective loss of motor ptojection neurons {Smith 2002) (Table 80.3).

Diagnosis

The diagnosis of PLS is essentially one of exclusion. There have been rare reports of UMN-onset ALS where the interval between onset of UMN signs and subsequent LMN signs was 8, 9, and 27 years, respectively. As such, it is vital to periodically reassess patients who are diagnosed with PLS in case they develop late signs of LMN involvement that would reclassify their disorder as UMN-onset ALS,

All definable causes for generalized UMN involvement should be excluded by appropriate testing. These include structural abnormalities (Chiari malformation and intrinsic *AIII]* extrinsic spinal cord lesions) and myelopathies such as multiple sclerosis, human immunodeficiency virus (HIV) myelopathy, human T-lymphotropic virus type 1 (HTLV-1) myelopathy, Lyme disease, syphilis, or adrcnomyeloiieuroparhy. Spondylotic cervical myelopathy and multiple sclerosis are probably the most common causes among these disorders. The family history must be negative, to rule out hereditan spastic paraplegia :IIM' /ramilial spastic paraparesis, spinocerebellar ataxia (SCA), hexosaminidase-A (Hex-A) deficiency, familial ALS (FALS), or adrenomyeloneuropathy. Paraneoplastic syndromes (especially in association u ith breast cancer) and Sjogren's syndrome may also clinically resemble PLS.

Treatment

No specific pharmacotherapies are available for this condition. However, antispasticity drugs such as the $GABA_B$ agonist baclofen and the central a_2 agonist

tizanidine may be tried for symptomatic treatment. Severe spasticity sometimes requires the insertion of an intrathecal baclofen pump. Pseudobulbar affect lability may be controlled with tricyclic antidepressants or selective serotonin reuptake inhibitors. Recent evidence suggests that a combination of dextromethorphan and quinidine may also be useful in managing emotional lability. Good supportive care is essential.

Hereditary Spastic Paraplegia

HSP (or familial spastic paraparesis) is a genetically and clinically heterogeneous group of disorders rather than a single entity. The clinical feature common to all cases is progressively worsening spasticity of the lower extremities, often with variable degrees of weakness. Its estimated prevalence is 0.5-11.9 in 100,000, but its worldwide prevalence may actually be underestimated because of the benign nature of the disease in many families. Although the most common mode of inheritance is autosomal dominant, it may also be inherited in a recessive or X-linked fashion. The clinical syndrome may be broadly classified as the *pure* form and the *complicated* form. In the pure form, patients develop only lower extremity spasticity. However, the complicated form may also include optic neuropathy, deafness, ataxia, ichthyosis, amyotrophy, peripheral neuropathy, dementia, autoimmune hemolytic anemia, and thrombocytopenia (Evans's syndrome), extrapyramidal dysfunction, mental retardation, and bladder dysfunction. Age at onset is extremely variable, from early childhood to [lie ninth decade oi life.

Genetic linkage studies of families around the world have mapped loci to several autosomes including chromosomes 2, 3, 8, 11, 12, 14, 15, and 19, as well as on the X chromosome. An estimated 40% of all families arc linked to an autosomal dominantly inherited locus on chromosome 2p22-21, which encodes a 616-amino acid protein called *spastin.* More than 50 mutations of various types (missense, nonsense, frameshift, and splice site) have been identified that affect the *spastin* gene. Spastin is a highly conserved member of the AAA family of proteins ((adenosine triphosphatase [ATPase] associated with various cellular activities). Its exact role in the pathogenesis of HSP has yet to be defined, although there is evidence that HSP may involve a disturbance in the interaction of spastin with cellular tubulin, thus disrupting axonal transport. Pathologically, degeneration of the longest corticospinal tracts and to a lesser degree the posterior columns of the spinal cord is seen. Genes have been discovered for five other types of HSP. Mutations in the *SPG3A* gene on 14qll-q21 encoding the novel protein, atlastin, give rise to an autosomal dominant form of pure HSP. This protein shares structural homology to guanylate-binding protein 1, which is a member of the dynamin family. Dy nam ins arc known to be important in intracellular trafficking of various kinds of vesicles. Autosomal dominant pure HSP linked to 2q24-34 is caused by a mutation in the *SPG 13* gene, which encodes a mitochondrial heat shock protein, whereas recessively inherited complicated HSP linked to chi-orinsi'Mi;- Ifn; is c.niscd by .1 imitation in a gene encoding a mitochondrial protein known as *paraplegin.* The genes for two different X-linked complicated HSP have been identified; in the first, mutant LI (neural) cell adhesion molecule (LICAM) may disrupt neuronal migration or differentiation; in the second, mutant proreolipid protein is found in association with changes in white matter (Fink 2002).

Diagnosis

The diagnosis of HSP is based on evidence of a family history. When there is no family history, excluding definable causes other than spastic paraplegia is essential; the differential diagnosis is the same as discussed earlier for PLS. Because there may be no clear family history in the recessive form, the diagnosis of autosomal recessive spastic paraparesis is difficult. Patients may exhibit the striking feature for corticospinal tract lesions of hyper-reflexia and spasticity with brisk abdominal reflexes and flexor plantar responses; this constellation is a strong clue to the diagnosis of HSP.

Treatment

At present, treatment of spastic paraplegia is limited to symptomatic interventions, supportive care to reduce spasticity, and orthotics, such as canes, walkers, and wheelchairs. Antispasticity drugs, such as baclofen, tizanidine, diazepam, or dantrolene, are often suboptimal, and patients with very disabling spasticity may require intrathecal baclofen administered through an implanted pump.

Human T-Lyniphotropic Virus Type 1-Associated Myelopathy or Tropical Spastic Paraparesis

HTLV-1 causes a chronic progressive myelopathy that is referred to as tropical spastic paraparesis (TSP) in the Caribbean or HTLV-1-associated myelopathy (HAM) in Japan. This retrovirus is endemic in the Caribbean area, southwestern Japan, equatorial Africa, South Africa, and parts of Central and South America. Recent evidence implicates high levels of activated HTLV-1-specific helper T cells and cytotoxic T cells in the pathogenesis of this syndrome; these immune cells appear to become activated in response to interactions with retroviral env and tax proteins.

11AM/TSP is a chronic, insidiously progressive myelopathy that typically begins after age 30 years. In addition to slowly progressive spastic paraparesis, patients complain of lower extremity paresthesias, a painful sensory neuropathy,

and bladder dysfunction, and some patients may also develop optic neuropathy and SCA. Overall, evidence of LMN involvement may be scant and objective sensory findings may be difficult to detect. The definitive diagnosis of TSP/HAM requires HTI.V-1 -positive serology in blood and cerebrospinal fluid (CSF). The most sensitive and specific CSF detection involves a combination of polymerase chain reaction amplification of viral DNA, together with evidence of an increased HTLV-1-spccific antibody index and oligoclonal bands (Puccioni et al. 2001). At present, no antiviral agents effectively treat TSP/HAM, but a recent case report showed partial benefit when using plasmapheresis {Narakawa et al. 2001). As more is learned about the molecular etiology of HAM/TSP, future therapies will likely target the pathogenic effects of HTf.V-1-reactive T cells.

Human T-Lympbotropic Virus Type 2-Associated Myelopathy

Though phylogenerically similar in many respects, HTLV-1 and HTLV-2 are still antigenically distinct. Nonetheless, using enzyme-linked immunosorbent assays and Western blot techniques, many laboratories worldwide often report the presence of seroindeterminate HTLV-1/2. It has long been thought that myelopathy in such seroindeterminate cases is due to HTLV-1 rather than HTLV-2, but cases are now being described of a syndrome characterized by spastic paraparesis, diffuse hyper-reflexia, spastic bladder, and periventricular white matter changes on MR] in patients infected with HTLV-2, but not HTLV-1. This retrovirus is endemic in some Amerindian tribes and is now often encountered worldwide among intravenous drug abusers. As such, it is worthwhile to test CSF and serum for the presence of this virus in known intravenous drug abusers who present with a spastic paraparesis (Silva et al. 2002).

Adrenomyeloneuropathy

Adrenomyeloneuropathy is a variant of adrenoleukodystrophy, an X-linked recessive disorder caused by mutations in the *ABCDl* gene on chromosome Xq28 that encodes a ubiquitously expressed integral membrane peroxisomal adenosine triphosphate-binding cassette transporter protein. Mutations in this gene lead to abnormal peroxisomal beta-oxidation, which results in the harmful accumulation of very-long-chain fatty acids (VLCFAs) in affected cells. It has recently been proposed that excessive levels of VLCFAs may interfere with the membrane components of both neurons and axons (Powers et al. 2000). The most common phenotype, adrenoleukodysr.rophy, affects young boys 4-8 years of age who develop severe adrenal insufficiency, progressive cognitive deteri-<>ia:i(in, Mi/uri-.. blindness, dealness, and spastic qiauln paresis. In contrast, the milder adrenomyeloneuropathy is clinically characterized by slowly progressive spastic paraparesis and mild polyneuropathy in adult men with or without sensory symptoms and sphincter disturbances. Mild adrenal insufficiency may also be present. Adult female carriers may present with slowly progressive spastic paraparesis. Obtaining a detailed family history and appropriate testing is crucial. In adrenomyeloneuropathy, sural nerve biopsies arc characterized by the loss of both myelinated and unmyelinated axons with some degree of onion bulb formation. In addition, electron micrographs of the sural nerve biopsy specimen may show cha ractcfistic empty lipid clefts in Schwann cells. Nerve conduction studies and needle electrode examination may reveal a predominantly axon-loss type of sensorimotor polyneuropathy with a lesser component of demyelination. The diagnostic test of choice, however, is to demonstrate increased VLCFA levels in plasma, red blood cells, or cultured skin fibroblasts.

Plant Fxeitotoxins

Lathy7ism

Lathyrism is a chronic toxic nutritional neurological disease caused by long-term (or subacute) ingestion of large quantities of flour made from the drought-resistant chickling pea *(l.athyrus sativus)* and is an important example of a disease in which a natural excitotoxin causes selective UMN impairment. The responsible neurotoxin is *fi-N*-oxalylamino-L-alanine (BOAA), an a-amino-3-hydroxyl-5-mcthyl-4-isoxa/olepropionare (AMPA) glutamate receptor agonist. Ingestion of this neurotoxin results in increased intracellular levels of reactive oxygen species and subsequent impairment of the mitochondrial oxidative phosphorylation chain. Degeneration is most prominent in those Betz's cells of the motor cortex (and corresponding pyramidal tracts) that subserve lower extremity function. Lathyrism has been found in the indigenous populations of Bangladesh, China, Ethiopia, India, Romania, and Spain. It was also described in the concentration camps during World War II. The condition may occur in epidemic form when malnourished populations increase consumption of flour made from L. *sativus* chickling peas in drought-prone areas during times of food shortage. A recent analysis of an epidemic of neurolathyrism in Ethiopia showed that boys aged 10-14 years were most often affected and that increased risk was associated with cooking grass pea foods in traditional clay pots (Getahun et al. 2002). The onset of clinical toxicity is either acute or chronic, manifesting as muscle spasms, cramps, and leg weakness. In addition to spastic paraparesis, there may be sensory (including leg formications) and bladder dysfunction. Occasionally, there is a coarse tremor of the upper extremities. Although irreversible, the disorder is self-limiting and there is no apparent shortening of life span.

Konzo ("tied legs") is another toxic nutritional disorder of cortical motor neurons caused by chronic dietary ingestion of a neurotoxin derived from flour made from short-soaked cassava roots. The disorder is endemic in protein-deficient communities in Tanzania, Zaire, and Eastern Africa and in times of famine can occur in epidemic form. The neurotoxic effect of chronic cassava root ingestion likely is derived from the liberation of cyanohydrins from the flour, which may be further metabolized to thiocyanate. The latter in turn may excessively stimulate the AMPA glutamate receptor subtype precipitating excitotoxic neuronal injury. As with lathyrism, there appears to be a selective effect on the lower extremity-directed Ber/'s cells of the cerebral cortex and their corresponding corticospinal tracts. As such, the clinical syndrome is also very similar to lathyrism; patients typically present with spastic paraparesis (although some may exhibit only lower extremity hyper-reflexia). Occasionally, one may detect weakness of the upper extremities but not to the same degree as that of the lower extremities.

DISORDERS OF LOWER MOTOR NEURONS

Neuroanatomy of Lower Motor Neurons

Interneurons

The interne urons constitute most of the anterior horn cells of the spinal cord and determine the final output of the LMNs. The interneuron system receives supranuclear excitatory and inhibitory motor control from the brainstem descending tracts, corticospinal tracts, and limbic system; this system also receives afferent information, directly and indirectly, from the afferent peripheral nerves. The interneuron system forms intricate neuronal circuits involving automatic and stereotyped spinal reflexes, to coordinate and integrate the activation of synergist muscles while inhibiting antagonist muscles, contralateral muscles, and sometimes even a distant motor pool. The same interneuron network that mediates such automatic and stereotyped reflex behavior is also known to act as the basic functional unit involved in highly skillful voluntary movements. Ultimately, all of the interneuronal paths converge on the LMNs that innervate skeletal muscles, which Sherrington has called the *final common path.*

Lower Motor Neurons

LMNs are located in the brainstem and spinal cord and send out motor axons that directly innervate skeletal muscle fibers. Spinal cord LMNs are also known as *anterior horn celts* and are clustered in nuclei forming longitudinal columns; those innervating the distal muscles of the extremities arc located in the dorsal anterior horn, whereas those innervating proximal muscles of the extremities are in the ventral anterior horn. Those LMNs that innervate the axial and truncal muscles are the most medially located. The normal cervical and lumbar enlargements of the spinal cord are the result of markedly enlarged lateral anterior horns containing the LMNs for the upper and lower limb muscles.

Large spinal cord LMNs are called *alpha motoneurons* and are the principal motor neurons innervating muscle fibers. Medium-sized motor neurons *(beta motoneurons)* innervate both extrafusal and intrafusal (muscle spindle) fibers and intermediate and small motor neurons *(gamma motoneurons* or *fusimotor neurons)* innervate only spindle muscle fibers. The rest of the small anterior horn cells are *interneurons.*

Alpha motoneurons are among the largest neurons of the nervous system. Each has a single axon that branches to its target muscles and a number of large dendrites that provide an extensive receptive field. The motor unit is the smallest unit of the motor system and consists of one alpha motoneuron, its axon, and all of its target muscle fibers,

Motor axons originating from LMN cell bodies (perikarya) leave the central nervous system (CNS) through the anterior (or ventral) spinal roots to become a part of the peripheral nervous system. Motor axons subsequently intermingle with sensory and autonomic nerve fibers in individual peripheral nerves. All peripheral nerve fibers are ensheathed by Schwann cells, and all motor axons are myelinated. The environment of the peripheral nervous system is controlled by the blood-nerve barrier and perineuria! sheath. Neurotrophic factors are thought to be absorbed at the axon terminal, but other macro molecules, neurotoxins and viral particles included, can also enter the motor axons at this site.

Signs and Symptoms of Lower Motor Neuron Involvement

Loss *of Muscle Strength (Weakness)*

The loss of an LMN will result in the denervation of its motor unit, whereas an impaired LMN may lead to abnormal or impaired activation of its motor unit. In either case, the number of fully functional motor units is decreased, which reduces overall muscle twitch tension.

In a disease that causes chronic motor unit depletion, neighboring axons belonging to healthy motor neurons may reinnervatc denervated muscle fibers belonging to a diseased motor unit. In this way, existing motor units are continually modified in the face of persistent losses of motor axons to maximize muscle strength. For example, in patients who have recovered from acute poliomyelitis, more than 50% of LMNs are usually found to be depleted before muscle weakness is clinically detected. Healthy individuals have more than enough motor units available to offset an unexpected loss of motor neurons (Table 80.4}.

Table SO.4: Signs and symptoms of lower motor neuron involvement

Loss of muscle strength (weakness)
Muscle a trophy-
Hypo re flcxia
Muscle hypotonicity or flaccidity
Fasciculations
Muscle cramps

Muscle Atrophy and Hyporeflexia. Muscle fiber denervation causes muscle fiber atrophy, and thus progressive LMN involvement results in reduced overall muscle volume and size. Hyporeflexia occurs with LMN involvement because the loss of active motor units reduces the overall muscle twitch tension; thus muscle stretch reflexes elicit less tension (diminished tcflexcs) or no visible twitch (absent reflexes).

Muscle Hypotonicity or Flaccidity

Hypotonicity, or *flaccidity,* refers to the decrease or complete loss of normal muscle resistance to passive manipulation. In contrast to spasticity, the muscle lies inert and flaccid.

Fasciculations

Fasciculations are spontaneous contractions of muscle fibers belonging to a single (or part of a) motor unit. Clinically, fasciculations appear on the muscle surface as fine, rapid, flickering, and sometimes vermicular contractions that occur irregularly in time and location. The impulse for the fasciculation appears to arise from hyperexcitable motor axons anywhere in their course. Fasciculations can occur both in healthy individuals and in patients with LMN involvement, so fasciculations themselves do not indicate LMN disease.

In general, the larger the muscle the greater the size of the fasciculations, but the sine of the motor unit is also a factor. In tongue muscles, for example, fasciculations produce small vermicular movements on the tongue surface. Fasciculations usually do not cause -ny joint displacement but when fasciculations occur in muscles going to the fingers, joint movements can occur (mini-polymyoclonus). Large fasciculations may be found in large muscles undergoing a highly chronic reinnervating process such as chronic spinal muscular atrophy (SMA) and the postpoliomyelitis syndrome.

Muscle Cramps

Muscle cramps are common in the general population and are another common symptom of LMN involvement. The pathogenesis of cramps in LMN disease is poorly understood, as it is in normal individuals. Cramps and fasciculations are likely to share a common pathogenic mechanism, such as hyperexcitability of the motor neurons. Muscle cramps are clinically defined as an abrupt, involuntary, and painful shortening of the muscle, which is accompanied by visible or palpable knotting, often with abnormal posture of the affected joint; they can be relieved by stretching or massaging.

Laboratory Evidence of Lower Motor Neuron Involvement

Electrodiagnostic Examination

The electrodiagnosric examination (LDX) consists of nerve conduction studies and needle electrode examination (see Chapter 36B). The loss of motor units is reflected in the loss of compound muscle action potential (CMAP) amplitudes. In a primarily demyelinatiug process, there may be a slowing of conduction velocity and in severe cases conduction block. In a primarily axon loss process, there is usually only a modest degree of conduction velocity slowing commensurate with dropout of large myelinated axons. Sensory nerve conduction studies ate normal in pure LMN disorders.

The needle electrode examination is crucial in obtaining electrophysiological evidence of abnormal motor units in LMN disorders. Muscle fibers that are actively denervated discharge spontaneous electrical activity, such as fibrillation potentials and positive sharp waves. Fasciculation potentials may also be detected, but as an isolated EDX finding, they are insufficient evidence of an axon loss disorder. The recruitment pattern during voluntary muscle activation is also altered in neurogenic disease, with a reduced number of motor units that have an increased firing rate; this reflects a compensatory effort on the part of surviving motor units to maintain a particular force.

Because denervation of muscle fibers triggers a reiimervation process, motor units are continuously remodeled. Early in the reinnervating process, newly formed neuromuscular junctions are electrically unstable, and thus the action potentials of the muscle fibers vary in amplitude. Furthermore, newly regenerated axons that reinnervate denervated muscle fibers tend to have slow conduction velocities, causing a prolonged conduction time within one motor unit. All these changes alter the configuration of the motor unit potential so that it becomes irregular and polyphasic. In a chronic reinnervating process, surviving motor units may reinnervate a greater number of muscle fibers, resulting in a potential that is broader in duration and higher in amplitude. Therefore the shape of a typical chronic neurogenic motor unit potential is polyphasic, broad, and high in amplitude, providing clear evidence of IAIN involvement.

Motor unit number estimation (MUNE) is a specialized neurophysiologies! tool that can estimate the number of functioning motor units that remain in a progressive

neurogenic process. Various techniques are in use including a statistical method and a multipoint stimulation technique, but issues of reproducibility remain, so MUNE remains largely a research tool.

Muscle Biopsy

Although EDX usually provides sufficient evidence of L.V1N involvement, muscle biopsy may also reveal early evidence of muscle fiber denervation. Denervated muscle fibers are small, angular, and stain darkly by oxidative enzyme and nonspecific esterase stains. As the denervation process progresses, small groups of atrophied muscle fibers (group atrophy) may appear. In normal human muscle, the different muscle fiber types that are distinguished using ATPasc stain appear in a random distribution, sometimes mistetmed a "checkerboard pattern." In chronic denervating disease, repeated denervation and reinncrvation eventually result in loss of this random pattern and in very chronic neurogenic disease large areas of the biopsy consisting of just one muscle fiber type, a process called *fiber type grouping.*

Magnetic Resonance Imaging

MR] neurography is a relatively novel technique in sequence acquisition that can detect early signal change both in injured axons and in denervated muscle on T2-weighted and short tau inversion recovery images. These signal changes can distinguish focal sites of nerve entrapment, regenerating nerve fibers, nerve tumor, and nerve transection. Those segments of peripheral nerve that are difficult to study using standard EDX, such as very proximal portions of the sciatic nerve and the above-elbow segment of the ulnar nerve, may be visualized with this technique. The MRI muscle signal change can occur as early as 4 days after a traumatic nerve injury and is reversible as long as reinnervation takes place. As such, this emerging field is being applied to the noninvasive evaluation of entrapment neuropathies, nerve trauma, peripheral nerve tumor surgery, brachial plexopathy, radiculopathies, and peripheral neuropathies (Grant et al. 2002).

Acute Poliomyelitis

Poliomyelitis (acute anterior poliomyelitis) is one of the most dramatic disorders causing acute LMN dysfunction. The disease is caused by poliovirus, a single-stranded RNA enterovirus belonging to the picornavirus family. The mode of spread is via the fecal-oral route, the virus first entering lymphoid tissue before being borne in the bloodstream to the CNS. Before the introduction of oral poliovirus vaccine, epidemics of acute paralytic poliomyelitis were relatively common in temperate zones and primarily affected children and young adults (infantile paralysis). In 1988 the World Health Organization resolved to eradicate poliomyelitis worldwide. However, this has yet to be achieved. The oral poliovirus vaccine itself is responsible for very rare cases of acute paralytic poliomyelitis in the developed world with an estimated risk of 1 case in 2.5 million vaccines ingested. Non-polioviruses can cause a paralytic polio-like syndrome, and it is still important that physicians be acquainted with this syndrome.

Clinical Features

After a brief 3-6 day incubation period, a viremia occurs, during which approximately 90% of individuals remain asymptomatic. However, most of the remaining 10% develop an acute, flu-like illness with cough, malaise, diarrhea, myalgia, headache, and fever. This self-limited, "abortive" polio usually lasts 2-3 days and patients do not progress to develop acute muscle weakness, although recent evidence indicates that some such patients may develop features of the postpolio syndrome many years later (Bruno 2000). Between 2-3% of patients develop aseptic meningitis characterized by severe headache due to meningeal irritation. This is typically self-limited and resolves within 7-14 days. Fewer than 1% of patients who ingest poliovirus develop the acute paralytic syndrome, characterized by localized fasciculations, severe myalgia, hyperesthesias, and usually fulminant focal and asymmetrical paralysis. Any muscle can be affected, including the diaphragm and intercostal muscles; the leg muscles are the most commonly affected, and the bulbar muscles the least common.

Physical examination reveals severe LMN-typc muscle weakness with hypoactive or absent deep tendon reflexes, decreased muscle tone, and fasciculations. With progression of the disease, muscle atrophy occurs. Objective signs of sensory loss are not characteristic. The risk of paralytic disease seems to increase with patient age and with the level of virulence of the virus. Most patients with paralytic disease recover significant strength. Improvement may begin as early as the first week after the onset of paralysis, and it has been estimated that 80% of recovery will occur by 6 months. Eutther improvement may be modest, but it may continue over the ensuing 18-24 months. Up to two thirds of patients are left with some degree of significant functional impairment.

Laboratory Features

Motor nerve conduction studies performed 21 or more days after the onset (see Chapter 36B) may reveal low-amplitude CMAPs. There is no evidence of significant demyelination-rclatcd motor slowing or conduction block. Sensory nerve action potentials (SNAPs) arc normal. When needle electrode examination is performed in the acute phase, profuse axon loss may be detected in the form of positive sharp waves and fibrillation potentials. In addition, fasciculations may be prominent. As motor axon loss

progresses, evidence of neurogenic motor unit potential changes may be detected. The CSF typically shows a pleocytosis, with polymorphonuclear cells predominating during the acute stages and lymphocytes predominating later in the disease. CSF protein levels are mildly to moderately increased. Identification of CSF poliovirus-specific immunoglobulin M (IgM) antibody allows a specific-diagnosis, Stool cultures are positive* for poliovirus in nearly 90% of patients by the tenth day of illness. Traditionally, the diagnosis is established by documenting a fourfold or greater increase in antibody titer against poliovirus in sera from the acute as compared to the convalescent phase.

Differential Diagnosis

Acute paralytic disease caused by enteroviruses other than poliovirus and West Nile virus can manifest identically to acute poliomyelitis. The documentation of an increase in neutralizing antibody titers of these other viruses from acute compared to convalescent sera or isolation of the virus in culture is the only way to make a cotrect diagnosis. Although acute paralytic poliomyelitis has a distinct clinical presentation, Guillain-Barre syndrome may mimic it because acute paralysis of the skeletal muscles occurs in both. Guillain-Barre syndrome has some sensory signs and symptoms, although it can present with predominantly motor symptoms. A dramatic or abrupt paralysis following severe pains and fasciculations is unusual in Guillain-Barre syndrome. A careful analysis of the CSF and electromyographic (FMG) findings should differentiate these diseases. Acute immune-mediated motor neuropathy (acute motor axonal neuropathy) should also be considered in the differential diagnosis. This motor neuropathy, which resembles Guillain-Barre syndrome, usually presents with rapidly progressive weakness in distal extremity muscles without sensory symptoms. One must also consider myasthenia gravis, neuralgic amyotrophy, acute intermittent porphyria, periodic paralysis, tic paralysis, and acute rhabdomyolysis.

Treatment

The treatment of acute paralytic poliomyelitis consists of aggressive general supportive care. Most patients will require hospitalization in an intensive care unit to optimize close monitoring of ventilatory and cardiovascular function. After the acute illness, aggressive rehabilitation is the mainstay of continued treatment.

Vaccination

Ultimately, the best cure for polio is prevention. Two vaccines are available, the Sabin and the Salk. The Sabin trivalent oral poliovirus vaccine contains all three live attenuated serotypes of poliovirus and is almost 100% effective in preventing acute paralytic poliomyelitis. Adults who plan to travel to areas where poliomyelitis is prevalent should receive an extra dose of this vaccine. Immunocompromised individuals, their household contacts, and adults who have never received poliovirus vaccine previously should receive the Salk formalin-inactivated poliomyelitis vaccine rather than the Sabin vaccine because there is an increased risk of these individuals developing acute paralytic poliomyelitis if the oral poliovirus vaccine is used.

Progressive Postpoliomyclitis Muscular Atrophy

In the United States alone, it is estimated that 250,000-640,000 people survived acute poliomyelitis, the last epidemic of which occurred in 1952. Many years after recovery from acute poliomyelitis, some patients experience progressive weakness, called progressive postpoliomyclitis muscular atrophy (PPMA). The reported incidence of PPMA among polio survivors ranges from 28,5-64.0%; an accurate estimate of the incidence is not known. By definition, patients with PPMA have recovered from acute poliomyelitis and the disease course has been stable fot at least 10 years after the recovery. Although PPMA appears to be well defined, an unusually wide disparity in the reported occurrence raises the concern that the identity of PPMA may be more ambiguous than previously thought. Although here we use the term *I'VMA* to describe a progressive LMN syndrome, terms such as *postpolio syndrome* or *late effects of remote polio* may be more appropriate because patients who have had remote poliomyelitis may develop a multitude of symptoms in addition to progressive muscle weakness and wasting (Table 80.5).

Etiology

The etiology of PPMA has yet to be established. Chronic persistent poliovirus infection is a possibility, but numerous studies have failed to convincingly identify poliovirus

Table 80.5: Characteristic features of progressive postpolio myelitis muscular atrophy

in PPMA. Similarly, there is a lack of solid evidence to implicate a persistent immune-mediated mechanism, which might explain the presence of oligoclonal bands in the CSF and occasional lymphocytic infiltrates in the muscle and spinal cords of patients with PPMA. The "peripheral disintegration model" is the most widely held theory. In the immediate aftermath of the acute paralytic poliomyelitis, there is ovcrsprouting of new axon terminals from surviving LMNs. This compensatory distal reinnervation expands the size of motor units and provides effective motor function; this stabilizes muscle strength for many years. However, this extensive nerve sprouting also increases the metabolic burden of surviving LMNs, so alter many years, an unidentified process first causes nerve terminal dysfunction presenting as fatigue and then nerve terminal disintegration presenting as muscle weakness and atrophy. It is possible that the normal age-related neuronal loss may be the process causing this late degeneration.

Clinical Features

Patients with PPMA note a stable course for many years after the acute poliomyelitis infection. These patients then experience progressive new muscle weakness and atrophy in previously affected muscles or sometimes in muscles that were apparently not affected by the original poliomyelitis. Needle electrode examination reveals that the muscles that were not clinically affected by acute poliomyelitis often have clear evidence of previous disease, indicating that PPMA is unlikely to affect muscles not affected during the acute poliomyelitis. Muscle cramps and fasciculations may accompany the new weakness, hut they are often present in stable muscles in these patients as well. Other common symptoms include pain, generalized fatigue, cramps, fascit :• ulations, sleep disturbances, cold intolerance, dysphagia, and dysarthria. The most common clinical presentation is that of insidious onset of muscle and joint pain with progressive weakness in muscles that were previously affected by acute paralytic poliomyelitis. Generalized fatigue is a characteristic accompaniment and is uften called the *polio wall.* As patients realize that their motor function is becoming progressively impaired after a lifelong compensation, they may become severely depressed. The neurological examination reveals focal and asymmetrical muscle weakness and atrophy, but it may be difficult to determine which weakness and atrophy is new and progressive and which is remote and static. Pasciculations can be unusually coarse and large in keeping with the giant motor units that may be seen during needle electrode examination.

Laboratory Features

Because **EMG** provides definitive evidence of remote poliomyelitis and excludes diseases mimicking PPMA, it is an indispensable lest when PPMA is suspected. It is extremely important to remember that the EMG studies do not provide the diagnosis of PPMA, however. In patients with PPMA, the motor nerve conduction studies may be abnormal {low CMAP amplitudes) when recorded from affected muscles. The needle electrode examination of affected weak muscles typically shows a reduced number of motor units and chronic neurogenic motor unit potentials. Giant motor units may be present, indicative of chronic denervation and reinnervation. Modest numbers of fibrillation potentials and occasional fasciculations may be observed in affected muscles. Sensory nerve conduction studies are normal. The muscle biopsy specimen usually shows acute and chronic neurogenic atrophy and often marked fiber type grouping; however, these biopsy findings are not diagnostic of I'PMA.

Diagnosis

A history of clinical stability for at least 10 years after recovery from acute poliomyelitis is an absolute prerequisite for considering the diagnosis of I'PMA. When this requirement is satisfied, PPMA is then a diagnosis of exclusion. All potential diseases causing progressive, focal, and asymmetrical weakness must be excluded. Cervical or lumbosacral radiculopathy, electrolyte abnormalities, endocrine diseases, diabetic amyotrophy, connective tissue disorders, entrapment neutopathies, inflammatory myositis, inflammatory neuropathy, and vasculitis are among the diseases to be ruled out by appropriate laboratory studies, including blood tests, neuroimaging, EMG, and lumbar puncture.

True AI.S is slightly more common in patients with remote poliomyelitis than in the general population. The diagnosis of ALS must be considered in patients with PPMA. Although ALS involves both UMN and LMN involvement, the progressive focal muscle weakens and atrophy seen in PPMA may raise the possibility of the progressive muscular atrophy (PMA) variant of ALS.

Treatment

No specific pharmacotherapy is available to treat PPMA. Thus management must focus on general supportive measures that preserve function. The care plan should focus on avoiding fatiguing activities that aggravate symptoms; mndifyins-, ^.cliv^ics tr. conserve energj and weight reduction for those who are overweight; and treating underlying medical disorders that reduce overall well-being. Careful screening and treatment for possible sleep apnea and depression are important.

Physical therapy should focus on nun fatiguing aerobic exercise and modest isometric or isokinetic exercise and stretching maneuvers are especially important. Studies have demonstrated that resistive exercise training can increase muscle strength over a period of more than 1 year. In patients with more serious functional decline, appropriate assistive devices must be prescribed so patients can maintain activities of daily living. Those whc> develop respiratory

insufficiency must be fully evaluated by pulmonologists to rule out primary pulmonary disease. Noninvasive positive pressure ventilatory assistance should be considered. Those patients whose employment or lifestyle involves significant physical exertion may need to substantially modify their work duties and other activities.

Multifocal Motor Neuropathy

Originally described in 1988, multifocal motor neuropathy (MMN) is a treatable motor neuropathy that superficially resembles motor neuron disease. MMN is characterized by a pure motor syndrome that develops in association with motor nerve fiber demyelination. The classic form of this is associated with elect".diagnostic evidence of multifocal demyelination conduction blocks and elevated titers of antibodies against d.Vl, gangliosidcs. Clinically, patients develop slowly progressive multifocal muscle weakness and atrophy (Table 80.6).

Etiology

The etiology of MMN is not established. However, the presence of high titers of anti-GMi ganglioside antibodies in approximately half (range 20-84%) of these patients suggests an autoimmune disorder with a predilection for myelinated motor nerves. Many experimental studies support this hypothesis; rabbits immunized with GM_L ganglioside develop ;i neuropath) resembling MMN; the adnxonnl GM) ganglioside content is greater in motor nerve fibers than sensory nerve fibers; anti-GMi antibodies can bind to the nodes of Ranvier and anterior horn cells; the antibody can alter K^+ and Na^{H}" currents in myelinated axons; many cases of MMN respond to immunomodulatory treatment. On the other hand, patients who are anti-GM, antibody negative are clinically and clcctrodiagnostically identical to those who are antibody positive. In addition, anti-GM i antibodies are not disease specific; low titers are detectable in approximately 5% of patients with ALS, a disorder not characterized by the presence of demyelinating conduction block, whereas extremely high titers may indicate a monoclonal gammopathy. These findings suggest that other antibodies may have a role to play in the pathogenesis ol MMN.

Clinical l-eatures

The age at onset is generally 20-75 years, and men are more often affected than women. Patients typically present for initial evaluation about 1 or more years after onset of -.yiuproins and the course rhri extends o\er many ve;irs. Many patients have been misdiagnosed as having ALS. Although MMN is associated with disability, most patients remain in the workplace and uncomplicated MMN is generally not a fatal disorder. Clinically, MMN is characterized by asymmetrical, slowly progressive weakness that most commonly begins in the distal upper extremities in the distribution of two or more individual peripheral nerves. Muscle weakness is usually greater than would be expected from the degree of muscle atrophy. MMN may also affect the lower extremities, often with slowly progressive foot-drop or focal leg weakness and atrophy. Rare presentations include respiratory failure from phrenic nerve involvement, bulbar dysfunction from hypoglossal nerve involvement, and ophthalmoplegia. In the early stages, the degree of muscle weakness is far in excess of the degree of muscle atrophy, indicative of a primarily demyelinating disorder rather than one of axon loss. In affected muscles, the muscle stretch reflexes are usually preserved albeit diminished. Regions with normal strength have normal reflexes. Fasciculations are not uncommon, which may raise concerns that one is dealing with LMN-onset ALS. However, subsequent examinations never reveal clear U.VfN signs to suggest a diagnosis other than MMN. Some patients may report paresthesias or reduced sensation, but objective sensory signs are either absent or clinically insignificant.

Laboratory Studies

A thorough EDX study is imperative to establish the diagnosis of MMN, The original American Ac.nlenn of Electrodiagnostic Medicine (AAEM) criteria required the presence of focal conduction block along two or more-motor nerve fibers, particularly at sites that are anatomically distinct from common entrapment sites. However, it is now recognized that some cases may have focal conduction slowing along segments of motor nerve rather than actual conduction block. Prolonged distal latencies, prolonged F-wave latencies, and temporal dispersion of CMAPs may also be seen. There may even be some degree of axonal degeneration (positive sharp waves and fibrillation potentials) detected on EDX (Taylor et al. 2000). Sensory nerve conduction studies are normal whether they arc recorded from pure sensory or mixed sensorimotor nerves.

High titers of serum IgM anti-GM, antibodies support a diagnosis of MMN. However, it is important to remember that low titers may be detected in ALS and extremely elevated anti-GM, antibodies (>1:40,000) should prompt an investigation for an IgM monoclonal gammopathy. CSF protein concentration is usually normal but may he modestly etc va led to less tii.m Kill ni(',.AU..

Differential Diagnosis

Although focal asymmetrical muscle weakness and atrophy occur both in ALS and in MMN, the former is characterized by the additional presence or later development of prominent UMN and pseudobulbar findings. It is thus crucial to perform follow-up examinations to distinguish between these disorders. PMA is a rare pure LMN syndrome that often presents with focal and asymmetrical weaknesses in distal extremity muscles, thus closely mimicking MMN. However, the weakness in PMA is regional rather than in the distribution of major motor nerves (as seen in the earlier stages of MMN). PMA is associated with neither conduction blocks nor high titers of anti-GM! antibodies and does not respond to immunomodulatory treatment.

One of the useful clinical clues is that weakness exceeds atrophy.

The combined electro diagnostic and serological criteria that support MMN serve to differentiate it from other predominantly motor disorders such as adult-onset SMA, benign focal amyotrophy/monomelic amyotrophy, and acute neuralgic amyotrophy (Parsonage-Turner syndrome). The classic anti-Hu antibody-associated paraneoplastic syndrome is a subacute sensory neuronopathy, but a recent retrospective analysis of 20 patients revealed that 5% of presentations were pure motor in nature and 10% were multifocal in distribution (Camdessanche et al. 2002). Furthermore, a subacute paraneoplastic pure motor neuropathy has been described in the setting of an underlying lymphoproliferative disorder.

There are many similarities between MMN and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP). Both are characterized by the presence of dcmyclination-range motor conduction slowing and/or conduction block. However, there are significant differences. MMN characteristically involves distal upper extremity muscles in an asymmetrical fashion, whereas CIDP typically involves proximal muscles in a symmetrical fashion. A remitting and relapsing course is uncommon in MMN but common in CIDP. Although CIDP can manifest as a predominantly LMN syndrome, clinical and electrodiagnostic sensory abnormalities arc the rule, which is in stark contrast to MMN. Reflexes are characteristically absent in CIDP, whereas they are usually present but diminished in MMN. CSF protein levels do not exceed 100 mg/dL in MMN and are usually normal, but very high CSF protein levels are not uncommon in CIDP. CIDP responds well to corticosteroids and plasma exchange, whereas these treatments are generally not effective in MMN.

MMN must also be clearly differentiated from multifocal acquired demyelinating sensory and motor neuropathy (MADSAM or Lewis-Sumner syndrome). This disorder may very closely mimic MMN. It presents in the same age-group and in the same tippet limb-predominant asymmetrical fashion in the distribution of multiple different distal peripheral nerves. Reflexes are usually diminished rather than absent. However, clinical examination and EDX typically reveal sensory abnormalities, which distinguish this unusual disorder from MMN. MADSAM may respond to intravenous immune globulin (IVIG) therapy or prednisone. Other immune-mediated demyelinating neuropathies, such as a nti-myel in -associated glycoprotein (anti-MAG) antibodies or polyneuropathy with monoclonal gammopathy, cause not only severe muscle weakness but also prominent sensory loss and often other systemic signs.

There has been a report of a small series of patients *(n* = 9) with a slowly progressive or nonprogressive pure axonal MMN in the absence of anti-GM, antibodies. No electrodiagnostic features of demyelination were detected, but there was evidence of a "relatively indolent axonal process." This condition, referred to as *multifocal acquired motor axonopatby,* may respond to corticosteroids or IVIG infusions (Katz et al. 2002).

Treatment

Although MMN is considered an immune-mediated disease, neither plasma exchange nor corticosteroids are effective and may even worsen the condition. The treatment of choice is IVIG prepared from pooled human immunoglobulin G (IgG) (Van den Berg-Vos et al. 2000). To date, four separate randomized placebo-controlled trials have shown the benefit of this therapy in MMN. Clinical improvement may be noticed within a matter of hours, but generally one may expect a benefit within 15 days. It appears that those patients who ate younger, who are anti-GMi antibody positive, have conduction blocks, and who are clinically milder at onset have the best response. In general, conduction blocks are not altered by this therapy despite improvements in clinical motor function. Similarly, treatment does not appear to reduce anti-GM i antibody titers. A total dose of 2 g/kg given as a slow intravenous infusion in divided doses over 2-5 days can improve strength in more than 50% of patients. The duration of benefit varies between patients, ranging from 2 weeks to *6* months or more. It is usually necessary to tailor the particular schedule on a case-by-case basis depending on how the individual responds and how long the effect lasts. A typical maintenance schedule is 400-600 mg/kg once every 3-8 weeks. Serum immunoglobulin A (IgA) should be checked before treatment: Those who have congenital IgA deficiency-may suffer an anaphylactic reaction to second and later infusions because of the presence of a small amount of IgA

contamination in the pooled IgG infusion. Side effects of iVIG include headaches, aseptic meningitis, allergic reactions {including acute renal failure), strokes, myocardial infarctions, and fluid overload. IVIG treatment is expensive; therefore objective documentation of improvement, including quantitative muscle strength testing and quantitative motor function testing, is important to prove efficacy.

Apart from IVIG, there have been no prospective, double-blind, randomized, placebo-controlled treatment trials completed to assess the value of alternative immunomodulatory treatments for MMN (Umapathi et al. 2002). However, several small scries and case reports show that cyclophosphamide treatment is also effective, ft is the only immunosuppressive treatment that may induce *a* long-term benefit and it does so in more than 50% of patients with MMN. I f i >', I • cunuiLime lilt-lime ik >,:-, (>7\i g) increase the risk of neoplasia, especially of the bladdet. Thus cyclophosphamide is reserved for more severe cases that cannot tolerate or do not respond to IVIG. Six monthly treatments with intravenous cyclophosphamide (1 g/M^2), each preceded by two plasma exchanges, are the recommended regimens. This regimen not only produces a sustained motor improvement but also a sustained 60-80% reduction in serum anri-GM, antibody liter in two thirds of patients. One or two more additional treatments may be given if the patient is not improving and anti-GM, antibody titers do not decline. There is often a 3-6-month delay in improvement after starting cyclophosphamide therapy, and remission usually lasts for 1-3 years, after which time antibody titers often rise and weakness recurs. Retreatment may then be necessary.

Several small case series have recently reported beneficial effects of interferon-/Ma in refractory cases of MMN. In addition, rituximab, a chimeric monoclonal antibody directed against the B-cell CD20 epitope, was effective in improving motor outcome in four patients with MMN. Clearly, further prospective controlled trials are necessary to define nie potential use ot interferon ,mtl IIKI:K>C1OI:;I1 antibody therapy in MMN.

Benign Focal Amyotrophy

Most diseases affecting LMNs begin as muscle weakness in a focal area and in one extremity. In most cases, the disease steadily and relatively rapidly spreads from one extremity to another. However, there is a condition involving a limited number of myotomes in one extremity that does not spread. The terms *benign focal amyotrophy, monomelic amyotrophy,* or *juvenile segmental muscular atrophy* are used to describe this intriguing entity (Donofrio 1994).

Etiology and Pathogenesis

The etiology is unknown. Autopsy studies have shown thai the affected cervical spinal cord is flattened; the anterior horn is markedly atrophied and giiotic and the numbers of both large and small motor neurons are reduced. Some researchers believe that this is a mechanically induced disease being the result of local compression of the dura and spinal cord against vertebrae during neck flexion. However, surgical decompression has not altered the course of the diseases, and this theory is no longer widely held. Another school of thought is that this is a segmental, perhaps genetically determined, SMA. Indeed, rare familial occurrence has been reported and a case of Werdnig-Hoffmann disease was found in a close relative of a patient who had benign focal amyotrophy. This may, of course, have been purely coincidental.

Clinical Features

The disease usually begins in the later teens, but many cases can present in the fourth decade. More than 60% of patients are men. Although originally described in men from India and japan, the disorder is now recognized around the world. The most common presentation is one of an idiopathic, slowly progressive, painless weakness and atrophy in one hand or forearm. The distribution of muscle weakness varies markedly from case to case, but a characteristic feature is that the condition remains limited to only a few myotomes in the affected limb. Muscle stretch reflexes arc invariably hypoactive or absent in muscles innervated by the involved cord segment but are normal elsewhere. UMN signs are not present. Approximately 20% have hypesthesia to pinprick and touch, usually located on the dorsum of the hand. The cranial nerves, pyramidal tracts, and the autonomic nervous system arc spared. Weakness and atrophy may progress steadily for the initial 2-3 years, but approximately 75% of patients have .stabilized within 5 years. I lit arm is affected in approximately 75% ol the patients, whereas the leg is affected in the remaining 25%,

Laboratory Studies

There are no pathognomonic laboratory or electrodiagnostic tests for this condition. Their main purpose is to exclude alternative diagnoses. Motor nerve conduction studies are either normal or reveal only slight reduction in the CMAPs and SNAPs are modestly reduced in up to one third of patients. The needle electrode examination may show some fibrillation and fasciculation potentials and chronic neurogenic motor unit changes are prominent. The C5-to-Tl myotomes are most commonly involved when the arms arc affected. Although benign focal amyotrophy clinically presents as a unilateral disorder, it may rarely involve the opposite side to a minor extent, and careful needle electrode examination may unearth neurogenic changes *on* the contralateral sitle. Tin scrum creatine kinase (CK) level may be modestly elevated, but other routine laboratory test results are normal. Cervical MKI may reveal segmental spinal cord atrophy or occasionally

an area of increased signal on T2-weighted scans of the cervical spinal cord enlargement. "Incidental" spondylosis and canal stenosis detected by MRI should be carefully evaluated before the diagnosis of benign focal amyotrophy is established.

Differential Diagnosis

Two diseases must be distinguished from benign focal amyotrophy: ALS, which is almost always a relentlessly progressive terminal disease, and MMN, which is treatable. A small proportion of ALS presents as an LMN monomelic disease albeit in an older patient population. It is only with follow-up examination that the more widespread anterior horn cell disorder becomes apparent and UMN signs appear. In classic ALS, the deep tendon reflexes will usually become abnormally brisk even in the presence of severely weak and atrophied muscles. The generalized widespread nature of motor neuron involvement, as detected on EMG, can distinguish ALS from the segmental motor neuron involvement of benign focal amyotrophy. The slowly progressive focal weakness that is distinctive of benign focal amyotrophy may also be the presenting picture of MMN, but detailed motor nerve conduction studies and serum tests for elevated titers of anti-GM! antibodies can differentiate these two conditions.

Cervical or lumbosacral radiculopathy may also appear in a manner somewhat akin to benign focal amyotrophy. However, radicular pains and sensory impairment are typical of radiculopathies. Neuralgic amyotrophy/ Parsonage Turner syndrome is typically heralded by severe pain before the onset of weakness and wasting in the distribution of predominantly motor nerves derived from the brachial plexus. It may also involve selected sensory nerves. Most cases arc monophasic and do not progress over years as does benign focal amyotrophy, although hereditary neuralgic amyotrophy can present as recurrent bouts of brachial plexopathy. Cervical syringo-myelia or a benign tumor involving nerve roots or the spinal cord may also cause progressive weakness in a monomelic fashion. Careful EMG studies and neuroimaging should differentiate these diseases.

Treatment

The term *"benign"* in *benign focal amyotrophy* is used to distinguish it from the "malignant" motor neuron disease as seen in ALS. Although this condition is certainly not life threatening, it still seriously impairs motor function in the involved extremity. Supportive care consisting of physical and occupational therapy and effective use of assistive devices (splinting and braces) is the main treatment component. Tendon transfers can be considered in selected patients with focal weakness in a muscle group whose function is crucial for certain activities of daily living.

Infantile and Juvenile Spinal Muscular Atrophy

The incidence of infantile and juvenile SMA is estimated to be I in 6000-10,000 births; SMA is one of the most common genetic causes of death and disability[7] in childhood. It is inherited by autosomal recessive transmission, with a gene frequency in the general population of about 1 in 80. Autosomal dominant childhood SMA is rare and probably accounts for less than 2% of all childhood cases. X-linked SMA associated with arthrogryposis and bone fractures has also been described. Traditionally, SMA is classified as one of the three types based on the age at onset: SMA type 1 (infantile SMA or Werdnig-Hoffmann disease); SMA type 2 (intermediate SMA); and SMA type 3 (juvenile SMA or Kugel berg- Welander disease) (Nicole et al. 2002) (Table 80.7).

Genetics and Etiology

Al! three types of autosomal recessive childhood SMA have been mapped to chromosome .SqlL2 -5ql3.3, which suggests that they are allelic disorders. The normal 5q region on each chromosome contains two inversely homologous copies of the survival motor neuron *(SMN)* gene, termed *SMN1* (t.elomeric) and *$MN2* (centromcric). The 5q region also contains the neuronal apoptosis inhibitory protein *(NAIP)* gene, the *p44* gene (encoding a subunit of the basal transcription factor, TKI1H), and the *H4F5* gene. It has recently been shown that *SMN1* is *the* SMA gene and that the severity of SMA relates to the dosage of *SMN1* inherited by the patient. The SMN1 protein is functionally absent in the vast majority (95-98%) of cases of SMA, and small amounts are present m the remaining few percent. The *SMN2* gene, which is unique to humans, is characteristically present in all patients (although up to 5% of the normal population may have loss of this gene). Although mutations in the .SMN/ gene

"['able SO.7: Childhood and adult spinal muscular atropines

SMA *type*	*Age at onset*	*Survival/prognosis*	*Inheritance*	*Defective gene*
Infantile SMA (Werdnig-Hoffmann)	Birth to 6 mo	Death by 2 yr old	AR	SMN gene
Intermediate SMA	Before IN mo	No walking, adulthood	AR	SMN gene
Juvenile (Kugel berg-We lander)	After 18 mo	Adulthood	AR	SMN gene
Adult-onset SMA	After 20 yt	Slow progression	AR	Unknown

AR ~ autosomal recessive; SMA = spinal muscular atrophy; SMN = survival motor neuron.

produce the disease, the clinical phenorype is related to the expression of *SMN2.* More copies of *SMN2* are present in patients with milder disease than in those with severe disease.

SMN is a ubiquitously expressed 38-kd polypeptide that is important in the processing of the primary transcripts of other genes. It is associated with both nuclear and cytoplasmic complexes involved in messenger RNA splicing and interacts with other proteins, such as fibrillarin, which arc important in the regulation of ribosomal RNA processing and modification, and p53, which is important in regulation of the cell cycle. Within the nucleus, SMN1 forms macTomolccular complexes with other nuclear proteins such as gemin 2, 3, and 4, which are important in the assembly of spliceosomal small nuclear ribonucleoproteins. Recent research using transgenic animal models indicates that impaired production of macromolecular complexes may lead to motor neuron degeneration.

It has yet to be discovered why human spinal motor neurons are selectively vulnerable to SMN1 protein deficiency. Certainly SMN is heavily expressed in the nucleus and cytoplasm of spinal motor neurons but is also expressed in all tissues. Perhaps selective motor neuron vulnerability reflects the absence of a vital interaction with other proteins important in RNA processing that are also heavily expressed in motor neurons and axons. SMN protein is obviously vital for normal cellular function. In mice, which only have one *SMN* gene, complete absence of SMN protein is lethal at the embryonic stage. Humans, however, are never completely without at least one *SMN* copy on one chromosome. In human SMA, it is possible that SMN2 protein is able to compensate for the loss of SMN1 in all tissue types except spinal motor neurons, where only partial protection is afforded. Incomplete compensation may be due to the slight difference in coding sequence between *SMN'i* and 5MN2; there is a cytosine-thymine change in the coding sequence for exon 7. Because of this change, 90% of the SMN2 transcript lacks exon 7 and the resulting protein is unstable and rapidly degraded. In the complete absence of SMN1 therefore, only 10% of normal SMN2 protein may be available to bear the entire cellular burden. Thus increasing the copy number of *SMN2* in the cell should reduce the severity of disease.

Clinical features

Spinal Muscular Atrophy Type 1, Infantile Form (Wcrdnig-Hoffmann Disease). The disease begins at or before birth or within the first few months of life. By definition, children with SMA type 1 are never able to sit without support and death from respiratory failure and pneumonia usually occurs before age 2 years. About one third of mothers notice decreased fetal movements toward the end of the pregnancy. The symptoms include severe hypotonia, a weak cry, respiratory distress, and absent head control, as evidenced by an inability to lift the head when placed prone and severe head lag when the infant is pulled from a supine to a seated position (a "floppy" baby) (Figure 80.1). The baby's posture at rest also takes a characteristic "frogleg" position, with the thighs externally rotated and abducted and the knees flexed. Limb weakness is severe, generalized, and worse proximally. The infant is unable to sit and raise its arms or legs from the examining table, but there may be antigravity movements of the hands and flickering movements of the feet. Muscle stretch reflexes are usually absent and the sensory examination is normal. Contractures usually do not develop in the early phases but may develop after several months of immobilization. Bulbar muscle weakness makes feeding laborious, causes a continuous gurgling, and eventually leads to aspiration pneumonia. Fasciculations of the tongue are reported in about 50% of affected infants. In contrast to bulbar and extremity muscles, the facial muscles are only mildly affected, if at all, giving these children an alert expression. Fxtraocular movements are always normal. Intercostal muscles are severely weakened but diaphragmatic strength is preserved. This dysequilibrium of ventilatory muscle function causes outward flaring of the lower ribeage and gives rise to a bell-shaped chest deformity.

Spinal Muscular Atrophy Type 2 (Intermediate Form; Chronic .Spinal Muscular Atrophy). The signs and svmptoms of SMA type 2 usually begin before the age of 18 months. Although the symptoms may be present at birth, an insidious progressive weakness occurs during the first year of life and delayed motor milestones are often the first clue to neurological impairment. Both parents and physicians commonly observe a fine hand tremor, which also suggests the diagnosis. The distribution, pattern, and progression of weakness are similar to that found in SMA type 1, but the type 2 disease is quantitatively much milder and progression is slower than in type i.

Most children eventually are able to roll over and sit unsupported, but they rarely achieve independent walking, In the sitting position, weakness of trunk muscles produces a characteristic rounded kyphosis, and as the shoulders weaken, the child becomes immobilized and wheelchair bound. Contractures of the hips and knees, clubfoot deformities, severe scoliosis, and dislocation of the hips may eventually develop. Observation of the fingers may reveal fine, small-amplitude involuntary movements called *minipolymyoclonus.* The long-term prognosis varies markedly; some die in childhood because of respiratory failure, but many others survive into the third or fourth decade of adulthood.

Spinal Muscular Atrophy Type 3, Juvenile Form (Kugelberg-Welander Disease). The onset of the juvenile form of SMA is typically after 18 months of age (usually between 5-15 years) and usually presents with difficulty in walking. As weakness in hip-girdle muscles increases, the child develops a waddling (Trendelenburg's) gait, with an

FIGURE 80,1 A 6-monrh-old baby with Werdnig-Hoffmann disease. (A) The baby has a typical "frogleg" posture. The mouth is triangular, and the facial expression suggests facial weakness. (B) On sitting, the baby cannot sustain his head upright. (C) When the baby is pulled by the arms, the head falls back. (D) When the body is held supine, the head and extremities drop by force of gravity, and there is no active body motion. (Courtesy Neil Friedman, Cleveland Clinic Foundation.)

exaggerated lumbar lordosis and trouble climbing stairs. As the weakness progresses, the patient starts using a Gowers' maneuver to arise from lying supine on the floor. Pseudohypertrophy of the calf muscles is sometimes reported, but this may be an illusion resulting from relative preservation of calf muscles as compared to thigh muscles. The disorder has an appearance not unlike a limb-girdle muscular dystrophy, but the pattern of muscle involvement is often somewhat different. **Eventually, wasting** and weakness of the neck, shoulders, and arms develop, but weakness in the lower extremities is nearly always more severe than in the upper extremities. Fasciculations are more prominent than in SMA-1 and SMA-2 and a fine action tremor is common. Reflexes are uniformly reduced or absent and the sensory examination is normal.

The clinical course of SMA-3 is one of slowly progressive limb-girdle weakness, but there may be long periods of stability that last for years. The eventual degree of disability is difficult to predict. In general, if onset is before the age of 2 years, it is likely that the patient will be unable to walk by the age of 15 years and most patients will require a wheelchair by the time they reach their mid-thirties. However, some patients remain ambulatory for as long as 30 years after the onset of illness.

Laboratory Studies. The first-line investigation is molecular genetic analysis to identify mutations in the SMN gene on chromosome 5q and no further workup is necessary if there is a mutation of *SMN1* in the correct clinical setting. However, if a mutation of *SMN1* is not detected in a patient with a clinical picture consistent with SMA, one can assay for the combination of a deleted *SMN* allele on one gene and a small mutation on the other. It should be remembered that not all SMA is related to chromosome 5cj region abnormalities; some cases are X-linked or autosomal dominant and the genes have yet to be identified.

If SMA is the suspicion, it is appropriate to carry out the more traditional tests to help confirm the diagnosis. Serum CK may be elevated to 10 times normal levels in SMA-3 but is typicall; normal in the otk-r two types. i[·].l)X is valuable in supporting the diagnosis, although it may be technically limited by the need to carry out the test under conscious sedation in a small infant or child. CMAPs may be reduced in amplitude, but conduction velocities and sensory nerve conduction study results are normal. The needle electrode examination may reveal evidence of acute denervation in the form of fibrillation potentials and positive sharp waves, along with fasciculation potentials and evidence of motor unit remodeling due to a chronic process of denervation and reinnervation. Reduced recruitment of large, polyphasic motor units is therefore characteristic, although full voluntary activation may be hampered by sedation. Complex repetitive discharges are an electrodiagnostic feature of SMA-3. Muscle biopsy can confirm the diagnosis of infantile SMA because the histological changes are highly distinct: Sheets of rounded, atrophied type 1 and 2 muscle fibers are present. A highly characteristic pattern is grouped fascicular atrophy, that is, entire fascicles or groups of fascicles are atrophied, whereas neighboring fascicles (often containing almost entirely type 1 fibers) are composed of hypertrophied fibers. In SMA types 2 and 3, EMG and muscle biopsy changes are more fully developed than in type 1, showing clear evidence of acute and chronic denervation. It is important to remember that long-standing dencrvating disorders, such as childhood SMA, can he complicated by secondary myopathic changes that include fiber size variability, fiber splitting, internal nuclei, and fibrosis.

Differential Diagnosis

For SMA-1, all causes of infantile hypotonia must be excluded including Pompc's disease, centronuclear myopathy, ncmaline myopathy, congenital muscular dystrophy, central core disease, and congenital or infantile myotonic dystrophy. For older children with suspected types 2 and 3 SMA, the differential diagnoses includes myasthenia gravis, various muscular dystrophies, inflammatory myopathies, and a variety of structural, metabolic, and endocrine myopathies. Clinical, laboratory, and muscle biopsy features usually distinguish these disorders with relative ease.

Treatment

No disease-specific pharmacotherapy is available for SMA. Future therapies may be focused on increasing the expression of protective *SMN2* gene product or stabilization of *SMN1* exon 7. It may also be possible to design therapies that are based on the protein interactions of SMN1 once these have been further clarified. As with several other neurodegenerative disorders, it may even be possible to use pluripotent stem cells to replace dead or dying neurons and muscles. However, the mainstay of current treatment is focused on supportive care, including physiotherapy, respiratory care, nutritional support, orthotics, and orthopedic interventions. Typical Werdnig-Hoffmann disease is almost uniformly fatal by age 2 years. However, because some affected infants survive beyond infancy and live into childhood, aggtessive management including physiotherapy and respiratory therapy is essential in all cases.

The management objectives in young children with the intermediate form arc twofold: (1) maintaining active mobility and independence as long as possible and (2) preventing the development of contractures and kyphoscoliosis. Any devices, even a scooter board, should be considered to maintain mobility. Because all patients invariably become wheelchair bound, they should be fitted for an electric-powered wheelchair. However, the timing of wheelchair use is critical because its use hastens the development of contractures and scoliosis. Stretching

exercises in major joints should be part of the patient's daily routine.

Patients with SMA have normal or increased intelligence. They attend school, and when they reach adulthood often work outside the home and live independently. A well-coordinated multidisciplinary approach is essential when attempting to optimize residual function, especially during periods of disease progression. Physical therapy for stretch exercise and chest clapping, occupational therapy for maintaining activities of daily living, an evaluation at a seating clinic to obtain the best wheelchair, and orthopedic evaluation to delay or if necessary correct scoliosis are among the most important aspects of management. It is also vital to pay attention to the emotional well-being of the patient, particularly during adolescence.

Maintaining an upright position delays the development of scoliosis. Therefore a specialized evaluation for wheelchair at a comprehensive seating clinic is critical. A back brace may also potentially delay the development of scoliosis, but bracing in these patients is still controversial. Bracing probably does little to retard the onset or progression of scoliosis and may actually impair function in some patients because bracing reduces spinal flexibility and tespitatory vital capacity. Potential benefits from bracing include reduced back discomfort and the ability to sit for longer periods.

Progressive scoliosis eventually requires surgical correction in most patients with juvenile SMA. In general, surgery should be delayed until growth ceases. However, in some patients who have never ambulated or who lost ambulation very early, surgical intervention for severe scoliosis may be considered even before growth has ceased. Improved aesthetics, ⊱ il.uu ❧. aiui M;IIN:;: cu:nk>n are among the benefits; however, lack of body flexibility, reduced pulmonary function, and general decline in overall motor function may occur after surgery. Pros and cons for scoliosis surgery must he openly discussed with the patient, although for most the benefits outweigh the disadvantages. Preoperative and postoperative physiotherapy and occupational therapy assessments are critical steps for the patient who contemplates spinal fusion for progressive scoliosis in SMA (Mitsumoto et al. 1997).

Genetic Counseling and Prenatal Diagnosis

SMA is one of the most devastating diseases of childhood and the parents of affected children and their relatives should receive genetic counseling, including determination of carrier status of .SMN genes. The available carrier detection test determines the SMN I gene dosage in an individual and is best catricd out in a family where an .SMN deletion has been found previously in an affected individual or for an individual who is about to marry a known carrier with a known .S'MN deletion. Noncarriers will have a single copy of the normal *SMN1* on each chromosome, whereas carriers will have only one normal and one mutated *SMN* gene. However, this standard test is not absolutely accurate in the setting of genetic variations. For example, up to 3% of the population may have a duplication of the *SMN1* gene on one chromosome and none on the other and it may require a hybrid technique to identify this variant. In those rare individuals, whose SMA is due to spontaneous *de novo* mutations in the *SMN1* gene, the parents will have normal *SMN1* genes.

Childhood Autosomal Dominant Spinal Muscular Atrophy. Autosomal dominant SMA is exceedingly rare, accounting for less than 2% of all childhood cases. Because of the rarity of this disorder, the natural history of autosomal dominant SMA k nm WL'.I Jc--;icd. i'ypii.illv, juvenile autosomal dominant SMA is a relatively benign disease.

Arypical Spinal Muscular Atrophies

Fazio-Londe Disease (Progressive Bulbar Paresis of Childhood). Fazio-Londe disease is a rare form of sporadic, autosomal dominant, or autosomal recessive progressive facial and bulbar palsy. Affected children are normal at birth but develop progressive bulbar palsy (PBP) and eventual respiratory failure with little or no evidence of involvement of other motor neurons and with usually normal extraocular motility. The differential diagnosis includes a structural brainstem lesion, myasthenia gravis, and the Miller Fisher variant of Guillain-Barre syndrome. Accurate diagnosis is important because of the implications for prognosis and treatment.

Adult-Onset Spinal Muscular Atrophy (Spina) Muscular Atrophy Type 4)

True adult-onset disease accounts for probably less than 10% of all cases of SMA with an estimated prevalence of 0.32 in 100,000. By definition, the symptoms of adult-onset SMA must begin in patients older than 20 years. The mean age at onset is the mid-thirties. The course is relatively benign; only a small proportion of patients become wheelchair bound over 20 years. The clinical presentation is very similar to that of SMA-3.

Inheritance and Genetic Abnormalities

Although autosomal recessive inheritance accounts for almost all (98%) of childhood SMA cases {type 1, 2, and 3), it constitutes only 70% of adult-onset SMA cases. Homozygous deletions in the 5MNJ gene responsible for childhood SMA are only rarely found in adult-onset SMA; homozygous deletions of the *SMN2* gene may be more commonly identified (Moulard et al. 1998). The remaining adult-onset SMA cases are autosomal dominant and are not linked to chromosome 5. This latter group is rather heterogeneous, and in time, it may well transpire that

it represents a series of quite separate disorders sharing certain SMA-like phcnotypical similarities.

Clinical Features

The characteristic clinical presentation is that of a slowly progressive limb-girdle weakness leading to difficulty in walking, climbing stairs, and rising from a chair or the floor. Fasciculations are an important finding and occur in 75% of patients. Quadriceps muscle weakness is often a prominent feature. Muscle cramps may occur but are not a prominent feature. Bulbar signs and bony deformities such as scoliosis arc rare and respiratory muscles are not affected. Although the distribution of muscle weakness is usually confined to limb-girdle muscles, it can be generalized or even distal predominant (Figure 80.2). Many cases have a distribution of weakness reminiscent of the limb-girdle imacular dysl noli it's, lead hi:-, ID i'.n- oldfi **term nl** pscudomyopathic SMA.

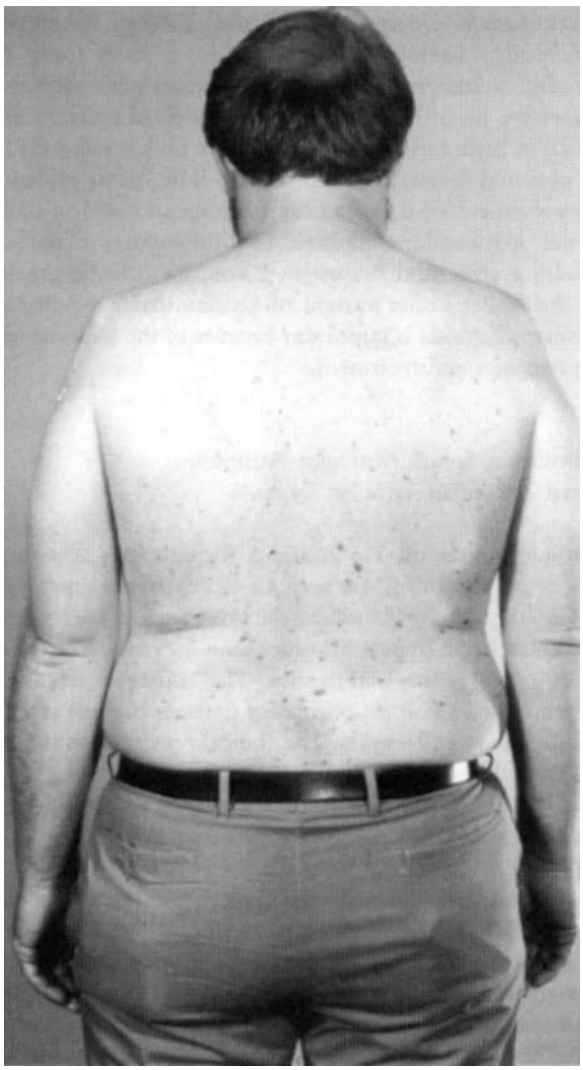

FIGURE 80.2 A patient with mild adult-onset proximal spinal muscular atrophy and marked shoulder-girdle muscle atrophy. Note subluxation at both shoulder joints and marked deltoid **muscle atrophy.**

Laboratory Features

Both serum CK and aldolase arc typically elevated to levels less than 10-fold the normal values. Motor nerve conduction studies may reveal normal velocities and reduced CMAPs in the presence of normal SNAPs. Needle electrode studies show marked chronic neurogenic motor unit changes and modest, if any, evidence of acute denervation. Myopathic changes are also common. Fasciculation potentials may be found in involved muscles.

Muscle biopsy typically shows evidence of a markedly chronic dencrvating disease process similar to that described in SMA-3, but with frequent changes of myopathy, with marked variation in fiber size, split fibers, necrotic fibers undergoing phagocytosis, and regeneration,

Differential Diagnosis

Limb-girdle muscular dystrophy may be difficult to distinguish from adult-onset SMA; it can be autosomal recessive, is often adult onset, and affects predominantly proximal muscles. The pattern of muscle weakness is often a pointer to the diagnosis; for instance, in adult-onset SMA, the triceps muscles may be weaker than the biceps, the opposite of the situation in iimb-girdle muscular dystrophy. Although muscle biopsy reveals a primary myopathy rather than a neurogenic process, one should be aware that some degree of secondary myopathic changes could occur in long-standing SMA. Immunohistochemistry and Western blotting can now be performed on muscle biopsy to distinguish SMA from Duchenue's and Becker's muscular dystrophy and the various limb-girdle muscular dystrophies with known protein deficiency, including sarcoglycanopathies, calpainopathies, and dysferlinopathies (Piccolo ct al. 2002). Other myopathics may also need to be considered including polymyositis and adult-onset acid maltase deficiency.

CIDP may mimic SMA because of chronic proximal muscle weakness, but the tendon reflexes are usually diffusely absent in CIDP and some are preserved in SMA. Electrodiagnostic studies reveal a demyelinating polyradiculoneuropathy and CSF protein levels arc increased in CIDP. It may be very difficult to distinguish between distal-predominant adult-onset SMA and hereditary motor and sensory neuropathy type 2 (neuronal form of Charcot-Maric-Tooth disease). Motor-predominant variants, such as hereditary motor neuronopathy type 5 (HMN-5), may present with a slowly progressive LMN-prcdominaut disorder affecting distal greater than proximal limb muscles. In HMN-5, transcranial magnetic stimulation studies may reveal prolonged central conduction times along motor pathways, a finding that is mirrored by brisk deep tendon reflexes in many cases. EDX characteristically shows

changes most consistent with a disorder of anterior horn cells, and sensory nerve studies are often normal (Auer-Grumbach M et al. 2000). Hex-A deficiency in infants is well known as the cause of Tay-Sachs disease, a rapidly terminal gangliosidosis. The same enzyme deficiency in adults (although the type of missensc mutation differs from the infantile form) causes a very different disease, which can have a similar phenotype to adult-onset SMA, although later other neuronal systems often become involved. Although most reported cases have been in Ashkenazi Jews, adult forms clearly occur in other populations. In the absence of a family history of SMA, it can be most difficult to distinguish adult-onset SMA from the PMA variant of ALS. However, several features distinguish between these conditions. Adult-onset SMA progresses very slowly, whereas PMA progresses relatively rapidly (though usually slower than classic ALS). Adult-onset SMA is mainly associated with muscle biopsy and EDX evidence of a markedly chronic disease, whereas PMA findings are consistent with more acute denervation and thus more modest evidence of neurogenic motor unit remodeling.

Treatment

No specific pharmacotherapy is available. Treatment is supportive and symptomatic. Generally, adult-onset SMA progresses very slowly, and patients often learn how to cope with the disease quite well. For patients who engage in physical work, appropriate vocational rehabilitation may help patients accommodate themselves to their eventual physical disabilities.

Kennedy's Disease (X-I.inked Recessive Bulbospinal Neuronopathy)

In 1968, Kennedy and colleagues reported a new X-linked recessive SMA with bulbar involvement and gynecomastia. The primary pathology was thought to be in the l.MNs, but sensory system involvement was later recognized, which led to a new term, *bulbospinal neuronopathy.* Recent progress in molecular genetics has shown Kennedy's disease to be a trinucleotide repeat disease. Though rare, it is more common than adult-onset SMA. Clinically, Kennedy's disease can be easily mistaken for ALS, and thus diagnosis of the disease is important because it has a much better prognosis than ALS (Table 80.8).

Tabic 80.8: Characteristic features of Kennedy's disease

Pathogenesis
X-linked recessive inheritance
Abnormal CAG expansion in the gene encoding androgen receptor protein
Neurological manifestations
Slowly progressive limb-girdle muscle weakness
Slowly progressive moderate bulbar dysfunction
Muscle cramps and prominent faseiculan'ons
Facial faseiculations
S y stem i e ma n i festa ti on s
Gynecomastia (60-90%)
Endocrine abnormalities (testicular atrophy, feminization, infertility)
Diabetes mellitus
Laboratory studies
Markedly abnormal sensory nerve conduction studies
Hlevated serum creatine kinase
Abnormal sex hormone levels
Ahnormal CAG repeats in the androgen receptor gene

Pathogenesis

In 1991, La Spada and colleagues found the gene abnormality responsible for Kennedy's disease: a cytosinc-adenine-guanine (CAG) trinucleotide repeat expansion on the andtogen receptor gene located on the X chromosome. In normal individuals, the repeats range from 17-26 in this coding region, whereas in patients with Kennedy's disease, the repeats range from 40-65. There are two independent components to the symptoms of Kennedy's disease, one androgen dependent and the other androgen independent. "Fhe gynecomastia and testicular atrophy seen in Kennedy's disease may be associated with the classic function of the androgen receptor, and thus the severity of symptoms might be related directly to the receptor's affinity for androgen. Studies of cultured scrotal skin fibroblasts found that direct high-affinity- d ihyd rotes to ste rone binding is decreased in some patients. The abnormal expansion of CAG repeats involves the first exon, an amino-terminal transactivating domain of the androgen receptor protein, The expansion of the CAG repeat in an androgen receptor causes a linear decrease in the transactivation function but does not completely eliminate androgen receptor activity. The residual androgen receptor activity is sufficient to ensure normal development of male primary and secondary sexual characteristics, as evidenced by the fact that affected men arc phenotypically male and usually fertile.

The subtle decline of androgen receptor transactivation may eventually lead to the loss of integrity of certain tissues that require continuously high androgen levels. Continuous androgen activity is probably required in spinal and bulbar motor neurons; for example, androgens are crucial for normal male development of motor neurons in the rat spinal nucleus of the bulbocavetnosus and for regenerating facial motor neurons in rats and hamsters. Therefore continuous androgen receptor function may be crucial to maintain normal motor neuron function throughout life.

As with most other trinucleotide repeat expansion disorders, such as Huntington's disease and several SCAs, the trinucleotide repeat expansion mutation appears to confer a toxic gain of function on the gene product rather than a loss of function. In fact, complete absence of the androgen receptor leads to an entirely different disorder

called *andmgen-insensitwity syndrome.* The mutant androgen receptor Ic.uU to an altered reeeptor-DNA interaction or receptor-protein interaction that interferes with neuronal function. The CAG repeat encodes an unusually long polyglutamine tract in the androgen receptor protein, which appears to alter the normal protein moiety resulting in mutant protein aggregation. Indeed, ubiquitinated neuronal inclusions have been identified in this disorder, and it has been suggested that these mutant protein aggregates interfere with proteasomal breakdown of cellular proteins and/or interfere with tubulin mediated cellular transport.

Clinical Features

Being an X-linked syndrome, this is a disorder of men who remain largely asymptomatic until after age 30 years. Prominent muscle cramps, muscle twitching, difficulty walking, and limb-girdle muscle weakness are the characteristic symptoms. Dysarthria and dysphagia occur in fewer than half the patients. Muscle weakness is typically LMN in type, involving the proximal hip and shoulder-girdle muscles, and is associated with decreased or absent reflexes, muscle atrophy, and occasionally, calf pseudohypertrophy. Kennedy's disease usually causes no respiratory muscle weakness. Coarse muscle fasciculations can be prominent in the extremities and trunk and hand/finger tremor is not unusual. Facial and particularly perioral fasciculations are highly characteristic, if not pathognomonic, of this disease, being present in more than 90% of patients. The tongue shows chronic atrophy, often as a longitudinal midline furrow. Although weakness in the facial and tongue muscles is nearly always present, bulbar symptoms are less often reported. Neurological examination of the sensory system may reveal only modest impairment.

Gynecomastia is one of the unique features of Kennedy's disease and is found in 60-90% of patients (Figure 80.3). Fndocrine abnormalities include testicular atrophy, feminization, and infertility in approximately 40% of patients. Diabeies mcllinis is also reported in II) 20% ot patients. It has recently been recognized that female carriers may manifest subtle neurological deficits such as late-onset btilbat dysfunction.

An inverse relationship exists between the number of CAG repeats and the age at disease onset. The greater the number of the repeats, the younger the age at onset. This is an example of genetic anticipation. However, the number of repeats has no correlation with other features, such as the severity of weakness, serum CK level, and presence or absence of gynecomastia, impotence, or sensory neuronopathy. The phenotypical expression varies markedly within and among the families. The course is one of slowly progressive **LMN** disease. If bulbar dysfunction is severe, the prognosis becomes less favorable (Mitsumoto et al. 1997).

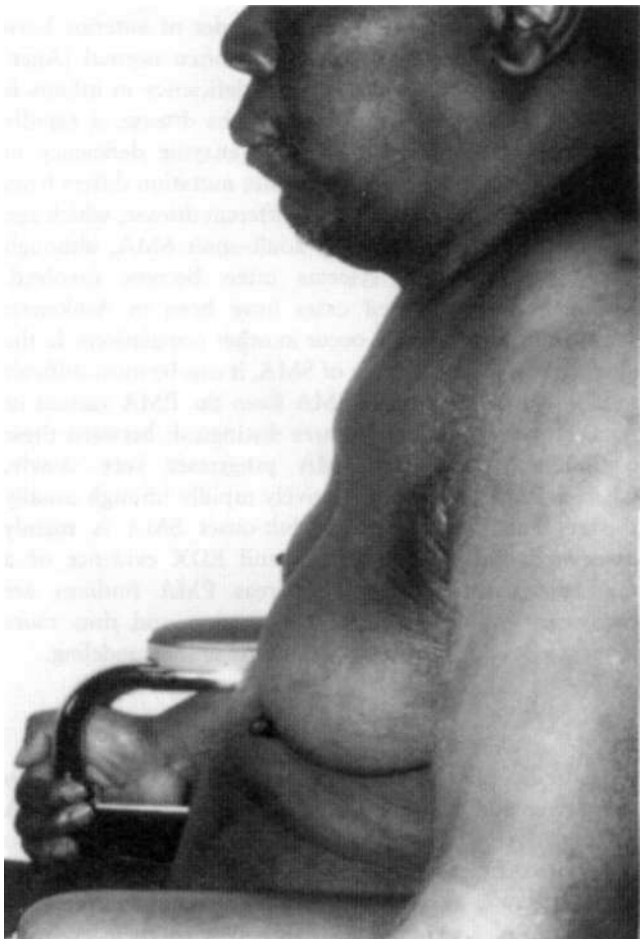

FIGURE 80.3 A man with X-linked recessive bulbospinal muscular atrophy (Kennedy's disease) showing gynecomastia.

Laboratory Studies

Molecular genetic testing is available to identify the abnormal expansion of the CAG repeat in the exon 1 ol the androgen receptor gene on the X chromosome. CK levels may be elevated as high as 10 times normal. **Serum** androgen levels are either normal or decreased, whereas estrogen levels are elevated in some patients. The estrogen-to-androgen ratio is also increased in some patients; however, there is no consistent finding regarding sex hormone levels.

EMG is highly useful. Motor nerve conduction study results are generally normal, although one third of the patients have reduced-amplitude CMAPs. Needle electrode examination of these patients shows prominent chronic denervation changes in motor units, but evidence of acute denervation is usually only modest. One of the most unique abnormalities in Kennedy's disease is EDX evidence consistent with a sensory neuronopathy. Another unique change is the presence of prominent fasciciilation potentials in the face (especially in the perioral region) and limbs.

Muscle biopsy shows modest denervation, prominent reinnervation, and fiber type grouping, that is, histological

findings consistent with those of a chronic SMA type of denervation. Sural nerve biopsy usually reveals a marked loss of myelinated fibers and the replacement of lost nerve fibers with connective tissue.

Differential Diagnosis

The clinical features, such as progressive limb-girdle weakness, bulbar signs, muscle cramps, and prominent fasciculations, resemble those of ALS, but a careful physical examination should provide sufficient clues to distinguish one from the other. Generally, ALS progresses rapidly, whereas Kennedy's disease is a largely indolent disorder. The EDX in Kennedy's disease shows abnormal sensory nerve conduction studies, which is highly unusual for any motor neuron disease, particularly ALS. Kennedy's disease may also be easily mistaken for adult-onset SMA because of the slowly progressive limb-girdle weakness in both, but bulbar involvement is very unusual in SMA. Hereditary sensorimotor neuropathy, limb-girdle dystrophy, or facioscapulohumeral muscular dystrophy also may mimic Kennedy's disease. Careful EDX studies and muscle or nerve biopsy analyses should distinguish these disorders. Ultimately, a molecular gene study to identify the abnormal CAG repeats in the androgen receptor gene will yield the answer.

Manifested Carrier

The female children of an affected male patient are all obligate carriers, as is the mother, except in the rare case of a new mutation. Male children of affected individuals cannot inherit the mutant gene on the X chromosome. Female siblings of an affected patient have a 50% chance of carrying the affected gene on the X chromosome. Through a process know ii .is *skeined X chromosome inactwalion* (lyoniziition), female carriers can present with neuromuscular symptoms, such as exertional muscle pain, cramps, and late-onset bulbar dysfunction, and the EDX may detect mild chronic denervation in both upper and lower limb muscles.

Treatment

Supportive and symptomatic therapy is the key to treatment, as outlined in the section on adult-onset SMA. Muscle cramps may be problematic but may he relieved by quinine sulfate, baclofen, or vitamin E. Patients with symptomatic diabetes require appropriate medical management.

In Kennedy's disease, dysarthria and dysphagia may cause marked disability. Although severe loss of bulbar function is rare in Kennedy's disease, speech therapy and appropriate communicative devices should be offered when appropriate. Careful nutritional management is also important. Enteral feeding provided via gastrostomy is the most effective and practical means to meet nutritional and fluid requirements. Genetic counseling is important for patients, potential carriers, and male siblings.

Progressive Muscular Atrophy

PMA, first described by Aran in 1850, is a disease that exclusively involves LMNs during its entire clinical course and comprises approximately 8% of all adult-onset motor neuron diseases, h has been questioned whether ['MA is an independent disease or represents one end of the spectrum of ALS. However, the recent description of a rapidly progressive PMA presentation in some cases of FALS and the finding of pyramidal tract pathology in some autopsied sporadic PMA cases lends support to the conclusion that PMA is indeed an ALS variant (Cervenakova ct al. 2000). For clinical therapeutic research trials, PMA must clearly be distinguished from ALS and is nor even included in the revised El Escorial criteria. However, PMA can he considered identical to ALS in all aspects of day-to-day patient care.

Etiology

All hypotheses about the cause of ALS are also applicable to PMA (see Etiology, under Amyotrophic Lateral Sclerosis, later in this chapter).

Clinical Features

By definition, the signs and symptoms of PMA are LMN in type throughout the entire clinical course. During the early stages of the illness, however, whether the disease will evolve into the ALS phenotype is uncertain, because most such cases do eventually develop UMN signs. Thus it is generally agreed that not until 3 years after rhe onset of the disease can one conclude that the disease will not spread to involve UMNs. Although PMA occurs in both sexes, nen arc slightly more often affected than women. The age at onset of PMA is younger than that of ALS, and the disease progresses more slowly so the average survival is longer; in one study, the mean duration of disease was 159 months (Norris et al. 1993).

A common presentation is that of focal asymmetrical muscle weakness in the distal extremities with gradual spread to other contiguous muscles. The weakness and muscle atrophy is purely LMN in type and eventually involves both the upper and the lower extremities. A less common presentation is that of proximal rather than distal muscle weakness. Bulbar and respiratory involvement eventually develops but is not as common in the early stages as in classic "spinal" ALS.

Laboratory Studies

The CK level can reach 10 times normal, particularly when patients are physically active. Patients with PMA do not have high titers of anti-GM[antibodies. The EMG examination reveals findings consistent with a widespread disorder of anterior horn cells and is useful to exclude other

diagnostic possibilities such as CIDP, MMN, or myopathy. Muscle biopsy will show denervation atrophy but is usually unnecessary unless the clinical features are unusual enough to suggest an alternative diagnosis.

Differential Diagnosis

PMA is usually a fatal disease and has no cure. Therefore the diagnosis of PMA should be made carefully after all other potentially treatable or definable diseases are excluded. In a recent review, 17 of 89 patients originally diagnosed with PMA were subsequently shown to have alternative diagnoses, including MMN, CIDP, inflammatory myopathy, and myasthenia gravis (Visscr ct al. 2002),

MMN may present with focal and asymmetrical weakness in the absence of UMN signs but may be distinguished by the relative disparity between weakness and atrophy, by typical electrodiagnostic features, and by the presence of anti-ganglioside antibodies. CIDP is readily differentiated on the basis of clinical and electrodiagnostic findings of sensory involvement, high CSF protein levels, and response to immunotherapy. Important clues that should lead one to suspect inclusion body myositis (IBM) are elevated serum CK to levels more than expected in typical PMA and a selective weakness in wrist flexors, finger flexors, and quadriceps muscles. EMG in IBM should show evidence of a primary necrotizing myopathy with or without additional neurogenic changes, but quantitative EMG may be required to clearly identify the myopathic nature of this disorder (Dahby et al. 2001). Muscle biopsy characteristically reveals rimmed vacuoles. Adult-onset SMA is a far more indolent disorder than I'M A and the very chronic process of denervation and re in nervation in SMA leads to fiber type grouping in muscle biopsy, which is not a characteristic feature of the I ess-protracted PMA. It is important to carry out regular follow-up examinations on patients with PMA, to search for signs of UMN involvement that indicate the diagnosis of ALS that has a rather worse average prognosis (Mirsumoto et al. 1997),

Treatment

The treatment of PMA is identical to that of ALS, as summarized later in this chapter.

Subacute Motor Neuronopathy in Lymp ho proliferative Disorders

A subacute, progressive, and painless motor neuron syndrome may rarely develop in patients who have Hodgkin's and non-Hodgkin's lymphoma with or without a paraproteinemia (Rudnicki and Dalmau 2000). Although UMN signs may develop in a small number of patients, an LMN syndrome is typical, with patchy, asymmetrical lower extremity predominant muscle weakness and wasting being the most common presentation. Neuropathology shows a loss of anterior horn cells and ventral root nerve fibers; some have evidence of inflammation in the anterior horns of the spinal cord. In some patients, the disease may be relatively benign; the rate of progression of muscle weakness and atrophy tends to slow down with time, and in rare instances, the motor syndrome may respond to treatment of the underlying lymphoproliferative disorder. However, the prognosis appears to be less favorable in those who develop a combined UMN and LMN disorder. Twenty percent of all cases so far reported with motor neuron presentations in the setting of lymphoproliferative disease had myeloma or macroglobulinemia (Rowland and Shneider 2001). The pathogenesis of this ALS-likc disorder is undetermined, but an immune mechanism may be at play; small patient series and case reports reveal that some patients who develop this LMN syndrome may have various autoantibodies (such as antisulfatide antibody), paraproteinemia, increased CSF protein, and/or oligoclonal bands.

Postirradiation Lower Motor Neuron Syndrome

Radiation directed to the lumbar paravertebral area for the treatment of testicular cancer can cause a pure LMN syndrome in the lower extremities that first appears many years after the irradiation. Sensory abnormalities and sphincter dysfunction are rare, and the EDX findings are consistent with a disorder of the cauda equina (the SNAPs are spared). The disease usually progresses over the first few years after symptom onset but subsequently becomes arrested (Bowen et al. 1996).

DISORDERS OF BOTH UPPER AND LOWER MOTOR NEURONS

Amyotrophic Lateral Sclerosis

ALS is a neurodegenerative disorder of undetermined etiology that primarily affects the motor neuron cell population. It is progressive and most patients eventually succumb to respiratory failure. The first detailed description in the literature was by Jean Martin Charcot in 1869, in which he discussed the clinical and pathological characteristics of "la sclerose laterale amyotrophique," a disorder that affected both UMNs and LMNs (Goetz 2000). ALS is known by several other names including Charcot's disease, motor neuron disease, and in the United States, "Lou Gehrig disease" in remembrance of the famous "Iron Horse" of baseball who was diagnosed with ALS in the late 1930s.

The World Federation of Neurology Research Group on Neuromuscular Disorders has classified ALS as a disorder of motor neurons of undetermined cause, and several variants are recognized. Included in this group are

PLS and PBP. As previously mentioned, PMA is also thought to be a variant of ALS despite its exclusion from cutrcnt clinical research trial criteria. It is important to recognize that ALS is a progressive dynamic disorder. Some cases present with the classic combination of UMK and LMN signs, but others may be UMN onset, LMN onset, or bulbar onset and only later develop signs of involvement of the other parts of the motor system (Table 80.9).

Between 5-10 ' . of A IS is familial rathe:" than sporadic. the most common inheritance pattern being autosomal dominant. Thus one comes across the terms, *sporadic ALS* (SALS) and *FALS.* A few other conditions have a phenotypical expression similar to that of ALS including Western Pacific ALS-parkinsonism-dementia complex (PDC) (or Guamanian ALS) and juvenile ALS.

The incidence and prevalence rates for non-Western Pacific ALS are surprisingly uniform throughout the world. The incidence is estimated at 1-3 per 100,000 and the prevalence varies from 6-8 per 100,000. Several epidemiological studies have suggested that the incidence of ALS may have increased in the past two decades and that this is a disease-specific finding rather than due to factors telated to better national health care, economic prosperity, or case ascertainment. In sporadic spinal ALS, men are more often affected than women by a ratio of 1.2-1.6:1. Howe vet, several clinical papers have shown that there is a slight female predominance in the bulbar-onset variety and that there appcats to be no consistent pattern of gender predominance in familial forms of the disease.

ALS is reported to occur as early as in the second decade of life, but the most common onset is in the patient's early sixties. It is notably rare in the vety oldest segment of the general population, that is, those older than 8.5 years. This has yet to be explained (Mitsumoto, Chad, and Pioro 1997). The mean disease duration from symptom onset to death is approximately 3 years, although some patients live for more than a decade, whereas others may succumb within a matter of a few months. Although no specific environmental factors have been linked with certainty to an increased tisk of ALS, epidemiological research suggested increased morralirv rates for ALS .untnis'. eledrical utility workers who were chronically exposed to electromagnetic fields (Johansen and Olson 1998), Population-based casc-control studies have also ascertained increased risk in those with a high dietary intake of glutamatc and in smokets (Nelson et al. 2000a, 2000b). A host of environmental trace elements have been evaluated as potential causative agents for ALS including selenium, aluminum, iron, manganese, copper, zinc, cadmium, and lead, but there is no convincing evidence that any one of these plays a major part in ALS pathogenesis,

Etiology

Significant inroads have been made into understanding the pathogenesis of SALS and FALS. Several hypotheses have been put forward, including that of viral infection, activation of the immune system, exogenous toxins, and hormonal disturbances. However, there has been insufficient evidence to implicate any of these as the major cause of motor neuron degeneration in ALS. Perhaps the most significant breakthrough in understanding the cause of ALS (be it sporadic or familial) came in 1993, when Rosen et al. identified mutations in the gene encoding an enzyme called copper/zinc superoxide dismutase (SODl) in patients with FALS. SODl mutations, which can cause elevated intracellular levels of reactive oxygen species, are now identified in up to 20% of all patients with FALS. Most recently, mutations in a gene encoding a novel protein called alsin have been identified in a form of recessively inherited juvenile-onset ALS of North African origin. This ptotein shares structural homology to a guanine nucleotide exchange factor, which suggests a role in altered cell signaling (Shaw 2001).

A significant body of basic and clinical research lends strong support to a new theory of ALS pathogenesis, which proposes selective motor neuron damage from a complex chain of injurious events involving excitotoxins, oxidative stress, neurofilament dysfunction, altered calcium homeostasis, mitochondrial dysfunction, enhanced motot neuron apoptosis, and proinflammatory cytokines (Cleveland and Rothstcin 2001). A number of ALS susceptibility genes have also been proposed, mutations of which are known to occur in small ALS populations or individual cases but which do not appear to account for the majority of SALS cases. The focus of the following discussion is on the role of excitotoxins, free radicals, neurofilaments, immune activation, inflammation, and candidate genes as they apply to the pathogenesis of SALS. The role of SOD) mutations and mutant alsin in disease pathogenesis is discussed in more detail in the sections covering FALS and juvenile ALS.

Pathogenesis of Sporadic Amyotrophic Lateral Sclerosis

Glutamatc Exci to toxicity and Free Radical Injury, Glutamatc, which is the most abundant ftce amino acid in the CNS, is one of the major excitatory amino acid (LAA) neurotransmitters. Glutamatc produces neuronal excitation and participates in many neuronal functions, including neuronal plasticity. In excess, however, it causes neurotoxicity. There are two types of glutamatc receptors: (I) ionotropic and (2) metabotropic. The former is an integral, cation-specific (particularly Ca^{+}) ion channel type, which is further grouped into two major subtypes depending on receptor characteristics: the N-methyl-D-aspartate (NMDA) teceptors and the non-NMDA receptors (AMPA-kainate receptor). Metabotropic receptors are coupled to G proteins and cyclic guanosine monophosphate (cGMP), modulating the production of intracellular messengers and influencing ionotropic glutamate teceptors. In ALS, motor neurons appear to receive the glutamate excitotoxic signal through non-NMDA receptors rather than NMDA teceptors.

The significance of glutamate excitotoxicity in neuro-degencration is strengthened by the observation that exogenous glutamate receptor agonists result in clinically observable neurotoxicity. Lathyrism (see previous section on UMN disease) is associated with chronic neurotoxicity exerted by /3-N-oxalylamino-L-alanine (BOAA), an AMPA receptor agonist. A similar disorder, Konzo, may also be due to glutamatc-mediated damage to cortical motor neurons. An outbreak of food poisoning associated with contaminated mussels that clinically presented with chronic dementia and motor neuron disease was caused by domoic acid, another potent non-NMDA receptor agonist. In patients with ALS, a series of endogenous glutamate abnormalities have been demonstrated; for example, EAA is significantly increased in serum, plasma, and CSF. On the other hand, glutamate in CNS tissue and the glutamare-to-glutamine ratio are significantly decreased in ALS. When glutamate metabolism is studied by loading with oral monosodium glutamate, plasma glutamate levels increase to a significantly greater degree in patients with ALS than in healthy patients. These studies clearly support the idea that glutamate excitotoxicity is involved in the pathogenesis of ALS, if not actually the cause.

Glutamate is normally released from presynaptic axon terminals into the synaptic cleft where it binds to its receptors causing signal transduction to occur. After signal transduction, interstitial glutamate must be reabsorbed into its main reservoir, the surrounding astrocytic glial cells. This absorption process involves specific transporter proteins known as GI.T (glutamate transporter) or EAAT (excitatory amino acid transporter) proteins, which have been subclassified according to their distribution within cells of the CNS. Among these, the astrocytic glutamate transporter, termed GLT1 or EAAT2, is markedly reduced in the motor cortex and anterior horn cells of patients with ALS, which supports earlier evidence that interstitial or extracellular (including CSF and plasma) glutamate is increased in ALS. Rothstein et al. found intriguing abnormalities in the DNA encoding GLT1 in more than 60% of patients with ALS (predominantly the sporadic form). However, subsequent research suggests that GLT1 does not appear to be a candidate gene for FALS or SALS.

Impaired glutamate transport reduces clearance of glutamate from the synaptic cleft, which may leave excessive amounts of free excitatory neurotransmitter to repeatedly stimulate the glutamate receptor and thus allow calcium ions enter the neuron. Excess calcium ions are usually buffered by intracellular calcium-buffering proteins, such as parvalbumin or calbindin, and by mitochondria that may also function as an extra calcium reservoir. Low levels of parvalbumin, calbindin, and altered mitochondrial function have been detected in ALS models. When calcium ion levels exceed this reduced buffering capacity, they may catalyze activity in specific destructive enzymes that are not activated under normal conditions including xanthine oxidase, phospholipase, and nitric oxide synthase. These enzymes produce ftee radicals, including reactive oxygen and nitrogen species, which cause harmful nitration of tyrosine residues on key neuronal proteins and ultimately may also cause apoptosis. It has recently been proposed that regional differences in the levels of activity of buffering systems and in glutamate receptor subtype expression may explain the selective vulnerability of certain motor neuron pools within the CNS.

Immunological and Inflammatory Abnormalities. Several pieces of evidence implicate an immune process in the pathogenesis of ALS. Immune complexes have been identified in gut and renal tissue from patients with ALS. Furthermore, up to .10% of patients with ALS may have a monoclonal gammopathy and fewer than 5% have low-level titers of anti-GMi antibody. Moreover, serum antibodies to [.-type voltage-gated calcium channels have been found in some patients with ALS but not in others. Activated spinal cord microglial cells, elevated inflammatory cytokine levels, and most recently, marked increased expression of cyclooxygcnase-2 have also been found in ALS tissue samples (Yasojima et al. 2001; Aimer et al. 2002) (Figure 80.4). However, all available immunotherapies, including cyclophosphamide, IVIG, plasmapheresis, corticosteroids, and total lymphoid irradiation, have failed to alter the course of ALS (Murray and Mitsumoto 2002}. Although this might indicate that immune mechanisms are not of primary importance in the pathogenesis of ALS, there is hope that cell-targeted immune therapy and anti-inftamnuinry therapy may :v usclal.

Neurofilament Dysfunction. Abundant neurofilaments are present in the cytoskeleton of motor axons w[r]here they are vital for bi-directional axonal transport. Abnormal axonal spheroids, consisting of neurofi lament-derived material, have been identified in tissue from patients with ALS. Subsequent research shows that abnormally slow axonal transport (referred to as "axonal strangulation") may be important in ALS, perhaps as a result of oxidative stress-induced neurofilament injury (Lamonte et al. 2002). However, it is possible that increased levels of neuro-filament may actually represent a protective reaction of the cell body to harmful calcium levels or to other substances.

Mutations in the genes for neurofilament subunits appear to confer increased risk for the later development of SALS (Cleveland and Rothstein 2001). The neurofila-ment heavy chain is thought to be important in the correct spacing of neurofilaments from each other and thus in the regulation n! axonal diameter. In rare cases of SALS (and very rarely FALS), mutations have been found in the heavy-chain gene segment that encodes an amino acid repeat motif. Over express ion of another intermediate motor neuron-specific protein called *peripheric* may lead to accumulation of toxic intraneuronal aggregates,

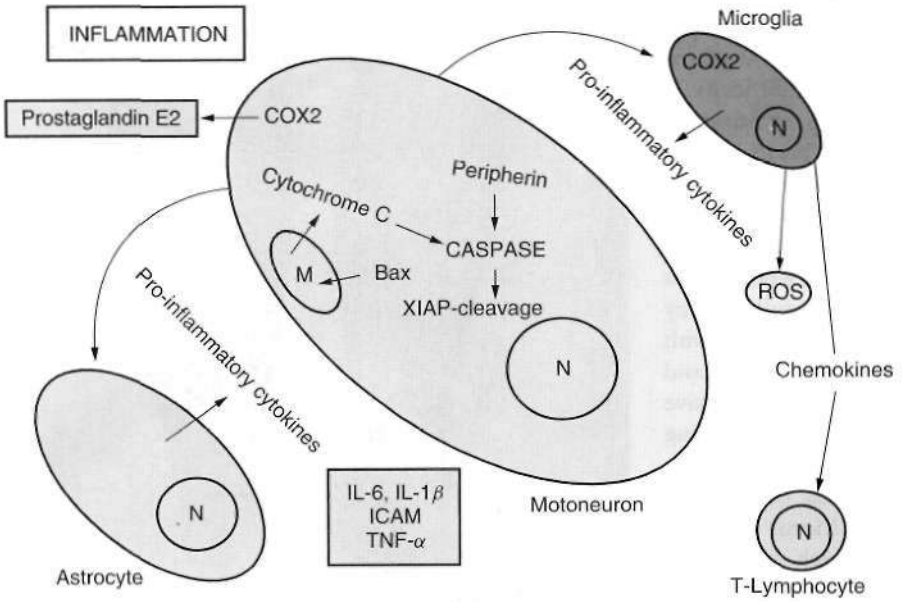

FIGURE 80.4 The role of inflammation in amyotrophic lateral sclerosis pathogenesis.

as has been demonstrated in patients with SALS and in mice with SOD1 mutations. In fact, selective motor neuron toxicity in the setting of pcriphcrin overexpression appears to occur in mice that lack light subunits, which implies that the light subunit may somehow prevent a harmful interaction between peripheral and other neurofilament subunits. Furthermore, proinflammatory cytokines appear to increase the duration of peripheral overexpression at sites of neuronal injury (Beaulicu, Kriz, and jalien 2002).

Susceptibility Genes for Sporadic Amyotrophic Lateral Sclerosis. The survival motor neuron (SMN) proteins are encoded by inversely homologous genes located on chromosome 5q (see Spinal Muscular Atrophy, earlier in this chapter). In one study, no deletions in the SMNl gene were found in SALS *(n* = 177) or FALS *(n* = 66), but a pure adult-onset LMN disorder associated with homozygous deletion of the SMN2 gene was described in five cases (Moulard et al. 1998). A French study of 167 patients with ALS revealed that the SMNl gene copy number was abnormal in 16% of cases compared with only 4% of controls, which suggests that the SMNl gene may be a susceptibility factor for ALS (Corcia et al. 2002).

Other rare mutations have been identified in patients with ALS, including in the APEX nuclease gene, cytochrome oxidase *c* subunit gene, the copper chaperone of SOD! gene, and the leukemia inhibitory factor gene. As with the genes for GLT1/EAAT2, neurofilament heavy chains, SMN protein, and the apolipoprotein H_4 genotype, there is insufficient evidence to implicate these mutations in the direct pathogenesis of all ALS, but they may act as genetically determined susceptibility factors.

Clinical Features

It is widely agreed that when the clinical symptoms of ALS first appear, the biological disease must have been developing for some time and is well into its course. Electrophysiological investigations in patients in the early stages of the disease suggest that an extensive remodeling of motor units takes place by continuous denervation and reinnervation process before affected individuals can recognize muscle weakness. A study in patients with acute poliomyelitis estimated that as many as 50% of the motor neurons are lost before muscle weakness is detected. Therefore an important preclinical asymptomatic stage likely precedes progressive muscle weakness in ALS.

Muscle weakness in ALS usually begins in a focal area, first spreading to contiguous muscles in the same region before involvement of another region. The first presentation may appear very similar to a focal mononeuropathy; this is sometimes called the *pseudo-neuritic presentation,* More commonly, however, limb weakness appears to occur in muscles derived from more than one peripheral nerve and/or nerve root distribution; this is called a *monomelic presentation.* Onset of muscle weakness is more common in the upper than the lower extremities (classic, spinal ALS), but in approximately 25% of patients, weakness begins in bulbar-innervated muscles (bulbar-onset ALS). On rare occasions (1% or 2% of patients), the weakness starts in the respiratory muscles (dyspnea onset). Some patients present with weakness that is restricted to one side of the body (Mills' hemiplegic variant) and up to 10% of patients appear with bilateral upper extremity wasting, which is known as the "flail arm" or flail person in the barrel variant.

Symptoms of muscle weakness vary, depending on which motor function is impaired. For example, when weakens begins in the hand and fingers, patients report difficulty in turning a key, buttoning, opening a bottle cap, or turning a door knob (Figure 80.5). When weakness begins in the lower leg, footdrop may be the first symptom or the patient may complain of instability of gait, falling, or fatigue when walking (Figure 80.6). When bulbar muscles are affected, the first symptoms may be slurted speech, hoarseness, or an inability to sing or shout, which may be soon followed by progressive dysphagia (Figure SO.7). Indeed, patients with bul bar-on set ALS often initially consult car, nose, and throat specialists and not only experience progressive impairment in bulbar function but also excessive drooling (sialorrhea) and weight loss. Pseudobulbar palsy may present with inappropriate or forced crying or laughter (see Signs and Symptoms of Upper Motor Neuron Involvement, earlier in this chapter), which is often a source of great emotional distress for patients. Excessive forced yawning may also be a manifestation of pseudo-bulbar palsy. In the rare patient who presents with progressive respiratory muscle weakness, the first port of call may be to a pulmonologist or even to the intensive care unit; the diagnosis of ALS is then made when the patient cannot be weaned from the ventilator. Head-drop (or droop) may be a feature in ALS and is caused by weakness of cervical and thoracic paraspinal muscles (Figure 80.8). However, weakness in these muscles is more commonly seen in myasthenia gravis and polymyositis.

FIGURE NO.6 A typical left footdrop in a 45-year-old patient whose amyotrophic lateral sclerosis began 2.5 years earlier with bulbar symptoms. When she was asked to dorsiflex both feet, she was able to move her right foot only. The footdrop developed 6 months before the photo was taken, and the patient wears a left ankle-foot orthosis.

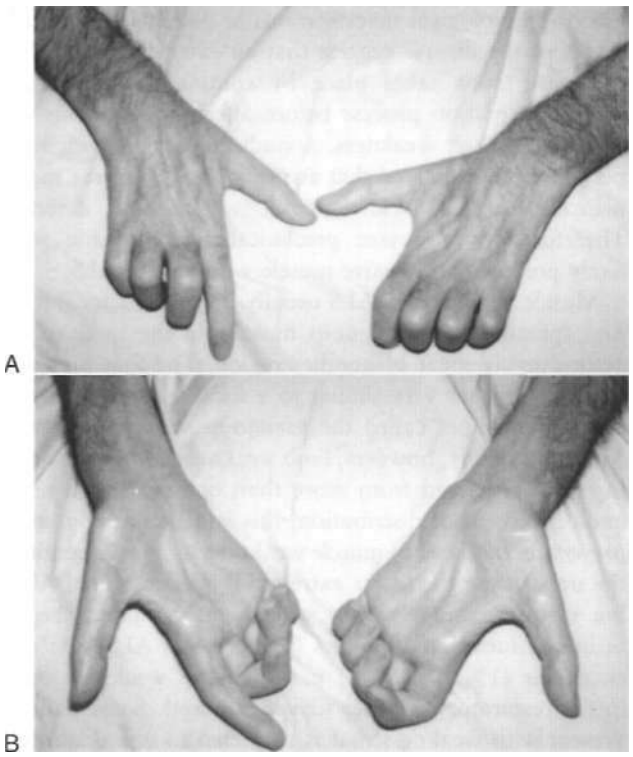

FIGURE 80,5 (A, B) Severe intrinsic hand muscle atrophy in a patient with amyotrophic lateral sclerosis. Note the "claw hand" and atrophy of muscles innervated by both ulnar and medial ncn i's.

Fascicular ions are not commonly the presenting feature of ALS, but they develop in almost all patients soon

FIGURE HO.7 Atrophy of the tongue in amyotrophic lateral sclerosis,

FIGURE 80.8 Patient with amyotrophic lateral sclerosis showing head droop caused by weakness of the thoracic and cervical pa rasp in til muscles,

after onset. In fact, absence of fasciculations should prompt one to seriously reconsider the diagnosis. In some patients, waves of fasciculations, called Lambert's waves, are seen spreading across the chest or back. Muscle cramps are one of most common symptoms in patients with ALS and often precede other symptoms by many 11 ninth-,. Although cramps arc common in health',- individuals and most commonly occur in calf muscles, in ALS they can occur in unusual muscles such as in the thigh, abdomen, hack, upper extremity, hand, neck, jaw, and even the tongue.

Other signs and symptoms include exertional tatn;ue that mimics myasthenia. As dysphagia worsens, reduced caloric intake worsens fatigue and accelerates muscle weakness. Aspiration of liquids, secretions, and food becomes a risk. Patients may complain that they produce copious amounts of abnormally thick oral secretions, which may drool excessively from the mouth. This sialorrhea is made worse as perioral muscles weaken and/or head-drop develops. Weight loss is often rapidly progressive; indeed it has been suggested that this does not simply reflect poor caloric intake but represents a form of ALS cachexia. Marked loss of muscle bulk exposes joints and associated connective tissues to abnormal mechanical stresses that can lead to joint contractures, joint deformities, painful pcricapsulitis, and bursitis. Sleep disturbances, in the form of increased awakenings from increased hypopneas and hypoxia, have been shown to be common in ALS and contribute to daytime sleepiness, morning headaches, and fatigue, As respiratory difficulty worsens, patients may be unable to lie supine because of worsening diaphragmatic weakness and thus compensate by using multiple pillows. In more advanced stages, patients are unable to he in bed at all. Other manifestations of ventilatory failure include dyspnea on exertion and eventually dyspnea at rest. As the disease advances, motor function is progressively impaired and activities of daily living (e.g., self-hygiene, bathing, dressing, toileting, walking, feeding, and verbal communication) become difficult. Accordingly, a patient's quality of life starts to progressively deteriorate. It may be difficult to distinguish daytime fatigue, broken sleep, affect lability, and sighing from depression, but it is vitally important to be aware of the latter. Depression is a common and underdiagnosed problem in ALS, which not only negatively affects quality of life but also shortens survival.

Atypical Features

There arc certain clinical features that are unusual if not absent in AI.S including sensory loss, dementia, extrapyramidal dysfunction, eye movement abnormalities, autonomic disturbances, and abnormal sphincter control. When patients have these signs, the diagnosis of ALS should not be made until all possible alternative diseases are excluded. Although the sensory system is characteristically spared, some patients do report vague sensory symptoms such as numbness or aching and there is electrophysiological evidence that ascending afferent pathways may be involved despite the absence of objective sensory loss on physical examination. Overt dementia is estimated to occur in approximately 5% of non-Western Pacific ALS where it may even be the presenting feature. It is usually of the frontotemporal dementia (FTD) variety, and most commonly presents with word-finding difficulties, deficits in visual perception, and abnormal confrontation naming. Patients may exhibit poor judgment and other deficits in executive processing. There is some evidence that this form of dementia or cognitive impairment is much more common not only in bulbar-onset ALS but also in all subtypes of ALS, One needs to be cautious that language disturbances (especially anomia) may be masked by dysarthria. A prospective neuropsychological study of cognition in ALS identified deficits in up to a third of patients and a subsequent study reported an incidence of FTD in almost 50% in patients with bulbar-onset ALS. Of 36 cases meeting criteria for FTD, 5 (14%) also met criteria for definite ALS (Lomen-Hoerth, Anderson, and Miller 2002). Dementia in ALS is pathologically distinct from other dementing illnesses; the most reliable pathological marker of cognitive impairment in SALS is

superficial linear spongiosis in neocorticai, entorhinal, and cingulate tissue (Wilson et al. 2001).

The motor neurons of Onufrowicz in the sacral cord are essentially spared in ALS, and thus patients generally do not complain of significant problems with sphincter control (although some may report mild urgency of micturition). Similarly, eye movements are typically normal in ALS; it takes detailed quantitative testing to be able to identify abnormal vertical ocular saccades. Approximately 5% of patients with ALS exhibit signs of extrapyramidal tract dysfunction, usually in the form of retropulsions during attempted ambulation. Autonomic symptoms do not come to the attention of patients with ALS, although there is electrophysiological evidence of abnormal sweat production and cardiac denervation in the early stages of disease in sonic panciiis : Keck et il. 200 >).

Natural History of the Disease

It has been estimated that up to 40% of anterior horn cell motor neurons are lost before the clinical detection of motor abnormalities; this suggests that a prolonged preclinical phase may be part of ALS. However, once the clinical phase-is evident, there appears to be a generally linear decline in motor function over time. There is a characteristic pattern of spread of disease. When onset is in one upper extremity, spread is often first to the contralateral side, then the ipsilateral lower extremity, the contralateral lower extremity, and finally the bulbar region. Onset in the lower extremity often follows a similar pattern, yet again with final involvement of the bulbar region (Brooks et al. 1994). Bulbar-onset ALS tends to spread to the distal upper extremities first, with spread to thoracic myotomes, and then the lower extremities. Overall, the pattern suggests that rostral-caudal involvement is faster than caudal-rostral spread. During the course of the disease, transient improvement, plateaus, or sudden worsening can occur, but spontaneous improvement is exceedingly rare.

Prognosis

Based on several epidemiological studies the median duration of ALS ranges from 23-52 months and the mean duration from 27-43 months (Mitsumoto, Chad, and Pioro 1997). About 25% of patients survive 5 years and 8-16% of patients survive beyond 10 years. A number of factors influence the prognosis of ALS including the age at onset, clinical type, and duration from onset to the time of diagnosis. However, it must be emphasized that there is a wide range of rates of progression in each category of patient; the previous rate of progression in a particular patient is a better indicator of prognosis than any other feature. In general, the younger the patient, or the longet the duration between onset and diagnosis, the better the prognosis. A worse prognosis is found in those whose rate of progression is rapid within the first 6 months of diagnosis (Chio et al. 2002). Several clinical subtypes harbor a better prognosis; these include PLS, I'M A, pseudobulbar (rather than bulbar) palsy, the pseudo-neuritic presentation, and the flail-arm variant. Those who survive beyond 46 months and those who are psychologically well adjusted or not depressed have a better prognosis. Those who have low-amplitude CMAPs in the setting of notmal sensory potentials (the *generalized low motor-normal sensory* pattern) as revealed by nerve conduction studies appear to have a poor prognosis. Dyspnea-onset ALS has a shorter survival. Low serum chloride levels are associated with a short-term survival without ventilatory support because they reflect accumulation of bicarbonate due to respiratory failure (Stambler et al. 1998). Data on bulbar-onset AI.S vary, bur mean survival ranges between 12 and 26 months. Malnutrition is an independent risk factor for poor outcome.

Laboratory Studies

In some instances a diagnosis of definite ALS can be reached based on the history and clinical examination alone. However, often the diagnosis is not so obvious and further investigations are necessary. Because there is no single test that can make a diagnosis of ALS, all of these investigations are performed to exclude other disorders that may clinically mimic ALS and its variants. All such testing is an extension of a thorough history and physical

examination and includes blood tests, the EDX, and neuroimaging.

There is no single blood test that may objectively diagnose SALS. However, there are several blood tests that are usually performed for the evaluation of patients with suspected ALS. The list includes serum CK concentration, blood count, chemistry panel (including calcium, phosphate, and magnesium), *Venereal Disease Research Laboratories* test results, GM| autoantibody titers, sedimentation rate, serum pro rem unmunofixation or Immunoelectrophoresis, thyroid function studies including thyroid-stimulating hormone, and vitamin B12 levels. The CK concentration may be modestly elevated, particularly early in the disease. Patients oldet than 50 years and smokers of any age should have a chest radiograph taken. If any lesion is identified, an anti-Hu antibody level should he determined. Certain patients may have clinical features that suggest a disorder of the neuromuscular junction and may therefore benefit from testing for antibodies against the acetylcholine receptor or voltage-gated calcium channel. If there is biochemical evidence of adrenal insufficiency, it is pnnlcnl in oh lin ;i \ cry long-chain fatly acid **[VI** CI'A) assay to investigate for possible adrenomyeloneuropathy. Young-onset ALS with atypical clinical features should prompt the physician to obtain a Hex-A assay. If there is a positive family history, it is important to counsel the patient in preparation for SOD1 mutation analysis. There arc no specific features on muscle biopsy to distinguish ALS from other neurogenic disorders and this test should be reserved for cases that are more suggestive of a myopathy.

The EDX examination is an invaluable tool in the investigation of ALS and its variants (see Chapter 36B). It serves as an adjunct to the clinical examination and is particularly useful in determining the presence or extent of LMN disease. Again, none of the EDX findings is ALS specific, but they can strongly suppott the diagnosis. Furthermore, this investigation may be repeated at intervals to more objectively monitor disease progression. Sensory nerve conduction study results are characteristically normal, unless the patient happens to have a coincidental mononcuropathy or polyneuropathy. Motor nerve conduction study results may be normal, although the conduction velocity and CMAP amplitude may be diminished in keeping with the extent of motor axon loss. There should be no evidence of conduction slowing or block, which would suggest a primarily dcmyclinating disorder. Severe motor axon loss may give rise to the "generalized low motor-normal sensory" EDX pattern, which may portend a poorer prognosis.

The needle electrode examination characteristically reveals a combination of acute (positive sharp waves and fibrillation potentials) and chronic (neurogenic firing pattern with evidence of increased amplitude and duration, polyphasic motor unit potentials) changes in a widespread distribution that is not in keeping with any single root or peripheral nerve distribution. Fasciculation potentials are usually identified; their absence should prompt an investigation for another disorder. Other common findings include moment-to-moment amplitude variation that indicates impaired motor unit stability and repetitive discharges known as *doublets.* Mention should be made of a special EDX finding, the split-hand phenomenon; in some patients, EDX reveals severe changes in muscles of the lateral hand (thenar eminence) but relative sparing of the medial hand (hypothenar eminence). EDX changes should be observed in a certain topographical distribution and ideally should be carried out in at least three of the four regions of the neuraxis (bulbar, cervical, thoracic, and lumbosacral).

Neuroimaging studies of the brain and spinal cord are important to exclude structural, inflammatory, or infiltrative disorders that may cause UMN signs (Mitsumoto, Chad, and Pioro 1997) (see Chapter 37). Furthermore, T2-wcightcd and proton density MRI scans of btain may also reveal abnormal signal within the motor tracts as they extend from the motor cortex to the brainstem. These changes are thought to represent wallerian degeneration. Nonspecific atrophy of the frontal and patietal cortex may also be appreciated. Novel MRI techniques such as magnetization transfer ration (MTR) and diffusion tensor **MRI** may also reveal specific changes in the motor tracts in ALS. Research using positron emission tomography (PET) has shown increased activity in several ipsilateral and contralareral cerebral cortical regions beyond the motor cortex, which supports the current theory that ALS is not a disorder solely of motor neurons, but that this cell population is especially vulnerable to the injurious process involved. Proton density MRI data may not only support the diagnosis but also provide useful motor neuron-specific information with which to track disease progression and response to therapy. Significantly abnormal values of the ratio of N-acetylaspartate (NAA) to creatine or choline have been detected in the motor tract of patients with probable or definite ALS when compared to controls and abnormalities in these levels change over time {Chan et al. *1999;* Suhy et al. 2002).

Diagnosis

In May 1990, at El Escorial, Spain, the World Federation nl Neurology established J agnostic criteria for Al S, which were later modified at Airlie House, Virginia (1998) (wAvw.wfnals.org). These criteria include clinical, electrodiagnostic, and pathological components. The clinical criteria divide candidates into those with definite, probable, lab-supported probable, possible, and FALS based on a careful history and examination of four regions of the neuraxis: bulbar, cervical, thoracic, and lumbosacral. The purpose of establishing these criteria was to facilitate entry of appropriate candidates into clinical research trials, but they have been proven invaluable in rhe assessment of all patients with ALS.

A patient is referred to as having "definite ALS" if there is clinical evidence of both UMN and LMN signs in three or

more regions. "Probable ALS" is diagnosed in those with UMN and LMN signs in two regions. "Possible ALS" implies that a patient cither has UMN and LMN signs in one region only or has UMN signs alone in two regions. In addition, "possible ALS" may be applied to those with LMN signs in two regions as long as these are detected rosrmlly to the L'MN siting- "lab supported probable ALS" refers to those patients who have clinical evidence of possible ALS but also have laboratory evidence of more widespread LMN involvement. The EDX is most valuable in providing such additional information. Follow-up examinations may be helpful in assessing patients with ALS, as disease progression may move a patient up a category, which not only may clarify the diagnosis but also may allow entry of that patient into research trials.

Differential Diagnosis

The differential diagnosis of ALS is rather extensive; motor symptoms and signs may be present in many other neurological and systemic disorders. Because there are no specific diagnostic markers for ALS, differentiating all other motor neuron diseases that may produce signs and symptoms of UMN, LMN, or both UMN and LMN involvement is essential for establishing the correct diagnosis. One may approach this task in an anatomical fashion and consider how ALS may appear similar to other disorders of the brain, brainstem, spinal cord, anterior horn cell, nerve root, peripheral nerve, neuromuscular junction, and muscle. Alternatively, one may approach this task in terms of the presentation; is it UMN only, LMN only, combined UMN-LMN, bulbar only, and so on? Are there any atypical features, such as prominent bladder or sensory involvement that suggest another diagnosis? For example, when UMN involvement is prominent, PLS, spastic paraparesis, or HAM should he considered, whereas pure LMN involvement suggests that one should also consider PMA, MMN, adult-onset SMA, or Kennedy's disease.

Severe cervical spondylosis may impinge upon the cervical cord and the nerve roots and thus present with both UMN and LMN signs. Because pain, spastic bladdet, and posterior column signs are not always present, F.MG and neuroimaging may he required to distinguish it from ALS. Neuroimaging is also invaluable in assessing other disorders ol the brainstem and spinal cord that nay superficially mimic certain features of ALS such as intrinsic or extrinsic tumors, foramen magnum meningiomas, syringobulbia, and syringomyelia. Multiple sclerosis usually presents with UMN signs, but on rare occasions, LMN signs develop when ventral root exit zones are affected by demyelinating plaques. Neuroimaging and lumbar puncture studies should distinguish the two conditions. GDI[1] may manifest as a predominantly LMN disorder, hut some patients also have demyelinating lesions in the CNS that cause additional UMN signs.

It may be difficult to differentiate PBP from bulbar myasthenia gravis, as even repetitive stimulation studies and testing for serum antibodies against acetylcholine receptor may be negative in the latter. Follow-up examinations, however, usually reveal the insidiously progressive nature of the motor neuron disorder. Bulbar symptoms in ALS may be mistaken for brainstem stroke, but the progressive nature of bulbar symptoms and negative brainstem **MRI** will usually clarify the picture. On rare occasions, the increased tone, dysarthria, and sialorrhea of Parkinson's disease may be confused with ALS. However, the former is characteristically responsive to i.-dopa and tremor is often prominent. Multiple system atrophy may present with a combination of UMN and LMN signs, together with dysarthria and dysphagia. However, cerebellar ataxia, eye movement abnormalities, sphincter disturbance, and dysautonomia are usually prominent features. SCA types 2 and 3 (Machado-Joseph disease) are also part of the differential diagnosis. Other diseases that mimic ALS include adult Hex-A deficiency, adrenomyeloneuropathy, and certain motor paraneoplastic syndromes. Hyperthyroidism may present with prominent UMN signs, weight loss, and fasciculations but also features tremor, heat intolerance, and tachycardia. Hyperparathyroidism may present with an LMN or even myopathic disorder that mimics PMA. Both the benign fasciculation syndrome and cramp fasciculation syndrome nun- lead to rclcnaL lor [he evaluation ol ALS, hut these patients do not have any other symptoms or signs that suggest a widespread progressive disorder of motor neurons.

/ *reatment*

See Table 80.10.

Presentation of the Diagnosis of Amyotrophic Lateral Sclerosis. The first step in the management of ALS is to present the diagnosis in a compassionate, yet informative manner. Because many patients and their families find it difficult to absorb the information at first, a second appointment a short time later is often required. The decision-making process must include the patient and the

family. At the appropriate time, it is important to bring up issues such as advance directives and issues regarding terminal care. Providing information on progress in research, newly available pharmacotherapies, and the possibility of active participation in clinical trials may increase hope for patients (Miller ct al. 1999).

Specific Pharmacotherapy. In 1996, riluzole (Rilutek) was approved by the United States Food and Drug Administration (FDA) as the first specific drug for the treatment of ALS. It is believed to principally function as an antiglutamate agent, although its mechanism of action is not yet fully understood. The two studies that led to riluzole approval showed that survival was significantly longer in patients with ALS who took 50 mg of riluzole twice a day compared with those who took placebo, although this survival benefit was only modest and was disproportionately beneficial in bulbar-onset disease, A subsequent systematic meta-analysis of three randomized trials carried out in French and Belgian populations has shown a significant survival advantage at *6,* 9, 12, and 15 months but not at 3 or 18 months. The median prolongation of survival was calculated at only 2 months. However, data from uncontrolled studies in other populations that were followed over longer periods have reported survival benefits of up to 20 months (Miller et al. 2002). In addition, riluzole appears to maintain patients in a milder state of disease for a longer period. Side effects are relatively uncommon and minor and include fatigue, gastrointestinal upset, and dizziness. Furthermore, there may an increase in liver function test results. To minimize side effects, we recommend 50 mg per day in the evening, and after a week or two, the patient can increase the dose to the regular dose of 50 mg twice a day. The cost of the drug (approximately S8000-S9000 per year) appears to be one of the main factors in whether patients elect to take riluzole.

Several agents with antiglutamate activity have been assessed in clinical trials including lamotngine, branched-chain amino acids, topiramate, dextromethorphan, and gabapentin. None of these has been proven to be of clinical benefit, although dextromethorphan has been shown to be of benefit in the treatment of pseudobulbar affect.

A series of agents with antioxidant and/or neuroproreetant properties have been studied in ALS including, L-deprenyl, N-aeety[cysteine, and calcium-channel blockers, but so far none has been shown to be of benefit. A trial of vitamin E taken orally at a dose of 1000 ug per day also did not show a clinical benefit. Nonetheless, many patients take high doses of natural antioxidants including combinations of vitamin E, vitamin C, flavonoids, coenzvme Qm, or all of them in various combinations. Many patients are taking creatine, a naturally occurring muscle component important in mitochondrial function that is widely available as an over-the-counter supplement in health food stores. As with coenzyme QJQ, there is experimental evidence that creatine improves motor function in transgenic SOD1 animal models of ALS, and trials are currently under way in humans (Klivenyi et al. 1999).

Neurotrophic factors are a heterogeneous group of basic peptides belonging to the cytokine family that are produced in regulated amounts from various tissues and are important in cellular proliferation, differentiation, maintenance, maturation, and repair. A number of recombinant neurotrophic factors have been studied in well-designed trials including ciliary neurotrophic factor, brain-derived neurotrophic factor, insulin-like growrh factor (IGF-1, Myotrophin), and glial cell-derived neurotrophic factor. Results from these trials have generally been disappointing, although some benefits have been noticed in certain. ALS subpopulations. It has been proposed that these negative findings may reflect poor drug delivery to target tissue and that future efforts should focus on trying to more closely mirror the natural biology of these and other neurotrophic factors: Systemic and intrathecal routes of administration do not appear to achieve adequate tissue levels and necessitate high doses that cause unpleasant side effects. The potential clinical benefits of IGF-1 are once again under investigation (Mitsumoto and Tsuzaka 1999). Another agent under clinical investigation is buspirone, an anxiolytic agent that also has neurotrophic factor-like effects.

Xaliproden (Sanofi SR57746A) is a novel small nonpeptide molecule with both neurotrophic and ncuroprotcctant properties and good CNS penetration. Preliminary trials suggested that this agent might be ot benefit in ALS. Based on evidence of benefit in cell culture systems and transgenic animal models, several other new agents are being investigated for potential use in the treatment of ALS. These include novel AMPA receptor antagonists, cyclooxygenase-2 antagonists, modified catalases, copper chelators, caspase inhibitors (such as minocycline), antiapoptotic antiviral agents (indinavir), anabolic steroids (oxandrolone), and modulators of cell signaling pathways. It may also be of benefit to administer several agents in combination, such as an antiglutamate agent with one or more neuioprotecrants and neurotrophic factors. Finally, there is early evidence from animals that gene therapy and/or stem cell therapy may be effective in the trearment, maintenance, and possibly even the regeneration of the motor neuron system, although many practical and ethical issues must be addressed before such treatment becomes a reality (Murray and Mitsumoto, 2002).

Aggressive Symptomatic Treatment. Although specific pharmacotherapy is still markedly limited for the treatment of ALS, symptomatic treatment can substantially improve a patient's symptoms and discomfott. Table 80.11 summarizes specific pharmacological and nonpharmacological symptomatic treatments (Miller et al. 1999).

Muhidisciplinary Team Approach at Amyotrophic Lateral Sclerosis Clinic. The care of patients with ALS has become increasingly complex. As a consequence, many patients are taken care of by ;; uuihidiseiplmary •.e.un rather

Table 80.11: Symptomatic treatment in amyotrophic lateral sclerosis

Symptoms	*Pha rtna cotherapy*	*Other therapy*
Fatigue	Pyridostigmine bromide	Energy conservation
	Antidepressants	Work modification
	Amantadine hydrochloride	Assistive devices
Spasticity	Baclofen	Physical therapy
	Tizanidine	Rangc-of-motion exercises
	Dantrolene sodium	
	Diazepam	
Cramps	Quinine sulfate	Massage
	Baclofen	Physical therapy
	Vitamin E	
Fa stimulations	Carbamazepine	Assurance
Sialorrhea	Anticholinergic drugs	Mechanical cleaning
Thick mucinous saliva	Beta blocker	None
Pseudobulbar laughing or crying	TCA	
	SSR1	
	L-d opa/ca r bi d o pa	
	Lithium	
Secretion and expectoration	Dextromethorphan	Hydration
	Organ id in	Moist air; aspiration devices; insufflator/exsufflator
Aspiration	Cisapride	Modified food consistency
		Tracheostomy
		Modified laryngectomy and tracheal diversion
Joint pains	Anti-inflammatory drugs	Range-of-motion exercises
	Analgesics	Heat
Depression	TCAs	Counseling
	SSRI	Support group meetings; psychiatry
Insomnia	Zolpidem tartrate	
	Lorazepam	
	Opioids	
Respiratory failure	Bronchodilators	Hospital bed
	Morphine sulfate	Nocturnal noninvasive ventilator
		1PPB
Constipation	Increase oral liquid	Noninvasive ventilation; permanent ventilation
	Metamucil	FJxercise
	Dulucored suppositories	
	Lactulose and other laxative	

1PPB = intermittent positive pressure breathing; SSRI = selective serotonin reuptake inhibitor; TCA = tricyclic antidepressant.

than by a single treating physician. The team often consists of neurologists, a nurse coordinator, physical therapists, occupational therapists, dietitians, speech pathologists, and social workers. Pulmonary specialists and other health professionals should also be available. Using this holistic approach, the aim is to maintain physical independence for as long as possible and to provide psychosocial support to patients and families {Mitsumoto, Chad, and Pioro 1997),

Ethical and Legal Issues. ALS is almost invariably a relentlessly progressive and terminal disorder. Thus physicians must raise the issues of the living will and durable power of attorney for health care relatively early after the diagnosis is made to allow the patient and family to prepare-ahead. However, it should be emphasized that such decisions are not final and may even be reversed at any time. Furthermore, some patients either do nor wish ro or cannot make such decisions.

Physical Rehabilitation, The main goal of rehabilitation for patients with ALS is to improve their ability to carry out activities of daily living for as long as possible without causing undue physical or emotional strain. Physical therapy also prevents complications secondary to disuse of muscles and immobilization, such as a frozen shoulder. Various types of exercise are employed that maintain or enhance strength, endurance, and range of motion. There have been concerns that exercising ALS-affected muscles to the point of fatigue may actually be harmful, but this has not been borne out in the literature.

The occupational therapist is another valuable member of the ALS care team. A range of assistive and adaptive devices is employed to improve mobility and comfort and to cany out activities ot daily living. For example, walkers, wheelchairs, splints, and collars are useful to manage wrist-drop, footdtop, head-drop, and gait instability. Successful rehabilitation also includes an evaluation of the

home environment and customized home equipment can easily help preserve a patient's independence and safety [Mitsumoto, Chad, and Pioro 1997),

Speech and Communication Management. Speech and communication dysfunction is probably one of the most serious factors reducing quality of life in the patient with ALS. Ideally, speech pathologists should assess speech and communication soon after the diagnosis is made so that the patient can maintain independent communication for as long as possible. To maximize communicative ability, we use a six-step approach as the disease progress:

- Step 1. Maximize intelligibility strategies (e.g., teaching the patient to speak slowly and face to face)
- Step 2. Introduce energy-conserving techniques
- Step 3. Train the patient's main listener or communication partner
- Step 4, Introduce nonverbal techniques (gestures and other body language)
- Step 5. Incorporate assistive (such as a palatal prosthesis) and augmentative communication devices and techniques
- Step 6. Refer for a complete augmentative and alternative communication evaluation by a speech pathologist

Numerous communication devices are available that vary in sophistication and complexity, ranging from simple and relatively inexpensive mechanical devices, such as alphabet or picture hoards, to specialized electronic devices such as a voice synthesizer.

Nutritional Care. Dysphagia and aspiration are distressing and dangerous complications of Al.S and are particularly prominent in the bulbar-onsct variety. As oral intake progressively declines, there is acceleration in weight loss and malnutrition, which not only aggtavates muscle weakness but also shortens survival. Therefore in every patient with Al.S, the nutritional status must be carefully evaluated at each visit. One of the best indicators of a change in nutritional status is a change in body weight. However, a detailed history of oral intake is also important, as is whether or not the patient has been coughing or choking during swallowing and whether there has been an increase in the duration of meals or an inability to finish meals. Although physicians can take such a history, evaluation by an experienced dietitian is often most helpful. Initially, patients should change the form and texture of their food and use a high-calorie food supplement, but eventually, such measures become insufficient to maintain the patient's weight, and proactive enteral tube feeding becomes imperative.

Percutaneous endoscopic gastroscopy (PEG) is a standard minor surgical procedure that not only improves quality of life but also prolongs survival by several months. Although it is a relatively simple surgery for otherwise healthy patients who have dysphagia, patients with ALS pose particular difficulties and often have impending respiratory failure that may complicate the procedure. The ALS Practice Parameters advocate placement of PEG tube in consenting patients with dysphagia, whose seated predicted forced vital capacity is more than 50% (Miller ct al. 1999). However, it has recently been shown in a small series of patients that a PEG may be performed for patients with a forced vital capacity of less than 50% predicted if noninvasive positive pressure ventilation is also used during the procedure (Gregory et al. 2002). It is important to emphasize that those who receive a PEG tube can continue to eat by mouth and that the purpose of enteral feeding is to provide calories and fluid and not merely to prevent aspiration. Indeed aspirarion is a continued risk to the patient even after PEG tube insertion, and if recurrent aspiration of PEG contents becomes a persistent problem, one can recommend percutaneous enteral jejunostomy (PEJ), which further reduces (but still does not eliminate) the risk.

Respiratory Care. Respiratory failure is the most common cause of death in ALS. Indeed, dyspnea-onset ALS presents with obvious ventilatory difficulties and it is for this reason that it harbors a particularly poor prognosis. However, it is important to make patients and family members aware that almost all forms of ALS will eventually be complicated by ventilatory failure, although symptoms may go largely unnoticed until relatively late in the disease course. It should he made clear to the patient that although positive pressure ventilation via a tracheostomy may indefinitely prolong life, there is no effect on the disease itself. In fact, by prolonging the natural history of the disorder, there is a strong possibility that atypical symptoms may arise, such as dementia, visual changes, sensory loss, and incontinence. Most patients and their physicians opt for the noninvasive approach. One technique, bilevel positive airway pressure ventilation (BiPAP), slows the rate of pulmonary decline, improves symptoms, and prolongs survival (Kleopa et a I. 1999; Ahoussouan et al. 2001). The current recommendation is that patients be offered noninvasive ventilatory assistance at the onset of dyspnea, when the forced vital capacity falls to less than 507o predicted, or a when a rapid rate of decline in pulmonary function occurs. However, it should be remembered that progressive weakness and wasting of perioral muscles would eventually prevent adequate use of the BiPAP mask; nasal pillows can be helpful in this circumstance and are often better tolerated than the mask at all stages. Furthermore, BiPAP does not prolong life indefinitely and these patients still face the difficult decision of whether to use an invasive ventilator. When the decision has been made to withdraw from ventilatory support, or when noninvasive means of ventilatory assistance are no longer sufficient, it is imperative that all attempts should be focused on effective and compassionate palliation. Judicious amounts of opioids, oxygen, and anxiolytics should be prescribed to allow the patients to live their final days with dignity and in as much comfort as possible.

Home Care and Hospice Care. When the patient's condition deteriorates, home care or admission to an alternative care site is required. Close collaboration among patients, their caregivers, home care nurses, and ideally the ALS clinic team will ensure effective and satisfying home care. When a patient has no caregiver, a site other than the home should he chosen for extended care. Hospice care provides highly effective palliative care to patients and their families. Just as important, hospice philosophy strongly affirms life so that patients who are in the terminal stages of their disease can maintain their independence and dignity to the gteatest degree possible.

Familial Amyotrophic Lateral Sclerosis

Between 5-10% of all ALS is familial, with the majority of cases being inherited in an autosomal dominant pattern. It is quite possible that the true frequency of FALS is an underestimate; anything less than a detailed family history may fail to identify an affected family member. ALS-1 is a form of late-onset motor neuron disorder that accounts for 15-20% of all cases of FALS (and thus 1-2% of all ALS) and is associated with mutations in the gene that encode SOD1 located on chromosome 21q21 (Siddique and Lalani 2002). Most cases are inherited in an autosomal dominant pattern, but a recessive variant has also been identified. ALS-2 is a rare, recessively inherited disorder mapped to a gene on chromosome 2q33 that encodes a novel protein that one group has dubbed a I sin. Al.S-4 and ALS-5 are also recessively inherited and have been mapped to chromosomes 9q2 l-q22 and 15ql5-q22, respectively. Fheir causative genes have yet to be identified. Most recently, a large European family has been identified with adult-onset autosomal dominant ALS linked to chromosome 18q21 (Hand et al. 2002). Fhis is currently classified in the ALS-3 category, but somewhat confusingly, ALS-3 has also been assigned to denote all familial cases that have yet to be linked to a chromosomal locus or associated with an inherited genetic mutation.

Autosomal Dominant Familial Amyotrophic Lateral Sclerosis

Genetics and Protein Chemistry

There are three SOD isoenzymes, termed SOD1, SOD2, and SOD5. The first of these, SOD1, is *A* cytosolic enzyme that scavenges the free radical by-products of oxidative respiration and is known to be important in the pathogenesis of some forms of FALS. Neither mitochondrial SOD2 nor extracellular SOD3 appears to be directly pathogenic in human ALS.

SOD1 is a 32-kd homodimeric protein encoded by a gene containing five exons located on chromosome 21, Faeb monomer contains one atom of copper and one of zinc. The zinc moiety maintains the dimer formation, which doubles the dismutasc activity. However, it is the copper within the active site that is important in catalyzing the conversion of 0_2~ to $Hi0_2$ and 0_2. SODl is ubiquitously expressed in every cell of every eukaryotic organism and its sequence and structure arc highly conserved. The biological importance of this protein is also evident in its great abundance within some cells; it accounts for as much ns 1% of nil protein of the CNS.

To date, more than 100 distinct point mutations have been found in all five exons of the SODl gene, the majority of which are missense mutations that usually result in the incorporation of a wrong amino acid into the gene product. Splice junction mutations, deletions, and insertions have also been detected in FALS (Siddique and Lalani 2002).

Pathogenesis

A simple pattern of loss of enzyme function has not been demonstrated in SODl-associatcd FALS. Mutant SODl proteins are often unstable, with activities ranging from completely normal or unaffected (aspartic acid replaced with alanine in codon 90) to entirely absent (glycine replaced with arginine in codon 85), and roral SODl enzyme activity correlates poorly with the severity of FALS. Moreover, SODl-knockout mice (animals genetically engineered to be born with no SODl proteins) are found to have no apparent motor neuron disease.

The weak association between enzyme activity and disease occurrence has led to an alternative hypothesis that there is a toxic gain of function in mutated SODl. Considerable support for this theory has come from cell culture and transgenic animal studies. Toxic gamed properties in human disease may arise from one or several processes (Cleveland and Rothstein 2001):

- Altered conformation of the copper-bound active site in mutant SODl protein may generate oxidative stress through an interaction with aberrant substrates such as hydrogen peroxide and peroxynitrite. Zinc-deficient mutant SODl may interact with nitric oxide to produce peroxynitrite, which in turn may cause harmful nitration of tyrosine residues on key intracellular proteins.
- Mutant SODl proteins have been shown to clump together as intracellular aggregates. These aggregates may interfere with proteasomal breakdown of ubiquirinatcd proteins or imp;vr axonal transport of various substances.
- SODl mutations may catalyze the inactivation of GIT I and thus cause excitotoxic cell injury via excessive influx of calcium into motor neurons. In addition, mutant SODl may also disturb calcium homeostasis through disruption of mitochondrial function.

- Both in vitro and in vivo research shows that mutant SOD1 protein is associated with enhanced programmed cell death (apoptosis). Increased expression or proapoptotic and reduced expression of antiapoptotic members of the bcl-2 family have been demonstrated in transgenic mutant SOD] mice. Furthermore, activated caspases, the effectors of apoptosis, have been demonstrated both in the anterior horn cells of transgenic SOD1 mice and in human ALS tissue. An experimental nonselective caspase inhibitor called *zVAD-fluorometbyl ketone* has been shown to prolong survival and improve motor performance in mutant SOD1 mice (Murray and Mitsumoto 2002).

Clinical features

There is a large degree of phenotypical variability in the expression of SODl-associated FADS, not only between different families but also between individual members of the same family. Furthermore, penetrance is rather variable and age dependent. Generally, the diagnosis of FALS can be established only by the fact that other family members in successive generations are or were affected by ALS, Unfortunately, a reliable history is not always available. The clinical features of individual FALS patients overlap considerably with those of patients with SALS, but there may be subtle differences between the two. For example, lower-limb onset is more common in FALS, whereas bulbar onset is rare. The age at onset for FALS averages at about 46 years, which is at least 10 years earlier than that of SALS; the male-to-female ratio is 1:1 in FALS but about 1.2-1.6:1 in SALS. Neuropathological analysis in FALS shows frequent posterior column involvement, although clinical signs for this pathological change are not usually apparent.

Certain clinical featutes arc often stereotypical within some families. For example, the two most common mutations, alanine replaced with valine at codon 4 in exon 1 (A4V) and histidine replaced with arginine at codon 43 in exon 2 (H43R), are associated with rapid progression, and most patients die within I year. In contrast, other mutations, such as histidine replaced with arginine at codon 46 in exon 2 (H46R) and glycine replaced with arginine at codon 37 in exon 2 (G37R), are associated with a disease duration averaging more than 15 years. SOD!-linked FALS presenting with predominantly LMN signs is associated with a mutation in which valine replaces leucine at codon 84 in exon 4 (L84V).

Auiosomal-Reeessivc and X-Linked Mutations

Substitution of aspartic acid with alanine at codon 90 in exon 4 (D90A) of the SOD1 gene can result in both autosomal dominant and recessive FALS. Although encountered worldwide, D90A FALS is particularly prevalent in Scandinavian countries where a common founder effect has been identified (Andersen et al. 1996). In Scandinavian counttics, the pattern of inheritance is autosomal recessive and only homo/.ygotes are clinically affected. Patients may present with atypical features such as sensory symptoms, urinary urgency, decubitus ulcers, posterior column dysfunction, and, rarely, ataxia,

Non-Scandinavian D90A families have been studied in Europe and the United States, in whom the pattern of inheritance is autosomal dominant. In these families, disease occurs in the heterozygous state, which suggests that Scandinavians may have a genetic protective factor on one or both gene copies that ensures normal cellular function until both alleles are affected.

X-linked dominant ALS, featuring a combination of both UMN and LMN signs, has been reported, the gene locus being on chromosome Xpll-Xq12 (Hong et al. 1998).

Juvenile familial Amyotrophic Lateral Sclerosis

An autosomal dominant form of juvenile-onset ALS has been mapped in one family to an interval of 5cM that harbors the ALS4 gene on chromosome 9q34, This autosomal dominant disorder, classified as ALS-4, typically manifests in the second decade of life (mean age is 17 years) with difficulty in walking, followed by weakness and wasting of intrinsic hand muscles and distal lower limbs. Progression is slow, so p; incuts become wheelchair bound by the sixth decade and sparing of bulbar musculature is a characteristic finding. An almost identical disorder has subsequently been described in three families diagnosed with distal HMN (spinal Charcot-Marie-Tooth disease). This disorder is also linked to the ALS4 locus. The authors have thus raised the possibility that ALS-4 and this HMN may be the same disorder (De jonghc et al. 2002).

Recessive juvenile ALS has been described in families of North African origin but is also present in Europe (ALS-5). The clinical syndrome is similar to SALS except for a younger age at onset. It has been linked to chromosome 15qlS-q22, but the pathogenic gene has not been identified.

Another juvenile recessive ALS syndrome, as yet unlinked to a chromosome site, has been described with a combination of both UMN and LMN signs. Symptoms and signs are more prominent in the lower extremities and bulbar function is spared,

Recessive juvenile ALS has also been mapped to chromosome 2q33 (ALS-2). Although it was originally described in consanguineous families from Tunisia, it has also been discovered in families from Saudi Arabia and Kuwait. The phenotype of this disorder varies according to the family of origin; in the Tunisian family, it presents as an ALS-iikc disorder with onset in the first or second decade of life; in the Kuwaiti family, the phenotype is similar to early onset PLS. Further work identified a new ALS gene called *ALS2* that encodes a protein that has been called alsin.

Sequence homology analysis of this protein suggests that it may function as a guanine-nucleotide exchange factor and thus be important in intracellular cell signaling and cytoskeleton organization. It appears that loss of function of this protein causes selective injury to motor neurons despite the fact that it is widely expressed in many tissue types. Furthermore, an ALS phenotype occurs when there is a onc-basc-pair deletion on exon 3, whereas a milder PLS presentation occurs in those with a rwo-base-pair deletion on exons 5 and 9. It has been proposed that the milder PLS phenotype occurs because of some residual function in a mutated longer protein product or an intact short protein product. Much has yet to he discovered about the structure and function of this protein, but the discovery of an ALS phenotype from a loss of function mutation, rather than a toxic gain of function, will likely lead to exciting new research into new models of ALS pathogenesis (Shaw 2001).

Amyotrophic Lateral Sclerosis-Parkinsonism-Dementia Complex (Western Pacific Amyotrophic Lateral Sclerosis)

In 1954, Mulder and colleagues described a disorder characterized by a combination of ALS and parkinsonism that was the most common cause of death in the adult-native Chamorro population on the Western Pacific island of Guam. A similar disorder was subsequently described in western New Guinea and the Kii peninsula of Japan, with an ALS incidence between 50 and 150 times than elsewhere. Clinically, about 5% of patients develop a predominantly ALS type of disorder, whereas 38% manifest principally with a combination of parkinsonism and dementia. The pathology of tins unusual disorder bears similarities to that of Alzheimer's disease (AD), with prominent loss of CNS neurons and the presence of abundant tau-immunoreactive neurofibrillary tangles. Alpha-synuclein pathology has recently been detected in the amygdala of affected brain tissue (Forman et al. 2002).

Multiple members of a single family may be affected, and it has recently been shown that fitst-degree relatives of patients with ALS-PDC have a significantly higher risk of developing the disease than controls. Despite these observations and a recent genetic association study implicating the tau gene as a susceptibility gene for ALS-PDC, accumulated epidemiological evidence MI ongb suggests that an environmental factor, rather than a genetic factor, is more important in disease pathogenesis, fhe incidence of the Guamanian ALS variant has rapidly declined over the past 50 years, a process thought to reflect the westernization of the region. Various environmental toxins have been implicated in the pathogenesis of ALS-PDC, chief among them being neurotoxins derived from the native cycad seed. This seed contains ^-methylamino [.-alanine (BMAA), an amino acid that is reversibly toxic to cortical and spina) motor neurons. They also contain a carcinogenic substance called *cycasin* that may act either alone or in concert with BMAA to damage motor neurons. Toxic sterol glucosides have recently been isolated from washed cycad flour, and it has been shown that they can cause the release of glutamate (Khabazian et al. 2002). Cox and Sacks (2002) have proposed a process of biomagnification of cycad toxins through the once popular Chamorro practice of eating flying foxes, which themselves feed on cycad seeds. The decline in the incidence of ALS-PDC may reflect the dwindling flying fox population on Guam through a massive increase in commercial hunting using firearms that were introduced to the island in the decades following World War II (Cox and Sacks 2002).

Spinocerebellar Ataxia Type 3 (Machado-Joseph Disease) (OMIM 109150)

Machado-Joseph disease is an autosomal dominant syndrome with onset varying from the third to seventh decade of life. Although cerebellar ataxia is the predominant clinical feature, patients with an early onset (age 20-30 years) often present with generalized spasticity and fasciculations of the face and tongue. Other characteristic findings include extrapyramidal signs, such as dystonia and rigidity, protuberant eyes, and progressive external ophthalmoparesis. Affected patients have a twofold to threefold expansion of a CAG trinucleotide on the ataxin-3 gene on chromosome 14q32.1. The expanded triplet repeat results in a mutant gene product containing an expanded polyglutamine tract, which appears to aggregate into intranuclear neuronal inclusion bodies and may interfere with (he function of the cellular proteasome in degradation of proteins (Schmidt et al. 2002). The Machado-Joseph disease phenotype may also occur in SCA-2, with slowly progressive ataxia, eyelid retraction, and facial fasciculations (Geschwind et al. 1997). Patients often have slow saccades or ophthalmoparesis and may have reduced or absent deep tendon reflexes. SCA-2 is caused by an expanded polygluta mine-encoding CAG triple repeat sequence on chromosome 12q.

Adult Hexosaminidase-A Deficiency (OMIM 606869)

Adult Hex-A deficiency is an autosomal recessively inherited late-onset GM_2 gangliosidosis (the other subtypes being infantile and juvenile). All three subtypes are caused by an abnormal accumulation of GM_2 ganglioside in neurons due to a deficiency in the activity of the lysosomal enzyme. Hcx-A is encoded by a gene on chromosome 15q23-q24 and normally degrades GM> ganglioside. Only about 10% of Hex-A activity is required for normal health, but in the severe infantile form of this disorder, also known as *Tay-Sacbs disease*, mutations in the w-subunit of Hex-A

result in complete deficiency of enzyme activity. Juveniles and adults with Hex-A deficiency, however, are compound heterozygotes with varying degrees of residual enzymnric activity and thus A deficiency is a later onset disorder with considerable variability in the phenotype.

The adult form may present as slowly progressive weakness of predominantly proximal muscles of the upper and lower extremities. In some patients, severe cramps may present in association with muscle weakness, mimicking SMA, In others, however, a combination of dysarthria, spasticity, and LMN signs may resemble ALS. Additional sensory, cerebellar, cognitive, psychiatric, and extrapyramidal features may later develop. The EDX may reveal prominent complex repetitive discharges and abnormal SNAPs. Generally, this constellation of symptoms and signs is not easily mistaken for ALS, but in the relatively early stages, patients with Hex-A deficiency may not manifest many features other than motor system dysfunction. Genetic counseling is important before assaying a patient's serum or leukocytes for deficiency of Hex-A activity.

Triple-A Syndrome (OMIM 231550)

Triple-A syndrome (Allgrove's syndrome) is a rare autosomal recessive disorder that derives its name from the combination of achalasia, dlacrima, and ddrenocorticotrophic insufficiency. The A A AS gene is located on chromosome 12ql3 and encodes a ubiquitous protein called *aladin*, which is heavily expressed in the neuroendocrine system and may be important in regulation of the cell cycle, cell signaling intracellular transport, and the cell cytoskeleton. The syndrome manifests a range of neurological problems, including mental retardation, optic atrophy, and seizures. A recent case report suggested that a further two A's be added to the name; they described a woman with additional features of autonomic disturbance (dry mouth, postural hypotension, and syncope) and bulbospinal amyotrophy (amyottophy of limbs and tongue with tongue fasciculations) (Goizet et al. 2002).

Disinhibhion-Dementia-Parkinsonism-Amyotrophy Complex (Wilhelmsen-Lynch disease) (OMIM 600274)

Disinhibition-dementi a-par kin son ism-amyotrophy complex (DDPAC) is an autosomal dominant progressive neurodegenerative disease described in a large Irish American family (family Mo) in the United States and is characterized clinically by disinbibited behavior (including excessive eating and inappropriate sexual behavior), personality changes, dementia, patkinsonian manifestations, and in two cases, amyotrophy with fasciculations. Autopsy studies showed widespread neuronal loss in the substantia nigra, cerebral cortex, and anterior horn of the spinal cord, together with extensive spongy degeneration in the temporal and frontal lobes. Subsequent research identified the presence of tau-immunorcactive inclusion bodies in affected regions of the CNS. Splice-site donor mutations in the gene encoding microtubule-associated protein tau are associated with DDPAC (Lynch et al. 1994).

Autosomal Dominant Frontotemporal Dementia with Motor Neuron Disease

Up to 5% of patients with SALS may also manifest overt signs of dementia, which is usually of the frontotemporal type. However, for more than half a century, various observers have pointed out that symptoms and signs of ALS and LTD appear to occur together in some families with increased frequency. A recent analysis of multiple pedigrees identified a locus for autosomal dominant ALS and FTD on chromosome 9q21-22. The mean age at disease onset in these families was about 54 years (range 40-62 years). Some patients developed symptoms and signs of ALS alone, but others also developed inappropriate behavior, impulsiveness, and eventually impaired memory. Both neuroimaging and pathological studies revealed frontotemporal atrophy and histology identified gliosis, vacuoles, rare Pick's bodies, and some neurofibrillary tangles and senile plaques (Hosier et al. 2000).

Adult Polyglucosan Body Disease

Polyglucosan body disease is a very rare, late-onset, slowly progressive disorder characterized by a combination of UMNand LMN signs, cognitive decline, distal sensory loss, and disturbances of bladder and bowel function. MRI of the brain may reveal diffuse white matter signal increase on T2-wcighted images. The diagnosis is clinched by the finding of characteristic pathological changes in tissue from peripheral nerve, cerebral cortex, spinal cord, or skin. Axons and neural sheath cells contain non-membrane-bound cytoplasmic periodic acid-Schiff-positive polyglucosan bodies. Ultrastructural examination shows that the inclusions consist of 6-8 nm branched filaments and arc most abundant in myelinated nerve fibers. In Ashkenazi Jewish patients (and one reported non-Ashkenazi Jewish patient), the disorder is caused by a deficiency of the glycogen-branching enzyme, but in other patient populations, this enzyme activity is normal. The recent (albeit inadvertent) generation of muscle polyglucosan bodies in a transgenic mouse engineered to overexpress glycogen synthase in the presence of normal levels of glycogen-branching enzyme suggests that an imbalance in the activities of these two enzymes is the possible molecular mechanism underlying this unusual disorder (Raben et al. 2001). It is interesting to note that two types of polyglucosan body may be seen in ALS, Lafora's bodies

and corpora amylacea, although neither is considered a characteristic pathological feature.

Paraneoplastic Motor Neuron Disease

There is evidence rhat motor neuron disease may rarely be a paraneoplastic phenomenon. Patients may present with features that are rather typical of pure "spinal" ALS or manifest in a manner akin either to PMA or PLS. Other motor neuron manifestations may represent only one part of a larger paraneoplastic syndrome, such as anti-Hu antibody associated encephalomyelitis, with atypical features such as dysautonomia or ataxia. Unfortunately, most paraneoplastic motor disorders are unresponsive to treatment of the underlying tumor. Rare motor disorders have been described in association with other paraneoplastic antibodies, including anti-Yo antibody in a patient with ovarian carcinoma, and a novel antincuronal antibody in a patient with breast cancer. A subacute, painless, and progressive LMN disorder has been well characterized in lymphoma (both Hodgkin's and non-Hodgkin's types). Patients may eventually develop UMN signs and some may improve either with treatment of the cancer or spontaneously. Elevated CSL protein levels or the presence of a paraprotein in the blood should prompt a detailed investigation for lymphoma. Although there is insufficient evidence to conclude that there is increased risk of cancer in ALS, a combination of UMN and LMN signs has been well described in patients with breast, uterine, ovarian, and non-small cell cancer. This ALS-like disorder is quite rapidly progressive and does not appear ro respond either to treatment of the underlying cancer or to immune therapies. UMN signs and symptoms that mimic PLS may rarely occur in patients with breast tumors and may in fact precede the cancer diagnosis by a few months. In general, one should invesiigate for a paraneoplastic disorder if there arc atypical features such as ataxia, sensory loss, and dysautonomia, and it would seem to be prudent to carry out bteast screening on women with a PLS presentation.

Viral Hypothesis and Human Immunodeficiency Virus Type 1-Associated Motor Neuron Disorder

Many viruses are neurotropic, that is, they have a unique capacity to gain access to and teplicate within cells of the CNS. As such, viral infection may be important in the pathogenesis of ALS. Of the many candidate viruses, greatest attention has been paid to enteroviruses (including pohovirus) and retroviruses. However, an as yet unidentified virus may be the culprit.

Although rare cases of patients who previously had poliomyelitis later present with a combination of both UMN and LMN degeneration, there is insufficient evidence to implicate poliovirus in the pathogenesis of ALS. However, other as yet unidentified enteroviruses may be important. One study identified enteroviral sequences in 88.3% of AI.S spinal cord tissue, but only 3.4% of control tissue (Berger et al. 2000).

Tt appears that retroviruses may be closely linked to motor neuron pathology. Using a highly sensitive reverse transcriptase assay, investigators showed that *59%* of patients in their study group with motor neuron disease were positive but only 3% of controls. However, their findings suggested that a novel retrovirus might be present because none of the usual human retroviruses such as HTV-1 or HTLV-1 was identified (Andrews et al. 2000). It is already known that HTI V-l can very rarely cause an ALS-mimic syndrome that may be clinically distinguished by the presence of sphincter disturbance. Indeed, certain protein sequences of both HTLV-1 and HTLV-2 have been detected with increased frequency in the peripheral blood lymphocytes ol pa lieu is with \\I.S.

A retrospective review of 1700 cases of HIV-1-infected patients with neurological symptoms identified 6 cases presenting as a reversible ALS-like syndrome (Moulignicr et al. 2001), representing a 27-fold increased risk of developing an ALS-like disorder in that particular HIV-1 patient population. Overall, patients were somewhat younger than the normal ALS population, all but one being younger than 40 yeats at the time of diagnosis. Onset was characteristically in a monomelic pattern followed by a very rapid spread to other regions over a period of weeks. There were clinical features of both UMN and LMN involvement, with fasciculations, cramps, and bulbar symptoms. Two patients also had rapidly progressive dementia, with other features suggesting an additional diagnosis of AIDS-dementia complex. Sensory and sphincter disturbances were not apparent. CSK protein levels were sometimes mildly increased and a lymphocytic pleocytosis was evident in three patients, but all remaining laboratory results il ll\ -1 sempositivit} apart were negative. l.D.X revealed a widespread disorder of anterior horn cells in the absence of dcmyelinating conduction block, and MRI in one patient showed diffuse white matter signal increase suggestive of AIDS-dementia complex. In each case, antiretroviral therapy was beneficial either in stabilizing or in two instances curing the disease. No similar cases have been identified in this patticular study population since the introduction of highly active antiretroviral combination chemotherapy in the management of HIV infection, Another case report found similar clinical features in a 32-year-old HIV-positive patient who also enjoyed a complete response to antiretroviral therapy. MRI of brain showed increased T2-weighted signal in the brachium pontis with some minimal contrast enhancement. The resolution of motor symptoms coincided with a lack of detectable HIV in plasma and CSF. In addition, the abnormal MRI signal almost completely resolved (MacGowan, Scelsa, and Waldron 2001). Other forms of HIV may also be related ro the pathogenesis of motor neuron

disease; a pure LMN syndrome was described in a woman who was seropositive for HIV-2,

Chapter 81
Disorders of Nerve Roots and Plexuses

David A. Chad

DISORDERS OF NERVE ROOTS

The anterior and posterior nerve roots run from the spinal cord to the dorsal root ganglia, where they unite to form the spinal nerve. They are susceptible to diseases specific to their location and to many of the disorders that affect the peripheral nerves in general. Although surrounded by a rigid bony canal, they are delicate structures subject to compression and stretching. Bathed by cerebrospinal fluid (CSF), they may be injured by infectious, inflammatory, and neoplastic processes that involve the leptomeningcs. Separated from the blood by an incomplete blood-nerve barrier, the dorsal root ganglion (DRG) neurons may be injured by circulating neurotoxins.

In the clinical sphete, it is usually not difficult to recognize that a group of symptoms and signs is caused by a lesion of a nerve root. Radicular pain and paresthesias are accompanied by sensory loss in the dermatome (the area of skin innervated by one nerve root), weakness in the myotome (defined as muscles innervated by the same spinal cord segment and nerve root), and diminished deep tendon reflex activity at a segmental level subserved by the nerve root in question. When many roots are involved by a disease process (polyradiculopathy), however, the clinical picture may resemble a disorder of the peripheral nerves, as in a polyneuropathy, or of the anterior horn cells, as in the progressive muscular atrophy form of amyotrophic lateral sclerosis (ALS). Diagnosis therefore may become more difficult. Clinicians then turn to laboratory studies for help in arriving at a diagnosis.

A disorder of the nerve roots is favored by abnormalities of the CSF (raised protein concentration and pleocytosis), of the paraspinal muscle needle electromyographic (EMG) examination (presence of positive shatp waves and fibrillation potentials), and of spinal cord magnetic resonance imaging (MRI) (compromise or contrast enhancement of the nerve roots *per se).*

The sections that follow cover some anatomical features relevant to an understanding of the pathological conditions that affect the nerve roots, as well as specific nerve root disorders.

Anatomical Features

Each nerve root is attached to the spinal cord by four to eight rootlets, which arc splayed out in a longitudinal direction (Stewart 1993). The dorsal roots are attached to the spinal cord at a well-defined posterolateral sulcus. The ventral rootlets are more widely separated and emerge over a greater area. At each spinal cord segment, a pair of dorsal and ventral roots unite just beyond the DRG to form a short mixed spinal nerve, which divides into a thin dorsal ramus and a thicker ventral ramus (Figure 8 1.1). The dorsal ramus innervates the deep posterior muscles of the neck and trunk (the paraspinal muscles) and the skin overlying these areas. The ventral ramus (the large anterior branch) contributes to the cervical, brachial, or lumbosacral plexus and thereby supplies the limb muscles.

The nerve roots lie freely in the subarachnoid space covered by a thin root sheath, which is a layer of flattened

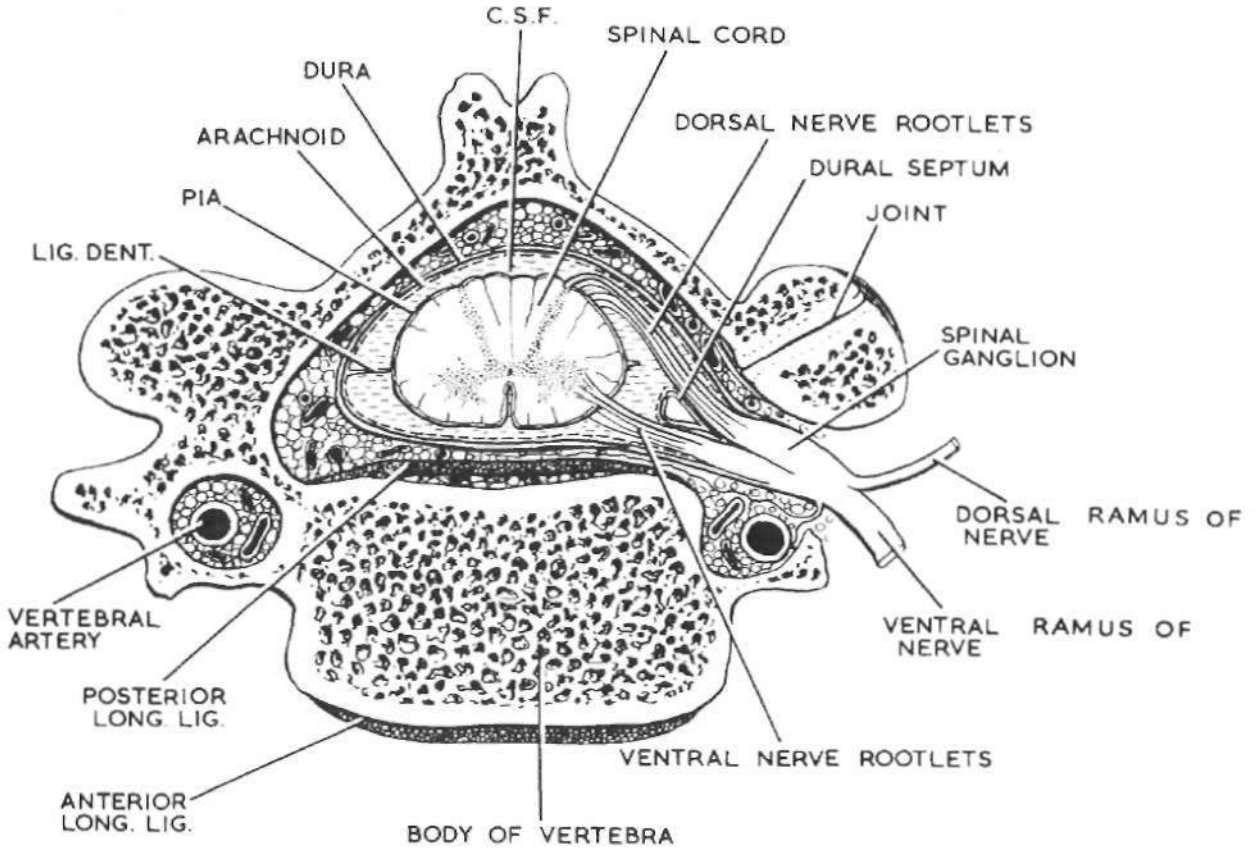

FIGURE 81.1 Relations of dura to bone and roots of nerve shown in an oblique transverse section. On the right, the telations between the emergent nerve and the synovial joint are seen, hut the joint between the vertebral bodies is not in the plane of the section. The dorsal and ventral roots meet at the dorsal root ganglion in the intervertebral foramen to form the mixed spinal nerve. The small dorsal ramus is the most proximal branch of the mixed spinal nerve and serves the cervical paraspinal muscles (not shown). The dura becomes continuous with the epineurium of the mixed spinal nerve at the intervertebral foramen. The posterior longitudinal *{Lung.)* ligament *{Lig.)* helps contain the intervertebral disc {not shown), preventing protrusion into the spinal canal. (C.S.F. = cerebrospinal fluid; Lig. dent. = ligament dentate.) (Reprinted with permission from Wilkinson, M. 1971, *Cervical Spondylosis: Its Early Diagnosis and Treatment,* WB Saunders, Philadelphia.)

cells continuous with the pial and arachnoidal coverings of the spinal cord. They lack the epineurial and perineuria] coverings found in peripheral nerves. Compared with spinal nerves, the roots have many fewer connective tissue cells in the endonenrium and considerably less collagen. A capillary network derived from the radicular arteries provides the blood supply to the spinal nerve roots (Levin 2002 .

Where the nerve roots form the mixed spinal nerve, the pial covering of the root becomes continuous with spinal nerve perineurium, and nerve takes the dutal nerve root sheath through the intervertebral foramen to become continuous with the epineurium of the mixed netve. At the intervertebral foramen, the root-DRG-spinal nerve complex is securely attached by a fibrous sheath to the transverse process of the vertebral body. In general, the DRG is located in a protected position within the mien. encbijl hii.uimu. hut ;it !:unhnr and S.KT;I1 levels, the DRG resides proximal to the neural foramina, in an intraspinal location (Levin 2002). There, they may be vulnerable to disc herniation and the complications of osteoarthritis (vide infra).

Nerve fibers, together with their meningeal coverings, occupy 35-50% of the cross-sectional area of an intervertebral foramen. The remaining space is occupied by loose areolar connective tissue, fat, and blood vessels. On computed tomographic (CT) and MRI scans, the fat acts as an excellent natural contrast agent that defines the thecal sac and nerve roots, allowing detection of nerve root compression.

The dorsal roots contain sensory fibers that are central processes of the unipolar neurons of the DRG, On reaching the spinal cord, these fibers either synapse with other neurons of the posterior horn or pass directly into the posterior columns. In the ventral root, most fibers ate essentially direct extensions of anterior horn motor neurons (alpha, beta, and gamma) or of neurons in the in ter mediolateral horn (preganglionic sympathetic neurons found in

lower cervical and thoracic segments). In addition, ventral roots contain a population of unmyelinated and thinly myelinated axons, which come from sensory and sympathetic ganglia (Hildebrand, Karlsson, and Risling 1997].

There are 31 pairs of spinal nerves that run through the intervertebral foramina of the vertebral column: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal (Figure 81.2). A feature of clinical relevance is the pattern formed by the lumbar and sacral roots as they leave the spinal cotd and make their way to their respective DRG to form spinal nerves (see Figure 81.2). In the adult, the spinal cord is much shorter than the spinal column, ending usually between LI and 1.2. Therefore the lumbar and sacral roots descend caudally from the spinal cord to reach the individual intervertebral foramina, forming the cauda equina; the concentration of so many nerve roots in a confined area makes this structure vulnerable to a range of pathological processes (vide infra).

Traumatic Radiculopathies

Nerve Root Avulsion

The spinal roots have approximately one tenth the tensile strength of the peripheral nerves because of lesser amounts of collagen and the absence of epineurial and penneurial sheaths in the roots. Therefore the nerve roots are the weak link in the nerve root-spinal nerve-plexus complex, and nerve root avulsion from the spinal cord typically results from a severe traction injury. Ventral roots are more vulnerable to avulsion than dorsal roots, a consequence of the dorsal roots having the interposed DRG and a thicker dural sheath. In most cases, root avulsion occurs in the cervical region. Lumbosacral nerve root avulsions are rare with only 35 cases reported between 1955 and 1996 and when they occur are generally associated with fractures of the sacroiliac joint with diastasis of the symphysis pubis or fractures of the pubic rami (Chin and Chew 1997).

In most cases, avulsion at the level of the cervical roots results in two distinct clinical syndromes. One is Erb-Duchenne palsy, in which the arm hangs at the side internally rotated and extended at the elbow because of paralysis of C5- and C6-innervated muscles (the supraspinatus and infraspinatus, deltoid, biceps). The second is Dejcrine-Klumpke palsy, in which there is weakness and wasting of the intrinsic hand muscles with a characteristic claw-hand deformity because of paralysis of C8- and Tl-innervated muscles. Injuries responsible for Erb-Duchenne palsy are those that cause a sudden and severe increase in the angle between the neck and shoulder, generating stresses that are readily transmitted in the direct line along the upper portion of the brachial plexus to the C5 and *C6* roots. Today, motorcycle accidents are the most common causes of this injury, but the incidence of C5 and C6 root avulsions in the newborn during obstetrical

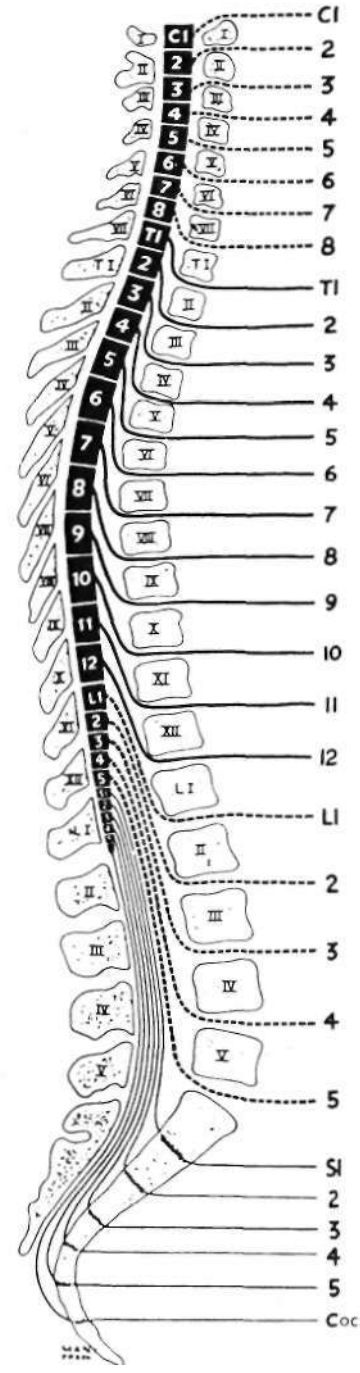

FIGURE 81.2 The relationship of spinal segments and nerve roots to the vertebral bodies and spinous processes in the adult. The cervical roots CI in *i',7* (i.e., all except C8) exit through foramina above the vertebral body of the same number. The C8 root passes through the C7-T1 neural foramen and all thoracic, lumbar, and sacral roots leave the spinal canal below the body of the vertebrae of the same number. The spinal cord is shorter than the spinal column, ending between vertebral bodies 1.1 and L2, The lumbar and sacral roots form the cauda equina and descend caudally, beside and below the spinal curd, ro exit at the intervertebral foramina. (Reprinted with permission from Haymaker, W. Si Woodhall, B. 1953, *Peripheral Nerve Injuries,* 2nd ed, WB Saunders, Philadelphia.)

procedures is increasing with the decline in the use of cesarean section. Brachial plexus injuries in the newborn are discussed in Chapter 86. The Dejerine-Klumpke palsy occurs when the limb is elevated beyond 90 degrees and tension falls directly on the lower trunk of the plexus, C8, and Tl roots. Such an injury may occur in a fall from a height in which the outstretched arm grasps an object to arrest the fall, leading to severe stretching of the C7, C8, and Tl roots.

Clinical Features and Diagnosis. At the onset of root avulsion, flaccid paralysis and complete anesthesia develop in the myotomes and dermatomes served by ventral and dorsal roots, respectively. Clinical features supplemented by electrophysiological and radiological studies help determine whether the cause of severe weakness and sensory loss is root avulsion or an extraspinal plexus lesion. For example, C5 root avulsion results in virtually complete paralysis of the rhomboids and spinatus muscles (innervated primarily by C5) and a varying degree of weakness of the deltoid, biceps, brachioradialis, and serratus anterior {which receive additional innervation from C6). A clinical sign of Tl root avulsion is an ipsilateral Horner's syndromi- caused by damage to preganglionic sympathetic fibers as they traverse the ventral root to their destination in the superior cervical ganglion.

The electrophysiological tests include the measurement of a sensory nerve action potential (SNAP) and needle EMG examination of the cervical paraspinal muscles. In the setting of an isolated C5 root avulsion, the SNAP should be preserved, despite complete anesthesia in the dermatome because the peripheral axons and the DRG cell bodies remain intact. Needle EMG of the cervical paraspinal muscles permits separation of damage of the plexus and of ventral root fibers because the posterior primary ramus, which an-:--. |HM lic\nid LV l)R(, ami proximal re tinplexus as the first branch of the spinal nerve, innervates these muscles (see Figure 81.1). Thus cervical paraspinal fibrillation potentials support the diagnosis of root avulsion. Paraspinal muscles have also been evaluated radiologically in the setting of root avulsion. Contrast-enhanced MRI studies of the cervical paraspinal muscles showing severe atrophy were accurate in indicating root avulsion injuries, and abnormal enhancement in the multifidus muscle was the most accutatc among paraspinal muscle findings (Hayashi et al. 2002), Intraspinal neuroimaging using postmyelographic CT or MRl usually demonstrates an outpouching of the dura filled with contrast or CSF at the level of the avulsed root. This post-traumatic meningocele results from tears in the dura and arachnoid sustained during root avulsion. Postmyelographic CT with 1- to 3-mm axial slices provides accurate diagnosis on the status of nerve roots in 85% of patients, compared to 52% for MRI (Carvalho et al. 1997). Gadolinium-enhanced MRI appears to offer a promising noninvasive means to evaluate traumatized nerve roots by visualizing the spinal cord surface at the root entry /one ("root-stump" enhancement) and by noting enhancement of intradural nerve roots (Hayashi et al. 1998}.

In most cases, these tests are helpful in ascertaining whether root avulsion has occurred. Sometimes, however, clinical assessment is difficult and results of testing are ambiguous. The physical examination may be limited because of severe pain. An absent SNAP indicates sensory axon loss distal to the ORG but docs not exclude coexisting root avulsion. Even when rhis test of sensory function points to avulsion of the dorsal component of the root, the status of the ventral root may remain uncertain if paraspinal fibrillation potentials are not found. There arc two reasons for their absence: First, they do not appear for 7-10 days after the onset of axonotmesis, and second, even if the timing of the needle EMG is right, they may not be seen because of innervation of the paraspinal muscles from multiple segmental levels. Finally, imaging studies are nor always diagnostically accurate, at times disclosing classic post-traumatic meningoceles in patients without root avulsion (but only dura] tear) or revealing normal findings in true root avulsion (dc Verdier, Collctti, and Terk 1993). The difficulty in establishing a definitive diagnosis of root avulsion based on FMG and ncuroiinaging in some cases has led to a potentially important role for intraoperative evoked potentials to establish whether the root in question is in continuity (Oberle et al. 1998).

Treatment. Root avulsion produces a severe neurological deficit that has long been considered an unbeatable injury. Carlstedt et al. (1995), however, repotted on a patient who had an avulsion injury involving C6-T1 in whom they were able to implant successfully two ventral roots (C6, directly; and C7, via sural nerve grafts) into the spinal cord through slits in the pia mater. The surgical treatment of patients with avulsion injuries is an area of active ongoing investigation with the promise that if continuity between spinal cord and nerve roots can be restored, subsequent recovery of function may be possible (Fournier et al. 2001). Until repair of spinal nerve roots has become a more effective and reliable procedure, other approaches to management will be needed. When paralysis of the limb is complete, amputation may be indicated. With a less profound degree of injury, muscle and tendon transplants are sometimes used. In the case of a more restricted injury affecting only the low cervical roots and T1, eatly below-elbow amputation plus a below-elbow prosthesis has been recommended. The sometimes intractable pain of cervical root avulsion injuries may be successfully treated with dorsal root entry zone coagulation procedures (Samii et al. 2001).

Disc Herniation

beginning in I he third or fourth decade of life, cervical and lumbar intervertebral discs are liable to herniate into the

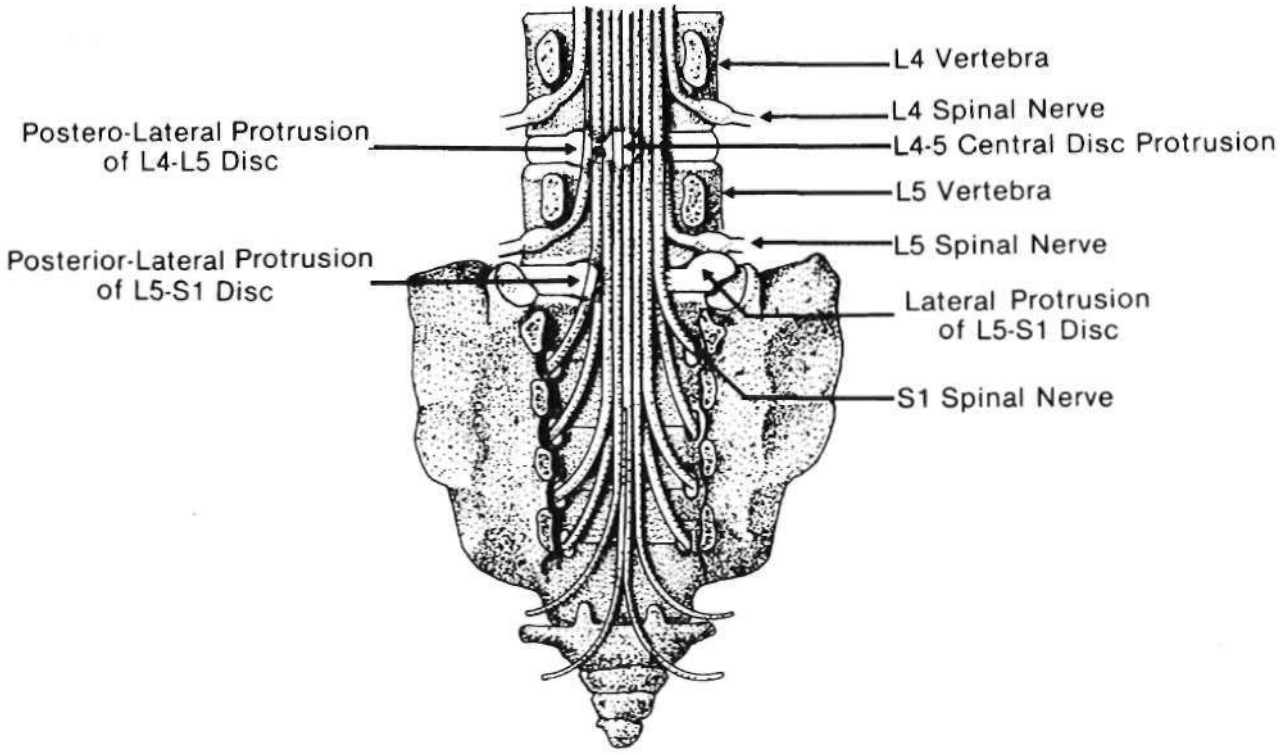

FIGURE SI.3 Dorsal view of the lower lumbar spine and sacrum, showing the different types of herniations and how different routs and the cauda equina an be compressed. (Reprinted with permission from Stewart, J. D. 1993, *focal Peripheral Neuropathies,* 2nd cd, Raven Press, New York.)

spinal canal or intervertebral foramina and impinge on the spinal cord (in the case of cervical disc herniations), nerve roots (in both cervical and lumbosacral regions), or both (at the cervical level, where on occasion large central and paracentral disc herniations may produce a myeloradiculopathy) (see Chapter 79). Two factors contribute to this alteration in the intervertebral discs: degenerative change and trauma. The fibers of the annulus fibrosus that surround the nucleus pulposus lengthen, weaken, and fray with age and use, thereby allowing the disc to bulge posteriorly. In the setting of such changes, relatively minor ttauma leads to further tearing of annular fibers and ultimately to herniation of disc material. This "soft-disc" herniation occurs mainly during the third and fourth decades of life when the nucleus is still gelatinous. In fact, although disc herniations may be preceded by unaccustomed strain or direct injury, in many instances, there is no history of clinically significant trauma preceding the onset of radiculopathy.

Reinforcing the annulus fibrosus posteriorly is the posterior longitudinal ligament, which in the lumbar region is dense and sttong ccnttally and less well developed in its lateral portion. Because of this anatomical feature, the direction of lumbar disc herniations tends to be posterolateral, compressing the nerve roots in the lateral recess of the spinal canal, I.ess commonly, more lateral (foraminal) herniations compress the nerve root against the vertebral pedicle in the intervertebral foramen (Figure 81.3). On occasion, the degenerative process may be particularly severe. This leads to large rents in the annulus and posterior longitudinal ligament, thereby permitting disc material to herniate into the spinal canal as a free fragment with the potentially damaging capacity to migrate superiorly or inferiorly and compress two or more nerve roots of the cauda equina. Most cervical disc herniations are posterolateral or foraminal.

In the cervical and lumbar regions, alteration in the integrity of the disc space is a component of a degenerative condition, tetmed *spondylosis,* characterized by osteoarthritic changes in the joints of the spine, the disc *per se* (desiccation and shrinkage of the normally semisolid, gelatinous nucleus pulposus) and the facet joints. [mmunohistochemica! examination of herniated cervical discs points to an inflammatory process associated with neovascularization and increased expression of matrix mctalloproteinase and inducible nitric oxide (NO) synthetase (Furusawa ct al. 2001), The release of NO by disc cells may contribute to the process of disc degeneration by inducing apoptosis of disc cells (Kohyama et al. 2000). Because it spawns osteophyte formation, spondylosis leads to compromise of the spinal cord in the spinal canal and the nerve roots in the i met vertebral foramina. The restriction in the dimensions of these bony canals may be exacerbated by thickening and hypertrophy of the ligamentum flavum,

which is especially detrimental in patients with congenital cervical or lumbar canal stenosis.

In the cervical region, nerve root compression in patients older than 50 years is often caused by disc herniation superimposed on chronic spondylotic changes. Isolated "soft" cervical disc herniation tends to occur in younger people in the setting of neck trauma. In the lumbosacral region, isolated acute disc herniation is a common cause of radiculopathy in the younger patient (<40 years), whereas bony root entrapment with or without superimposed disc herniation is the more typical cause of lumbosacral radiculopathy in the patient older than 50 years.

Clinical Features. Root compression from disc herniation gives rise to a distinctive clinical syndrome, which in its fully developed form comprises radicular pain, dermatomal sensory loss, weakness in the myotome, and reduction or loss of the deep tendon reflex subserved by the affected root. Nerve root pain is variably described as knifclike or aching and is widely distributed, projecting to the sclerotome (defined as deep structures, such as muscles and bones innervated by the root). Typically, root pain is aggravated by coughing, sneezing, and straining at stool movement (actions that produce Valsalva maneuver and raise intraspinal pressure). Accompanying the pain are paresthesias referred to the specific dermatome, especially to the distal regions of the dermatomes; indeed, these sensations sttongly suggest that the pain has its origins in compressed nerve roots, rather than spondylotic facet joints. Sensory loss caused by the compromise of a single root may be difficult to ascertain because of the overlapping tetritories of adjacent roots, although loss of pain is usually more easily demonstrated than loss of light touch (Figure 81.4).

Most radiculopathies occur in the lumbosacral region; compressive root lesions in this area account for 62-90% of all radiculopathies. Cervical radiculopathies are less common, comprising 5-36% of all radiculopathies encountered.

In the lumbosacral region, 95% of disc herniations occur at the L4-L5 or L5-S1 levels; L3-L4 and higher lumbar disc herniations are very uncommon (Stewart 1993; Deyo and Weinstein 2001). Knowing that the L4 root exits beneath the pedicle of L4 through the 1,4-1.5 foramen and that 1,5

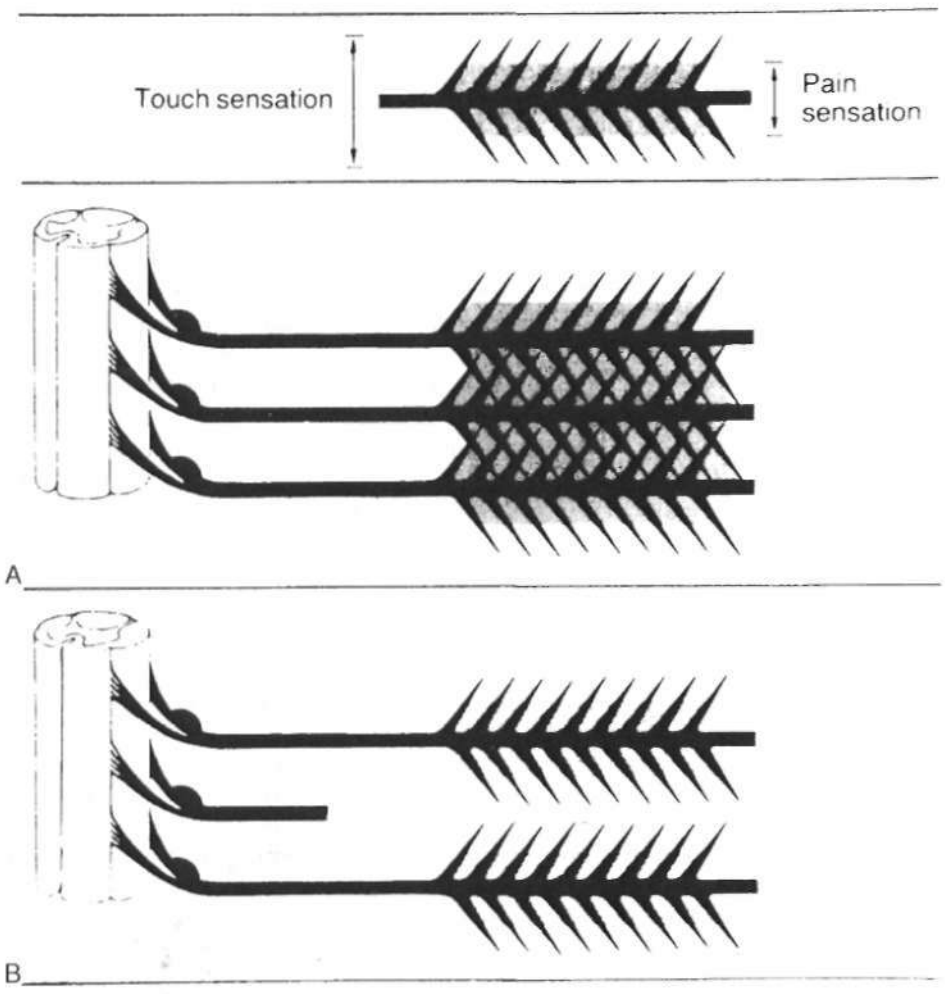

FIGURE 81.4 The zones of radicular touch and pain sensation. The area for rouch sensation *{hatched)* supplied by one single roor is wider than the area of pain sensation *(gray).* The areas of pain sensation do not overlap or at most overlap incompletely, whereas the areas of touch sensation of a single root are completely overlapped by those of the ulj.H'cir roiiK i A). A.V(>IV,111:-1\ . monoradicular lesions (B) produce a hypalgesic or analgesic zone while touch sensation remains intact or only minimally impaired. Only after tw» roots are involved is an anesthetic zone present. (Reprinted with permission from Mumenthaler, M. & Schliack, H. *1991, Peripheral Nerve Lesions. Diagnosis and Therapy,* Thieme, New York.)

exits through the L5-S1 foramen, one might predict that disc herniation at these levels would generally compress the L4 and L5 roots, respectively (see Figure 81.3). In perhaps only 10% of cases of the disc herniating far laterally into the foramen is there compression of the exiting nerve root. More commonly, the posterolateral disc herniation compresses the nerve root passing through the foramen below that disc. Thus 1.4-1.5 and 1.5-SI herniations usually produce 1.5 and SI radiculopathies, respectively.

In an SI radiculopathy, pain radiates to the buttock and down the back of the leg (classic sciatica), often extending below the knee; paresthesias are generally felt in the lateral ankle and foot. The ankle jerk is generally diminished or lost, and weakness may he detected in the plantar flexors and gluteus maxinms.

In an 1.5 radiculopathy, the distribution of pain is similar, but paresthesias are felt on the dorsum of the foot and the outer portion of the calf. The ankle reflex is typically normal, but there may be reduction of the medial hamstring reflex. Weakness may be found in L5-inncrvated muscles served by the peroneal nerve, including the extensor hallucis longus, tibialis anterior and peronei, as well as the tibialis posterior (served by the tibial nerve) and the gluteus medius (innervated by the superior gluteal nerve). Weakness may be restricted to the extensor hallucis longus. A positive straight-leg-raising test result is a sensitive indicator of 1.5 or SI nerve root irritation. The test is deemed positive when the patient complains of pain radiating from the back into the buttock and thigh with leg elevation to less than 60 degrees. The test result is positive in *95%* of patients with a proven disc herniation at surgery. A less sensitive but highly specific test is the crossed straight-leg-raising test, when the patient complains of radiating pain on the affected side with elevation of the contralateral leg.

The less common L4 radiculopathy is characterized by pain and paresthesias along the medial aspect of the knee and lower leg. The patellar reflex is diminished, and weakness may be noted in the quadriceps and hip adductors (innervated by the femoral and obturator nerves, respectively). When large herniations occur in the midline at either the L4-L5 or the 1.5-SI level, many of the nerve roots running past that level to exit through intervertebral foramina below that level may be compressed, producing the cauda equina syndrome of bilateral radicular pain, paresthesias, weakness, and attenuated reflexes below the disc level, as well as urinary retention. This is a surgical emergency requiring urgent decompression.

In the cervical region, it is likely that the high degree of the greater mobility at levels C5-C6 and C6-C7 promotes the development of cervical disc degeneration with annulus fraying and subsequent disc protrusion. Cervical nerve roots emerge above the vettebra that shares the same numerical designation. Therefore C7 exits between C6 and C7, and spondylotic changes with or without additional acute disc herniation would be expected to compress the C7 nerve root. Similarly, disc protrusion at C5-C6 and C7-T1 would compress the C6 and C8 roots, respectively. In the classic study of Yoss et al. (1957), clinical and radiological evidence of radiculopathy was found to occur most often at C7 (70%), less frequently at C6 (19-25%), uncommonly at C8 (4-10%) and C5 (2%). Radiculopathy involving the Tl root is a clinical rarity (Levin 1949).

Involvement of C6 is associated with pain at the tip of the shoulder radiating into the upper part of the arm, lateral side of the forearm, and thumb. Paresthesias arc felt in the thumb and index finger. The brachioradialis and biceps reflexes are attenuated or lost. Weakness may occur in the muscles of the *C6* myotome supplied by several different nerves, including the biceps (musculocutaneous nerve), deltoid (axillary nerve), and pronator teres (anterior interosseus branch of the median nerve). The clinical features of C5 radiculopathies are similar, except that the rhomboids and spinatus muscles are more likely to be weak.

When the C7 root is compressed, pain radiates in a wide distribution to include the shoulder, chest, forearm, and band. Paresthesias involve the dorsal surface of the middle finger. The triceps reflex is usually reduced or absent, A varying degree of weakness usually involves one or more muscles of the C7 myotome, especially the triceps and the flexor carpi radialis. Less common C8 root involvement presents a similar clinical picture with regard to pain. Paresthesias, however, are experienced in the fourth and fifth digits, and weakness, when it occurs, affects muscles innervated by several nerves, including finger extensor muscles (posterior intcrosseus branch of radial nerve), finger abductors and adductor muscles (ulnar nerve), and thumb abductor and opposer muscles (median nerve).

Diagnosis. Diagnosis is aided by a variety of imaging techniques, including plain radiography, myelography, CT myelography, and MRI (sec Chapter .37). Although plain radiography is not helpful in the identification of herniated disc *per se,* in both the cervical and the lumbar area, it reveals spondylotic changes when present. It also may be useful in the identification of less common disorders that produce radicular symptoms and signs, such as bony metastases, infection, fracture, and spondylolisthesis.

In the cervical region, the best methods for assessing the relationship between neural structures (spinal cord and nerve root) and their fibro-osscous surroundings (disc, spinal canal, and foramen) arc postmyelography CT (unenhanced CT reveals little more than the presence of bony changes) and MRI. MRI is equivalent in diagnostic capacity to postmyelography CT and therefore is preferred. In the lumbosacral region, CT is an effective method ot evaluation of disc disease, but when available, **MRI** is considered the superior imaging study because of excellent

resolution; multiplanar imaging; the ability to see the entire lumbar spine, including the conns; and the absence of ionizing radiation.

A variety of ncurophysiologicnl tests are used to assess patients with disc herniation, including motor and sensory nerve conduction studies, late responses, somatosensory evoked potentials, nerve root stimulation, and needle electrode examination. Sensory conduction studies are useful in the evaluation of a patient suspected of radiculopathy because SNAPs are typically normal (because of the lesion being rostral to the DRG in the intervertebral foramina) even in the face of clinical sensory loss, in contrast to the situation in plcxopathy and peripheral nerve trunk lesions, where SNAPs are attenuated or absent. In the specific instance of L5 radiculopathy, however, because the I "i l')K(! may rcsua- proximal to the neural foramen (vide supra), if intraspinal pathology is severe enough, compression of the 1.5 DRG may lead to loss of the superficial peroneal nerve SNAP (Levin 199S).

Needle EMG is the most useful procedure in the diagnosis of suspected radiculopathy. A study is considered positive if abnormalities {especially acute changes of denervation, including fibrillation potentials and positive sharp waves) are present in two or more muscles that receive innervation from the same root, preferably via different peripheral nerves; no abnormalities should be detected in muscles innervated by the affected root's rostral and caudal neighbors. Reduced motor unit potential (MUP) recruitment (manifested by decreased numbers of MUPs firing at an increased rate) and MUP abnormalities of reinnervation (high-amplitude, increased duration, poly phasic potentials) are also sought by the needle electrode but are not as reliable as fibrillation potentials in establishing a definitive diagnosis of radiculopathy. Absence of fibrillation potentials docs not, however, exclude the diagnosis of radiculopathy. Two main reasons for this exist. First, examination in the first 1-3 weeks after onset of nerve root compromise may be negative because it takes approximately 2 weeks for these potentials to appear, (At the early stages in the process of nerve root compression, the only needle electrode examination manifestation of radiculopathy might be reduced MUP recruitment resulting from either axon loss, conduction block, or both.) Second, fibrillation potentials disappear as denervated fibers arc rcinnervated by axons of the same or an adjacent myotome beginning 2-3 months after nerve root compression (Figure 81.5). (Thus in the later phases of nerve root compression, the only needle EMG changes indicative of radiculopathy might be

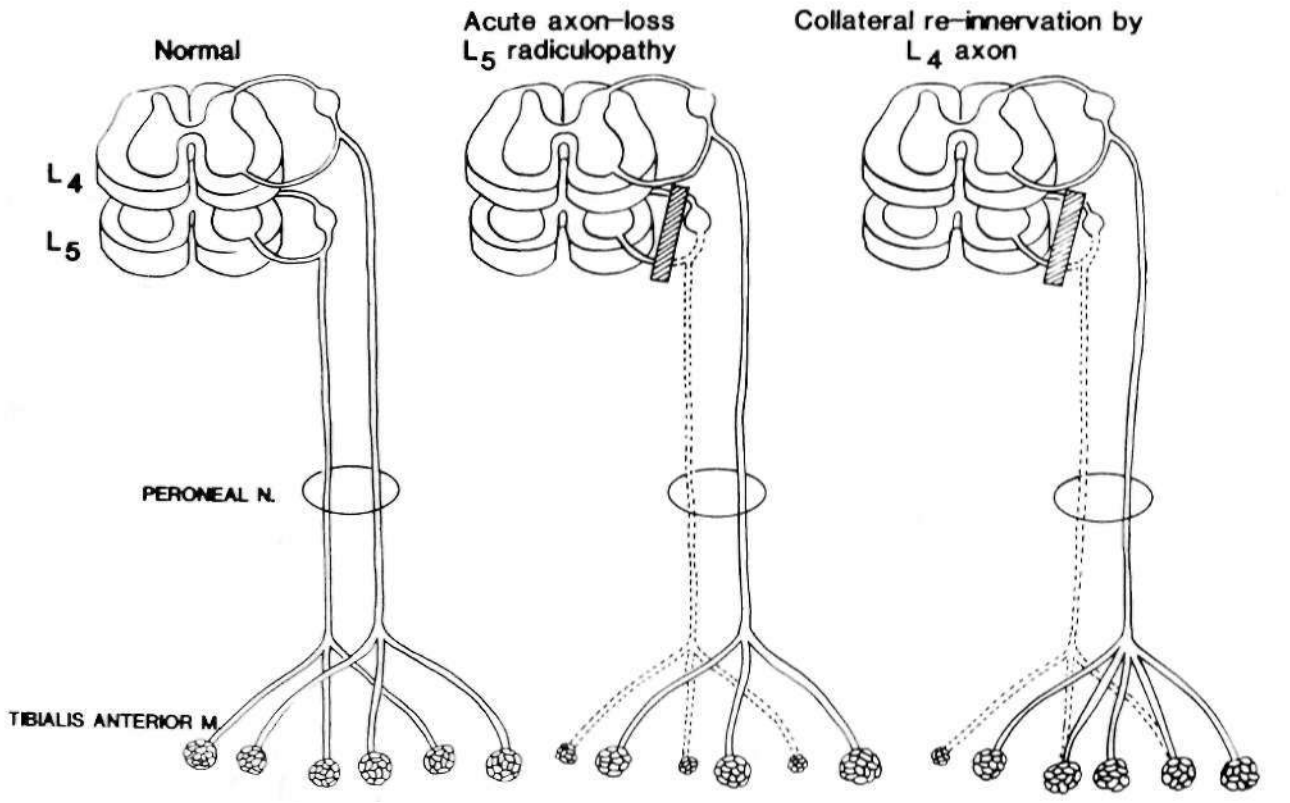

FIGURE 81.5 Diagram illustrating how muscle (M.) fibers denervated by a radiculopathy are reinnervated by collateral sprouting despite persisting root compression, (N, = nerve,) (Reprinted with permission from Wilbourn, A. J. 6i Aminoff, M. J. 1988, "The electrophysiologic examination in patients with radiculopathies," *Muscle Nerve,* vol. 11, pp. 1099-1114.)

chronic neurogenic changes of reduced recruitment and MUP remodeling.) The distribution of fibrillation potentials is relatively stereotyped for C5, C7, and C8 radiculopathies, whereas C6 radiculopathy has the most variable presentation; in one half of patients, the findings are similar to C5 radiculopathy, whereas in the other half, findings are identical to C7 radiculopathy (Levin, Maggiano, and Wilbourn 1996). A patient with the uncommon disc compression of Tl was found to have-isolated fibrillation potential activity of the abductor pollicis brevis (Levin 1999).

Treatment. For cervical disc protrusion and spondylotic radiculopathy, the mainstay of treatment is conservative management—a combination of a period of reduced physical activity with use of a soft cervical collar, physiotherapy, and ahti-inflammatory and analgesic agents. Most patients improve, even those with mild to moderate motor deficits. Indeed, in some cases herniated cervical discs have been observed to regress on MRI images; a circumstance that appears more likely to occur if disc material has extruded and becomes exposed to the epidutal space (Mochida et al. 1998). Although there appears to be a short-term benefit to surgical decompression of an affected nerve root with regard to pain, weakness, or sensory loss, at 1 year, there is no significant difference between the outcome of surgical or conservative management (Fonyas et al. 2001). A surgical approach may be warranted, however, in selected cases: (1) if thete are clinical and radiological signs of an accompanying new onset of myelopathy, (2) if there is untenanting pain despite an adequate trial of conservative management, or (3) if there is progressive weakness in the territory of the compromised nerve root.

In the lumbosacral region, disc herniation and spondylotic changes respond to conservative management in more than 90% of patients. Bed rest had been recommended as the centerpiece of patient care, but controlled trials have demonstrated that back-strengthening exercises under the direction of a physical therapist, performed within the limits of the patient's pain, result in more rapid resolution of pain and return to normal function (Vroomcn et al. 1999). Follow-up MRI studies in conservatively managed patients indicate reduction in size or disappearance of herniated nucleus pulposus corresponding to improvcmenl in clinical findings (Komori ct a I. 1996). Epidural corticosteroid injection may help relieve pain but does not improve neutological function or reduce the need for surgery (Carette et al. 1997). Three situations occur, however, in which surgical referral is indicated: (1) in patients presenting with cauda equina syndtome (for which surgery may be required urgently), (2) if the neurological deficit is severe or progressing, or (3) if severe radicular pain continues after 4-6 weeks of conservative management.

Diabetic Polyradiculoneuropathy

Diabetic neuropathies can be classified anatomically into two major groups: symmetrical polyneuropathies and asymmetrical focal or multifocal disorders. Examples of the latter include the cranial mononeuropathies and the conditions covered in this section: thoracoabdominal and lumbosacral polyradiculoneuropathies. Though treated separately in the following paragraphs, they often coexist in an individual patient. Occasionally, a similar syndrome can occur in the cervical roots.

When there is predominant involvement of the thoracic roots, the presenting symptoms are generally pain and paresthesias of rapid onset in the abdominal and chest wall. The trunk pain may be severe, described variably as burning, sharp, aching, and throbbing. It may mimic the pain of acute cardiac or intra-abdominal medical emergencies and may simulate disc disease, but the rarity of thoracic disc protrusions and the usual development of a myelopathy help exclude this diagnosis. Findings of diabetic thoracoabdominal polyradiculoneuropathy include heightened sensitivity to light touch over affected regions; patches of sensory loss on the anterior, lateral, or posterior aspects of the trunk; and unilateral abdominal swelling due to localized weakness of the abdominal wall muscles (Longstreth 1997).

Diabetic lumbosacral polyradiculoneuropathy involves the legs, especially the anterior thighs, with pain, dysesthesia, and weakness, reflecting rhe major involvement of upper lumbar roots. A variety of names have been used to describe it, including *diabetic amyotrophy, proximal diabetic neuropathy, diabetic lumbosacral plexopathy, diabetic femora! neuropathy,* and *Bruits-Garland syndrome.* Because it is likely that the brunt of nerve pathology falls on the nerve roots, it can be designated as diabetic polyradiculoneuropathy. Motor, sensory, and autonomic fibers are all affected by the disease process (Dyck, Norcll, and Dyck 1999).

In most patients, onset is fairly abrupt, witli symptoms developing over days to a couple of weeks. Early in the course of the condition, the clinical findings are usually unilateral and include weakness of muscles supplied by [.211 roots iiMo]>M>;is. quadriceps, and hip adductors), reduced or absent patellar reflex, and mild impairment of sensation over the anterior thigh. As rime passes, there may be *territorial spread,* a term used by Bastron and Thomas in 19S1 to describe proximal, distal, or contralateral involvement as the polyradiculoneuropathy evolves. Worsening may occur in a steady or a stepwise fashion, and it may take several weeks to progress from onset to peak of the disease, At its peak, weakness varies in seventy and extent from a mildly affected patient, with slight, unilateral thigh weakness, to a profound degree of bilateral leg weakness in the territory of the L2-S2 nerve roots. Upper extremity involvement appears to occur in approximately 15% of patients with diabetic lumbosacral radicular plexopathy as

a unilateral or asymmetrical sensorimotor neuropathy that primarily affects hands and forearms. Like the lumbosacral syndrome, EMG findings suggest a multifocal axon-loss process localized to roots, plexus, or peripheral nerve (Karz et al. 2001). Rarely, the process of territorial spread is so extensive that ir involves a multiplicity of nerve roots along the entire spinal cord and leads to profound generalized weakness, a condition designated *diabetic cachexia.*

Diabetic polyradiculoneuropathy tends to affect patients in the sixth or seventh decade of life, who are known to have non-insulin-dependent diabetes of several years' duration. The syndrome of painful polyradiculoneuropathy, whether referable to thoracic or lumbosacral roots, may, however, be the presenting manifestation of diabetes. In 30-50% of patients, the disorder is preceded by substantial weight loss of 30-40 pounds.

1 abnnitory studies disclose devated fasting blood glucose in the vast majority of patients; when values arc normal, they ate found in treated diabetics. The erythrocyte sedimentation rate is usually normal, but in a subgroup of patients with diabetic lumbosacral polyradiculoneuropathy, it is elevated, a clue perhaps to an immune-mediated pathogenesis (vide infra). The typical electrodiagnostic findings comprise features of a sensorimotor axon-loss polyneuropathy with additional needle electrode examination findings of lumbosacral root and plexus involvement (active and chronic denervation changes in paraspinal, pelvic-girdle, and thigh muscles). Although clinical findings may point to unilateral involvement, the electrodiagnostic examination generally discloses bilateral signs. Imaging studies of the thoracic and lumbosacral spinal canal with CT, myelography, and MRI are typically normal and almost always necessary to exclude a structural abnormality of the nerve roots that may simulate diabetic polyradiculopathy. The CSF protein level is usually increased to an average of 120 mg/dL, but in some patients, values exceed 350 mg/dL; pleocytosis is not a feature of this condition. Biopsy of proximal nerve sensory branches reveals axon loss and dcmyclination; in more severely affected patients, inflammatory cell infiltration and vasculitis is found {Said et al. 1994). Further studies of nerve biopsy specimens indicate that a microscopic vasculitis {involvement of small arterioles, venules, and capillaries) leads to ischemic injury, which in turn causes axonal degeneration and secondary segmental demyelination (Dyck, Norell, and Dyck 1999). The presence of a small-vessel vasculitis with distinctive pathological features including transmural polymorphonuclear leukocyte infiltration of postcapillary venules and endothelial deposits of immunoglobulin M (IgM) and activated complement supports an immune-mediated inflammatory pathogenesis for this disorder (Kelkar, Masood, and Parry 2000).

Electrophysiological studies have suggested that a demyelinating polyneuropathy indistinguishable from chronic inflammatory demyelinating polyneuropathy occurs frequently in diabetes and may be the cause of a severe motor sensory polyneuropathy, sometimes with features of a plexopathy (Sharma et al. 2002a, 2002b).

The natural history of diabetic polyradiculoneuropathy is for improvement to occur in most patients, although the recovety phase is lengthy, ranging between 1 and 18 months with a mean of 6 months. Pain and dysesthesias improve or disappear entirely in 85% of patients; numbness improves or recovers in 50%; and strength is partially or completely restored in 70%. In some patients, episodes recur.

Therapy is usually directed toward ameliorating the severe pain of this condition. The tricyclics, especially nortriptyline (with a better side-effect profile than amitriptyline), selective serotonin reuptake inhibitors (such as sertraline and nefazodone hydrochloride), anticonvulsants (gabapentin and carbamazepine), clonazepam, baclofen, clonidine, mexiletine, intravenous lidocaine, and topical capsaicin may have a role separately or in combination. Histopathological findings {vide supra) indicative of an immune-media ted pathogenesis have led to treatment of selected patients with intravenous immunoglobulin or immunosuppressive treatment or both (Krendcl, Costigan, and Hopkins 1995; Younger, Rosoklija, and Hays 1998). Although immunotherapy may be beneficial, spontaneous improvement in some patients with painful proximal diabetic neutopathy with different patterns of inflammatory nerve lesions has been described (Said et al. 1997). Prospective studies have suggested a role for immunotherapy in the treatment plan of diabetic polyradiculoneuropathy where electrophysiological findings arc those of chronic infla minatory dc:mduutmg poK in'iinipailn (Sharma et al. 2002a, 2002b).

The major differential diagnostic considerations are polyradiculoneuropathies related to degenerative disc disease and infectious, inflammatory, and neoplastic processes. These can usually be excluded by history, examination, and routine laboratory investigations, including CSF analysis. In our experience, however, the clinical presentation provoking the most anxiety is the frail elderly patient not known to be diabetic who has weight loss and the abrupt onset of lower extremity pain and weakness that progresses over months. In such a patient, the specter of neoplasia looms large, and thorough imaging studies of the nerve roots and plexuses are mandatory.

Neoplastic Polyradiculoneuropathy (Neoplastic Meningitis)

A wide variety of neoplasms are known to spread to the leptomeninges. These include solid tumors (carcinoma of the breast and lung and melanoma), non-Hodgkin^{n}s lymphomas, leukemias, and intravascular lymphomatosis (Viali et al. 2000), Although neoplastic polyradiculoneuropathy usually occurs in patients known to have an underlying neoplasm, meningeal symptoms may be the first

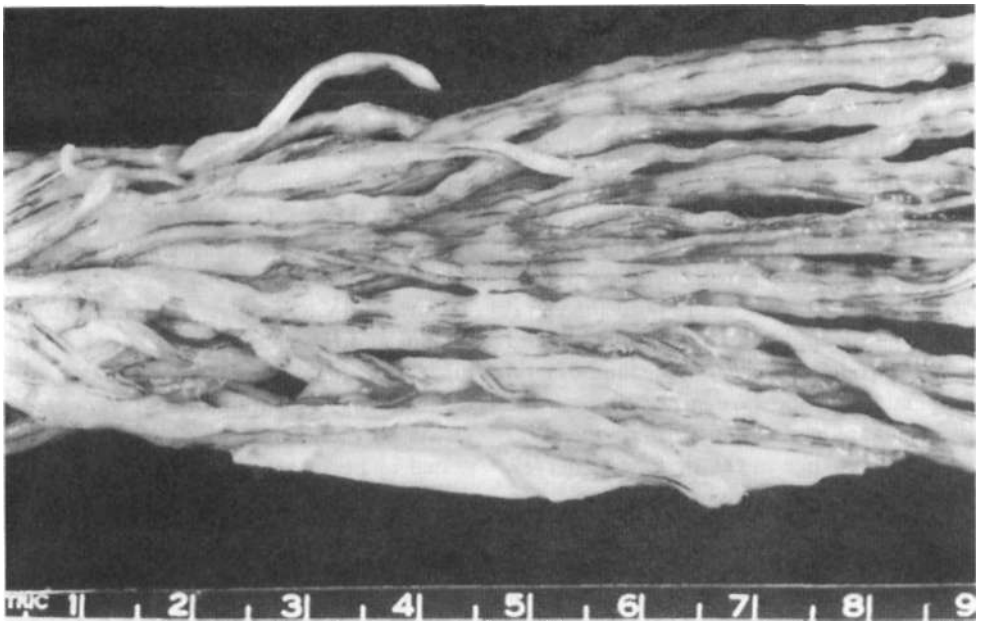

FIGURE 81.6 Cauda equina in leptomeningeal carcinomatosis. Seeding of multiple nerve roots by adenocarcinoma produces a nodular appearance. (Courtesy Dr. T. W. Smith, Department of Pathology [Neuropathology!, University of Massachusetts Medical Center, Worcester.)

manifestation of malignancy. The clinical features of neoplastic polyradiculoneuropathy include radicular pain, dermatoma) sensory loss, areflexia, and weakness of the lower motor neuron type (Balm and Hammack 1996). Often, the distribution of the sensory and motor deficits is widespread and simulates a severe sensorimotor polyneuropathy. Often, associated clinical manifestations result from infiltration of the meninges, such as nuchal rigidity, confusion, and cranial polyneuropathies.

At postmortem examination, the cauda equina shows discrete nodules or focal granularity (Figure 81.6). Microscopy discloses spinal roots encased by tumor cells, which appear to infiltrate the root. It is presumed that disturbed nerve root function results from several mechanisms, including nerve fiber compression and ischemia.

The most revealing diagnostic procedure is the lumbar puncture, which is almost always abnormal, disclosing one or more or the following: mononuclear pleocytosis, reduced CSF glucose, elevated protein, and neoplastic cells. Spinal fluid cytology is, however, persistently negative in about 10% of patients with leptomeningeal carcinomatosis (Grossman and Krabak 1999}. A sensitive electrophysiological indicator of nerve root involvement is a change in the F wave. In the symptomatic patient with cancer, prolonged F-wave latencies or absent F responses should raise suspicion of leptomeningeal metastases. Postmyelqgraphy CTadds srrong evidence in support of the diagnosis if it demonstrates multiple nodular defects on the nerve roots. Spinal MRI, especially with gadolinium enhancement, however, is the test of choice in the patient with cancer in whom leptomeningeal involvement of the spine is suspected {Watanabe, Tanaka, and Takeda 1993). Approximately 50% of patients with neoplastic meningitis and spinal symptoms have abnormalities on these studies. Gadolinium-enhanced MRI of the brain discloses abnormalities, including contrast enhancement of the basilar cisterns or cortical convexities and hydrocephalus.

Standard therapy for neoplastic meningitis that increases median survival to 3-6 months includes radiotherapy to sires of symptomatic disease, intrathecal chemotherapy [methotrexate, thiotcpa, and Ara-C), and optimal treatment of the underlying malignancy. A complication of aggressive treatment is a necrotizing leukoenecphalopathy that becomes symptomatic months after treatment with radiation and intrathecal methotrexate (Grossman and Krabak 1999).

Infectious Radiculopathy

Tabes Dor sal is

Tabes dorsalis, the most common form of neurosyphilis, begins as a spirochetal *{Treponema pallidum)* meningitis (see Chapter 59). After 10-20 years of persistent infection, damage to the dorsal roors is severe and extensive, producing a set of characteristic symptoms and signs. Symptoms are lightning pains, ataxia, and bladder disturbance; signs are Argyll Robertson pupils, areflexia, loss of proprioceptive sense, Charcot joints, and trophic ulcers. Lancinating or lightning pains are brief, sharp, and stabbing; they are more apt to occur in the legs than elsewhere. Sensory disturbances, such as coldness, numbness, and tingling, also occur and are associated with

impairment of light-touch, pain, and thermal sensation. Sudden visceral crises, characterized by the abrupt onset of epigastric pain that spreads around the body or up over the chest, occur in some 20% of patients.

Most of the features of tabes dorsaiis can be explained In lesions D] rlu' posterior roots. Ataxia is caused by flu-destruction of proprioceptive fibers; insensitivity to pain is the result of partial loss of small myelinated and unmyelinated fibers; and bladder hypotonia with overflow incontinence, constipation, and impotence is the result of sacral root damage. Pathological study discloses thinning and grayness of the posterior roots, especially in the lumbosacral region, and the spinal cord shows degeneration of the posterior columns. A mild reduction of neurons in the ORG occurs, and there is little change in the peripheral nerves. Inflammation may occur all along the posterior root.

The CSF is abnormal in active cases. The opening pressure is elevated in 10% of patients. Fifty percent of patients have a mononuclear pleocytosis (5-165 cells/mL). More than 50% have mild protein elevation (45-100 mg/dL, with rare instances of values between 100-250 mg/dL), and 72% have positive CSF serology. In all cases of neurosyphilis, antibodies specific for T. *pallidum* are found, and the preferred treatment is aqueous penicillin C, 2-4 million units intravenously every 4 hours for 10-14 days, with careful CSF follow-up. CSF examination 6 months after treatment should demonstrate a normal cell count and decreasing protein content. If not, a second course of therapy is indicated. The CSF examination should be repeated every 6 months for 2 years or until the fluid is normal.

Polyradiculoneuropathy in Human Immunodeficiency Virus-Infected Patients

Cytomegalovirus (CMV) polyradiculoneuropathy is a rapidly progressive, opportunistic infection that usually occurs late in the course of human immunodeficiency virus (HIV) infection, when the CD4 count is very low (<200 cells/pL) and acquired immunodeficiency syndrome (AIDS)-defining infections are present. Uncommonly, it is the initial manifestation of AIDS (Anders and Goebel 1998}. Patients often have evidence of systemic CMV infection (retinitis, gastroenteritis!. The presentation is marked by the rapid onset of pain and paresthesias in the legs and perineal region, associated with urinary retention and progressive ascending weakness of the lower extremities. Examination discloses a flaccid paraparesis, absent deep tendon reflexes in the legs, reduced or absent sphincter tone, and variable loss of light-touch, vibration, and joint position sense.

The CSF has an elevated protein level, depressed glucose level, polymorphonuclear pleocytosis, and a positive CMV polymerase chain reaction (PCR) (Anders and Goebel 1998). CMV may be isolated from CSF cultures. The nee.lie 1'.\Ki discloses widespread tibrill.uion p<>leii(iaU in lower extremity muscles, and sensory conduction studies may reveal an associated distal sensory neuropathy that is common in the late stages of HIV infection. Imaging of the lumbosacral region is usually normal, but adhesive arachnoiditis has been described. The pathological features are marked inflammation and extensive necrosis of dorsal and ventral roots. Cytomegalic inclusions may be found in the nucleus and cytoplasm of endothelial and Schwann cells (Figure 81.7).

Untreated CMV polyradiculoneuropathy is rapidly fatal within approximately 6 weeks of onset. The antiviral nucleoside analogue ganciclovir may benefit some patients if treatment is instituted early; improvement occurs over weeks to months. Viral resistance to ganciclovir is suggested by persistent pleocytosis and depressed CSF glucose and should prompt consideration of an alternate antiviral agent, such as foscarnet; unlike ganciclovir, it does not require intracellular phosphorylation for its effect.

Other causes of rapidly progressive lumbosacral polyradiculoneuropathy in the HIV-infected patient are meningeal lymphomatosis, *Mycobacterium tuberculosis,* and axonal polyradiculoneuritis associated with HIV infection *per se* (Corral et al. 1997). Additionally, one must consider acute inflammatory demyelinating polyradiculoneuropathy. Syphilis has an accelerated course in the patient with AIDS, and syphilitic polyradiculoneuropathy may present with rapidly progressive pain, paraparesis, muscle wasting, and hyporeflexia. In addition to markedly elevated CSF protein level, hypoglycorthachia, and brisk pleocytosis, the CSF and serum Venereal Disease Research Laboratories serology results are positive. Intravenous penicillin leads to prompt improvement. Other considerations include herpes simplex virus type 2 and varicella zoster virus infections that involve the lumbosacral nerve roots and the spinal cord, producing a radiculomyelitis. *Toxoplasma gondii* may also cause myelitis, presenting as a subacute conus medullaris syndrome that simulates the clinical features produced by CMV polyradiculoneuropathy. In the case of T. *gondii,* MR1 may reveal abscess formation.

Lyme Radiculoneuropathy

Lyme disease is caused by the spirochete *Borrelia burgdorferi* transmitted by the deer tick *Ixodes dammini* and is most prevalent in the American northeast and upper Midwest. It is a multisystem disease affecting skin, peripheral nervous system, central nervous system (CNS) (referred to as *neuroborreliosis),* musculoskeletal system, and heart. To help bring order to the understanding of this illness, it may 1IL- LI:\ ILIL-J inlo three clinical stages. Stage I follows within 1 month of the tick bite and is marked by a characteristic skin rash in 60-80% of patients, designated *erythema chronica migrans* (oval or annular shape with a clear center in the area of the bite}, and influenza-like symptoms of fatigue, fever, headache, stiff neck, myalgias, and arthralgias. In stage 2, also known as the stage of

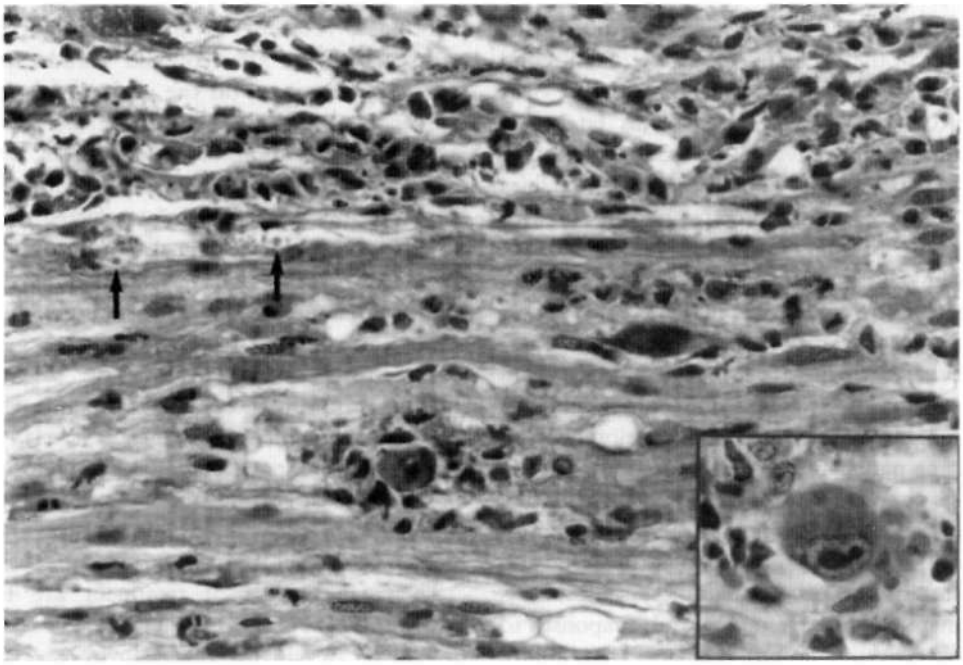

FIGURE 81.7 Cytomegalovirus polyradiculoneuropathy. Numerous mononuclear inflammatory cells are apparent, and the presence of myelin ovoids *(arrows)* reflects axon loss (hcmatoxylin-eostn stain, xlOO). Inset: A cytomegalic cell with intranuclear inclusion (hematoxylin-eosin stain, xl50). (Courtesy Dr. T. W. Smith, Department of Pathology [Neuropathology], University of Massachusetts Medical Center, Worcester.)

dissemination of the spirochete from the initial lesion, and occurring within weeks of the rash, peripheral nerve, joint, and cardiac abnormalities may appear. Stage 3, caused by late or persistent infection, may occur up to 2 years after the tick bite and is characterized by chronic neurological syndromes among them neuropathy, encephalopathy, myelopathy, and psychiatric disturbances and migratory oligoarthritis.

Nerve root and peripheral nerve abnormalities that characterize stage 2 develop in about 15% of untreated patients in the United States (Steere 2001}. Possible manifestations occurring within weeks after the onset of erythema chronica migrans include headache with lymphocytic (aseptic) meningitis, cranial neuropathy (especially facial mononeuroparhies, bilateral in 25% of cases), multifocal radiculoneuropathy, radiculoplexopathy, mononeuritis multiplex, myelitis, subtle encephalopathy, and cerebellar ataxia (Steere 2001). The clinical features of nerve root involvement include burning radicular pain, with sensory loss, and hyporeflexia in the territory of the involved roots. Nerve conduction studies provide evidence for an associated primarily axon-loss polyneuropathy, Chronic ncuroborrcliosis, seen in stage 3, occurs in some 5% of untreated patients and is characterized by an axon-loss polyneuropathy that is manifested as radicular pain or distal paresthesias (Steere 2001). In a nonhuman primate model of neuroborreliosis, spread of *B. burgdorferi* within the nervous system—lep to meninges, motor and sensory roots, ORG. but not the brain parenchyma—has been demonstrated. In peripheral nerve from such animals, spirochetes were seen in the perineurium (Steere 2001). Treatment of Lyme radiculoneuropathy with intravenous ceftriaxone (cefotaxime or penicillin G are acceptable alternates) for 2-4 weeks is associated with resolution of symptoms and signs in most patients.

Her pus Zoster

I lerpes zoster, also known as *shingles,* is a common, painful, vesicular eruption occurring in a segmental or radicular (dennatomal) distribution caused by the reactivation of latent varicella-zoster virus in DRG (see Chapter *59).* Primary infection presents as varicella (chickenpox) earlier in life, usually in epidemics among susceptible children (Gnann and Whitley 2002). Involvement may occur at any level of the neuraxis but is most commonly seen in the thoracic dermatomes, followed by the face. Zoster may present in a division of the trigeminal nerve (e.g., herpes zosrer ophthalmicus) where it is often accompanied by keratitis (a potential cause of blindness requiring immediate treatment), in the maxillary and mandibular nerves, and in the seventh nerve where it is associated with a facial palsy and ipsilateral external car or hard palate vesicles (known as the *Ramsey Hunt syndrome)* (Gildcn et al. 2000).

Zoster occurs during the lifetime of 10-20% of all people, with an incidence in the general population of approximately 3—5 per 1000 per year. The incidence is low in young people and increases with age (among persons older than 75 years exceeds 10 cases per 1000 person-years) and when immunocompetence is compromised,

For example, the incidence among HIV-positive individuals is 15-fold greater than that of a control group (Gnann and Whitley 2002). During primary infection, the virus colonizes the DRG. There, the virus remains latent for many decades, until it is reactivated, either spontaneously or when virus-specific cell-mediated immunity declines (secondary to specific conditions fly nip ho proliferative disorders, treatment with immunosuppressive drugs, organ transplant recipients, seropositivity for HIV] or normal aging), and travels down sensory nerves. Pathological changes, which are characterized by lymphocytic infiltration and variable hemorrhage, are found in the DRG and spinal roots; involvement of the ventral roots and, on occasion, the spinal cord explains the development of motor signs in some patients (see later discussion).

Herpes zoster is characterized by sharp and lancinating radicular pain (associated with itching and dysesthesias [alu-ivd Mrisiiiion]), sometimes accompanied hi fever and malaise and rash. In affected dermatomes, sensation is decreased yet there is allodynia (painful response to normally non-noxious stimulation) (Gilden et al. 2000). The cutaneous eruption (unilateral and respecting the midline) begins as an erythematous maculopapular rash and progresses to grouped clear vesicles that continue to form for 3-5 days (Gnann and Whitley 2002). These become pustules by 3^4 days and form crusts by 10 days. In the normal immunocompetent host, lesions resolve in 2—4 weeks, often leaving a region of reduced sensation, scarring, and pigmentation. Pain usually disappears as vesicles fade, but 8-70% of patients experience persisting, severe pain, termed *postherpetic neuralgia* (PHN), defined as "pain that persists more than 30 days after the onset of rash or after cutaneous healing" (Gnann and Whitley 2002). This complication is more likely to develop in the elderly, occurring in 50% of patients older than 60 years. In one half of patients affected with PHN, the pain resolves within 2 months, and 70-80% of patients are pain free by 1 year. Rarely, pain persists for years.

In the immunologically normal host, dissemination of the virus is rare, occurring in fewer than 2% of patients. In the immunocompromised patient, however, dissemination occurs in 13-50% of patients. Most often, spread is to distant cutaneous sites, but involvement of the viscera (lung, gastrointestinal tract, and heart) and CNS may occur. A serious complication of herpes zoster ophthalmicus is delayed contralateral hemiparesis caused by cerebral angiitis. The syndrome usually develops 1 week to 6 months after the onset of zoster and occurs in patients of all ages, 50% of whom are immunologically impaired. The mortality from cerebrovascular complications is 25%, and only approximately 30% of survivors recover fully.

An uncommon complication of cutaneous herpes zoster is segmental motor weakness, which occurs in 3-5% of patients (Merchut and Gruener 1996). Segmental zoster paresis is approximately equally divided between the arms and legs, reflecting weakness in cervical and lumbar myotomes, respectively; the diaphragm and abdominal muscles may be affected; and bladder and bowel dysfunction may occur (in the setting of lumbosacral zoster [Gilden et al. 2000]). The interval between skin eruption and paralysis is approximately 2 weeks, with a range of 1 day to 5 weeks. Weakness peaks within hours or days; spread to muscles served by unaffected segments does not usually occur. The prognosis for recovery is good, with 55% showing full recovery and another 30% showing significant improvement. One in five patients is left with severe and permanent residua.

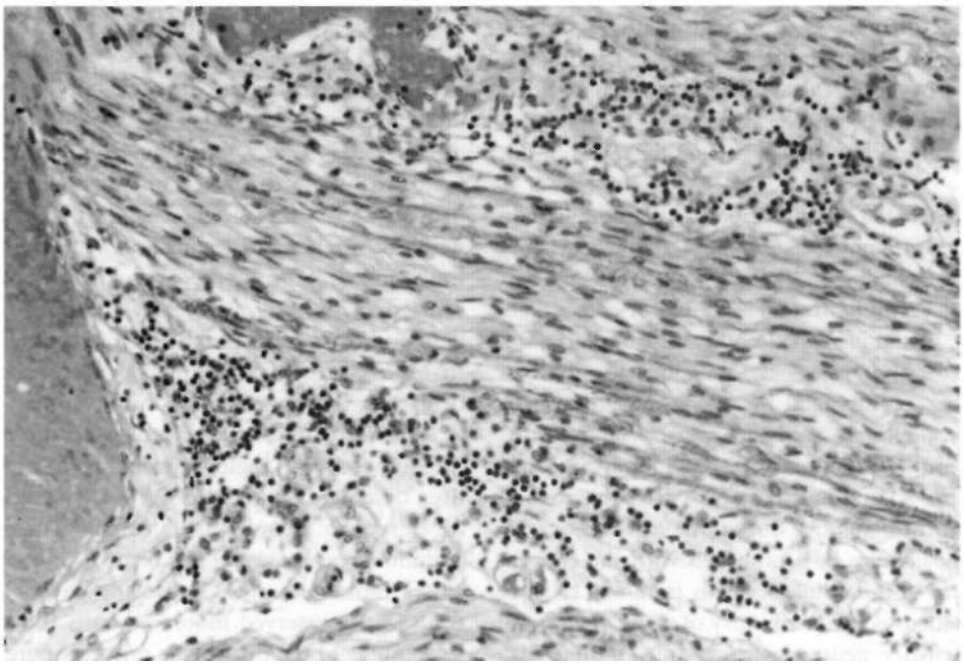
The histopathological correlate of herpes zoster is inflammation and neuronal loss in the DRG that correspond to the affected segmental levels. In the case of segmental zoster paresis, there is lymphocytic inflammation and vasculitis involving adjacent motor roots and the spinal cord gray matter with resulting motor fiber degeneration (Gilden et al. 2000).

The major goals of treatment are to relieve local discomfort, prevent dissemination, and reduce the severity of PHN. Acyclovir, valacyclovir, and famciclovir arc indicated for the immunocompetent patient older than 50 years with herpes zoster. They reduce the duration of viral shedding, limit the duration of new lesion formation, and accelerate healing and pain resolution. They are all safe and well-tolerated dtugs, but because of superior pharmacokinetic profiles and simpler dosing regimen, the latter two are preferred to acyclovir (Gnann and Whitley 2002).

The pain of PHN, described variably as continuous deep aching, burning, sharp, stabbing, and shooting, and triggered by light touch over the affected dermatomes, is often debilitating and difficult to treat (Watson 2000). Singly or in combination, tricyclics (amitriptyline or desipraminc), selective serotonin reuptake inhibitors (sertraline or ncfazodone hydrochloride), anticonvulsants (carhamazepine and gabapentin), oral opioids (oxycodone), and topical capsaicin cream or lidocainc parches are helpful in about 50% of patients. For intractable cases, intrathecally administered methylprcdnisolone and lidocainc has been shown to provide relief without adverse effects of arachnoiditis or neurotoxicity in more than 90% of patients treated (Kotani et al. 2000).

Acquired Dcinyelinating Polyradiculoneuropathy

Acquired dcmyclinating polyradiculoneuropathy has two major clinical forms. One develops acutely and is known as *Guilhin-Barre syndrome* (GBS); the other is chronic, progressive, or relapsing and remitting and is designated *chronic inflammatory demyelinating polyradiculoneuropathy* (CIDP). These disorders are described in detail in Ghapter 82 but ate mentioned here briefly because pathological changes may be pronounced in the spinal nerve roots, especially the ventral roots. There may be a dense mononuclear inflammatory infiltrate characterized by



F1GURK 81.8 Cauda equina in Guillain-Barre syndrome, A dense inu mom vicar infNnraU' in the eonnective tissue surrounding the nerve roots is shown (hematoxylin-eosin stain). (Courtesy Dr. 1. W. Smith, Department of Pathology (Neuropathology!, University of Massachusetts Medical Center, Worcester.)

lymphocytes, monocytes, and plasma cells (Figure SI .8), as well as nerve fibers display segmental demyelination with relative sparing of axons. Ncuroimaging with MRI discloses contrast enhancement of lumbosacral roots in both GBS and GDP (Berrorini et al. 1995). The predilection for root involvement in these conditions helps explain certain features, including the CSF formula, some neurophysiologies! findings, and disturbances in autonomic function that may be especially problematic in patients with GBS.

A CSF profile of albuminoeytological dissociation is characteristic of this syndrome. A high lumbar CSF protein concentration in the lace of a normal cisternal protein level supports the hypothesis that increased CSF protein derives largely from capillaries of the spinal roots. Nerve conduction studies usually disclose slowed motor conduction velocities, dispersed motot responses, and partial conduction block, but additional abnormalities include delayed or unobtainable F-wavc responses or H-rcflexcs, reflecting demyelination in nerve roots. Indeed, abnormalities of these late responses may be the sole finding in 10-20% of patients with GBS in the first few weeks of the illness. Last, a host of autonomic disturbances occur in GBS, some of which could be caused by involvement of preganglionic sympathetic fibers, which travel in the ventral roots en route to the paravertebral sympathetic ganglia.

Acquired Disorders of the Dorsal Root Ganglia

DRG may be selectively vulnerable to a variety of malignant and nonmalignant conditions. The resulting neurological disorder is a sensory neuronopathy syndrome whose clinical features are explained by the loss of Jarge- and small-diameter DRG neurons (Bryer and Chad 1999). Large cell dropout leads to kinesthetic sensory impairment, poor coordination, loss of manual dexterity, ataxia, and ateflexia; whereas small cell depletion contributes to a hyperalgesic state marked by burning pains and painful paresthesias.

Perhaps the best known of these uncommon conditions is paraneoplastic subacute sensory neuropathy (or neuronopathy), a disorder developing over weeks to months, characterized b\ ataxia and hyperalgesia while IHILM le strength is well preserved (Posner and Dalmau 1997). Some patients have clinical signs of brainstem and cerebral dysfunction, reflecting a more widespread encephalomyelitis. The neuropathy may antedate the diagnosis of cancer, usually small cell lung carcinoma, by months to years. The CSF profile discloses elevated protein concentration and a mild mononuclear cell pleocytosis. Nerve conduction studies reveal widespread loss of sensory potentials. Neuropathological features include inflammation and phagocytosis of the sensory neurons in the DRG. This condition is associated with the presence of specific antineuronal antibodies (anti-Hu), which are complement-fixing, polyclonal immunoglobulin G (IgG) antibodies that react with the nuclei of the CNS and sensory ganglia but not with non-neuronal nuclei. The antigens recognized by the anti-Hu antibodies have been characterized as protein antigens with molecular weights of 35-40 kd. The presence of identical protein antigens in small cell lung cancer cells and neuronal nuclei supports the view that the pathogenesis

of paraneoplastic subacute sensory neuropathy is immunologically mediated, with tumor antigens triggering the production of cross-reactive antibodies. Morphological studies provide evidence for both cytotoxic T-cell-media ted attack and humoral mechanisms in the pathogenesis of this **condition.**

Other causes of DRG neuronopathy include hereditary, toxic, and autoimmune disorders. Hereditary sensory neuropathies are usually marked by their chronicity, acrodystrophic ulcerations, fractures, bouts of osteomyelitis, and lack of paresthesias. Pyridoxine abuse and cisplatin neurotoxicity arc generally easily recognized. Sjogren's syndrome may be accompanied by ataxia and kinesthetic sensory loss very similar to subacute sensory neuropathy. The presence of antibodies to extractable nuclear antigens, such as anti-Ro (SS-A) and anti-La (SS-B) arc suggestive of the diagnosis, but their absence does not exclude Sjogren's syndrome. Diagnosis may be established with the demonstration of clusters of inflammatory cells in minor salivary glands (focal sialadenitis) from a biopsy of clinically normal lip mucosa. A sensory neuronopathy syndrome has also been associated with elevated titers of an autoantibody that reacts with the GDn, ganglioside, an acidic glycolipid—composed of a lipid component (ceramide), a carbohydrate nnnciy, and two sialic acid groups- pivscm on the surface of neurons in the DRG (O'Leary and Willison 1997).

Radiculopathies Simulating Motor Neuron Disease

Disorders of the motor toots may lead to clinical features that resemble those encountered in motor neuron disease. Detailed study of such motor neuron syndromes is important because it might provide clues to the pathogenesis of the most common form of motor neuron disease, ALS. Clinicians should consider **the** possibility of an ALS-mimic syndrome when a patient with clinical features of lower motor neuron involvement is found to have a monoclonal gammopathy (Chad and Harris 1999). In that instance, investigations must vigorously pursue the possibility that physical findings stem from ventral root involvement, rather than anterior horn cell degeneration. An elevated CSF protein level, along with a demyelinating process identified by nerve conduction studies, suggests a potentially treatable motor polyradiculoneuropathy.

In some patients with a lower motor neuron syndrome, the presence of a monoclonal gammopathy and raised CSF protein concentration with oligoclonal bands in the CSF increases the likelihood of detecting an underlying **lym**phoproliferative disease. In some instances of IgM monoclonal gammopathy, there is antibody specificity for the gangliosides GM|, asialo-GM,, and GDn, among others. In rare instances, immunotherapy that reduces the serum concentrations of IgM gangliosides is associated with improvement in the lower motor neuron syndrome, thereby suggesting a possible pathogenic role of antiganglioside antibodies.

The association between lower motor neuron findings and lymphoma has been known since the 1960s and is designated *subacute motor neuronopathy,* but the site of major pathology is not certain and could be at a root and a neuronal level. It is characterized by subacute, progressive, painless, often patchy, and asymmetrical weakness of the lower motor neuron type, with greater involvement of the arms than the legs. The illness often progresses independently of the activity of the underlying lymphoma and tends to follow a relatively benign course, with some patients demonstrating spontaneous improvement.

A postradiation lower motor neuron syndrome affecting the lumbosacral region, probably a radiculopathy, has been described occurring 3-25 years after radiation therapy for testicular neoplasms. In some patients, MR1 shows gadolinium enhancement. Neuropathological study discloses radiation-induced vasculopathy of proximal spinal roots with preserved motor neurons (Bowen et al. 1996). The course of the disorder is one of progression for several years and eventual stabilization.

DISORDERS OF THE BRACHIAL PLEXUS

Anatomical features

The brachial plexus is formed by five ventral rami (C5-TI), each of which carries motor, sensory, and postganglionic sympathetic fibers to the upper limb. It is a large and complex peripheral nervous system structure that contains 100,000-160,000 individual nerve fibers (Fcrrante and Wilbourn 2002). These five rami unite above the level of the clavicle to form the three trunks of the brachial plexus (Figure 81.9): C5 and C6 join to form the upper trunk; Tl and C8 unite to form the lower trunk; and C7, the largest of the five rami, continues as the middle trunk. (To review, a ventral ramus—anterior primary ramus—derives from a mixed spinal nerve that is formed in turn by the fusion of the posterior dorsal and ventral roots in the intervertebral foramen.) Beneath the clavicle, each trunk divides into an anterior and posterior branch, leading to six divisions, which become the three cords of the brachial plexus, the lateral, medial, and posterior. The cords, which lie behind the pectoralis minor, take their names from their relationship to the subclavian artery. The lateral and medial cords carry motor fibers to the ventral muscles of the limb. The lateral cord is formed from anterior divisions of the upper and middle trunks; the medial cord from anterior division of the lower trunk. The posterior cord carries motor fibers to the dorsal muscles of the limb; it is formed from posterior divisions of the upper, middle, and lower trunks.

The major named nerves of the upper limb derive from the cords. After contributing a branch to the formation

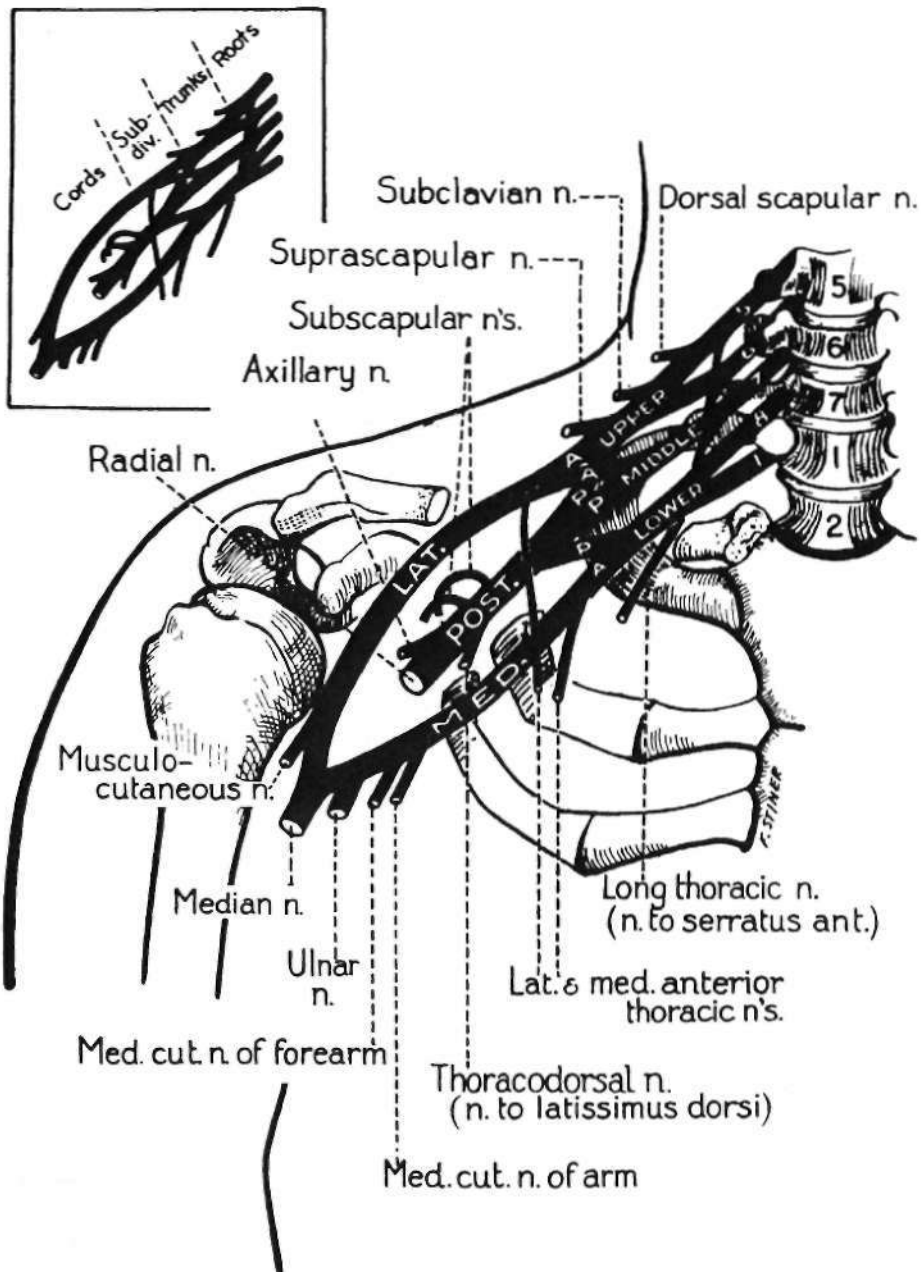


FIGURE 81.9 Brachial plexus. The components of the plexus have been separated and drawn out of scale. The five ventral rami {C5-T1) unite to form the upper, middle, and lower trunks of the plexus above the clavicle. Beneath the clavicle, each trunk divides into anterior *[ant.)* and posterior divisions. Three cords (lateral *[Lat.]*, posterior *[Post.]*, and medial *[Med.])* lie below the pectoralis minor muscle (not shown). Mnjor upper limh nerves (n's) originate from the cords. (cut. = cutaneous.) (Reprinted with permission linin I laymaker, W. & Woodhall, B. 1953, *Peripheral Nerve Injuries*, 2nd ed, WB Saunders, Philadelphia.)

of the median nerve, the lateral cord continues as the musculocutaneous nerve. Similarly, after making its contribution to the median nerve, the medial cord continues as the ulnar nerve. The posterior cord divides into a smaller axillary nerve, which leaves the axilla via the quadrangular space to supply the deltoid and teres minor and the larger radial nerve. Also, from the level of the cords, branches are distributed to the pectoralis major and minor muscles (from the lateral and medial cords, respectively) and to the subscapulars, latissimus dorsi, and teres major muscles (from the posterior cord). In addition to these motor branches, sensory branches also arise at a cord level: The posterior cutaneous nerve of the arm arises from the posterior cord, and the medial cutaneous nerve of the arm and the medial cutaneous nerve of the forearm come from the medial cord.

Nerve branches to the serratus anterior, levator scapulae, rhomboids, and supraspinatus and infraspinatus muscles derive from more proximal levels of the plexus. The first three muscles are supplied by branches of the anterior primary rami: the serratus anterior from C5, C6, and C7 (the long thoracic nerve) and the levator scapulae and rhomboids from branches of C5 (the dorsal scapular nerve). The supraspinatus and infraspinatus muscles are supplied by the suprascapular nerve, a branch of the upper trunk of the plexus.

Clinical Features and Diagnosis

Not surprisingly, disorders of the brachial plexus are determined in large part by its anatomical relationships (Ferrante and Wilbourn 2002): Because of its location between two highly mobile structures, the neck and the shoulder, it is vulnerable to trauma. And, because neighboring tissues such as lymph nodes, blood vessels, and lung parenchyma may themselves be targets of a variety of disease processes, the brachial plexus itself may be secondarily affected as an innocent bystander.

Neurological Examination

Patients with a brachial plcsaipathy present with a variety of patterns of weakness, reflex change, and sensory loss, depending on whether the whole or a portion of the plexus is disturbed. Most commonly encountered arc three patterns resulting from involvement of the entire plexus, the upper trunk, and the lower trunk; less commonly seen are partial plexopathies caused by selective cord lesions.

In a pan-plexopathy, paralysis of muscles supplied by segments C.5 through Tl occurs. The arm hangs lifelessly by the side, except that an intact trapezius allows shrugging of the shoulder. The limb is flaccid and areflexie, with complete sensory loss below a line extending from the shoulder diagonally downward and medially to the middle of the upper arm.

Lesions of the upper trunk produce weakness and sensory loss in a C5 and C6 distribution. Affected muscles include the supraspinati and infraspinati, biceps, hrachialis, deltoid, and brachioradialis, so the patient is unable to abduct the arm at the shoulder or flex at the elbow. If a lesion is so proximal that it involves the C5 ramus, the rhomboids and levator are also affected. The arm hangs at the side internally rotated at the shoulder, with the elbow extended and the forearm pronated in a "waiter's tip" posture. The biceps and brachioradialis re flexes are diminished or absent, and sensory loss is found over the lateral aspect of the arm, forearm, and thumb.

Lesions of the lower trunk produce weakness, sensory loss, and reflex changes in a C8 and Tl distribution. Weakness is present in both median- and ulnar-supplied intrinsic hand muscles and in the medial finger and wrist flexors. The finger flexion reflex is diminished or absent, and there is sensory loss over the medial two fingers, the medial aspect of the hand, and the forearm.

Cord lesions are usually found in the setting of trauma. A posterior cord lesion produces weakness in the territory of muscles innervated by both radial and axillary nerves. Sensory loss occurs in the distributions of the posterior cutaneous nerve of the forearm and the radial and axillary nerves. This results in sensory loss over the posterior aspect of the arm, the dorsal surface of the lateral aspect of the hand, and a patch of skin over the lateral aspect of the arm.

Lateral cord injuries produce weakness in muscles supplied by the musculocutaneous nerve as well as weakness in the muscles of the median nerve supplied by the C6 and C7 roots (the pronator teres and flexor carpi radialis muscles). The median and ulnar nerve fibers originating from C8 and Tl segments are spared, and thus there is no intrinsic hand muscle weakness. In medial cord lesions, there is weakness in all ulnar nerve-supplied muscles and in the C8 and Tl median nerve-supplied muscles.

Electro diagnostic Studies

Nerve conduction studies and needle EMG provide information that is helpful in confirming the clinical diagnosis of brachial plexopathy, in determining the character of the lesion—predominantly axon loss, demyelinating, or both—and in arriving at a judgment with respect to prognosis for recovery of function. In axon-loss brachial plexopathies, sensory nerve action potentials (SNAPs) and compound motor action potentials (CMAPs) are attenuated or lost depending on the severity of the disease process, because the amplitude of these responses correlates directly with number of conducting fibers. (In preganglionic lesions [at a root level], sensory responses are expected to lie spared, and only miiiiir responses will lie affected.) As long as at least some fast conducting fibers are spared, the conduction velocities and distal latencies are unaffected. In the case oi demyelinating lesions, however. nerve conduction velocities are typically slowed, motor evoked responses dispersed and distal latencies prolonged. (Most brachial plexus lesions are axon loss in nature [Ferrante and Wilbourn 20021.) The needle examination is very sensitive for detecting even mild motor fiber loss, because fibrillation potentials develop in affected muscles by 3 weeks after the onset of a disease process.

Ferrante and Wilbourn (2002) note that axon-loss brachial plexus neuropathies fall along a spectrum of .seventy that may be determined by the results of the electro diagnostic study. In the context of a minimal lesion affecting both sensory and motor fibers, SNAPs and CMAPs will typically be unaffected, but needle examination will disclose fibrillation potentials (because the loss of one motor fiber will result in the denervation of hundreds of muscle fibers). With an increase in lesion severity, SNAPs become attenuated while CMAPs are still spared. The most severe lesions compromise seusor\ responses and arlivl motor responses. Ferrante and Wilbourn (2002) observe that it is the CMAPs that are m fact the most useful for quantifying the amount of loss suffered by a nerve; in contrast, SNAPs may be attenuated, even absent with only partial lesions; and needle electrode examination, as we have seen, may reveal prominent fibrillation potentials with only mild motor axon loss. The needle examination is helpful in evaluating whether or not tecovery from axon-loss lesions is ongoing, because features of motor unit

potential remodeling (increased duration and complexity of motor unit potentials) indicate the ongoing process of collateral reinnervation, distal-to-proximal reinnervation, or both.

In a postganglionic plexopathy, numbness and sensory loss are associated with reduced or absent SNAPs because the lesion is located distal to the DRG. As we have seen, by contrast, in a pure radiculopathy, sensory loss is found in the face of a normal SNAP because the lesion is proximal to the DRG. In certain conditions, preganglionic and post-ganglionic lesions coexist, so the electrodi a gnostic studies disclose paraspiual muscle fibrillation and absent SNAPs. This situation is encountered most commonly in patients with traumatic plexopathics that damage the plexus and injure or avulse nerve roots *per se.* It is also found in peripheral neuropathies, such as diabetes, and in malignant plexopathics, in which tumor not only injures the plexus but also infiltrates the nerve roots by tracking through the intervertebral foramina. Specific EMG changes are covered under individual disorders of the plexus, later in the chapter.

Radiological Studies

Plain films of the neck and chest are often very helpful in evaluating arm weakness that is thought to be caused by a disorder of the brachial plexus. The presence of a cervical rib or long transverse process of C7 may provide an explanation for hand weakness and numbness, as seen in thoracic outlet syndrome. A lesion in the pulmonary apex, erosion of the head of the first and second rib, or the transverse processes of C7 and TI may reveal the cause of a lower brachial plexopathy, as found in cases of Pancoast's tumor. CT scanning and MRI of the brachial plexus are also useful in detecting mass lesions of the plexus and may allow early diagnosis and specific therapy (Bilbey, Lamond, and Mattrey 1994). CT-guided biopsy can be used to obtain cytological or histological material for precise diagnosis.

Traumatic Plexopathy

Three general categories of brachial plexus injury exist: (1) direct trauma; (2) secondary injury from damage to structures around the shoulder and neck, such as fractures of the clavicle and first rib; and (3) iatrogenic injury, most commonly seen as a complication of the administration of nerve blocks. Direct injury may be either open {gunshot wounds and lacerations) or closed (sttetch or traction). The main causes of brachial plexus palsies are traction and heavy impact. Injuries are usually secondary to motor-cycle and snowmobile accidents, but sporting accidents in football, bicycling, skiing, and equestrian events are also important. Supraclavicular injuries are more common and more severe and have a worse prognosis than infraclavicular injuries (Midha 1997}. Another form of brachial plexus traction is seen in rucksack paralysis. The straps of a rucksack or backpack pressed to the shoulders may exert heavy pressure in the region of the upper trunk of the brachial plexus and thus lead to weakness in the muscles supplied by the suprascapular and axillary nerves and sensory loss in the C5 and C6 distributions.

Early Management

The consequences of brachial plexus injury are weakness and sensory loss referable to a part or the whole of the plexus. The ultimate objective in management is to restore as much neurological function as possible with the hope of returning the limb to its preinjury status, but one must first ensure that the cardiovascular and respiratory systems are stable. In open injuries, there may be damage to great vessels in the neck and injury to the lung, in which case immediate operative intervention is necessary to save the patient's life. At the time of this early acute intervention, it is important to assess to what degree the various elements of the plexus have been injured. As far as possible, disrupted elements should be tagged for later repair. It may be difficult to suture damaged fascicles, and the formation of scar may prevent successful nerve regeneration. Most authors agree that nerve resection, grafting, and anastomosis are all very difficult in the acute situation because nerve continuity may be difficult to assess. If portions of a plexus have been sharply transected, however, primary repair should be carried out.

Long-Term Management

Once the patient's general condition has stabilized, a careful assessment of motor and sensory function should be made. At iln- stage, an important i-su- is wlii-thcr thi-rc has been root avulsion. This is a critical determination, with implications for management, because the outlook for return of motor and sensory function in territories supplied by avulsed roots is currently not good, although promising results of surgical repair have recently been noted. Root avulsion and its management are discussed m the section Disorders of Nerve Roots, earlier in this chapter. If Ilir I'-lrMi-- Heliums ;i it :n i.(>:Hinini\ and the nerve 11 bits have received a neuropraxic injury with minimal axonotmesis, then return of normal strength and sensation is expected. In the face of axonotmesis, the main factor limiting return of function is the distance the regenerating axon sprouts must traverse before making contact with end organs. Unless the muscles and sensory receptors are rcinnervated within approximately 1 year, a good functional result is unlikely. Thus recovery of proximal muscle strength from upper portions of the plexus is more likely than recovery of hand function when lower elements have been damaged.

Often, surgery must be performed to provide an exact intraoperative definition of the lesion's extent (see Chapter 56D) (Berger and Becker 1994). Intraoperative motor evoked potentials are helpful in assessing the functional state of anterior motor roots and motor fibers. Depending on the findings, neurolysis, nerve grafting, or re-neurotization is performed. Primary nerve reconstruction combined with joint fusion and tendon transfers provides a worthwhile return of function to many patients. The joint and tendon surgeries are best performed as secondary operations after a period of physiotherapy. Intensive physiotherapy and use of orthoses are often necessary to help restore maximum function. In general, the outcome after nerve grafting is relatively good for recovery of elbow flexors and extensors and for those of the shoulder girdle, but it is very pooi for forearm and hand ir.lniisic muscles. Ou.iliu "I life surveys after brachial plexus surgery indicate that 78% of patients report at least moderate satisfaction (Choietal. 1997).

Neurogenic Thoracic Outlet Syndrome

Although it is frequently diagnosed, neurogenic thoracic outlet syndrome is a rare entity, seen only once or twice a year in busy EMG laboratories. Most patients are women. The mean age at onset is 32 years, but patients as young as 13 and as old as 73 years have been reported. Pain is usually the first symptom, with either aching noted on the inner side of the arm or soreness felt diffusely throughout the limb. Tingling sensations accompany pain and are felt along the inner side of the forearm and in the hand. Most patients note slowly progressive wasting and weakness of the hand muscles. The physical examination discloses hand muscle weakness and atrophy, most marked in the lateral part of the thenar eminence. In a smaller number of patients, there is mild atrophy and weakness in the forearm muscles. Sensory loss is present along the inner side of the forearm. Except for the occasional Ravnaud's-type episode, vascular symptoms and signs are uncommon.

In many cases, cervical spine roentgenograms disclose small bilateral cervical ribs or enlarged down-curving C7 transverse processes. When not visualized in anteroposterior radiographs of the cervical spine, they can he seen on oblique views. MRI of the brachial plexus is a useful diagnostic method, revealing deviation or distortion of nerves or blood vessels and suggesting the presence of radiographically invisible bands (Panegyres et al. 1993). Electrodiagnostic studies on the affected side disclose a reduced median motor response with normal median sensory amplitudes along with a mildly reduced ulnar motor response and reduced ulnar sensory amplitude. The needle electrode examination typically discloses features of chronic axon loss with mild fibrillation potential activity in C8- and Tl-innervated muscles. The cluneal and electrophysiological findings point to a lesion of the lower trunk of the brachial plexus. Levin, Wilbourn, and Maggiano {1998) have refined our understanding of the precise lesion localization of the neurogenic thoracic syndrome. They compared electrophysiological results between a group of patients with true neurogenic thoracic outlet syndrome and a group with "brachial plexopathy" stemming from median sternotomy. In the former group, the findings pointed to severe axon loss in the medial antebrachial cutaneous nerve and the abductor pollicis brevis, both sharing Tl root innervation. In the latter, an iatrogenic disorder resulting from rib retraction, the findings indicated axon loss in the ulnar sensory and motor nerves, conforming most to involvement predominantly of C8. These findings suggest that thoracic outlet syndrome and median sternotomy brachial plexopathy are more accurately described as "extraspinal radiculopathies" with damage i<> the root fillers .n die level of die anterior primary rami (Levin 2002)—distal to the C8 or Tl nerve roots *per se,* but proximal to the lower trunk of the brachial plexus.

In most patients, a fibrous band extending from the rip of a rudimentary cervical rib to the scalene tubercle of the first rib causes angulation of either the C8 and Tl roots or the lower trunk of the brachial plexus (Figure 81.10). Surgical division of the fibrous band can be expected to relieve pain and paresthesias and arrest muscle wasting and weakness in the majority of patients; return of muscle bulk and strength, however, is unlikely.

Metastatic and Radiation-Induced Brachial Plexopathy in Patients with Cancer

Metastatic Plexopathy

Damage to the brachial plexus in patients with cancer is usually secondary to either metastatic plexopathy or radiation-induced injury. Lung and breast carcinoma are the tumors that most commonly metastasize to the brachial plexus; lymphoma, sarcoma, melanoma, and a variety of other types are less common. Tumor metastases spread via lymphatics, and the area most commonly involved is adjacent to the lateral group of axillary lymph nodes.

The hallmark of metastatic plexopathy is pain, which is often severe. It is generally located in the shoulder girdle and radiates to the elbow, medial portion of the forearm, and fourth and fifth digits of rhe hand. In many patients, the neurological examination discloses signs referable to the lower plexus and its divisions; more than one half the patients have Horner's syndrome, whereas few have lymphedema of the affected limb. The predilection for involvement of the C8 and Tl spinal nerves and the lower trunk can be explained by the fact that the lateral group of axillary lymph nodes that drain the commonly located sites (breast and lung J are in close contact with the divisions of

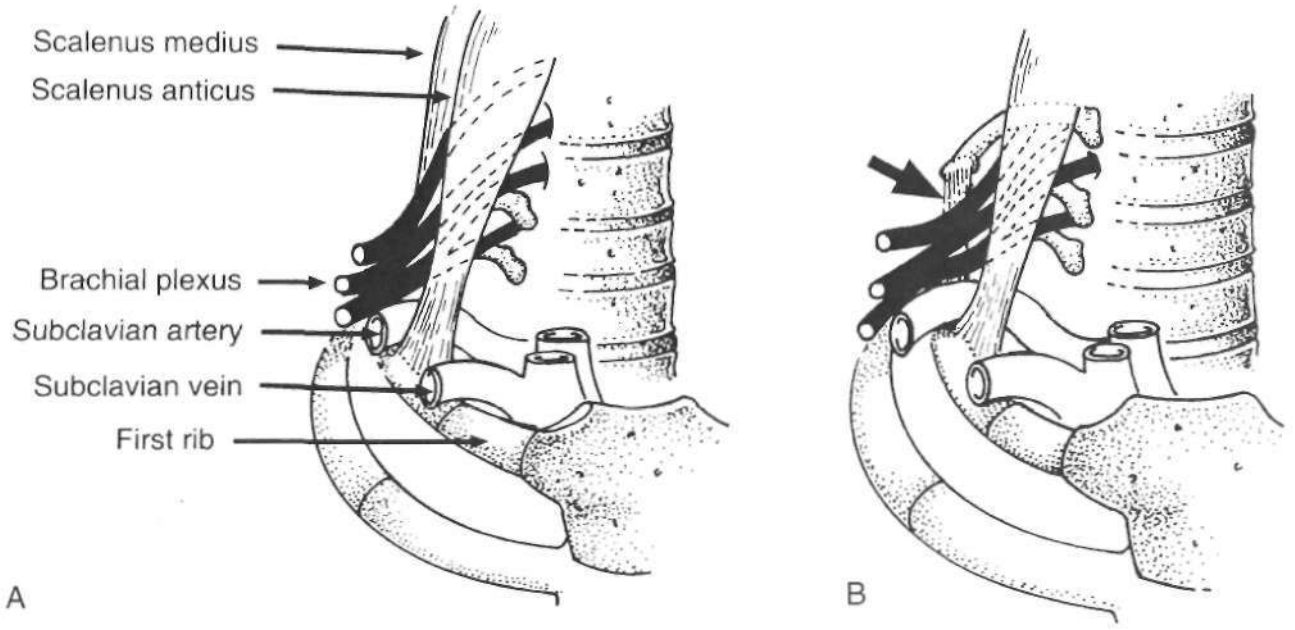

FIGURE 81.10 (A) The normal relationships of the subclavian artery and the brachial plexus as they course over the first rib between the scalenus medius and anterior muscles. {15} From the end of a short cervical rib arises a fibrous band *{arrow),* which attaches to the upper surface of the normal first rib. This stretches and angulates chiefly the lower trunk of the brachial plexus, causing neurogenic thoracic outlet syndrome. (Reprinted with permission from Stewart, J. 1), 1993, *Focal Peripheral Neuropathies,* 2nd ol, R.uvn I'IVSS. New York.)

the lower trunk; the upper trunk and its divisions arc remarkably free of lymph nodes. Some patients have signs indicating involvement of the entire plexus. In most of these patients, however, cervical CT myelography or MRI discloses epidural deposits that explain the upper plexus (C5 and C6 root) signs.

An important syndrome first described by Pancoast in 1932 is a superior pulmonary sulcus rumor, the vast majority of which are non-small cell bronchogenic carcinomas (Arcasoy and Jett 1997). The tumor arises near the pleural surface of the apex of the lung and grows into the paravertebral space and posterior chest wall, invading the C8 and Tl extraspinal roots, the sympathetic chain and stellate ganglion, the necks of the first three ribs, and the transverse processes and borders of the vertebral bodies of C7 through T3. The tumor may eventually invade the spinal canal and compress the spinal cord. Clinical features include a number of symptoms and signs: severe shoulder pain tadiating to the head and neck, axilla, chest, and arm; pain and paresthesias of the medial aspect of the arm and the fourth and fifth digits; and weakness with atrophy of intrinsic hand muscles.

On occasion, metastatic brachial plexopathy may be difficult to distinguish from radiation plexopathy (see Radiation-Induced Plexopathy, later in this section). Imaging studies are usually informative. In patients with metastases, MRI can identify a mass adjacent to the brachial plexus and reveal whether the tumor has encroached on the epidural space. CT remains a valued alternative investigation technique for this region because it provides good definition of the vertebral bodies. Nevertheless, sometimes exploration and biopsy by direct visualization may he the only definitive way to distinguish metastatic from radiation-induced plexopathy.

Results of the treatment of metastatic plexopathy are disappointing. Radiotherapy to the involved field and chemothetapy of the underlying tumor are the mainstays of treatment. Radiotherapy may relieve pain in 50% of patients but has little effect on return of muscle strength. A variety of procedures have been implemented to ameliorate the severe pain of this condition, including transcutaneous stimulation, paravertebtal sympathetic blockade, and dorsal rhizotomies.

In the patient with Pancoast's tumor, preoperative radiotherapy followed by extended surgical resection is the most common treatment, with an overall 5-year survival rate of 20-35% (Arcasoy and Jett 1997).

Radiation-Induced Plexopathy

Radiation-induced plexopathy is unlikely to occur if the dose is less than 6000 eGy. If more than 6000 cGy is given, the interval betw-een the end of radiation therapy and the onset of symptoms and signs of radiation plexopathy ranges from 3 months to 26 years, with a mean interval of approximately 6 years. The brachial plexus is more vulnerable to large fraction size, and thus fractions of

200 cGy or less are recommended. Cytotoxic therapy adds to the damaging effect of radiotherapy (Olsen et al. 1993). Limb paresthesias and swelling arc common complaints. Although the pain of radiation plexopathy is usually less intense than that of metastatic plexopathy, it may nonetheless be problematic (severe and persistent) requiring opioids; and in refractory cases responding to chemical sympathectomy (Fathers et al. 2002). Weakness is usually most prominent in muscles innervated by branches of the upper trunk, but involvement of the entire limb, from damage to the upper and lower portions of the plexus, has also been described. Indeed, in a group of women with radiation plexopathy following treatment for carcinoma of the breast, progressive weakness resulted in loss of hand function in 90% of patients (Fathers et al. 2002).

The relative resistance of the lower trunk of the brachial plexus to radiation injury is perhaps explained by the protective effect of the clavicle and the relatively shorter course of the lower trunk and its divisions through the radiation port. The pathogenesis of radiation damage is thought to involve two factors: radiation-induced endoneurial and perineuria! fibrosis with obliteration of blood vessels (triggered by small-vessel endothelial injury), and direct radiation-induced damage to myelin sheaths and axons. Arteritis (radiation-induced) of large vessels was found in a patient with delayed onset of brachial plexopathy following radiation therapy for breast carcinoma (21 years), who underwent arteriography for acrocyanosis in the affected limb (Rubin et al. 2001). The natural history of radiation-induced plexopathy is that of steadily increasing deterioration, although at times a plateau may be reached after 4-9 years of progression.

A diagnostic dilemma arises when symptoms and signs of brachial plexopathy develop in a patient who is known to have had cancer and radiation in the region of the brachial plexus, A painful lower trunk lesion with Horner's syndrome strongly suggests metastatic plexopathy, whereas a relatively painless upper trunk lesion with lymphedema favors radiation-induced plexopathy. **MRI** is inn always discriminating between metastatic and radiation because it may reveal an appearance of high signal intensity on T2-weighted images and contrast enhancement in cases of both radiation fibrosis and tumor infiltration (Wouter van Es et al. 1997). In the early and middle stages of radiation plexopathy, nerve conduction studies disclose features of de myelin a ting conduction block, but as time passes, studies reveal evidence of conversion to axon loss (Ferrante and Wilbourn 2002). Needle EMG is helpful in separating radiation-induced plexopathy from neoplastic plexopathy by the presence of myokymic discharges in the former. These are spontaneously occurring grouped action potentials {triplets or muitiplets) followed by a period of silence, with subsequent repetition of a grouped discharge of identical potentials in a semi rhythmic manner. They appear to result from spontaneous activity in single axons induced by local membrane abnormalities. They have not been reported in cases of tumor plexopathy.

Idiopathic Brachial Plexopathy

Arm pain and weakness are the cardinal manifestations of idiopathic brachial plexopathy. It occurs in all age-groups, but most patients are distributed fairly evenly between the third and seventh decades. Men arc affected two to thtee times more often than women; there appears to be a higher incidence among men engaged in vigorous athletic activities, such as weight lifting, wrestling, and gymnastics. Although half of the cases seem unrelated to any precipitating event, in others the neuropathy follows an upper respiratory tract infection, a flulikc illness, an immunization, or prior surgery, or :: occurs postpartum. Rare hereditary forms have also been described: a painless brachial plexopathy in patients with hereditary neuropathy with liability to pressure palsies and a painful or painless hereditary neuralgic amyotrophy with predilection for the brachial plexus (Pellegrino et al. 1996).

Clinic ill Features

The illness begins with the abrupt onset of intense pain, described as sharp, stabbing, throbbing, or aching, located in a variety of sites, including the shoulder, scapular area, trapezius ridge, upper arm, forearm, and hand. The pain may last from hours to many weeks, and then it gradually abates. Lessening of pain is associated with the appearance of weakness. This may have been present during the painful period but was not appreciated because the pain prevented the patient from moving the limb. Weakness may progress for 2-3 weeks after the onset of pain. Although pain subsides in most patients, it may continue for several weeks after weakness has reached its peak, and, rarely, it recurs episodically for a year or more. Paresthesias occur in approximately one third of patients but do not correlate with the severity or extent of weakness.

On examination, approximately one half of patients have weakness in muscles of the shoulder girdle, one third have weakness referable to both upper and lower parts of the plexus, and approximately l.i% haw evidence ol lower plexus involvement alone. Most appear to be incomplete because there is sparing of one or more muscles in the same root distribution. The patient may hold the arm in a characteristic posture, with flexion at the elbow and adduction at the shoulder, perhaps to reduce mechanical tension on the plexus.

Recognition is growing that the typical syndrome of brachial plexopathy need not always be associated with lesions of trunks or cords but can be caused by discrete

lesions of individual peripheral nerves, including the suprascapular, axillary, long thoracic, median, and anterior interosseous. Individual fascicular involvement—of the musculocutaneous nerve causing isolated brachialis wasting—has also been reported (Watson et al. 2001). Thus the term *brachial pi ex its neuropathy* may be appropriate. Sensory loss, found in two thirds of patients, most commonly over the outer surface of the upper arm and the radial surface of the forearm, is usually less marked than is the motor deficit. One third of cases are bilateral, but many fewer are symmetrical. In a small number of patients, unilateral or bilateral diaphragmatic paralysis occurs (Lahrmann et al. 1999), and the combination of acute shoulder pain with respiratory symptoms should suggest the diagnosis of brachial plexus neuropathy.

Diagnosis

The major differential diagnostic consideration in a patient with acute arm pain and weakness is cervical radiculopathy related to ccrvicogenic disease. In this condition, however, pain is usually persistent, neck stiffness is invariable, and it is unusual for radicular pain to subside as weakness increases. Nonetheless, an upper trunk brachial plcxopathy can simulate a *CS* or C6 radiculopathy. The cervical paraspinal needle EMG done several weeks after the onset of pain should be normal in brachial plexus neuropathy but show increased insertional activity and fibrillation potentials in cervical radiculopathy. Another differential diagnostic consideration is neoplastic plcxopathy, discussed earlier in this chapter, This entity is usually unremittingly painful, and neurological findings are most often referable to lower plexus elements. A third consideration might be a focal presentation of motor neuron disease, but pain is not a feature of this disease and sensation is .;K\a>s spared.

Electtodiagnostic testing is helpful in confirming the diagnosis and ruling out other conditions. Sensory studies are abnormal in *ouc* llniil ol patient-;; flit most ciiiiiiiion abnormality is reduced amplitude of sensory action potentials of the median, ulnar, and radial nerves. Also helpful are musculocutaneous nerve conduction studies, which disclose significant reduction in the amplitude of the biceps compound muscle action potential. Needle EMG is helpful because ir shows absence of fibrillation potentials in the cervical paraspinal muscles, thereby pointing to a pathological process distal to the DRG. Needle EMG is ilso lu-lpt'ul III Mining oui the problems ot localization, identifying lesions localized to the brachial plexus, individual peripheral nerves, or peripheral nerve branches. Finally, in a small number of patients, needle EMG is abnormal on the asyuipiomatn. side and on the symptom atic side, indicating that brachial plexus neuropathy can sometimes be subclinical. Other laboratory studies are not helpful. In general, there are no specific immunological abnormalities, but syndromes resembling brachial plexus neuropathy have been found in association with systemic lupus erythematosus.

Pathophysiology and Etiology

The pathophysiology and pathogenesis of the disotdet are not clear. An abrupt onset might suggest an ischemic mechanism; ptior history of a viral syndrome or an immunizarion raises the possibility of an immune-mediated disorder. Complement-dependent, antibody-mediated demyelination may have participated in the peripheral nerve damage and nerve biopsy findings in four cases of brachial plexus neuropathy, which tevealed florid multifocal mononuclear infiltrates, suggesting a cell-mediated component as well (Suarez et al. 1996). In some cases, rapid recovery bespeaks demyelination and remyeI ination; in others, a long recovery period is more in keeping with axonal degeneration followed by axonal regeneration. Indeed, a biopsy of a cutaneous radial branch in a severe case of plcxopathy showed profound axonal degeneration. In most patients, electrophysiological abnormalities are restricted to the affected limb, whereas in a small number of cases, there is evidence of a more generalized polyneuropathy. Nerve biopsy studies of patients with autosomal dominant attacks of brachial plexus neuropathy during symptomatic phases disclosed prominent perivascular inflammatory infiltrates with vessel wall disruption, suggesting that the hereditary disorder has an immune pathogenesis, possibly caused by genetic abnormalities of immune regulation (Klein et al. 2002).

Treatment and Prognosis

In the acute stage of the disotder, opioid analgesics are often required to control pain. A 10-day course of corticosteroids may be beneficial in a small number of patients. Arm and neck movements often aggravate pain; therefore, immobilization of the arm in a sling is helpful. With the onset of paralysis, range-of-motion exercises help to prevent contractures. In the small number of patients with significant permanent functional disability, orthotic devices may be helpful.

The natural history of brachial plexus neuropathy is benign; improvement occurs in the vast majority of patients, even in those with considerable muscle atrophy. Thirty-six percent have recovered by the end of 1 year, seventy-five percent by the end of 2 yeats, and eighty-nine percent by the end of 3 years. Although some patients think they have made a full functional recovery, careful examination may disclose mild neurological abnormalities, such as isolated winging of the scapula, slight proximal or distal weakness, mild sensory loss, or reduced retlex activity. In two thirds of patients, onset of improvement is noted in the first month after symptoms begin. Those who

continue to be bothered by pain and lack any signs of improvement within the first 3 months of the illness take a longer time to recover.

DISORDERS OF THE LUMBOSACRAL PLEXUS

Anatomical Features

The lumbar plexus is formed within the psoas major muscle by the anterior primary rami of lumbar spinal nerves LI, L2, L3, and L4. It is connected to the sacral plexus in the :nn- pelvis '^y tin .interior div'sion of 1.4 Figure 8 1.1 I A), Branches of the lumbar plexus include the iliohypogastric and ilioinguinal nerves arising from LI (with a contribution from T12), the lateral femoral cutaneous nerve of the thigh originating from the posterior divisions of L2 and L3, and the genitofemoral nerve arising from the anterior division of LI and L2. Other branches are the femoral nerve, formed from the posterior divisions of L2, L3, and L4 within the substance of the psoas muscle, and the obturator nerve, formed by the anterior divisions of L2, L3, and L4.

The lumbar plexus communicates with the sacral plexus via the anterior division of L4, which joins with L5 to form the lumbosacral trunk at the medial border of the psoas at the ala of the sacrum, The trunk enters the pelvis and joins the sacral plexus in the piriformis fossa. The sacral plexus, derived from the anterior rami of spinal nerves L4, L5, SI, 52, and S3, forms in ftont of the sacroiliac joint (Figure 81.1 IB). Like the lumbar plexus, the sacral plexus has anterior and posterior divisions. The anterior division contributes to the tibial portion, and die posterior division contributes to the peroneal portion of the sciatic nerve, which leaves the pelvis through the greater sciatic notch. A number of important branches come from the sacral plexus in the pelvis; the superior and inferior gluteal nerves arise from posterior divisions of the sacral plexus and supply the gluteus medius and minimus muscles and the gluteus maximus, respectively. The posterior cutaneous nerve of the thigh is formed by the anterior divisions of SI, S2, and 53. It passes through the greater sciatic fotamen into the buttock. The pudendal nerve originates from the undivided anterior primary rami of S2, S3, and S4 and extends into the gluteal region via the greater sciatic foramen.

Clinical Features

Neurological Examination

Lumbar plexopathy produces weakness, sensory loss, and reflex changes in segments 1.2 through L4, whereas sacral

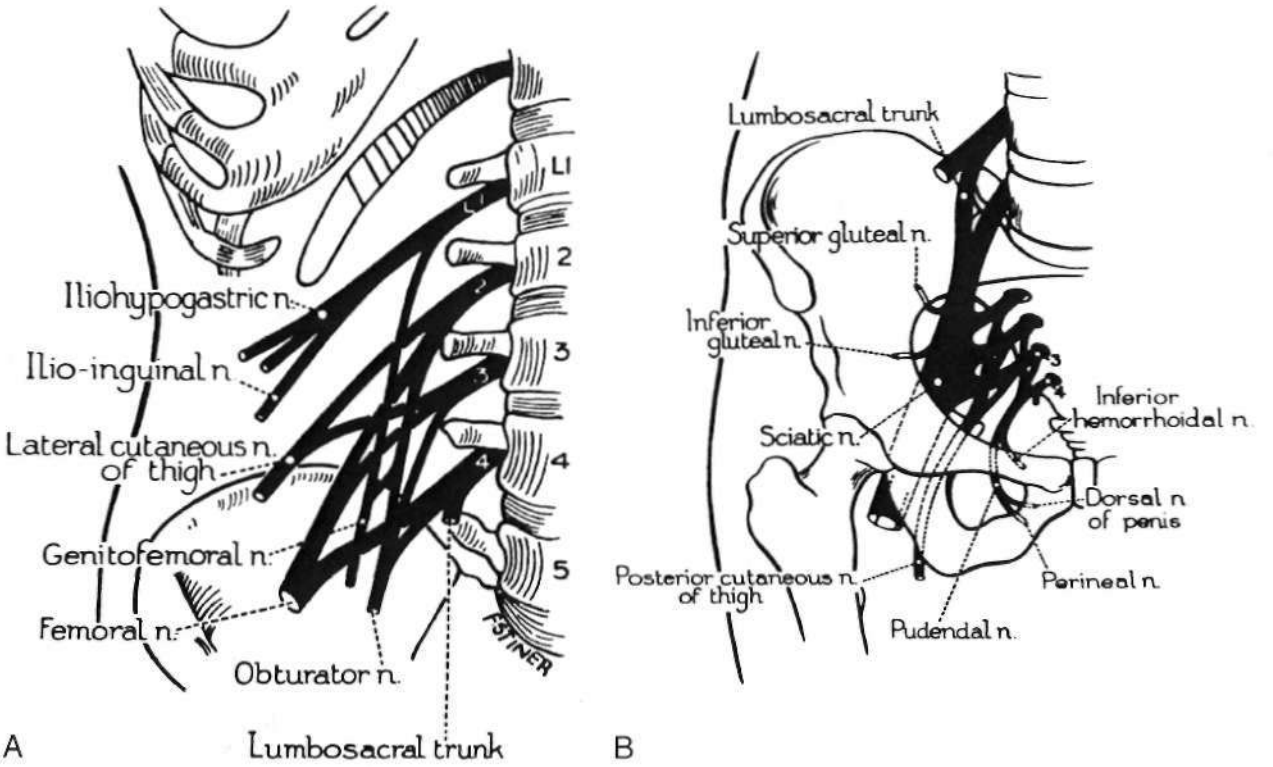

FIGURE 81.11 (A) The lumbar plexus is formed by anterior primary rami of lumbar spinal nerves (M'S) LI, L2, L3, and L4 (note the branches that arise from the plexus). (B) The sacral plexus is connected to the lumbar plexus by the lumbosacral trunk (note the branches that arise from the plexus in the pelvis). (Reprinted with permission from Haymaker, W. & Woodhall, K. 195.3, *Peripheral Nerve injuries,* 2nd ed, WB Saunders, Philadelphia.)

plexopathy leads to similar abnormalities in segments LJ through S3. Characteristic findings in lumbar plexopathy include weakness and sensory loss in both obturator- and femoral-innervated territories. Weakness of hip flexion, knee extension, and hip adduction, with sensory loss over the anteromedial aspect of the thigh, occurs; the knee jerk is absent or depressed. This combination of hip flexor and adductor weakness marks the disorder as either a plexopathy or radiculopathy. More precise localization depends on laboratory studies, including needle EMG, CT, and MRL

Findings in sacral plexopathy include weakness and sensory loss in the territories of the gluteal {motor only), peroneal, and tibial nerves. Extensive leg weakness involving the hip extensors and abductors, knee flexors, and ankle plantar flexors and dorsiflcxors exists. Sensory loss is found over the posterior aspect of the thigh, the anterolateral and posterior aspects of the leg below the knee, and the dorsolateral and plantar surfaces of the foot. Vasomotor and trophic changes may also be found in these areas. The ankle jerk is reduced or absent. Weakness of rhe gluteal muscles points to involvement of sacral plexus fibers proximal to the piriformis muscle in the ttue pelvis or to a more proximal sacral root level. As in lumbar plexopathy, accurate diagnosis often depends on electrodiagnostic studies and neuroimaging procedures.

Electrodiagnostic Studies

Electrodiagnostic studies are performed for several reasons. First, the EMG is helpful in identifying a motor sensory syndrome as a plexopathy and not a radiculopathy. The diagnosis of plexopathy is confirmed if the EMG discloses denervation (fibrillation potentials and positive sharp waves) and reduced recruitment (reduced numbers of motor units, firing rapidly) in muscles innervated by at least two lumbosacral segmental levels and involving at least two different peripheral nerves. An isolated plexopathy should not be associated with EMG abnormalities in paraspinal muscles. As will be seen, however, a number of pathological processes, including diabetes, radiation-induced changes, inflammation, vasculitis, and neoplasia may all involve the roots in addition to the plexus and produce a radicuioplexopathy. Second, EMG findings help to determine if a lumbosacral plexopathy is associated with a polyneuropathy. In the presence of the latter, signs of denervation and rcinnervation are found bilaterally, especially in the distal muscles. Third, EMG findings may strongly suggest a particular type of plexopathy; for example, myokymic discharges point to the diagnosis of radiation plexopathy.

Routine nerve conduction studies may help establish the diagnosis of plexopathy. Reduction in the amplitude of the sensory (sural and superficial peroneal) nerve action potentials indicates lo^s of axons distal to die l)K(r of SI and L5, respectively, F responses are also sometimes useful in the diagnosis of a plexopathy. Prolongation in F-wave latency with normal motor nerve conduction studies distally suggests a proximal lesion, either at a root or plexus level. Finally, conduction across the lumbar and sacral plexuses with root stimulation in a plexopathy may show an increased latency across a particular portion of the plexus.

Neuroimaging Studies

Bone destruction found in plain radiographs of lumbar and sacral vertebrae and the pelvis provides evidence for a structural plexopathy. Intravenous pyelography may demonstrate distortion of a ureter or the bladder. Barium enema may disclose displacement of the bowel. CT scanning of the abdomen and pelvis from a rostral point at the level of L1-E2 to a caudal point below the level of the symphysis pubis allows the regional anatomy of the entire lumbosacral plexus to be scrutinized (see Chapter 37).

The resolution of modern CT and MRI scanners allows identification of individual plexal components. The administration of oral or intravenous contrast is usually required to demonstrate the extent of structural abnormalities of the lumbosacral plexus, but it may not differentiate benign and malignant neoplasms, inflammatory masses, and hematoma. A normal MRI makes a structural plexopathy very unlikely. The CT may provide guidance for percutaneous needle biopsy of a lesion. Clues to the nature of a plexopathy are given in Table 81.1. An approach to evaluation of a plexopathy is summarized in Figure 81.12.

Differential Diagnosis

The differential diagnosis of lumbosacral plexopathy includes spinal root disorders, such as lumbosacral radiculopathy, polyradiculoneuropathy, cauda equina syndrome,

Tabic 81.1: Clues to the nature of a plexopathy

Structural disorders
I listory or pri-suiie of malignancy
Hemophilia or treatment with an anticoagulant
Pelvk trauma
Known atherosclerotic vascular disease and hypertension (aneurysm)

Abdominal (pelvic) surgery
Nonstructural disorders
Diabetes mellitus*
Vasculitis

]'u--. ions pi-lvii • ijiano::

"Diabetics may develop a polyradiculoneuropathy that simulates a lumbosacral plexopathy.

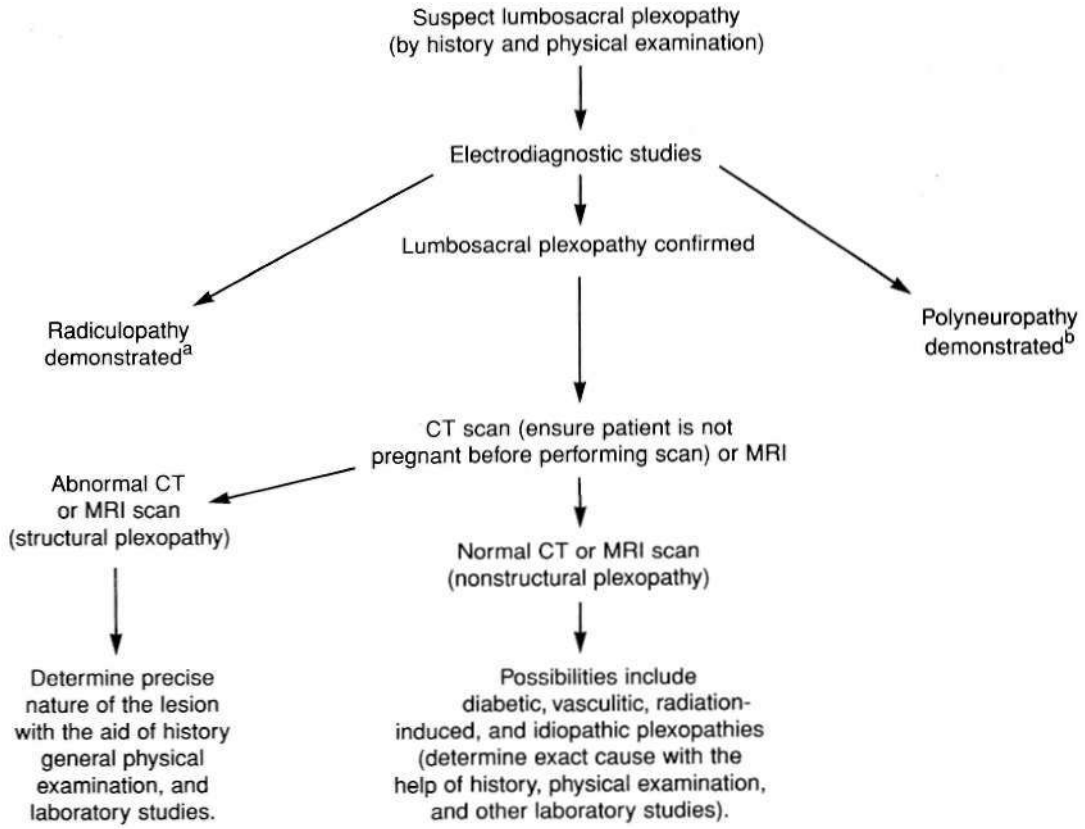

FIGURE 81.12 Approach to evaluation of lumbosacral plexopathy. Electrophysiological identification of radiculopathy may require spinal CT myelogram or MRI for confirmation and precise diagnosis. (CT computed tomography; MRI = magnetic resonance imaging.) "Radiculopathy is associated with plexopathy in diabetes, vasculitis, radiation, and malignancy. "Polyneuropathy may accompany plexopathies due to diabetes, vasculitis, and certain malignancies (paraneoplastic neuropathies).

anterior horn cell disorders, and myopathic conditions. Radiculopathies are usually painful, and the pain follows a predictable radicular distribution. Weakness is usually found in several muscles supplied by the same root, and the EMG usually demonstrates paraspinal muscle involvement. It is sometimes difficult to separate plexopathy from radiculopathy on clinical grounds alone, especially if several roots are involved.

Anterior horn cell disorders give rise to painless, progressive weakness with atrophy and fasciculation in the absence of sensory loss. When fully developed, such disorders should no! he contused will'; Ismsbiisacr.d plexopathy. In rare cases, however, a restricted anterior horn cell disorder, focal spinal muscular atrophy involving one leg, is seen. Absence of pain and sensory loss, normal imaging studies, and absence of diabetes and vasculitis all help point away from a disturbance of the lumbosacral plexus.

Myopathics are rarely confused with lumbosacral plexopathy, Myopathies with a focal, lower extremity onset can be distinguished from lumbosacral plexopathy by elevation of muscle enzymes, myopathic features on EMG (early recruitment of short duration, low-amplitude motor unit potentials), and muscle biopsy (variation in muscle fiber size, internalized nuclei, degeneration, regeneration, and inflammation),

Structural **Lumbosacral** Plexopathy

Hematoma

Patients with hemophilia and those receiving anticoagulants can develop hemorrhage in the iliopsoas muscle complex. It is important to recall that major components of the lumbar plexus, the femoral and obturator nerves, course from their origins in the lumbar paravertebral regions to their destinations in the thigh under cover of a tight layer of fascia. Over the iliac muscle, it is referred to as the *fascia iliaca,* and it becomes progressively thicker as it passes down, behind the inguinal ligament; at this site, it forms a dense and in distensible funnel enclosing the lower portions of iliacus and psoas.

Two major anatomical syndromes are associated **with** iliopsoas hematoma. In the first, the femoral nerve is the sole affected portion of the lumbar plexus. The hematoma arises in the iliacus and causes distention of the dense,

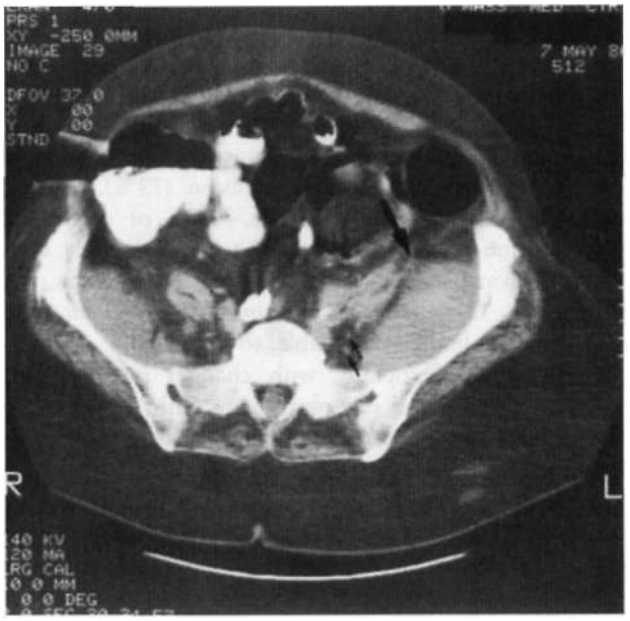

FIGURE **81.13** Hemorrhagic lumbosacral plexopathy. Computed tomographic scan at the L5-S1 level shows enlargement of die iliacus muscles, especially on the left side, owing to iliacus hematoma *(large arrow).* Small arrows indicate plexal elements. This large hematoma compresses the femoral and obturator nerves and the lumbosacral trunk.

overlying fascia above the inguinal ligament. In the second syndrome, hemorrhage arises in the psoas muscle or begins in the iliacus muscle and extends into the psoas. In this case, other components of the plexus, the obturator and lateral femoral cutaneous nerves, are involved.

Pain, often severe, is usually the first manifestation of a retroperitoneal hematoma. The pain is present in the groin and radiates to the thigh and leg. It is associated with gradually increasing paresthesias and weakness. When the femoral nerve is involved, weakness and sensory loss occur in its territory; when other components of the plexus are involved, changes are more extensive and conform to the territories supplied by the involved branches of the plexus. If the hemorrhage is large, a mass may develop in the lower abdominal quadrant. It typically arises from the lateral wall of the pelvis and can be seen in a CT scan to obscure the normal concavity of the innet aspect of the wing of the ilium (Figure 81.13). The patient usually lies in a characteristic posture with the hip flexed and laterally rotated because hip extension aggtavates the pain. Several days after the onset of the hematoma, a bruise may appear in the inguinal area or femoral canal. In most patients, recovery is satisfactory, although 10-15% of patients show no improvement. Pain usually disappeats within a week, and paresthesias and weakness resolve slowly.

Abscess

Psoas abscess was more common when tuberculosis was prevalent, but neurological complications, such as lumbar plexopathy and femoral neuropathy, were rare. This phenomenon was explained by the slow distention of the psoas sheath and by the fact that the abscess ruptured through the psoas fascia before the femoral nerve could be damaged by raised intra-psoas compartment pressure, Similarly, acute no *a* tuberculous psoas infection rarely produces nerve compression in cases of psoas abscess, presumably because the psoas fascia is distensible. Femoral neuropathy, however, does occur with iliacus muscle abscess because the fascia iliaca is relatively indistensiblc. Rarely, lumbar plexopathy is a complication of pelvic hydatidosis, caused by the tapeworm *Eckinococcus granulosus* (Serradilla et al. 2002).

Aneurysm

Back and abdominal pain ate often early manifestations of abdominal aortic aneurysms. Knowledge of abdominal and pelvic regional anatomy helps to explain the radiating characteristics of these pains. An expanding abdominal aortic aneurysm may compress the iliohypogastric or ilioinguinal nerve, leading to pain radiating into the lower abdomen and inguinal areas. Pressure on the genitofemoral nerve produces pain in the inguinal area, testicle, and anterior thigh. Compression of nerve trunks L5 through 52, which lie directly posterior to the hypogastric artery, may give rise to sciatica (Shields et al. 1997}. Thirteen percent of patients with aneurysms of the iliac artery will present with features of sciatica (Delgado-Garcia et al. 1999).

Hemorrhage from an abdominal aortic aneurysm may produce prominent neurological problems because of the retroperitoneal location of the hemorrhage or false aneurysm formation. In the case of an abdominal aortic aneurysm, a large retroperitoneal hematoma may injure the femoral and obturator nerves and even branches of the sacral plexus. Rupture of a hypogastric or common iliac artery aneurysm extends into the pelvis, compressing the L5 through S2 nerve trunk.

Ideally, the aneurysm should be diagnosed before rupture. Early recognition of an aneurysm is important because the mortality rate for operation on unruptured aneurysms is 5-7%, whereas that for symptomatic ruptured aneurysms is 35-40%. Unexplained back pain, leg pain, or pain radiating in the distribution of cutaneous nerves coming from the lumbar plexus should raise the suspicion of an aneutysm of the aorta or its major branches. A pulsatile mass felt while palpating **the** abdomen or, rarely, on rectal examination strongly suggests the presence of an aneurysm. Lumbosacral radiographs show a curvilinear calcific density, and abdominal sonography or CT scanning can confirm an aneurysm,

Trauma

Because of the relatively protected position of the lumbosacral plexus, traumatic lesions ate not common.

However, fracture of the pelvis, acetabulum, or femur or surgery on the proximal femur and hip joint may injure the lumbosacral plexus. Sacral fractures or sacroiliac joint separation accounts for most cases (68%) of traumatic lumbosacral piexopathy, while acetabular and femoral fractures are much less frequently implicated {14% and 9%, respectively) (Kutsy, Robinson, and Routt 2000). The latter, however, are more likely to cause injury to proximal nerves originating from the plexus. The mechanism of post-traumatic paresis in lumbosacral plexopathies may involve a number of factors, including nerve crush caused by fractured bone fragments; retroperitoneal hemorrhage; and traction as a result of hyperextension, hyperflexion, or rotation around the hip joint. Conservative measures appear to be the most appropriate way to manage post-traumatic injuries. More than two thirds of patients show good or moderate recovery of paresis after 18 months of follow-up after injury.

Pregnancy

The lumbosacral trunk may be compressed by the fetal head during the second stage of labor. This tends to occur in prolonged labor with midforceps rotation in a short, primigravida mother carrying a relatively large baby. A day or so after delivery, when the patient gets out of bed, she notes difficulty walking because of foot dorsiflexor weakness. Examination discloses weakness in dorsiflexion and inversion, with reduced sensation over the lateral aspect of the leg and dorsal surface of the foot. Nerve conduction studies disclose attenuation or absence of the superficial peroneal SNAP on the affected side, and needle EMG reveals denervation in muscles innervated by L5 below the knee (Katirji et al. 2002). The primary pathology is predominantly demyelination and the prognosis for complete recovery within 5 months is very good. In subsequent pregnancies, a trial of labor can be allowed as long as there is no evidence of disproportion or malpresentation. If labor proceeds, forceps should be used with great caution. Midforceps use in a woman with a previous obstetrical lumbosacral trunk palsy invites danger, it is prudent to perform cesarean section if the trial of labor is unsuccessful or if the infant is very large.

Femoral neuropathy may occur in a thin patient during cesarean section in cases managed with self-retaining retractors (Alsever 1996). In the thin abdominal wall, a deep, lateral insertion of retractor blades exerts pressure on the psoas and may injure the femoral nerve. After surgery, the patient notes weakness and numbness in the territory of the femoral nerve. Recovery is usually rapid and full. The obturator nerve may be compressed by the fetal head or forceps near the pelvic brim. Patients note pain in the groin and anterior thigh as well as weakness and sensory loss in the territory of this nerve.

Neoplasia

The lumbosacral plexus may be damaged by tumors that invade the plexus either by direct extension from intra-abdominal neoplasm or by metastases. Most tumors involve the plexus by direct extension (73%), whereas metastases account for only one fourth of cases. The primary tumors most frequently encountered are colorectal, cervical, and breast, as well as sarcoma and lymphoma. Three clinical syndromes occur: upper piexopathy with findings referable to the L1-L4 segments (31 %}; lower piexopathy with changes in the L4-S1 segments (51%); and pan-plexopathy with abnormalities in the LI-S3 distribution (18%). Neoplastic piexopathy typically has an insidious onset over weeks to months. Pain is a prominent early manifestation and is aching or cramping in quality. Weeks to months after pain begins, numbness, paresthesias, weakness, and leg edema develop. Incontinence or impotence occurs in fewer **than** 10% of patients. The most commonly encountered tumors arc colorectal in upper piexopathy, sarcomas in lower piexopathy, and genitourinary tumors in pan-plexopathies. The majority of neoplastic plexopathies **are** unilateral, although bilateral plexopathies, caused usually by breast cancer, occur in approximately 25% of patients. The prognosis in lumbosacral piexopathy caused by neoplasm is poor, with a median survival of 5.5 months.

Three special syndromes do not fit easily into upper, lower, or pan-plexopathy categories. In the first, there are paresthesias or pain in the lower abdominal quadrant or groin, with little or no motor abnormality. These patients are found to have a tumor next to LI leading to involvement of the ilioinguinal, iliohypogastric, or genitofemoral nerves. A second group has numbness over the dorsomedial portion of the foot and sole, with weakness of knee flexion, ankle dorsiflexion, and inversion. These patients have a lesion at the level of the sacral al.i, with involvement of the lumbosacral trunk. A third group presents with perineal sensory loss and sphincter weakness and have neoplastic involvement of the coccygeal plexus, caused usually by rectal tumors.

Neuroimaging with CT or MRI usually establishes the diagnosis of neoplastic piexopathy, but MRI is probably more sensitive (Taylor et al. 1997). Because pelvic neoplasms may extend into the epidural space, most often below the conus medullaris, MRI of the lumbosacral spine is indicated in most patients. On occasion, a plexus neoplasm is difficult to discern by the best neuroimaging procedures. Two main explanations for this phenomenon exist. First, patients who have received previous radiotherapy may have developed tissue fibrosis that cannot be distinguished from recurrent tumor. Second, some tumors track along the plexus roots and do not produce an identifiable mass. In these instances, ancillary imaging tests (high-resolution MRI, bone scan, plain films, intravenous

pyelogram), a biopsy of the plexus, or both may be required to determine the etiology,

Nonstructural Lumbosacral Piexopathy

Radiation Piexopathy

Radiation piexopathy usually produces slowly progressive, painless weakness. Pain develops in approximately one half of patients with radiation piexopathy, but it is not usually a major problem. Most patients with radiation piexopathy eventually develop bilateral weakness, which is often asymmetrical and affects predominantly the distal muscles in the L5-S1 distribution. In most patients, leg reflexes are absent, and superficial sensation is impaired. Symptoms referable to bowel or urinary tract are usually the result of proctitis or bladder fibrosis. The latent interval between radiation and the onset of neurological manifestations is between 1 and 31 yeats (median, 5 years), although very short latencies of less than *6* months have also been reported. An acute presentation of lumbosacral piexopathy 10 weeks following completion of radiation therapy for cervical cancer has also been observed (Abu-Rustum et al. 1999). No consistent relationship is evident between the duration of the symptom-free interval and the amount of radiation.

In most patients, radiation piexopathy is gradually progressive and results in significant or severe disability. CT and MRI of the abdomen and pelvis are normal. EMG discloses paraspinal fibrillation potentials in 50% of patients, suggesting that radiation damages the nerve roots in addition to the plexus; hence, a more appropriate designation is *radiation radiculoplexopathy.* In almost 60% of patients, the tMG discloses myokymic discharges, a feature that is only rarely seen in neoplastic piexopathy.

Vasculitis

Vasculitic neuropathy has generally been associated with the pattern of multiple mononeuropathy, but other neuropathic syndromes have also been described, including painful lumbosacral piexopathy. The portions of the peripheral nervous system most susceptible to vasculitis-induced ischemia are the segments of peripheral nerve-located at the midhumetus and midfemur levels, regions of nerve that appear to be watershed zones between vascular territories of the vasa nervorum. Proximal nerve trunks and nerve roots may also be vulnerable to the vasculitic process.

When a lumbosacral piexopathy syndrome occurs in a patient known to have a vasculitis, such as polyarteritis nodosa or rheumatoid arthritis, vasculitic piexopathy is an obvious diagnosis. The clinical diagnosis is more difficult in the setting of a seemingly idiopathic polyneuropathy or piexopathy because the process may be monosystemic and restricted to the peripheral nervous system. In such a case, a nerve biopsy may be required to establish the correct diagnosis,

Idiopathic f.umbosacral Piexopathy

Lumbosacral piexopathy may occur in the absence of a recognizable underlying disorder. Thus it can be considered a counterpart of idiopathic brachial plexus neuropathy (van Alfcn and van Engelen 1997). It may begin suddenly with pain, followed by weakness, which progtesses for days or sometimes many weeks. In many patients, the condition stabilizes, but in some, the course is chronic progressive or relapsing and remitting. Weakness is found in the distribution of upper and lower portions of the lumbosacral plexus in 50% of cases; major involvement occurs in the territory of the upper portion in 40% and in the lower portion in only 10% of patients. Most patients recover over a period of months to 2 years, although recovery is often incomplete. The EMG discloses a patchy pattern of denervation in the distribution of part or all of the lumbosacral plexus, but the paraspinal muscles are spared, indicating that the process docs not affect the lumbosacral roots. Dyek, Norell, and Dyck (2001) designated idiopathic lumbosacral piexopathy as *non-diabetic lumbosacral radicidoplexns neuropathy* and found that it resembles diabetic polyradiculoplcxopathy (see earlier section) in terms of its clinical presentation (subacute, asymmetrical, and painful with delayed and incomplete recovery) and pathological findings (ischemic injury and microvasculitis), and suggested that it probably has an immune pathogenesis. Indeed, preliminary data from controlled trials suggest that immune-modulating therapy may be beneficial (Verma and Bradley 1994; Dyck and Windebank 2002).

Chapter 82
Disorders of Peripheral Nerves

E. Peter Bosch and Benn K. Smith

CLINICAL APPROACH TO DISORDERS OF PERIPHERAL NERVES

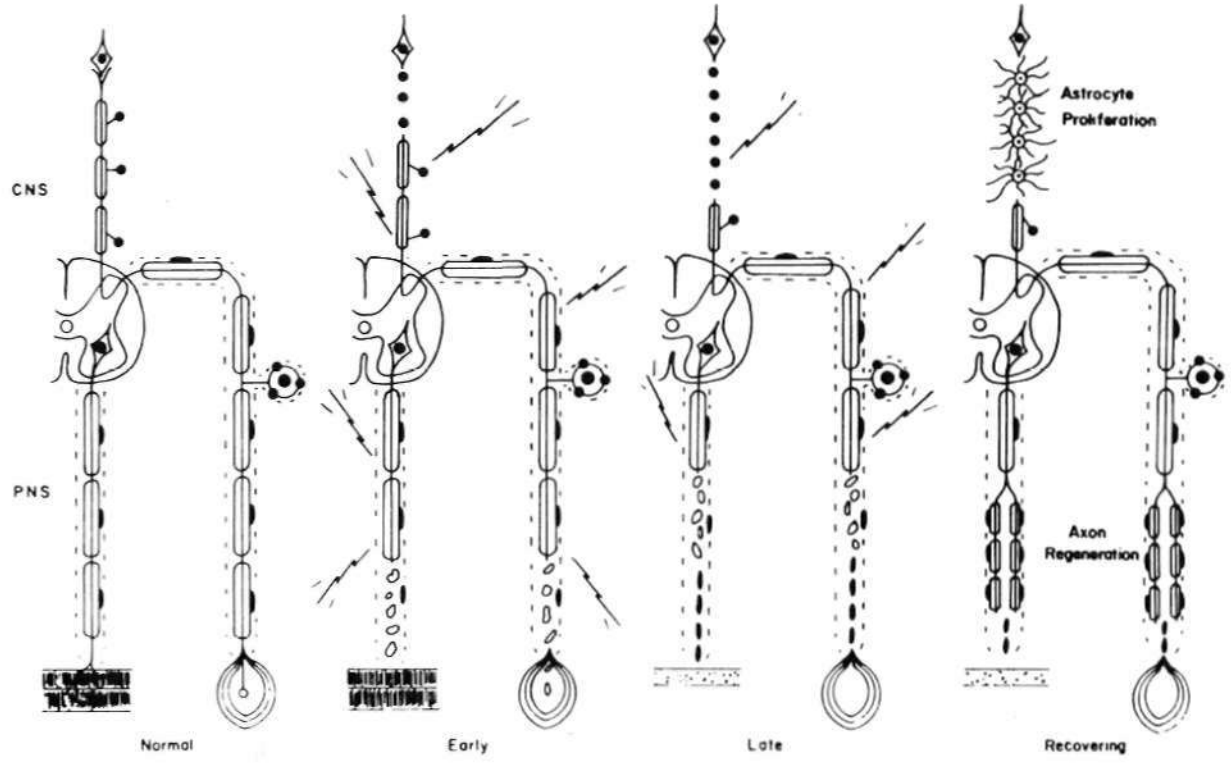
Peripheral neuropathies are caused by deranged function and structure of peripheral motor, sensory, and autonomic neurons. The main causes of neuropathy arc entrapment, Hansen's disease, diabetes, and other systemic diseases; inherited disorders; inflammatory demyelinating, ischemic, and paraneoplastic conditions; deficiency states; and toxins. A logical systematic diagnostic approach consists of (1) a careful history, (2) a detailed physical examination, and (3) electrophysiological studies, which not only confirm the presence of a peripheral nerve disorder but also may shorten the list of diagnostic possibilities. Further laboratory studies are often performed based on the outcome of the initial evaluation to arrive at a specific diagnosis. It is possible to establish a specific diagnosis in up to 75% of patients evaluated in tertiary referral centers by experts in neutomuscular disorders.

Pathological Processes Involving Peripheral Nerves

Despite the large number of causes of neuropathy, the peripheral nerve has a limited repertoire of pathological reactions to physical or metabolic insults. In general, these pathological reactions can be divided into four main categories: (1) wallerian degeneration, which is the response to axonal interruption; (2) axonal degeneration or axonopathy; (3) primary neuronal (perikaryal) degeneration or neuronopathy; and (4) segmental demyelination. The patient's symptoms, the type and pattern of distribution of signs, and the characteristics of nerve conduction study abnormalities provide information about the underlying pathological changes.

Any type of mechanical injury that causes interruption of axons leads to wallerian degeneration (degenctation of axons and their myelin sheaths) distal to the site of transection. Whereas motor weakness and sensory loss arc immediate in the distribution of the damaged nerve, distal conduction failure does not DI\ ur until 3 [vl] J;ivv Liter as the distal nerve trunk becomes progressively inexcitable. Motor response amplitudes begin to decline by the third to fifth day after injury and excitability is lost by the seventh to ninth day. For sensory nerves the loss of evoked potentials is delayed a further 2-3 days. The temporal sequence of wallerian degeneration is length dependent, occurring earlier in shorter than in longer distal nerve stumps. Denervation potentials ate typically seen in affected muscles 10-14 days after injury. Axonal interruption initiates morphological changes of the nerve cell body, termed *chromatolysis,* and produces a reduction in proximal axonal caliber. Regeneration from the proximal stump begins as early as 24 hours following transection but proceeds slowly and is often incomplete. The quality of recovery depends on the degree of preservation of the Schwann cell-basal lamina tube and the nerve sheath and surrounding tissue, as well as the distance of the site of injury from the cell body, and the age of the individual.

Axonal degeneration, the most common pathological reaction of peripheral nerve, signifies distal axonal breakdown resembling wallerian degeneration, presumably caused by metabolic derangement within neurons (Figure 82.1). Systemic metabolic disorders, toxin exposure, and some inherited neuropathies are the usual causes of axonal degeneration. The myelin sheath bteaks down concomitantly with the axon in .i process that starts at the most distal part of the nerve fiber and progresses toward the nerve cell body, hence the term *dyi/t^-hack neuropathy.*



FIGURK 82.1 A diagram of the main pathological events of distal axonal degeneration or axonopathy. The jagged lines indicate that either a toxin or a metabolic insult acts at multiple sites along motor and sensory axons in the peripheral nervous system (PNS) and central nervous system (CNS). Axonal degeneration begins at the most distal part of the nerve fiber and progresses proximally by the late stage. Recovery occurs by axonal regeneration but is impeded by astroglial proliferation in the CNS. (Reprinted with permission from Schaumburg. H. H., Spencer, P. S., *&c* Thomas, P. K. 1983, *Disorders of peripheral nerves,* Davis, Philadelphia.)

A similar sequence of events may occur simultaneously in centrally directed sensory axons, resulting in distal degeneration of rostral dorsal column fibers. The selective length-dependent vulnerability of distal axons could result from the failure of the perikaryon to synthesize enzymes or structural proteins, from alterations in axonal transport, or from regional disturbances of energy metabolism. In some axonopathies, alterations in axon caliber, either axonal atrophy or axonal swelling, may precede distal axonal degeneration. Clinically, dying-back neuropathy presents with symmetrical, distal loss of sensory and motor function in the lower extremities and extends proximally in a graded manner. The result is sensory loss in a stocking-like pattern, distal muscle weakness and atrophy, and loss of ankle reflexes. Axonopathies result in low amplitude sensory nerve action potentials iSKAPs) and compound muscle action potentials (CMAPs), but they affect conduction velocities only slightly. Electromyography (EMC) of distal muscles shows acute, chronic, or both kinds of denervation changes (see Chapter 36B). Because axonal regeneration proceeds at a maximal rate of 2-3 mm per day, recovery may be delayed and is often incomplete.

Neuronopathy designates primary loss or destruction of nerve cell bodies with resultant degeneration of their entire peripheral and central axons (Figure 82.2). Either lower motor neurons or dorsal root ganglion cells may be affected. When anterior horn cells arc affected as in anterior poliomyelitis or motor neuron disease, focal weakness without sensory loss is the result. *Sensory neuronopathy* or *polygangtionopathy* means damage to dorsal root ganglion neurons that results in the inability to localize the limb in space, diffuse areflexia, and sensory ataxia. A number of toxins such as organic mercury compounds, doxorubicin, and high dose pyridoxinc produce primary sensory neuronal degeneration. Immune-mediated inflammatory damage of dorsal root ganglion neurons occurs in paraneoplastic sensory neuronopathy and other conditions. It is often difficult to distinguish between neuronopathies and axonopathies on clinical grounds alone. Once the pathological processes are no longer active, sensory deficits become fixed, and little or no recovery takes place.

The term *segmental demyelination* implies injury of either myelin sheath or Schwann cells, resulting in breakdown of myelin sheaths with sparing of axons (Figure *823).* This occurs in immune-mediated demyelinating neuropathies and in hereditary disorders of Schwann ccll-myelin metabolism. Primary myelin damage may be produced c\pcni:iciit:ilb by mvclmoioxic agents, such :is diphtheria toxin, or mechanically by acute nerve compression.

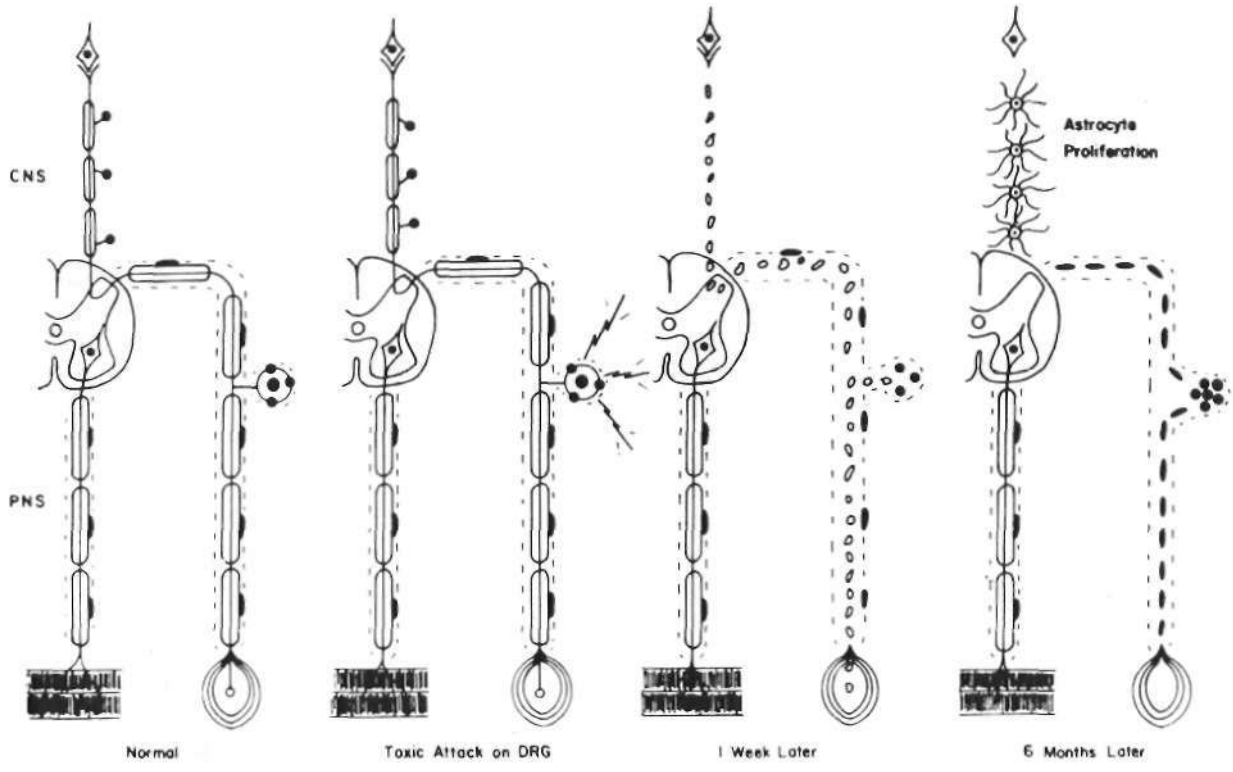


FIGURE 82.2 A diagram of the main pathological events of a sensory neuropathy or ganghopathy. A toxin, identified by the jagged lines, produces destruction of dorsal root ganglion (DRG) neurons, which results in degeneration of the peripheral-central axonal processes. Recovery is poor, as no axonal regeneration can take place. (CNS = central nervous system; PNS = peripheral nervous system.) {Reprinted with permission from Scha um burg, H. H., Spencer, P. S., Sc Thomas, P. K. 1383, *Disorders of peripheral nerves,* Davis, Philadelphia.)

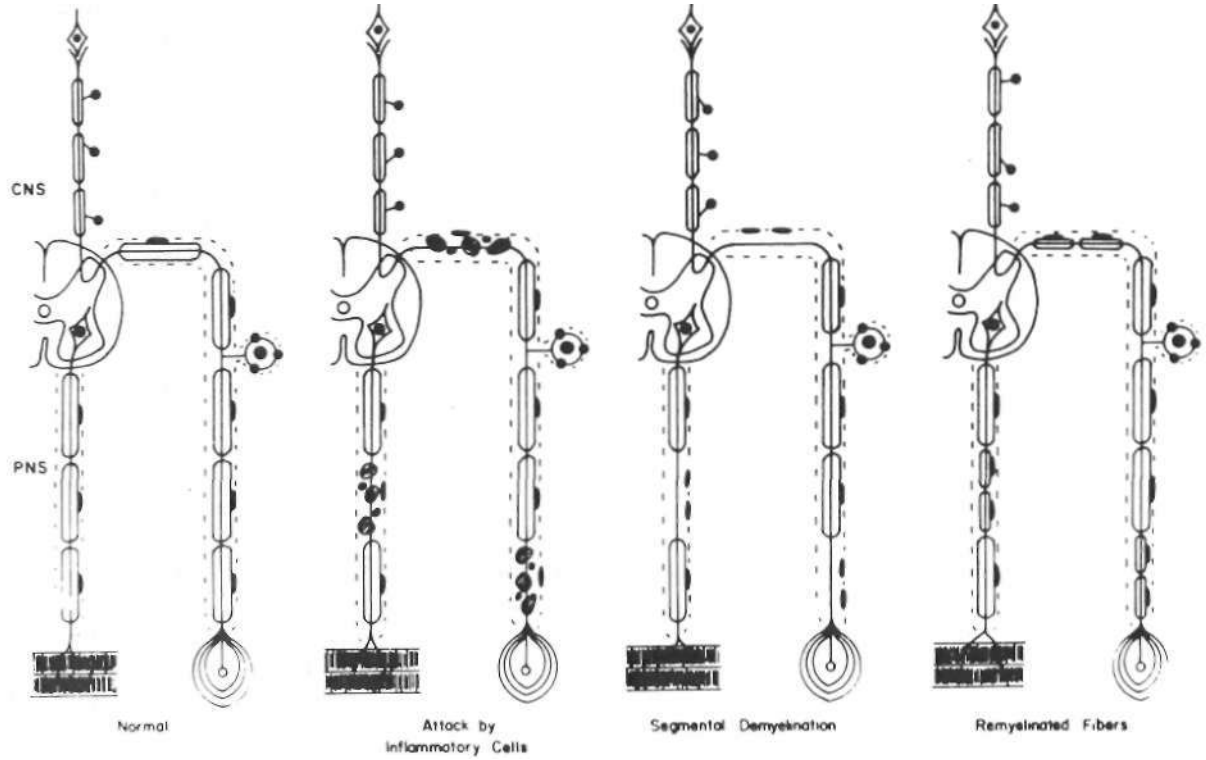

FIGURE 82.3 A diagram of the main pathological events of primary segmental demyelination in immune-mediated inflammatory polyradiculoneuropathies. The attack by inflammatory cells causes patchy multifocal demyelination along the nerve fibers but spares their axons. Recovery occurs by remyelination. The demyelinated segments become invested by several Schwann cells, resulting in a decrease in the internodal length of those areas. (CNS = central nervous system; PNS = peripheral nervous system.) {Reprinted with permission from Schaumburg, H. H., Spencer, P. S., & Thomas, P, K. 1983, *Disorders of peripheral nerves,* Davis, Philadelphia.)

Demyelination also may occur secondary to alterations in axonal caliber, cither atrophy or swelling, which may cause myelin remodeling over many consecutive internodes. Axonal atrophy and secondary demyelination are seen typically in uremic neuropathy. Remyelination of demyelinated segments usually occurs within weeks. The newly formed rernyelinated segments have thinncr-than-normal myelin sheaths and internodes of shortened length. Repeated episodes of demyelination and remyelination produce proliferation of multiple layers of Schwann cells around the axon, termed an o«io« *bulb.* The physiological consequence of acquired demyelination (i.e., inflammatory demyelination, but not hereditary myelinopathies) is conduction block, resulting in loss of the ability of the nerve action potential to reach the nerve, thereby producing weakness, though the axon remains intact, and hence there is little muscle atrophy. Relative sparing of temperature and pinprick sensation in many demyelinating neuropathies reflects preserved function of unmyelinated and small-diameter myelinated fibers. Early generalized loss of reflexes, disproportionately mild muscle atrophy in the piTsena ol proximal .ind distal weakness, neuropathic tremor, and palpably enlarged nerves are all clinical clues that suggest demyelinating neuropathy. Nerve conduction studies or analysis of single osmicated teased nerve fibers can provide confirmation of demyelination. Demyelination is considered if motor and sensory nerve conduction velocities (NCVs) arc reduced to less than 70% of the lower limits of normal with relative preservation of response amplitudes. The presence of partial motor conduction block, temporal dispersion of CMAPs, and marked prolongation of distal motor and F-wave latencies are all features consistent with acquired demyelination (see Chapter 36B). Recovery depends on remyelination, and therefore clinical improvement may occur within days to weeks. In many neuropathies, axonal degeneration and segmental demyelination coexist.

Diagnostic Clues from the History

The symptoms of neuropathic disorders fall under the general headings of motor, sensory, or autonomic disturbances. The inquiry should seek both negative and positive symptoms. Muscle cramps, fascieulations, myokymia, or tremor are positive manifestations of motor nerve dysfunction. In polyneuropathies motor symptoms produce early distal toe and ankle extensor weakness, resulting in tripping on rugs or uneven ground. Complaints of difficulty walking do not distinguish muscle weakness from sensory,

pyramidal, extrapyramidal, or cerebellar disturbance. If the fingers are weak, paiiems may complain of difficulty in opening jars or turning a key in a lock.

Positive sensory symptoms include prickling, scaring, burning, and tight bandlike sensations. Unpleasant sensations arising spontaneously without apparent stimulus are called *paresthesia.* The presence of spontaneously reported paresthesia is helpful in distinguishing acquired (paresthesias occurring in more than 60% of patients) from inherited (parasthesias reported in only 17% of patients) neuropathies. *Allodynia* refers to the perception of nonpainful stimuli as painful. Painful hypersensitivity to noxious stimuli is called *hyperalgesia.* Neuropathic pain, the extreme example of a positive symptom, is a cardinal feature of many neuropathies. Neuropathic pain often has a deep, burning, or drawing character that may be associated with jabbing ot shooting pains and typically increases during periods of rest.

Autonomic dysfunction can be helpful in directing attention toward specific neuropathies that have prominent autonomic symptoms. It is important to ask about orthostatic lightheadedness, fainting spells, reduced or excessive sweating, and heat intolerance, as well as bladder, bowel, and sexual dysfunction. Anorexia, early satiety, nausea, and vomiting are symptoms suggestive of gastroparcsis. The degree of autonomic involvement can be documented by noninvasive autonomic function studies (Low 1993) (see Chapter 83).

Histotical information regarding onset, duration, and evolution of symptoms provides important clues to diagnosis. Knowledge about the tempo of disease (acute, subacute, or chronic) and the coutse (monophasic, progressive, or relapsing) narrows diagnostic possibilities. Guillain-Barre syndrome (GBS), acute potphyria, vasculitis, and some cases of toxic neuropathy have acute presentations. A relapsing course is found in chronic inflammatory demyelinating polytadiculoneutopathy (C1DP), acute porphyria, Refsum disease, hereditary neuropathy with liability to pressure palsies (HNPP), familial brachial plexus neuropathy, and repeated episodes of toxin exposure.

In patier.is will: a chionii.- iiulnkni course over many years, inquiries about similar symptoms and foot deformities such as pes cavus in immediate relatives often point to a familial neutopathy. Inherited neuropathies are a major cause of undiagnosed neuropathy, accounting for 30—40% of patients teferted to tertiary centers for diagnosis. .Molecular genetic testing or the clinical and electrophysiological evaluation of relatives of patients with undiagnosed neuropathy may corroborate that the disorder is familial. Many neuropathies are caused by systemic disease. The presence of constitutional symptoms such as weight loss, malaise, and anorexia suggests an underlying systemic disorder. Inquiry should be made about preceding or concurrent associated medical conditions (diabetes mellitus, hypothyroidism, chronic renal failure, liver disease, intestinal malabsorption, malignancy, connective tissue diseases, human immunodeficiency virus [HIV] seropositivity); drug use, including over-the-counter vitamin preparations (vitamin Bg); alcohol and dietary habits; and exposure to solvents, pesticides, or heavy metals.

Diagnostic Clues from the Examination

The first step is to determine the anatomical pattern and localization of the disease process and the involvement of motor, sensory, or autonomic neurons inferred from the examination. Single root (monoradiculopathy) and brachial or lumbar plexopathies produce typical unilateral motor and sensory signs and symptoms (see Chapter SI).

Mononeuropathy means focal involvement of a single netve and implies a local process. Direct trauma, compression or entrapment, vascular lesions, and neoplastic infiltration are the most common causes. Electrophysiological studies provide a more precise localizarion of the lesion than may he possible by clinical examination and can scpatate axonal loss from focal segmental demyelination. Nerve conduction studies may reveal widespread changes, indicating an underlying neuropathy that predisposes ro nerve entrapment, such as in diabetes mellitus, hypothyroidism, acromegaly, alcoholism, and HNPP.

Multiple mononeuropathy or mononeuropathy multiplex signifies simultaneous or sequential damage to multiple noncontiguous nerves. Confluent multiple mononeuropathies may give tise to motor weakness with sensory loss that can simulate a peripheral polyneuropathy. Electrodiagnostic studies ascertain whether the primary pathological process is axonal degeneration or segmental demyelination (Table 82.1). Approximately two thirds of patients with multiple mononeutopathies display a picture of axonal damage. Ischemia caused by systemic, nonsystemic, or monosystemic (peripheral nerve) vasculitis or microangiopathy in diabetes mellitus should be considered. Other less common causes are disorders affecting interstitial structures of nerve, namely infectious, granulomatous, leukemic, or neoplastic infiltration, including Hansen's disease, and sarcoidosis. In the event thai focal demyelination or motor conduction block leads to multiple

Table 82.1: Causes of multiple mononeuropatiiii's

Axonal injury

Multifocal motor neuropathy
Multiple compression neuropathies (hypothyroidism, diabetes)
Hereditary neuropathy with liability to pressure palsies

mononcuropathies, multifocal acquired demyclinating sensory and motor neuropathy, multifocal motor neuropathy, or hereditary liability to pressure palsies should be considered.

Polyneuropathy is characterized by symmetrical, distal motor, and sensory deficits that have a graded increase in severity distally and by distal attenuation of reflexes. The sensory deficits produce a stocking-glove pattern. By the time sensory disturbances have reached the level of the knees, paresthesias are noted in the tips of the fingers. When the sensory impairment reaches the midthigh, involvement of anterior intercostal and lumbar segmental nerves gives rise to a tent-shaped area of hypesthesia on the anterior chest and abdomen. Motor weakness is greater in extensor muscles than in corresponding flexors. For example, walking on heels is affected earlier than toe walking in most polyneuropathies. It is helpful to deter- 11111;• the relative extent of sensory, motor, and autonomic neuron involvement, although most polyneuropathies produce mixed sensorimotor deficits and some degree of autonomic dysfunction.

Mntar deficits tend to dominate the clinical picture in acute and chronic inflammatory demyelinating neuropathies, hereditary motor and sensory neuropathies, and in neuropathies associated with osteosclerotic myeloma, porphyria, lead and organophosphate intoxications, and hypoglycemia. Asymmetrical weakness without sensory loss suggests motor neuron disease or multifocal motor neuropathy with conduction block (Table 82.2}. The distribution of weakness provides important information. The facial nerve can be affected in several peripheral nerve disorders (Table 82.3). In most polyneuropathies the legs are moiv si/vm-k al'liiicd ih.iii the arm;,. Notable excep tions to this rule are lead neuropathy, which frequently presents with wrist drop, multifocal motor neuropathy with conduction block, familial amyloid neuropathy type 2, occasionally porphyria, and adult-onset Tangier disease. Polyradiculoneuropathies cause both proximal and distal muscle weakness. The nerve root involvement is confirmed by denervation in paraspinal muscles on needle EMG.

Gelsolin familial amyloid neuropathy (Finnish)
Tangier disease

For example, proximal and distal weakness is encountered in acute and chronic inflammatory demyelinating radiculoneuropathies, osteosclerotic myeloma, porphyria, and diabetic lumbar radiculoplexopathy.

Predominant sensory involvement may be a feature of neuropathies caused by diabetes; carcinoma; Sjogren's syndrome; dysprotcincmia; acquired immunodeficiency syndrome (AIDS); vitamin B_{12} deficiency; celiac disease; intoxications with cisplatin, thalidomide, or pyridoxine; and inherited and idiopathic sensory neuropathies.

Autonomic dysfunction of clinical importance is seen in association with specific acute (e.g., GBS) or chronic {e.g., amyloid and diabetic) sensorimotor polyneuropathies, Rarely, an idiopathic panautonomic neuropathy can be the exclusive manifestation of a peripheral nerve disorder without somatic nerve involvement (Table 82,4).

Loss of sensation in peripheral neuropathies usually involves all sensory modalities, but occasionally the impairment may be restricted to selective sensory modalities. The latter situation makes it possible to correlate the type of sensory loss with the pattern of afferent fiber loss according to fiber diameter size (Figure 82.4). Pain and temperature sensation are mediated by unmyelinated and small myelinated A'; libers, -A hereas vibratory vnsi, proprioception, and the afferent limb of the tendon reflex are subserved by large myelinated *Act* and A^i fibers. Light touch is mediated by both large and small myelinated fibers. Quantitative sensory testing assessing both vibratory and thermal detection thresholds has become a useful addition to the bedside sensory examination in controlled clinical trials. Its use in routine clinical practice remains

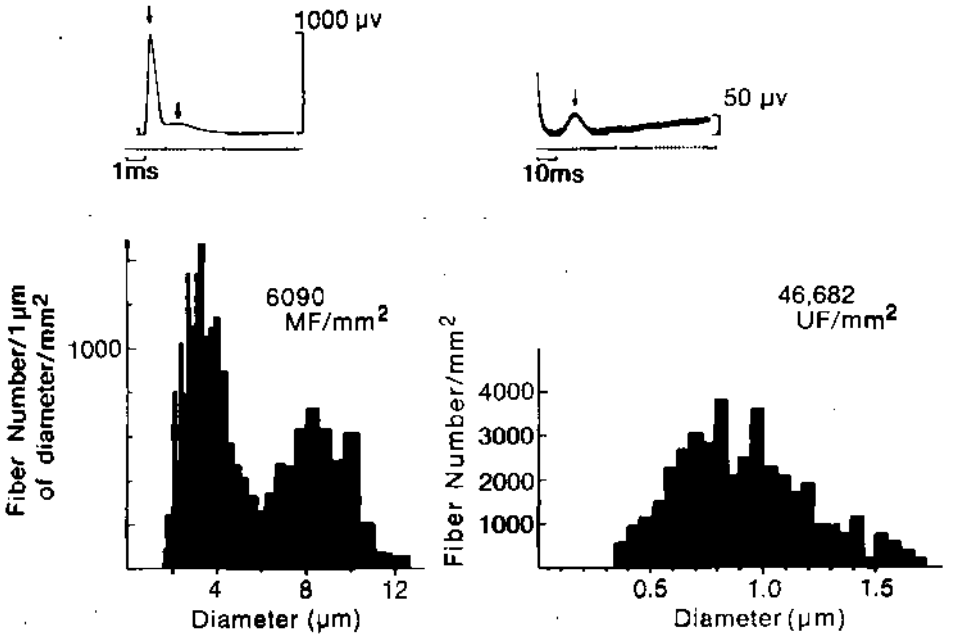

FIGURE 82.4 Myelinated fiber (ME) and unmyelinated fiber (UE) size-frequency histograms of a normal sural nerve. Fiber size distribution is bimodal for ME but ummodal for UR The ME tli n~~it y iv. iKirrn.il MII.II HIT-,:- ranges from 6000 to 10,000 fibers/mm^1 of fascicular area. The number of UEs is normally approximately four times that of Mi's. The corresponding compound nerve action potential recorded from the sural nerve in vitro is shown at top. Three distinct peaks indicated by arrows are, from left to right, Act, A<S, and C-potentials, which correspond to large MF, small ME, and UF peaks, respectively.

limited because the test is still subjective in that it requires patient cooperation and is time-consuming. In polyneuropathies preferentially affecting small fibers, diminished pain and temperature sensation predominate, along with burning pain, painful dysesthesias, and autonomic dysfunction. There is relative preservation of tendon reflexes, balance, and motor strength, and hence few abnormal objective neurological signs are found on examination, A pattern of sensory loss that is very characteristic (though still dependent upon the patient's subjective response) is distal loss of pinprick sensation, above which is a band of hyperalgesia (exaggerated pain from noxious stimuli), with normal sensation above this level.

Because routine sensory conduction studies assess only large myelinated fibers, such studies may be entirely normal in selective small fiber neuropathies. Quantitative sensory testing assessing cooling and heat-pain thresholds, tests of sudomotor function, and skin biopsy with analysis of intraepidermal nerve fiber density may be necessary for confirmation. Sweating mediated by unmyelinated sympathetic cholinergic fibers is often involved. The quantitative sudomotor axon reflex that evaluates sweating is a highly specific and sensitive method (sensitivity of 80%) to confirm small nerve fiber damage. Skin biopsies that demonstrate loss of intraepidcrmal nerve fibers is an alternative sensitive method for documenting small fiber neuropathy (MendelI and Sahenk 2003), About 10% of patients with normal sudomotor testing will have abnormal skin biopsies. This useful technique is currently limited to few academic centers. Relatively few disorders cause selective small fiber neuropathies (Table 82.5).

Selective large fiber sensory loss is characterized by areflexia, sensory ataxia, pseudoathctosis (involuntary movements of fingers and hands when the arms are outstretched and the eyes are closed), and loss of joinr position and vibration sense. A feature of sensory ataxia is ∴ positive Romberg sign, meaning disproportionate Kiss of balance with eyes closed compared with eyes open. Striking sensory ataxia together with inability to localize the limb in space or asymmetrical truncal or facial sensory loss directs attention to a primary disorder of sensory neurons or polyganglionopathies. The differential diagnosis of ataxic sensory neuropathies is limited (Table 82.6),

Palpation of peripheral nerves is an important though unreliable part ot I lie examination, i lypertrophy of a single nerve trunk suggests either a neoplastic process (neurofibroma, Schwannoma, or malignant nerve sheath tumor) or localized perineurial hypertrophic neuropathy. Generalized or multifocal nerve hypertrophy is found in a limited number of peripheral nerve disorders including leprosy, neurofibromatosis, Charcot-Marie-Tooth (GMT) disease types 1 and 3, acromegaly, Refsum's disease, and rarely CIDP.

Certain tell-tale signs of the skin and its appendages may direct the experienced examiner to a specific diagnosis

Tabes dorsalis produces severe ataxia with damage to the sensory nerve fibers at the root entry zone of the dorsal roots.

(Table 82.7): Alopecia is seen in thallium poisoning; tightly curled hair in giant axonal neuropathy; white transverse nail bands termed MceV *lines* in arsenic or thallium intoxications; telangiectasias over the abdomen and buttocks in Fabry's disease; purpuric skin eruptions of the legs in cryoglobulinemia and some vasculitides; skin hyperpigmentation or hypertrichosis in POEMS syndrome (characterized by polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes); enlarged yellow-orange tonsils in Tangier disease; pes cavus and hammer toes in CMT disease; and overriding toes and ichthyosis in Refsum's disease.

Electrodiagnostic Studies

It is helpful to follow a decision-making pathway initially based on the overall pattern of distribution of deficits, followed by the electrophysiological findings, and finally the clinical course (Figure 82.5). Electro diagnostic studies, carefully performed and adapted to the particular clinical situation, play a key role in the evaluation by (1) confirming the presence of neuropathy, (2) providing precise localization of focal nerve lesions, and (3) giving information as to the nature of the underlying nerve pathology (see Chapter 36B).

Tahle 82.7: Neuropathies with skin, nail, or hair manifestations

Disease	*Skin, nail, or hair manifestations*
Vasculitis	Purpura, livedo reticularis
CryOglohiikiiriiH.i	PlIipiMM
Fabry's disease	Angiokeratomas
Leprosy	Skin hypopigmentation
Osteosclerotic myeloma (POEMS syndrome)	Skin hyperpig mentation
Variegate porphyria	Bullous lesions
Refsum's disease	Ichthyosis
Arsenic or thallium intoxication	Mees" lines
Thallium poisoning	Alopecia
Giant axonal neuropathy	Curled hair

POF.MS = polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes.

Nerve Biopsy

N'erve biopsy should be performed only in centers with established experience with the technique; otherwise little useful information is likely to be obtained. The sural nerve is selected most commonly for biopsy because the resultant sensory deficit is restricted to a small area over the heel and dorsolateral aspect of the foot, and because its morphology has been well characterized in health and disease. The superficial peroneal nerve represents an alternative lower extremity cutaneous nerve suitable for biopsy and has the advantage of allowing simultaneous access to the peroneus brevis muscle through the same incision. This combined nerve and muscle biopsy procedure increases the yield of identifying suspected vasculitis (Collins et al. 2000). In patients with proximal involvement of the lower limbs, the intermediate cutaneous nerve of the thigh combined with a muscle biopsy can be selected. Nerve biopsy has proved to be particularly informative when techniques such as single teased fiber preparations, scmithin sections, ultrastructural studies, and morphometry are applied to quantitate the nerve fiber pathology. Relatively few disorders exist in which a nerve biopsy is essential for diagnosis (Table 82.8; Said 2002). In general, nerve biopsy is most useful in suspected vasculitis and amyloid neuropathy. It is helpful in the recognition of CIDP, inherited disorders of myelin, and some rare axonopathies in which there are distinctive axonal changes such as giant axonal neuropathy and polyglucosan body disease. The availability of molecular genetic tests for CMT type I A, hereditary liability to pressure palsies, and familial transthyretin amyloidosis has decreased the necessity for nerve biopsy in these conditions. Nerve biopsy is an invasive procedure and is associated with a 15% complication rate. Minor wound infections, wound dehiscence, and stump neuromas may occur. Approximately one third of patients (particularly those without much sensory loss initially) report unpleasanl sensory symptoms at the biopsy site after 1 year (Gabriel et al. 2000). The area of the original sensory deficit declines by 90% after 18 months because of collateral reinnervation (Theriault etal. 1998).

Punch skin biopsy is a promising, minimally invasive technique to evaluate cutaneous innervation in sensory neuropathies. Intraepidermal networks of unmyelinated nerve fibers can be demonstrated by immunostaining with the panaxonal marker protein gene product 9.5 and the use of confociI microscopy. The density of intraepidermal nerve fibers has been found to be reduced in skin biopsies obtained from patients with idiopathic, HIV-associated, and diabetic sensory neuropathies (Kennedy et al. 1999). This technique does not permit the study of melinated fibers or the detection of interstitial pathological processes.

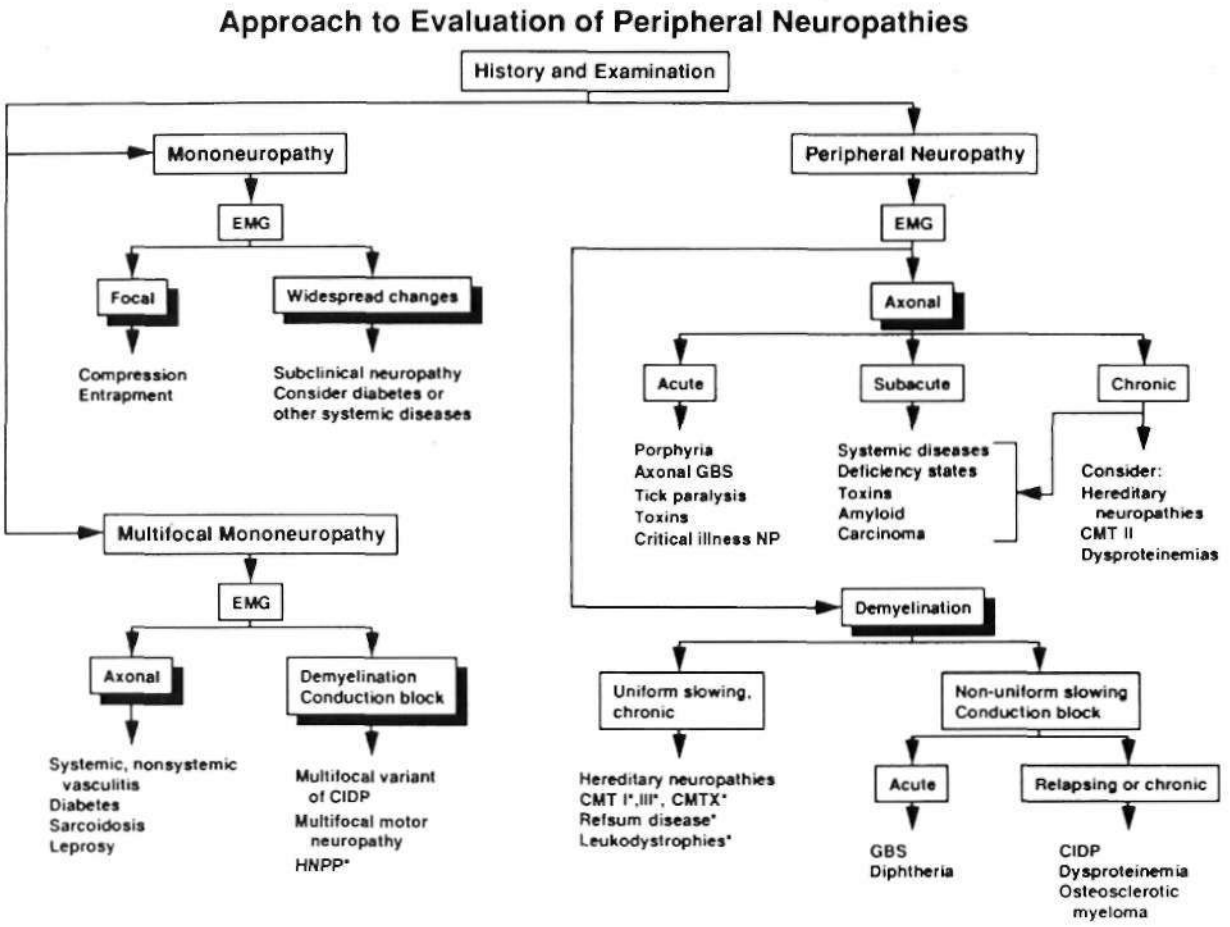

FIGURE 82.5 Diagnostic approach to the evaluation of a patient with peripheral neuropathy. Electromyography (EMG] denotes clectrodiagnostic studies. DNA diagnostic resting or specific biochemical tests are available for those conditions marked with asterisks. C1DP —chronic inflammatory dcmyclinating polyradiculoneuropathy; CMT = Charcot-Marie-Toorh disease; CMTX — Chareot-fvtarie-Tooth disease X-linked; GBS = Guillain-Barrc syndrome; HNPP = hereditary liability to pressure palsies; NP = neuropathy.

Other Laboratory Tests

The clinical neuropathic patterns and the results of clectrodiagnostic studies guide the experienced clinician to select the most appropriate laboratory tests. A few laboratory tests slit mid he *a* brained routinely in all patients with peripheral neuropathy. These include complete blood count, sedimentation rate, chemistry profile, fasting blood sugar, thyroid studies, vitamin Bj2 level, and serum protein electrophoresis with immunofixation electrophoresis. It is important to screen for monoclonal proteins in all patients with chronic undiagnosed neuropathy, particularly those older than *b0* years, because 10% ot suck patients have a monoclonal gammopathy. Several serum autoantibodies with reactivity to various components of peripheral nerve have been associated with peripheral neuropathy syndromes, and reference laboratories offer panels of nerve antibodies for sensory, sensorimotor, and motor neuropathies. It must be emphasized that the clinical relevance of most autoantibodies has not been established for the management of patients, and that their use is not cost-effective. Those of greatest clinical utility are listed in Table 82.9 (Kissel 1998).

An ever increasing number of molecular genetic tests for inherited neuropathies is available at reference

Ig = immunoglobulin.

laboratories (see Inherited Neuropathies). Cerebrospinal fluid {CSF) examination is helpful in the evaluation of suspected demy el mating neuropathies and poly radiculopathies related to meningeal carcinomatosis or lymphomatosis. In two large unselected series of patients with initially undiagnosed peripheral neuropathy referred to specialized centers, a definite diagnosis could be made in 76-87%. Inherited neuropathies, CIDP, and neuropathies a SMH.1 ate J wit a OIIUT diseases accounted foi most diag noses. The improved diagnostic rate was in large measure because of detailed clinical and laboratory evaluations and study of relatives of patients with undiagnosed neuropathy.

Chronic Idiopathic Axonal Polyneuropathy

Despite all efforts, a group of acquired neuropathies remains idiopathic. Acquired chronic sensorimotor and sensory neuropathies are common in individuals older than 50 years, with an estimated prevalence of more than 3%. Chronic idiopathic axonal neuropathy afflicts patients in the fifth or sixth decade and has either mixed sensorimotor or pure sensory features. Patients complain of tingling, prickling, numbness or burning of the feet, and stiffness of the toes. There is loss of pin-prick together with loss of vibratory sensation in the feet, absent ankle reflexes, and mild toc-cxtensor weakness. These abnormal signs must be distinguished from normal manifestations of the aging peripheral nervous system (PNS). Loss of vibratory sense that is restricted to the the toes can be a normal finding in healthy elderly controls (e.g., present in 28% of individuals aged 65 years and older). Absent ankle reflexes are found in 38% of healthy controls older than *65* years. Nerve conduction and nerve biopsy studies are compatible with a length-dependent a\u:ul ccmop.r.liy. Absent sural SNAPs combined with spontaneous muscle fiber activity in the anterior tibialis muscle supports the diagnosis of neuropathy as such abnormalities are tarely found in healthy, older individuals (Vrancken et al. 2002). Idiopathic small fiber neuropathy presents with painful, burning feet, with or without numbness. The condition also occurs in older patients without associated systemic diseases or exposure to identifiable toxins. Most patients have elevated thermal thresholds on quantitative sensory examination and impaired distal sweating, measured by the quantitative sudomotor axon reflex test. Sural SNAPs are preserved if there is exclusive small-fiber involvement but are frequently reduced or absent in painful sensory-neuropathies affecting both large and small fibers. Reduced intraepidermal nerve fiber density on punch skin biopsy-provides objective evidence of distal small fiber neuropathy in these patients (Lacomis 2002). There is recent evidence that impaired glucose tolerance may be associated with chronic axonal sensory neuropathies of unknown cause. Among 73 patients referred for distal idiopathic sensory neuropathy and screened with glucose tolerance testing, *56%* had abnormal results, either impaired glucose tolerance (36%) or frank diabetes (Sumner et al. 2003).

Both idiopathic sensorimotor and sensory polyneuropathies pursue a very slow progressive course or reach a stable plateau. Even after a course of more than 10 years severe disability docs not occur. Independent ambulation is almost always maintained,

The management of these common neuropathies centers on the treatment of neuropathic pain and patient education about the favorable long term outcome (Wolfe and Barohn *1998).*

PAIN IN PERIPHERAL NEUROPATHY

Pain is one of the cardinal symptoms of peripheral nerve disorders. Neuropathic pain can occur spontaneously without provocation (stimulus-independent) or be provoked by noxious or non-noxious stimuli. *Hyperalgesia* is an. increased pain response to noxious stimuli. *Allodynia* is the sensation of pain elicited by non-noxious stimuli (e.g., from contact with clothing, bedsheets, or air-flow).

The sensation of pain in peripheral neuropathies is generated by nerve impulses triggered when free nerve endings (nociceptors) in sensitive tissues, particularly the skin, respond to noxious stimuli. A number of neurophysiologies! studies have determined that both small myelinated *AS* fibers, and unmyelinated nociceptive C fibers, mediate the afferent impulse of pain stimuli.

Intraneural microstimularion of human sensory nerves showed that stimulating *AS* nociceptors evokes an acute sensation of sharp, well-localized pain. In contrast, the stimulation of polymodal C nociceptors evokes a sensation of delayed, more diffuse burning pain. Peripheral nerve injury results in the upregulation of sodium channels in nociceptive terminals and unmyelinated axons that leads to ectopic activity in sensitized C fibers and spontaneous firing in nociceptive primary sensory neurons. The increase in peripheral activity generates a cascade of secondary changes in the dorsal horn with the end-result of central sensitization in second and third-order neurons. The peripheral and central sensitization involves a number of recently recognized neurobiological events which involve altered expression of sodium channels, increased glutamate activity at N-methyl-D-aspartate (NMDA) receptors, down regulation of y-aminobutyric acid (GABA) receptors and opiod receptors. Reorganizational changes can occur at the level of the dorsal horn and dorsal root ganglion, These include the sprouting of sympathetic axons into the dorsal root ganglion forming baskets around nociceptive neurons, and the sprouting of non-nociceptive *Afi* central axon terminals into the superficial dorsal horn (Woolf and Mannion 1999). For a more detailed discussion of neuropathic pain mechanism, sec Chapter 50,

Neuropathic pain can be a prominent presenting symptom in a great number of peripheral neuropathies (Table 82.10; Mendell and Sahenk 2003). Pain is characteristic of neuropathies with predominant small fiber involvement, but even in large fiber neuropathies a sufficient number of small fibers may be damaged to cause pain. The poor clinical correlation between morphological changes seen in nerve biopsy specimens and pain is not surprising if one considers that ectopic impulses may arise from regenerating axonal sprouts or dysfunctional fibers at more proximal or distal sites than the nerve segment examined at biopsy. Neuropathic pain usually affects distal skin and subcutaneous structures, may be constant or intermittent (stabbing, electrical jolts), may often have a temporal pattern of worsening ;it periods ol rest in bedtime, ;iinl is described with words such as *searing, burning,* or *icy-cold.* Sensory examination should use techniques to elicit abnormal positive sensory phenomena, Allodynia can be elicited by light touch or nonpainful cold stimuli using tuning forks kept in a refrigerator. When testing for hyperpathia, single and repeated pinpricks are used. Patients with hyperpathia may often complain of summation (pain perception increases with repeated stimulation) and aftersensations (pain continues after stimulation has ceased). Nerve trunk pain, a second type of neuropathic pain, is a deep-seated, sharp, knifelike proximal pain along nerve roots or trunks that improves with rest or optimal position but is aggravated by movement. Nerve trunk pain seems to be mediated by spontaneous impulses arising from nervi nervorum innervating nerve sheaths of affected nerve roots or trunks. Muscle pain and tenderness may develop with acutely evolving denervation of muscle as it occurs in GBS or acute poliomyelitis.

Table 82.10: Peripheral neuropathies frequently associated with pain

Paraneoplastic sensory neuronopathy
Sjogren's syndrome
Human immunodeficiency virus-related distal symmetrical polyneuropathy
Uremic neuropathy
Fabry's disease
Hereditary sensory autonomic neuropathy

Management of Neuropathic Pain

Regardless of the underlying cause, the management of neuropathic pain is identical for all painful neuropathies (see Chapter SO). Symptomatic treatment of neuropathic pain seldom provides complete relief. At best, current therapies refill !ii .1 ;"" id", reduction -n p.iin. Simple analgesics (aspirin, acetaminophen, and certain nonsteroidal anti-inflammatory drugs) are rarely beneficial. Most patients require additional pharmacotherapy. Drugs from several different pharmacological classes have been shown to be safe and effective in alleviating neuropathic pain. These include tricyclic antidepressants (TCAs), anticonvulsants, sodium-channel blockers, opioids and non-narcotic analgesics, and topical agents (Galer 1995). In general, once an agent is selected for treatment, the medication is started at the lowest possible dosage and slowly titrated by increasing the dose every 3-7 days until significant pain relief or intolerable side effects occur. Many treatment failures can be attributed to insufficient dosing or intolerance caused by rapid dose escalations. The use of the following drugs can be supported by the results of randomized controlled studies. To compare efficacy among the different agents the number needed to treat (NNT) is given whenever possible. The NNT is an estimate of the total number of patients who need to be treated to achieve 50% pain reduction (Sindrup and Jensen 2000).

TCAs have been established to reduce pain independent of their effect on mood. These drugs block the reuptake of norepinephrine and serotonin, two neutotransmitters

that are implicated in nociceptive modulation, and inhibit sodium channels. Tricyclic antidepressants are effective for both constant and lancinating, paroxysmal pain. Based on the evidence of several controlled studies in patients with painful diabetic neuropathy, they are very efficient, with an NNT between 2 and 3. Treatment should be initiated with low-dose (10-25 mg) amitriptyline, desipramine, or nortriptyline given at bedtime and increased by similar increments no more than twice weekly. Most studies have shown that doses of tricyclics of 75-150 mg (less for elderly patients) arc required for pain suppression. At such high-dose levels, sedation, confusion, anticholinergic effects (constipation, dry mouth, urinary retention), and orthostatic hypotension are common side effects, particularly in elderly patients. Desipramine and nortriptyline cause less sedation and less orthostatic hypotension and have fewer anticholinergic effects than amitriptylinc. TCAs should be started with caution in elderly patients and in patients with ischemic heart dieasc, narrow angle glaucoma, or prostatism. Selective serotonin reuptake inhibitors are less effective than TCAs in relieving neuropathic pain.

Venlafaxinc is a potent inhibitor of norepinephrine and serotonin reuptake but has fewer side effects than TCAs. YiT'.if;i\ir;' *ill* i mg iLuly'i showed benefit with an NNT ol 5 in a cohort of 40 patients with painful neuropathies but was less efficacious than imipramine (Sindrup ct al. 2003). Bupropion (300 mg daily), a specific inhibitor of norepinephrine reuptake, reduced neuropathic pain by 30% in a small group of patients.

Anticonvulsants (carbamazepine, oxcarbazepine, lamotrigine, and gabapentin) are considered second-line agents compared with antidepressants but are frequently given to suppress shooting or stabbing pains. Carbamazepine reduces neuronal membrane excitability by blocking sodium channels. In painful diabetic neuropathy carbamazepine (1000-1600 mg daily) was compared to placebo, and the NNT was 3, equivalent to that of TCAs. In practice, intolerance to side effects limits its use. It is important to initiate treatment with carbamazepine at a low dose {50 mg twice daily) and increase slowly to avoid initial symptoms of nausea, disequilibrium, and memory impairment. Oxcarbazepine, a keto-acid analogue, is better toletated.

Gabapentin is an anticonvulsant with unknown mechanism of action. Its effect may be mediated by binding to voltage dependent calcium channels expressed in the substantia gelatinosa of the dorsal horn. Two controlled studies demonstrated benefit in patients with painful diabetic neuropathy. The NNT was 4. When compared head to head with amitnptylme, gabapentin had equal efficacy but fewer side effects. Treatment is initiated at 300 mg at bedtime. The dose is escalated by 300 mg increments every 3-5 days until adequate pain relief is achieved. The median effective dose ranges from 900-1600 mg, although some patients require doses of 3600 mg per day.

Lamotrigine acts by by blocking sodium channels and by inhibiting the presynaptic release of glutamine. Lamotrigine (200—400 mg daily) resulted in moderate pain relief in controlled studies of painful diabetic and HIV-associated neuropathies (Eisenberg et al. 2001).

Mexilctinc, the oral analogue of hdocame, is the prototype of a sodium channel blocker. There have been inconsistent results with the use of mexilctinc. Two of the studies showed a beneficial effect in patients with diabetic neuropathy whereas four other studies failed to demonstrate benefit, resulting in an NNT of 38.

Tramadol, a non-narcotic centrally acting analgesic, has been proved effective in painful neuropathies related to diabetes and other causes in two clinical trials in doses ranging from 200-400 mg per day (Harati et al. 1998). The combined NNT for both studies was 3.4. Low-affinity binding to ^-opioid receptors and inhibition of norepinephrine and serotonin uptake contribute to its analgesic action. The drug is generally well tolerated but nausea and constipation occur in about 20% of patients,

High-dose dextromethorphan, a low-affinity NMDA glutamate antagonist, provided partial relief in painful diabetic neuropathy but was associated with significant sedation and ataxia.

Narcotic analgesics should be limited to patients who have failed adequate treatment trials of other agents. Randomized, controlled studies of oxycodone and levorphanot have demonstrated efficacy of opiods in postherpetic neuralgia and painful diabetic neuropathies (Rowbotham et al. 2003). Specific guidelines for chronic opioid therapy in neuropathic pain have been published and should be followed.

Topical agents that act through local skin absorption have the advantage of minimal or no systemic side effects and may be useful in patients with painful, burning feet. Capsaicin, an extract of chili peppers, presumably produces relief of pain through the depletion of substance P in unmyelinated nociceptive fibers. Capsaicin cream {0.025% or 0.075%) is applied to the affected area of skin three to four times a day. An initial intense burning frequently occurs after its application before any improvement is seen. h\ i:-.e \li:,iU v o>r:iin.H\l tor .u leasi 4 weeks before rejecting its effectiveness. Patches containing 5% lidocainc have been shown to reduce pain in postherpetic neuralgia. Some patients may receive relief from burning feet and allodynia by topical application of such patches on areas of excessive pain.

It may be necessary to use drugs in combination to achieve optimal pain relief. For example, if pain is still poorly controlled on a maximum tolerated dose of gabapentin, tramadol or a TCA may be added. There are no data from clinical trials to provide guidance regarding which combination to choose. Nonpharmacological treatments including low-intensity transcutaneous electrical nerve stimulation, acupuncture, medical hypnosis, and meditation may reduce the perception of pain and suffering. A comprehensive pain management program should be considered for patients with chronic refractory neuropathic pain.

ENTRAPMENT NEUROPATHIES

Entrapment neuropathy is defined as a focal neuropathy caused by restriction or mechanical distortion of a nerve within a fibrous or fibro-osseous tunnel or less commonly by other structures such as bone, ligament, other connective tissues, blood vessels, or mass lesions. Compression, constriction, angulation, or stretching arc important mechanisms that produce nerve injury at certain vulnerable anatomical sites (Tables 82.11 and 82.12). The term entrapment is a useful one in that it implies that compression occurs at particular sites where surgical intervention is often required to release the entrapped nerve, such as in the case of the median nerve at the wrist in moderate to severe carpal tunnel syndrome. Overuse has been implicated as the cause of entrapment neuropathies in certain occupations, including the playing of musical instruments by professional musicians.

In chronic entrapment, mechanical distortion of the nerve fibers leads to focal demyelination or, in severe cases, to wallerian degeneration. Morphological studies show a combination of active demyelination, remyelination, wallerian degeneration, and axonal regeneration at the site of entrapment. Endoncurial swelling, collagen proliferation, and thickening of perineuria! sheaths accompany the nerve fiber changes. Ischemia is not a significant contributing factor to nerve fiber damage in chronic compression. In contrast, ischemia plays a more significant role in nerve injury associated with acute compression secondary ro space-occupying lesions such as hematoma or the compartment syndromes.

The characteristic feature of entrapment neuropathy is either short segment conduction delay or conduction block across the site of entrapment (see Chapter 36B). In severe cases, wallerian degeneration gives rise to extensive denervation in affected muscles. Nerve conduction study measurements together with EMG are essential for diagnosis and reliable documentation of the site and severity of nerve entrapment. Although plain radiography, computed tomography (CT), or magnetic resonance imaging (MR!) may be of occasional value in identifying rare structural abnormalities, these imaging procedures arc not required for routine diagnosis.

Double Crush Syndrome

When a sizable cohort of patients with clcctrodiagnostic evidence of distal upper limb entrapment neuropathies was found to have either electrophysiological or radiological and clinical evidence of cervical radiculopathy, Upton and McComas proposed that focal compression of single nerve fibers proximally might so alter axoplasmic transport as to render the distal nerve more susceptible to symptomatic entrapment neuropathy, resulting in a double crush syndrome. Although the concept of double crush syndrome has since been invoked in a wide variety of entrapment neuropathies, often as an explanation for failed decompressive surgeries of the neck or limb or as a rationale to decompress a nerve in multiple proximal to distal sites along its course, this phenomenon is of uncertain validity (Wilbourn and Gilliatt 1997).

Upper Extremities

Median Nerve Entrapment at the Wrist (Carpal Tunnel Syndrome)

Carpal tunnel syndrome is by far the most common entrapment neuropathy. This entrapment occurs in the tunnel through which the median nerve and flexor

Tabic 82.11: Entrapment neuropathies of upper limbs

Nerve	*Sits of compression*	*Predisposing factors*	*Major clinical features*
Median	Wrist (carpal tunnel syndrome)	Tenosynovitis, arthritis, etc.	Paresthesia, pain, thenar atrophy
	Anterior interosseous	Strenuous exercise, trauma	Abnormal pinch sign, normal sensation
	Elbow (pronator teres syndrome)	Repetitive elbow motions	Tenderness of pronator teres, sensory loss
Ulnar	Elbow (cubital tunnel syndrome)	Elbow leaning, trauma	Clawing and sensory loss of fourth and fifth fingers
	Guyon's canal	Mechanics, cyclists	Hypothcnar atrophy, variable sensory loss
Kadij	Axilla	Crutches	Wrist drop, triceps involved, sensory loss
	Spiral groove	Abnormal sleep postures	Wrist drop, sensory loss
	Posterior interosseous	Elbow synovitis	Paresis of finger extensors, radial wrist deviation
	Superficial sensory branch (cheiralgia paresthetica)	Wrist bands, hand cuffs	Paresthesias in di irsi. . . . .' hand
Suprascapular	Suprascapular notch	Blunt trauma	Atrophy of supraspiiiatus and infraspinatus muscles
Dorsal scapular	Scalene muscle	Trauma	Winging of scapula on arm abduction
Lower trunk of the brachial plexus or C'S/TI roots	Thoracic outlet	Cervical rib, enlarged C7 transverse process	Atrophy of intrinsic hand muscles, paresthesias of hand and forearm

Table 82.12: Entrapment neuropathies of lower limbs

Nerve	*Site of compression*	*Predisposing factors*	*Major clinical features*
Sciatic	Sciatic notch	Endometriosis, intramuscular injections	Pain down thigh, footdrop, absent ankle jerk
	Hip Piriformis muscle	Fracture dislocations	
	Popliteal fossa	Popliteal Baker's cyst	
Fibular	Fibular neck	Leg crossing, squatting	Footdrop, weak evertors, sensory loss in dorsum of foot
	Anterior compartment	Muscle edema	Footdrop
Posterior tibial	Medial malleolus (tarsal tunnel syndrome)	Ankle fracture, tenosynovitis	Sensory loss over sole of foot
Femoral	Inguinal ligament	Lithotomy position	\\ ,ik Liu:. I'siniMiiii. .lbseni knee jerk
Lateral femoral cutaneous	Inguinal ligament (mcralgia paresthetica)	Tight clothing, weight gain, utility belts	Sensory toss in lateral thigh
Ilioinguinal	Abdominal wall	Trauma, surgical incision	Direct hernia, sensory loss in the iliac crest, crural area
Obturator	Obturator canal	Tumor, surgery, pelvic fracture	Sensory loss in medial thigh, weak hip adduction

digitorum tendons pass. Because the transverse carpal ligament is an unyielding fibrous structure forming the roof of the tunnel, tenosynovitis or arthritis in this area often produces pressure on the median nerve.

Symptoms consist of nocturnal paresthesias, most often confined to the thumb, index, and middle fingers. Patients complain of tingling numbness and burning sensations, often awakening them from sleep. Referred pain may radiate to the forearm and even as high as the shoulder (Stevens el al. 1999), Symptoms are often worse after excessive use of the hand or wrist. Objective sensory changes may be found in the distribution of the median netve, most often impaired two-point discrimination, pinprick and light touch sensation, or occasionally hyperesthesia, with sparing of the thenar eminence. Thenar (abductor pollicis brevis muscle) weakness and atrophy-may be present with prolonged entrapment (Figure 82.6). The syndrome is frequently bilateral and usually of greater intensity in the dominant hand. A positive Tinel's sign, in which percussion of the nerve at the carpal tunnel causes paresthesias in the distribution of the distal distribution of the median nerve, is present in approximately 60% of affected patients, but is not specific for carpal tunnel syndrome. Flexing the patient's hand at the wrist for 1 minute (Phalen's maneuver) or hyperextension of the wrist (a reversed Phalen's maneuver) can reproduce the symptoms. Carpal tunnel syndrome may alter sensory hand somatotopy in the parietal cortex.

Work-related wrist and hand symptoms (repetitive motion injury) from cumulative trauma in the workplace

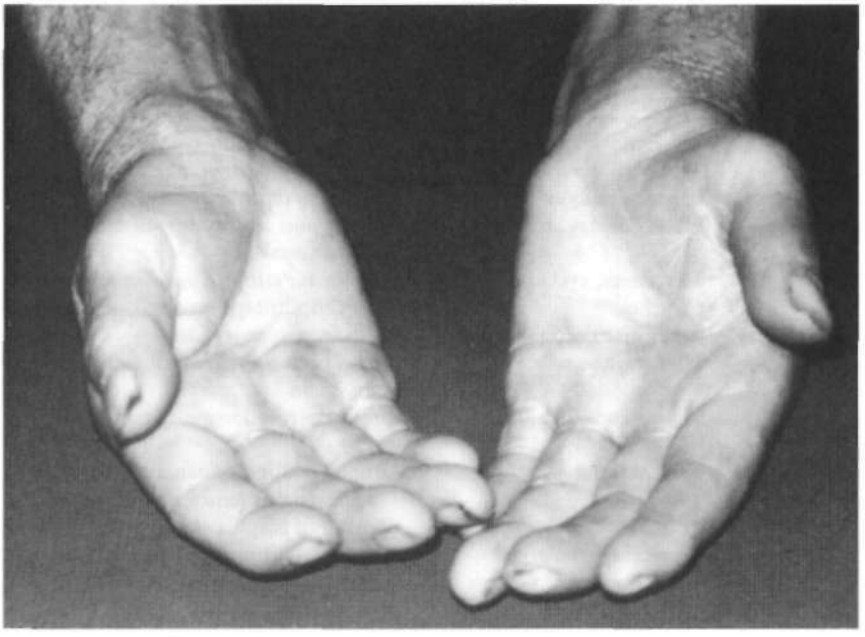

FIGURE 82.6 Thenar atrophy in chronic bilateral carpal tunnel syndrome.

have received increasing attention by the general public in recent years (Thomsen et al. 2002). Although a proportion of these cases have bona fide carpal tunnel syndrome, longitudinal natural history data suggest that the majority of industrial workers do not develop symptoms of carpal tunnel syndrome (Nathan ct al. 1998), Symptoms consistent with hand and wrist arthritis in a variety of occupational settings are now recognized as being much more common than complaints suggesting carpal tunnel syndrome (Dillon, Petersen, and Tanaka 2002). Carpal tunnel syndrome appears to occur in work settings that include repetitive forceful grasping or pinching, awkward positions of the hand and wrist, direct pressute ovet the carpal tunnel, and the use of handheld vibrating tools. Increased risk for the syndrome has been found in meat packers, garment workers, butchers, grocery checkers, electtonic assembly workers, musicians, dental hygienists, and housekeepers. The highest reported incidence of work-related carpal tunnel syndrome based on the number of carpal tunnel surgeries performed was 15% among a group of meat packers (Dawson 1993). Although computer keyboard use has long been thought to be related to developing carpal tunnel symptoms, recent data suggest that there is no convincing correlation between intensive keyboard use and the subsequent development of median neuropathy at the wrist (Stevens et al. 2001), This study found an overall prevalence of carpal tunnel syndrome of 3.5% in the study population, which is similar to that found for the general population by others {Papanicolaou, McCabe, and Firrell 2001).

The most sensitive electrodiagnostic test for carpal tunnel syndrome is the median nerve sensory conduction study, which exhibits a delayed sensory latency across the wrist in 70-90% of patients. Recording the latency at short distances over the course of the median nerve from palm to wrist and comparing this latency with the latency for the ulnar nerve at the same distance (palmar nerve conduction studies) can increase the sensitivity of sensory conduction studies (Stevens 1997). Most cases with moderate to severe involvement have prolonged median nerve distal motor latency. Some patients with carpal tunnel syndrome have significantly narrower-than-averagc carpal canals.

Diseases and conditions that have been found to predispose to the development of carpal tunnel syndrome include pregnancy, diabetes, obesity, age, rheumatoid arthritis, hypothyroidism, amyloidosis, gout, acromegaly, certain mucopolysaccharidoses, arteriovenous shunts for hemodialysis, old fractures at the wrist, and inflammatory diseases involving tendons or connecrive tissues at the wrist level (Becker ct al. 2002). On rare occasions, carpal tunnel syndrome may be familial.

Mild carpal tunnel syndrome must be distinguished from early median nerve involvement in polyneuropathy; occasionally the two conditions coexist.

In cases with only mild sensory symptoms, treatment with splints in neutral position, nonsteroidal anti-inflammatory agents, and local corticosteroid injection often suffice. Although nonoperative treatments have been advocated (Osterman, Whitman, and Porta 2002), a comparison of splinting versus surgery suggested that the latter may have a better longterm outcome than the former (Gerritsen et al. 2002). Evidence for the use of oral pyridoxine for carpal tunnel syndrome is conflicting at best and comes with the risk of toxic sensory polygauglionopathy (see Toxic Neuropathies, larer in this chapter). Use of a range of devices and appliances to protect the band against carpal tunnel syndrome, including gel-padded gloves, has shown little if any improvement in objective measures of nerve function. Severe sensory loss and thenar atrophy suggest the need for surgical carpal tunnel release. Although open surgical sectioning of the volar carpal ligament is still performed by some surgeons, the procedure is increasingly being approached using fiberoptic techniques, often resulting in more than 90% of patients having prompt resolution of pain and paresthesias {Mirza and King 1996), Improvement in distal latencies may lag behind the relief of symptoms. Comparing with preoperative values, nerve conduction studies demonstrate improveineur in those with moderate abnormalities preoperatively, whereas patients with severe or no abnormalities on baseline nerve conduction studies had poorer results (Bland 2001). A correlation between patients seeking workers' compensation who hire attorneys and poorer operative outcomes has also been reported (Katz J. N. et al. 2001). Older individuals may not improve as much as younger patients (Porter et a I. 2002), and factors such as poor mental health, significant alcohol consumption, longer disease duration, and male gender also portend a poorer outcome. Rarely, symptoms persist after operation. Poor surgical results usually are associated with incomplete sectioning of the transverse ligament, surgical damage of the palmar cutaneous branch of the median nerve by an improperly placed skin incision, scarring within the carpal tunnel, or an incorrect preoperative diagnosis. Surgical re-exploration may be required in diagnostically certain cases with poor response to the initial operation (Steyers 2002).

Other Entrapment Syndromes of the Median Nerve

Anterior Interosseous Nerve Syndrome. The anterior interosseous nerve is a pure motor branch of the median nerve that supplies the flexor pollicis longus, pronator quadrants, and flexor digitorum profundus muscles of the index and middle fingers. In the relatively rare anterior interosseous nerve syndrome, rhe nerve may be compressed by fibrous bands attached to the flexor digitorum superficialis muscle. Isolated involvement of this nerve more often occurs spontaneously in the context of a partial idiopathic brachial plexus neuropathy (Parsonage-Turner syndrome) or less commonly as a restricted form of multifocal motor neuropathy with conduction block. Patients often complain of pain in the forearm or elbow. The clinical manifestations

of an anterior interosseous nerve lesion include the inability to fk-x ilk- Ji.sUl dialings ol the thumb .11111 index finger. This makes it impossible to form a circle with those fingers. Nerve conduction study results of the median nerve are normal. In;: the -rotor latency from dhow to *r\-.s* pronator quadratus muscle is often prolonged, EMG is necessary to document denervation in muscles innervated by the anterior interosseous nerve.

Spontaneous recovery usually occurs, and therefore surgery may not be necessary unless penetrating injury, fracture, or progressive deterioration and weakness is detected.

Pronator Teres Syndrome. In the pronator teres syndrome, the median nerve is compressed in the proximal forearm between the two heads of the pronator teres muscle, a fibrous arcade of the flexor digitorum superficialis muscle, or the lacertus fibrosus. This entrapment may develop in individuals engaged in repetitive pronating movements of the forearm. Patients complain of paresthesias and numbness of the radial fingers, as well as pain and tenderness in the proximal forearm that is increased by resistance to pronation. Weakness of the flexor pollicis longus and abductor pollicis brevis is demonstrated, whereas pronation of the forearm is normal. Nerve conduction study results of the median nerve may sometimes show slowing in the elbow-wrist segment. In contrast to the carpal tunnel syndrome, the distal median motor and sensory latencies at the wrist are normal. Injection of corticosteroids into the pronator teres muscle and immobilization often provide relief of symptoms, but on occasion surgery may be necessary,

Median Nerve Entrapment at the Ligament of Struthers. A supracondylar spur of the humerus is present in a small proportion of normal individuals. A fibrous band, the ligament of Struthers, extends from this spur to the medial epicondyle and may compromise the median nerve along with the brachial artery. Clinical symptoms resemble the pronator teres syndrome, but the radial pulse diminishes when the forearm is fully extended in supination because of the concomitant entrapment of the brachial artery, Electrodiagnostic studies may allow differentiation from the pronator teres syndrome, because the ligament of Struthers syndrome involves the pronator teres muscle.

Ulnar Nerve Entrapment

Ulnar Nerve Entrapment at the Elbow. Ulnar mononeuropathy is the second most common entrapment or compression mononcuropathy, although it is considerably less common than carpal tunnel syndrome. Ulnar neuropathies at the elbow are caused by direct compression in the retrocondylar groove or entrapment as the nerve passes through the cubital tunnel, a fibro-osseous canal, the floor of which is formed by the medial ligament of the elbow joint, and the roof by the aponeurosis of the flexor carpi ulnaris muscle (Khoo, Carmichael, and Spinner 1996), The term *tardy ulnar palsy* is applied to an ulnar nerve lesion developing years after elbow trauma (usually fracture of the humerus). Other possible sources of injury of the ulnar nerve at the elbow include direct compression following general anesthesia while the patient recovers in bed (Stewart and Shantz 2003) or periods of unconsciousness, repetitive chronic trauma, and arthritis of the elbow joint. Symptoms and signs sometimes attributed to ulnar neuropathy after coronary bypass surgery are most often the result of stretch injury to the lower trunk of the brachial plexus. Ulnar nerve lesions at the elbow cause weakness of the flexor carpi ulnaris, flexor digitorum profundus of the ring and little fingers, and the intrinsic hand muscles. Pinch strength is reduced by weakness of adductor pollicis, flexor pollicis brevis, and first dorsal interosseous muscles. As a compensatory maneuver during attempted pinch of the thumb and index fingers, the flexor pollicis longus, a median nerve-innervated muscle, is used involuntarily and flexes the distal phalanx of the thumb (Fromcnt's sign). Weakness of the interossei muscles results in inability to produce a forceful extension of the interphalangeal joints as used in finger-flicking movements. Prominent atrophy of the first dorsal interosseous muscle ensues, together with clawing of the fourth and fifth fingers, the result of lumbrical weakness with secondary hyperextension of the metacarpophalangeal joints. The small muscles of the hand are always more severely involved than the forearm muscles (length-dependency or "dying-back" pattern). Sensory loss or hypesthesia involves the fifth finger, part of the fourth finger, and the hypothenar eminence and extends to the dorsum of the hand. Electrodiagnostic tests are useful in localizing the entrapment at the elbow. Focal slowing or localized reduction in the CMAP amplitude may be found in the elbow segment in more than 75% of cases (Azrieli et al. 2003). In the remaining patients localization is less precise because of predominant axonal loss.

Conservative treatment should be attempted in patients with mild symptoms or in those with symptoms brought on by occupational causes. Avoidance of repetitive elbow flexion and extension or direct pressure on the elbow may alleviate the symptoms. Elbow protectors are helpful in patients with a history of excessive elbow leaning. Conservative treatment should be continued for at least 3 months before surgery is considered. Surgical approaches to the ulnar nerve lesion at the elbow include simple release of the flexor carpi ulnaris aponeurosis, anterior transposition of the netve trunk, and resection of the medial epicondyle. The choice of procedure should be tailored to the specific lesion found at surgery. Only approximately 60% of patients benefit from surgery, and some experience worsening of symptoms.

Ulnar Nerve Entrapment at the Wrist in (he I Inar Tunnel (Guyon's Canal). Distal to the wrist, the ulnar nerve

enters Guyon's canal, which is formed between the pisiform bone and the hook of the hamate, covered by the volar carpal ligament and the palmaris brevis muscle. Within Guyon's canal the ulnar nerve divides into its terminal deep and superficial branches. Depending on the exact location of entrapment, motor or sensory impairment may occur alone or in combination. Because the palmar cutaneous branch leaves the ulnar nerve proximal to the wrist and does not enter Guyon's canal, sensory loss is confined to the palmar surface of the ulnar-innervatcd fingers. Ulnar nerve entrapment in Guyon's canal occurs much less frequently than at the elbow. The usual cause is chronic or repeated external pressure by tools, bicycle handlebars, the handles of canes, or excessive push-ups. Compression also may be caused by degenerative wrist joint ganglia, rheumatoid arthritis, or distal vascular anomalies. The diagnosis is confirmed with prolonged distal motor latencies to the first dorsal interosseous or abductor digiti minimi muscles and when denervation is documented in ulnar-innei vated hand muscles. MR] through Guyon's canal may demonstrate a structural lesion if compressive trauma is not the cause; in such cases surgical exploration may be tequired.

Radial Nerve Entrapment

Radial nerve compression in the axilla may result from crutches or from the weight of a sleeping partner's head (honeymoon palsy) or may occur at the spiral groove of the humerus during drunken sleep wherein the arm is draped over a chair (Saturday night palsy) (Spinner, Poliakoff, and Tiel 2002). Lesions at the axilla are characterized by weakness of the triceps brachii, brachioradialis, supinator, and extensor muscles of the wrist and fingers. If compression occurs in the spiral groove of the mid-upper arm, the triceps brachii is spared, resulting in weakness confined to the brachioradialis, wrist, and finger extensors. Minimal sensory abnormalities may occur over the dorsum of the hand, thumb, index finger, and middle finger. Radial nerve lesions caused by pressure usually improve in 6-8 weeks. This compression neuropathy must be differentiated from radial nerve injury caused by fractures of the humerus. The radial nerve is often involved in isolation or in combination with other single nerves in multifocal motor neuropathy with conduction block.

Posterior Interosseous Nerve Syndrome. The posterior interosseous nerve, or deep radial nerve, is a pure motor branch of the radial nerve in the forearm. Before entering the supinator muscle, the radial nerve supplies the brachioradialis, extensor carpi radialis longus and brevis, and supinator muscles. The rest of the extensor muscles, including the extensor carpi ulnaris, are innervated by the posterior interosseous nerve. The nerve appears most vulnerable to entrapment at the level of the supinator muscle. This uncommon syndrome occurs in association with rheumatoid arthritis, trauma, fracture, soft tissue masses, or strenuous use of the arm. The clinical manifestations of a posterior interosseous nerve lesion are an inability to extend the fingers at the metacarpophalangeal joints and radial deviation of the wrist on wrist extension caused by the weakness of the extensor carpi ulnaris muscle. EMG confirms the diagnosis by demonstrating denervation in the muscles supplied by the posterior interosseous nerve with sparing of more proximal radial-inncrvatcd muscles.

In rheumatoid arthritis, local injection of corticosteroids may be helpful. If the syndrome is progressive, surgical exploration, including synovectomy or decompression of the posterior interosseous nerve, may become necessary (Shergill et al. 2001).

Cheiralgia Paresthetica. A mononeuropathy of the superficial dorsal sensory branch of the radial nerve occurs as a result of trauma from tight wristbands or handcuffs and is called cheiralgia paresthetica. Paresthesias and pain in the distribution of the superficial sensory branch of the radial nerve characterize this benign, self-limiting condition. The symptoms can be aggravated by ulnar flexion of the hypcrpronated forearm. A small area of hypoesthesia in the dorsoradial aspect of the hand is frequently identified. Nerve conduction study results can show a low amplitude or absent dotsal radial SNAP.

Musculocutaneous Nerve Entrapment

The musculocutaneous nerve arises from the upper and middle trunks of the brachial plexus, penetrates the coracobrachialis muscle, and courses down the anterior aspect of the upper arm berween the two muscles it innervates, the biceps brachii and brachialis. Although most often involved in idiopathic brachial plexus neuropathy, this nerve also may be damaged with shoulder dislocations, following genetal anesthesia, or with vigorous exercise such as weight lifting. In carpet carrier's palsy, the nerve is compressed by repetitive carrying of heavy objects on the shoulder that arc held in place by the arm (Sander et al. *1997).* The differential diagnosis includes *C6* radiculopathy, restricted brachial plcxopathy, and rupture of the biceps tendon.

Clinically, patients with musculocutaneous mononeuropathy present with weakness and atrophy of the biceps brachii and brachialis muscles, diminished biceps brachii reflex, and sensory loss over the lateral aspect of the forearm anteriorly. EMG demonstrates denervation limited to the biceps brachii and brachialis muscles. Nerve conduction studies show a reduced musculocutaneous biceps CMAP and a low-amplitude lateral antebrachial cutaneous sensory response.

Spontaneous recovery is the rule. Local corticosteroid injection may provide some relief of pain. Surgical decompression is contemplated if no improvement occurs.

Suprascapular Nerve Entrapment

The suprascapular nerve is a pure motor branch of the upper trunk of the brachial plexus, which passes through the suprascapular notch to innervate the supraspinatus and infraspinatus muscles. Entrapment occurs after repetitive forward traction of the shoulders. This nerve also may be involved in a restricted form of idiopathic brachial plexus neuropathy. Diffuse aching pain in the posterior aspect of the shoulder is a cardinal symptom. Atrophy and weakness are confined to the infraspinatus and supraspinatus muscles. Slow and steady abduction of the arm starting from a vertical position alongside the chest is not possible with a severe lesion of the suprascapular nerve. 1 endoil ruptures of the rotator cuff need to be considered in the differential diagnosis. FMG shows denervation restricted to the supraspinatus and infraspinatus muscles. Local corticosteroid injection may give temporary relief of pain, although surgery is sometimes required (Antoniou et al. 2001).

Intercostobracbial Nerve Syndrome

The intercostobrachial nerve is a cutaneous sensory nerve derived from the second and third thoracic nerve roots and supplies the skin on the medial surface of the upper arm and axilla as well as the adjacent chest wall. It may be injured in modified radical mastectomy and other surgical procedures involving the axilla and lateral pectoral tegion (Wallace et al, 1996).

Neurogenic Thoracic Outlet Syndrome

Neurogenic thoracic outlet syndrome with objective neurological deficits is very rare, and the diagnosis is usually incorrect.

Lower Extremities

Entrapment neuropathies of lowet limbs arc shown in Table 82.12.

Sciatic Nerve Lesions

The sciatic nerve consists of two distinct nerves, the posterior tibial and the common fibular (peroneal) nerves, which share a common sheath from the pelvis to the popliteal fossa. The ^L:,uic nerve is occasionally vulnerable to entrapment as it crosses over the sciatic notch leaving the pelvis. Most sciatic nerve lesions result from trauma, such as fracture dislocations, hematomas in the posterior thigh compartment, intramuscular injections, and complications of hip replacement surgery (Plewnia, Wallace, and Zochodne 1999). Recurrent sciatic mo no neuropathy may be caused by endometriosis involving the nerve at the sciatic notch. Direct compression of the sciatic nerve is rare but occasionally occurs during coma, anesthesia, or prolonged sitting on a hard surface (toilet scat palsy). Either or both divisions of tile nerve may be compressed by a Baker cyst in the popliteal fossa,

A complete sciatic nerve lesion results in weakness of knee flexors and all muscles below the knee, as well as sensory loss of the entire foot except for the small region supplied by the saphenous nerve over the medial malleolus. The fibular division is more commonly involved than the posterior tibial in proximal lesions of the sciatic nerve and may mimic a common fibular neuropathy. In such patients, evidence of denervation in the short head of the biceps femoris and posterior tibialis muscles and abnormal sural or medial plantar SNAPs help localize partial proximal sciatic nerve lesions (Yuen and So 1999). On rare occasions, the pyriformis muscle may entrap the sciatic nerve trunk as it passes through or over the pyriformis muscle (the pyriformis syndrome). However, this clinical picture is almost always the result of lumbosacral root, sacral plexus, or sciatic nerve damage at other locations.

Common Fibular (Peroneal) Nerve Entrapment

Entrapment of the common fibular (peroneal) nerve is the most frequent entrapment neuropathy in the leg. Because of confusion between the terms *peroneal* and *perineal,* the Federative Committee on Anatomic Terminology has renamed the peroneal nerve the *fibular nerve.*

This nerve is particularly vulnerable in the region of the fibular neck as it passes through the origin of the fibularis (pcroneus) longus muscle. Near this opening, the nerve divides into three main terminal divisions: the superficial, deep, and accessory fibular nerves. A common fibular nerve lesion leads to weakness of foot **and** toe extension **and** foot eversion, wirh a footdrop and steppage gait. Sensory impairment is found over the lateral aspect of the lower leg and the dorsum of the foot. Direct pressure to the fibular head area, habitual leg crossing, weight loss, or a recurrent stretch injury as a result of an unstable ankle causing excessive foot inversion may result in fibular neuropathy. Improperly applied plaster casts or unrecognized pressure on the nerve in debilitated or unconscious patients may also be responsible for this nerve injury.

Fibular mononeuropathy needs to be differentiated from anterior tibial compartment syndrome, in which the deep fibular nerve is compressed by muscle swelling within the anterior compartment, caused by injury, heavy exercise, trauma, or ischemia. This results in an acute syndrome of severe lower leg pain, swelling, and weakness of foot and toe extensors. The anterior tibial compartment must be decompressed rapidly by fasciotomy to prevent irreversible nerve and muscle damage.

Electrodiagnostic studies are useful for localizing lesions and may provide clues to the underlying cause and a guide to prognosis. Although it is often possible by nerve

conduction studies to demonstrate focal conduction block or localized slowing in the region of the fibular head, contrary to common belief, the mosr frequent patho-physiological process is axonal loss regardless of the cause. EMG is important to exclude other sites of injury such .is the sciatic nerve, lumbosacral plexus, and L5 nerve root.

The prognosis is uniformly good in cases of acute compression, whereas recovery is delayed in those with stretch injuries. Bracing with a custom-made plastic ankle-foot orthosis is necessary to improve the gait in the presence of severe footdrop. The few patients who do not improve spontaneously after 3 months, or those who have pain or a slowly progressive fibular nerve lesion, may require MRI studies and surgical exploration (Kim and Kline 1996).

Posterior Tibial Nerve Entrapment (Tarsal Tunnel Syndrome)

Entrapment of the posterior tibial nerve occurs behind and immediately below the medial malleolus. In this region, the laciniate ligament covers the tarsal tunnel through which the nerve passes together with the tendons of the tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles, as well as the posterior tibial artery and veins. Burning pain occurs in the toes and the sole of the foot. If the calcaneal sensory branches are involved, pain occurs at the heel. Examination usually reveals plantar sensory impairment and wasting of the intrinsic foot muscles. Percussion at the site of nerve compression or eversinn of the foot may elicit pain and paresthesia. Electrodiagnostic study results should confirm the entrapment of the posterior tibial nerve at the tarsal tunnel by demonstrating mvolvcmenl til motor fibers to the abductor digiti minimi and abductor hallucis muscles as well as involvement of the medial and lateral plantar sensory fibers with sparing of the sural nerve. EMG is important to exclude involvement of muscles proximal to the foot such as the gastrocnemius muscle. The majority of suspected cases of tarsal tunnel syndrome turn out to have generalized peripheral neuropathy, SI radiculopathy, or non-neurological foot pain. Electrodiagnostie findings arc sometimes complicated by previous failed surgical procedures in the foot that may have injured the nerves of interest.

Local injection with corticosteroids underneath the laciniate ligament may temporarily relieve the symptoms. Surgical decompression is needed for permanent results in those rare cases m which objective evidence of this syndrome exists.

Sural Nerve Lesions

Although the vast majority of sural nerve lesions are iatrogenic as the result of diagnostic sural nerve biopsy, mononeuropathy of the sural nerve has been reported with a number of other conditions including lower limb vein stripping surgery, Baker's cyst surgery, local trauma, tightly laced high-topped footwear such as ski boots or ice skates, and rarely as the initial presentation of vasculitic mononeuriris multiplex.

Femoral Nerve Lesions

Femoral mononeuropathy is rare but may occur as the result of direct trauma or acute compression rather than from chronic entrapment.

Lateral Femoral Cutaneous Nerve Entrapment (Meralgia Paresthetica)

The lateral femoral cutaneous nerve, which is a pure sensory nerve, passes medial to the anterior superior iliac spine under the inguinal ligament to enter the thigh under the fascia lata and supplies the skin of the anterolateral part of the thigh. The site of entrapment is usually at the level of the inguinal ligament. Rarely, the nerve can be affected in its proximal segment by retroperitoneal tumors or be injured during appendectomy. The disorder is most often seen in association with obesity but may occur with enlargement of the quadriceps muscles from increased exercise and from pregnancy, ascites, or other conditions that increase intra-abdominal pressure. Direct compression by a belt or corset, fracture of the anterior portion of the ilium, or pelvic tilt causing undue stresses on the abdominal musculature are other causes. Patients develop numbness, painful burning, and itching over the anterolateral thigh. Pressure at the inguinal ligament medial to the anterior superior iliac spine elicits referred pain and dysesthesias.

Electrophysiological study results of the femoral nerve and quadriceps femoris muscle are normal, which helps to exclude lumbar radiculopathy.

A local anesthetic nerve block may have diagnostic value. Trcarmcnt consists of symptomatic measures such as rest, analgesics, and weight loss. Postural abnormalities should he corrected. Neurolysis is rarely beneficial.

Ilioinguinal Nerve

The ilioinguinal nerve is analogous to an intercostal nerve. Muscle branches innervate the lower portion of the transverse abdominal and internal oblique muscles. The cutaneous sensory nerve supplies the skin over the inguinal ligament and the base of the scrotum or labia. As the nerve takes a zigzag course, passing through the transverse abdominal and internal oblique muscles, it is subject to mechanical irritation. Pain is referred to the groin, and weakness of the lower abdominal wall may result in the formation of a direct inguinal hernia. Trauma, surgical procedures, and scar tissue are frequently responsible. Increased abdominal muscle tone, caused by abnormal

posture as seen in chronic back pain or Parkinson's disease, also can result in this neuropathy.

Conservative treatment includes rest and nonsteroidal anti-inflammatory agents. Neurolysis may be required in refractory cases when a mechanical lesion is suspected.

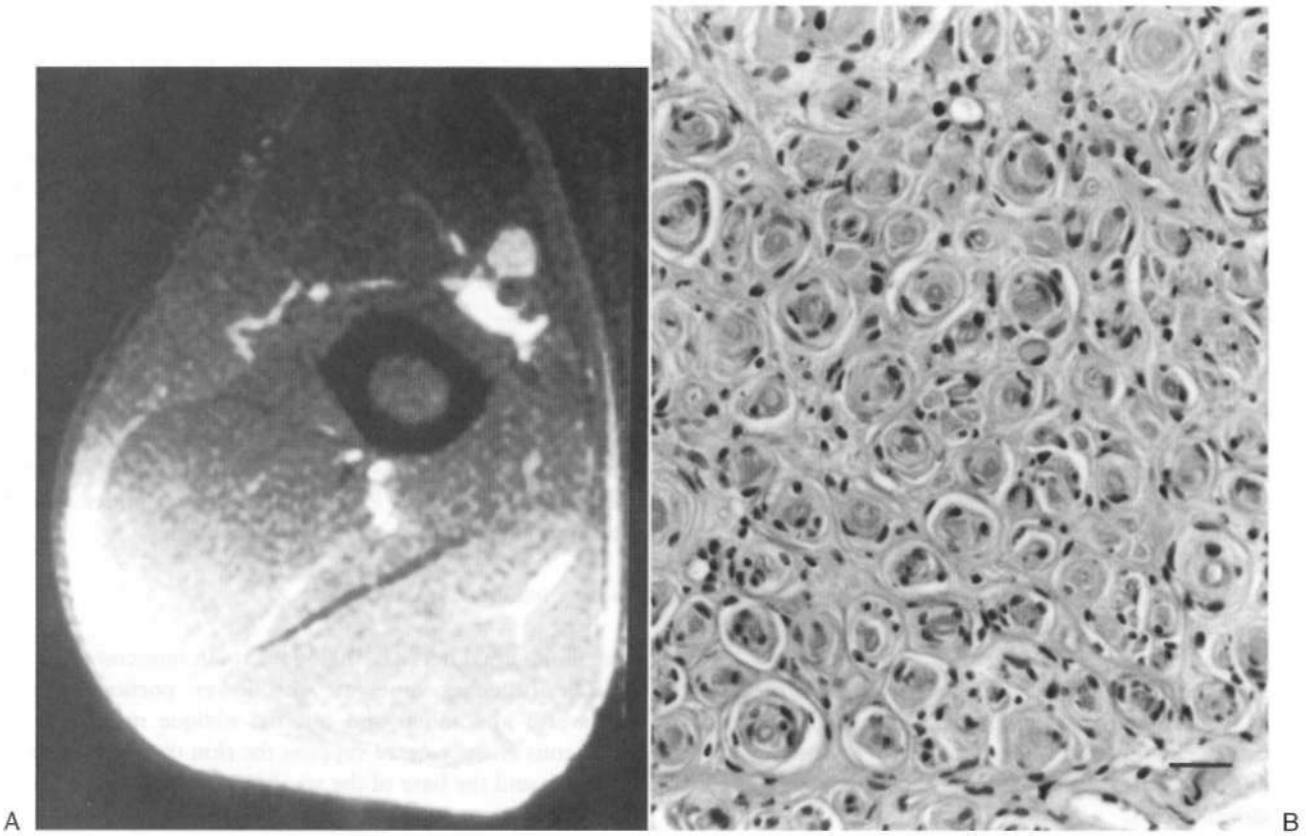
Obturator Nerve

The obturator nerve is vulnerable to entrapment as it passes through the obturator canal, for instance, by an obturator hernia or osteitis pubis. It is most often associated with pelvic malignancies (prostate, cervical, or uterine cancers), but can also be seen as a surgical complication, with trauma, and m the sctiing of diabetes mellitus. The entrapment produces radiating pain from the groin down the inner aspect of the thigh. There is weakness of hip adduction and sensory impairment in the upper medial thigh. Many patients appear to have hip-flexor weakness as a false localizing sign. Although this phenomenon may be explained by pain, it is more likely due to mechanical disadvantage of the hipflexors in the presence of weak thigh adductors, CT or MRI scanning of the pelvis is helpful in finding primary or metastatic pelvic tumors (Rogers et al. 1993).

This entrapment neuropathy is treated conservatively. If such treatment fails, or if symptoms progress to involve other nerves in the region, careful search for occult pelvic or retroperitoneal malignancy must be pursued.

Localized Perineurial Hypertrophic Mono neuropathy

A slowly progressive painless mononeuropathy that cannot be localized to entrapment sites and is caused by a focal fusiform enlargement of the affected nerve, termed *localized hypertrophic neuropathy,* is an uncommon condition affecting young adults (Simmons et al. 1999). The fusiform enlargement is mainly composed of "onion bulb-like whorls" formed by layers of perineurial cells (Figure 82.7B). The lamellae of the whorls stain for epithelial membrane antigen. The cause of the perineurial cell proliferation is not known. The condition may involve any major nerve trunk but is seen more frequently in the upper limbs, particularly the posterior interosseous nerve.



I•I(il."Ki' S2.7 (A) Axial magnetic resonance imaging of the right upper arm 10 cm proximal to the epicondyles demonstrates a focal enhancing enlargement of the median nerve after gadolinium administration. The fusiform enlargement of the nerve extended approximately 4 cm in length and measured 7 mm in diameter at its greatest thickness on serial axial cuts. (B) Fascicular biopsy specimens of the enlarged median nerve segment shows numerous onion bulb-like structures. By immunochemistry, the onion bulbs consist of epithelial membrane antigen-positive cells, confirming their perineurial cell origin. (Hematoxylin and eosin; original magnification *xSO;* bar = 20 |im.) (Courtesy Dr. P. J. Uyck, Mayo Clinic, Rochester, MN.)

It typically results in painless, slowly progressive weakness and atrophy in the distribution of the affected nerve, Sensory symptoms arc minor, although sensory nerve fibers are obviously involved. Electro diagnostic study results show an axonal mononeuropathy and help in the precise localization of the focal nerve lesion. MRI shows a focal enlargement of the affected nerve, increased signal on 12 weighted images, and enhancement with gadolinium (Figure 82.7A).

Surgical exploration and a fascicular biopsy by a surgeon experienced in peripheral nerve microsurgery confirm the diagnosis and excludes malignant peripheral nerve sheath tumors, which can be difficult to exclude on clinical grounds alone. Surgical resection of the involved nerve segment with graft repair offers the possibility of some recovery in selected cases (Gruen, Mitchell, and Kline 1998).

HEREDITARY NEUROPATHIES

The hereditary neuropathies constitute a complex, heterogeneous group of diseases, which frequently shate insidious onset and indolent course over years to decades. The number of such disorders in which the metabolic deiec. is known, such as in familial amyloid neuropathies, Refsum's disease, Fabry's disease, porphyria, hypolipoproteinemias, and many forms of CMT disease, is increasing rapidly. i or other inherited neuropathies classification still depends on clinical phenotype, mode of inheritance, and class of neurons predominantly affected. These conditions include hereditary motor neuropathy or spinal muscular atrophy (see Chapter 80), hereditary motor and sensory neuropathy, and hereditary sensory and autonomic neuropathy (HSAN). Major advances in understanding the molecular basis of inherited neuropathies have come from identifying chromosomal loci or causative genes for a given disease phenotype. These investigations have led to the discovery of 15 genetic loci and an ever increasing number of genes, each of which codes for a specific gene product (including PMP-22, myelin protein zero [P_0], connexin-32, the early growth response gene-2, and the periaxin gene), all of which are essential to myelin function (Lupski 1998; Kamholz et al. 2000; Berger, Young, and Suter 2002),

Hereditary neuropathies are common disorders, the inherited nature of which may remain unrecognized in a surprisingly large percentage of patients. Eliciting historical evidence of long-standing neuromuscular complaints, obtaining detailed family histories, looking for skeletal abnormalities such as hammer toes or high arches, and performing neurological evaluations in relatives arc means of identifying previously unsuspected inherited neuropathy. Spontaneously reported paresthesia is three times more common in acquired than in inherited neuropathies. The possibility of an inherited neuropathy cannot be dismissed even in the face of a truly negative family history. Such a situation may arise in cases of early death of one or both parents, few blood relatives, or autosomal recessive disease. Available diagnostic DNA testing shows that one third of isolated cases may result from *de novo* gene mutations (Boerkoel et al. 2002).

Charcot-Marie-Tooth Disease (Hereditary Motor and Sensory Neuropathy)

The syndrome of peroneal muscular atrophy or CMT disease was first described in the second half of the nineteenth century by Charcot and Marie in Paris, and Tooth m London. CMT disease is the most common inherited neuropathy, with an estimated prevalence of 1 in 2500 in the United States. Clinical studies combined with electrophysiological and sural nerve biopsy investigations of a large number of families with peroneal muscular atrophy allowed a separation into two main groups: (1) the hypertrophic or dcmyelinating form of CMT disease or CMT1, also referred to as hereditary motor and sensory neuropathy (HMSN) type I, in which there is marked reduction in motor NCVs and nerve biopsy findings of demyelination and onion bulb formation; and {2) the axonal form of CMT disease (CMT2), or HMSN type II, in which motor NCVs arc normal or near normal, with nerve biopsy findings of axonal loss without dcmyclination (Harding 1995). The peroneal muscular atrophy phenotype without sensory involvement on either clinical or electrophysiological examination has been classified as hereditary distal spinal muscular atrophy. In addition to CMT types 1 and 2, there are rare cases of severe demyelinating neuropathy with onset in early childhood that are referred to as *Dejerirte-Sottas disease.*

Both CMT1 and CMT2 display autosomal dominant inheritance. A minoriry of cases occur sporadically or in siblings only and have therefore been attributed to autosomal recessive inheritance or to *de novo* gene mutations. Because a great variability in clinical expression exists among affected kin in the dominant disotders, a recessive inheritance can only be accepted after clinical and electrophysiological examinations of both parents have proved to be normal; even then nonparental conception and new mutations have to be considered. CMT with X-linked inheritance (CMTX) phenotypically resembles CMT1.

Charcot-Marie-Tooth Disease I

In CMT I, symptoms often begin during the first or second decade of life. Presenting symptoms include foot deformity *And* difficulties in running or walking. Symmetrical weakness and wasting is found in intrinsic foot, peroneal, and anterior tibial muscles. Similar distal involvement of the upper limbs develops later in two thirds of patients. Inspection reveals pes cavus and hammer toes in nearly 75% of adult patients; mild kyphosis in approximately

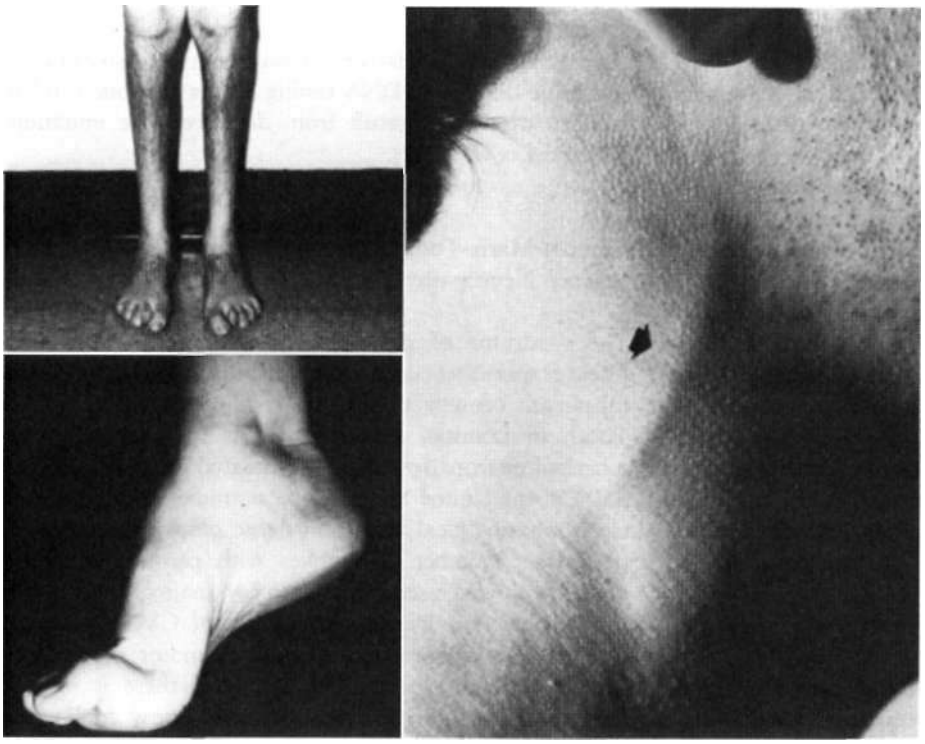


FIGURE 82.8 I eg atrophy, pes cavus, and enlarged great auricular nerve *(arrow)* are evident in a patient with Chare or-Marie-Tooth type 1 disease.

10%; and enlarged, hypertrophic peripheral nerves in as many as *25%* (Figure 82.8). Absent ankle reflexes are universal and frequently are associated with absent or reduced knee and upper limb reflexes. Some degree of distal sensory impairment (diminished vibration sense and light touch in feet and hands) is usually found by examination, lint *rwrcW* ;'jvvs rise m symptoms. Occasionally, paiienis have an essential or postural upper limb tremor. Such cases have been referred to as *Roussy~Lei/y syndrome,* although convincing evidence suggests that this is not a separate clinical or genetic syndrome. Severity in affected kin varies considerably. Approximately 10% of patients arc asymptomatic but have slowing of NCVs. At the other end of the clinical spectrum, there are patients with severe neurological deficits who may become wheelchair dependent.

Motor nerve conduction studies show uniform slowing by more than 25% of the lower limits of normal in all nerves. Motor conduction of upper limb nerves proves more useful than studies of lower limb extremity nerves because distal fiber degeneration in the legs is often complete. A conduction velocity below 38 m per second in the forearm segment of the median nerve is proposed as a cutoff value to distinguish between CMT disease types 1 and 2. In a prospective study of CMT1A, the median motor NCV was slowed to less than 43 m per second in all subjects with documented chromosome 17pl 1.2-12 duplications (Kaku et al. 1993). Sensory conductions are similarly abnormal. SNAPs are usually absent with surface recordings. Motor nerve conduction studies provide an early, age-independent, easily accessible marker for clinical involvement. Routine hematological, biochemical, and CSF studies provide normal results. Sural nerve biopsy typically shows the changes of a hypertrophic neuropathy characterized by onion bulb formation, increased frequency of fibers with demyelinated and remyehnated segments, an increase in endoneurial area, and loss of large myelinated fibers (Figure 82.9).

Charcot-Marie-Tooth Disease 2

CMT2 constitutes one third of all autosomal dominant CMT disease. Clinical symptoms begin later than in CMT1, most commonly in the second decade, but may be delayed until middle age or beyond. Foot and spinal deformities tend to be less prominent in CMT2. The clinical features closely resemble those of CMT1 but differ in that peripheral nerves are not enlarged and upper limb involvement, tremor, and general areflexia occur less frequently. However, in individual cases it is often impossible to determine the type of CMT disease on the basis of clinical findings alone. Approximately 20% of patients arc asymptomatic. CMT2B linked to chromosome 3q13 has prominent sensory loss with ulcerations (De Jotlghe et al. 1997). A distinct subgroup of severely affected patients, designated CMT2C, develop vocal cord, intercostal, and diaphragmatic muscle weakness. Because of respiratory failure, life expectancy is shortened in these patients (Dyck, Litchy, and Kratz 1994).

Motor NCV may be normal or mildly reduced. SNAPs are either absent or reduced in amplitude. Sural nerve biopsy specimens show preferential loss of large myelinated

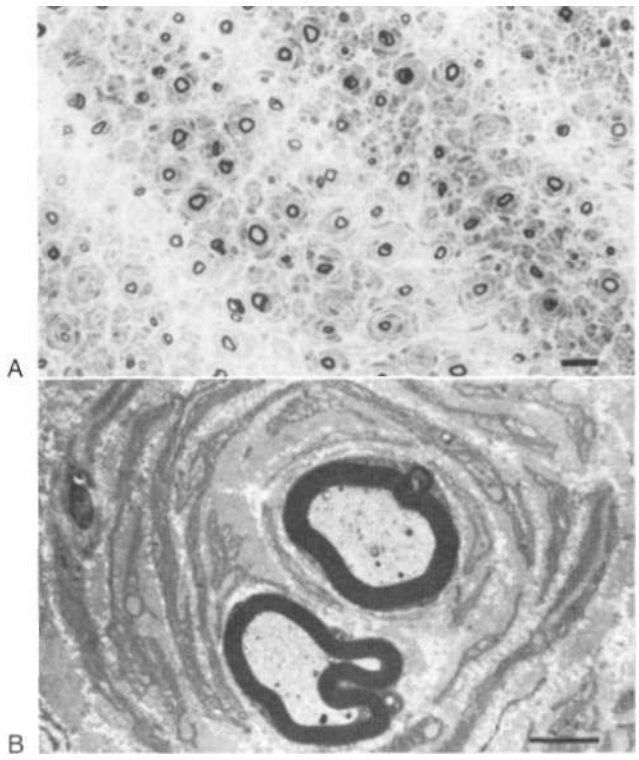

FIGURE *82.9* Chareot-Maric-Tooth disease type 1. (A) Semithin transverse section of sural nerve showing numerous onion bulbs. (Toluidine blue; bar = 20 urn.) fibers without significant demyelination; there may be clusters of regenerating myelinated fibers.

Linkage studies to identify the genes for CMT2 indicate that the disorder is genetically heterogeneous. CMT2 has been mapped to chromosomes 1 (lp35-36, designated CMT2A), 3 (3ql3-22, CMT2B), 7 (7pl4, CMT2D), and 12 (12q24, CMT2C) (Saito et al. 1997). Within the last few years the first gene defects (e.g., mutations of the neurofilament light chain, the kinesin superfamily, and specific myelin protein 0 gene mutations) have been identified in CMT2.

X-linked Charcot-Marie-Tootb Disease

CMTX is phenotypically similar to CMT1. Affected male subjects tend to be more severely affected, whereas affected females may have a mild neuropathy or be asymptomatic. No male-to-male transmission occurs. Transient ataxia, dysarthria, unci weakness associated with central nervous system (CNS) white matter abormalities on MRI studies have been described in patients when they returned from high altitude travel (Paulson et al. 2002). NCVs in men show significant slowing, whereas in women the slowing parallels the loss of CMAP amplitude. Brainstem auditory evoked responses are often abnormal,

Charcot-Marie-Tootb Disease 3 or Dejerme-Sottas Disease

CMT3, or Dejerine-Sottas disease (DSS), is an uncommon progressive hypertrophic neuropathy with onset in childhood. Motor development is delayed; proximal weakness, global areflexia, enlarged peripheral nerves, and severe disability are the rule. Although originally the disorder was thought to be autosomal recessive, the majority of cases are sporadic and in some instances have been shown to result from a new dominant mutation.

Motor conduction velocities arc severely slowed, often to less than 10 m per second. The CSF protein is frequently increased. Pathologically, pronounced onion bulb changes are associated with hypomyclination and myelinated fiber loss. Defective myelination is confirmed by an increased axon-to-fibcr diameter ratio. Cases of congenital hypomyeliuation neuropathy probably represent a variant of CMT3 at the far end of a spectrum of defective myelination. I >SS i-. miu^KLilK :II'UTU;.:,ITICUI:S .L11.i is caused bj differenl structural myelin protein and transcription factor gene mutations.

Charcot-Marie-Tootb Disease 4

CMT4 is an autosomal recessive neuropathy characterized by onset in early childhood and progressive weakness, leading to inability to walk in adolescence. NCV studies are slowed (20-30 m per second); CSF protein is normal. Nerve biopsy shows loss of myelinated fibers, hypomyclination, and onion bulbs. To date, 10 chromosomal loci and 5 genes are identified. Affected families of ethnic Tunisian background are linked to chromosome 8 (8q21.1) and designated CMT4A (Othmane et al. 1993).

Complex Forms of Cbarcot-Maric-Tooth Disease

A number of families with peroneal muscular atrophy exhibit additional features such as optic atrophy, pigmentary retinal degeneration, deafness, and spastic paraparesis. Cardiac involvement is encountered in occasional patients, but prospective family studies find no association between cardiomyopathy and CMT disease. A syndrome of CIDP responding to prednisone and immunosuppression has been reported in patients with inherited CMT disease, providing evidence that nongenetic factors may play a role in clinical expression of the mutant gene. Any patient with a hereditary neuropathy who suffers a recent rapid deterioration should be considered for a secondary CIDP.

KhilcciiUir Utt'a/Wi's of (barcnt Marie Tooth Disease and Related Disorders

Major advances have been made in recent years in the molecular genetics ol CMT or hereditary motor and sensory neuropathies (Figure 82.10; Kamhol/. et al. 2000;

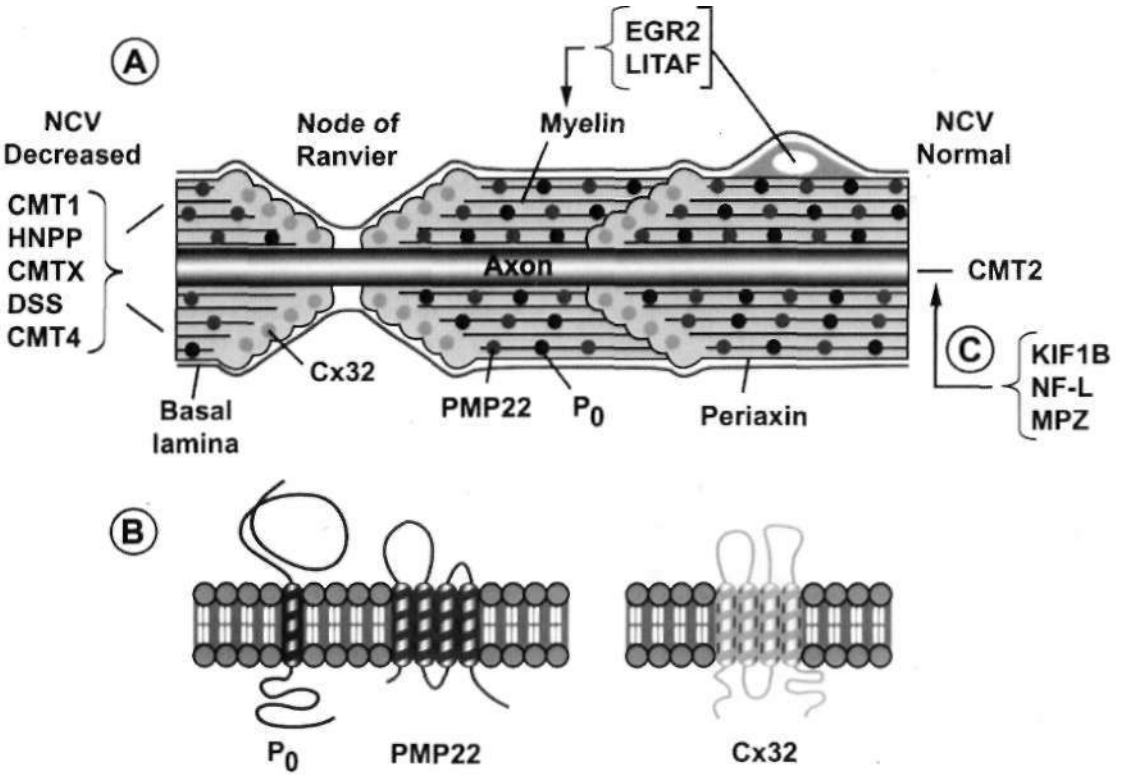

FIGURE 82.10 (A) Charcot-Marie-Tooth disease (CMT) and related disorders: CMT1, CMT with X-linked inheritance (CMTX), hereditary neuropathy with liability to pressure palsies (I INPP), Dejerine-Sottas syndrome (DSS), and CMT4 are inherited disorders of myelin. CMT2 is a primary axonal disorder. Alterations in dosage of peripheral myelin protein-22 (PMP-22) gene account for the majority of patients with CMT1A and HNPP. (B) Point mutations of these genes (connexin-32 [Cx32], myelin protein zero |MPZ, P_0], PMP-22, EGR2, periaxin) result in CMTX, CMT1B, CMT1A, DSS, and CMT4. Mutations of the LITAF gene result in CMT1C. (C) Point mutations of the KTF1B and NF-L genes and specific MPZ missense mutations result in CMT2. (NCV = nerve conduction velocity.) (Adapted with permission from I.upski, J. R. 1998, "Molecular genetics of peripheral neuropathies," in *Molecular neurology*, ed J. D. Martin, Scientific American, New York. All rights reserved.)

Bennett and Chance 2001; Berger, Young, and Suter 2002). Most CMT1 patients have DNA rearrangements on chromosome 17pll.2 as the molecular mechanism of their disease. A 1.5-mcgabase tandem duplication accounts for 70% of CMT1A cases. The peripheral myelin protein-22 (PMP-22) gene lies within the CMT1A duplication, resulting in three copies of the dosage-sensitive PMP-22 gene. PMP-22 is a membrane glycoprotein found in the compact portion of the peripheral myelin sheath. A minority of CMT1A patients have mis-sense mutations in the PMP-22 gene, similar to the natural mouse mutants trembler and trembler-J that have a severe hypomyelinating neuropathy. The normal function of PMP-22 remains unknown. A deletion of the same 1.5-megabase region on chromosome I7pll.2 is found u: *SS"-,. n* p.a-.iTiis with HNPP resulting in a single copy of the normal PMP-22 gene (Lupski, Chance, and Garcia 1993). The CMTIA duplication or HNPP deletion is caused by reciprocal recombination events that occur in male germ cell meiosis. The PMP-22 duplication or deletion can be detected in blood samples using pulse-field electrophoresis followed by hybridization with specific CMTIA duplication junction fragments or cytogenetic testing with a PMP-22 probe by fluorescence in situ hybridization.

Myelin Gene Mutations

Myelin protein zero (P_0; gene symbol MPZ) is the major peripheral myelin glycoprotein and is thought to function as an adhesion molecule in the formation and compaction of peripheral myelin. Mutations in the gene encoding for MPZ, located on chromosome lq22-23, have been associated with CMT1B, DSS, and congenital hypomyclination neuropathy. Different MPZ mutations have resulted in divergent morphologic effects on myelin sheaths consisting of uncompacted myelin or focal myelin foldings (Gabrefils-Fcsten et al. 1996). Specific MPZ mis-sense mutations have been reported with a CMT2 phenotypc showing only mild slowing of nerve conduction velocities (Marrosu et al. 1998). The Thr 124 Met mutation in the MPZ gene has been detected in several families with a distinct CMT2 phenotypc characterized by late onset, marked sensory loss, and sometimes deafness and pupillary abnormalities (De Jonghe et al. 1999).

The *early growth response 2 gene (ECR2)* encodes a zinc-finger transcription factor expressed in myelinating Schwann cells lli;u regulates the expression ol myelin proteins including PMP-22, Po, Cx32, and periaxin (Kamholz et al. 2000). EGR2 gene mis-sense mutations have been reported in patients with CMT1D, DSS, or congenital hypomyelination neuropathy (Warner et al. 1998; Timmerman et al. 1999).

Connexin-32 (Cx32) is a gap junction protein found in noncompacted paranodal loops and Schmidt-Lantcrmann incisures of Schwann cell cytoplasm, which is encoded by a four-exon gene located on chromosome Xq. As a gap junction protein, Cx32 forms small channels that facilitate transfer of ions and small molecules between Schwann cells and axons. Cx32 is also expressed in oligodendroglial cells in the central nervous system. This may explain the common abnormal brainstem auditory evoked potentials found in affected males. More than 200 different mutations in Cx32 have been identified in CMTX families. Genotypc-phenotype correlations among patients with Cx32 mutations suggest that most mis-sense mutations result in a mild clinical phenotype, whereas nonsense and framcshift mutations produce more severe phenotypes (Ionascscu et al. 1996a). CMTX is the second most frequent cause of CMT1, accounting for 10-20% of patients.

The designation CMT1C is reserved for autosomal dominant CMT1 families not linked to either CMT1A or CMT1B. Three such families showed linkage to chromosome 16pl3. Mis-sense mutations were found in the *LITAF* (lipopolysaccharide-mduccd tumor necrosis factor-a factor) gene, which encodes a lysosomal protein that may play a role in protein degradation pathways (Street et al. 2003).

Periaxin is a cy to skeleton-associated protein that links the cytoskcleton of the Schwann cell with the basal lamina, which is necessary to stabilize the mature myelin sheath. Periaxin frameshift and nonsense mutations have been found in families with DSS and autosomal recessive CMT type 4F (Takashima et al. 2002).

Point mutations of signal transduction proteins such as myotubularin-related protein-2 (MTMR2), N-myc downstream regulated gene-1 (NDRG1), andganglioside-induced differentiation-associated protein-1 (GDAP1) are found in severe childhood-onset, autosomal-recessive demyclinating neuropathies or CMT4, Mutations of MTMR2 give rise to a severe demyclinating neuropathy characterized by redundant loops of focally folded myelin (Houlden et al. 2001). GDAP1 mutations may be the most common cause of autosomal recessive CMT and can result in demyelinating as well as axonal phenotypes (Nelis et al. 2002).

In general, DNA rearrangements such as PMP-22 duplication or deletion result in milder clinical phenotypes than point mutations for structural myelin proteins or the transcription factor gene I'.RG2, Most known imitations cause disease manifestations in the heterozygous state, behaving as cither gain-of-function or loss-of-funetion-dominant mutations. Rare recessive mutations in PMP-22, EGR2, MTMR2, NDRG1, and periaxin have been reported (Lupski 2000). DNA sequencing tests are available for PMP-22, Cx32, MPZ, F.GR2, and periaxin in commercial laboratories.

Charcot-Marie-Tooth Disease Type 2

CMT2 is a genetically heterogeneous group of axonal neuropathies with normal or slightly slow nerve conduction velocities inherited in an autosomal dominant pattern, CMT2 accounts for approximately 30% of CMT patients (De Jonghe 1998; Vance 2000). Although molecular genetic research has been less productive in CMT2, three responsible gene defects have been identified. Genetic linkage studies have mapped five different disease loci on chromosomes lp35, 3ql3-q22, 7pl4, 8p2l, and 12q24 (Table 82.13). CMT2A, linked to chromosome lp35, is caused by a mutation in a microtubule motor KIFIB^ gene encoding for a kinesin superfamily of proteins involved in axonal transport of synaptic vesicle precursors (Zhao et al. 2001). CMT2B, linked to chromosome 3ql3-q22, has prominent distal sensory loss with ulcerations (De Jonghe et al. 1997; Auer-Grumbach et al. 2000). CMT2C, linked to chromosome 12q24, is characterized by vocal cord and diaphragmatic paralysis (Klein et al. 2002). CMT2D, linked to chromosome 7p15, involves prominent weakness and wasting of hand muscles (Ionasescu et al. 1996b). Mutations in the neurofilament light chain gene (NF-I.) have been found in several families with linkage to chromosome 8p21; this neuropathy is designated CMT2F, (Mersiyanova et al. 2000). These patients often have early onset and a severe clinical phenotype (Jordanova et al, 2003). A DNA sequencing test for NF-L is commercially available. The CMT2 phenotype with only mild slowing of nerve conduction velocities is sometimes caused by specific mutations in -In- MPZ gene and Cx32. Such families with CMTX do not show male-to-male transmission {Birouk et al. 1998).

CMT can be classified by mode of inheritance (autosomal dominant, X-linkcd, and rarely autosomal recessive), chromosomal locus, or causative genes (see Table 82.13). The classification remains fluid and may change as experts alter and revise these designations based on new molecular findings. An up to date listing of loci and genes can be found at the CMT mutation database (http://molgen-www.uia.ac.be/CMTMutations/). DSS, previously designated as CMT3, may no longer be a useful designation because it is genetically heterogeneous, caused b\ different structural myelin protein and transcription factor gene mutations. One proposal is to reserve CM 13 tor rare axonal types of autosomal recessive neuropathy (Vance 2000).

Reappraisal of Electrophysiological Studies of Inherited Demyelinatmg Neuropathies

Uniform conduction slowing has been used to differentiate CMT1 from acquired demyelinating neuropathies

(Lewis and Sumner 1982). The nerve conduction studies of patients with uniform slowing result in conduction slowing in all nerves and along the entire length of nerves, suggesting that inherited myelinopathies affect conduction in all nerves and nerve segments to the same degree. The conduction slowing evolves over the first 5 years of age and does not change appreciably after the age of 5 years. Neurological deficits correlate with reductions in CMAP and sensory nerve action potential amplitudes, indicating that clinical weakness results from reduced numbers of axons. In contrast, acquired dcmyelinating neuropathies result in multifocal or nonuniform conduction slowing together with excessive temporal dispersion and conduction block. Lewis and colleagues (2000) revisited the topic of electrophysiological studies in inherited demy el in a ting neuropathies and correlated conduction changes with molecular diagnoses.

Uniform conduction slowing is found in CMTIA with PMP-22 duplication or point mutations; CMT1B with MPZ point mutations; DSS, including PMP-22, MPZ, and EGR2 gene mutations; metachromatic leukodystrophy; Cockayne's disease; and globoid cell leukodystrophy. In DSS, severe nerve conduction slowing below 10 m per second is consistently found. Temporal dispersion and amplitude reduction on proximal stimulation may be found in such cases due to high electrical stimulation thresholds in hypertfophic nerves. Motor conduction block can also be found in rare CMT1B patients with specific MPZ mutations (Street et al. 2002)

Multifocal conduction slowing is typically seen in HNPP, CMTX, adreuomyeloncuropathy, Pelizaeus-Mer/.bacher disease with proteolipid protein-null mutation, and Refsum's disease.

Nerve conduction velocities in CMTX with Cx.32 mutations range from near normal to intermediate slowing in the 30- to 40-m per second range. There is debate as to whether CMTX should be classified as a primary axonal or demyelinating disorder (Birouk et al. 1998). Careful studies of individual patients suggest nonuniform conduction slowing consistent with demyelination (Gutierrez et al. 2000; Lewis 2000). Conduction changes in affected women can be subtle and frequently are in the range found in patients with CMT2. Before considering a diagnosis of CMT2 in such cases, it is important to review the family history, In kindreds with no male-to-male transmission, the presence of intermediate conduction velocities (>42 m/s) in female carriers and delayed brainstem auditory evoked response latencies in affected men is highly supportive of Cx32 mutations (Nicholson, Yeung, and Cotbett 1998). Certain mutations in MPZ, NF-L and GDAP1 genes can be associated with either demyelinating or axonal phenotypes.

Practical Molecular Diagnostic Testing for Patients with Charcot-Marie-Tooth Disease and Related Disorders

Molecular diagnostic testing should be considered in CMT and related peripheral neuropathies. Commercial reference laboratories can detect PMP-22 duplication/deletion or point mutations by DNA sequencing of PMP-22, Cx32, MPZ, EGR2, periaxin, and NF-L in samples of peripheral blood (Table 82.14). In families with at least two-generation involvement, known male-to-male transmission, and uniform conduction slowing, the PMP-22 duplication test should be obtained and, if normal, followed by PMP-22 and MPZ DNA sequencing. Patients who have neither the CMTIA duplication nor malc-to-male transmission should be screened for Cx32 mutations. Given the high spontaneous mutation rate, the diagnoses of CMTIA and HNPP should even be considered in the absence of a positive family history. Because of the severe consequences of vincristine therapy in CMT patients, the CMTIA duplication should be ruled out in any patient with either unexplained chronic neuropathy or a family history of

neuropathy before the initiation of cancer chemotherapy (Graf et al. 1996). DNA sequencing tests for Cx32, MPZ, and NF-L mutations are available for selected patients with the axonal CMTl phenotypc. The PMP-22 duplication test followed by DNA sequencing of PMP-22, MPZ, EGR2, and periaxin should be considered in childhood cases with severe demyelinating neuropathy suggestive of DSS or congenital hypomyelination neuropathy,

Treatment and Wdiiagcnivnt

The rates of progression of CMTl and CMT2 arc slow, disability occurs relatively late, and life span may be normal. Management is mainly symptomatic. Patients should be instructed in proper foot care and advised to wear broad, well-fitting shoes. Insoles may be used to distribute body weight more evenly in patients with foot deformity. Ankle-foot braces or orthopedic procedures are indicated for severe footdrop. Patients should be warned to avoid neurotoxic drugs because of greater susceptibility to agents such .is vincristine. Tlu- isU'.:-.lun;- .uU.uiccs "• ihi- molecular understanding of CMT neuropathies will likely bear fruit in the clinical management of patients in the future.

Hereditary Neuropathy with Liability to Pressure Palsies

HNPP is an autosomal dominant disorder of peripheral nerves leading to increased susceptibility to mechanical traction or compression. Patients present with recurrent episodes of isolated mononeuropathies, typically affecting, in order of decreasing frequency, the common peroneal, ulnar, brachial plexus, radial, and median nerves. Painless brachial plexus neuropathy is seen in up to one third of patients. Most patients experience the initial episode in the second or third decade of life. Attacks usually are provoked by compression, slight traction, or other minor trauma. Most attacks are of sudden onset, painless, and usually followed by complete recovery within days or weeks. Less common presentations include transient, positional sensory symptoms, progressive mononeuropathy, chronic sensory polyneuropathy, CMT phenotype with pes cavus, and a diffuse, chronic sensorimotor neuropath) resembling chronic inflammatory demyelinating polyneuropathy (Mouton ct al. 1999). About 15% of mutation carriers remain asymptomatic.

Nerve conduction studies in patients with HNPP associated with PMP-22 deletion typically consist of prolonged distal motor latencies with only mild slowing of forearm segments of median and ulnar nerves, focal slowing of ulnar and fibular nerves at compression sites, and diffuse reduction of sensory nerve action potential amplitudes (Mouton et al. *1999;* Dubourg et al. 2000). Prolonged median distal motor latencies and abnormal sensory conduction studies are frequently found in asymptomatic carriers (Infante et al. 2001).

Sural nerve biopsy specimens demonstrate focal sausage-like thickenings of myelin termed *tomacula* (Figure 82.11), segmental demyeliiiacion, and axonal loss.

Linkage studies show a 1.5-megabase deletion of chromosome 17pl 1.2-12 that includes the PMP-22 gene and corresponds to the duplicated region in CMT1A in 85% of affected patients with HNPP. The remaining patients have a variety of mutations in PMP-22 that lead to frameshift or nonsense mutations causing functional changes in the protein (Lenssen et al. 1998; van de Wetering et al. 2002). Molecular diagnosis of the 17pl 1.2 deletion is available in reference laboratories and has replaced nerve biopsy as means of diagnosis. Testing should be considered regardless of family history in any patient presenting with painless multiple mononeuropathies, brachial plcxopathy, or recurrent demyelinating neuropathy (Tyson et al. 1996). The primary treatment strategy is to prevent nerve injury by avoiding pressure damage.

Giant Axonal Neuropathy

Giant axonal neuropathy (GAN) is a rare autosomal recessive multisystem disorder of intermediate filaments

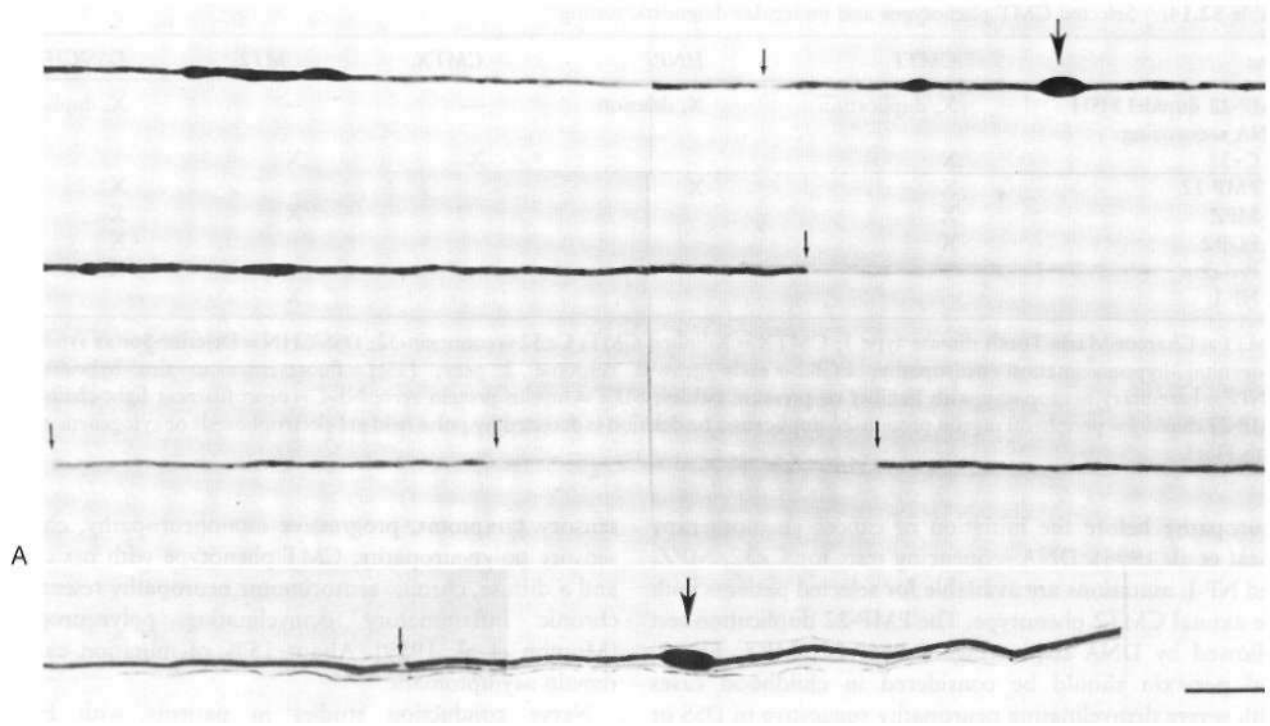

FIGURE 82.11 Single teased nerve fibers from a patient with hereditary liability to pressure palsies, showing examples of focal sausage-shaped enlargements of the myelin sheath *{large arrows)* in two fibers (A, U). Fiber A shows thinly remye! mated inter nodes. Successive nodes of Ranvier *(thin arrows)* can be followed from left to right. (Bar= 100 urn.) (Reprinted with permission from Bosch, E. P., Chili, H. C., Martin, M. A., er al. 1980, "Brachial plexus involvement in familial pressure-sensitive neuropathy: Electrophysiologic and nt(irphulo;u. finding," *Ana* \V;;.:.i/, vol. S. pp. nil) ➪Il I.j

affecting the peripheral and central nervous system. GAN presents as a slowly progressive axonal sensorimotor neuropathy in early childhood and leads to death by late adolescence. Most affected children have tightly curled hair and distal leg weakness. Some develop a peculiar gait disturbance with a tendency to walk on the inner edges of the feet (Figure 82.12). With disease progression, evidence of CNS involvement occurs, including optic atrophy; nystagmus; cerebellar ataxia; upper motor neuron signs and intellectual decline; and abnormal visual, auditory, and somatosensory evoked potentials. MRl of the brain demonstrates cerebellar and cerebral white matter abnormalities. Nerve conduction studies show reduced CMAP and SNAP amplitudes with normal to only slightly reduced conduction velocities. Sural nerve biopsy demonstrates the pathognomonic changes of large focal axonal swellings

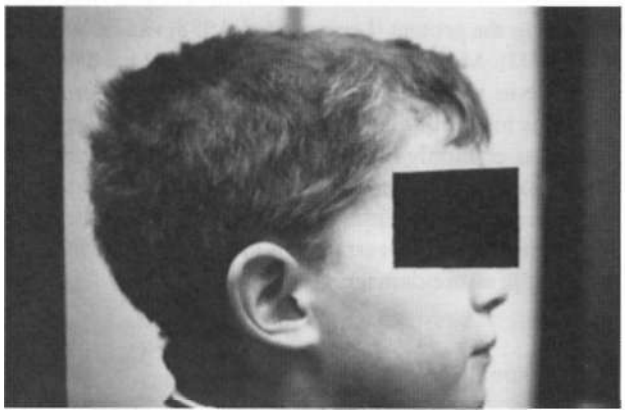

FIGURE *H2A2* i 'fitly curled hair in a young child with giant axonal neuropathy.

that contain densely packed disorganized neurofilaments (Figure 82.13). The disease locus was mapped to chromosome 16q24. Giant axona! neuropathy is caused by mutations of the GAN gene which encodes a novel protein called gigaxonin (Bomont et al. 2000; Kuhlenbaumcr ct al. 2002). Gigaxonin is a ubiquitously expressed cytoskelctal protein and a member of the kelsch superfamily which is involved in diverse cellular functions and may be important in the cross-linking of intermediate filaments (Hermann and Griffin 2002).

Hereditary Sensory and Autonomic Neuropathy

HSAN is a group of neuropathies characterized by prominent sensory loss with autonomic features but without significant motor involvement. Currently, these neuropathies are divided into five main groups based on inheritance, clinical features, and populations of sensory neurons affected (Table 82.15). HSAN is distinctly rare compared with GMT. Genetic studies have led to successful chromosomal localization and gene mutations in HSAN I, III and IV. Sensory loss in HSAN predisposes to unnoticed, recurrent trauma that may lead to neuropathic (Charcot) joints, nonhealing ulcers, infections, and osteomyelitis resulting in acral mutilations aerodystrophic neuropathy). These complications are preventable by avoiding trauma to the insensitive distal limb segments.

Hereditary Sensory and Autonomic Neuropathy Type I

HSAN' type I is an autosomal dominant disorder that is the most common familial sensory neuropathy. Symptoms begin in the second to fourth decade with sensory loss and subsequent tissue injury mainly affecting the feet and legs. Sensory loss initially affects pain and temperature perception more than touch-pressure sensation, but includes all modalities as the disease progresses. Patients present with calluses on the soles, painless stress fractures, neuropathic foot and ankle joints, and recurrent plantar ulcers. If ulcers arc neglected and become infected, severe acromutilations may result (acrody strop hie neuropathy) (Figure 82.14).

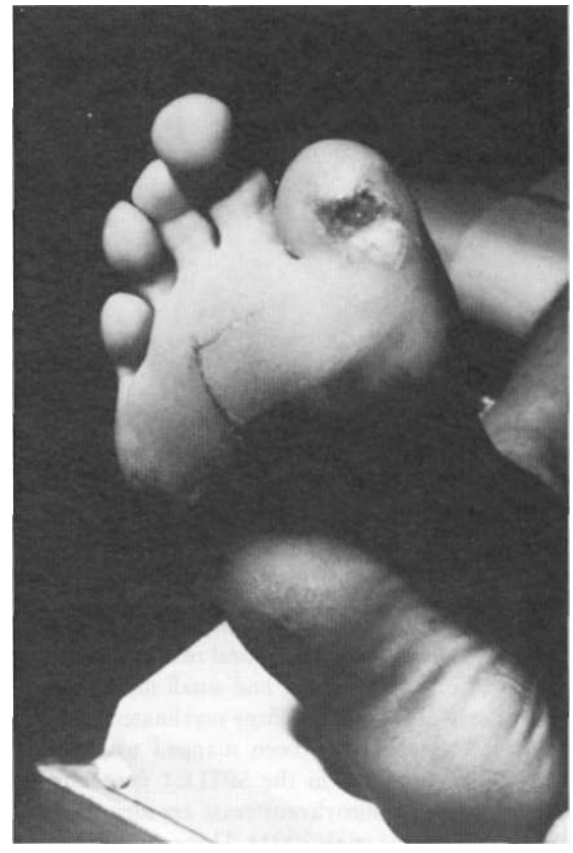

FIGURE 82.14 Nonhealing foot uker in a 33-year-old man with hereditary sensory and autonomic neuropathy type I. In his kinship, 10 individuals are affected in three generations.

Lancinating or shooting pains ate often prominent. Distal muscle weakness and wasting are present in all advanced cases. Such motor involvment creates confusion with CMT 2B with dense sensory loss (linked to chromosome 3ql 3) or with certain axonal MPZ gene mutations. Variable neural hearing loss, or, rarely, spastic paraparesis may be seen in HSAN type I. Some families present with burning feet or neurogenic arthropathy suggesting clinical as well as genetic heterogeneity among patients with HSAN type 1 (Dyck et al. 2000a).

Table 82.15: Hereditary sensory and auronomie neuropathies

Disease	*inheritance*	*t · ICIIS*	*(..·:::·*	*Clinical features*
HSAN l(HSNI)	AD	9q22	**SPTLC1***	Small > large MF sensory loss, distal weakness, onset in second to fourth decade

HSAN **III** (FD)	AR	9q31	1KBKAP"	Sensory loss, autonomic dysregulation, absent tears, fungiform tongue papillae
HSAN IV	AR	lq21	TRKA/NGF receptor	Inseusitvity to pain, anhidrosis at birth, nl SNAPs
HSAN V	AR			Insensitiviry to pain at birth, nl SNAPs, absent small MF

AD = autosomal dominant; AR = autosomal recessive; FD = familial dysautonomy; IKBKAP = IKAP, the protein encoded by 1KBKAP gene is a member of the human elongator complex; HSAN = hereditary sensory and autonomic neuropathies; MF = myelinated fibers; nl SNA['=-norrnal sensory nerve action potential; SPTLCl =SPTLC1 encodes serine palmitoyltransferase long chain 1; TRKA/NGF = TRKA encodes for the high affinity NGF (nerve growth factor) receptor; * =molecular gene testing is clinically available.

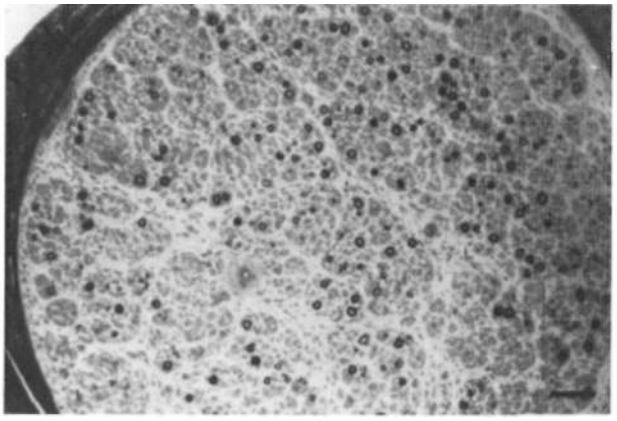

FIGURE 82.15 Semithin transverse section of sural nerve from a patient with hereditary sensory and auitmomic neuropathy rs pi- I. Note loss of large and small myelinated fibers. (Toluidine blue; bar = 50 urn.)

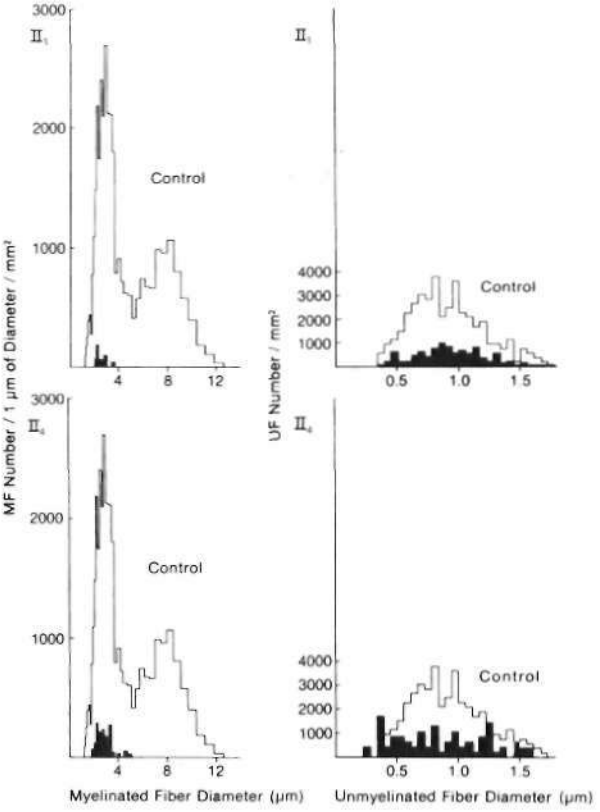

FIGURE 82.16 Sural nerve fiber size-Frequency histograms of myelinated fibers (ME) *[left]* and unmyelinated fibers (UF) *(right)* of two affected siblings with hereditary sensory and autonomic neuropathy type I] *[black bars)* and control nerve *{white ban).* In the patients, the number of myelinated fibers was less than 500/mm^2 and that of the unmyelinated fibers less than 10,000/mm^2.

SNAP amplitudes are reduced late in the disease. Motor conduction velocities remain normal but CMAP amplitudes arc reduced in advanced cases. Sural nerve biopsy confirms a severe loss of unmyelinated and small myelinated axons and to a lesser degree loss of large myelinated fiber (Figure H2.15). HSAN type 1 has been mapped to chromosome 9t|22.1-22,3, Mutations in the SPTI.C1 gene encoding a subunit of serine palmitoyltransferase are identified in 90% of patients (Dawkins et al. 2001). These mutations result in increased *de novo* ceramide synthesis. Since ceramide plays a role in the regulation of programmed cell death, the neuronal degeneration in 1 [SAN type I may be caused by ceramide-induced apoptosis. Molecular genetic testing is clinically available. HSAN type I is genetically heterogeneous as families without linkage to chromosome 9q22 have been described (Aucr-Grumbach et al. 2000).

Hereditary Sensory and Autonomic Neuropathy Type II

HSAN type II is recessively inherited and rarely begins later than infancy. All sensory modalities are affected and involve distal upper and lower limbs more than trunk and face. The hands, feet, lips, and tongue are at risk for mutilation because ol generalized paninndal::y seiw>n loss. Autonomic symptoms include bladder dysfunction and impotence. Associations with spastic paraplegia, retinitis pigmentosa, motor weakness, or neurotrophic keratitis have been described. The clinical course is slowly progressive, with progressive axonal loss. SNAPs ate absent. Sural nerve biopsy specimens show almost complete absence of myelinated fibers and reduced unmyelinated fiber populations (Figure 82.1 6). No chromosomal linkage has been identified in this group of patients.

Hereditary Sensory and Autonomic Neuropathy Type III

HSAN type 111 or familial dysautonomia (FD) is an autosomal recessively inherited sensory neuropathy affecting children of Asbkenazi Jewish ethnicity with prominent autonomic manifestations. Symptoms begin at birth and include poor feeding, esophageal dysmotiliry, episodes of vomiting, recurrent pulmonary infections, attacks of fever, and cardiovascular instability. Emotional stimuli provoke i|iiM'.lk- hypcru-iisioi], pn>l;iM^i sweating, and marked skin blotching caused by defective autonomic control. Hypotonia in infancy contributes to delayed motor milestones. Later in childhood, hyporeflexia, insensitivity to pain, gait ataxia, stunted growth, and scoliosis become apparent. Defective lacrimation (absence of overflow tears with crying), absence of fungiform papillae of the tongue giving it a smooth appearance, and pupillary hypersensitivity to parasympathomimetic agents arc tell-tale signs. Patients ate at risk to develop profound hypoxemia following anesthesia or with high-altitude ttavel as a result of diminished respiratory response to hypercapnia and hypoxia.

Motor NCVs are generally normal, whereas SNAP amplitudes are frequently reduced. A marked reduction in the density of unmyelinated axons and small myelinated fibers is seen in sural nerve biopsy specimens.

The number of neurons in the sympathetic, parasympathetic, and spinal ganglia is reduced. Linkage studies have mapped the gene locus to chromosome 9q31-q33, The diagnosis is established by molecular genetic testing of the IKBKAP gene, which encodes an essential protein named *IKAP* of the human elongation complex. The major FD mutation is a splice mutation that results in aberrent tissue-specific mRNA splicing (Slaugenhaupt and Gusella 2002).

I'D is a potentially life threatening disorder with a high mortality due to aspiration pneumonia or autonomic crises. Improved supportive treatment has extended the survival of patients into adulthood (Axelrod et al. 2002),

Hereditary Sensory and Autonomic Neuropathy Type IV

HSAN type IV is a rare autosomal recessive disorder characterized by congenital insensitivity to pain with anhidrosis, repeated episodes of fever, self-mutilating behavior, and mild mental retardation. Tendon reflexes and SNAPs are preserved. Cutaneous sensory nerves show selective loss of unmyelinated axons and small myelinated fibers. Confirmation of a neuropathic abnormality in cases of congenital indifference to pain without apparent neurological signs therefore depends on the morphometric study of unmyelinated and myelinated fiber populations in nerve biopsy specimens and is supported by quantitative sensory testing, and lack of sweating by the quantitative sudomotor axon-reflex test. Intradermal histamine injection produces a wheal but no flare response. Skin biopsy has demonstrated a lack of intradermal nerve fibers and sweat glands devoid of nerve fibers (Verze et al. 2000), The gene locus for HSAN type IV maps to chromosome lq21-22. Mutations in the *trkA* gene encoding the tyrosine kinase receptor for nerve growth factor (NGF) have been described in patients with HSAN type IV (Indo 2002), These findings indicate that the NGF-trkA system plays a crucial role in the development of unmyelinated nociceptive and sudomotor fibers.

Clinically similar cases with selective loss of only small myelinated fibers have been designated HSAN type V. Mutations in the trkA gene have been found in some cases suggesting that the two disorders may be allelic (Houlden et al. 2001).

Treatment and Management

The prevention of stress fractures and plantar ulcers is of utmost importance. This can be achieved by meticulous foot care, avoiding barefoot walking, daily inspection of feet and shoes, and proper skin care with moisturizing lotions. Whenever plantar ulcers develop, weight bearing should be discontinued until the ulcers heal. Infusion of pamidronate, a bisphosphonate has been helpful in the management of Charcot's neurogenic arthropathy,

Neuropathy Associated with Spinocerebellar Ataxias

Friedreich's ataxia is an autosomal recessive neurodegenerative disease characterized by degeneration of large sensory neurons and spinocerebellar tracts, cardiomyopathy, and increased incidence of diabetes (see Chapter 78). Even in the early stages of the disease, examination reveals lower limb areflexia and impaired joint position and vibration sense, with preserved pain and temperature sensation. Pes cavus and hammer toes occur in approximately 90% of cases.

Motor NCVs arc normal or slightly reduced, and SNAPs are invariably reduced or absent. A selective loss of large myelinated fibers occurs in the sural nerve. Friedreich's ataxia is the result of a large GAA triplet repeat expansion on chromosome 9ql3-q21.1 leading to loss of frataxin expression (see Chapter 78). Peripheral nerve involvement has been found in association with other spinocerebellar ataxias, most notably spinocerebellar ataxia type 3 (SCA3) in older patients and SCA type 4.

Familial Amyloid Polyneuropathy

Familial amyloid polyneuropathy (FAP) is a group of autosomal dominant disorders characterized by the extracellular deposition of amyloid in peripheral nerves and other organs. Amyloid is a fibrillar protein characterized by (1) green birefringence of Congo red-stained sections viewed in polarized light; (2) the presence of uonbranched 10-nm amyloid fibrils on electron microscopy; and (3) a *fi*-pleated sheet structure on x-ray diffraction. More than 10 different proteins can be deposited as amyloid in tissues. In FAP one of three aberrant proteins (transthyretin, apolipoprotein A1, or gelsolin [Falk, Comenzo, and Skinner 1997J) can be found in the peripheral nerves. In acquired, primary systemic amyloidosis, polypeptides of immunoglobulin light chain origin arc deposited in tissues as amyloid, which is referred to as *AL amyloid* (sec Primary Systemic Amyloidosis, later in this chapter).

The classification of FAP was traditionally based on clinical presentation. Progress in understanding the protein composition and molecular genetics of these disorders justifies a different approach (Table 82.16).

Transthyretin Amyloidosis (Familial Amyloid Polyneuropathy Types I and 11)

The majoriry of patients with FAP have mutations of the plasma protein transthyretin (TTR). This is a transport protein for thyroxin and retinol-binding protein, is predominantly synthesized in the liver, and consists of a single polypeptide chain of 127 amino acid residues. The gene for TTR is located on chromosome 18ql 1.2-ql2.1. Mutations ot the TTR gene result in transcriptions of aberrant proteins with predisposition toward amyloid

Table 82.16: Familial amyloid neuropathies

Aberrant protein	*Type*	*Decade of onset*	*Neuropathy*	*Associated lesions*
TTR	FAP I	Third through fifth	Sensorimotor neuropathy, autonomic neuropathy	Heart, kidney
TTR	FAP II	Fourth through fifth	Carpal tunnel syndrome	Heart
Apolipoprotein Al	FAP III	Third through fourth	Sensorimotor neuropathy	Kidney, peptic ulcers
Gelsolin	FAP IV	Third	Cranial	Corneal lattice dystrophy

FAP = familial amyloid polyneuropathy; TTR = transthyretin.

formation and deposition in peripheral nerve, heart, kidney, eye, and rarely leptomeninges.

TTR-related amyloid polyneuropathies demonstrate two disparate clinical phenorypes. The original cases described by Andrade in Portugal are referred to as FAP type I. Two other large foci of patients are found in Sweden and Japan. This is the most common form of FAP and has been observed in many ethnic groups. The neuropathy begins insidiously in the third and fourth decades with dissociated sensory impairment (loss of pain and thermal sense) in the lower extremities, often associated with lancinating pain and paresthesia. Autonomic dysfunction common]j includes impotence, postural hypotension, bladder dysfunction, distal anhidrosis, and abnormal pupils with scalloped margins. Gastrointestinal symptoms characterised by constipation alternating with diarrhea, delayed gastric emptying, and weight loss may be prominent. Eventually panmodality sensory loss, distal wasting, weakness, and areflexia develop. Systemically, amyloid is deposited in the ocular vitreous, heart, and kidneys. The disorder is relentlessly progressive. Patients usually die of cardiac or renal failure or malnutrition 10-15 years after onset.

Electrophysiological studies reveal a distal axonal neuropathy that affects sensory fibers earlier and more prominently than motot fibers. Early changes include low-amplitude or absent SNAPs, mild reduction in CMAP amplitudes, and preserved motor conduction velocities. Evidence of denervation is found in distal leg muscles. Until specific biochemical and genetic studies became available, the diagnosis was confirmed by the presence of amyloid in tissue biopsy specimens. In early cases, sural nerve biopsy specimens show a predominant loss of unmyelinated and small myelinated fibers. Amyloid deposits are usually seen within the endoneurium or around vasa nervorum. Immunostaining with antibodies to TTR can frequently identify the specific type of amyloid. The pattern of myocardial involvement varies according to specific TTR mutations. Many but not all mutations have evidence of myocardial infiltration on echocardiography. The mechanisms ui nerve fiber injury and their relationship u> am; loid deposits are incompletely understood. It has been proposed that the preferential deposition of amyloid in sensory and autonomic ganglia interferes with neuronal function, leading to length-dependent axonal degeneration. An alternative theory suggests that endoneurial edema associated with amyloid deposition in blood vessels and the endoneurium results in ischemic nerve fiber injury.

Rukavina and colleagues described a more restricted form of the disease, referred to as FAP type II, which presents with carpal tunnel syndtome in the fourth or fifth decade and slowly progresses to peripheral polyneuropathy. Autonomic manifestations are absent. Vitreous opacities are common and cardiac involvement may develop. Surgical decompression of the carpal tunnel provides symptomatic relief. Demonstration of amyloid infiltration of the flexor retinaculum obtained at surgery establishes the diagnosis.

More than 80 different amino acid substitutions of the TTR protein have been identified as causing the clinical phenorypes, referred to as *FAP I* and //, Among these, substitution of valine by methionine at position 30 (VaBOMet) is by far the most frequent and found in clusters in distinct atcas of Portugal, Sweden, and Japan. Other TTR variants, including isoleucine 33, alanine 60, and tyrosine 77 substitutions, have similar features of generalized polyneuropathy with varying degrees of autonomic involvement, A serine substitution at position 84 and histidine at position 58 are the two TTR mutations seen most commonly in FAP type II, beginning in the upper limbs with carpal tunnel syndrome. The age of onset varies greatly with specific TTR mutations. Even in families with the VaBOMet mutation variation in age of onset is observed in different geographic regions (Ikeda ct a I, 2002), Specific TTR mutations may produce unique phenotypes with predominantly cardiac ot lepto meningeal amyloidosis (Hund et al. 2001).

Apolipoprotein AI Amyloidosis (Familial Amyloid Polyneuropathy Type III, Van Allen)

The clinical manifestations of the type III variant have much in common with those of type I except for early renal involvement and a high incidence of duodenal ulcers among affected individuals. Uremia is the most common cause of death, typically occurring 12-15 years after the onset of neuropathy. An abertant fragment of apolipoprotein Al with a substitution of arginine for glycine accumulates in the tissues in FAP type III.

Gelsolin Amyloidosis (Familial Amyloid Polyneuropathy Type IV, Meretoja)

Gelsolin amyloidosis was first described in Finland, but subsequently isolated cases have been reported elsewhere. Symptoms begin in the third decade with corneal clouding

caused by a fine network of amyloid filaments, referred to as *lattice corneal dystrophy.* This is followed in the fifth decade by progressive cranial neuropathies with prominent facial palsy and skin changes producing a typical baggy skin over the atrophic face. Other bulbar signs may develop together with mild peripheral neuropathy without autonomic dysfunction.

Gelsolin, the amyloid protein isolated from tissues of FAP type IV, is an actin-binding protein found in plasma, leukocytes, and other cell types. The gelsolin gene maps to chromosome 9. Amino acid substitutions (asparagine or tyrosine at position 187) result in amyloid-forming mutant gelsolin.

DNA *Diagnosis of Familial Amyloid Polyneuropathy*

The diagnosis of FAP requires several steps. Initially, the diagnosis is established by confirming the presence of amyloid in nerve and muscle, rectal biopsies, or a sample of subcutaneous abdominal fat. Immunostaining using specific antibodies against one of the three aberrant proteins may identify the tesponsible protein. In sporadic cases, the more common AL amyloidosis should be excluded by a search for clonal plasma cell dyscrasia (see Primary Systemic Amyloidosis, later in this chapter). If no evidence of plasma cell dyscrasia exists, TRR can be identified by isoelectric focusing of the serum, which separates vatiant and wild-type TTR. The finding of a variant TTR should prompt genetic testing. DNA isolated from peripheral leukocytes or tissue can be amplified with the polymerase chain reaction and specific oligonucleotide primers used to amplify regions of the gene of interest, thereby demonstrating specific point mutations. DNA testing for the most common TTR mutations (Mcr-30, Ile-33, Ala-60, Tyr-77, Ser-84) is readily available in reference laboratories. Mutation analysis of the entire TTR gene detects more than 99% of amyloidogcnic mutations.

Treatment

The prognosis of TTR amyloidosis varies with the specific mutation, age of onset, and otgan involvement. Supportive measures are essential for both the neuropathy and specific organ system involved, including cardiac pacing, dialysis, parenteral nutrition, and physical therapy. Because over 90% of TTR is synthesized in the liver, orthotopic liver transplantation has been proposed as definite therapy for this disorder. Transplantation results in rapid clearance of the variant TTR from serum; it may halt progression of neurological deficits in patients with mild neuropathy and stop the rate of axonal degeneration; autonomic dysfunction remains largely unchanged (Adams et al. 2000). The reported 5-year survival rate is approximately 80%. Liver transplantation is recommended for patients who are younger than 50 years, have mild neuropathy (walking unaided), and have no significant cardiac or renal involvement. Transplanation is not effective in cardiac or leptomeningeal amyloidosis. Alternative treatment modalities with agents which stabilize the variant TTR and inhibit fibril formation are under investigation,

Porphyric Neuropathy

Hepatic porphyrias are caused by inactivation of one of a pair of allelic genes that encodes for an enzyme of the heme biosynthctic pathway. The consequent 50% reduction of enzyme activity provokes a compensatory overproduction of porphyrins and their precursors through the negative feedback regulation by heme of the first and rate-limiting enzyme of the heme hiosynthetic pathway, ^-aminolevulinic acid synthase (ALA-S). These dominantly inherited disorders include acute intermittent porphyria (A1P), variegate porphyria (VP), and hereditary ctipropor phyria (HCP). A fourth disorder referred to as *plumboporphyria* is inherited as an autosomal recessive trait and is caused by a deficiency of 3-aminolevulinic acid (ALA) dehydratase (Table 82.17). Mote than 90 mutations in the PBG deaminase gene have been identified that decrease enzyme activity and cause AIP (F.lder, Hift, and Meissner 1997). These partial enzyme defects remain latent until precipitating factots trigger acute attacks. Precipitating factors include certain inducing drugs, the menstrual cycle, alcohol, hormones, and fasting (cither intentional or during an intercurrent illness). Precipitating factors share the ability to induce hepatic 5-ALA synthase, the rate-limiting enzyme in heme biosynthesis, which leads to the overproduction and overexcretion of porphobilinogen (PBG) and 5-ALA.

Clinical Features of the Acute Porphyric Attack

The manifestations of the acute attack are identical regardless of the specific type of hepatic porphyria. All clinical symptoms can be explained by dysfunction of the autonomic nervous system, PNS, and CNS. Characteristically, porphyric attacks fits! occur during the third and fourth decades of life and are five times more common and severe in women than men. The most frequent presenting symptoms arc abdominal pain, nausea, vomiting, and severe constipation. Other autonomic manifestations are tachycardia, labile hypertension, orthostatic hypotension, .Hid difficulty with micturition. Only a few patients progress to develop the more ominous motor neutopathy or CNS involvement. Onset of the predominantly motor neuropathy is subacute, with generalized, proximal, or asymmetrical muscle weakness developing over days or weeks. The arms rather than the legs may be affected first, and proximal muscles may be preferentially involved. Muscular activity before onset of symptoms may influence the pattern of weakness. Cranial nerve involvement is common. In severe cases, flaccid quadriplegia with

respiratory failure ensues. Rapidly progressive muscle wasting is a striking feature. Tendon reflexes are diminished or absent, but paradoxically ankle jerks may be retained. Sensory impairment may occur in a distal stocking-glove distribution or may affect the trunk and proximal limbs in an unusual bathing suit pattern. In exceptional cases a bilateral radial motor neuropathy without abdominal pain may be the only manifestation of AIP (King et al. 2002). The rate of improvement is variable. Some patients rapidly recover function, suggesting a reversible acute toxic-metabolic neuronal injury. Those with fixed weakness caused by axonal degeneration improve slowly (mean time to recovery, 10.6 months for proximal muscles and nearly twice as long for distal muscles). The protean CNS manifestations during severe attacks include anxiety, confusion, delirium, seizures, and coma.

Patients with VP and HCP develop cutaneous photosensitivity during adult life. The skin manifestations consist of blisters, hyperpigmentation, hypertrichosis, and increased skin fragility. AIP occurs in all ethnic groups, but is most common in individuals of Scandinavian or English descent. VP is also common among South Africans of Afrikaans descent.

Laboratory Studies

The biochemical hallmark of the porphyric attack is the marked elevation of PBG and ALA in blood and urine. Rapid screening tests for urinary PBG such as the Watson-Schwartz and Hocsch tests give positive test results during virtually all acute attacks and are useful in an emergency. A positive screening test result must be confirmed with quantitative urinary determinations of PBG and ALA. Levels of urinary ALA and PBG may decrease rapidly after an attack of VP or HCP, but remain elevated in AIP. Subsequently, Stool assays for protoporphyrins aiul cupru porphyrins are necessary to distinguish VP and HCP from AIP, The diagnosis of <S-ALA dehydratase deficient is supported by increased urinary excretion of ALA without accompanying PBG elevation. Certain medical ions and disorders other than porphyrias are associated with increased urinary porphyrins, including lead poisoning, liver disease, alcoholism, chronic renal failure during hemodialysis, and hereditary tyrosinemia (Tefferi, Solberg, and Lllcfson 1994). CSF is normal. Hyponatremia related to inappropriate antidiuretic hormone release is common.

Electrophysiological studies in patients with porphyric neuropathy reveal low-amplitude CMAPs but normal or borderline slow motor conduction velocities. SNAPs are reduced in amplitude or absent. EMG obtained early in the course reveals poor recruitment of normal motor unit potentials. Denervation changes appear later, first in the paraspina) and proximal muscles and subsequently in distal muscles. Morphological study results support length-dependent axonal degeneration and preferential loss of large myelinated axons (Suarez et al. 1994).

Pathogenesis

The hepatic porphyrias have a lifelong genetic defect in hepatic heme synthesis. In AIP, a partial defect of PBG deaminase activity can be demonstrated in erythrocytes, fibroblasts, and hepatocytes. Individuals bearing the mutation responsible for AIP can be identified readily by measuring red cell PBG deaminase. In HCP, the block is more distal, involving coproporphyrinogen oxidase, whereas in VP it involves protoporph yrinogen oxidase, with resultant excessive fecal excretion of coproporphyrin and protoporphyrin, respectively. Assays for the latter two enzymes in skin fibroblasts are limited to research laboratories. F.n/.yme assays may mislead and should not be used in place of porphyrin analysis.

The mechanism of the neuronal axonal injury remains uncertain. The two leading hypotheses implicate neuronal

heme deficiency with impaired energy metabolism or direct neurotoxicity of ALA.

Treatment and Management

The treatment of patients with acute hepatic porphyria involves three important steps: (1) prevention of attacks; (2) attempts to repress hepatic <5-ALA synthase activity, thereby reducing porphyrin production; and (3) supportive care, Ideally, attacks should be prevented by avoiding drugs and situations that induce them. Among the inducing drugs, barbiturates are the most common precipitants, followed by sulfonamides, analgesics, nonbarbiturate hypnotics, anticonvulsants, and female sex hormones. Intentional fasting and alcohol consumption should be avoided. Gonadotropui-relL'asiug hormone agonists may benefit women with recurrent attacks related to the menstrual cycle. The attack must be treated promptly, as outlined in Figure 82.17. First, all offending drugs are removed and any intercurrent infection is treated. A high-carbohydrate diet orally or by nasogastric feeding (at least 400 g daily, or the equivalence of glucose or levulose infusions) results in reduced porphyrin precursor production. Persistent symptoms or neurological deficits that progress for 24 hours after carbohydrate loading are indications for treatment with hematin (a hydroxide of heme), which represses the activity of hepatic o-ALA synthase and may restore cytochrome functions by replenishing an endogenous heme deficit. Hematin therapy, at the recommended dose of six infusions of 4 m^/kg body weight at 12-hour intervals, has resulted in consistent reduction of porphyrin precursors in serum and urine, and clinical improvement in more than 80% of attacks. The only placebo-controlled study suggested a more modest clinical benefit of intravenous hematin. Early administration of hematin is advocated to correct the metabolic insult before neuronal damage becomes irreparable.

Supportive treatment consists of the correction of fluid imbalance, close attention to respiratory function, and physical therapy. Abdominal pain can often be controlled with simple analgesics, but may require narcotics. Sedation with chlorpromazine is often helpful. The treatment of seizures poses a difficult therapeutic problem because most anticonvulsants may exacerbate the disease. Intravenous diazepam or parental magnesium sulfate are both effective and safe for immediate seizure control.

Fabry's Disease

Fabry's disease is an X-linked lysosomal storage disorder caused by a deficiency of the lysosomal enzyme a-galactosidase A, which results in the accumulation of the glycolipid globotnacylccramide (ceramidetrihexoside) within vasculat endothelial cells of the kidneys, heart, brain, and skin. Over time, progressive vascular disease leads to renal failure, cardiac disease, and strokes. Skin involvement gives rise in the typical angioki raromas, \\ Hi.li are dark red, punctate telangiectases found mainly over the lowet part of the trunk, buttocks, and scrotum (Figure 82.18). A painful small fiber neuropathy develops in childhood or adolescence. Distal paresthesias and lancinating pain are intensified by exertion, fever, or hot environments. Autonomic dysfunction includes diminished sweating, impaired tear and saliva formation, and decreased intestinal motility. Except for impairment of temperature sensation, overt neurological signs are absent. Female carriers often show clinical involvement but rarely develop the renal failure, which is characteristic of affected men.

NCVs are mildly reduced in two thirds of patients. Deposition of glycolipid in small neurons of sensory and peripheral autonomic ganglia results in neuronal degeneration and selective loss of small myelinated and unmyelinated fibers in sural nerve biopsy specimens. Ultrastructurally, perineuria!, endothelial, and perithelia! cells contain typical lamellated glycolipid inclusions. Leukocyte preparations or skin fibroblasts are used for the diagnostic tf-galactosidase assay.

Analgesics, phenytoin, or carbama/.epine, along with avoidance of aggravating factors, are effective for pain

relief. Recombinant a-galactosidase A replacement therapy has been shown to be safe and effective in the removal of microvascular endothelial deposits from target organs (Enget al. 2001).

Leukodystrophies with Neuropathy

The leukodystrophies result from inherited abnormalities of myelin metabolism thar may affect both the CNS and PNS. Peripheral nerve involvement is seen in metachromatic leukodystrophy (MLD), Krabbe's disease, adrenomyeloneuropathy, and Cockayne's syndrome. Recognition of an associated neuropathy may he helpful in the differential diagnosis of the underlying leukodystrophy. Mis-sense mutations in proteolipid protein, a major component of central myelin, cause a spectrum of X-linked CNS disorders without peripheral neuropathy, including Pelizaeus-Merzbacher disease and hereditary spastic paraparesis. Proteolipid protein is expressed also in Schwann cells and compact peripheral myelin. Absence of proteolipid protein expression caused by a frameshift mutation has been reported to produce a demyelinating neuropathy with less severe CNS manifestations (Gabern et al. 1997).

Metachromatic Leukodystrophy

MI.D is an autosomal recessive disorder of sulfatide metabolism caused by deficiency of the lysosomal enzyme arylsulfatase-A (ASA) and subsequent accumulation of sulfatides in brain, peripheral nerve, and other tissues. The storage of sulfatides affects central and peripheral myelin, leading to progressive dcmyclination. The ASA gene is localized to chromosome 22q13, and thus far over 60 mutations have been identified. Some gene mutations have been correlated with different clinical phenotypes.

Three main clinical forms have been divided by age of onset: (1) late infantile (6 months to 2 years), (2) juvenile (3-16 years), and (3) adult. Peripheral nerve involvement characterized by a progressive gait disorder, hypotonia, and lower limb arcflcxia is an early manifestation that frequently precedes CNS involvement in late infantile and early juvenile MI.D, In contrast, behavioral abnormalities and progressive dementia predominate over subtle neuropathic signs in adult-onset MI.D. A homozygous mis-sense mutation has been described in an adult patient presenting with an isolated polyneuropathy without CNS involvement {Felice et al. 2000), Marked uniform slowing of nerve conduction is seen in late infantile and juvenile cases. Reduced NCVs and delayed visual and somatosensory evoked potential latencies arc present in most adult cases. Extensive segmental dcmyelination and abnormally thin myelin sheaths are seen in nerve biopsy specimens of ail MLD variants, along with metachromatic inclusions within Schwann cells and macrophages. Peripheral nerve biopsy therefore otters a means ot continuing the diagnosis, although this is rarely needed now. The diagnosis of MI.D is supported by MR] of the brain and confirmed by an increased urinary sulfatide excretion and abnormal ASA en/.vine assays in leukocytes or fibroblasts.

Bone marrow Transplantation may increase brain levels of ASA sufficiently to stop disease progression.

Globoid Cell Leukodystrophy

Globoid cell leukodystrophy, or Krabbe's disease, is an autosomal recessive disease caused by an inherited deficiency of the lysosomal enzyme galactocerehroside *fi*-galactosidase. The gene for Krabbe's disease has been localized to chromosome 14q31. The disorder is characterized by extensive CNS and peripheral nerve demyelination and the presence of multinucleated macrophages (globoid cells) in the cerebral white matter. The classic presentation in early infancy consists of rapidly progressive deterioration in intellectual and motor development, accompanied by hypcrtonicity, opisthotonic posture, optic atrophy, and seizures. In the late-onset form, peripheral neuropathy and spasticity may be the only manifestations. Peripheral nerve involvement is demonstrated by marked uniform slowing of motor conduction velocities. Segmental demyelination, together with ultrastructurally characteristic tubular or crystalloid inclusions within Schwann cells and macrophages, is seen in sural nerve. Hematopoietic stem cell transplantation provides a source of the missing enzyme and can thereby prevent and reverse the CNS manifestations (Krivit et al. 1998).

Adrenomyeloneuropathy

Adrenoi-nyeloneuroparbv (AMN), rhe adult piieiiiilype ol adrenolcukodystrophy, is an X-linkcd recessive disorder of fatty acid metabolism characterized by adrenal insufficiency, progressive myelopathy, and peripheral neuropathy. A defect in beta-oxidation of saturated very-long-chain

fatty acids (VLCFA) in peroxisomes leads to the accumulation of tetracosanoic (C24:0) and hexacosanoic (C26:0) acid in tissues and body fluids in affected patients. A significant increase of VLCEA levels in plasma, fibroblasts, or both allows reliable detection in patients and heterozygote female carriers. The defective gene (ABCDl) is located in the region Xq28 and codes for a peroxisomal membrane protein referred to as *ALD protein* that belongs to the ABC transporter protein family (Moser 1997). Adrcnomyeloneuropathy presents in the second to third decades with progressive spastic paraparesis, distal muscle weakness, sensory loss, and sphincter disturbances. Neurological features frequently are preceded by clinical or laboratory evidence of hypoad renal ism. Approximately 10% of patients have primary adrenal insufficiency without evidence of nervous system involvement. At least 20% of female carriers develop spasric paraparesis similar to that in men, but less severe and later in onset.

Electrophysiological studies are helpful in identifying peripheral nerve involvement that may escape clinical detection because of prominent upper motor neuron signs, Nerve conduction studies demonstrate a distal axonoparhy with low CMAP amplitudes and mildly reduced NCVs. Less than 10% of patients have significant nerve conduction slowing suggestive of dcmyelination (van Geel et al. 1996). Sural nerve biopsy shows loss of myelinated fibers, occasional small onion bulbs, and curvilinear lamellar lipid inclusions ir Schwann a'lls. [iram MRI M-HI I.-•.-':-. are abnormal, demonstrating white ma net changes in one half of patients with AMN at some time in the course of their disease.

Dietaty restriction of VLCFA combined with the administration of oleic and erucic acids (Lorenzo's oil) lower plasma levels of VLCFA, but have no effect in arresting the rate of neurological progression (van Geel et al. 1999). Adrenal insufficiency responds readily to corticosteroid replacement, In contrast to the cerebral form, patients with AMN arc not considetcd suitable candidates for bone marrow transplantation.

Phytanic Acid Stotagc Disease (Refsum's Disease)

Refsum's disease, heredopathia atactica polyneuritiformis, is a rare autosomal recessive disorder of phytanic acid metabolism. The gene defect has been localized to chromosome 10 and encodes the peroxisomal enzyme phytanoyl-CoA-hydroxylase. The defect in the enzyme that initiates the alpha-oxidarion pathway of ^-methyl substituted fatty acids leads to phytanic acid accumulation in serum and tissues. Phytanic acid is derived exclusively from dietary sources, mainly chlorophyll, dairy products, meats, and fish oils. Clinical onset spans from childhood to the third decade of life. The cardinal manifestations include pigmentary retinal degeneration, with night blindness or visual field constriction, chronic hypertrophic neuropathy, ataxia, and other cerebellar signs such as nystagmus and intention tremor. Initially, the neuropathy affects the lower limbs with distal leg atrophy, weakness, areflexia, large fiber sensory impairment, and sometimes palpably enlarged nerves. Weakness becomes generalized later in the illness. In addition to pes cavus, overriding toes caused by symmetrically short fourth metatarsals are a helpful sign for Refsum's disease. Progressive sensorineural hearing loss, anosmia, cardiomyopathy, and ichthyosis are common. The course may be either progressive or fluctuating with exacerbations and remissions. Exacerbations are often precipitated by fasting, which mobilizes phytanic acid from endogenous fat stores.

Motor conduction velocities arc markedly slowed, and SNAPs are reduced or absent. CSF protein is increased in the range of 100-700 mg/dL. Sural nerve biopsy reveals a hypertrophic neuropathy with prominent onion bulb formation. The diagnosis is confirmed by elevated serum levels of phytanic acid.

Chronii dietary rrrarnioni by ivitniini;; ilu- t-\ou,enoiis sources of phytanic acid (<10 nig/day) and its precursor phytol results in reduction of serum phytanic acid levels and clinical improvemenr. The diet should provide sufficient calories to avoid weight loss. Plasma exchange has been used ro lower toxic scrum phytanic acid levels more rapidly in critically ill patients.

Tangier Disease

Tangier disease is an autosomal recessive disorder named after Tangier Island, VA, the origin of the first described cases. It is characterized by severe deficiency of plasma alpha or high-density lipoproteins, resulting in the deposition of cholesterol esters in many tissues, including the reticuloendothelial system and peripheral nerves. The accumulation of lipids leads to enlarged yellow-orange tonsils, which may provide a clue to the diagnosis. In adolescence or adult life, approximately one half of the affected patients develop one of two distinct neuropathic syndromes. The first is a progressive symmetrical neuropathy, with dissociated loss of pain and temperature sensation in the face, arms, and upper trunk combined with faciobrachial muscle wasting and weakness. These findings bear a superficial resemblance to sytingoinyelia. The second syndrome consists of relapsing multifocal mononeuropathies involving the cranial, trunk, or limb nerves.

High-density lipoprotein and serum cholesterol are markedly reduced, whereas triglyceride concentrations are elevated. A neuropathic disorder is confirmed by absent or low-amplitude SNAPs and reduced conduction velocities. Nerve biopsy specimens from patients with the multiple mononeuropathy variant have shown segmental demyelination and remyelinarion. By contrast, a preferential loss of small myelinated and unmyelinated axons is found

in the syringomyelialike variant. Typically abundant lipid vacuoles in vliv./.mi CL-!1S are nrcseiu in both. No specific treatment is known.

Abetalip o protein em ia (Bassen-Kornzweig Syndrome)

Abetalipoproteinemia is a rare autosomal recessive disorder of lipoprotein metabolism. The condition is associated with gene defects coding for the microsomal triglyceride transfer protein, resulting in abnormal very-low-density lipoprotein secretion. Fat malabsorption is present from birth and results in a severe deficiency of the fat-soluble vitamins A, E, and K. Steatorrhea, hypocholesterolemia, and abnormally spiky red cells (acanthocytes) are present from birth. Most untreated patients develop retinitis pigmentosa, peripheral neuropathy, and spinocerebellar degeneration during the first two decades of life, A progressive, mainly large fiber sensory neuropathy occurs, with gait ataxia, areflexia, impaired proprioceptive sensation, and modest distal weakness. Patients have absence of serum *fi*-lipoproteins and very low levels of vitamin E.

Clinical manifestations of vitamin E deficiency can also be found in familial vitamin E deficiency caused by mutations of the a-tocopherol transfer protein gene. These gene mutations result in the failure to incorporate ^-tocopherol in very low density lipoprotein in the liver and lead to low vitamin E levels in the absence of malabsorption (Martinello et al. 1998).

Dietary fat restriction and large oral doses of vitamin E (100 mg/kg/day) can prevent the onset of symptoms or arrest progression of neurologic complications in abetalipoproteinemia and familial vitamin E deficiency.

Mitochondrial Cytopathies and Polyneuropathy

The molecular basis has been established for several mitochondrial cytopathies, including Kcarns-Sayre syndrome, MELAS (mitochondrial myopathy, encephalopathy, /actic acidosis, and stroke), and MERRF (myoclonus epilepsy with /-agged-red /ibers; see Chapter 85). In these syndromes, myopathy is the predominant neuromuscular manifestation, although a mild, often asymptomatic, sensory polyneuropathy is detected commonly by system a tic electrophysiological and pathological studies. Peripheral neuropathy is a presenting clinical feature in three mitochondrial syndromes: neurogenic weakness, ataxia, and retinitis pigmentosa syndrome; mitochondrial ncurogastrointestinal encephalomyelopathy; and sensory ataxic neuropathy associated with dysarthria and chronic progressive external ophthalmoplegia. The last subgroup of patients presents with a familial, disabling ataxic sensory neuropathy and progressive ophthalmoparcsis that is associated with multiple mitochondrial DNA deletions (Fadicet al. 1997).

INFLAMMATORY DEMYELINATTNG POLYRADICULONEUROPATHIES

Inflammatory dcmyclinating polyradiculoneuropathies are acquired and immunologically mediated. These neuropathies can be classified by their clinical course into two major groups: an acute inflammatory demy el inn ting polyradiculoneuropathy (All)l'), or CHS, *:\\\<.]* C1DP. In GBS, the maximal deficits develop over days (maximum 28 days), followed by a plateau phase and gradual recovery. Chronic forms pursue either a slowly progressive or a relapsing course.

Acute Inflammatory Dcmyclinating Polyradiculoneuropathy (Guillain-Barre Syndrome)

In 1916, Guillain, Barre, and Strohl emphasized the main clinical features of GBS: motor weakness, areflexia, paresthesias with slight sensory loss, and increased protein in CSF without pleoeytosis (albuminocytological dissociation). Our current understanding of the pathology was greatly enhanced when Asbury and co-workers described multifocal inflammatory demyelination of spinal roots and peripheral nerves. The frequent finding of motor conduction block and reduced NCVs provided electrophysiological confirmation of widespread demyelination, Improvement in modern critical care has dramatically changed outcomes in CBS. The mortality has fallen from 33% before introduction of positive pressure ventilation to the current rate of approximately 5-10%. The diagnosis of GBS depends on clinical criteria supported by electrophysiological studies and CSF findings (Table 82.18). These diagnostic criteria define AIDP, which is the most common form of GBS in Europe and North America. Observations

have confirmed that axonal immune-mediated injury may produce similar clinical presentations, ifeasby and colleagues first called attention to axonal GBS, noteworthy for its severity and poor recovery. This axonal variant is called *acute motor sensory axonal neuropathy* (AMSAN) because of involvement of both motor and sensory fibers. A second, pure motor axonal form called *acute motor axonal neuropathy* (AMAN) has been described in northern China where it occurs in summer epidemics in children and young adults. A tentative classification of GBS subtypes has been proposed based on variant clinical expressions and different electrophysiological and pathological findings (Table 82.19; Griffin et ai. 1996).

Clinical Features

GBS is a nonseasonal illness that affects persons of all ages. With the decline of acute anterior poliomyelitis, GBS is the most common acute paralytic disease in Western countries. The mean annual incidence is 1.8 per 100,000 population. Incidence rates increase with age from 0.8 in those younger than 18 years to 3.2 for those 60 years and older.

Approximately two thirds of patients report a preceding event, most frequently an upper respiratory or gastrointestinal infection, surgery, or immunization 1–4 weeks before the onset of neurological symptoms (Govoni and Granicri 2001; Table 82.20). The agent responsible for the prodromal illness often remains unidentified. Specific infections linked to GBS include cytomegalovirus (CMV), Epstein-Barr virus, varicella zoster virus, hepatitis A and B, 111V, *Mycoplasma pneumoniae,* and *Hemophilus influenzae.* The most common identifiable bacterial organism linked to GBS and particularly its axonal forms is *Campylobacter jejuni,* a curved gram-negative rod that is a common cause of bacterial enteritis worldwide. Evidence of C. *jejuni* infection from stool cultures or serological tests was found in *26%* of patients with GBS admitted to hospitals in the United Kingdom, compared with 2% of case controls (Rccs, Gregson, and Hughes 1995). Retrospective studies from the United Stares, Holland, Germany, and Australia report serological evidence of recent C. *jejuni* infection ranging from 17-39% of patients with GRS. C, *jejuni* infection may play an even greater role in northern China where infection rates of 76% in patients with AMAN and 42% in patients with AIDP were found (Ho et a). 1995). Epidemiological data suggested a slight increase in cases of GBS following the 1976 A/New Jersey influenza vaccine, although no excess risk of developing GBS was seen with subsequent influenza vaccines. A current risk estimate of GBS after influenza vaccination is one in a million persons vaccinated. Ptior CBS should not preclude the administration of influenza vaccines in high risk individuals. Other vaccines (notably tetanus and diphtheria toxoids, rabies, and oral polio vaccines); drugs, including streptokinase, suramin, gangliosides, and heroin; and Hymenoptera stings have been associated in a few cases. Several cases have occurred in immunocompromised hosts with 1 lodgkin's lymphoma or in pharmacologically immunosuppressed patients after solid organ or bone marrow transplantation.

Patients may initially present with patesthesia, sensory symptoms with weakness, or weakness alone. The fairly symmetrical weakness of the lower limbs ascends proximal I y over hours to several days to involve arm, facial, and oropharyngeal muscles, and in severe cases respiratory muscles. Less often, weakness may begin in proximal or cranial nerve innervated muscles. Its severity varies from mild involvement, in which patients are still capable of walking unassisted, to quadriplegia. Hyporeflexia or arcflexia arc invariable features but may be missing early in the course of the disease. By definition progression ends by 1–4 weeks into the illness; if it continues longer, the condition is termed either *subacute inflammatory demyelinating polyradiculoneuropathy* if progression continues for 4-10 weeks or CiDP if there is chronic progression or multiple relapses. Cranial nerve involvement ranges from 45-75% in different series. Facial paresis, usually bilateral, is found in at least one half of patients. Involvement of extraocular muscles and lower cranial nerves is seen less often. Occasional patients develop facial myokymia. Pseudotumor cerebri with papilledema occurs as a rare complication and is almost always caused by chronically elevated intracranial pressure. The proportion of patients developing respiratory failure and requiring assisted ventilation seems to increase with age and ranges from

12% in epidemiological series to 30% in hospital-based series. Sensory loss is not a prominent feature and is limited frequently to distal impairment of vibration sense. Moderate to seven.' pain occurs in S.v'.. of patients on admission to the hospital. Interscapular or tow back pain with radiation into the legs is most common, sometimes causing concern about the possibility of an epidural hematoma or abscess. Dyscsthctie extremity pain described as burning or tingling is present in approximately one half of patients, whereas myalgic limb pain associated with joint stiffness is less common (Moulin et al. 1997). Unusual clinical variants with restricted patterns of weakness may cause diagnostic difficulties. Isolated weakness of the face, oropharynx, neck, and arms without involving the legs is a distinctive feature of the pharyngeal-cervical-brachial variant. Rarely, weakness remains confined to the lower limbs, resembling a cauda equina lesion. Autonomic dysfunction of various degrees has been reported in 65% of patients admitted to the hospital (Zochodne 1994). Its manifestations may be related to either increased or decreased sympathetic activity. Signs of decreased sympathetic {orthostatic hypotension, anhidrosis) or decreased parasympathetic {urinary retention, gastrointestinal atony, or iridoplegia) function may be seen. Signs of excessive sympathetic activity include episodic or sustained hypertension, sinus tachycardia, tachyarrhythmias, episodic diaphoresis, and acral vasoconstriction. Excessive vagal activity accounts for sudden episodes of bradycardia, heart block, and asystole. These vagal spells may occur spontaneously or may be triggered by tracheal suctioning. Serious cardiac arrhythmias with hemodynamic instability tend to be more frequent in patients with severe quadriparesis and respiratory failure. Autonomic dysfunction can result in eiectrocardiographical changes including T-wave abnormalities, ST-segment depression, QRS widening, QT prolongation, and various forms of heart block.

Guillam-Barre Syndrome Variants

Several variations from this typical presentation have been described. Their link to GBS is supported by preceding infectious episodes, diminished reflexes, elevated CSF protein levels, and immune-mediated etiologies.

The Miller-Fisher syndrome (MFS), which accounts for 5% of cases, is characterized by ophthalmoplegia, ataxia, and areflexia. Patients present with diplopia followed by gait and limb ataxia. Ocular signs range from complete ophthalmoplegia, including unreaenve pupils, to external ophthalmoparesis with or without ptosis. Cranial nerves other than ocular motor nerves may be affected. Motor strength is characteristically preserved, although overlap with typical GBS seems to occur when some patients develop quadriparesis. The ataxia is attributed to a peripheral mismatch berween proprioceptive input from muscle spindles and kinesthetic information from |omt receptors. Patients present with rapid onset of symmetrical, multiple cranial nerve palsies, mosr notably bilateral facial palsy (polyneuritis cranialis), that may be a *forme fruste* of this syndrome. Elcctrodiagnostic studies demonstrate an axonal process affecting predominantly sensory fibers with only mild motor conduction abnormalities. SNAP amplitudes arc reduced or absent. Motor conducrion srudies, including F-wave latencies, are usually normal. Most patients have increased CSF protein without plcocytosis one week after onset. Brain MRI scans do not demonstrate brainstem or cerebellar lesions, though there are reports of cases appearing to be identical to MFS where there have been MRI brainstem lesions. Gadolinium enhancement of ocular motor nerves has been reported. Serum IgG antibodies to the ganglioside GQ1b are found in acute phase sera of mosr parienrs with MFS and GBS with ophthalmoplegia, which suggests that the antibodies are disease-specific and related to the pathogenesis (Chiba et al. 1993). MFS has a benign prognosis, with recovery after a mean of 10 weeks.

Acute pandysatttonomia is characterized by the rapid onset of combined sympathetic and parasympathetic failure without somatic sensory and motor involvement, although reflexes are usually lost during the course of the illness. These patients develop severe orthostatic hypotension, anhidrosis, dry eyes and mouth, fixed pupils, invariant heart rate, and disturbances of bowel and bladder function. About half of the patients have autoantibodies to ganglionic acetylcholine receptors which may play a pathogenetic role by blocking cholinergic transmission in autonomic ganglia (Venimo LI al. 2000). (iangliome receptor blocking antibodies serve as serological markers of autoimmune autonomic neuropathies and are elevated in both acute pandysautonomia and paraneoplastic autonomic neuropathy.

Feasby and coworkers drew attention to cases of fulminant GBS with poor prognosis for recovery (AMSAN), All patients had a hyperacute course progressing to a peak deficit in less than 7 days, developed profound quadriparesis with severe muscle wasting, and required prolonged respiratory support. Electrodiagnostic studies showed markedly reduced or absent C'MAPs with distal supramaximal stimulation without conduction delay and absent SNAPs. The subsequent appearance of abundant fibrillation potentials on needle EMG, together with persistently mexcitable motor nerves, and poor recovery suggested a primary axonopathy as the underlying disease process. Ex tensive wa lie nan axonal degeneration without significant inflammation or demyelination has been described in ventral and dorsal roots and in peripheral nerves at autopsy (Griffin et al. 1996).

Sporadic cases of a pure motor variant presenting with acute flaccid paralysis without clinical or electrophysiological involvement of sensory nerves have been observed in large series of patients with GBS. These case descriptions are similar to AMAN occurring in epidemic proportions among children and young adults in northern China during

summer months (McKhann et al. 1993). AMAN differs from GBS by electrophysiological study results that demonstrate reduced compound muscle potential amplitudes but normal motor disral latencies and conduction velocities. Autopsy studies of some cases have shown noninflammatory wallcrian-likc degeneration of ventral roots and motor axons in mixed nerves. However, nerve biopsy studies in others have shown intrusion of macrophages between the axon and the surrounding myelin sheath, with relatively little axonal degeneration. Extensive axonal degeneration of motor nerve terminals was confirmed by motor point biopsy in a patient with AMAN. Most patients with AMAN recover as rapidly as patients with AIDP (Ho et al. 1997), The rapid clinical recovery rates and the paucity of pathological findings in some fatal cases could be explained by either conduction block of motor axons at nodes of Ranvier because of macrophage intrusion or by axonal degeneration of motor nerve rerminals. Extensive axonal degeneration of motor nerve terminals was confirmed by motor point biopsy in a patient with AMAN. Antecedent C. *jejuni* infection was found by using serological tests in 76% of AMAN patients from northern China, which suggests that this organism plays a major role in the pathogenesis.

The exisrance of a sensory variant of GBS affecting mainly sensory nerve fibers has long been suspected but rarely confirmed. Such patients present with acute sensory loss, areflexia, high spinal fluid protein, and nerve conduction features of demyelination (Oh, LaGanke, and Claussen2001).

Laboratory Studies

CSF examination and serial electrophysiological studies arc critical for confirming the diagnosis of GBS. Other laboratory studies are of limited value. Mild transient liver enzyme elevations without obvious cause are found in approximately one third of patients. Hyponatremia is seen most frequently in ventilated patients because of inappropriate secretion of antidiuretic hormone. Deposition of immune complexes may rarely lead to glomerulonephritis and result in microscopic hematuria and proteinuria. In the first week of neurological symptoms the CSF protein may be normal but then becomes elevated on subsequent examinations. In approximately 10% of cases, the CSF protein remains normal throughout the illness. Transient oligoclonal IgG bands and elevated myelin basic protein levels may be detected in some patients. Moderate CSF pleocyrosis is a distinctive feature of GBS associated with HIV infection. Abnormalities of electrophysiological studies are found in approximately 90% of established cases and reflect an evolving picture of multifocal demyelination associated with secondary axonal degeneration. The most common electrophysiological abnormalities include prolonged distal motor and F-wave latencies, absent or impersistent F waves, conduction block, reduction in distal CMAF amplitudes with or without temporal dispersion, and slowing of motor conduction velocities (Cros and Triggs 1996). Conduction block of motor axons is the electrophysiological correlate of clinical weakness and is recognized by a decrease of greater than 30% in CMAP amplitude from disral to proximal stimulation in the absence of temporal dispersion. Electrodiagnostic studies may not be diagnostic early in the course of the disease. Absent H-reflexes, delayed or absent F waves, and low amplitude or absent SNAPs in the upper extremity combined with normal sural SNAPs are changes supportive of the diagnosis in the first week of illness (Gordon and Wilbourn, 2001). Needle EMG initially shows decreased motor unit recruitment. Subsequently, if any amount of axonal degeneration occurs, fibrillation potentials appear 2—4 weeks after onset. Electrodiagnostic studies performed in the patients enrolled in the North American GBS Study found abnormalities of distal motor latencies and F-wave latencies in approximately one half of patients studied within 30 days of onset. Partial motor conduction block (30%), slowing of motor conduction velocity (24%), and reduced distal CMAP amplitudes (20%) were less frequent. In cases with axonal degeneration, reduced CMAP and SNAP amplitudes are found. Such patients tend to have a slower and less complete recovery than those whose weakness is related primarily to conduction block. Electrodiagnostic parameters arc the most reliable indicators of prognosis. A distal CMAP amplitude of less than 20% of the lower limit of normal was associated with poor outcome in the North American GBS Study.

Lumbosacral spinal MRI may demonstrate gadolinium enhancement of lumbar roots. The value of specific serological tests in the diagnosis of GBS is limited. Elevated serum antibodies to *Mycoplasma,* CMV, or C. *jejuni* can pinpoint the preceding infection. Serological tests for C. *jejuni* infection arc difficult both to perform and interpret. The proportion of GBS cases associated with *Campylobacter* infection remains uncertain but seems to range from 17-76% in various parts of the world. Preceding *Campylobacter* infection li.i-. brer, linked u> .]\<>n;il variants, worse ourcome, and high titers of anti-GMj, anri-GDu,, anti-$GD_{[:1}$, and anti-GalNAc-$GD_{1:}$, gangliosidc antibodies of the IgG class {Jacobs, van Doom, and Schmitz 1996). Other studies confirmed the presence of IgG antiglycolipid antibodies in 10-40% of patients with GBS but failed to show a correlation with *Campylobacter* infection ii lo et al. 1995). FJevated anti-GQib gangliosidc antibodies are consistently found in MFS. Anti-galactocerebroside antibodies have been detected in patients with precedent *Mycoplasma* infection. Complement fixing antibodies to peripheral nerve myelin are present in most patients during the acute phase of GBS.

Differential Diagnosis

Care should be taken to distinguish GBS from other conditions leading to subacute motor weakness (Table 82.21).

Table 82.21: Differential diagnostic considerations in Guillain-Barre syndrome

1. Acute neuropathies
   Hepatic porphyrias
   Critical illness neuropathy
   Diphtheria
   Toxins
   Arsenic, thallium, organophosphates, lead
   Neurotoxic fish and shellfish poisoning (ciguatoxin, retrodotoxin, saxitoxin)
   Buckthorn
   Tick paralysis
   Vasculitis
   Inflammatory meningoradiculopathies
   Lyme disease, cytomegalovirus lumbosacral ra d i c u 1 omy e Io pa thy
II. Disorders of neuromuscular junction
   Botulism, myasthenia gravis
HI. Myopathies
   Hypokalemia, hypophosphatemia
   R ha bdomyo lysis
   Polymyositis
   Intensive care myopathy
IV. Central nervous system disorders
   Poliomyelitis
   West Nile virus poliomyelitis
   Rabies
   Transverse myelitis
   Basilar artery thrombosis

Among the neuropathies with acute onset, acute porphyria, diphtheria, and occasional toxic neuropathies (arsenic, thallium, buckthorn, acrylamide, organophosphorous compounds, and w-hexane) must he considered. Flaccid general weakness and failure to wean from the ventilator are common features of critical illness neuropathy that develops in patients confined to the intensive care unit with sepsis and multiorgan failure. Elcctrodiagnostic features of an axonal neuropathy and normal CSF findings distinguish critical illness neuropathy from GBS. A related syndrome, the acute myopathy of intensive care, follows the use of nondepolarizing neuromuscular blocking agents in combination with intravenous corticosteroids. Metabolic disturbances (severe hypophosphatemia, hypokalemia, hypermagnesemia), myopathies, disorders of neuromuscular transmission, and tick paralysis should be considered also. Botulism develops after the consumption of contaminated foods, with symptoms of oph thai mo paresis and facial and bulbar weakness. Nerve conduction studies reveal low-amplitude compound muscle potentials. High-frequency repetitive nerve stimulation ot maximal voluntary contraction leads to an incremental response that is typical for presynaptic neuromuscular transmission defects. Acute brainstem infarcts, spinal cord compression, epidural abscess and postinfectious transverse myelitis may present diagnostic difficulties before upper motor neuron signs develop and before results of elcctrodiagnostic and CSF studies become available. Among other signs, early urinary retention and a sharply demarcated sensory level on the trunk suggest spinal cord disease and call for spinal MRI. CSF pleocytosis (>50 cells per ul) casts doubt on the diagnosis of uncomplicated GBS and suggests inflammatory meningoradiculopathies caused by Lyme disease, **HIV** infection, or CMV in acquired immunodeficiency syndrome. Anterior poliomyelitis causes rapidly evolving asymmetrical weakness accompanied by fever and CSF pleocytosis. A poliomyelitis-like condition producing flaccid paralysis is seen in up to 27% of patients with neurological complications of West Nile virus infection. A common pitfall to avoid is misdiagnosis of early GBS as hysterical weakness.

Pathology

Classic pathological studies of AIDP have demonstrated endoneurial perivascular mononuclear cell infiltration together with multifocal demyelination. The peripheral nerves may be affected at all levels from the roots to distal intramuscular motor nerve endings, although the brunt of the lesions frequently falls on the ventral roots, proximal spinal nerves, and lower cranial nerves. Intense inflammation may lead to axonal degeneration as a consequence of a toxic bystander effect. Ultrastructural studies have shown that macrophages play a major role in demyelination by stripping off myelin lamellae from its axon. The inflammatory infiltrates consist mainly of class 11-positive monocytes and macrophages and T lymphocytes. The expression of class II antigen is increased in Schwann cells, raising the possibility that Schwann cells may present the antigen to autoreactive T cells and activate the desttuction of myelin. Extensive primary wallerian-like degeneration of motor and sensory roots and nerves without significant inflammation or demyelination is found in cases of AMSAN.

Pathogenesis

A considerable body of evidence points to an organ-specific autoimmune disorder mediated by autoreactive T cells and humoral antibodies to still incompletely characterized periphera nerve antigens (1 laming. Willison, and Kieseier 2002). A preceding infection may trigger an autoimmune response through molecular mimicry in which the host generates an immune response against an infectious organism that shares epitopes with the host's peripheral nerves. At the onset of disease, activated T cells play a major role in opening the blood-nerve barrier to allow circulating antibodies to gain access to peripheral nerve antigens. T-cell activation markers (interleukin-6, interleukin-2, soluble intcrleukin-2 receptor, and interferon-^) and tumor necrosis factor-a, a proinflammatory cytokine released by T cells and macrophages, are increased in serum of patients. In addition, adhesion molecules and matrix metalloprotcinases arc critically involved in facilitating recruitment and transmigration of activated T cells and

monocytes through the blood-nerve barrier. Soluble E-selectin, an adhesion molecule produced by endothelial cells, and metailoproteinases are increased in patients with GBS during the early stages of disease. A cell-mediated immune reaction against myelin components is supported by experimental allergic neuritis, the accepted animal model for AIDP. Experimental allergic neuritis can be produced by the injection of peripheral nerve myelin or PNS-specific myelin basic protein P2.

Several observations indicate that humoral factors participate in the autoimmune attack on peripheral nerve myelin, axons, and nerve terminals: (1) immunoglobulins and complement can be demonstrated on myelinated fibers of affected patients by immunostaining; (2) MPS and AMAN are strongly associated with specific anti-ganglioside antibodies; (3) serum from MFS and AMAN patients contains IgG antibodies that block neuromuscular transmission in a mouse nerve-muscle preparation; (4) complement Cl-fixing antiperipheral nerve myelin anti-body can be detected in the serum of patients during the acute phase of GBS; *(5)* plasmapheresis or immunoglobulin infusions result in clinical improvement; and (6) intraneural injection of GBS serum into rat sciatic nerve results in secondary infiltration of the injection site at the time of the appearance of the hind limb weakness.

Understanding of the immune mechanisms of GBS and its axonal variants was enhanced by the detailed immu.no.-histochemical and ultrastructural studies of clinically well-defined, autopsied cases from northern China. The earliest changes seen in AIDP within days of onset consisted of deposition of complement activation products and mem-brane attack complex on the outermost Schwann cell surface followed by vesicular myelin changes at the outermost myelin lamellae with subsequent recruitment of macrophages and progressive demyelination (Hafcr-Macko et al. 1996). Previously, the role of complement has been suspected by finding increased levels of complement activation products in CSF and soluble terminal comple-ment complexes in serum of patients with AIDP. The immune attack in AIDP appears to begin with binding of autoantibodies to specific epitopes on the outermost Schwann cell membrane with consequent activation of complement (Figure 82.19). The nature of the epitope in AIDP, although still uncertain, is likely a glycolipid. Pathological studies of early cases of AMAN found deposition of activated complement components and immunoglobulins at nodal axolemma. This was followed by disruption of the paranodal space, allowing the entry of complement and immunoglobulins along the axolemma, with subsequent recruitment of macrophages to affected nodes. Finally, macrophages were shown to invade the periaxonal space leading to wallerian-like degeneration of motor fibers (Hafcr-Macko et al. 1996; Figure 82.20). These findings suggest that AMAN is caused by an antibody- and complement-mediated attack on axolemmal epitopes of motor fibers. The most attractive candidate targets arc GM_r and asialo-GM_rlike gangliosides, which are present in nodal and internodal membranes of motor fibers. Certain C. *jejuni* strains associated with axonal GBS and MFS variants contain GM_rlike epitopes in their polysaccharide coats. Anti-GM| and GQlb antibodies that cross-react to these lipopolysaccharide epitopes arc found in a high proportion of patients with AMAN and MFS and some patients with GBS. These observations have led to the concept of molecular mimicry in which epitopes of the infectious agent elicit antibodies that cross-reacr with shared epitopes on axons. The nerve fibers thereby become the inadvertent targets of an immune response directed against an infectious organism. The anti-ganglioside anti-bodies obtained from AMAN and MFS patients block neuromuscular transmission in an in vitro nerve-muscle preparation. The blocking activity of these IgG antibodies can be neutralized by intravenous immunoglobulin (Bucbwald et al. 2002). Furthermore, rabbits immunized wiili GM I develop AMAN. thereby fulfilling the postulates for an autoimmune pathogenesis (Sheikh and Griffin 2001). AMSAN may be caused by a more severe immune injury triggered by axonal epitopes because similar pathological changes affecting motor and sensory fibers have been observed in cases of AMSAN.

Treatment

Patients with rapidly worsening acute GBS should be observed in the hospital until the maximum extent of progression has been established. The reduction in mor-tality to less than 5% reflects improvements in modern critical care. Supportive care in intensive care units and the prevention of complications, of which respiratory failure and autonomic dysfunction arc the most important, provide the best chance for a favorable outcome (Bosch 1998). Respiratory and bulbar function, the ability to handle secretions, heart rate, and blood pressure should be closely monitored during the progressive phase. Respiratory failure requiring mechanical ventilation develops in up to 30% of patients with CBS. Signs of impending respiratory failure include deterioration in forced vital capacity (FVC), declining maximal respiratory pressures, and hypoxemia caused by atelecrasis. Initially, it may be necessary to monitor FVC and negative inspiratory pressure every 4-6 hours while the patient is awake. Patients should be monitored by pulse oxymetry, especially at nighr, for rhe early detection of oxygen desaturation. Clinical parameters that allow the prediction of future need of mechanical ventilation have been identified; rapid disease progression (onset to admission in less than 7 days), bulbar dysfunction, bilateral facial palsies, and autonomic instability. Serial measures of decline in respiratory function that could predict future respiratory failure included vital capacity of less than 20 mL/kg or a decline by 30% from baseline, maximal inspiratory pressure less than 30 cm, and maximal expiratory respiratory pressure of less than 40 cm of H_20

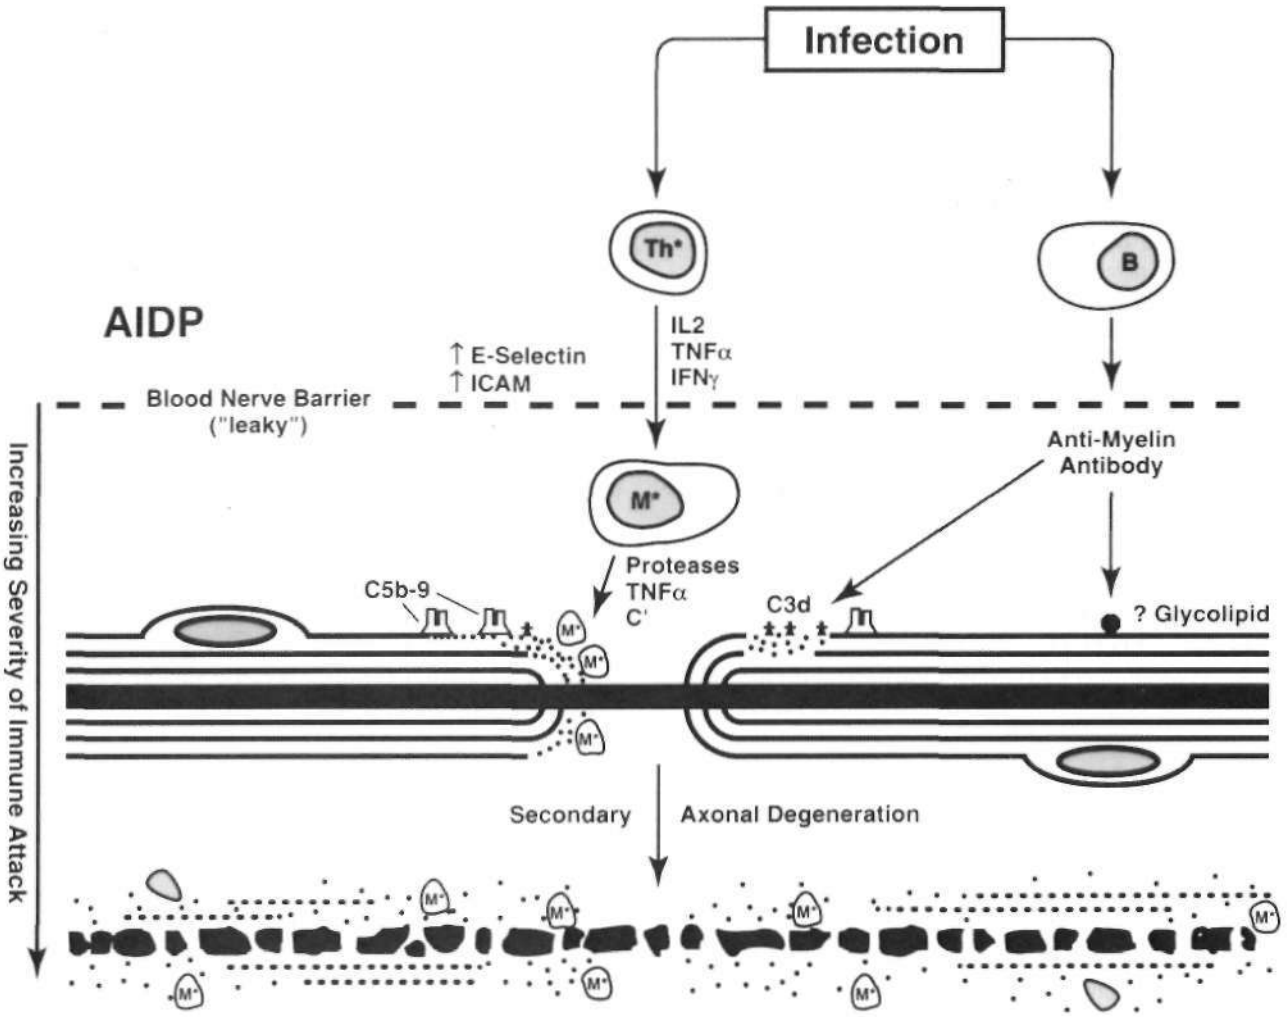

FIGURE 82.19 Immune injury to nerve fibers in acute inflammatory demyelinating polyradiculoneuropathy (AIDP). A preceding infection may trigger the formation of anrimyclin autoantibodies and activated T-hdper cells (Th*). Proinflammatory cytokines (tumor necrosis factors [TNFor], interferon-/ [INF/]) and upregulation of adhesion molecules (E-selectin, intercellular adhesion molecule jICAM|) facilitate the breakdown of the blood-nerve barrier to activated T cells, macrophages, and anrimyclin antibodies, Autimyclin anribodies react with epitopes on the abaxonal Schwann cell membrane with consequent activation of complement. Deposition of complement activation products (C3d) and membrane attack complex (C.5b-9) on the outermost Schwann cell membrane leads to vesicular myelin changes, followed by recruitment of macrophages (M*) and progressive demyelination. Intense inflammation may lead to secondary axonal degeneration. (B = Bcell; IL2 = interleukin 2.} (Reprinted with permission from Bosch, F.. P. 1998, "Gnillain-Barre syndrome: An update of acute immune-mediated polyradiculoneuropathies," *Neurologist,* vol. 4, pp. 21 1-226.)

(Lawn et al. 2001). This so called "20-30-40" rule allows patients at risk to be identified and transferred to an intensive care unit for even closer monitoring. In a series of 200 patients, short disease duration, inability to lift the head, and a vital capacity of less than 60% predicted the need for mechanical ventilation in 85% of patients with all three risk factors (Sharshar er at. 2003). Elective intubation for ventilatory assistance should be performed when FVC falls below 12-15 mL/kg or below 18 raL/kg in patients with severe oropharyngeal weakness, or when arterial Po_2 values fall below 70 mm Hg with inspired room air. When respiratory assistance is needed for longer than 2 weeks, a tracheostomy should be performed.

In the event of cardiac arrhythmias or marked fluctuations of blood pressure, continuous elccrrocardiographic.il and blood pressure monitoring allow early detection of life-threatening situations that require prompt treatment. Antihypertensive and vasoactive drugs must be used with extreme caution in the presence of autonomic instability. Tracheal suctioning may trigger sudden episodes of hypotension or bradyarrhythmia. Back and radicular pain often respond to nonsteroidal anti-inflammatory drugs. At times oral or parenteral opioids are required for adequate pain control. Increased metabolic requirements together with negative caloric intake caused by impaired swallowing may-lead to a state of relative starvation in severely affected

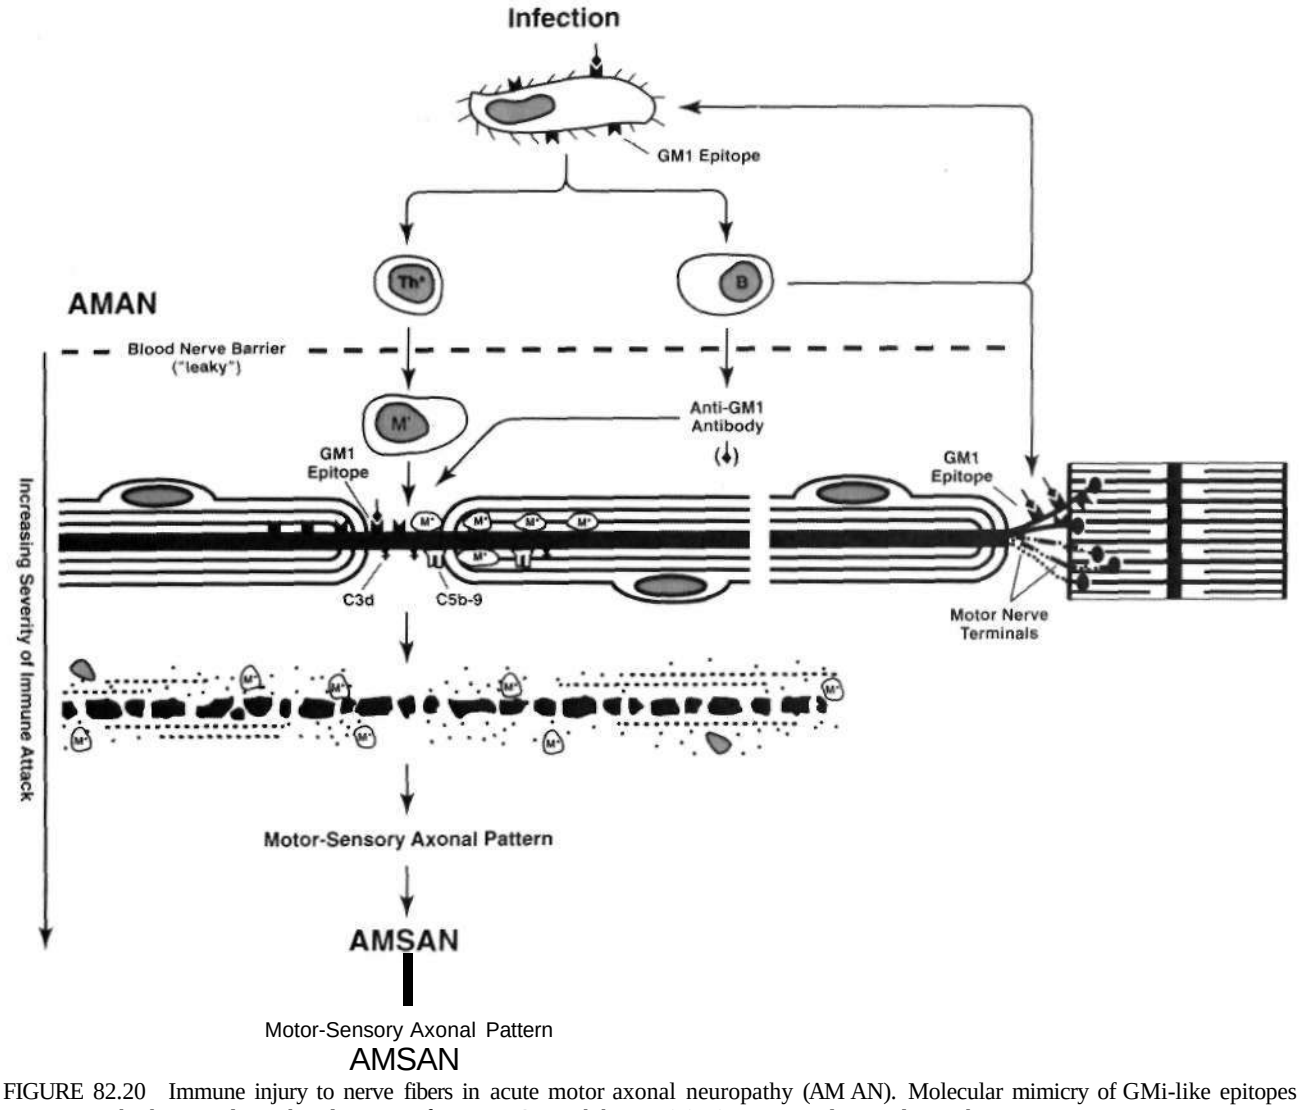

FIGURE 82.20 Immune injury to nerve fibers in acute motor axonal neuropathy (AM AN). Molecular mimicry of GMi-like epitopes common to both Iipopolysaccharide coats of certain *Campylobacter jejuni* strains and axonal membranes may cause an autoimmune response. Activated complement components (C3d, C5b-9) and immunoglobulins arc found at nodes of Ranvier and along axolemma of motor fibers. Macrophages (M*) are recruited to the targeted nodes and invade the periaxonal space, leading to wallenan degeneration. The lack of blood-nerve barrier at motor nerve terminals may make these distal axons vulnerable to circulating GM] antibodies. (AMSAN = acute motor sensory axonal neuropathy; R = B cell.) (Reprinted with pi-nuissiori irom linsdi 1' I. IOTX "Guillain-Barri: Syndrome: An update of acute immune-mediated polyradiculoneuropathies," *Neurologist*, vol. 4, pp. 211-226.)

patients. Nutritional requirements should be met by providing a high-caloric protein diet or by beginning enteral feedings as early as possible.

Subcutaneous heparin or low-molecular-weight heparin together with calf compression devices should be ordered routinely in immobilized patients to lower the risks of venous thrombosis and pulmonary embolism. Infections of the lung and urinary tract develop in almost half of patients with GBS in the intensive care unit. Prevention and prompt treatment of nosocomial infections are important aspects of care. Chest physiotherapy and frequent oral suctioning aid in preventing atelectasis in patients with impaired cough and sigh. Skillful nursing care with regular turning and attention to skin, eyes, mouth, bowel, and bladder are essential. Exposure keratitis is avoided in cases of facial diplegia by using artificial tears and by taping the eyelids closed at night. Pressure-induced ulnar or fibular nerve palsies are prevented by proper positioning and padding. Physical therapy is started early because it helps prevent contractures, joint immobilization, and venous stasis. Psychological support and constant reassurance about the potential for recovery are important for the morale of patients and family members. In the recovery phase, skillful physical therapy and rehabilitation hasten recovery.

Among specific therapeutic interventions aimed at mitigating the harmful effects of autoantibodies, plasma exchange and high-dose intravenous immune globulin (IVIG) infusions have been shown to be equally effective. Six large randomized, controlled trials involving more than 600 patients have established the benefit of plasma exchange in acute GBS by shortening the recovery time. Therapeutic plasma exchange is recommended for patients with moderate to severe weakness (defined as the ability to walk only with support or worse). Benefits are clearest

when plasma exchange is begun within 2 weeks of onset. The recommended plasmapheresis schedule entails a series of five exchanges (40-50 mL/kg) with a continuous flow machine on alternate days using saline and albumin as replacement fluid. The effect of plasma exchange in mildly affected patients and the optimal number of exchanges were investigated by the French Cooperative Group on Plasma Exchange (1997). Even mildly affected patients benefited from two exchanges. Four exchanges were optimal for moderate and severe cases. The Cochrane review confirmed the value of plasma exchange over supportive therapy in hastening the recovery from GBS when started within 30 days after disease onset (Raphael cr al. 2002). Treatment-related relapses tend to occur in approximately 10% of patients within 3 weeks after treatment. Plasmapheresis should be performed only in centers with experience in exchange techniques in critically ill patients. Most serious complications are linked to venous access problems including hematoma formation at puncture sites, pneumothorax after insertion of central lines, and catheter-related septicemia. Septicemia, active bleeding, and severe cardiovascular instability are contraindications for plasmapheresis. Cerebrospinal fluid filtration, a new treatment approach, has been compared to plasma exchange. Although no difference in outcomes was shown, the trial was too small to draw conclusions on the value of CSF filtration.

Three randomized trials comparing IV1G with plasma exchange demonstrated the benefit of five daily infusions of immunoglobulin (0.4 g/kg/day) given in the first 2 weeks of the disease (Plasma Exchange/Sandoglobulin Guillain-Barre Syndrome Trial Group 1997), Both treatment modalities were equally effective. There was no advantage of using both together. These findings were confirmed by another Cochran systematic review (Hughes et al. 2001b). Anti-idiotypic antibodies supplied by rVIG that have the potential to bind and neutralize pathogenetic antibodies are the proposed mode of action. Minor side effects such as headaches, myalgias and arthralgias, flulike symptoms, fever, and vasomotor reactions arc observed when infusion flow rates arc excessive. More serious complications, such as anaphylaxis in IgA-dcficicnt individuals who develop anti-IgA antibodies after the first course of lgA-containing IVIg infusions, aseptic meningitis, congestive heart failure, thrombotic complications (strokes *And* myocardial infarction), and transient renal failure, have rarely been reported (Brannagan 2002). There is a higher rate of vascular complications, particularly stroke and coronary thrombosis, in patients treated with the schedule of IVIG 1.0 g/kg/day for 2 days than in those receiving the more standard schedule of 0.4 g/kg/day for .5 days. The slower schedule is recommended. To prevent headache from a mild sterile meningitis, patients should be treated with acetaminophen 500-1000 g and ibuprofen 600 mg one hour before each infusion, and the dose can be repeated six hours later if headache develops. IVIg has become the preferred treatment for acute GBS because of ease of administration (Figure 82.21). The optimal effective dose of IVIG has not been established. Six daily infusions of 0.4 g/kg were reported to be superior to 3 daily infusions in patients who could not receive plasma exchange (Raphael ct al. 2001). In patients with hyperviscosity, congestive heart failure, chronic renal failure, or congenital IgA deficiency plasma exchange is preferred.

Corticosteroids have been advocated in the treatment of GBS but cannot be justified, because two randomized,

controlled trials, one using conventional doses of prednisolone and the other using high-dose intravenous methyl prednisolone, have found no benefit (Guillain-Barre Syndrome Steroid Trial Group 19931. The combination of IVIG with methyl prednisolone failed to find significant advantage over IVIG alone in one trial.

('.nurse and Prognosis

liy ilrhmlior., pa'kails should reach their **iraxirnam** deticil within 4 weeks of onset; if the disease progresses for longer, it is classified as subacute or CI DP. Up to 30% of patients develop respiratory insufficiency requiring assisted ventilation, and between 2% and 5% die of complications. After progression stops, patients enter a plateau phase lasting 2-4 weeks or longer before recovery begins. Although most patients recover functionally, 20% still have residual motor weakness 1 year later. Approximately 70% of patients complete their recovery in 12 months and 82% in 24 months. Approximately *V'4,* of patients may have a recurrence following recovery. The North American Guillain-Barre Syndrome Study Group found that older age (>60 years), ventilatory support, rapid progression reaching maximum deficit in less than 7 days, and low amplitudes of distal CMAPs (20% of lower limit of normal or less) were poor prognostic factors that were associated with a less than 20% probability of walking independently at 6 months. Acute hypoxic-ischemic and infectious episodes also probably worsen the prognosis.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

Many similarities exist between CIDP **and the acute** form, GBS. Both disorders have similar clinical features and share the CSF albuminocytological dissociation and the pathological abnormalities of multifocal inflammatory demyclination, with nerve conduction features reflecting demyelination. *Av.* autoimmune basis is suspected lor bmh disorders although the supporting evidence remains incomplete. The major differences between the two conditions arc in the time course and their response to corticosteroids. **CIDP** has a more protracted clinical course, is rarely associated with preceding infections, has an association with human lymphocyte antigens, and responds to corticosteroid therapy. Two patterns of temporal evolution of **CIDP** can be seen. More than 60% of patients show a continuous or stepwise progressive course over months to years, whereas one third have a relapsing course with partial or complete recovery between recurrences. The age of onset may influence the course of the disease. In one large series, the age of onset was younger (mean 29 years) in those who had a relapsing course than in those pursuing a chronic progressive course (mean 51 years). A history of preceding infection is found in less than 10%. In contrast, pregnancy is associated with a significant number of relapses, occurring mainly in the third trimester and the immediate postpartum period. Human lymphocyte antigen-linked genetic factors may influence susceptibility to CIDP.

The prevalence of CIDP ranges from one to two per 100,000 of the populations in South East England and Australia (I.unn ct al. 1999), Although precise prevalence figures are not available for the United States, CIDP represents 13-20% of all initially undiagnosed neuropathies referred to specialized neuromuscular centers.

Clinical Features

The disease is seen at all ages, with peak incidence in the fifth and sixth decades. The majority of patients have symmetrical motor and sensory involvement, although occasional cases with predominantly motor involvement may be seen (Rotta et al. 2000). To fulfill diagnostic criteria for CIDP, weakness must be present for at least 2 months. Proximal limb weakness is almost as severe as distal limb weakness. In fact, the presence of proximal muscle weakness sets this neuropathy apart from most othets. Both upper and lower limbs are affected, although the legs are often more severely involved. Muscle wasting is rarely pronounced. These signs provide helpful clinical clues to separate **CIDP** patients from those with axonal neuropathies. Generalized hyporeflexia or areflexia is the rule. Sensory symptoms in a stocking-glove distribution (numbness or tingling) implicating large fiber involvement occur frequently, whereas pain is uncommon. Children differ from adults by a more precipitous onset and more prominent gait abnormalities. Additional findings, listed in decreasing order of frequency, are postural tremor of the arms, enlargement of peripheral nerves, papilledema, and facial or bulbar weakness. Massive nerve root enlargement causing myelopathy or symptomatic lumbar stenosis, or vision loss caused by progressive pseudotumor cerebri, are umisii.il el mi! al l-.-alinv-, VI id mm and 1 "> ^ •. .-, *l'>'"'i'i.*

Atypical clinical variants with different distribution of weakness and sensory deficits have received recent attention (Saperstein et al. 2001). A multifocal distribution of weakness and sensory deficits is seen in some patients. This multifocal form of CIDP initially identified by Lewis and Sumner (hence the term *Lewis-Sumner variant)* is also described by the acronym *MADSAM* (multifocal acquired demyelinating sensory and motor neuropathy). Electrophysiological studies demonstrating focal conduction block or severe slowing of nerve conduction distinguish this multifocal demyelinating neuropathy from the more common vaseulitic multiple mononeuropathies. Unlike multifocal motor neuropathy, patients with this multifocal variant of CIDP have clinical and electrophysiological involvement of both motor and sensory nerves, increased CSF protein, and a good response to corticosteroids. Some patients fulfilling the diagnostic criteria for CIDP

have only distal limb involvement (distal acquired symmetrical demyelinating neuropathy). Nearly two thirds of these patients have IgM monoclonal gammopathies, and though they have been reported to respond poorly to immune-modulating therapy (Katz et al. 2000), IVIG treatment is often beneficial. CIDP may be associated occasionally with a relapsing multifocal demyelinating CNS disorder resembling multiple sclerosis, with CNS demyelination confirmed by abnormal visual and somatosensory evoked potentials and brain MRI. A CIDP-likc syndrome may develop in cases of inherited neuropathy. These patients typically have a positive family history of affected kin and bony abnormalities such as pes cavus and hammer toes from an early age, but subsequently develop subacute deterioration with proximal muscle weakness and increased CSF protein. The newly acquired symptoms may respond to corticosteroid therapy; hence the term *prednisone-responsive hereditary motor and sensory neuropathy.*

Acquired demyelinating polyradiculoneuropathies meeting the diagnostic criteria for CIDP may be associated with HIV-I infection, systemic lupus erythematosus, monoclonal gammopathy of undetermined significance (MGUS) and plasma cell dyscrasias (macroglobulinemia, osteosclerotic myeloma, POEMS syndrome, Castleman disease), chronic active hepatitis, inflammatory bowel disease, and Hodgkin lymphoma. Compared with idiopathic CIDP, the patients with a monoclonal gammopathy tend to be older, have a more protracted course but less severe functional impairment at presentation, and seem to respond less well to immunomodulatory therapy (Simmons et al. f 993). There are patients with either insulin-dependent or non-insulin-dependent diabetes mellittis with associated polyradiculoneuropathy who meet the electrophysiological criteria for CIDP. Some of these patients respond to intravenous immunoglobulin therapy (Sharma et al. 2002a). Occasional patients with malignant melanoma or after therapy by vaccination with melanoma lysates develop CIDP. The association between melanoma and CIDP might be explained by molecular mimicry because both melanoma and Schwann cells are derived from neural crest tissue and share common glycolipid antigens (Weiss et al. 1998). Appropriate laboratory studies are necessary to separate these polyradiculoneuropathies from idiopathic CIDP without concurrent disease.

Laboratory Studies

The diagnosis of CIDP is supported by a laboratory profile including electrophysiological, CSF, and nerve biopsy findings (Table 82.22). There is a pattern of nerve conduction changes that strongly supports acquired multifocal demyelination. This includes (1) nonuniform reduction in motor conduction velocities below 70% of normal in at least two motor nerves; (2) partial conduction block (proximal CMAP amplitude or area <50-70% of distal; different authors recommend different thresholds for diagnosis of conduction block) or abnormal temporal dispersion in at least one motor nerve; (3) prolonged distal latencies in at least two motor nerves; and (4) absent F waves or prolonged F-wavc latencies in at least two motor nerves. Only 60% of patients with CIDP fulfill these criteria. Less restrictive electrophysiological criteria have been proposed (Nicolas et al. 2002). CSF protein values in excess of 45 mg/dL are found in 95% of oases ami levels above 100 mg/dL are common. CSF pleocytosis is rare except in HIV-associatcd CIDP. Anti-myclin antibodies directed against MPZ (P0) have been found in a small proportion of patients (Yan et al. 200 I). MRI scanning may demonstrate gadolinium enhancement of lumbar roots, providing radiological evidence of an abnormal blood-nerve barrier {Bertorini et al. 1995; Figure 82.22).

Table 82.22; Diagnostic criteria for chronic inflammatory demyelinating polyradiculoneuropathy

I. Mandatory clinical criteria
  Progressive or relapsing muscle weakness for 2 months or longer
  Symmetrical proximal and distal weakness in upper or lower extremities
  Hyporeflexia or areflexia
11. Mandatory laboratory criteria
  Nerve conduction studies with features of demyelination (motor nerve conduction <70% of lower limit of normal)
  Cerebrospinal fluid protein level >45 mg/dL, cell count <10/|d
  Sural nerve biopsy with features of demyelination and remyelination including myelinated fiber loss and perivascular inflammation
III. Mandatory exclusion criteria
  Evidence of relevant systemic disease or toxic exposure
  Family history of neuropathy
  Nerve biopsy findings incompatible with diagnosis
]V, Diagnostic categories
  A. Definite: Mandatory inclusion and exclusion criteria and all laboratory criteria
  R, Probable: Mandatory inclusion and exclusion criteria and 2 of 3 laboratory criteria
  C. Possible: Mandatory inclusion and exclusion criteria and lof 3 laboratory criteria

Source: Adapted from Cornblath, D. R., Asbury, A. K., Albers, J. W., et al, "1991, "Research criteria for diagnosis of chronic inflammatory demyelinating polyneuropathy (CIDP)," *Neurolagy*, vol. 41, pp. 617-618.

Blood cell counts, sedimentation rate, and biochemical screening tests are important to exclude systemic disorders. Scrum and urine immunoetcctrophorcsis with immunofixation, a skeletal bone survey, or both are required to look for an associated monoclonal gammopathy or underlying osteosclerotic myeloma.

The changes in sural nerve biopsy specimens do not fully represent the pathological process taking place in motor roots or more proximal nerve segments. In one large series of biopsies, demyelinating features were seen in only 48%; 21% had predominantly axon a I changes, 13% had mixed demyelinating and axonal changes, and 18% were normal.

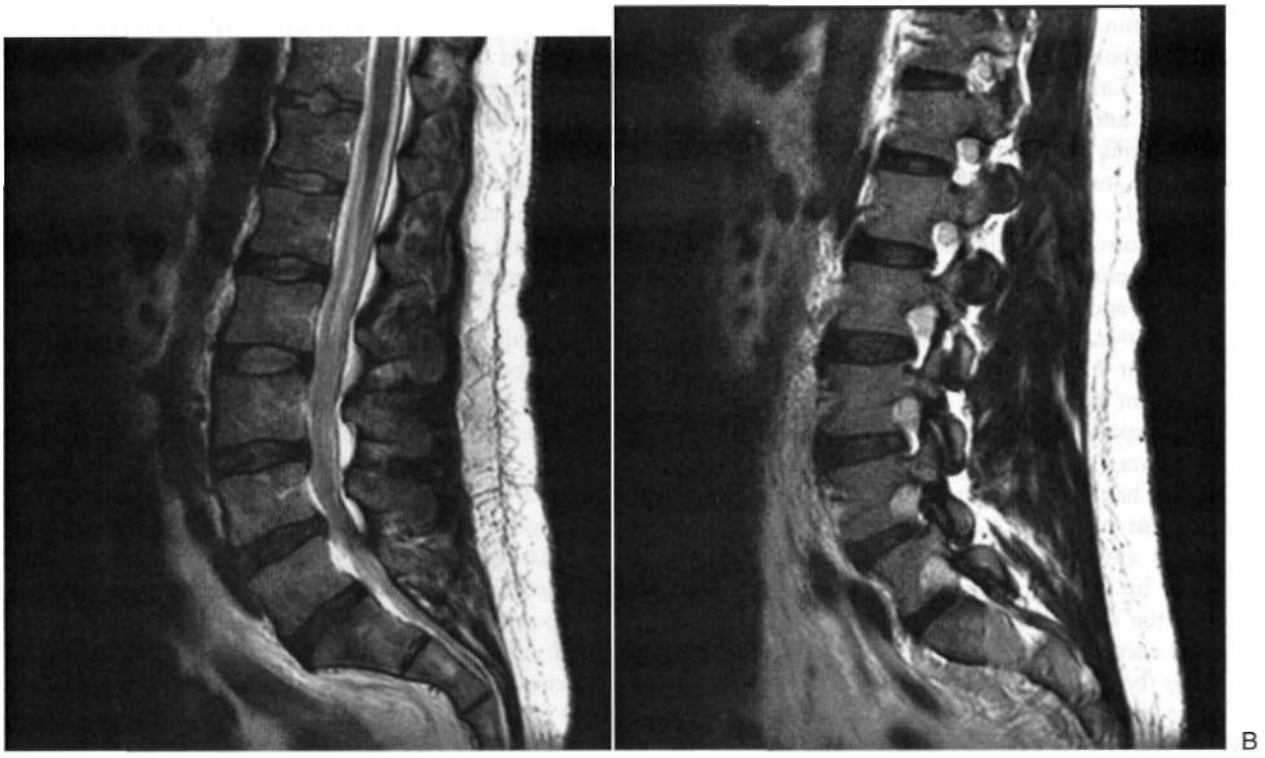

FIGURE 82.22 T2 weighted post-gadolinium sagittal lumbar MR: Diffuse enlargement of the cauda equina with abnormal enhancement in patient with C1DP (A). The hypertrophic nerve mots arc best appreciated in parasagittal images (B).

The value of nerve biopsy as a routine diagnostic tool for CIDP has been questioned. A study conducted in 64 patients with CIDP used multivariate logistic regression analysis of sural nerve biopsy finding and othet clinical and laboratory criteria to assess the value of nerve biopsy. Only high CSF ptotein (>100 mg/dL) and nerve conduction studies consistent with demyelination were strong predictors of CIDP. An independent predictive value of the sural nerve biopsy could not be demonstrated (Molenaar et al. 1998). Nevertheless, sutal netve biopsy may be helpful in support of the diagnosis and in excluding other causes of neuropathy. Typically, moderate reduction in myelinated **fibers,** endoneural and subperineurial edema, and segmental demyelination and remyelination occur. Onion bulb formations, a sign of repeated episodes of segmental demyelination and remyelination, may be absent or abundant, depending on chronicity. Endoneural and epineurial mononuclear inflammatory cells are a helpful diagnostic sign when ptesent. The presence of inflammatory infiltrates can be highlighted using immunocytochemical markers. One study demonstrated epineurial T cells in perivascular clusters and endoneural infiltration of macrophages and T cells.

Treatment

Prednisone, plasmapheresis, and IVIg are .ill effective in CIDP and arc the mainstays of treatment.

A single randomized controlled trial provided weak evidence to support the extensive use of corticosteroids. Daily single-dose oral prednisone is started at 60-80 mg {1.0-1.5 mg/kg for children). Improvement can be anticipated within 2 months; by 3 months 88% improve. Following improvement, the dose is converted to an alternate-day single-dose schedule. The initial daily dose is tapeted to alternate-day prednisone by reducing the even-d.u dnsr by 10 mg per week; high dose, alternate day prednisone is maintained until a remission or plateau phase is achieved. More than 50% of patients teach this point by 6 months. After attaining maximum benefit, a slow taper of prednisone (e.g., 10 mg/month followed by 5-mg decrements at doses below 50 mg on alternate days) can then begin. The individual patient's clinical improvement and side-effect profile setve as guides to the tapidity of the taper. Some patients are exquisitely sensitive to reduction in corticosteroid dosage, in which case this must be reduced slowly to avoid producing a severe relapse. Patients may need alternate-day prednisone (10-30 mg) for years to suppress disease activity. Side effects from prolonged prednisone use are significant. Osteoporosis causing vertebral compression ftaetutes, diabetes, and hypertension cataracts are the most common long-tetm complications. Patients should be followed for the development of cataracts, increased intraocular pressure, hypertension, truncal obesity, hyperglycemia, aseptic necrosis of bone, peptic ulcer disease, and susceptibility to infection. Ptccautions

taken to diminish complications include a low-sodium (2 g) and low-carbohydrate diet and proton pump inhibitors for all patients. Calcium and vitamin D supplements should be considered, and bone density should be monitored in an effort to limit osteoporosis. In patients with coexisting osteoporosis, oral bisphosphonates or nasal calcitonin may be beneficial.

Three controlled studies have confirmed the benefit of therapeutic plasma exchange for CIDP of both chronic progressive and relapsing course. Ten plasma exchanges performed over 4 weeks resulted in substantial but transient improvement in 80% of patients (1 lahn et al, 1996a). Improvement began within days of starting therapy, yet 70% of responders relapsed within 14 days after plasma exchange was stopped. The optimal schedule for plasma exchanges has no! been established, and prohabl) varies from patient to patient. A common approach employs three exchanges (50 mlikg) weekly for the first 2 weeks, followed by two exchanges per week from the third through the sixth week. Then the treatment frequency is repeated according to clinical response. Plasma exchange can only be performed in medical centers with special expertise in aphcresis and requires secure vascular access. Venous access problems may be overcome by placement of central venous catheters, although this approach carries the risk of pneumothorax, hematoma, brachial plexus injury, and serious infection. Plasmapheresis may be maintained for months and even years. The majority of patients needing prolonged plasmapheresis require the addition of prednisone for lasting benefit and stabilization.

The svstemanc Cochrane review of six controlled studies confirmed the benefit of high-dose !VIC in CIDP compared with placebo (Van Shaik ct al. 200.3). A double blind, sham-controlled trial of IVIG using 0.4 g/kg per day on 5 consecutive days resulted in significant improvement of 63% of patients with both chronic progressive and relapsing disease. Improvement was seen as e.irK as the tusi week oi treatment, whereas maximal benefit was reached at 6 weeks (Hahn et al. 1996b). Those patients who respond to the initial series of infusions may need maintenance infusions in single daily doses of 0.4-1.0 g/kg at intervals dependent on the disease response. The beneficial effect of IVIG was confirmed in a prospective study comparing IVIG (0.4 g/kg once a week for 3 weeks, followed by 0.2 g/kg weekly for the next 3 weeks) with plasmapheresis (Dyck, Litchy, and Kratz 1994). Both treatments were equally efficacious but short lived, and most patients required continued intermittent treatment for sustained improvement. One trial compared IVIG (2 g/kg given over 1 or 2 days) with oral prednisolone (60 mg for 2 weeks followed by a taper over 4 weeks) in a cross-over design. Both treatments resulted in improvement after 2 and *6* weeks, although IVIG tended to be slightly superior to oral prednisolone (Hughes et al. 2001a). The benefit of IVIG as the initial treatment of CIDP has also been established (Mendel! et al. 2001). In this randomized controlled study using IVIG (1 g/kg given on days 1, 2, and 21) in patients with untreated CIDP, a favorable response occurred in 79% of patients after 6 weeks with improvement starting within 2 weeks. The high level of effectiveness combined with low incidence of adverse events makes IVIG a good, although costly, first treatment choice. The therapeutic dose of IVIG has been empirically set at 2 g/kg. Much needs to be learned about optimal dosage schedule as each trial used different dosage and infusion regimens. The standard schedule of 0.4 g/kg daily for 5 days should be used for elderly patients and patients who have impaired renal or cardiovascular function or who have high serum viscosity. In general adverse reactions to PVIG therapy are usually minor and occur in no more than 10% of patients (Brannagan 2002). Infusion-related reactions include headaches, chills, nausea, and myalgias. These can be controlled by reducing the rate of infusion (<200 mL/hr) or by pretreatment with acetominophen and ibuprofen (sec previous discussion) or diphenhydramine. Thrombotic events including stroke, myocardial infarction, retinal vein occlusion, and deep vein thrombosis may occasionally occur in patients with cardiovascular risk factors and increased serum viscosity, particularly with infusion rates of greater than 0.4 g/kg per day. Patients with pre-existing renal disease, especially the elderly, and those with diabetes mcllitus and hypovolemia are at risk of developing acute renal tubular necrosis. This rare complication has been associated with IVIG products containing high concentrations of sucrose. Close monitoring of renal function, correction of hypovolemia, discontinuation of concomitant nephrotoxic drugs, and the use of products without sucrose are measures to prevent renal tubular necrosis in patients with kidney disease. The serum immunoglobulin A (IgA) level should be determined in each patient before the first infusion, because those with very low IgA levels may have allergic or anaphylactic reactions during later infusions. IVIG infusions may trigger migraine attacks and aseptic meningitis. Skin allergic reactions arc seen in about 6% of patients treated with IVIG.

In clinical practice, treatment with IVIG, plasma exchange, ot prednisone should be limited to those patients with neuropathic deficits of sufficient magnitude to justify the risks and expense of treatment (Figure 82.23). There is an increasing trend to use IVIG as the first line treatment. The best IVIG dosage schedule in patients with CIDP has not been established. Most patients receive an initial course of IVIG of 2 g/kg over 2-5 days. An essential aspect of the management of CIDP is the assessment of patients at baseline and at follow-up visits after treatment using objective and validated means of determining the severity of the neuropathic deficits, hollowing the initial post-treatment period of 3-6 weeks, responders are monitored at monthly intervals. When secondary deterioration occurs, patients ate retreated with single IVIG infusions (0.4—1.0 g/kg), depending on the severity of the relapse. The interval of repeat infusions is determined by the expected duration of the clinical benefit. For patients with residual

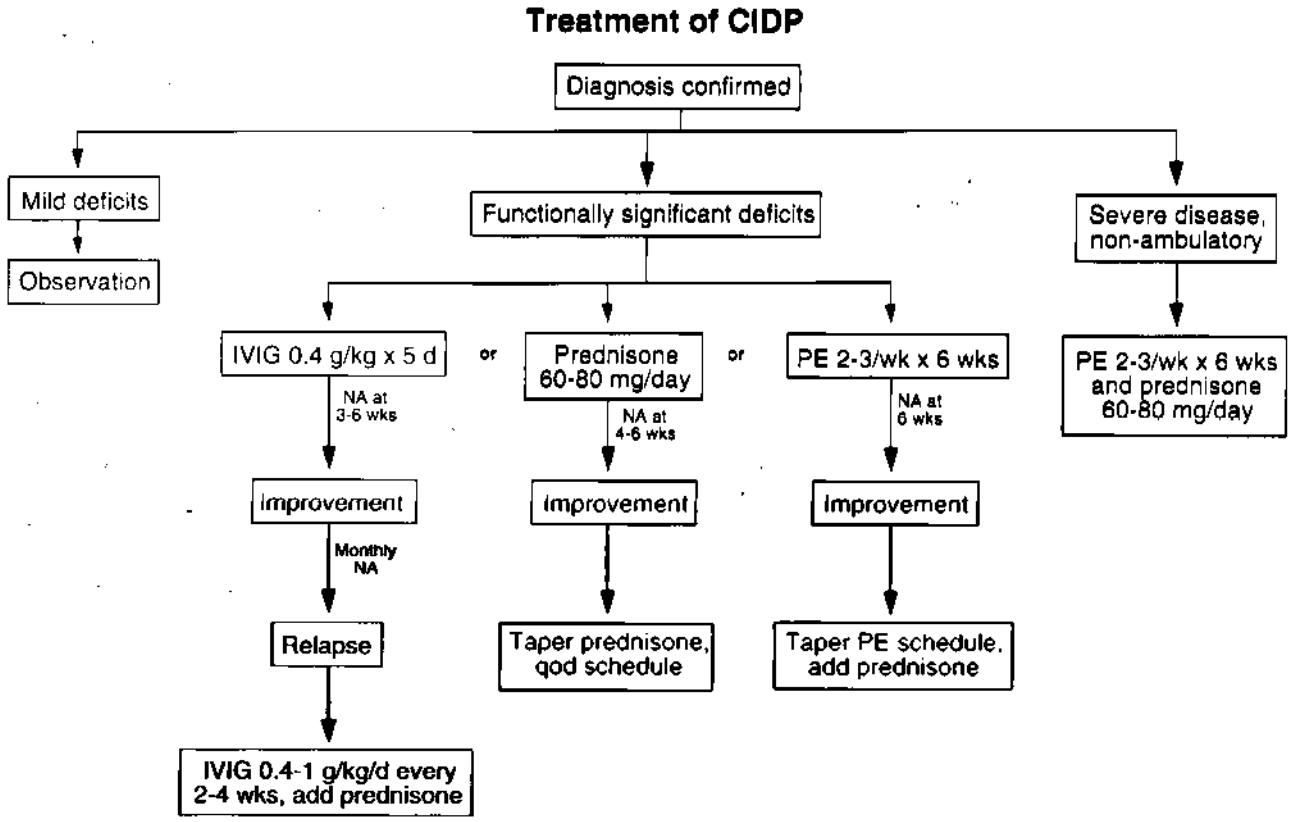

FIGURE 82.23 Dec is ion-ma king pathway in the management of chronic inflammatory demyclinating polyradiculoneuropathy. (IVIG = intf a venous immune globulin; NA = neurological assessment; PE= plasma exchange.)

deficits, small to moderate doses of prednisone may provide additional benefit. Patients who fail to respond to IVIG are treated either with plasma exchange or high-dose prednisonc. Plasma exchange is combined with prednisone for severely affected, nonambulatory patients because of the slightly higher response rates of these treatments. The absence of any therapeutic response from these immune-modulating therapies should lead to a reappraisal of the diagnosis.

Alternative forms of immunosuppressive treatment should be considered for patients with CIDP who arc refractory to prednisone, plasma exchange, and IVIG. None of the alternative agents, however, have proven efficacy in controlled trials. Azathioprine {2-3 mg/kg per day) or mycophcnolate mofetil (1000 mg twice daily) are used frequently as corticosteroid-sparing, adjunctive agents in long-term management. Use should be limited to patients with inadequate response to corticosteroids or those who require high corticosteroid maintenance doses with unacceptable side effects. Other immune interventions include cyclosporine A {5 mg/kg in two divided doses per day), monthly infusions of cyclophosphamide (lg/m^2 monthly for 3 to 6 months), and interferon-or (3 million IU subcutaneously three times a week for 6 weeks; Gorson et al. 1998). A small proportion of patients remain unresponsive or have significant residual deficits despite all efforts.

Prognosis

In contrast to the good prognosis in GBS, CIDP tends to be associated with prolonged neurological disability and is less likely to have spontaneous remissions. Although *95%* of patients with CIDP show initial improvement following immunosuppressive therapy, the relapse rate is high and the degree of improvement modest. Despite the initial responsiveness, only 40% of patients in one series remained in partial or complete remission while receiving no medication, The presence and degree of axonal loss have been considered responsible for incomplete recovery. Confirmation of this view was provided by a systematic study comparing clinical outcome and biopsy findings. In a series of 83 patients evaluated on average 6 years after onset, 56% had good outcome, 24% deteriorated and failed to respond to all treatments, and 11 % died of complications of the disease. Axonal loss on the nerve biopsy correlated with poorer outcome (Bouchard et al. 1999).

Multifocal Motor Neuropathy with Conduction Block

Multifocal motor neuropathy has received much attention because it is a treatable immune-mediated motor neuropathy that bears a superficial clinical resemblance to motor

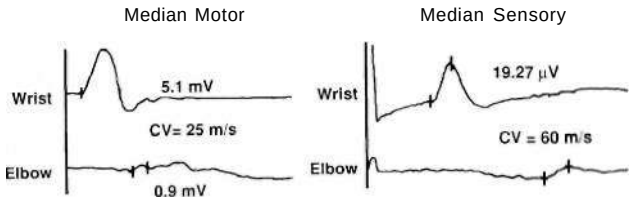
neuron disease. Whether multifocal motor neuropathy is a distinct nosological entity or simply a multifocal motor variant of CIDP is not established.

Clinical Features

Multifocal motor neuropathy is more common in men and mainly affects young adults; two thirds of affected individuals arc *45* years or younger. Progressive, asymmetrical, predominantly distal limb weakness and, to a lesser extent, atrophy develop over months to years. The upper extremities are more frequently affected than the lower. Wrist drop, grip weakness, or footdrop are the most common presenting features. Muscle cramps and fasciculations are common. Profound weakness in muscles with normal bulk or focal weakness in tile distribution of individual nerves rather than in a spinal segmental pattern are clues that should alert the clinician to suspect this disorder. Cranial nerve involvement is unusual. Tendon reflexes arc depressed or absent. Upper motor neuron signs are absent. Minor transient paresthesias are commonly reported by patients, but objective sensory deficits are usually absent. The course is slowly or less often stepwise progressive over months to years (Nobiie-Orazio 2001).

Laboratory Studies

The diagnosis depends on electrophysiological studies demonstrating persistent focal motor conduction block in one or more motor nerves at sites not prone to compression (see Chapter 36B). Additional features of multifocal motor demyelination are frequently present in nerve segments without conduction block, including motor conduction slowing, temporal dispersion, and prolonged F-wave and distal motor latencies (Katz et al. 1997). What makes multifocal neuropathy unique is that the block is confined to motor axons. SNAPs and sensory conduction are preserved (Figure 82.24). Abnormal amplitude reduction with proximal stimulation may be seen occasionally in other disorders; ttansient conduction block may occur in vasculitic neuropathy during the early stage of wallerian degeneration. There is no satisfactory explanation for the selective vulnerability of motor fibers. Kaji et al. (1993) reported a patient with pure motor weakness of the arm and proximal conduction block who underwent biopsy of a motor nerve branch adjacent to the site of focal conduction block that revealed scattered demyelinated axons and small onion bulbs without inflammatory changes. Needle EMG shows signs of denervation almost invariably confined to muscles that are clinically weak. Fasciculations are common, and myokymia may be seen. The spinal fluid protein is frequently normal although moderately increased protein levels (<100 mg/dL) can be found in one third of patients. The sural nerve frequently shows subtle pathological changes of demyelination and rcmyelination quite similar to those in CIDP but of lesser degree. These morphological abnormalities indicate that sensory nerves are involved in this disorder despite the lack of clinical or electrophysiological findings. MRI of the brachial or lumbosacral plexus may be helpful by demonstrating focal enlargement and increased signai intensities of affected nerve trunks (Van Es et al. 1997).



EIGURK 82.24 Partial motor conduction block of the median nerve. The compound muscle action potential (CMAP) was recorded from the abductor pollicis brevis muscle. Supramaximal stimulation at tlit; elbow produced an 80% drop in the amplitude of the median CMAP compared with stimulation at the wrist. Sensory conduction along the same nerve segment was preserved. (CV = conduction velocity.) (Courtesy Dr. J. C. Stevens.)

Attention has focused on a possible relationship between antiganglioside antibodies and acquired lower motor neuron syndromes. Among the gangliosides, GMj is abundantly found on the outer surface of neuronal membranes where potential binding sites could serve as antigenic targets. High titers of IgM anti-GM, antibodies can be found in up to 80% of patients with multifocal motor neuropathy and conduction block. High titers are occasionally (<15%) seen in amyotrophic lateral sclerosis and GBS variants including AMAN and the axonal form of GBS associated with *C. jejuni* infection, but rarely (<5%) in other peripheral neuropathies and non-neurological autoimmune disorders. Thus anti-GM| antibodies are neither specific nor required for the diagnosis of multifocal motor neuropathy but can be considered a marker for the disease.

The differential diagnosis of progressive limb weakness and atrophy without sensory symptoms is mainly restricted to motor neuron disease, including amyotrophic lateral sclerosis and its lower motor neuron form, progressive muscular atrophy, CIDP, and multifocal motor neuropathy (Table 82.23). Other conditions to be considered include post polio svudrome, lead- or dapsone-induced motor neuropathies, the hereditary motor ncuronopathies or spinal muscular atrophies, and hexosaminidase-A deficiency.

Treatment

Identifying patients with multifocal motot neuropathy is important because many such patients can be treated. In contrast to CIDP, prednisone or plasma exchange have little or no benefit. Treatment with IVIG is currently the preferred treatment because high dose cyclophosphamide previously reported to be effective is not an attractive drug for a chronic, non-life-threatening disorder. [VIG (0.4 g/kg body

Table 82.23: Differential diagnosis of multifocal motor neuropathy

Features	*Multifocal motor neuropathy*	*at>r*	*Amyotrophic lateral sclerosis*

CIDP = chronic inflammatory demyelinating polyradiculoneuropathy; SNAP = sensory nerve action potential

weight per day for 5 consecutive days) has been reported to benefit 70% of patients in open uncontrolled and small double-blind, placebo-controlled trials il'irdenco el al. 2000). Improvement begins within three weeks of treatment but lasts only for weeks to months. Criteria have been proposed to predict a favorable response to IVIG (Van den Berg-Vos et al. 2000). Younger age at onset, a smaller number of affected limb regions, elevated GM1 antibody titers, definite conduction blocks, and higher distal CMAP amplitudes were found significantly more often in respondcrs. Most patients require maintenance infusions for years. Based on such observations, it is appropriate to initiate treatment with IVIG and continue maintenance infusions (0.4 g/kg once every 1-8 weeks) in patients who have a functionally meaningful response. Dose and frequency of repeated IVIG administration must be individualized for each patient, giving another dose just before the anticipated time of relapse. Despite IVIG maintenance therapy neurological improvement decreases over time, and electrophysiological studies demonstrate either new conduction blocks or axona! loss in long-term studies (Van den Berg-Vos et al. 2002). Oral cyclophosphamide or interferon-^! may reduce the frequency and dosage of infusions. For nonrcsponders, intravenous cyclophosphamide is indicated depending on the degree of disability and the patient's understanding of the seriousness of potential side effects such as bone marrow depression, gonadal damage, hemorrhagic cystitis, and a long-term increased risk of cancer. Pestronk et al, (1994) suggested that monthly intravenous cyclophosphamide (1 g/m) for 6-8 months, preceded on each occasion by two plasma exchanges, may be an effective treatment. As an alternative to cyclophosphamide, rituximab, a monoclonal antibody directed against the B cell surface marker CD20, has shown promising results in an open, uncontrolled study of patients with multifocal motor neuropathy (Pestronk et al. 2003).

PERIPHERAL NEUROPATHIES ASSOCIATED WITH MONOCLONAL PROTEINS

Patients undergoing evaluation for chronic peripheral neuropathy of unknown cause should be screened for the presence of a monoclonal protein (M protein). A monoclonal protein is produced by a single clone of plasma cells and usually composed of four polypeptides: two identical heavy chains and two light chains. The M protein is named according to the class of heavy chain (IgG, IgM, IgA, IgD, IgE) and type of light chain, *K* or *k.* Approximately 10% of patients with idiopathic peripheral neuropathy have an associated monoclonal gammopathy, which represents a sixfold increase over the general population. The pailm physiological relationship between the M protein and the neuropathy is often obscure but some M proteins have antibody properties directed against components of myelin or axolemma. Finding an M protein among patients with neuropathy may lead to the discovery of underlying disorders such as primary amyloidosis, multiple or osteosclerotic myeloma, macroglobulinemia, cryoglobulinemia, Castelman's disease, lymphoma, or malignant lymphoproliferative disease. In two thirds of patients with a monoclonal protein, no detectable underlying disease is found, and they are described as having MGUS. MGUS has replaced the term *benign monoclonal gammopathy* because up to one fourth of patients go on to develop malignant plasma cell dyscrasias after long-term follow-up, The risk of progression of MGUS to a malignant plasma cell proliferative disorder is about 1% per year (Kyle et al. 2002). The characteristic features distinguishing MGUS from other plasma cell dyscrasias are listed in Table 82.24.

Routine serum protein electrophoresis frequently lacks the sensitivity required to detect small M proteins. Immunoelectrophoresis or immunofixation is required to detect small amounts of M proteins, confirm the monoclonal nature, and characterize the heavy- and light-chain types. Urine studies detect excretion of light chains (Bencejones protein) that often accompany multiple myeloma or primary amyloidosis. All patients with neuropathy and associated M protein, as well as patients suspected of amyloidosis or myeloma, should have a 24-hour urine collection for detection of Bencc-Jones protein. Following discovery of an M protein, a complete blood cell count with differential is necessary, immunoglobulins should be quantitated, and a radiological skeletal bone survey is indicated to detect lytic or sclerotic bone lesions of

Tabic 82.24: Characteristic findings in monoclonal gammopathy of uiuk'UTimiu'd significance

Ig = immunoglobulin.

myeloma. If the monoclonal spike exceeds 1.5 g/dL, a bone marrow aspirate and biopsy should be obtained to differentiate a malignant plasma cell dyscrasia from MGUS. Rectal, fat, or cutaneous nerve biopsies may be required to confirm a suspected diagnosis of amyloidosis (Kissel and Mendell 1995).

Monoclonal Gammopathy of Undetermined Significance

Approximately 5% of patients with MGUS have an associated polyneuropathy. The frequency of monoclonal IgM is over represented in patients with neuropathy (60% IgM, 30% IgG, and 10% IgA) compared with patients with only MGUS. The light-chain class is usually *K* in contrast to patients with osteosclerotic myeloma or amyloidosis (Ropper and Gorson 1998).

Clinical Ventures

The clinical presentation of the neuropathies associated with different heavy-chain classes are generally indistinguishable from each other. Symptoms begin in later life with the median age of onset in the sixth decade, appear insidiously, and progress slowly over months to years. There is a male predominance. The most common presentation is a distal symmetrical sensorimotor polyneuropathy. Cranial nerves and autonomic functions arc preserved. Sensory impairment can be prominent with variable involvement of light touch, pinprick, vibration, and position sense. Muscle stretch reflexes are universally diminished or absent. The lower limbs are involved earlier and to a greater extent than the upper. In approximately one half of patients, a polyradiculoneuropathy occurs that shares clinical and laboratory features with CIDP. Patients with CIDP and MGUS tend to be older and have a more indolent course with fewer motor than sensory findings but poorer long-term functional outcome than the idiopathic CIDP group without M protein (Simmons et al. 1995). A predominantly sensory neuropathy may be seen in up to 20% of patients. Gait ataxia and upper limb postural tremor can be prominent, particularly in patients with IgM MGUS.

Laboratory Features

Electrophysiological studies show evidence of demyelination or more often both demyelination and axonal degeneration. Slow motor conduction velocities in the demyelinating range are more common in patients with IgM MGUS in which there is a predilection for distal demyelination. SNAPs are reduced in amplitude or unobtainable. EMG shows denervation. A small number of patients, usually with IgG MGUS, have electrophysiological featutes of a pure axonal neuropathy. When the frequency of MGUS in older patients is considered, the relationship between MGUS and neuropathy may be coincidental in these patients (Notcrmans et al. 1996a). Elevation of CSF protein is common, sometimes in excess of 100 mg/dL.

In at least 50% of patients with IgM MGUS neuropathy, the IgM monoclonal protein has reactivity against myelin-associated glycoprotein (MAG). MAG is a glycoprotein that makes up only 1% of peripheral nerve myelin. It is concentrated in periaxonal Schwann cell membranes, paranodal loops of myelin, and areas of noncompactcd myelin, where it plays a role as an adhesion molecule for interactions between Schwann cells and axons. Anti-MAG antibodies cross-react with other components of peripheral nerve including several complex glycosphingolipids, PMP-22, *and* the P„ protein of myelin. Which of these reactivities relates to the neuropathy is unclear. Antibody activity to MAG can be detected by "Western blot and enzyme-linked immunosorbent assay and can be demonstrated by immunocytochemical staining of nerves. Immunofluorescence studies show that IgM with anti-MAG activity binds to the periphery and periaxonal regions of myelinated fibers that correspond to the distribution of MAG. Ultrastructurally, the myelin lamellae show a widened periodicity {myelin splitting), which is considered the pathological hallmark of anti-MAG antibodies (Figure 82.25). No consistent binding of monoclonal proteins to myelinated fibers is seen in nerve biopsy specimens from patients with IgG and IgA MGUS. Sural nerve biopsy findings of patients with M proteins of all three immunoglobulin classes show nerve fiber loss, segmental demyelination, and axonal degeneration.

Approximately 15% of patients with IgM-MGUS neuropathy have autoantibodies directed against gangliosides, and those with IgM antibodies to GD1b and GQ1b have been associated with sensory ataxic neuropathies (Eurclings et al. 2001). Patients who have disialosyl-ganglioside IgM antibodies and cold agglutinins present with a chronic sensory ataxic neuropathy, areflexia, and fixed or relapsing-remitting ophthalmoplegia. This rare clinical syndrome has been described under the acronym *CANOMAD:* chronic ataxic weuropathy, ophthalmoplegia, **Ig-M** monoclonal protein, cold agglutinins and <fisialosyl antibodies (Willison et al. 2001).

The underlying mechanism of nerve fiber damage in MGUS neuropathy remains unknown, although an

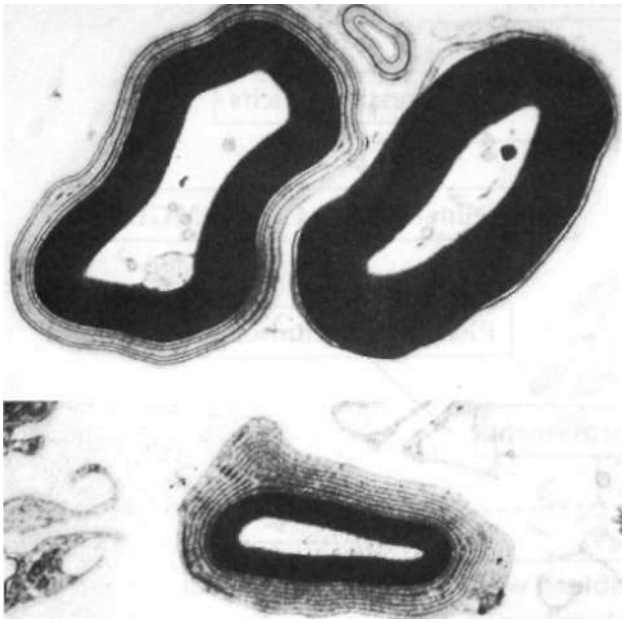

FIGURE 82.25 Electron micrographs showing fibers with myelin splitting. In the upper p;inel, the myelinating filler on the left shows splitting of the myelin lamellae tit the intra period line, whereas the nerve fiber on the right has normal compact myelin (x 15,000), The lower panel illustrates similar myelin splitting (x 20,000). The findings are characteristic of antimyclin-associated glycoprotein antibody deposits in the myelin sheath. (Reprinted with permission from Mendell, j. R., Barohn, R. J., Bosch, E. P., et al. 1994, "Continuum-peripheral neuropathy," *Am Acad Neurol.*, vol, 1, p. 42.)

immune-mediated etiology is suspected (latum 1993). The case for pathogenic activity of IgM antibodies directed against MAG and other glycosphingolipids is better established than that for other antigens or for IgG and IgA antibodies. On the other hand, the lack of correlation between the deposition of anti-MAG antibody and the degree of pathological nerve damage and the poor correlation between the amount of M protein in serum and the severity of neuropathy raise questions about causal linkage.

Treatment

The optimal treatment of MGUS neuropathy has not been established, and there are few controlled trials on which to base treatment decisions. The decision to treat depends on the severity of the neuropathy. Patients with minor deficits and indolent course are best followed without treatment. This view is supported by the long-term outcome of patients with IgM MGUS neuropathy. Neurological impairment did run differ between treated and untreated patients after an average follow-up of 8 years but current immune-modulatory treatments resulted in serious adverse events in half of the patients (Nobile-Orazio et al. 2000). The more closely the neuropathy fulfills the criteria for CIDP, the more likely the patient will respond to immune-modulatory therapies. Patients have been treated with plasmapheresis, IVIG, and prednisone, often in combination with immunosuppressants, with temporary benefit in about half of the treated patients. In 1991, Dyck and colleagues confirmed the short-term benefit of plasmapheresis in the IgG and IgA but not IgM subgroups in a randomized, controlled trial. Intravenous immunoglobulin (2 g/kg given over 1-5 days) may produce short term benefit in 50% of patients with IgM-MGUS (Comi et al. 2002).

Patients with progressive, disabling neuropathy caused by IgM MGUS with or without anti-MAG reactivity may respond to aggressive immune interventions aimed at lowering the IgM level. This may be achieved by intermittent courses of oral cyclophosphamide (300 mg/m body surface daily for 4 days) combined with prednisone (40 mg/m^2 body surface daily for 5 days) given at 4-week intervals for 6 months (Notermans et al. 1996b), combination treatment with two plasma exchanges followed by intravenous cyclophosphamide given monthly for 5-7 months, or fludarabinc. The initially reported benefit of interferon-a could not be confirmed in a randomi/.ed, cmitrolled 1ii.il. kni:\im.ik .1 rumod:>n:il i. D:'.O .mlibmlv directed against B cells, holds promise but is yet to be subject to controlled trials (Pcstronk et al. 2003). An algorithm for the treatment of MGUS neuropathy is proposed in Figure 82.26. Patients with rapid clinical deterioration of their neuropaihy despite treatment should be re-evaluated for the development of underlying malignant lymphoproliferative disorders or amyloidosis.

Waldenstrom Macroglobulinemia

Waldenstrom macroglobulinemia (WM) is characterized by proliferation of malignant lymphocytoid cells in bone marrow and lymph nodes that secrete an IgM monoclonal spike of more than 3 g/dL. WM typically affects elderly men; systemic symptoms of fatigue, anemia, bleeding, and hyperviscosity dominate. Peripheral neuropathy occurs in approximately one third of patients with WM and is a chronic symmetrical, predominantly sensory polyneuropathy similar to that associated with nonmalignant IgM M proteins. Other presentations include pure sensory or pure motor neuropathies, multiple mononeuropathies associated with cryoglobulins, and typical amyloid neuropathy, Anti-MAG reactivity is found in approximately 50% of WM patients with neuropathy. Patients with positive anti-MAG antibodies have slowed motor NGVs and prolonged distal latencies consistent with demyelination. Nerve biopsy findings are indistinguishable from those seen in IgM MGUS neuropathy. Patients with demyelinating polyneuropathy may respond to chemotherapy, plasmapheresis, or both, but the response appears to be less consistent than in IgM MGUS-related neuropathy.

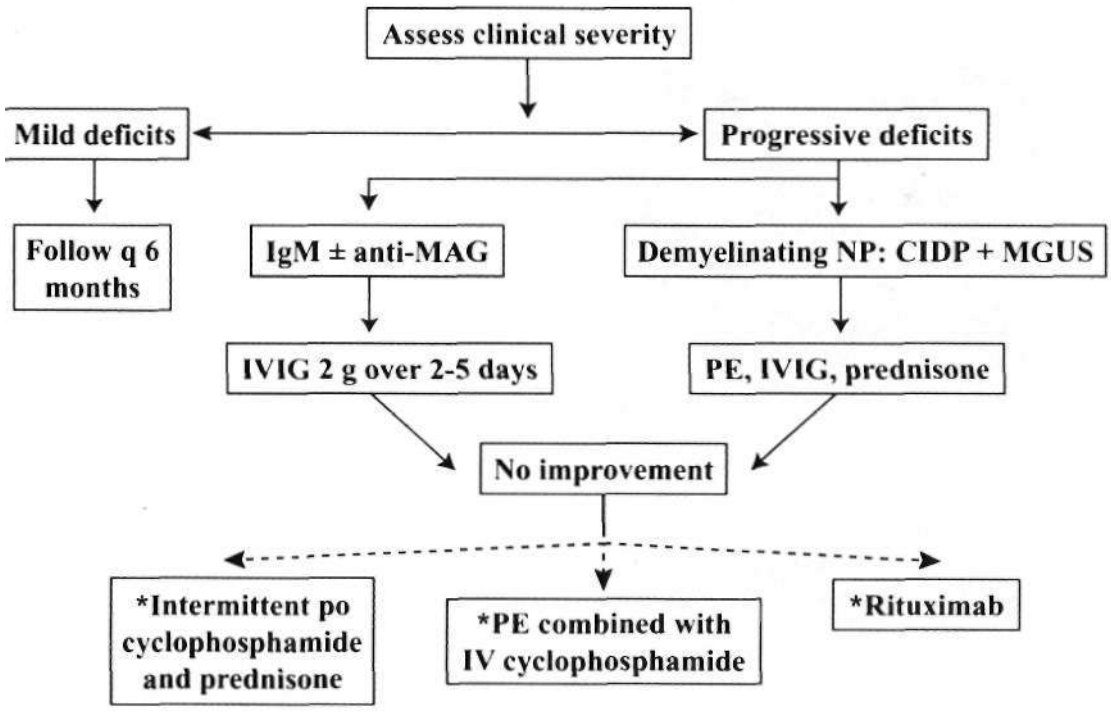

FIGURE 82.26 Decision-making pathway in the management of peripheral neuropathy with monoclonal gammopathy of undetermined significance (MGUS). (CIDP = chronic demyelinating polyradiculoneuropathy; IVIG = intravenous immune globulin; MAG = myelin-associated glycoprotein; NP = neuropathy; PE = plasma exchange. *There are anecdotes of improvement with these drugs hut controlled studies are not available to support their use.)

Multiple Myeloma

Polyneuropathy occurs in approximately 5% of patients with multiple myeloma. One third of patients arc found to have abnormalities on careful electrophysiological studies. The most common neurological complications of multiple myeloma are related to cord and root compression from lytic vettehral lesions. Diffuse bone or radicular pain resulting from vertebral body involvement, concurrent anemia, renal insufficiency, and hypercalcemia may provide clues as to the underlying disorder. The clinical manifestations of myeloma neuropathy are heterogeneous. Must patients present with mild distal sensorimotor polyneuropathy. Less frequently, a pure sensory neuropathy is seen. Furthermore, AL amyloidosis complicates multiple myeloma in 30-40% of cases, and these patients have a high likelihood of death within the next 2 years. Painful dysesthesias, preferential involvement of small fiber sensory modalities, autonomic dysfunction, and carpal tunnel syndrome are suggestive of amyloid neuropathy. Rectal, abdominal fat, or sural nerve biopsy specimens can be obtained in patients with progressive myeloma neuropathy to identify the patients with amyloidosis.

Nerve conduction and sural nerve biopsy studies arc consistent with an axonal process with loss of myelinated fibers. Treatment of the underlying myeloma may sometimes improve the neuropathy.

Osteosclerotic Myeloma and POEMS Syndrome

Osteosclerotic myeloir.,; occurs 1:1 less ill an .:"u i>: all patients with myeloma but 85% of these patients present with an associated peripheral neuropathy. In tins disorder, the plasma cell proliferation occurs as single or multiple plasmacytomas that manifest as sclerotic bone lesions. The neuropathy of osteosclerotic myeloma is different from that associated with multiple myeloma in several aspects; It occurs at an earlier age and mostly in men; it is a demyelinating, predominantly motor neuropathy with slow motor NCVs and elevated CSF protein levels, usually in excess of 100 mg/dL; an M protein is found in 90% of cases and virtually always composed of A light chains associated with IgG and IgA heavy chains; it responds to irradiation or excision of the isolated plasmacytoma; and it is associated with systemic manifestations referred to as Crow-Fukase or POEMS syndrome. To reiterate, POEMS is the acronym for polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes, facilitating recognition of the most constant features of this multisystem syndrome.

The neuropathy of osteosclerotic myeloma bears a striking resemblance to C1DP with symmetrical proximal and distal weakness with variable sensory loss. Cranial nerves are spared except for occasional cases of papilledema. The clinical and electrophysiological similarities between litis condition and *i'.UW* emphasize the need to screen for an occult M protein and sclerotic bone lesions in

FIGURE 82.27 Radiography of the pelvis showing a dense sclerotic area in the upper sacrum and two smaller focal sclerotic lesions in the right pubic hone and the left femoral neck. Biopsy of one accessihle lesion confirmed osteosclerotic myeloma.

all adult patients presenting with an acquired demyclinating neuropathy.

The skeletal lesions can be single or multiple and tend to involve the axial skeleton, the majority being in the spine, pelvis, and ribs. Their radiographical appearance varies from dense ivory to mixed sclerotic and lytic lesions with a sclerotic rim (Figure 82.27). Radioisotope scans are less sensitive than radiographical skeletal surveys in detecting the lesions. Open biopsy is usually necessary to confirm the presence of an isolated plasmacytoma.

Most patients develop one or more of the multisystem manifestations of the POEMS syndrome. Hepatosplenomegaly is often encountered. Gynecomastia and impotence in men, secondary amenorrhea in women, diabetes mellitus, and hypothyroidism are the most common endocrinopathies, Hyperpigmentation, hypertrichosis, diffuse skin thickening, hemangiomas, and white nail beds are dermatological features. Pitting edema of the lower limbs, ascites, pleural effusions, and eh:':v • i 11: r. :·: die Miners are other signs. Approximately one fourth of patients with POEMS syndrome have no associated bone lesions. Some of these patients have Castleman's syndrome (a nonmalignant form of angiofollicular lymphadenopathy), and others have a plasma cell dyscrasia restricted to the lymphorericLilar system.

The pathogenesis of this multiorgan disorder is poorly understood. The associated plasma cell dyscrasia seems to play a crucial role, as clinical improvement follows the disappearance of the monoclonal ptoteins. Elevated levels of proinflammatory cytokines, such as tumor necrosis factot-a, interleukins, and vascular endothelial growth factor have been implicated in the multisystem manifestations (Gherardi et al. 1994).

The importance of recognizing this rate syndrome lies in its potential for treatment. Patients with solitary lesions are treated with tumoricidal irradiation, complete surgical extirpation, or both. Patients with multiple bone lesions receive radiation combined with prednisone and melphalan. High-dose chemotherapy with autologous blood steincell support is another option for patients with multifocal bone lesions or diffuse bone marrow plasmacytic infiltration (Jaccard et al. 2002), Substantial improvement of both neurological and systemic features is seen in some patients, but the response may take many months.

Cryoglobulinemia

Cryoglobulins are immunoglobulins that precipitate on cooling and redissolve on warming to body temperature. Cryoglobulins are classified into three groups; type I are monoclonal immunoglobulins that are associated with myeloma, mactoglobulinemia, and other lymphoproliferative disorders; type II consists of a mixture of a monoclonal protein, usually IgM-*- with antitheumaroid factor activity, and polyclonal IgG; and type III are polyclonal IgM and

IgG immunoglobulins. Mixed cryoglobulinemia may occur as a primary condition without any apparent underlying process, termed *essential mixed cryoglobulinemia,* or may he secondary to autoimmune diseases and chronic hepatitis C virus (HCV) infections. The detection of anti-HCV antibodies and HCV RNA in serum and ctyopreeipitate of most patients with essential cryoglobulinemia firmly establishes a causal role for HCV in the formation of cryoglobulins (Apartis et al. 1996). Mixed cryoglobulinemia is a systemic disease characterized by recurrent purpura of the legs and cutaneous vasculitis, often precipitated by cold temperatures, arthralgias, renal impairment, and peripheral neuropathy. The reported prevalence of peripheral neuropathy varies from 37-57% using electrophysiological criteria for confirmation. The most common presentation is a painful sensory or sensorimotor polyneuropathy or less often mono neuropathy multiplex (Tembl et al. 1999).

Electrodiagnostic studies show axonal changes with denervation, particularly in distal leg muscles. In most cases the sural nerve biopsy confirms necrotizing vasculitis or perivascular inflammation affecting small-sized epineurial vessels together with multifocal or global myelinated fiber loss and acute axonal degeneration. Low serum complement levels and the deposition of immunoglobulin in the walls of affected vessels suggest cryoprccipitablc immune complexes are responsible for the disease manifestations.

Treatment of cryoglobuiinemic neuropathy rests on expert opinion and uncontrolled trials. Patients with biopsy-proven vasculitis and progressive neurological deficits initially require immunosuppression with either oral or intravenous cyclophosphamide and corticosteroids. Plasmapheresis has been recommended for the rapid removal of cryoglobulins during acute exacerbations of neurological deficits or glomerulonephritis. Once clinical remission is achieved, immunosuppresive therapy is tapered off, and then specicfic treatment directed against the underlying HCV infection is offered. The recommended treatment regimen consists of peginterferon-a 2a in combination with ribavirin for 6 to 12 months.

Primary Systemic Amyloidosis

Systemic amyloidosis are multisystem disorders caused by extracellular deposition of insoluble fibrillar proteins arranged in a /i-plcated sheet conformation in various organs and tissues throughout the body. The /3-plcated sheet configuration seems to be responsible for the typical staining properties with Congo red stain, appearing red under normal light microscopy, but apple-green in polar ized light. Several unrelated proteins can form amyloid fibrils and cause specific acquired as well as inherited forms of amyloidosis. In both primary systemic amyloidosis and amyloidosis complicating multiple myeloma or WM, amyloid is composed of fragments of immunoglobulin light chains from the amino-terminal variable regions, or less commonly the complete immunoglobulin light chain, and is designated *AL* for amyloid light chain (Falk, Comenzo, and Skinner 1997). In primary (AL) amyloidosis clonal populations of nonproliferative plasma cells synthesize light chain polypeptides that are deposited in tissues as amyloid. Al, amyloidosis in association with multiple myeloma and WM is distinguished from primary amyloidosis by the number and morphology of plasma cells in the bone marrow and the amount of M protein in the serum, Amyloid fibrils from patients with familial amyloid neuropathies are composed of one of three aberrant proteins caused by genetic mutations: transthyretin, apolipoprotein A-1, and gelsolin (see Familial Amyloid Polyneuropathy, earlier in this chapter). Mutations in the genes encoding fibrinogen A, apolipoprotein A-II, lysozyme, and cystatin C are associated with non-neuropatbic familial amyloidosis. Immunohistocbemical techniques using specific antibodies can distinguish the different types of amyloidogenic proteins on biopsy material.

Clinical Features

Primary amyloidosis usually occurs after age 40, with a median age of onset of 65 years. Men are twice as likely to be affected. The initial symptoms are frequently fatigue and weight loss followed by symptoms and signs related to specific organ involvement. The organs most commonly affected, either individually or together, are the kidney, heart, liver, and the autonomic and peripheral nervous system. I'eripheral neuropathy occurs in 15-35% of patients and is the presenting manifestation in 10%. The majority have renal or cardiac presentations with peripheral neuropathy as a later manifestation. The neuropathy begins with painful dysesthesias in the legs and follows a chronic progressive course. Pain and temperature sensation are lost before light touch or vibratory sensation. Distal symmetrical weakness and a pansenson Ins^ evob.es I.IUT in the course of disease. Most patients develop features of autonomic dysfunction, including postural hypotension, impotence, gastrointestinal disturbances, impaired sweating, and loss of bladder control. Nearly 25% of patients develop a superimposed carpal tunnel syndrome caused by amyloid infiltration of the flexor retinaculum at the wrist. The constellation of painful dysesthesias, autonomic dysfunction, and a history of carpal tunnel syndrome should alert the clinician to the possibility of amyloidosis. Pitting edema related to hypoalbuminemia; spontaneous periorbital purpura caused by vascular infiltration; macroglossia, a sign occurring in 20% of patients (Figure 82.28); and hepatomegaly are typical findings on examination. Amyloid deposition between muscle fibers may cause pseudohypertrophy of muscles. Renal amyloidosis usually manifests as proteinuria and renal failure. Rapidly progressive congestive heart failure caused by cardiac infiltration is seen in one third of patients.

FIGURE 82.28 Macroglossia in AL amyloidosis. Tongue enlargement may be found in 20% of patients with AL amyloidosis. (AL = amyloid light chain.)

Laboratory Features

Electrodiagnostic studies show changes of axonal neuropathy, with low-amplitude or absent SNAPs and low-amplitude CMAPs but preserved motor conduction velocities. Distal median motor latencies are prolonged in patients with carpal tunnel syndrome. EMG frequently provides evidence of active denervation, A monoclonal protein or light chains are detected in 90% of patients by means of immu no fixation of serum or urine. Monoclonal *k* light chains are more common than *K* light chains (ratio of *X* to *K,* 3 to 1). A quantitative light-chain assay is the most sensitive method for detecting low level monoclonal proteins. Bone marrow examination reveals slightly increased plasma cells and clonal dominance of a light chain isotype by immunohistochemical staining.

The diagnosis is established by the histological demonstration of amyloid deposition in tissues. Abdominal fat aspiration, bone marrow aspirate, or rectal biopsy are convenient procedures that provide approximately an 80% yield of positive results. In patients with suspected amyloid neuropathy, combined muscle and sural nerve biopsy is the most sensitive technique that provides confirmation in more than 90% of cases. One tenth of patients wilh AI. amyloidosis lack monoclonal proteins in serum or urine by immunofixation and therefore are difficult to distinguish from familial or secondary amyloidosis. In most of these patients, a clonal dominance of plasma cells can be identified by immunocytochemical staining of a bone marrow specimen, or positive identification of AL amyloid can be achieved in tissue samples by immunohistochemical staining using labeled antibodies specific for human light chains. If confirmation of a plasma cell clone cannot be obtained, familial amyloidosis should be considered even in the absence of a positive family history. In such patients molecular genetic testing to identify TTR mutations is indicated (see Familial Amyloid Neuropathy, earlier in this chapter). Amyloidogenic mutations, most often in the genes encoding tor fibrinogen A and TTR, were found in 10% of 350 patients who had initially been misdiagnosed with presumed Al amyloidosis II .ulimann il ,il. 201)2). Results of sural nerve biopsy show amyloid deposition around blood vessels and within the endoneurial space (Figure 82.29), severe loss of myelinated and unmyelinated fibers, and active axonal degeneration. The pathogenetic mechanism of nerve fiber damage remains uncertain.

The prognosis in primary amyloidosis is poor, with a median survival of less than 18 months. Death is commonly caused by progressive congestive heart failure or renal insufficiency. Patients with amyloid neuropathy without cardiac or renal involvement have a more favorable prognosis, with a median survival of 40 months. The treatment of AL amyloidosis remains unsatisfactory but some aspects of disease may respond to chemotherapy that suppresses the underlying clonal plasma cell disorder. Intermittent oral melphalan and prednisone are reported to slow progression of renal and cardiac amyloidosis, but the treatment has no effect on the neuropathy. High-dose melphalan with autologous blood stem cell transplantation has shown promising results with improvement of neurological deficits in selected patients. Due to the high treatment-related mortality, stem cell transplantation is currently applicable to a minority of patients such as those with limited organ disease and no significant cardiac involvement (Comenzo and Gertz 2002).

NEUROPATHIES ASSOCIATED WITH SYSTEMIC DISORDERS

Diabetic Neuropathies

Diabetes mellitus is estimated to affect over 5 million people in the United States, and this number is growing by approximately *5%* per year. The complications specific to diabetes include retinopathy, nephropathy, and neuropathy. Patients with all forms of diabetes of sufficient duration, including insulin-dependent (IDDM) and non-insulin-dependent diabetes (NIDDM), are vulnerable to these complications (Nathan 1993). Diabetes is probably the leading cause of peripheral polyneuropathy in developed countries. Reliable estimates of the prevalence of diabetic neuropathy have only recently become available. The reported frequency of neuropathy among diabetics varies from 7-80%. This is due in part to bias of patient selection and different criteria used for the definition of diabetic neuropathy. The diagnosis of diabetic neuropathy should be based on clinical symptoms, objective neurological signs, and electrodiagnostic confirmation (Dyck 1988).

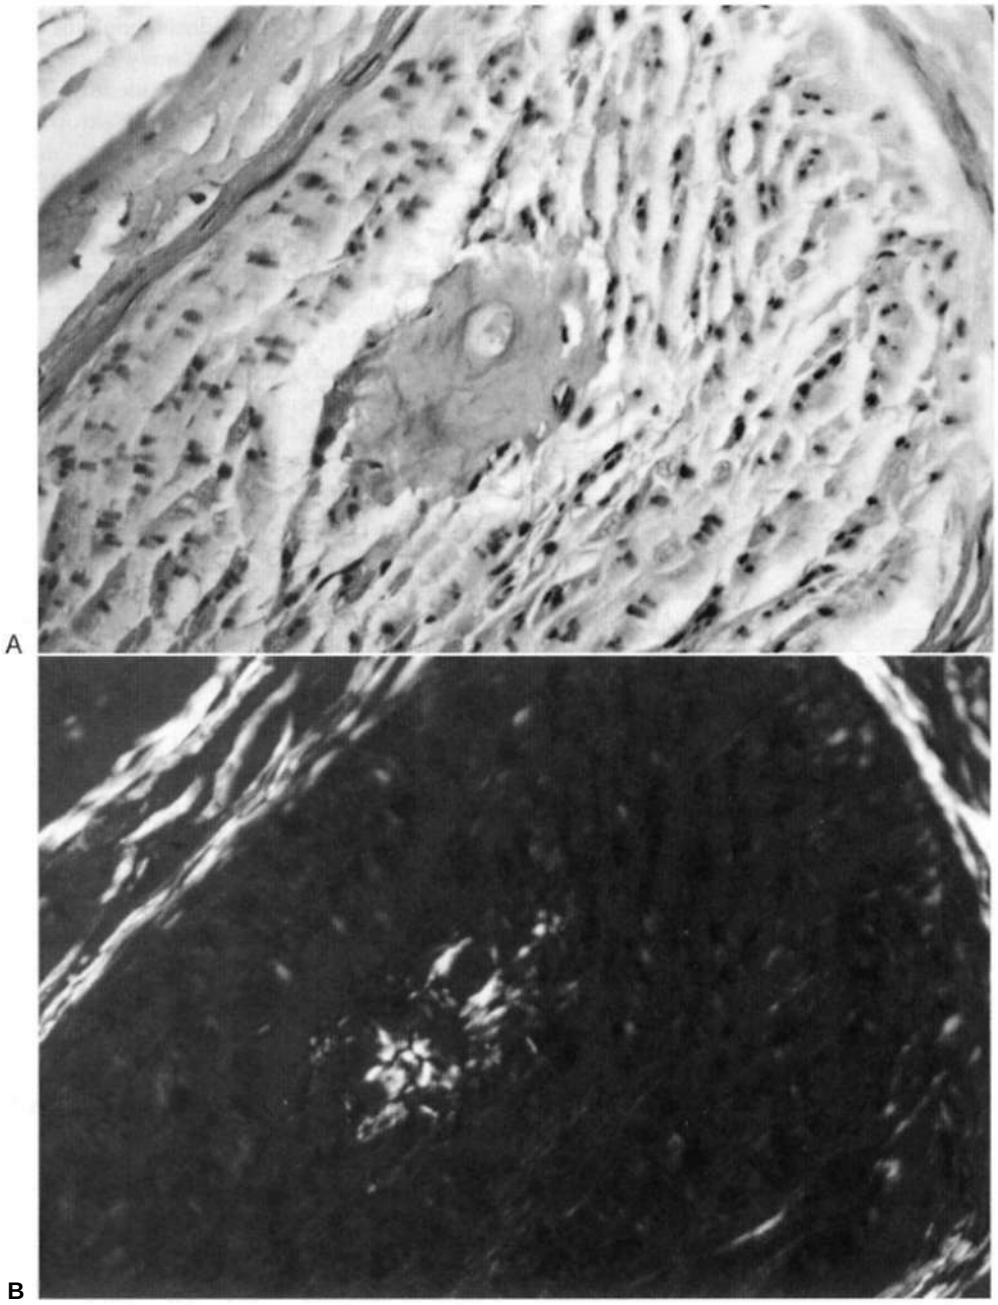

FIGURE 82.29 Amyloid neuropathy. (A) Sural nerve biopsy shows deposition of amyloid in the wall of an endoneural vessel and loss of myelinated fibers. (B) Under polarized light the Congo red-positive area shows apple-green birefringent deposits typical of amyloid. (Congo red, original magnification x250.)

Quality of life measurements provide an additional vantage point from which to judge the impact of neuropathy on everyday life (Padua et al. 2001). The risk of developing symptomatic neuropathy in patients without neuropathic symptoms or signs at the time of initial diagnosis of diabetes is estimated to be 4-10% by 5 years and up to 15% by 25 years. In a population cohort of diabetic patients, two thirds of diabetics had objective evidence of some type ol neuropathy, bill only 15% ol ID]XVI and 13% of NIDDM patients had symptomatic degrees of polyneuropathy (Dyck et al. 1993b). Among 894 women older than *65* years in Maryland, both age and diabetes were found to correlate with increased vibratory detection threshold values (Resnick et al. 2001). Longer duration of diabetes and male gender may predispose to the development of neuropathy in younger patients with IDDM. Those with NIDDM have an increased risk for neuropathy over time, as evidenced from a Finnish study which showed that 8.3% of such individuals have neuropathy at baseline, increasing to 41.9% after 10 years,

Tabic 82.25: Classification of diabetic neuropathies

Symmetrical polyneuropathies
- Distal sensory or sensorimotor polyneuropathy
- Small fiber neuropathy
- Autonomic neuropathy
- Large fiber neuropil thy

Asymmetrical neuropathies

with a yet higher percentage in those with low serum insulin concentrations (Partanen et al. 1995). In a cohort of 775 U.S. veterans with diabetes, 50% were found to have decreased foot sensation at baseline using monofilament sensory testing, arid an additional 20% developed hypoesthesia over the average *2.6* years follow-up period. Factors associated with an increased risk of decreased foot sensation included poor glycemic control, height, age, and alcohol consumption. Electrophysiological studies demonstrate subclinical conduction abnormalities in most patients with IDDM after 5-10 years of diabetes.

The many peripheral nerve manifestations associated with diabetes can be grouped into distinct clinical syndromes, each having a characteristic presentation and course. A useful classification divides the diabetic neuropathies into symmetrical polyneuropathies versus focal or multifocal neuropathies (Table 82.25). However, there is significant overlap between these syndromes.

Clinical features

Distal Symmetrical Polyneuropathy. Distal symmetrical polyneuropathy is the most common type of diabetic neuropathy. Many physicians incorrectly assume that the term *diabetic neuropathy* is synonymous with distal symmetrical polyneuropathy, because the latter constitutes perhaps three fourths of all diabetic neuropathies. Sensory loss predominates and autonomic symptoms correlate with severity. Most patients have minor motor involvement affecting the distal muscles of the lower extremities. Sensory disturbances have a stocking-glove distribution. Early sensory manifestations begin in the toes, gradually spreading proximally; when these reach above knee level the fingers and hands become affected. In more advanced cases, sensation becomes impaired over the anterior chest and abdomen producing a truncal wedge-shaped area of sensory loss (see Figure 31.7). The pattern of sensory impairment in diabetic distal symmetrical polyneuropathy follows a length-dependent dying-back process.

The distal symmetrica! polyneuropathy may be subclassified further into two major subgroups, depending on the nerve fiber type most involved: large-fiber and small-fiber variants. Although diabetic sensory neuropathy frequently forms a continuous spectrum ranging between these two polar types, selective nerve fiber involvement does occur, giving rise to relatively pure large- or small-fiber-type presentations.

The large-fiber variant presents with painless paresthesias beginning at the toes and feet, impairment of vibration and joint position sense, and diminished muscle stretch reflexes. In advanced cases, significant ataxia may develop due to sensory deafferentation. Earge-fiher involvement is often asymptomatic, but sensory loss may be found by careful examination,

A relatively common variant of diffuse diabetic polyneuropathy is *diabetic polyradiculoneuropathy.* Often beginning as a distal symmetrical polyneuropathy, this disorder comes to involve proximal segments of the peripheral nervous system including multiple lumbosacral roots, thoracic posterior primary rami, and less commonly cervical myotomes. Patients with ordinary distal symmetrical diabetic polyneuropathy are sometimes found by electromyography to have low grade, active denervation changes in multiple thoracic paraspinal muscle levels, which may herald the development of a more widespread neuropathy. The trigeminal "blink reflex" is often spared in advanced diabetic neuropathy and polyradiculoneuropathy, providing an important method to distinguish between this and immune related polyradiculoneuropathies such as chronic inflammatory polyradiculoneuropathies (Kirk et al. 1991). Much less commonly encountered is *diabetic polyradiculopatby,* in which peripheral sensory nerve conduction studies are normal and the focus of disease appears both clinically and eleetrodiagiiu-aicalK to be at the root level. There are patients with either IDDM- or NIDDM-associatcd neuropathy who meet electrodiagnostic criteria for chronic inflammatory demyelinating polyradiculoneuropathy (Sharma et al. 2002a). Some of these patients respond to high dose intravenous immunoglobulin therapy, although a controlled clinical trial has not yet been completed (Sharma et al. 2002b),

In contra-,: to the large lihci ncu: op.it h\. I lie small fiber variant frequently presents w-irh pain of a deep, burning, stinging, aching character, often associated with spontaneous shooting pains and allodynia to light touch. Pain and temperature modalities are impaired with relative preservation of vibration and joint position sensation and muscle stretch reflexes. The small-fiber variant is often accompanied by autonomic neuropathy (Santiago et al. 1999). At times, a painful small-fiber neuropathy may develop soon after the onset of IDDM (Said et al. 1992).

It is now clear that peripheral neuropathy can occur before the onset of clinically diagnosablc diabetes mellitus, so-called *impaired glucose tolerance neuropathy.* Individuals with impaired glucose rolcrance, as determined by oral

glucose tolerance testing (OGTT), have been demonstrated to have symptoms, electrophysiological abnormalities, and intracpidcrmal nerve fiber density reduction consistent with a predominantly small fiber neuropathy, although with changes less pronounced than in their diabetic counterparts (Sumner et al. 2003). The implication for clinical practice is that patients with undiagnosed painful peripheral neuropathy should undergo OG1T (Singleton, Smith, and Bromberg 2001).

An acute painful neuropathy may be precipitated following initiation of treatment with insulin *(treatment-induced neuropathy).* Burning pain and paresthesias develop in the distal lower extremities shortly after establishing glucose control. Pain persists for weeks or up to several months. Pathological studies demonstrate active axonal regeneration, which may act as generators of spontaneous nerve impulse^ Resoiadon usualb occurs, perhaps when the axonal sprouts reach the sensory nerve terminals in the extremities. This phenomenon may he more common in the rare form of diabetes mellitus associated with a mitochondrial transfer RNA mutation at position 3243 (Suzuki etal. 1997).

In patients with newly diagnosed diabetes, there may be transient pain and paresthesias in the distal lower extremities (hyperglycemic neuropathy). The symptoms will usually resolve when the hyperglycemia is brought under control.

Diabetic neuropathic cachexia is a term referring to an acute painful diabetic neuropathy associated with precipitous, severe weight loss, depression, insomnia, and impotence in men. The syndrome is more common in men with poor glucose control. Improved glucose control and weight gain often result in recovery (Yuen et al. 2001).

Sensory loss makes patients with diabetes susceptible to repetitive, often unnoticed injuries that set the stage for foot ulcers and distal joint destruction *[acrodystrophic neuropathy).* Chronic foot ulceration is one of the more severe complications of diabetes mellitus, due to a combination of unnoticed, traumatic tissue damage, vascular insufficiency, and secondary infection (Laing 1998). Prevention is better than treatment. Daily inspection and proper foot care can prevent or lessen the severity of this complication (Birke et al. 2002).

Neuropathic arthropathy or a *Charcot joint* formation is a complication seen in patients with diahetes, who often have foot ulcers and autonomic impairment. Unlike the Charcot joint seen in syphilis, diabetic arthropathy tends to involve the small joints in the feet. The term *diabetic pseudotabes* is applied to patients having severe lancinating pains, loss of joint sensation, and diabetic pupillary abnormalities (pseudo-Argyll Robertson pupils).

Electrodiagnostic studies are helpful in confirming the diagnosis of distal symmetrical polyneuropathy. Generalized slowing of conduction velocities has been emphasized (Herrmann, Ferguson, and Logigian 2002), but this is not the most common feature in this type of diabetic neuropathy (Wilbourn 2002). Absent or decreased amplitudes of the sural nerve potentials or absent tibial H-reflexes are found in almost all patients. Active denervation in intrinsic foot muscles or decreased amplitudes of CMAPs together with mild slowing of conduction velocities in the motor nerves are found in more than two thirds of patients. Abnormal sensory nerve conduction studies are found in more than one half. Even in the small-fiber variant, EMG examination is often abnormal.

Diabetic Autonomic Neuropathy. Autonomic neuropathy usually correlates with the severity of somatic neuropathy. The spectrum of autonomic involvement ranges from subclinical functional impairment of cardiovascular reflexes and sudomotor function to severe cardiovasculat, gastrointestinal, or genitourinary autonomic dysfunction (Low 2002).

Orthostatic hypotension, resting tachycardia, or a heart rate unresponsive to respiration are the hallmarks of diabetic autonomic neuropathy. Significant orthostatic hypotension occurs mainly because of failure of the sympathetic nervous system to increase systemic vascular resistance in the erect posture, and compensatory cardiac acceleration is impaired. It is crucial to exclude confounding effects of medications or coexisting hypovolemia when diagnosing neurogenic postural hypotension. Vagal denervation of the heart results in a high resting pulse rate and loss of sinus arrhythmia. An increased incidence of painless or silent myocardial infarction is reported in diabetic patients with autonomic neuropathy.

Gastrointestinal motility abnormalities and fecal incontinence may occur. Delayed gastric emptying leads to nausea, early satiety, and postprandial bloating. Diabetic diarrhea, due to small intestine involvement, typically occurs at night, and is explosive and paroxysmal. Associated weight loss or malabsorption is rare. Bacterial overgrowth may occur and can often be successfully treated with small doses of tetracycline (250-500 mg/day in a single dose given at the onset of a diarrheal attack) in adult patients. Colonic atony produces constipation. Bladder atony leads to prolonged intervals between voiding, gradually increasing urinary retention, and finally overflow incontinence. The symptoms develop insidiously and progress slowly. Patients with diabetes who have neurogenic bladder should be encouraged to void routinely every few hours to prevent urinary retention. Impotence is often the first manifestation of autonomic neuropathy in men with diabetes, occurring in more than 60% and causing serious emotional distress. Autonomic dysfunction involves both erectile failure and retrograde ejaculation. The majority of men with diabetes with impotence have some evidence of associated distal symmetrical polyneuropathy.

Sudomotor abnormalities produce distal anhidrosis, causing compensatory facial and truncal sweating and heat intolerance. A peculiar hyperhidrosis called *gustatory sweating* is characterized by profuse sweating in the face

and forehead immediately following food intake. Pupillary abnormalities include constricted pupils with sluggish light reaction. A blunted autonomic response to hypoglycemia produces an inadequate sympathetic and adrenal response and hence an unawareness of hypoglycemia that may seriously complicate intensive insulin treatment.

Asymmetrical Proximal Diabetic Neuropathy or Lumbosacral Radiculoplexopathy. Since Garland coined the term "diabetic amyotrophy" to describe this special type of diabetic neuropathy, the clinical definition and limits have been confusing because the term itself is ambiguous. Some experts have suggested that this term be abandoned and replaced with diabetic proximal neuropathy, emphasizing the proximal motor weakness as a distinguishing clinical feature (Asbury 1977). Diabetic amyotrophy, thoracic radiculopathy, and proximal or diffuse lower extremity weakness should probably be grouped under the single term diabetic poly radiculopathy, since these disorders seem to be different presentations of the same basic involvement of multiple nerve roots or proximal nerve segments. The eponymic designation Bruns-Garland syndrome avoids anatomical inconsistencies. Clinically, asymmetrical weakness and wasting of pclvi-fcmoral muscles may occur either abruptly or in a stepwise progression in individuals with diabetes who arc older than 50 years. Most patients have NIDDM, but the onset is unrelated to the duration of glucose intolerance. Typically, unilateral severe pam m the lower back, hip, and anterior thigh heralds the onset of neuropathy. Within days to weeks weakness ensues, affecting proximal and distal lower extremity muscles (iliopsoas, gluteus, thigh adductor, quadriceps, hamstring, and anterior tibial muscles). In some cases, the opposite leg becomes affected after a latency of days to months. Reduction or absence of knee and ankle jerks are the rule. Numbness or paresthesias are minor complaints. Weight loss occurs in more than half of patients and is more pronounced than in individuals with nondiabetic lumbosacral radiculoplexopathy {Dyck, Norell, and Dyck 2001). The progression may be steady or stepwise, and may continue for many months. The result is often a debilitating, painful, asymmetrical motor neuropathy with profound atrophy of proximal leg muscles. Pain usually recedes spontaneously long before motor strength begins to improve. Recovery takes up to 24 months, because of the slow rate of axonal regeneration. In many cases mild to moderate weakness persists indefinitely (Barohn et al. 1991). Overlap with distal symmetrical polyneuropathy is noted in up to 60% of patients. Those with polyneuropathy more commonly have gradual onset of symptoms, bilateral findings, significant weight loss, and diffuse paraspinal muscle denervation. The typical HMG findings include low amplitude femoral nerve motor responses, prominent fibrillation potentials in thoracic and lumbar paraspinal muscles, and active denervation in affected muscles. Neuroimaging studies ot the lumbar spine, lumbosacral plexus, or both should be considered when lumbar root, Cauda equina lesions or structural lumbosacral plexopathy are suspected (sec Chapter 81). Sural nerve biopsy specimens in these individuals show multifocal nerve fiber loss suggesting ischemic injury and perivascular infiltrates, inferring an immune mechanism (Figure 82.30; Dyck et al, 2000b). A vascular pathogenesis of this proximal neuropathy was documented by autopsy showing infarcts of the proximal nerve trunks and lumbosacral plexus.

Truncal Neuropathy. Diabetic truncal neuropathy or thoracic radiculopathy involving the T4-T12 roots causes pain or dysesthesias in areas of the chest or abdomen. Bulging of the abdominal wall as a result of weakness of abdominal muscles may occur (Figure 82.31}.

This unique truncal pain is seen in older patients with NIDDM and may occur either in isolation or together with the typical lumbosacral radiculoplexopathy. The regions ot sensory loss or dysesthesia involve the trunk in a highly variable pattern affecting either the entire dermaromal distribution of adjacent spinal nerves or, more often, restricted areas limited to the distribution ot the dorsal or ventral rami of spinal nerves. Patients describe burning, stabbing, boring, beltlike pain. Contact with clothing can be very unpleasant. The onset may be either abrupt or gradual. The clinical picture can mimic intra-abdominal, intrathoracic, or intraspinal disease, or even herpes zoster, requiring careful differential diagnostic consideration. Neurological findings are limited to hypesthesia or hyperpathia over the thorax or abdomen. The symptoms maypersist for several months before gradually subsiding,

Electrodiagnostic studies are helpful by demonstrating active denervation in paraspinal and abdominal muscles, although these features are not specific for truncal mononeuropathy. Focal anhidrosis on the trunk correlating with the area of pain can be readily noted with the help of the thermoregulatory sweat test.

Limb Mononeuropathy. Single mononeuropathics, which are often seen in diabetic patients, arc thought to be caused by two basic mechanisms: nerve infarction or entrapment (Asbury 1977). Mononeuropathy secondary to nerve infarction has a stereotyped presentation, with the abrupt onset of pain followed by variable weakness and atrophy. Because the primary pathological lesion results in acute axonal degeneration, recovery tends to be slow. The median, ulnar, and fibular (peroneal) nerves are most commonly affected.

Mononeuropathics caused by nerve entrapment are more common than nerve infarctions. These rwo conditions can usually be distinguished by clinical and electrophysiological features. Entrapment neuropathy has an insidious onset and is found at characteristic sites. F.lectrodiagnostic studies demonstrate axonal loss in nerve infarction in contrast to focal conduction block and/or focal slowing in entrapment.

(Hematoxylin and eosin, original magnification *x25.)* (13) In the same patient, semithin transverse section illustrates selective involvement of one fascicle with marked loss of myelinated fibers, a pattern highly suggestive of nerve ischemia. (Paraphenyleuediamine-stained semithin cpoxy section, original magnification x80.) (Courtesy Dr. P. J. Dyck, Mayo Clinic, Rochester, MN.I

Multiple Mononeuropathies. Multiple mononeuropathies refers to the affection of two or more nerves. As in mononeuropathy, the onset is abrupt in one nerve, then other nerves ate involved sequentially at irregular intervals. Multiple mononeuropathies involving proximal nerves are considered the cause of "diabetic amyotrophy." Nerve infarction results from occlusion of the vasa nervorum. Because mononeuritis multiplex occurs most frequently in systemic vasculitis, this possibility should always be considered in the differential diagnosis of diabetic multiple mononeuropathies.

Cranial Mononeuropathies. A detailed description is given elsewhere (see Chapter 76). A third nerve palsy is the most commonly encountered diabetic cranial mononeuropathy. Pupillary sparing is the hallmark of diabetic third nerve palsy reflecting injury to centtifascicular axons but sparing the peripherally located pupillary motor fibers of the third nerve. With decreasing frequency, the fourth, sixth, and seventh nerves are affected. Acute ischemic nerve damage is the presumed cause of these cranial neuropathies. Patients with Bell's palsy have a significantly higher frequency of diabetes than an

FIGURE 82.31 Bulging of the right lower thoracic abdominal wall at the level of the umbilicus associated with diabetic truncal monoradiculopathy.

age-matched population. Most make a full recovery in *3-5* months.

Thete are two serious, though somewhat rare, infectious syndromes closely linked to diabetes mellitus, which characteristically affect one or more cranial nerves by local inflammation. Rhinoccrcbral mucormycosis and "malignant" external otitis were often fatal before the advent of early diagnosis and effective treatment strategies (Smith 1998).

Increased Incidence of Entrapment Neuropathy. Diabetes mellitus is a risk factor for single or multiple entrapment neuropathies. Diabetes is found in 8-12% of patients presenting with carpal tunnel syndrome. Electrophysiological abnormalities consistent with carpal tunnel syndrome but without symptoms are found in one fourth of diabetic patients, while symptomatic carpal tunnel syndrome is found in 8% (Dyck et al. 1993b). Similar population studies indicate that the risk for carpal tunnel syndrome is about 2.2 times greater in female and 2.5 times greater m male patients with diabetes than in the general population. The reason diabetes predisposes to nerve entrapment is unknown, but aggravation of ischemia in nerves already sm^scd by chronic endoneurial hypoxia may be one factor. The possibility of occult diabetes should always be kept in mind in every case of entrapment neuropathy.

Laboratory Findings

The diabetes mellitus can be confirmed by finding one of the following: (1) a random plasma glucose of >200 mg/dL (11.1 mmol/L), associated with symptoms of hyperglycemia (polyuria, polydipsia, unexplained weight loss); (2) a fasting plasma glucose of >126 mg/dL (7.0 mmol/L); or (3) a 2-hout glucose of >2()0 mg/dL (11.1 mmol/L) after a 75-g glucose load in the OGTT. Any of these criteria is sufficient fot diagnosis, but each should be confirmed on a separate day. Impaired glucose tolerance (IGT) on the other hand is defined as plasma glucose levels between 140 and 200 mg/dL (7.8 and 11.1 mmol/L) 2 hours after a 75-g oral glucose load; the new category impaired fasting glucose (IFG) is defined as a fasting plasma glucose of between 110 and 125 mg/dL and is analogous to IGT (Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus 1997). Glycosylated hemoglobin (hemoglobin Ale) is a useful indicator of the long-term control of hyperglycemia, but is not generally used to diagnose diabetes, IGT, or IFG.

Evoked nerve action potential amplitudes are often reduced in patients with diabetes, while NCVs are typically slower in this group than in healthy subjects, all hough strict criteria for demyelinating neuropathy are not often met (Shanua et al. 2002a). Abnormalities occur more commonly in sensory than in motor fibers, in the legs more than in the arms, and in distal more than proximal nerve segments.

Pathology

The underlying pathological processes differ in the various types of diabetic neuropathy. Cranial and limb mononeuropathy and multiple mononeuropathies are thought

to be caused by small vessel occlusive disease (Smith and Dyck 1992).

The precise location of the primary pathological process in diabetic asymmetrical proximal neuropathy remains unsettled. Postmortem examination of the obturator nerve in a single case of proximal neuropathy showed multiple infarcts due to the occlusion of vasa nervorum. However, lumbar nerve roots were not examined. Studies of peripheral sensory nerves in patients with diabetic lumbosacral radiculoplexopathy provide evidence suggesting immune-mediated neuropathy and ischemia (Dyck, Norell, and Dyck 2001). Whether ischemic or inflammatory lesions in multiple lumbar roots, plexus, or proximal nerve segments are responsible for this particular neuropathy still remains to be proven.

The pathological lesions of symmetrical distal polyneuropathy have been extensivelj investigated Engelstad et al. 1997). The sural nerve shows loss of myelinated fibers, acute axonal degeneration, some degree of demyelination, and almost invariably evidence of a small endoneurial blood vessel vasculopathy. The latter is characterized by narrowing or closure of the endoneurial capillary lumen by hyperplastic endothelial cells, thickening of the capillary wall, and marked redundancy of basement membranes. Axonal degeneration has been shown to result from a dying-back centripetal degeneration of peripheral axons. Painless distal polyneuropathy affects predominantly the large nerve fiber populations, while painful distal diabetic polyneuropathy often shows marked depletion of small myelinated and unmyelinated fibers. In the latter condition, there is active axonal regeneration giving rise to abnormal netve impulses and neuropathic pain (Said etal. 1992).

The dcmyelinating process in diabetes has been interprclcd either as [he result ⊳! priman progressive axonal atrophy or from direct damage to Schwann cells, either by ischemia or metabolic disturbances. Extensive histometric studies of sural nerves demonstrate that the nerve fiber loss in diabetic neuropathy is distributed multifocaliy between and within different fascicles. The pattern of such multifocal nerve fiber loss is similar to that reproduced in experimental microsphere occlusion studies. Three-dimensional studies from nerves along proximal to distal segments indicate increasing nerve fiber depletion in distal nerve segments. This finding correlates with electrophysiological studies demonstrating a diffuse abnormality of NCVs with proximodistal gradients. The current investigations point to microvascular abnormalities contributing significantly to the development of both multifocal neuropathies and symmetrical polyneuropathies.

Pathogenesis of Diabetic Neuropathy

Although the causes of diabetic neuropathies remain unknown, currently accepted hypotheses focus on the possibilities of metabolic and ischemic nerve injury. Hyperglycemia has been implicated in many different pathogenic mechanisms in diabetic neuropathy (Simmons and Fcldman 2002). Hyperglycemia generates rheological changes that increase endoneurial vascular resistance and reduce nerve blood flow. Hyperglycemia also causes depletion of nerve myoinositol through a competitive uptake mechanism. In addition, persistent elevated blood glucose levels activate the polyol pathway in nerve tissue through the enzyme aldose reductase, which leads to the accumulation of sorbitol and fructose in nerve and induces nonenzymic glycosylation of structural nerve proteins (Thornalley 2002). Another adverse effect of hyperglycemia is auto-oxidation of glucose, which results iii the generation of toxic reactive oxygen intermediates (Sheetz and King 2002). Over-exuberant activation of protein kinase C has been linked to vascular damage in diabetic neuropathy (Eichberg 2002). These metabolic changes arc likcK to cause abnormal neuronal, Schwann cell, and axonal metabolism and subsequently impaired axonal transport. Direct measurements of sugar alcohols in sural nerves from patients with diabetes confirm increased levels of glucose, sorbitol, and fructose that correlate with the severity of the neuropathy. Endoneurial hypoxia is produced by decreased blood flow to the nerve and increased endoneurial vascular resistance. Once hypoxia is established, a vicious cycle of further capillary damage is set in motion that escalates hypoxia. F.ndoneurial hypoxia is thought to impair axonal ttansport and reduces nerve sodium-potassium-ATPase activity. The impairment of these functions causes axonal atrophy, leading to tednecd NCVs. Although the precise mechanisms leading to capillary abnormalities that initiate hypoxia ate unknown, the hypoxic hypothesis provides a framework for further research into the pathogenesis of diabetic neuropathy.

Unfortunately, basic research in diabetic neuropathy has focused almost exclusively on carbohydrate metabolism and, to a lesser extent, immune mechanisms, to the exclusion of the amino acid, electrolyte, and lipid biochemical abnormalities long known to be present in diabetes mellitus.

Treatment

The cotnetstone in the treatment of diabetes and its complications remains optimal glucose control. There is considerable evidence that good diabetic control is associated with less frequent and less severe peripheral nerve complications. Although the data arc less compelling for NIDDM, there is an association between poor glycemic control and neuropathic deficits (Adler et al. 1997). The Diabetes Control and Complication Trial (1995) showed that intensive glucose management by insulin pump or by multiple daily insulin injections in patients with IDDM reduces the development of neuropathy by 64% at 5 years compared to conventional therapy. Successful pancreatic transplantation is beneficial in preventing the progression

of diabetic neuropathy and the effect may be sustained in long-term follow-up (Navarro, Sutherland, and Kennedy 1997). Attempts to treat diabetic neuropathy by manipulating nerve metabolism have been disappointing. Clinical trials of myoinositol supplementation have shown conflicting results, and those of aldose reductase inhibitors have so far failed to produce convincing clinical improvement, though there were modest changes in nerve conduction and nerve pathology.

Despite promising preliminary evidence, neuropeptide treatments for diabetic neuropathy, such as NGF, have been disappointing (Apfel 2002). Based on experimental data suggesting that oxidative stress mediated by free radical species may be involved in diabetic neuropathy, two large multi-center randomized controlled clinical trials of *a*-lipoic acid have bqcn undertaken (A1.ADIN and NATHAN 1) (Ziegler 2002). The NATHAN 1 study is the first longitudinal multi-year human study to evaluate a pathogenicallv based treatment for diabetic polyneuropathy. A randomized controlled double blind human study ol intravenously administered a-lipoic acid in patient with symptomatic diabetic polyneuropathy showed improvement of sensory symptoms (Ametov et al. 2003). Despite two multi-center controlled clinical trials of or-linoleic acid in diabetic neuropathy, which showed lessening of neuropathic deficits and improvement in measures of nerve conduction (Keen et al. 1993; Horrobin 1997), because of licensing problems no further trials with this substance arc planned. Vascular endothelial growth factor (VEGF) gene transfer into small mammals has been shown to improve NCVs, increase blood vessel density, and enhance nerve blood flow (Schratzberger et al, 2001), giving impetus to pursuing this approach to human diabetic neuropathy. Because human C-peptide prevents neuropathy in diabetic rats in a dose-dependent fashion (Zhang et al. 2001), clinical interest has developed for this compound as well. For unclear reasons, a number of pathogenic ally sound therapeutic approaches using neuropeptides or other small molecules to halt progression or reverse diabetic neuropathy have shown great promise based on in vitro and in vivo animal studies, only to be proven ineffectual or unimpressive when carried out in human diabetic subjects.

Symptomatic treatment for pain, autonomic manifestations, and the complications of sensory loss can be offered to lessen the impact of neuropathic symptoms.

The use of intravenous methylprednisolone therapy is currently under investigation for patients with diabetic lumbosacral radiculoplexopathy. Use of high dose intravenous immunoglobulin or methylprednisolone has been reported to benefit patients with progressive deficits and biopsy evidence of inflammation in uncontrolled studies (Dyck and Windcbank 2002).

Several therapeutic interventions may reduce the symptoms of autonomic dysfunction. Patients with symptomatic orthostatic hypotension arc advised to sleep with the head of the bed elevated 6-10 inches. The head up tilt prevents salt and water losses during the night, and will combat supine hypertension. Practical suggestions include drinking two cups of strong coffee or tea with meals, eating more frequent small meals rather than a few large meals, and increasing the daily fluid intake (>20 oz per day) and salt ingestion (10-20 g per day). Elastic body stockings may be beneficial by reducing the venous capacitance bed, but are poorly tolerated by many patients. Plasma volume expansion can be achieved by fludrocortisone (0.1-0,6 mg daily). Nonsteroidal anti-inflammatoty drugs, which inhibit prostaglandin synthesis, represent the next class of drugs to be considered; ibuprofen, 400 mg four times a day, is better tolerated than indomethacin. Phenylpropanolamine (25-50 mg three times a day), a direct-acting alpha-agonist, was once used for orthostatic hypotension; although a sustained-release form of phenylpropanolamine can be obtained over-the-counter (e.g., Dcxatrim), the association of hemorrhagic stroke makes this medication an undesirable option (Morgenstcrn et al. 1997). Delayed gastric emptying is often relieved with metoclopramide; because it is a dopamine antagonist, extrapyramidal symptoms may occur at higher doses. Diabetic diarrhea may be treated with short courses of tetracycline or erythromycin, if appropriate. In some cases, clonidine has been reported to reduce the troublesome diarrhea.

Genitourinary complications of diabetic autonomic neuropathy require close collaboration with a urologist. Patients with a neurogenic bladder should be encouraged to adhere to a frequent voiding schedule during the day, which helps diminish the amount of residual urine. For more severe involvement, manual abdominal compression or intermittent sclf-carherenzation may be needed. Treatment of erectile impotence should be directed by a urologist, who can counsel the patient regarding the options of either oral treatment with sildenafil, pharmacological erections with direct injections into the corpora cavernosa, or penile implants.

Proper skin care in diabetics with cutaneous sensory loss, impaired sweating, and vascular disease is extremely important to prevent foot ulcers.

Peripheral Neuropathy in Malignancies

Advances in the diagnosis and management of malignancy have accelerated in recent years, leading to novel chemotherapeutie strategies and prolonged survival rates for many cancers. With these welcome improvements come an increasing awareness ot peripheral nerve complications in patients with various forms of neoplasm. The frequency with which neuropathy occurs in cancer depends on the type of neoplasm and the method of detection. If clinical criteria alone are used, 2-16% of cancer patients are estimated to have peripheral neuropathy. When quantitative sensory testing or electrophysiological studies are carried out, approximately 30-40% of patients have

abnormalities suggestive of peripheral nerve involvement (Amatoand Collins 1398).

Peripheral nerve complications may result from one or more mechanisms related to cancer or its treatment. These include (1) compression or invasion of nerve trunks or nerve plexus by direct extension of primary or metastatic tumor; (2) meningeal metastases with involvement of multiple nerve roots; (3) remote effects of cancer affecting neuronal cell bodies, nerve axons, Schwann cells or myelin, terminal axons, neuromuscular junction, and muscle; {4) entrapment neuropathies in individuals with profound cachexia; and (5) treatment with chemotherapy or radiation.

Compression/Invasion of Nerves

Apart from head and neck tumors invading cranial and cervical peripheral nerves, focal neuropathies from primary neoplasms are uncommon. Salivary gland cancers are known to affect the facial and other cranial nerves, often growing insidiously by perineuria! spread, thereby eluding early detection even by sophisticated imaging procedures. Nasopharyngeal carcinomas, meningiomas, and skull base tumors may interrupt cranial nerve fibers directly. Primary or recurrent neoplasms of the breast or lung apex in particular may invade the brachial Ht'\u-. Siir.ikirly. primary or recurrent pelvic or retroperitoneal cancers may involve the lumbosacral plexus (these conditions are discussed in Chapter 81),

Metastases

Discrete single metastatic lesions may rarely cause crania! or somatic mononcuropathy. The "numb chin" syndrome results from invasion of the inferior alveolar nerve by metastases to the mandible. Patients complain of numbness of the chin and lower lip. Leukemias, lymphomas, and breast cancer are the most common neoplasms responsible for the "numb chin" syndrome. More commonly widespread metastases arise in the leptomcninges from carcinoma or lymphoma leading to leptomeningeal carcinomatosis or lymphomatosis, respectively.

Entrapment

Individuals who lose substantial weight or are bedridden are subject to fibular (peroneal) and ulnar compression neuropathies (Rubin, Kimmel, and Cascino f 998).

Iatrogenic Neuropathies

ChemoiluTapcutic agents ilui cause pniiianh (HI i^lu-r.il neurotoxicity include vinca alkaloids, platinum compounds and taxancs, are discussed in the section on toxic neuropathy. The neurological complications of radiation plcxopathy are discussed in Chapters 64 and K3. Surgical resection of bulky cancers may result in trauma to peripheral nerves, which may be unavoidable because of inextricable adherence or transit of nerve fibers through the tumor mass.

Paraneoplastic Neuropathies

Paraneoplastic disorders are defined as remote effects of cancer, unrelated to treatment or deficiency states, that often involve both the central and petipheral nervous systems alone or in combination. In paraneoplastic neuromuscular disorders, sensory or autonomic ganglia, petipheral nerves, nerve terminals, neuromuscular junction and muscle may be affected, and thereby result in diverse clinical syndromes. Small cell carcinoma of the lung (SCLC) is the most common malignancy associated with paraneoplastic neurological syndromes bur carcinoma of breast, ovaries, kidney, prostate, thymoma, and Hodgkin's and non-Hodgk in's lymphoma have also been reported to be associated. The neurological symptoms may precede the detection of the underlying cancer by 4 to 12 months. The clinical course is often rapidly progressive, leaving the patients severely disabled in only a few weeks or months. Any neuropathy, especially a sensory or autonomic neuropathy of subacute onset occurring in a smoker, should raise suspicion ol a paraneoplastic disorder.

Paraneoplastic neurological syndromes are considered autoimmune disorders because of the presence of autoantihodics dcki.:cd in si-rum and CS1 nt some affected patients that are reactive with protein antigens in the neoplastic tissue and CNS neurons. Paraneoplastic neuropathies have been associated with an ever-increasing number of autoantibodies (Chan, Vernino, and Lennon 2001; Table 82.26).

The type 1 antincuronal nuclear antibody (ANNA-I or anti-Hu, named after the first two letters of the name of the patient in whom this antibody was first discovered) is associated with malignant inflammatory sensory polyganglioneuropathy, gastrointestinal dysmotility, autonomic neuropathy, and limbic encephalomyelitis. Small cell lung cancer is found in more than 80% of ANNA-I seropositive patients (Lucchinetti, Kimmel, and Lennon 1998). These polyclonal IgG autoantibodies are directed against *35* to 40 kDa proteins that belong to the Hu-family of RNA binding proteins expressed in nuclei of neurons and malignant cells. The type 2 antincuronal nuclear antibody (ANNA-II, or anti-Ri) was originally described in women with opsoclonusniyoelonns associated with breasi cancer. Inn may also he seen in men with peripheral neuropathy in association with lung cancer. ANNA-IH is highly associated with SCLC or adenocarcinoma of the lung in patients with sensorimotor neuropathies, cerebellar ataxia, and encephalomyelitis. Three IgC autoantibodies related to lung cancer are directed against neuronal cytoplasmic antigens. These are amphiphysin antibody (also related to breast carcinoma), type 2 Purkinje cell cytoplasmic antibody (PAC-2), and the collapsin response-mediator protein-5 antibody (CRMP-5).

Table 82,26: Autoantibodies in neuromuscular paraneoplastic syndromes

AntibvJy	*Neurological n xanifes tations*	*Types of tumors*
ANNA-1 (niiti-Hu)	MISP, GI dysmotility; autonomic N, PF.M	SCLC
ANNA-2 (anti-Ri)	Opsoclonus/myoclonus, jaw dystonia, ataxia, SMN	SCLC, breast carcinoma
ANNA-3	Sensory N, SMN, ataxia, PEM	SCLC, adenocarcinoma of lung, esophagus
CRMP-5 (anti-CV-2)	Dementia, SMN, vision loss, chorea	SCLC, thymoma
PCA-1 (anti-Yo)	Cerebellar ataxia, SMN	Ovarian, breast carcinoma
PCA-2	PEM, ataxia, autonomic and motor N	SCLC
Amphiphysin	Stiff man syndrome, sensory N	SCLC, breast carcinoma
P/Q type calcium channel	1 EMS	SCLC
N type calcium channel	LEMS, SMN	SCLC, breast, ovarian carcinoma
Ganglionic AChR	Autonomic N, GI dysmotility, PN hyperexcitabiliry	SCLC, thymoma
Voltage-gated potassium channel	PN h\ pcrcxcirabilin	Thymoma, lung carcinoma

AChR = acetylcholine receptor; ANNA = antineuronal nuclear antibody; CRMP-5 = eo]lapsm response-media tor prorcin-5; LEMS = Lambert-Eaton myasthenic syndrome; MISP = malignant inflammatory sensory polyganglionopathy; N = neuropathy; PCA-l=type 1 Purkinje cell cytoplasmic antibody; PCA-2 = rype 2 Purkinje cell cytoplasmic antibody; PEM = paraneoplastic encephalomyelitis; PN hyperexcitability = peripheral nerve hyperexcitability; SCLC = small-cell lung carcinoma; SMN = sensorimotor neuropathy.

CRMP-5 IgG (or anti-CV-2) antibodies are associated with SCLC and rarely thymoma and occur in patients with multifocal neurological signs, including sensory or sensorimotor neuropathies, chorea, optic neuropathy, and disturbance of smell and taste (Yu et al. 2001). Autoantibodies directed aginst neuronal ion channel antibodies include P/Q and N-type calcium channel antibodies, ganglionic acetylcholine receptor and voltage-gated potassium channel antibodies. P/Q type calcium channel antibodies are present in more than 90% of patients with Lambert-Eaton syndrome (LES). N-type calcium channel antibodies are markers for lung, breast, or ovarian cancers and are found in patients with various neurological manifestations including LES and peripheral neuropathy. Ganglionic acetylcholine receptor antibodies are found in patients with both idiopathic and paraneoplastic types of autonomic neuropathy (Vernino et aI. 2000). Voltage-gated potassium channel antibodies are detected in patients with autoimmune disorders of peripheral nerve hyperexcitability. These include neuromyotonia, myokymia, and cramp-fasciculation syndrome. These van- disorders can be seen in association with thymoma, lung cancer, and Hodgkin's lymphoma (Hart et al. 2002).

Peripheral neuropathies associated with carcinoma may be classified according to the distribution of involvement into the following clinical types: (1) malignant inflammatoty sensory polyganglionopathy; (2) autonomic neuropathy; (3) sensorimotor polyneuropathy (either axonal or demyclinating types); and (4) multiple mononouropathy.

Ma !i tit unit Inflammatory Sensory Polyganglionopathy

In 1948, Denny-Brown recognized the association between sensory neuropathy and cancer when he described two cases with rapidly progressive severe sensory loss and ataxia without weakness as a remote effect of bronchogenic carcinoma. The terms *subacute sensory neuropathy, carcinomatous sensory neuropathy, paraneoplastic sensory neuronopathy,* and *malignant inflammatory sensory polyganglioneuropathy* are synonyms to describe the distinct sensory neuropathy associated with cancer. The term *malignant inflammatory sensory polyganglionenropathy* is preferred because it emphasizes the sensory ganglion cell as the primary site of injury, while recognizing that other neurons including autonomic ganglia and CNS nerve cells arc often involved as well. The presence of an autoantibody directed against a nuclear protein that is shared by neuronal nuclei and tumor antigens, and the intense inflammatory response found in affected dorsal root ganglia, support an immune-mediated mechanism for this condition. Paraneoplastic syndromes affect only a small minority of cancer patients, occurring less commonly than direct tumor invasion or neurotoxic complications of chemotherapy.

Clinical Features. Patients are middle-aged or older, and many are heavy smokers. "Women are affected twice as often as men in the United States, in contrast to a European study and to the overall male predominance of SCLC; (Graus et al. 2001). The most common underlying neoplasm is SCLC (approximately 90%), followed in decreasing order of frequency by breast carcinoma, ovarian cancer, and lymphoma. In 9 of 10 cases neurological symptoms are the presenting features and precede the discovery of the tumor by several months. The median interval from onset of neuropathic symptoms to diagnosis of the underlying neoplasm is .5 months. Symptoms may develop fulminantly within days or more gradually over months. Numbness, painful paresthesia, and lancinating pain often begin in one limb and progress to involve all four limbs. Occasionally, the ttunk, face, or scalp are affected in somatotopic regions highly suggestive of

neuronopathies. There is global loss of all sensory modalities with a striking loss of proprioception and the ability to localize the limb in space, leading to sensory ataxia and pseudoathctosis of the upper extremities. Tendon reflexes are globally reduced or absent. Although muscle strength is preserved or only mildly decreased, patients are often severely disabled and unable to walk because of their sensory deficits.

Approximately one half of patients have symptoms and signs reflecting more widespread involvement of myenteric plexus neurons, autonomic ganglia, spinal cord, brainstem, cerebellum, and limbic cortex. These patients display varying degrees of gastrointestinal dysmotility, autonomic dysfunction, myelopathy, cerebellar signs, brainstem findings, and subacute dementia.

Laboratory Features. The CSF is frequently abnormal with either mild pleocytosis or elevated protein. Nerve conduction studies show low-amplitude or absent SNAPs with relatively preserved amplitudes of CMAPs. F.MGs may demonstrate minor abnormalities. The sural nerve frequently shows a combined loss of myelinated and unmyelinated fibers, axonal degeneration, and minimal axonal regeneration, sometimes with mononuclear inflammatory cells around epineurial vessels. The principal neuropathological features include degeneration of dorsal root ganglion cells with intense mononuclear cell inflammation, subsequent loss of sensory axons, and degenctation of the posterior roots, peripheral sensory nerves, and the posterior columns of the spinal cord. Many patients have pathological evidence of a more generalized encephalomyelitis characterized by inflammatory infiltrates and neuronal loss in hippocampus, brainstem, and spinal cord.

Patients presenting with sensory neuronopathy, encephalomyelitis, or gastrointestinal dysmotility associated with SCLC harbor characteristic autoantibodies in their serum and spinal fluid called type I antineuronal nuclear antibodies (ANNAT) or anti-Hu. About 90% of patients with sensory neuronopathy associated with SCLC' have significantly elevated titers of ANNA-1 antibodies by immunohistochemistry or Western blot analysis; low titers have been found in 16% of patients with SCLC without neurological disease. The reported sensitivity of positive ANNA-I antibodies is 88%, and the specificity is 99%. In contrast, all patients with idiopathic sensory neuronopathy without cancer are seronegative for ANNA-I antibodies. These results highlight the value of serological testing fot ANNA-I antibodies as an aid in the differential diagnosis of ataxic sensory neuronopathies. When a paraneoplastic neuropathy is suspected in relation to lung cancer, screening for an entite panel of autoantibodies that includes ANNA-I, CRMP-5, amphiphysin, PCA-2, ANNA-type 2, and ANNA-type 3, and calcium channel antibodies provides an even greater diagnostic yield. Seropositive patients should have chest CT or MRI because the tumor may go undetected by chest roentgenography. When cancer is not found by conventional radiological procedures, positron emission tomography (PET) should be considered.

Differential Diagnosis. The diagnostic possibilities of acquired sensory neuronopathies include malignant inflammatory sensory polyganglioneuropathy, the ataxic sensory neuronopathy associated with Sjogren syndrome or HIV infection, and idiopathic sensory neuronopathies. These conditions share similar pathological lesions characterized by an inflammatory ganglionopathy. The toxic sensory neuronopathies caused by high dose pyridoxine or following chemotherapy with cisplatinum arc readily excluded by history. Although it can be difficult to distinguish patients with malignant inflammatory sensory polyganglioneuropathy from those with other causes of sensory neuronopathy, (!) discovery of prominent dvsuurouomi.i, (2) neurological signs suggesting disease outside the dorsal root ganglion (and particularly CNS deficits), or (3) ANNA-I antibodies should prompt a careful search for malignancy, and especially SCLC.

Prognosis. The outlook for patients with paraneoplastic sensory neuronopathy is poor. Early diagnosis and prompt treatment of the underlying neoplasm provide the best chance to stabilize the condition. More often the neuronopathy pursues a relentless, independent course, despite treatment of the underlying tumor. Treatment with plasmapheresis, intravenous immune globulin, and immunosuppressive agents has had disappointing results. Nevertheless, minor modifications of the clinical course have been observed in a few patients receiving immunoinniluhinirv therapy [drau.ss el al. 200 f 1.

Paraneoplastic Autonomic Neuropathy

Subacute panautonomic failure may be associated with malignancies, most commonly SCLC. The majority of patients have focal or generalized gastrointestinal dysmotility presenting wirli abdominal pain, nausea, vomiting, and severe constipation with subtle or no sensory deficits. Ganglionic acetylcholine receptor and ANNA-I antibodies are found in most patients.

Sensorimotor Polyneuropathy

It is far more common for cancer patients to have distal symmetrical sensorimotor polyneuropathy than malignant inflammatory sensory polyganglioneuropathy. Clinically, these more frequently encountered length-dependent neuropathies are often of slow onset, progress gradually, and are indistinguishable from distal axonal neuropathies in individuals without malignancy. Sites of neoplasm reported in association with this nondescript polyneuropathy, in decreasing order of frequency, include lung, stomach, breast, colon, pancreas, and testis. Whether these neuropathies are paraneoplastic remains to be proven.

Acute and chronic polyradiculoneuropathies have occasional!) been linked In undciK MSL ni.ihs'.tuiicies. t. 1*S lias been reported in a few patients with Hodgkin's lymphoma. C1DP may occur in patients with leukemia, myeloma, melanoma, and lymphoma. Molecular mimicry of common antigens shared by both melanoma and Schwann cells may explain the increased association of CIDP with melanoma. It is important to recognize these acquired acute or chronic immune-mediated polyradiculoneuropathies in the clinical setting of malignancies because both respond to immunomodulatory therapies.

Multiple Mononeuropathies

Paraneoplastic vasculitis is recognized to occur in association with malignancies as a remote effect of cancer and frequenrly presents as cutaneous vasculitis in hairy cell leukemia and lymphoma. Peripheral nerve vasculitis is a rare complication of Hodgkin's and non-Hodgkin's lymphoma, SCLC, adenocarcinoma of the lung, prostate, endometrium, and renal cell cancer. Patients present with multiple mononeuropathy or painful, asymmetrical sensorimotor neuropathy that precedes the discovery of tumor in most. The association of vasculitis with SCLC and seropositive ANNA-I autoantibodies supports a paraneoplastic etiology. Two thirds of patients have responded to either chemotherapy of the underlying malignancy or cyclophosphamide with or without steroids (Oh 1997).

Lymphoma, Neurolymphomatosis, Leukemia, and Polycythemia Vet J

Neurological complications of lymphoma result from (1) direct involvement of the leptomeninges or brain; (2) compression ol [hi spinal cord or nerve roots b\ epidural masses; (3) bacterial, fungal, and viral infections; (4) complications of treatment (e.g., chemotherapy, radiation, bone-marrow transplantation); and (5) remote effects. Spinal cord compression is the most frequent complication, followed by varicella zoster virus infection and toxic neuropathies related to chemotherapy. Peripheral neuropathy unrelated to chemotherapy is found in approximately 5% of patients with lymphoma (Hughes, Britton, and Richards 1994).

Neurolymphomatosis is a rare condition with diffuse infiltration of peripheral and cranial nerves, plexus, or nerve roots by lymphoma cells. Patients present in several ways depending on the site of PNS involvement as ascending paralysis mimicking GBS, progressive polyradiculoneuropathy, Cauda equina syndrome, distal sensorimotor polyneuropathy, or multiple mononeuropathy. The diagnosis is confirmed by positive CSF cytology or lymphoma - tous infiltration of nerves as seen by cutaneous nerve biopsy or autopsy. Neurolymphomatosis responds poorly to systemic chemotherapy because the nerve-blood barrier limits the access of cytotoxic drugs (Odabasia et al. 2001).

Intravascular lymphomatosis or angiotropic large cell lymphoma is characterized by the proliferation of maligant lymphocytic cells within small blood vessels of the brain, spinal cord, peripheral nerves, and skin. Neurological manifestations include multifocal strokes, myelopathy with or without cauda equina lesions, and polyradiculoneuropathies. Intravascular lymphoma may be confirmed by biopsy of involved tissues such as skin, muscle, or peripheral nerve. Untreated the disease is rapidly fatal. Survival has been reported after chemotherapy (Oei, Kraft, and Sarnat 2002).

Acute and chronic demyelinating polyradiculopathies have been described in association with Hodgkin's and non-Hodgkin's lymphoma. About 8% of patients with monoclonal gammopathy have a low grade lymphoma or lymphocytic leukemia and may develop a distal demyelinating neuropathy in association with IgM paraproteinemia.

I.ymphoproliferative disorders may be overrepresented in patients with motor neuron disease. This association was initially restricted to lower motor neuron syndromes, named *subacute motor neuronopatby,* occurring as a remote effect ol lymphoma. Only a few patients with pure lower motor neuron syndromes have improved following treatment of the concurrent lymphoproliferativc disorder.

Neurological complications of chronic lymphocytic leukemia develop in the advanced stages of the disease. These include herpes zoster infection, followed by opportunistic infections and treatment related complications. Peripheral nerve involvement is rare (less than 1%) and consists of leukemic nerve infiltrations and immune-mediated neuropathies.

Neurological complications of acute leukemias stem from hemorrhage into the brain or nerve trunks; leukemic infiltration of the brain, lepromeninges, cranial nerves, spinal roots, and peripheral nerves; CNS infections; or chemotherapy-related neurotoxicity.

Mild distal sensory neuropathy is a rare complication of polycythemia vera. Positive sensory complaints such as pruritus, paresthesias, and burning feet are common. Polycythemia vera-associated pruritus, which is typically precipitated by contact with water, may be an agonizing aspect of the disease. Selective serotonin reuptake inhibitors such .is paroxetine or fluoxetine have been beneficial in alleviating pruritus.

Neuropathies Related to Bone Marrow Transplantation

Peripheral neuropathy is an uncommon complication of bone marrow transplantation. In a prospective study of 115 patients with leukemia undergoing allogeneic bone marrow transplantation, 4% developed neuropathy in the first three months after transplantation. There arc a number of potential neuromuscular complications that may occur in the post-transplant period: neurotoxicity of drugs used in the conditioning regimen, critical illness neuropathy,

corticosteroid myopathy, and immune-mediated polyradiculoneuropathies associated with graft-versus-host-disease (Openshaw 1997), Polymyositis, myasthenia gravis, neuromyotonia, and chronic polyradiculoneuropathies have all been described in association with chronic graft-versus-host-disease. The observed predominately motot polyradiculoneuropathy meets clinical and laboratory features for CIDP (Amato et ai. 1993). Patients improve after immunomodulatory therapy consisting of intravenous immunoglobulin, plasma exchange, or immunosuppressant therapy.

Acute inflammatory demyelinating polyradiculoneuropathy or GBS has been reported in patients after allogeneic and autologous bone marrow transplantation (Wen et al. 1997). Intravenous immunoglobulin or plasmapheresis arc considered effective treatments.

Neuropathy in Connective Tissue Diseases

Peripheral nerves, including cranial nerves, arc affected Irequvnlb in connective tissue disorders (Olney 1998). Peripheral nerve manifestations may develop in patients with well-established disease or may be the initial manifestation of an undiagnosed connective tissue disease. Neuropathy may occur as part of the multisystem disease process itself; it may be secondary to complications of other organ involvement (e.g., uremic neuropathy, nerve entrapment as a result of joint deformities), or iatrogenic drug toxicity. Finally, neuropathy may be coincidental and unrelated to the underlying disease. The pathogenesis of peripheral neuropathy in connective tissue disorders is complex and may vary with the specific disorder. Circulating itnmuiiu complexes detected in .i variety ol connective tissue disorders may play a significant role. Vascular lesions arc found in all types of connective tissue disorders. In some there is occlusion of the small vasa nervorum, whereas in others cpincurial arterioles and small arteries arc involved by necrotizing vasculitis, producing ischemic nerve damage.

Peripheral Nerve Vasculitis

The vasculitides represent a elinieopathological spectrum of disorders characterized by inflammation and destruction of blood vessel walls, leading to luminal occlusion and ischemia ot hemorrhage in the affected organ systems. Vasculitis can be observed in two clinical settings: primary vasculitis without known underlying cause, or secondary vasculitides whereby vasculitis occurs in the setting of infectious, malignant, or metabolic diseases or drug exposure. PNS involvement is a common complication of systemic vasculitis (50-80%), especially in polyarteritis nodosa and small vessel vasculitides because the small and medium-si zed vessels affected in these types of vasculitis correspond to the size of the vasa nervorum (Langford 2003). The types of vasculitis that may affect the PNS and the estimated frequency with which they present to neurologists are provided in Tabic 82.27. Systemic necrotizing vasculitis refers to a diverse group of diseases affecting multiple organ systems including the PNS and CNS. On the other hand, peripheral neuropathy may be the only manifestation of a more indolent condition, nonsystemic {or monosystemic) vasculitic neuropathy.

Table 82.27: Classification of vasculitides affecting the peripheral nervous system*

Systemic necrotizing vasculitis
- Classic polyarteritis nodosa (22%)
- Wegener's granulomatosis (1%)
- Clmrg-Strauss syndrome
- Microscopic polyangiitis (11%)

Vasculitis associated with connective tissue disease (14%)
- Rheumatoid vasculitis (18%)

Hypersensitivity vasculitis
(.i.i11; cell [teiiipiir.ili anerr.is
Localized vasculitis (organ-specific)
- Nonsystemic vasculitic neuropathy (34%)

'Relative frequency is based on more than 200 patients, with biopsy-proven vasculitis pooled from six neuromuscular centers.
Source: Adapted from Olney, R. K. 1998, "Neuropathies associated with connective tissue disease," *Semin Neurol,* vol. 18, pp. 63-72.

Polyarteritis nodosa, by far the most common vasculitis in this group, is characterized by necrotizing inflammation of medium-sized or small arteries affecting the kidneys, skeletal muscle, gastrointestinal tract, skin, PNS, and CNS. Peripheral nerve involvement occurs in 50-75% of patients. Hepatitis B surface antigen is found in one third of the cases. Churg-Strauss syndrome typically presents with asthma, cosinophilia, and systemic vasculitis of small and medium-sized vessels. The frequency of peripheral nerve involvement is similar to that seen in polyarteritis nodosa (Hattori et al. 1999). Wegener's granulomatosis affects the upper and lower respiratory tract accompanied by glomerulonephritis and necrotizing vasculitis. The PNS is involved in 10-20% of cases. Cranial nerve involvement and external ophthalmoplegia occurs in 11% of patients as a result of granulomatous infiltration of the orbit or cavernous sinus (Nishino et al. 1993).

When vasculitis develops in association with connective tissue disorders, the clinical and pathological features resemble polyarteritis nodoi.i. Anions: the connective tissue disorders, rheumatoid vasculitis is by far the most common cause of vasculitic neuropathy. Approximately 15-30% of patients cannot be catcgotized and are classified as *microscopic polyangiitis.* In the hypersensitivity vasculitides, cutaneous manifestations dominate the clinical picture, although peripheral nerves may be involved. Peripheral nerve lesions may complicate giant cell arteritis in 14% of cases. More than 10% of patients with vasculitic neuropathy present in the setting of malignancies, most commonly myeloproliferative or lymphoproliferattve disorders and infections including HIV and hepatitis B and C

virus. One third of patients with biopsy-proven vasculitic neuropathy lack evidence of systemic disease or a definable connective tissue disease (see following section, Non-systemic Vasculitic Neuropathy).

Non systemic Vasculitic Neuropathy

A restricted necrotizing vasculitis affecting only peripheral nerves and skeletal muscle is the most common cause of vasculitic neuropathy in patients presenting to a neurologist. Multiple mononeuropathies are the most common clinical presentation, followed by asymmetrical neuropathy or symmetrical distal polyneuropathy (Davies ct al. *J996).* I'hi'-r are generally no constitutional symptoms or scro logical .lhrmniulities, because joints, visceral organs, and skin are unaffected. The severity of symptoms and deficits varies considerably. The disease course is indolent and protracted over years without ever becoming life threatening. The diagnosis depends exclusively on results of nerve and muscle biopsy. The pathological features are identical to those seen in classic polyarteritis nodosa affecting small and medium-si^ed arteries in muscle and nerve.

Pathogenesis

The precise immunological events leading to vessel injury in vasculitis is not well understood. Immune complex deposition within vessel walls and T cell-dependent, cell-mediated cytotoxic reactions arc the two basic immunopathogenetic mechanisms causing destruction of vessel walls. Vascular endothelial cells may serve as antigen-presenting cells and have important functions initiating the cell-mediated immune process. Although drugs and certain infectious agents, including HIV-1 and hepatitis B and hepatitis C viruses, have been implicated as triggers of the immune responses, in most instances an etiological agent cannot be identified. Small vessel vasculitis and pathological features of ischemic nerve injury have been described in peripheral sensory nerves of patients with diabetic and nondiabetic lumbosacral radieuloplexopathies (Dyck, Norell, and Dyck 2001). The final common pathway of vasculitic neuropathy is the extensive occlusion of vasa nervorum at the level of epineurial arterioles of 50-300 urn diameter leading to nerve ischemia. Nerve ischemia results in axonal degeneration. Because of the random, focal nature of vasculitis, axonal degeneration typically shows a pattern of asymmetrical, patchy involvement both between and within nerve fascicles. The ischemia is most pronounced in proximal nerves, such as the fibulat division of the sciatic nerve at the mid-thigh or the ulnar nerve at the mid-upper arm, in watershed areas between the distributions of major nutrient arteries. The extensive branching and intermixing of nerve fibers may result in a more homogeneous nerve fiber loss in distal sensory nerves, which arc suitable for biopsy. Large myelinated fibers appear to be more susceptible to ischemia than unmyelinated fibers.

Clinical Features

In systemic vasculitis, there are multisystem signs together with fever, malaise, weight loss, and hypertension. The majority of patients with PNS involvement present with peripheral neuropathy as the initial manifestation of disease. Irrespective of the underlying vasculitic syndrome, the clinical features of vasculitic peripheral neuropathy are similar and depend on the extent, distribution, and temporal progression of ischemia. Three types of peripheral nerve involvement can be distinguished, although considerable overlap occurs between types (Figure 82.32): (I) multiple mononeuropathies with motor and sensory deficits restricted to the distribution of individual nerves (10-15%); (2) overlapping or confluent multiple mononeuropathies obscuring individual nerve involvement (60-70%) with severe flaccid weakness and pansensory loss in one or more extremities; and (3) subacute symmetrical, distal sensorimotor neuropathy caused by extensive widespread vasculitis (approximately 30%). This presentation of vasculitic neuropathy can be difficult to distinguish from other types of distal axonopathies and requires a high index of clinical suspicion. A detailed history may indicate that the neuropathy began focally and then followed a course of step-wise progression of deficits before becoming generalized. Initially, acute onset of deep-seated proximal pain in the affected limb is common. Burning pain, sensory loss, and weakness in the distribution of affected nerves develop over several days. However, a more chronic and indolent course with progressive deficits is not uncommon.

Laboratory Features

The laboratory evaluation of patients with suspected vasculitis should be directed toward identifying an underlying disorder or documenting serological abnormalities that may point to a specific vasculitic syndrome. These studies should include sedimentation rate, complete blood count with total eosinophil count, renal function, urinalysis, hepatic enzymes, rheumatoid factor, antinuclear antibody, extractable nuclear antigens, serum complements, antineutrophilic cytoplasmic antibodies, cryoglobulins, hepatitis B antigen and antibody, and hepatitis C antibody. Antineutrophilic cytoplasmic antibody (ANCA) is helpful in the diagnosis of Wegener's granulomatosis, Churg-Strauss syndrome, and microscopic polyangiitis. Two types of ANCA can be detected with indirect immunofluorescence by using alcohol fixed neutrophils as substrate, producing two major staining patterns: cytoplasmic (c)-ANCA and perinuclear (p)-ANCA. c-ANCA directed against the neutrophil proteinase 3 (PR3 ANCA), is strongly (75-90%) associated with Wegener's granulomatosis. p-ANCA directed against the neutrophil en/.yme myeloperoxidase (MPO-ANCA) is found with variable frequency (5-50%) in microscopic polyangiitis, Churg-Strauss, and Wegener's granulomatosis.

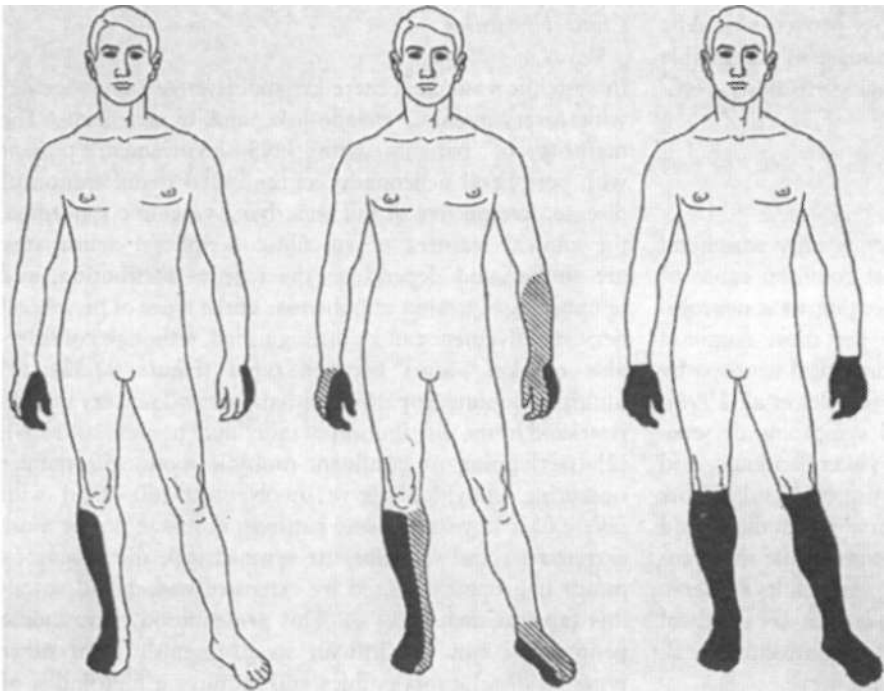

FIGURE 8232 Clinical patterns of neuropathic involvement in vasculitic neuropathy. The left figure illustrates multiple mononeuropathies or mononeuritis multiplex; the middle figure illustrates overlapping mulriple mononeuropathies obscuring individual nerve involvement; the right figure illustrates symmetric;!I sensorimotor polyneuropathy resulting from extensive proximal ischemic nerve lesions. (Reprinted with permission from Mendel!,]. R., Barohn, R. J., Bosch, E. P.,et al. 1994, "Continuum-peripheral neuropathy," *Am Acad Neurol,* vol. 1, p. 31.)

Electrodiagnostic studies are helpful in establishing the pattern of involvement and in documenting axonal nerve damage. Careful study may reveal that what clinically appeared to be a symmetrical polyneuropathy may in fact be an asymmetrical neuropathy, resulting from overlapping mononeuropathies. Nerve conduction studies rcve.il low-amplitude SNAPs and CMAPs in a multifocal distribution with normal or minimally reduced conduction velocities. Partial motor conduction block may be seen transiently with acute nerve infarcts. F.Y1G demonstrates more wide-Spread denervation than anticipated clinically. A definite diagnosis of vasculitis depends on confirmation of vascular lesions in nerve or muscle biopsies. Combined muscle and cutaneous nerve biopsies have been advocated as a way to increase the diagnostic yield. Of the cutaneous nerves suitable for biopsy, the superficial peroneal nerve is preferred because a simultaneous peroneus brevis muscle biopsy can be obtained through the same incision. In a cohort of patients with clinically suspected vasculitis the estimated sensitivity of a positive superficial peroneal nerve/ peroneus brevis muscle biopsy was 60% and increased to 86% if pathological features suggestive of vasculitis were included (Collins et al. 2000). A pathological diagnosis of vasculitis requires the presence of transmural mononuclear inflammatory cells and vessel wall necrosis (Figure 82.33). Cellular infiltrates are composed predominant];, of 1" cells and macrophages. Vascular deposits of immunoglobulins and complement including membrane attack complex can be demonstrated by immunostaining in more than 80% of cases. The nerve itself characteristically shows selective fascicular involvement with extensive liber loss or renin focal subfascicular or central fascicular loss of fibers with acute axonal degeneration. Osmicatcd teased fiber preparations demonstrate fibers at various stages of axonal degeneration,

Treatment

In systemic necrotizing vasculitis, disease activity must be suppressed rapidly to limit ongoing organ and nerve damage. Such patients are treated with a combination of prednisone and a cytostatic agent (usually cyclophosphamide). Treatment is started with daily prednisone (1 mg/kg per day) together with either oral cyclophosphamide at 2 mg/kg of body weight per day, or intravenous cyclophosphamide at 0.5 g/m body surface area per month, adjusted upward to 1 g/m on the basis of the patient's leukocyte count. For all but the most fulminant cases, cyclophosphamide should be started at a lower dose and worked up to the full dose over 3-6 weeks; the goal is to lower the total lymphocyte count to 750/mm^3. In fulminant cases, corticosteroids may be initiated by giving intravenous methylprednisolone (500-1000 mg) daily for 3 days followed by oral prednisone. The role of plasmapheresis in the management of severe vasculitis remains controversial but may provide additional benefit in patients with life-threatening disease (Allen and Bressler 1997), Cyclophosphamide is associated with substantial toxicity including bone marrow suppression, life-threatening infections, hemorrhagic cystitis, infertility, myeloproliferative disease, and bladder cancer. From the onset of treatment, complete blood cell counts should be monitored frequently. The dose of cyclophosphamide should be adjusted to maintain the total leukocyte count above 3000 per pi, and the total neutrophil count greater than 1500 per pi. Liberal fluid intake and frequent voiding may lessen the risk of

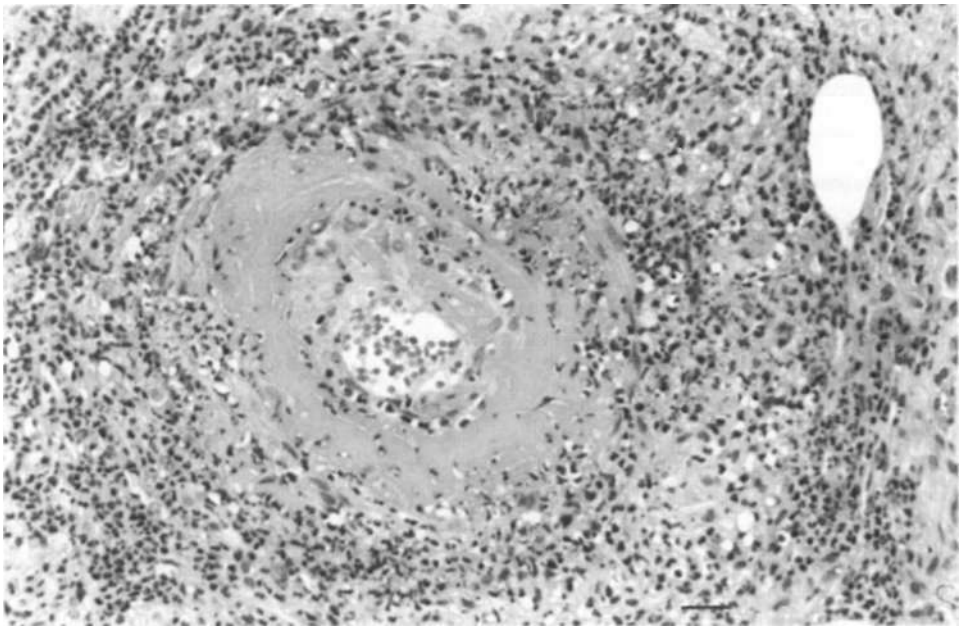

FIGURE 82.33 Sural nerve biopsy from patient with systemic vasculitis. A medium-si zed epineurial blood vessel with fibrinoid necrosis of its wall and perivascular and transmural mononuclear cell infiltration is shown. (Hematoxylin and cosin, x75; bar = 25 urn.)

hemorrhagic cystitis. Urine should be monitored for the presence of microscopic hematuria. Once clinical remission is achieved, prednisone can be tapered over a period of 4-6 weeks to a dosage of 1 mg/kg every other day. Patients are kept on both drugs until significant improvement occurs, at which time prednisone is gradually tapered further. Cyclophosphamide is maintained for 1 year after the disappearance of all traces of disease activity. In patients with non-life-thrcatening vasculitis prednisone given together with methotrexate (20-25 mg per week) has been found effective. Methotrexate may also be useful in maintaining remission. Combination immunosuppressive therapy results in an 80-90% remission rare in Wegener's granulomatosis and systemic necrotizing vasculitis. Physical and occupational therapy is indicated to optimize activities of daily living. Meaningful recovery has been reported in 60% at 6 months and 86% of patients at 1 year. Long term treatment results may be complicated by chronic sequelae from organ damage, disease relapses, and medication side effects. High dose prednisone is often adequate in patients with nonsystemic vasculitic neuropathy.

Rheumatoid Arthritis

Peripheral neuropathy occurs in 1-10% of patients with rheumatoid arthritis. At least four distinct types of peripheral neuropathies are seen in association with rheumatoid arthritis: (1) compression neuropathies, often found with early disease and caused by periarticular inflammation and fibrosis; (2) a distal, symmetrical, sensory polyneuropathy, possibly related to occlusive vasculopathy; (.3) mononeuropathy or multiple mononeuropathies; and (4) a severe fulminating sensorimotor polyneuropathy, both caused by rheumatoid vasculitis.

Compression neuropathies in rheumatoid arthritis occur as a result of joint deformity or, on rare occasions, rheumatoid nodules. Treatment includes splint applications, local corticosteroid injection, or surgical decompression.

A symmetrical, predominantly sensory polyneuropathy causes dysesthesias, paresthesias, and loss of sensation in a patchy, stocking-glove distribution. It is not associated with severe active rheumatoid arthritis; most patients recover partially or completely. The pathogenesis is pootly understood. Ischemia caused by occlusive vasculopathy or low-grade vasculitis has been suggested as a possible :n;tl).i:iMii. IVcauso [In- (lrusLiiusis :•. j'.ciir: a 11 > good, no specific treatment is recommended.

Systemic vasculitis develops in the setting of severe chronic rheumatoid arthritis, characterized by severe joint deformities, rheumatoid nodules, and cutaneous vasculitic lesions such as digital ulcerations, purpura, and livedo reticularis. Rheumatoid vasculitis is the second most frequently identified cause of vasculitic neuropathy, because rheumatoid arthritis is a common disorder affecting 2-5% of the general population. Acute mononeuropathy, mononeuropathy multiplex, and a distal symmetrical sensorimotor polyneuropathy develop as a result of widespread vasculitis. In contrast to other connective tissue disorders, cranial nerve involvement is rare.

The sedimentation rate and rheumatoid factor titer are always elevated. The C4 complement level is frequently low. Cutaneous nerve or muscle biopsy demonstrates a necrotizing vasculitis. The development of systemic vasculitis confers ;i poor prognosis in rheumatoid arthritis, with a reported 5-year survival rate of 60% (Puechal et al. 1995).

Treatment should be started with high-dose prednisone and oral cyclophosphamide. Early aggressive intervention may arrest the progression of neuropathy.

Systemic Lupus Erythematosus

CNS manifestations arc more prevalent than those of the PNS in systemic lupus erythematosus. Peripheral neuropathy develops in 6-21% of patients; the higher frequency is tuji'.J by usmg i| nan nun i\c sensory testing confined with extensive nerve conduction studies. A symmetrical, subacute, or chronic axonal polyneuropathy with predominant sensory symptoms is most common. Mononcuropathies of limb or cranial nerves, brachial plexopathy, and GBS or CIDP have occasionally been described in association with systemic lupus erythematosus. The basis for such associations is unknown but specific autoantibodies against peripheral nerve antigens or an immune-media ted vasculitis arc proposed pathogenetic mechanisms.

In sural nerve biopsy specimens, perivascular inflammatory cell infiltration is seen around cpincurial vessels, but only occasionally is there definite vasculitis. Immune complex deposition leading to vasculitis is the presumed cause of nerve damage.

If the polyneuropathy associated with systemic lupus erythematosus results in significant disability, immunosuppressive treatment should be considered. In patients with proven vasculitis, treatment with plasmapheresis, prednisone, and cyclophosphamide has led to improvement.

Systemic Sclerosis

Systemic sclerosis (scleroderma} is a connective tissue-disease characterized by excessive deposition of collagen. It affects the skin, gastrointestinal tract, lungs, heart, and kidneys. Neurological complications are uncommon, consisting mainly of myopathies. Peripheral nerve involvement unexplained by gastrointestinal or renal complications is rare. Peripheral sensorimotor neuropathy, isolated trigeminal neuropathy, and mononeuropathy related to carpal and cuhir.il tunnel syndromes have been reported. Multiple mononeuropathies are seen with greater frequency in CREST (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclcrodactyly, and telangiectasia) syndrome than in control subjects. Frank vasculitis, perivascular inflammation, and multifocal fiber loss is found in sural nerve biopsy specimens of CREST patients with multiple mononeuropathies (Dyck, Hunder, and Dyck 1997).

Sjogren's Syndrome

Sjogren's syndrome is an autoimmune disorder of exocrine glands characterized by diminished lacrimal and salivary gland secretion resulting in dry eyes and dry mouth (sicca complex). The sicca complex is related to lymphocytic and plasma cell infiltration and destruction of lacrimal and salivary glands. Sjogren's syndrome occurs as a primary or secondary disorder in association with other connective tissue disorders. Peripheral nerve involvement occurs in 10-32% of patients with primary Sjogren's syndrome and has a strong predilection for women (9 to 1), Neuropathic symptoms often precede and overshadow the sicca symptoms and may be the major presenting complaint (Grant et al. 1997). A distal symmetrical sensory neuropathy with mixed large and small fiber deficits is the most common presentation. Less common patterns of nerve involvement include sensorimotor neuropathy, polyradiculoneuropathy, multiple mononeuropathies, painful dorsal root ganglionopathy, and trigeminal sensory neuropathy. A distinct subgroup of patients with sensory ataxic neuronopathy presents with loss of kinesthesia and proprioception caused by an inflammatory sensory polyganglionopathy (Figure 8234).

Laboratory abnormalities include elevated sedimentation rate, positive rheumatoid factor, and hypergammaglobulinemia. Antibodies to extractable nuclear antigens (especially SS-A) considered to be the most specific serological test for Sjogren's syndrome are less common in patients with neuropathy. The diagnosis depends on specific inquiry about sicca symptoms and ophthalmological tests for keratoconjunctivitis sicca (e.g., Rose Bengal staining of the cornea or Schirmer test: <5 mm wetting of a paper strip at 5 minutes). When an abnormal test result is found, a minor salivary gland biopsy of the lower lip showing chronic lymphocytic infiltrates is helpful for confirmation. Diagnostic criteria for Sjogren's syndrome have been proposed (Fox, Tornwall, and Michclson 1999). Reduced or absent SNAPs and normal or only mildly abnormal motor conduction studies are typical findings. High intensity lesions of the posterior columns may be detected on l'2-weighted MRI of the cervical cord in patients with sensory g.uiglionopathy (Mori et al, 2001). Sural nerve-biopsy frequently shows nonspecific perivascular lymphocytic (T cell) infiltrates together with diffuse decrease in myelinated fibers. Vasculitis is rarely found in patients with multiple mononeuropathies.

The role of immunosuppressive therapy is uncertain. Treatment recommendations arc based on small retrospective, uncontrolled series or individual case reports. Most reporl some inipiovrnvm w ith the use or ennicoste roids, either alone or in combination with immunosuppvs.s:ir.:s. nruir;ili/ing antibodies to tumor necrosis factor-ur, or intravenous immunoglobulin.

Trigeminal Sensory Neuropathy

Slowly progressive trigeminal sensory neuropathy is characterized by advancing unilateral or bilateral facial

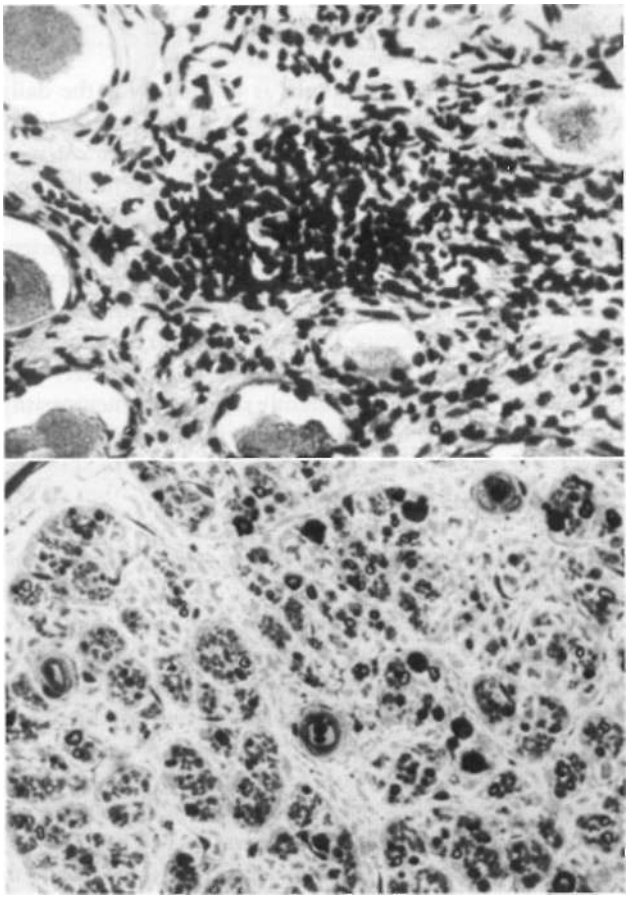

FIGURE 82.34 Thoracic dorsal root ganglion and sural nerve biopsies from patient witli Sjogren's syndrome and nonmalignant inflammatory sensory polyganglionopathy. In the upper panel, a prominent mononuclear cell infiltrate is seen adjacent to neuronal cell bodies, (Hematoxylin and eosin, x25.) The lower panel illustrates the sural nerve in the same patient showing marked decrease in fiber density and abnormality in size distribution of myelinated fibers. (Paraphenylenediamine-srained semithin epoxy section, x2.5.) (Reprinted with permission from Smith, B. E. 1992, "Inflammatory sensory polyganglionopathies," *Neurol Clin,* vol. 10, pp. 735-759.)

numbness. An association has been reported with several Lonnecme tissue diseases, including systemic sclerosis, mixed or undifferentiated connective tissue disease, Sjogren's syndrome, systemic lupus erythematosus, rheumatoid arthritis, and dermatomyositis. Sensory loss begins in perioral and cheek areas and is often associated with painful paresthesia. The frequent bilateral involvement (70%), sparing of muscles of mastication, and negative neuroimaging study results help to distinguish this condition from other causes of facial numbness. Disfiguring neuropathic ulceration of the nares may occur. The trigeminal blink reflex study confirms an afferent lesion that is detected by delayed or absent ipsilateral R1 and bilateral R2 responses in 50% of patients. The precise etiology of this presumed immune-mediated cranial sensory ganglionopathy remains unclear. Immunosuppressive therapy is not recommended in isolated trigeminal sensory neuropathy.

Other causes of trigeminal neuropathy are acute toxic reactions to trichloroethylene and the "numb chin" syndrome associated with a carcinoma or leukemia (sec Chapter 76),

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disorder involving lung, lymph nodes, skin, and eyes. Neurological involvement (ncurosarcoidosis) occurs in approximately 5% of patients, and 6-18% of neurological manifestations arc caused by various forms of peripheral neuropathy (Scott 1993). Cranial neuropathies, particularly facial nerve palsy, are the most common neurological manifestations (73%). PNS involvement includes multiple mononeuropatlnes, bilateral phrenic nerve palsies, truncal sensory mononeuropathies, acute polyradiculoneuropathy resembling GBS, cauda equina syndrome, and chronic symmetrical sensorimotor neuropathy. The latter can produce severe wrist extensor and foot dorsiflexor weakness, and distal sensory loss in the legs. Neurological manifestations may be the presenting feature in more than 50% of cases or may develop at a time when there is little evidence of systemic sarcoidosis.

Electro diagnostic studies show evidence of axonal degeneration. Sarcoid granulomas may be seen in muscle and sural nerve biopsy specimens. The nerve damage has been attributed to granulomas and angiitis of vasa nervorum producing axonal degeneration (Said et al. 2002). Inflammatory changes in the CSF (such as pleocytosis, increased protein level, elevated IgG index, and occasionally hypoglycorrhachia) imply granulomatous lep-[omciiim;eal involvement. Gallium scanning is ohm UMILLI in the search for systemic involvement. An elevated scrum angiotensin-converting enzyme level may suggest active systemic sarcoidosis. Biopsies of lymph nodes, muscle, or conjunctiva or bronchoalvcolar lavage may be needed to obtain tissue for histological confirmation, because all the other tests are nonspecific.

The response to corticosteroid therapy in sarcoid neuropathy is generally favorable. In patients refractory to corticosteroids, cyclosporine, cyclophosphamide, or azarhioprine may be used as adjunctive therapy (Agbogu et al. 1995).

Alcoholic Neuropathy and Nutritional Deficiencies

Alcoholic Neuropathy (See also Chapter 63)

Alcoholic neuropathy is one of the most common peripheral neuropathies seen in general practice. Covert

alcoholism may only be uncovered by a focused history provided by family members. A close association between alcoholic neuropathy and nutritional deficiency is well established.

Clinical Features. The symptoms of alcoholic neuropathy-begin insidiously and progress slowly. Muscle weakness begins distally and spreads to more proximal muscles. Gait difficulty, weakness, and muscle cramps are common. Sensory loss and burning paresthesias are frequent. Hyperpathia and dysesthesias are troublesome in many patients. The legs are always more affected than the arms. Distal muscle wasting, loss of tendon reflexes, and sensory-loss of all modalities in a stocking-glove distribution are common. In advanced cases, sensory ataxia caused by loss of joint position sense may coexist with alcoholic cerebellar ataxia.

F.lectrodiagnostic studies show a predominantly axonal sensorimotor polyneuropathy. NCVs are only slightly diminished. Low-amplitude or absent SNAPs are common. EMG shows active denervation with chronic reinnervation in distal muscles. Sural nerve biopsy specimens demonstrate loss of nerve fibers of all sizes. Acute axonal degeneration is particularly common in patients after binge drinking, whereas axonal regeneration is frequently seen in chronic alcoholism.

Etiology. Deficiency of thiamine and other B vitamins, caused by inadequate dietary intake, impaired absorption, and greater demand for thiamine to catalyze the metabolism of the alcohol, is the major cause of polyneuropathy in alcoholic patients.

Treatment. Abstinence from alcohol, expert counseling, and a nutritionally balanced diet constitute the principal therapy. Supplementation with thiamine and other B vitamins is important. In patients with significant gastrointestinal symptoms, parenteral vitamin treatment is initially required. Improvement in the polyneuropathy may be very slow, because it requires axonal regeneration. For the management of painful alcoholic neuropathy, see the earlier section on neuropathic pain.

Niacin Deficiency (Pellagra Neuropathy)

Dietary deficiency of nicotinic acid (niacin) produces the syndrome of pellagra. Pellagra affects the gastrointestinal tract, skin, and nervous system resulting in the triad of dermatitis, diarrhea, and dementia. A distal sensorimotor polyneuropathy develops in 40-56% of patients with pellagra, and if diarrhea and skin changes are absent is clinically indistinguishable from rhiamine-deficiency neuropathy, Nonendemic pellagra rarely occurs in patients with alcoholism or malabsorption. Oral nicotinic acid is sufficient to treat symptomatic patients.

Pyridoxine (Vitamin BJ Deficiency

The regular diet of most adults is adequate for the daily-requirement of J.5-2.0 mg of vitamin B_6. Isolated pyridoxine deficiency, however, may occur during treatment with Lsoniazid (INH), hydralazine, or, rarely, penicillamine. These drugs structurally resemble vitamin B_{fi} and interfere with pyridoxine coenzyme activity, vitamin B^-deficient peripheral neuropathy is characterized by distal sensory and motor deficits of insidious onset. When using INH, supplementary pyridoxine (100 mg daily) is recommended. Paradoxically, high dose (500 mg/day and greater) pyridoxine may cause a predominantly sensory polyneuropathy (sec Toxic Neuropathies, later in this chapter).

Folate Deficiency Polyneuropathy

Folate deficiency may cause an axonal sensory polyneuropathy, characterized clinically by loss of joint position and vibratory sense and absent tendon reflexes. In addition, there may be evidence of spinal cord involvement, with spasticity of the legs and extensor plantar responses. In severe cases, encephalopathic symptoms may predominate. Macrocytic anemia is an important clue to either folate or vitamin B^ deficiency. Coexisting vitamin B12 deficiency must be excluded because in such cases folate therapy without cobalamin replacement may exacerbate neurological manifestations. Patients have been reported with neurological disease indistinguishable from subacute combined degeneration who rapidly responded to folate replacement.

Vitamin B_{lz} Deficiency Polyneuropathy: Subacute Combined Degeneration

Cobalamin (vitamin B_{12}) and folate are essential vitamins necessary for effective DNA synthesis. Animal products (meat, poultry, fish, and dairy products) are the primary dietary source of cobalamin. The average Western diet provides an excess of the vitamin (daily requirement, *3-9* ug), which is stored in the liver. Within the acid environment of the stomach cobalamin is released from dietary proteins. Free cobalamin initially binds to gastric glycoproteins known as R-binders. In the duodenum the cobalamin-R-binder complexes are degraded by pancreatic enzymes, The released cobalamin then binds avidly to intrinsic factor, a 60-kD glycoprotein produced by gastric parietal cells. The vitamin B^-intrinsic f_{ac}ror complex is absorbed by means of binding to intrinsic factor receptors in the terminal ileum. Malabsorption of cobalamin in patients with pernicious anemia is the result of intrinsic factor deficiency caused by-progressive autoimmune destruction of parietal cells from the gastric mucosa. Acquired malabsorption of vitamin B12 may occur also following gastric and terminal ileal resection and in the setting of a wide range of gastrointestinal disorders. Unusual causes include dietary insufficiency in

strict vegetarians (vegans) and intestinal infection with fish tapeworms. Intraoperative use or recreational abuse of nitrous oxide, which inactivates cobalamin-dependent enzymes, may cause neurological manifestations, particularly in patients with marginal cobalamin stores. Intracellular^, cobalamin is converted into two coenzymes required for the formation of methionine and succinyl-CoA synthesis. Reduced methionine synthesis may be responsible for the neurological manifestations of cobalamin deficiency.

Population surveys estimate that 2% of persons 60 years and older have undiagnosed pernicious anemia. The disease is especial!; common in Northern buropcans and blacks. The full-blown clinical picture of vitamin B12 deficiency consists of macrocytic anemia, atrophic glossitis, and peripheral and central neurological complications (Toh, Van Oriel, and Glecson 1997}. The latter include peripheral neuropathy and optic atrophy, as well as lesions in the posterior and lateral columns of the spinal cord (subacute combined degeneration) and in the brain. The peripheral neuropathy results in paresthesias and large fiber modality sensory loss (vibration and proprioception). The spinal cord manifestations consist of posterior column damage, which may include a sensory level, and upper motor neuron defects causing limb weakness, spasticity, and extensor plantar responses. Cerebral involvement ranges from subtle behavioral changes and forgetfulness to dementia or stupor. An unsteady gait, positive Romberg sign reflecting a sensory ataxia, diffuse hyper-reflexia, and absent ankle jerks should raise [lie suspicion of cobalaiiiini deficiency.

Nerve conduction studies show low-amplitude or absent SNAl's. Conduction velocities are normal. CNS involvement is suggested by abnormal visual and somatosensory evoked potential study results and is occasionally documented by symmetrical dorsal column lesions on cervical MRI. Evidence of axonal degeneration is found in sural nerve biopsy specimens. The diagnosis is confirmed by low serum vitamin B12 levels (<170 pg/mL) and normal serum folate concentration. Approximately 30-40% of patients with neurological symptoms caused by vitamin B_{12} deficiency have borderline low levels of 150-200 pg/mL. hi as many as 30% of patients, megaloblastic anemia with elevated red cell mean corpuscular volume (>94 fl) may be absent. Elevated serum methylmalonic acid and homocysteine levels, which are the substrates for cobalamin-dependent enzymes, are helpful when there is diagnostic uncertainty (Chanarin and Metz 1997). The two-part Schilling tests confirm that vitamin B_{12} deficiency is the result of intestinal malabsorption and is caused by intrinsic factor deficiency. Antibodies to intrinsic factor are found in 70% of patients with pernicious anemia; antiparietal cell antibodies arc more sensitive (90%) but lack specificity.

Initial treatment consists of daily intramuscular injections of 1 mg of cyanocobalamin or hydroxocobalamin in the first week, followed by weekly injections, until a series of 12 doses is completed. Then maintenance schedules of monthly injections of 100 ug or 1000 wg every 3 months has been found satisfactory in preventing relapses (Savage and Lindenbaum 1995). This treatment corrects the anemia and may reverse the neurological complications completely if given soon after their onset. Major neurological improvement can be expected to occur during the first 3-6 months of therapy. For maintenance therapy, oral administration of vitamin BQ is feasible in compliant patients, because 1% of vitamin $B|_2$ is absorbed without intrinsic factor mediation. The initial severity of neurological deficits, duration of symptoms, and hemoglobin level before treatment correlate with neurological outcome. The inverse correlation between degree of anemia and neurological damage is not understood.

Vitamin E Deficiency

Significant vitamin E deficiency is seen in children and young adults with chronic severe intestinal fat malabsorption, as occurs in cholestatic liver disease, cystic fibrosis, celiac disease, following extensive intestinal resections, and in the inherited disorder of abeta lipoprotein em i a (see Hereditary Neuropathies, earlier in this chapter). Rarely, vitamin E deficiency develops in the absence of fat malabsorption (Jackson, Amato, and Barohn 1996). Isolated familial vitamin *E* deficiency is an autosomal recessive disorder in which mutations in the ^-tocopherol transfer protein gene cause failure to incorporate *a*-tocopherol into very-low-density lipoprotein in the liver. Prolonged vitamin E deficiency of any cause may lead after years to a spinocerebellar syndrome with a large fiber sensory neuropathy, ataxia, proprioceptive loss, areflexia, ophthalmoplegia, and pigmentary retinopathy that may be indistinguishable from Friedreich's ataxia. Myopathy and peripheral nerve disease may predominate in some cases. In adults with chronic cholestasis it may take 2 years to deplete vitamin E stores and an additional 5-10 years to develop neurological complications.

Vitamin E deficiency results 111 a central and peripheral distal axonopathy of large-caliber axons affecting peripheral nerves and the posterior columns of the spinal cord. Lipofuscin-like accumulations are found in the Schmidt-La ntennaim clefts of large diameter myelin sheaths in sural nerve biopsy specimens. Impaired antioxidant protection may account for neurological and retinal lesions in long-standing deficiency. Electtopbysiological study results show normal NCVs and low-amplitude or absent SNAPs. vitamin E deficiency is established by low fasting plasma levels of vitamin E (<5 ug/mL). Laboratory studies used to confirm fat malabsorption include 72-hour fecal fat determination, vitamin A and D levels, amylase, liver function tests, peripheral blood smear to search for acanthocytes (present in Bassen-Kornzweig syndrome), and apolipoprotein B level.

Vitamin E supplementation is indicated regardless of etiology in all patients with low serum vitamin E levels.

Oral supplementation with vitamin E in large doses (initially 400 mg twice daily and up to 100 mg/kg per day) may result in neurological improvement ot cessation of further deterioration. If no absorption can be documented after large oral doses of standard vitamin E, a water-soluble form of tocopherol is recommended.

Neuropathy Associated with Malabsorption Syndromes

Intestinal malabsorption may lead to myopathy or periph-;T.I! neuropath). A can till search tor n u n iii.il.il^oi-prion or celiac disease should be part of the routine investigation ;il ;li]v;i: Mr, Willi neuromuscular disease oi obscure cause, particularly in patients with ataxia and peripheral neuropathy. Celiac disease (CD) or gluten-sen si five enteropathy is characterized by malabsorption due to inflammatory injury to the mucosa of the small intestine after ingestion of wheat gluten in genetically predisposed individuals. More than 90% of patients with CD express the human lymphocyte antigen HLA-DQ2 or DQ8, Patients with or without gastrointestinal symptoms may rarely (5-8%) develop varied neurological complications including a predominantly sensory axonal neuropathy, multiple mononcuropathies, cerebellar ataxia, myopathy, and encephalopathy (Hadjivassiliou, Griinewald, and Davie-Jones 2002). The cause of PNS involvement is poorly understood. Earlier studies have implicated vitamin deficiencies {B_{12}, E, D, folic acid, or pyridoxine). However, vitamin replacement rarely improves neurological deficits. Immunological factors have been proposed in patients without vitamin deficiencies and are supported by the common association of CD with other autoimmune disorders. The diagnosis is facilitated by highly sensitive and specific serological markers (antiendomysial and tissue transglutaminase antibodies) and established by small bowel biopsy. A strict gluten-free diet may stabilize the neurological disease process.

Severe sensorimotor or predominantly sensory neuropathies with ataxia or burning feet may occur in starvation. After gastric partitioning proccdutes for morbid obesity, the patients at risk for developing neurological complications are those with accelerated weight loss and frequent vomiting in the postoperative period.

Uremic Neuropathy

Peripheral neuropathy develops in 60% of patients with end-stage renal failure who require chronic dialysis. Severe uremic neuropathy has become less common as a result of earlier treatment with dialysis and renal transplantation.

Utcmic neuropathy is inexplicably more common in men than in women. The clinical features are those of a slowly progtessive, predominantly sensory polyneuropathy. Severe pains arc unusual, but cramps, unpleasant dysesthesias, and restless legs are common symptoms. Neurological signs include distal sensory loss, especially of vibratory sensation, absent reflexes, and symmetrical toe-extensor weakness. On occasions, .i rapidl; progressive, predominantly motor polyneuropathy mimicking GBS may develop during the initial weeks of dialysis. Such a fulminant severe neuropathy is also seen in the setting of concurrent critical illness or diabetes mellitus. An unusual feature of these cases is the relative absence of denervation potentials in clinically weak muscles on needle EMC. Some patients have improved by switching from conventional to high-flux hemodialysis, possibly related to enhanced removal of advanced glycosylation products (Bolton et al. 1997).

Chronic renal failure and the commonly associated malnutrition render peripheral nerves susceptible to compression neuropathies, such as the ulnar nerve at the elbow and the fibular nerve at the knee. Carpal tunnel syndrome may develop in more than 20% of patients on hemodialysis. Nerve compression from local edema secondary to the forearm arteriovenous shunts or ischemia from a fistula-induced vascular steal syndrome are likely mechanisms in the early course of dialysis. Patients on long-term hemodialysis may develop carpal tunnel syndrome because of the deposition of fo-microglobulin-derived amyloid in the carpal ligament. Ischemic monomelic neuropathy is an acute complication of the placement of a more proximal shunt between the cephalic vein and brachial artery; the monomelic neuropathy occurs mainly in diabetic patients with concomitant peripheral vascular disease. Ir is characterized by abrupt, painful sensory loss of the affected hand, and weakness of median, ulnar, and radial innervated distal muscles. Prompt sutgica! closure of the fistula is required to avoid permanent neurological deficits.

The diagnosis of uremic polyneuropathy should only be made in the context of chronic end-stage renal failure (creatinine clearance <10 mlVminute) of at least several months' duration. Drug toxicity or other systemic diseases, such as diabetes mellitus, vasculitis, or amyloidosis that may affect both kidneys and peripheral nerves, must first be excluded. CSF protein is often elevated, but rarely beyond 100 mg/dl.. Generalized slowing of motor and sensory NCVs is common, and distal latencies are prolonged. Late responses (H-reflex and F-wave latencies) become abnormally prolonged early in the course of chronic renal failure at a time when motor conduction velocities are still normal. EMG examination shows evidence of active denervation in distal foot muscles. Regular hemodialysis rarely improves impaired conduction velocities in patients despite clinical improvement. Sural nerve biopsy shows axonal loss of large myelinated fibers and segmental demyelination. Morphometry; investigations led to the conclusion that the segmental demyelination is secondary to primary axonal arrophy.

Occasionally exacerbation of the neuropathy occurs in patients with chronic renal failure at the onset of hemodialysis. Acute fluxes of water and solutes may be

the cause, and reduction in the intensity of dialysis is usually recommended.

The precise cause of uremic neuropathy remains unknown although a number of potential neurotoxins accummulate in end-stage renal disease (Gallassi et al. 1998). Ethylene oxide has been proposed as a contributing neurotoxin in patients on hemodialysis.

Treatment

Severe polyneuropathy in patients on chronic dialysis has become rare as a result of earlier initiation of treatment and improved techniques of hemodialysis using more biocompatible dialy/er membranes and high-flux dialyzers. Attention should be given to avoid drugs such as colchicine or nitrofurantoin, which arc potentially neurotoxic and may accumulate in renal insufficiency. Numerous investigations have been conducted to assess the long-term effects of hemodialysis on peripheral nerve function. A consensus has emerged that chronic hemodialysis will stabilize an existing uremic neuropathy in most patients. Manipulating the frequency or duration of dialysis may not alter its course. Chronic peritoneal dialysis provides no advantage over hemodialysis. Successful renal transplantation results in significant clinical, electrophysiological, and morphological recovery over a period of 3-12 months. However, renal transplantation may have little effect on the course of the neuropathy in diabetic patients with end-stage renal disease.

Peripheral Neuropathy in Liver Disease

Various peripheral neuropathies may develop as a direct consequence of acute and chronic liver disease. These disorders include cryoglobulinemia neuropathy linked to hepatatis C virus infection, vitamin E deficiency in chronic cholestatic liver disease, and neuropathies associated with end-stage liver disease and primary hilary cirrhosis. Viral hepatitis types A, B, and C have been reported as antecedent infections in Guillain-Barrc syndrome. Isolated cases of CI DP have been described in chronic hepatitis B and as a complication after orthotopic liver transplantation. Hepatitis B antigenemia is found in one third of patients with polyarteritis nodosa.

Although a clinically overt neuropathy is uncommon, electrodiagnostic studies arc frequently abnormal in patients with chronic liver disc-use. The highest frequency of neuropathy by clinical criteria (75%) and confirmed by electrophysiological studies in an even greater percentage (87%) was reported in a cohort of patients who were candidates for liver trans pi a nation for end-stage liver disease (lani et al. 1999). The neuropathy is not disabling and often remains clinically inapparent. Paresthesias in feet, distal loss of vibratory sensation, and loss of ankle reflexes are the most common findings. Electrophysiological abnormalities consist of reduced SNAPs and mild slowing of motor conduction velocities. Histological studies of the sural nerve show evidence of demyeIination and remyelination. A high incidence of autonomic dysfunction has been reported in patients with end-stage liver disease by means of formal autonomic testing. The presence of autonomic neuropathy in such patients has been associated with a five-fold increase in mortality over invi duals with normal autonomic function. Early liver transplantation should be considered for patients with autonomic neuropathy.

Patients with primary biliary cirrhosis may develop a sensory polyneuropathy or sensory ganglionoparhy. In a few patients with strikingly elevated serum lipid levels and cutaneous xanthomas, xanthomatous infiltration of cutaneous nerves has been found on nerve biopsy. In others an autoimmune process affecting sensory ganglia is suspected. The prevalence of associated autoimmune diseases is high in primary biliary cirrhosis, most notably Sjogren's syndrome, which in turn is linked to predominantly sensory neuropathies. Large fiber sensory neuropathies develop in children and young adults with chronic cholestatic liver disease and secondary vitamin E deficiency.

Endocrine Disorders Associated with Peripheral Neuropathy

Hypothyroid Neuropathy

Carpal tunnel syndrome is the most common peripheral nerve complication of hypothyroidism. One third of patients with hypothyroidism may have clinical evidence of a general polyneuropathy, which is predominantly sensory with paresthesias and muscle pain, distal sensory loss, and incoordination. Nerve conduction studies show absent or decreased SNAPs and slow motor conduction velocities. Sural nerve biopsy demonstrates deiiiyelin.itiou, remyelination, and increased glycogen and lysosomes in axonal and Schwann cell cytoplasm. Thyroid hormone replacement usually improves the neuropathy. Thyroid function studies should be checked in all patients presenting with carpal tunnel syndrome or a sensory polyneuropathy,

Acromegaly

Carpal tunnel syndrome is a well-recognized complication of acromegaly, but a generalized neuropathy also may develop independent of concomitant diabetes mellitus. Approximately one half of patients have distal paresthesias, sensory loss in a stocking-glove distribution, diminished muscle stretch reflexes, and distal muscle weakness. SNAPs are diminished and motor NCVs are slightly to moderately reduced. Nerve biopsy shows a reduced number of myelinated and unmyelinated fibers, and enlargement of nerve fascicles because of an increase in endoneurial and subperincurial tissue.

Hypoglycemic Amyotrophy

Primary hypoglycemia caused by an insulinoma may cause slowly progressive distal muscle atrophy and weakness. Painful paresthesias are common, but there are usually no objective signs of sensory loss. The amyotrophy may precede the onset of typical recurrent hypoglycemic episodes by a few years. Electrodiagnostic studies show evidence of acute denervation and reinncrvation.

Ischemic Monomelic Neuropathy

Ischemia caused by acute thromboembolic occlusion of major limb arteries or proximal arteriovenous shunt placement infrequently causes multiple axonal mononeuropathies that develop disrally in the ischemic limb (ischemic monomelic neuropathy). Abrupt lightning or burning pains affect the involved extremity. Sensory examination shows a graded impairment of all modalities, particularly those mediated by largc-dia merer fibers. Muscle strength is usually maintained, although distal weakness may often develop in severe cases. Tendon reflexes may be preserved.

Electro diagnostic studies provide evidence of multiple axonal mononeuropathies in the involved ischemic limb. SNAPs are either absent or markedly reduced in amplitude, and motor conduction velocities are slowed. Acute denervation is limited to very distal extremity muscles. Both large and small fibers appear to be affected equally.

Surgical endarrerectomy or bypass surgery may result in recovery ot neurological deficits in ,1 period of several months, even in long-standing ischemic neuropathy. Ischemic monomelic mononeuropathy following shunt placement demands immediate surgical closure of the arteriovenous fistula.

Severe aortoiliac occlusive disease or prolonged use of an intra-aortic balloon pump may occasionally lead to proximal sciatic and femoral nerve or lumbosacral plexus lesions.

Peripheral Neuropathy in Chronic Obstructive Lung Disease

Approximately 20% of patients with chronic obstructive lung disease may develop a mild, distal sensorimotor polyneuropathy that appears to be correlated with severe hypoxemia.

Critical Illness Polyneuropathy

Critical illness polyneuropathy is a common problem in intensive care units (ICU). The neuromuscular syndrome of acute limb and respiratory weakness after admission to the ICU tends to be underappreciated. It is a major cause of difficulty in weaning patients from the respiraror after cardiac and pulmonary causes have been excluded. Clinical evaluation of muscular weakness acquired in the intensive care unit is difficult because patients arc often cnccphalopathic or sedated, and the examination may be hindered by multiple lines required for intensive support. Most patients have generalized flaccid weakness with depressed tendon reflexes. Pain or paresthesias are not features of critical illness neuropathy. When prospectively investigated, at least 50% of critically ill patients admitted to intensive care units with sepsis and multiple organ failure for at least two wci-k- 11a •. i. i-li-Liruiliagiiostii features o] an axonal neuropathy.

Electrodiagnostic studies are necessary to establish the diagnosis. Nerve conduction studies reveal a distal axonal neuropathy with reduced CMAP and SNAP amplitudes, in conjunction with fibrillation potentials and decreased motor unit potentials on F.MG. CSF is almost always normal. Primary axonal degeneration, more severe distally than proximally, is seen at autopsy. The neuropathy is thought to be a complication of the systemic inflammatory response syndrome that is triggered by sepsis, severe trauma, ot burns. The pathophysiology of this syndrome is currently under intense investigation. Severe infections or trauma of any type appear to initiate a series of events that ultimately lead to impaired microcirculation and multiple organ dysfunction (Bolton 1995).

Critical illness myopathy is another cause of acquired weakness after admission to the intensive care unit and is difficult to distinguish clinically from its neuropathic counterpart. This complication usually occurs in patients with acute respiratory distress syndrome or severe asthma receiving intravenous corticosteroids, nondepolarizing neuromuscular blocking agents, or most commonly both. Plasma creatine kinase levels are transiently elevated. Muscle biopsy shows many fibers with loss of thick filaments (Lacomis et al. 1996). The presence of normal sensory conduction studies in the setting of small, short-duration, poly phasic motor unit potentials on EMG helps to support a diagnosis of critical illness myopathy. However, both conditions may occur concurrently. Severe weakness was found in 25% of consecutively admitted ICU patients who required mechanical ventilation. All patients had an axonal neuropathy on electrophysiological testing, and all patients who had a muscle biopsy had myopathic changes unrelated to denervation (De Jonghe et al. 2002). Repetitive nerve stimulation studies should be performed to exclude a defect of neuromuscular transmission caused by defective clearance of neuromuscular blocking agents.

Survivors recover spontaneously in 3-6 months following discharge from the intensive tare unit.

TOXIC NEUROPATHIES

Peripheral neuropathy is one of the most common reactions of the nervous system to toxic chemicals. Industrial. environmental, and biological agents; heavy metals; and

pharmaceutical agents are known to cause toxic neuropathies (see also Chapter 64). Medications, most notably anticancer drugs, are the leading offenders in clinical practice rod ay. Neurotoxic agents may produce distal axonal degeneration (axonopathy), nerve cell body degeneration (neuronopathy), or primary dcmyelination (myelinopathy) (see Pathological Processes Involving Peripheral Nerves, earlier in this chapter). For most toxic neuropathies the biochemical mechanisms underlying the pathogenesis of nerve damage remain poorly understood.

Most toxins produce symmetrical axona! degeneration in a dying-back pattern, beginning in the distal segments of long, large-caliber nerve fibers, eventually spreading proximally with continued exposure. A number of toxic axonopathies also affect the central nervous system with concurrent degeneration of dorsal column projections of sensory neurons and optic nerve axons. Central axon involvement has been linked to incomplete clinical recovery. Agents such as n-hexanc and organophosphates cause simultaneous degeneration of peripheral nerve, dorsal column, and corticospinal pathways, often resulting in spasticity, which may become apparent following recovery from the peripheral axonopathy. Electrophysiological investigations typically disclose an axonal pattern on nerve conduction studies.

The second type of toxin-induced injury targets nerve cell bodies such as the dorsal root ganglion cell. Cisplatm, methyl-mercury compounds, high-dose pyridoxine, and doxorubicin are examples of toxins that produce neuronal degeneration. When the neuronal insult leads to apoptosis and cell death, the resulting sensory neuropathy is often severe and irreversible with limited functional recovery.

Primary demyelination is a less common mechanism in toxic neuropathy hut occurs with diphtheria; buckthorn toxin; and exposure to perhexiline, amiodarone, or suramin. Slowed nerve conduction velocities can also be seen in certain forms of hcxacarbon neuropathy, as in habitual glue sniffers.

To establish a causal link between a putative neurotoxin and neuropathy, the following two clinical criteria should be met:

1. Exposure can be verified and temporally related to the onset of clinical symptoms. Neuropathic symptoms usually occur concurrently with the exposure or following a variable latency of up to several months.
   There must be neurological signs and abnormal e lee trod i agnostic study results. Because many toxic neuropathies arc subclinical, there may or may not be subjective symptoms.
2. Removal from the exposure results in cessation of the progression of symptoms and deficits. This is variably followed by improvement, although in certain axonopathies cessation of exposure may be attended by a worsening of symptoms for up to 4 months (so-called "coasting") before recovery begins.

In addition, the clinician must recognize that certain factors may increase susceptibility to toxic neuropathy, These include pre-existing neuropathy (for instance, CMT), simultaneous use of multiple neurotoxic drugs or compounds, and systemic disorders which cause impaired drug metabolism (Chaudrey et al. 2003). Any of these may increase the risk and severity of toxic neuropathy.

A focused history probing for a background of occupational, environmental, or drug exposure is important. Most toxic neuropathies present clinically with length-dependent sensorimotor or purely sensory deficits. Autonomic dysfunction is rarely a prominent feature, though exceptions include acrylamide, cisplatin, and *Vinca* alkaloids. Predominantly motor toxic neuropathy is rare, being limited to dapsonc, lead, and organophosphate-induced delayed polyneuropathy. Rarely do typical pathological features such as neurofilamentous axonal swellings in hexacarbon neuropathy, axonal vacuolation in thallium, or lamellar Schwann cell inclusions in amiodatone and perhexiline intoxication allow specific identification of the cause by nerve biopsy.

The most important steps in treatment involve recognition of the offending agent and elimination of exposure.

Industrial and Environmental Toxins

Industrial and environmental agents that cause toxic neuropathies are discussed in Chapter 64 (see also Shaumburg and Kaplan *1995).*

Drug-Induced Neuropathies

Many medications can cause peripheral neuropathy, which is generally reversible when the offending drug is discontinued. If the causal relationship between a potentially neurotoxic drug and neuropathy is established, additional investigations to search for alternative etiologies may be unnecessary. Premedication with such compounds as ncurotrophins may in the future allow clinicians to blunt or prevent the dose-limiting neurotoxic effects of anticancer drugs. Ncurotrophins are naturally occurring polypeptides (e.g., NCF, neurotrophin-3, brain-derived NGF, and insulin-like growth factor-1) that play a role in nerve regeneration and demonstrate neuroprotective properties in experimental studies.

Awareness of the possibility of drug-induced peripheral nerve damage is important. A careful drug history including over-the-counter nutritional supplements and vitamin preparations should be obtained in every patient with polyneuropathy. Some of the drugs reported to produce pcriphetal neuropathy are listed in Table 82.28. Many anecdotal reports of neuropathy possibly induced by other drugs may represent coincidental occurrences and remain to be substantiated.

Tabic 82.28: Neuropathies caused by pharmaceutical drugs

Drugs	*Clinical and pathological features*	*Comment*
Antineoplastic		
Cisplarin	S, DA, N	Binds to DNA; disrupts axonal transporr?
Suramin	SM, DA, SD	DA: inhibits binding of growth factors; SD: immunomodulating effects?
Taxanes (paclitaxel docetaxel)	S, DA	Promote microtubule assembly; disrupr axonal Transport
Vincristine	S>M, M, DA	Interferes with microtubule assembly; disrupts axonal transport
Antimicrobial		
Chloroquinine	SM. DA	Myopathy
Daps one	M, DA	Oprk atrophy
[soniazid	SM, DA	Pyridoxine antagonist
Metronidazole	S, DA	
Nirrofurantoin	SM, DA	
Anriviral (NRTIs)		
Didanosine (ddl)	SM, DA	Reversible neuropathy
Fialuridine (FIAU)	S, DA	Irreversible neuropathy; also myopathy
Lamuvidine (3TC)	S, DA	Least common NRTI neuroparhy
Sravudine (d4T)	SM, DA	More associated with lipodystrophy syndrome
/...Aii;ibii!.- •:Lkk	SM, DA	Single tnosi neurotoxic NRTI
Zidovudine (AZT)	-	Myoparhy only
Cardiovascular		
Amiodarone	SM, SD	Lysosomal lamellar inclusions, myopathy
Hydralazine	SM, DA	Pyridoxine antagonist
Perhexiline	SM, SD	Lipid inclusions
Other		
Colchicine	SM, DA	Neuromyopathy, raised creatine kinase levels
Disulfiram	SM, DA	
Gold	SM, DA	Myokymia
Lipid-lowering agents (statins)	s\i. DA	May also cause rhabdomyolysis
Nitrous oxide	S, DA	Inhibits vitamin B^-dependent methionine synthase; myeloparhy
Phenytoin	SM, DA	Asymptomatic in most
Pyridoxine	S, N, DA	Doses >250 mg/day
Thalidomide	S, N	
[.-Tryptophan (tainted)	SM, DA	Eosinophilia-myalgia syndrome

CNS = ecntral nervous system-active drugs; DA = disral axonopathy; M = motor; N = ncuronopathy; NRTI = nucleoside analogue reverse transcriprasc inhihiror; S = sensory; SD = segmental demyelination; SM = sensorimotor neuropathy.

Amiodarone

Amiodarone is a class III antiarrhythmic drug used in the management of refractory ventricular arrhythmias. Adverse effects include thyroid abnormalities, photosensitivity dermatitis, corneal microdeposits, hepatic dysfunction, pulmonary fibrosis, and a dose-dependent polyneuropathy. Sensorimotor polyneuropathy may develop in patients receiving long-term amiodarone (400 mg per day) therapy. There is moderate sensory impairment and distal and sometimes proximal muscle weakness. Electrophysiological studies show mild slowing of nerve conduction velocities as well as distal denervation. Nerve biopsy demonstrates loss of myelinated and unmyelinated fibers, axonal degeneration, and segmental demyelination. A distinctive feature is the presence of lysosomal lamellar inclusions in Schwann cells, fibroblasts, and endothelial cells resulting from inactivation of the lysosomal enzyme sphingomyelinase.

Amphetamines and Cocaine

Abusers of amphetamines and cocaine may develop multiple mono neuropathies associated with a necrotizing hypersensitivity angiitis.

Ch I or a mp benicol

Chloramphenicol can produce a peripheral and optic neuropathy following prolonged, high-dose therapy.

Chloroquine

Chloroquine is an antimalarial drug that is used also in the treatment of connective tissue disorders. Typically, a painful vacuolar myopathy with increased serum muscle enzymes develops after prolonged therapy. Chloroquine produces only mild neuropathy. Muscle and sural nerve biopsies show lamellar inclusions in muscle fibers and

Schwann cells. Other antimalarial agents in the same chemical class may cause a similar neuropathy,

Cisplatin

Cisplatin is used widely in the treatment of ovarian, hladder, and testicular malignancies as well as squamous cell carcinomas. Cisplatin exerts its chemothcrapeutic effects by cross-linking DNA, thereby disrupting cell division. Sensory polyganglionopathy is the dose-limiting side effect. Cisplatin causes a dose-dependent, predominantly large fiber sensory polyneuropathy. Ototoxicity is common, manifested by tinnitus and high-frequency hearing loss. Paresthesia, Lhermittc's sign, loss of tendon reflexes, prominent proprioceptive loss, and sensory ataxia usually occur when cumulative doses exceed 400 mg/m . Autonomic symptoms, especially gastroparesis and vomiting, are common and may reflect enteric ganglion cell loss, The neuropathy may develop as late as 4 months after the drug has been stopped ("coasting"). Nerve conduction studies show reduced or absent SNAPs. Nerve biopsy reveals loss of large myelinated fibers and acute axonal degeneration. Most patients receiving cumulative doses below 500 mg/m improve following cessation of therapy. Neurotrophins are currently under investigation to prevent or ameliorate the neurotoxicity of cisplatin. Carbiplatin is less neurotoxic.

Colchicine

Colchicine is used primarily for the treatment of gout. Subacute proximal weakness and an associated mild distal axonal neuropathy may occur in patients with mild renal insufficiency receiving conventional doses of colchicine, or in patients receiving long-term colchicine for suppression of gout. Markedly elevated serum creatine kinase levels and electro diagnostic findings of a neuromyopathic process occur. Both weakness and creatine kinase elevations typically remit after the drug is discontinued.

Dapsone

Dapsone is used in the management of leprosy and other skin disorders. High doses may cause a predominantly motor neuropathy characterized by weakness and atrophy of distal muscles, particularly intrinsic hand muscles. Severe optic neuropathy may occur also. Reduction of minor NCV is slight, even in the presence of severe denervation, suggesting an axonal neuropathy. Recovery is slow after the drug is discontinued.

Dideoxynu deosides

The nucleosides zakitabine (dideoxvcytidine or ddC), didanosine (dideoxyinosinc), and stavudinc arc inhibitors of reverse transcriptase used to treat HIV-1 infection. These agents cause a dose-limiting dysesthetic sensory neuropathy (Dalakas 2001). High doses of ddC produce an acute painful sensory neuropathy that may progress for 3 weeks after treatment is stopped. Lower doses cause a less painful, sensory neuropathy in 10-30% of patients. Pre-existing neuropathy, diabetes mellitus, heavy alcohol consumption, and low serum cohalamin levels are risk factors that predispose to nucleoside neuropathy. Partial reversal of symptoms following withdrawal of drug allows the ddC neuropathy to be distinguished from the clinically similar HEV-1-assoeiated distal sensory polyneuropathy.

Disopyramide

A few cases of reversible sensorimotor peripheral neuropathy have been associated with the cardiac antidysrhytlimic agent disopyramide (Briani, Zara, and Ncgrin 2002).

Disulfiram.

Disulfiram is used in the treatment of alcoholism. The incidence of neuropathy is dose-related, as most patients receiving daily doses of 500 mg or more develop nerve damage after 6 months. The clinical manifestations are initial distal sensory impairment and later progressive weakness. Nerve conduction studies and EMG indicate an axonal neuropathy. Acute axonal degenetation and loss of myelinated fibcts are seen in sural nerve biopsy specimens. After the drug is stopped improvement takes place over a period of months.

F.thambutol

Ethambutol is an antitubetculous drug that causes peripheral sensory and optic neuropathy after prolonged administration at doses above 20 mg/kg per day.

Et op aside

Etoposide is a semisynthetic derivative of podophyllotoxin with established antineoplastic activity in SCLC and lymphoma. Distal sensory axonal neuropathy develops in approximately 10% of patients after high-dose therapy with this agent.

Gold

Organic gold salts ate sometimes used in the treatment of rheumatoid arthritis. Toxic allergic reactions involving skin, kidneys, and blood are well known, whereas neurotoxic complications are uncommon. A dosc-relatcd, distal axonal polyneuropathy may develop in patients receiving gold therapy. Many have the distinctive features of profound myokymia, muscle aches, insomnia, and autonomic dysfunction such as sweating and labile hypertension. After the drug is discontinued improvement

is the rule. Isolated case reports suggest that gold therapy may precipitate a Guillain-Barre-like syndrome with rapidly ascending limb weakness, sensory paresthesia, and elevated CSF protein. In these cases, nerve conduction studies show evidence of demyelinating neuropathy.

Heroin

Both nontraumatic brachial and lumbosacral plexopathies have been reported in heroin addicts. On resumption of heroin use after a period of abstinence the symptoms recur in one third of patients. Intense pain is a common clinical presentation, whereas weakness and sensory impairment are less prominent. Spontaneous recovery occurs slowly over weeks or months. The mechanism of these plexopathies is unclear.

/ lydralazine

Hydralazine is an antihypertensive drug that can produce a lupus-like syndrome and rarely produces a predominantly sensory polyneuropathy. Distal "tingling asleep numbness" in the extremities without overt clinical signs may develop in 15% of patients on hydralazine. The neuropathy may be caused by pyndoxine deficiency by a mechanism similar to that associated with isoniazid. Symptoms improve after withdrawal ol the drug or with low dose vitamin B_6 supplementation (50-100 mg daily).

Isoniazid

INH is an effective antituberculous drug that interferes with vitamin B^-dependent coenzymes and thus leads to pyridoxine deficiency. INH is acetylated in the liver by the enzyme acety(transferase. Individuals unable to acetylate at a norma! rate (slow acetylators) maintain high blood levels of free INH for a longer time than do vapid acetylators and arc iheretore more susceptible to toxic neuropathy. The slow acetylation is inherited as an autosomal recessive trait. INH polyneuropathy occurs in approximately *2%* of patients receiving conventional doses (3-5 mg/kg per day), its incidence increasing with higher doses. Typically 6 months pass before neuropathic symptoms of paresthesia, impaired distal lower extremity sensation, and weakness begin. The primary pathological process is axonal degeneration affecting both myelinated and unmyelinated fibers, often with prominent axonal regeneration. Unless recognition of this complication is delayed, recovery is rapid. Co-administration of vitamin B_6 (50-100 mg daily) prevents the neuropathy.

Ltpid-Lowering Agents

The 3-hydroxymeihylglutaryl-(HMG)-CoA-reductase inhibitors or statins have grown in popularity for their lipid- and particularly cholesterol-loweting properties. A number of patients on these medications have been found to have a reversible, predominantly axonal distal sensorimotor peripheral neuropathy. An epidemiological study from Denmark concluded that long term exposure to statins increased the risk of developing polyneuropathy 4- to 14-fold compared with the background population (Gaist et al. 2002). Although less severe than the better known myopathy with rhabdomyolysis that can occur with the statin lipid-lowering agents, this toxic neuropathy appears to be much more common, often going unrecognized.

Metronidazole and Misonidazole

Metronidazole is used for the treatment of protozoal and anaerobic bacterial infections as well as inflammatory bowel disease. It may produce a predominantly sensory polyneuropathy following cumulative doses exceeding 30 g. Axonal degeneration of both myelinated and unmyelinated fibers can occur, with slow improvement after the agent is stopped. Misonidazole, a related compound used as an experimental radiation-sensitizing agent, causes a similar sensory neuropathy.

Nitrofurantoin

Nitrofurantoin is a broad-spectrum antibiotic used to treat urinary tract infections. A sensorimotor polyneuropathy of the distal axonal type may develop weeks to months after beginning therapy. Distal numbness, paresthesia, and weakness are common. Renal insufficiency predisposes patients to the development of neuropathy because of excessive tissue concentrations of nitrofurantoin, which is normally excreted by the kidneys. Elcctrophysiological studies show the typical changes of distal axonopathy. Improvement occurs after the medication is discontinued.

Nitrous Oxide

A predominantly sensory neuropathy and associated myelopathy develop in individuals repeatedly abusing or exposed to nitrous oxide (N_20), an inhalation anesthetic agent that is also used in the food industry as whipping cream propcllant. Neurological symptoms occur following intentional abuse or rarely through contamination in operating rooms or pediatric dental offices with faulty N_20 scrubbers. Sharp radicular pains are common symptoms, along with numbness and distal sensory loss. A Lhcrmittc's or reverse I .he mime's sign (neck flexion induces an electrical shock sensation traveling from the feet upward), increased reflexes, and extensor plantar signs may be present. Nerve conduction studies show decreased SNAP amplitudes. Nitrous oxide inhibits the vitamin $B|_2$-dependent enzyme methionine synthase, producing a clinical syndrome indistinguishable from vitamin !i|2 deficiency. Nitrous oxide anesthesia may even precipitate

subacute combined defeneration in patients with unrecognized cobalamin deficiency. Serum methylmalonic acid and homocysteine can be significantly elevated. Prognosis following cessation of exposure is good, unless the myelopathy is severe.

Perhexiline

Perhexiline maleate, previously used to treat angina pectoris, may cause hyperglycemia, abnormalities of liver function, and polyneuropathy. Mild to severe sensorimotor polyneuropathy commonly develops in patients treated with perhexiline (30CMO0 mg/day) for several months. Painful paresthesias, weakness, frequently involving proximal as well as distal muscles, and loss of reflexes occur, occasionally accompanied by orthostatic hypotension and papilledema, CSF protein is commonly elevated. Marked slowing of conduction velocities is characteristic. Sural nerve biopsy specimens show segmental demyelination and lamellar Schwann cell inclusions. Recovery occurs if the medication is stopped.

Phenytoin

Phenytoin, a widely used antiepileptic drug, may cause mild or asymptomatic polyneuropathy after many years of exposure. Typical manifestations are confined to lower extremity areflexia, distal sensory loss, and mildly reduced motor conduction velocities. The degree of abnormality is generally proportional to the duration of phenytoin treatment. Folate deficiency, which may develop during phenytoin therapy, is not related to the onset of neuropathy.

Pyridoxin?

High dose pyridoxine (vitamin B_6, 250-3000 mg/day) may cause a severe sensory polyganglionopathy. Painful paresthesias, sensory ataxia, and l.hermittc's sign are common features. Nerve conduction studies show low-amplitude or absent SNAPs. Severe depletion of myelinated fibers and acute axonal degeneration are found in sural nerve biopsy specimens. Pyridoxine use should be queried in all patients with sensory neuropathy. In experimental studies, high **dose pvi HI::\IIU-** IOO **i** iH'Aj!.' produced **widespread do: s.i I** root ganglion degeneration. The fact that most clinical cases gradually recover suggests that dysfunctional dorsal root ganglion neurons may regain their functional capacity despite severe sensory deficits early in the course of disease.

Sodium Cyanate

Sodium cyanate was previously used to treat sickle cell anemia. An insidious sensorimotof polyneuropathy may develop following prolonged therapy.

Suramin

Originally introduced as an antiparasitic agent, suramin is used currently as an antineoplastic drug for refractory malignancies. It acts by inhibiting DNA polymerase activity and displacm;; several growth laciors from tlicii respective receptors. Suramin neurotoxicity is the dose-limiting side el tea leading to two distinct patterns of neuropathy, one a length-de pen dent axonal polyneuropathy and the other a subacute demyelinating polyradiculoneuropathy (Chaudhry et al. 1 996). The distal sensorimotor neuropathy that occurs in 30-55% of patients presents with paresthesias and mild distal leg weakness. In vitro experiments suggest that NGF inhibition by suramin may be an important neurotoxic mechanism. Approximately 15% of patients develop a subacutely evolving, demyelinating polyradiculoneuropathy. Severe generalized flaccid weakness with bulbar and respiratory involvement, nerve conduction studies consistent with demyelination, increased **CS1**: protein levels, and perivascular inflammation on sural nerve hiopsy are rypical features making this neuropathy virtually indistinguishable from GRS. The severe neuropathy occurs predominantly at peak plasma suramin concentrations above 350 ug/mL. Suramin may induce inflammatory demyelination by its many immunomodulatory effects. Patients improve after drug discontinuation and with plasmapheresis.

Tacrolimus

Tacrolimus, an immunosuppressive agent used in organ transplantation, may trigger an immune-mediated neuropathy by its complex actions on T cells. The few patients who developed a subacute, multifocal demyelinating polyneuropathy resembling CIDP after initiation of tacrolimus improved following plasmapheresis or intravenous immunoglobulin (Wilson et al. 1994).

Taxanes

Paclitaxel (Taxol), a plant alkaloid isolated from the bark of the western yew, is used toi die irc.unu-nl ol ovarian cancer and other solid neoplasms. Taxol and its semisynthetic analogue docetaxel bind to tubulin and promote irreversible microtubule assembly, thereby forming bundles of disordered microtubules and disrupting axonal transport. A dose-related sensory ganglionopathy results with doses above 250 mg/m^2 body surface **area.** Cumulative dosages of greater than 1000 mg/m" invariably result in a sensory motor neuropathy. Burning paresthesias, sensory loss affecting all sensory modalities, and areflexia are followed by sensory ataxia and mild distal weakness. Disabling weakness is rare except in the presence of additional risk factors such as pre-existing diabetic neuropathy or combination therapy with other neurotoxic chemothcrapeutic agents such as cisplatin. Neurotrophic have prevented paclitaxel neutotoxicity in animal models.

Docctaxel (Taxotere) is used in metastatic breast and ovarian cancer causing a dose-dependent sensory neuropathy similar to its parent compound. Motor symptoms are present only in the most severely affected patients (Newetal, *1996).*

Thalidomide

Thalidomide was introduced as a sedative-hypnotic agent in the 1950s, but was taken off the market when its disastrous teratogenic properties became evident. The drug has, however, been found to be useful to treat erythema nodosum leprosum and other rare skin conditions, graft-versus-host disease, a number of complications of HIV infection, and multiple myeloma as well as other malignancies. This compound owes its therapeutic effects to its inhibition of tumor necrosis factor-c (TNF-a) production and anti-angiogenic properties. Thalidomide causes dorsal root ganglion degeneration with selective involvement of large-diameter sensory neurons. Painful distal paresthesia and numbness occur with palmar erythema and brittle nails as prominent signs. In most patients the neuropathy is dose related, occurring after high doses or chronic administration for more than 6 months. After discontinuation of the drug, symptoms and signs improve very little. A prospective study of 135 patients with dermatological problems found objective clinical and electrophysiological evidence of predominantly sensory neuropathy in 25% of those treated (Bastuj-Gann et al. 2002}. In this cohort the neuropathy-was found to be dose-related, with a relative risk for daily doses greater than 75 mg of 20.2, a relative risk of 8.2 for daily doses between 50 and 75 mg, and no neuropathy in patients on less than 25 mg each day. Cumulative dosages gteater than 100 g result in significant neuropathy. As thalidomide produces neurotoxicity in a dose-dependant manner, monitoring for peripheral neuropathy with sensory conduction studies in patients receiving thalidomide allows for early detection of neuropathy preventing severe disability.

Glutethimide, a structurally related hypnotic compound, may produce a similar sensory polyganglionopathy in patients taking high doses for many months.

L-Tryptophan

An unusual syndrome called eosinophiha-myalgia syndrome was recognized in 1989 in individuals taking preparation* coma in i lit: I .-tryptophan. In \'-->-)*l,* n-.ore than 1500 patients had been diagnosed in the United States. A contaminated L-tryptophan source originating from a single manufacturer was responsible for the epidemic. One of the chemical impurities associated with eosmoph ilia-myalgia syndrome, designated *peak* E, is an unusual dimeric form of L-tryptophan. This abnormal tryptophan metabolite may activate eosinophils and trigger immune-mediated mononuclear cell infiltrates in connective tissues of many organs. Eosinophilia-myalgia syndrome is a systemic illness characterized by myalgia, fatigue, arthralgia, skin rash, swelling, and induration of the limbs and an elevation of the blood eosinophil count (>1000 cells/ul). Many patients develop florid inflammatory myopathy. The onset of eosinophilia-myalgia syndrome may be delayed for months after i-tryptophan use, and clinical deterioration may peak months after stopping the medication. A severe axonal sensorimotor polyneuropathy may be a prominent feature in some patients (Smith and Dyck 1990). Electrodiagnostic studies are in keeping with an axonal process. EMG may show neurogenic and myopathic motor unit potential alterations. Pathological studies demonstrate acuteaxonal degeneration, epineurial and perineuria] inflammatory infiltrates, and associated inflammatory vasculopathy in sural nerves. Inflammation is observed also m biopsy specimens of muscle, skin, and subcutaneous tissues. The clinical and pathological findings resemble those of the Spanish toxic oil syndrome, which was caused by denatured rapeseed oil. In general, clinical severity of the neuropathy seems to be positively related to the total dose ingested. Prednisone is not of benefit.

Vinca Alkaloids

Vincristine, the Vinca alkaloid most used in chemother apeutic regimens, has length-dependent sensorimotor polyneuropathy as its dose-limiting side effect. Vinblastine and two semisynthetic derivatives, vindesine and vinorelbinc, are less neurotoxic. Vinca alkaloids function as mitotic spindle inhibitors. Their neurotoxicity is related to tubulin binding, which interferes with axonal microtubule assembly, thereby impairing axonal transport.

Vincristine produces a dose-dependent neuropathy with sensory symptoms beginning at 5 mg and motor symptoms at cumulative doses of 30-50 mg. There are several reports of vincristine-induced severe paralysis at conventional doses in patients with pre-existing hereditary neuropathies. Paresthesias, often starting in the fingers before the feet, and loss of ankle jerks are common initial findings. Distal muscle weakness and sensory impairment follow. Autonomic dysfunction, particularly gastroparesis, constipation, occasionally paralytic ileus, and urinary retention, is an early manifestation. Weakness, often accompanied by muscle pains, may evolve rapidly to severe motor impairment. Occasionally, isolated mononeuropathies have been reported. Cranial nerve involvement occurs infrequently and includes trigeminal sensory loss, ocular motility disorders, facial weakness, and recurrent laryngeal nerve palsies.

Electrophysiological studies reflect the degeneration of distal axons. SNAPs are reduced in amplitude, whereas nerve conduction velocities arc preserved. EMG shows denervation in distal muscles. The predominant pathological features are axonal degeneration and myopathic changes with spheromembranous inclusions in the muscle fibers on electronmicroscopy. Reduction in dose or

withdrawal from therapy at an early stage usually leads to complete recovery. Coadministration of glutamic acid or ORG 2766, an adrenocorticotropic hormone-derived synthetic peptide, has shown promising results reducing the severity of vincristine neuropathy in preclinical trials but there was no benefit in a clinical trial. Neurotrophins have neuroprotective effects in experimental studies as well, although there is reticence to use these compounds in patients with established neoplasms, due to the fear that growth factors may stimulate tumor growth.

NEUROPATHIES ASSOCIATED WITH INFECTIONS

Peripheral neuropathy occurs in a number of infectious diseases including viral, prion, bacterial, and parasitic infections.

Viral Infections and Neuropathy

Human Immunodeficiency Virus Type 1

HIV-1 infection is associated with a wide variety of peripheral neuropathy syndromes, with onset from the time of seroconversion to the late stages of AIDS (Table 82.29; see Chapter *59).* These arc divided into neuropathies occurring early and late in the course of disease. The CD4 count inversely parallels the frequency of neuropathy, with normal counts in inflammatory demyelinating neuropathies and low counts in distal symmetrical polyneuropathies and lumbosacral polyradiculopathy. The estimated prevalence of peripheral neuropathy in patients with HIV-1 infection ranges from 15-30% based on clinical findings and increases substantially if electrophysiological variables are used for inclusion. More than 75% of patients with AIDS have pathological evidence of peripheral nerve involvement at autopsy.

Acute and Chronic Inflammatory Demyelinating Polyradiculoneuropathies. Of the neuropathies that occur in HIV-1 infection, AIDP and CIDP predominate during seroconversion and the early stages of disease.

An acute inflammatory demyelinating neuropathy clinically and electrophysiological!)' indistinguishable from GBS is seen in individuals who ha\< pnsicve tcs! results *:oi-* HIV-1. Its clinical course, spontaneous recovery, or response to plasmapheresis or intravenous immunoglobulin therapy arc similar to IKin I 11V I related (.lis. I S! pruiein is elevated (>100 mg/dL), and pathologically dcmyclination with prominent inflammation in nerves and roots occurs. This acute polyradiculoneuropathy differs from run 1:1V i related GBS by a CSF pleocytosis ranging from 10-50 cells/ul and by HIV-1 seropositivity.

Similar to HIV-1 seronegative patients, CIDP may be seen in association with HIV-1 infection, CSF pleocytosis and prominent inflammatory infiltrates consisting primarily of cytotoxic-suppressor T lymphocytes and macrophages in sural nerve biopsy specimens separate these patients from those with seronegative CIDP. It is advisable to test for the presence of HIV-1 antibodies in those patients with acquired demyelinating neuropathies who have conceivable HIV-1 risk factors or suspicious laboratory results, such as CSF pleocytosis, positive hepatitis B serology, or polyclonal hypergammaglobulinemia. In one series from a large urban center, 8% of patients with inflammatory demyelinating neuropathies tested HIV-1 seropositive. Plasmapheresis or IVIG is the preferred treatment for both acute and chronic inflammatory demyelinating polyneuropathies if the illness is sufficiently severe to warrant intervention.

Tabic 82,29: Neuropathies associated with human immunodeficiency virus infection

Neuropathies	*Cluneal features*	*Human immunodeficiency virus 1 stage*
Distal symmetrical polyneuropathy	Pain, sensory loss	Late: CDC IV, AIDS, ARC
Autonomic neuropathy		
Treatment-induced	ddC, ddl, 3TC, d4T, F1AU	
Lumbosacral polyradiculoneuropathy	Cauda equina syndrome	Late: CDC IV, AIDS
CVIV radiculopathy	CSF pleocytosis (polymorphonuclear cells)	
Lymphoma	CSF cytology (malignant cells)	
Diffuse infiltrative lymphocytosis syndrome	CDS lymphocytosis	
Multiple mo no neuropathies	Limited to extensive mononeuropathies	CDC III-IV; ARC, AIDS
Vasculitis		
CMV		
Lymphoma		
Inflammatory demyelinating polyneuropathies	Guillain-Barre syndrome or CIDP; CSF pleocytosis	Harly: CDC Mil
Cranial mono neuropathy	Facial palsy	Early: CDC I-III
Sensory neuronoparhy	Sensory ataxia	Early: CDC I-III
Herpes zoster radiculitis	Dermatomal vesicular eruption	Early and late

AIDS = acquired immunodeficiency syndrome; ARC = AIDS-related complex; CDC I-IV= Centers for Disease Control and Prevention classification system for human immunodeficiency virus infection stages I-IV; CMV = cytomegalovirus; ddC, ddl, 3TC, d4T, FIAU = dideoxycytidinc, dideoxyinosine, lamuvidine, stavudine, fialuridine, respectively.

Mononeuropathy and Multiple Mononeuropathies. Although isolated involvement of single cranial nerves, and particularly the facial nerve, may occur in the asymptomatic or early stages of symptomatic HIV-1 infection, multiple mononeuropathies associated with HIV-1 disease more frequently occur late in the course of illness. These may be associated with superimposed infection (including herpes zoster, CMV, hepatitis C, and syphilis), lymphomatous infiltration, or necrotizing vasculitis.

Unilateral or bilateral facial neuropathy may accompany HIV-1 seroconversion. Patients with involvement of one or two cranial or spinal nerves in association with CD4 counts greater than 200/ul often have a good prognosis, and many recover spontaneously. Multiple mononeuropathies with severe deficits, on the other hand, are more likely to occur in immunocompromised AIDS patients with CD4 counts below 200/ul; these patients should be investigated for CMV infection. If CMV cannot be demonstrated, peripheral nerve vasculitis is the most likely etiology. Peripheral nerve biopsy in multiple mononeuropathies demonstrates multifocal decreased density of myelinated fibers, degenerating fibers, and interstitial abnormalities dominated by epineurial mononuclear cell infiltrates and vessel wall necrosis. Schwann cells may he infected directly by HIV-1 particles (Mahadevan et at. 2001).

When CMV is confirmed or even suspected clinically, treatment should begin immediately with ganciclovir. Other therapies that have been noted in case reports as being effective include corticosteroids, plasmapheresis, IVIG, and foscarnet. Use of corticosteroids might seem theoretically risky but is surprisingly well tolerated.

Distal Symmetrical Polyneuropathy. The most common neuropathy related to HIV-1 infection is painful distal symmetrical polyneuropathy. The onset occurs often with burning feet, painful paresthesia, and distal sensory loss, combined with mild distal weakness and autonomic dysfunction. In patients with symptomatic distal symmetrical polyneuropathy, nerve conduction studies show borderline- to low-amplitude sensory and motor responses, often accompanied by denervation changes in distal muscles. Electrophysiological evaluations of patients with HIV-1 infection demonstrate that as many as two thirds may have peripheral nerve involvement. Sural nerve biopsy shows loss of myelinated fibers and unmyelinated fibers with no distinctive interstitial abnormalities. Skin biopsy demonstrates reduction in nerve fiber density, increased frequency of fiber varicosities, and fiber fragmentation (Keswani et a I. 2002). The severity of neuropathic pain and elevation of distal cooling detection threshold values in distal symmetrical polyneuropathy appear to correlate with plasma HIV-1 RNA levels (Simpson et al, 2002).

Although the cause of distal symmetrical polyneuropathy in HTV-1 infection is unknown, direct infection of peripheral nerve is thought to be unlikely. Although low levels of HIV-1 in dorsal root ganglia macrophages may play a role, macrophage infiltration and the release of proinflammatory cytokines appear to be the primary mediators of the "dying hack" axonal degeneration. Specific treatment for distal symmetrical polyneuropathy in HIV-1 infection has been disappointing. Although symptomatic approaches may be helpful, clinical trials of NGF, peptide T, plasmapheresis, and accupuncture have not shown efficacy. Current interest in such agents as I.-acetylcarnitine and prosaptide may lead to further therapeutic trials (Simpson 2002).

A significant proportion of patients with 1 lIV-1-related distal symmetrical polyneuropathy have antibodies to human T-cell lymphotropic virus 2, suggesting eoinfection (Zehcnder et al. *1995).* Nutritional deficiencies (chiefly vitamin B]> and folate deficiencies) have also been implicated as have neurotoxic drugs including vincristine, dapsone, iNH, and nucleoside analogue reverse transcriptase inhibitors. Mounting evidence supports the observation that several nucleoside analogue reverse transcriptase inhibitors used in highly active antiretroviral therapy (IIAART) have contributed to both improved survival and an increase in toxic neuromuscular disorders in individuals infected with HIV-1 (Brinley, Pardo, and Verma 2001). Among these agents, zidovudine (AZT) may lead to myopathy, zalcitabinc (ddC), didanosine (ddl), and lamvudine (3TC) have been linked with neuropathy, whereas stavudine (d4T) and fialuridine (FIAU) cause neuropathy or myopathy and lactic acidosis (Dalakas 2001). A subset of HIV-1-positive patients with distal symmetrical polyneuropathy have been found to have necrotizing vasculitis (Bradley and Verma 1996).

Lumbosacral Polyradiculoneuropathy. Even though uncommon, acute lumbosacral polyradiculoneuropathy often associated with CMV infection is among the most devastating neurological complications in AIDS. Hie usual presentation is rapidly progressive flaccid paraparesis, sphincter dysfunction, perineal sensory loss, and lower limb areflexia (So and Olney 1994).

Electrophysiological studies show low-amplitude CMAPs and prolonged or absent F-wave latencies. Reduced or absent SNAPs are attributed to concomitant polyneuropathy. Within a few weeks of onset, EMG signs of active denervation become apparent. LSI- examination in CMV-related lumbosacral polyradiculoneuropathy shows plcocytosis (>50 per ul; typically with more than 40% polymorphonuclear cells), elevated protein levels, and low glucose concentrations. With this CSE profile, a presumptive diagnosis of CMV polytadiculoncuropathy can be made, leading to empiric therapy, even before the demonstration of positive CSF culture results. MR! with gadolinium may demonstrate enhancement of cauda equina nerve roots. Other rare causes of lumbosacral polyradiculoneuropathy in AIDS include syphilis, mycobacterial infections, toxoplasmosis, and leptomeningeal lymphomatosis.

Another condition associated with HIV-1 infection, diffuse infiltrative lymphocytosis syndrome, is a nonmalignant CDtJ lymphocytosis that may affect multiple viscera as well as peripheral nerve and may respond to either corticosteroid or antirctroviral treatment (Gherardi et al. 1998).

Empirical treatment with intravenous ganciclovir should be started promptly in AIDS patients with polymorphonuclear CSF pieocytosis and progressive flaccid paraparesis. Foscarnet alone or in combination with ganciclovir may be an alternative for patients who develop this syndrome daring ganciclovir treatment for systemic CMV infection. Although early antiviral therapy may preserve neurological function, long-term prognosis is poor.

Herpes zoster radiculitis occurs in perhaps 10% of HIV-l infected patients. Early in the course of HIV-1 infection, often at seroconversion or during the asymptomatic phase, ataxic sensory polyganglionopathy may develop; it remains unclear whether this syndrome or the associated degeneranon of ilu- ťiLKLi- ir.ici arc lvkucd directly in HIV [infection.

Cy Iomega lovirus

CMV commonly causes an asymptomatic infection. In immunocompromised individuals, however, a life-threatening disseminated illness may result, often with fatal men ingoeneep ha litis. Antecedent CMV infection has been associated with A1DP. In patients infected with the HIV-1 virus, severe painful lumbosacral polyradiculoneuropathy is known to occur (sec Lumbosacral Polyradiculoneuropathy, earlier in this chapter).

Epstein-Barr Virus

Although most well known as the chief cause of infectious mononucleosis, the Epstein-Barr virus is associated with a variety of neurological complications. Those with peripheral nerve manifestations include rhombencephalons with cranial nerve involvement, myelitis with spread to adjacent nerve roots, multiple mononeuropathies, and brachial as well as lumbosacral plexopathy.

Herpes Simplex Virus

Herpes simplex virus is a group of neurotropic DNA viruses that colonize primary sensory neurons. In the case of herpes simplex virus 1, the gasserian ganglion is most often affected, and repeated eruption of oral and labial ulceration ensues. With herpes simplex virus 2, a sexually transmitted disease, sacral dorsal root ganglion cells are the site of infection, leading to the periodic appearance of genital ulcers. Although segmental recurrence is most common, more widespread disease may result in disseminated eruptions in immunocompromised hosts. Antiviral treatment with acyclovir (200 mg five times daily for 10 days) or famciclovir (125 mg twice a day for 5 days) can reduce the duration of eruption and prolong the time to subsequent outbteak.

Herpes Zoster Virus

The most common symptomatic peripheral nerve viral infection is with the neurotropic varicella zoster (herpes) virus. It has been estimated that over the age of 70 years, the lifetime percent probability of segmental varicella zoster virus infection approximates years of life. The spectrum of peripheral neurological involvement in varicella zoster virus includes cranial zoster (chiefly affecting the trigeminal or less often the geniculate ganglion), radicular zoster (also called segmental zoster, zoster radiculopathy, or shingles), and polyradiculoneuropathy. Although sensory pathways are most affected, in cases with radicular zoster affecting one or two spinal root levels, there is *An* approximate 5% probability of significant motor involvement, leading to the designation segmental zoster paresis. Careful EMG study results show as many as 50% of segmental zoster patients may have subtle motor involvement (Haanpaa, Hakkinen, and Nurmikko 1997). In severe segmental zoster inflammation will often spread into the spinal cord, and can be responsible for long tract signs. Occasional patients present with painful unilateral dermatomal pain and CSF evidence of varicella zoster virus DNA, but no cutaneous vesicular eruption (zoster sine hcrpete). Treatment with famciclovir (500 mg three times a day for 7 days) or acyclovir (800 mg five times daily for 10 days) is indicated at the onset of symptoms.

/ lepatttis Viruses

Hepatitis B vitus infection has been reported in association with demyelinating GBS and with multiple mononeuropathies and necrotizing vasculitis.

Infection with hepatitis C virus is often transmitted by sexual contact, through blood transfusion, or via other means and may be particularly common in urban populations. I lepatitis C virus has been associated with essential cryoglobulinemia and may be its most common cause. The syndrome of hepatitis C virus infection, cryoglobulinemia, and vasculitic neuropathy has been recognized as a previously overlooked cause of multiple mononeuropathies. Although no controlled clinical trials have been carried out, individual patients have been observed to respond to immunosuppressive therapy followed by antiviral treatment of the underlying HCV infection (refer to preceding section on cryoglubulinemic neuropathy).

Human T-Celt Lympbotropic Virus Type i

Although the majority of patients infected by human T-cell lymphotropic virus type 1 present with a progressive spinal

cord syndrome and spastic paraparesis, sphincter disturbances, and impotence, many affected patients have dysesthesia and mild distal sensory loss, implicating additional involvement of peripheral nerve and dorsal column pathways. Because the syndrome is much more common in tropical regions, the terms *tropical spastic paraparesis* (TSP) or HTLV-1 associated myelopathy (HAM) have been used. CSF examination is essentially normal, but may show a mild lymphocytic pleocytosis. Somatosensory evoked potential studies are said to be abnormal in more than one half of patients. NCVs are minimally slowed in approximately one third of those studied. Progression is slow, although most patients eventually become severely disabled 10 years or more after onset of symptoms.

Tropical Ataxic Neuropathy

Tropical ataxic neuropathy is a predominantly sensory syndrome occurring in middle age that presents with burning feet, distal sensory loss, gait ataxia, and lower limb areflcxia. Mild distal lower motor neuron signs, optic atrophy, and sensorineural hearing loss may be present also. Although nuttitional, toxic, and infectious etiologies have been considered, some evidence suggests that infection with human '['-cell lymphotropic virus 2 may play a significant role.

West Nile Virus Motor Neuronopatby

West Nile virus infection may present with symmetrical or asymmetrical flaccid limb and facial weakness without sensory deficts and with few or no signs of encephalitis; the picture is like acute poliomyelitis (Li ct al. 2003).

Peripheral Neuropathy in Creutzfeldt-Jakoh Disease

Creutzfeldt-Jakob disease is a transmissible neurodegenerative disorder caused by prions, proteinaceous infectious particles (see Chapter 59). Prions interact with a normal host protein to produce clinical Creutxfeldt-Jakob disease, Although the CNS is the main target of Creutzfeldt-Jakob disease, a number of patients have been described with a demyelinating peripheral neuropathy that may precede cognitive and intellectual deterioration (Antoine et al. 1996).

Bacterial Infections and Neuropathy

Neuropathy Associated with Mycobacterium leprae

Hansen's disease (leprosy) is a major cause of neuropathy worldwide, especially in tropical and subtropical regions. As improvements in public health and use of mtiltidftig therapy have advanced, the prevalence of Hansen's disease, as measured by registered cases, has dropped from 5.4 million in 1991 to 0.9 million in 1996. The Centers for Disease Control and Prevention reports that in the United States there were 144 new cases in 1995, whereas the total number of reported U.S. cases was 7500. Of new cases, approximately 20% originate in this country (mainly Hawaii, Florida, Louisiana, and southern Texas), with the balance immigrating mainly from Asia or the South Pacific, and to a lesser extent from Mexico, India, and othct parts of the world.

Mycobacterium leprae is thought to be ttansmitted through the upper respiratory tract. Once the nasal mucosa is colonized, the organism spreads slowly to other regions, with an estimated incubation time of 3-10 years. Particularly vulnerable tissue are those with mean daily temperatures in the 27° to 30° C range, as this promotes more rapid bacterial growth. The skin and superficial nerve trunks arc particularly vulnerable, leading to cutaneous lesions, anesthesia, and paralysis of face and limb muscles. The disease is classified by host reaction to infection into two polar forms, tuberculoid and lepromatous, with three intermediate forms termed *borderline tuberculoid, intermediate borderline,* and *borderline lepromatous.* Recent data suggest that the Hansen bacillus has a proclivity for Schwann cell invasion. These cells may then serve as a sequestered reservoir of infection with relative protection from host defenses. One model for the early interaction of *Mycobacterium leprae* with peripheral nerve suggests that the bacillus activates a-dystroglycan receptors on Schwann cells via the G domain of laminin-2 (LN»2G), a major component of Schwann cell basal lamina (Rambukkana 2000).

The vigor of host cell-mediated immunity appears to dictate the course of events. Tuberculoid Hansen's disease is characterized by active cell-mediated immunity, intense delayed hypersensitivity response to lepra antigens such as lepromin, localized destruction of infected nerves by intense inflammators lesions, and rare organisms dctct ted in skin and nerve. Lepromatous Hansen's disease, on the other hand, is typified by unopposed proliferation of organisms, complete anergy to lepra antigens, and disseminated skin and nerve lesions with minimal inflammatory response. Intermediate forms share features of the two extremes. A comprehensive review of Hansen's disease neuropathy by Walters and Jacobs (1996) is recommended.

Clinical Features. The unique propensity of M. *leprae* to invade cutaneous nerves causes the cardinal symptom of sensory loss. In tuberculoid Hansen's disease sensory loss, initially affecting pinprick and temperature sensation, is detected within sharply demarcated bypopigmented skin lesions. Adjacent cutaneous nerves or mixed nerve trunks are apt to become involved. The associated intense inflammatory response can affect underlying nerve trunks and cause a mononeuropathy in the distribution of those nerves, which may become indurated and palpable because

of fusiform swelling. Attention should he paid to the palpation of peripheral nerves that course close to the skin surface, including the great auricular, ulnar, radial, common fibular, and sural nerves, in order to detect nerve enlargement. The predominant sensory loss, particularly for pain, can lead to painless trauma with acrodystrophic deformities and autoamputations.

Lepromatous Hansen's disease is characterized by symmetrica! hacillary infiltration of the skin with a predilection for cooler areas of the body, avoiding the scalp, palms, soles, and midline of the back. The skin may have multiple nodules, papules, macules, and ulcerations, or there may be diffuse cutaneous involvement with a waxy, myxedema-like appearance. Similarly, the distribution of sensory loss is telated to the local skin temperature, the coolest parts such as the pinna of the car; the tip of the nose; malar areas of the face; dorsal surfaces of the hands, forearms, and feet; and dorsolateral surfaces of the lower legs being affected first. Because of the minimal inflammatory response, nerve trunk involvement occurs late in this form. Commonly affected nerves include the ulnar, common peroneal, and superficial branches ot the facial and median nerves, in that order. The selective involvement of small branches of the facial nerve leads to the typical patchy nature of facial paralysis with early weakness of medial iotvheae elev.'Ltors. Preserved tendon relieves are an important differential diagnostic sign, in contrast to the loss of reflexes seen in most polyneuropathies.

Either spontaneously or during the course of treatment, acute leprosy reactions may complicate the insidious course because of a sudden alteration in the host-immune response. In the reversal reaction, which is usually seen in the borderline-lepromatous stage, patients develop an increase in cell-mediated immunity. This reaction is identified clinically by swelling and exacerbations of existing skin and nerve lesions. Marked reversal teactions can be associated with intensely painful nerve trunks, and total loss of sensory and motor functions may develop within hours because of the pronounced inflammatory reaction of the affected nerves. These acute reactions appear most commonly during the first year of therapy and require immediate treatment with systemic corticosteroids or other anti-inflammatory agents to prevent further nerve damage.

Nerve conduction studies show reduced amplitudes of CMAPs and SNAPs, together with focal conduction slowing at sites of nerve enlargement. For diagnosis and accurate classification, a skin punch biopsy is necessary and should be taken from the active borders of the lesions. The architecture of cutaneous nerves is destroyed by an intense granulomatous inflammation in tuberculoid Hansen's disease (Figure 82.35). In lepromatous disease, multiple acid-fast organisms are found in Schwann cells, foamy macrophages, and axons of involved nerves, together with recurrent demyelination and progressive nerve fiber loss.

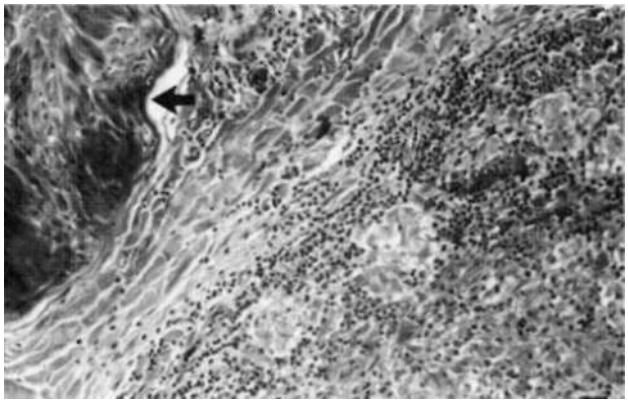

FIGURE 82.35 Tuberculoid leprosy. Biopsy of enlarged sural nerve demonstrates extensive epineurial inflammatory granuloma consisting of epithelioid and mononuclear inflammatory cells. The adjacent nerve fascicle *[arrow)* is devoid of myelinated fibers. (Hematoxylin and eosin; bar = 300 ^im.)

Treatment. Management consists of specific chemotherapy and prevention and treatment of deformities. The current recommendation for paucibacillary infections (those classified as indeterminate. : nlu rvnloid. or hordcr line tuberculoid Hansen's disease) is the combination of dapsone, 100 mg per day, and rifampin, 600 mg per day for at least 6 months, followed by dapsone monotherapy for *3-5* years. Patients with multibacillary infections (borderline or lepromatous leprosy) receive the same combination therapy, with the addition of clofazimine (50 mg daily). Treatment is continued for a minimum of 2 years or until skin smear results arc negative. For dapsone-resistant strains or patients with glucose-6-phosphate dehydrogenase deficiency, clofazimine and rifampin are used together, with consideration of a third agent, either ofloxacin (400 mg daily), clarithromycin (250 mg twice a day), or minocycline (100 mg daily).

Diphtheritic Neuropathy

Diphtheria is a localized infection of the upper respiratory tract or skin produced by *Cnrynebacterium diphtberiae.* The organism elaborates a protein exoloMii responsible tor the delayed systemic manifestations, including cardiomyopathy and segmental demyelination of nerve roots and peripheral nerves. Diphtheria toxin is used as an experimental model of PNS demyelination. Local injection of the toxin produces focal demyelination of nerve fibers without inflammation.

The disease is now rate except in poor socioeconomic conditions where immunization is inadequate. It begins with a pharyngeal infection associated with a characteristic grayish-white exudate. Neurological complications occur in approximately 15% of patients admitted with diphtheria. Neurological symptoms begin with paralysis of the soft palate, impaired pharyngeal sensation, and paralysis of

pupillary accommodation. Occasionally, the diaphragm becomes weak at this stage (Logina and Donaghy *1999).* A local limb neuropathy may appear adjacent to cutaneous diphtheria. The focal palatal-pharyngeal neuropathy may progress 3—15 weeks after the infection to a generalized mixed sensorimotor polyneuropathy, or less frequently to a sensory polyneuropathy presenting with ataxia in approximately 10% of patients (McDonald and Koeen 1993).

Culture of C. *diphtberiae* from the pharynx or the cutaneous ulcer establishes the diagnosis. CSF protein may be normal or elevated to more than 100 mg/dL. Mildly increased distal motor latencies and decreased NCVs arc seen in most patients 2 weeks after the onset of neurological symptoms. However, maximal slowing, with conduction velocities ranging from 15-35 m/sec tends to occur later when clinical recovery has already begun. The brunt of the pathological changes, segmental demyelination with sparing of axons, is seen in the dorsal root ganglia and nerve roots, which have an ineffective blood-nerve barrier to the toxin because of fenestrated capillaries.

Prompt administration of antitoxin within 48 hours of the ouset of the primary infection reduces the incidence and severity of neuropathy, but is likely to be ineffective if administered later in the course of disease. Respiratory support may be needed for severe cases. Recovery takes place over a period of weeks and is usually complete if antitoxin is given within 48 hours of symptom onset. In one series of 50 adults with diphtheritic polyneuropathy, identical rates of death (18%) and peak severity of neuropathic deficits (25% in the severe category) were recorded in those who received antitoxin on days 3-6 and those who did not receive it at all (Logina and Donaghy 1999).

Peripheral Manifestations of Lyme Borreliasis

Lyme disease is a multisystem illness caused by the tick-borne spirochete *Borrelia burgdorferi sensu la to* with characteristic early and late neurological manifestations. Most cases i.V?".. in ike L hi :i.-J Nuies h.ne been reported from nine states in the Northeast, uppet Midwest, and Pacific coastal regions. Endemic foci occur in northern and central Europe. It is now recognized that Lyme disease is distributed widely in temperate zones worldwide (sec Chapter 59).

From the initial appearance of the pathognomonic dartboard-like skin lesion, known as *erythema migrans,* a distinctive early neurological syndrome results in approximately 15% of patients. This consists of cranial neuropathy (usually facia! palsy), radiculoneuropathy, or lymphocytic meningitis, often in combination. These conditions usually abate without intervention over weeks to months, but they improve more rapidly with appropriate antibiotic treatment. Months to years after the initial infection, a late neurological syndrome may emerge. This consists of a predominantly sensory polyradiculoneuropathy that may present with distal sensory symptoms or proximal radicular pain and does not often resolve on its own, but rather regresses only after use of efficacious antibiotics {Logigian 1997).

Laboratory investigations helpful in the diagnosis of early Lyme disease include CSF analysis, which shows a lymphocytic pleocytosis and mild elevation of the total protein. Intrathecal production of anti-B, *burgdorferi sensu tato* antibodies can usually be documented in these cases. Electrodiagnostic study results in patients with chronic Lyme polyradiculoneuropathy confirm a multifocal or widespread axonal process, with borderline to low-amplitude distal responses, greater involvement of sensory rhan motor fibers, and little or no slowing of NCVs, F.MG often shows signs of chronic partial denervation in distal and proximal muscles, including fibrillation potentials and neurogenic motor unit potential changes. Sural nerve biopsy confirms axonal degeneration as well as interstitial alterations with perivascular and perineurial mononuclear inflammation. Serological confirmation of Lyme disease documents prior exposure, although scropositivity alone is not sufficient to establish a causal relationship, because in endemic .Hi .is II le.isl ID", nl ;iv. mpluiii.ilK :mlfvukul\ are seropositive. The diagnosis must depend on appropriate exposure in endemic regions and a plausible clinical context. High titers of anti-B. *burgdorferi sensu tato* antibody in CSF are helpful to link the peripheral neurological manifestations to Lyme disease. Polymerase chain reaction assays to identify spirochetal DNA in CSF are promising techniques (Schmidt 1997).

The majority of patients treated with intravenous ceftriaxone, 2 g daily for 2—4 weeks, improve slowly over 3-6 months. Oral antibiotic therapy with doxycycline or amoxicillin may be effective in mild cases without CSF abnormalities.

Parasitic Infections Associated with Peripheral Neuropathy

American Trypanosomiasis (Cbagas' disease)

American trypanosomiasis (Chagas' disease) occurs from the southern United States to southern Argentina and is known to have affected 17 million individuals, of whom approximately 5 million develop clinical symptoms attributed to the disorder. Chagas' disease is a parasitic infection caused by the flagellate protozoan *Trypanosoma cruzi-* The parasite is transmitted to humans by reduvid bugs of the order *Hemiptera* when the proboscides (sucking mouth parts) pierce the skin of their host to feed. The micro-organism is not introduced with the insect bite, but rather it is passively deposited in reduvid feces and subsequently penetrates the bite wound into the bloodstream.

Once the protozoan gains access to the host circulation three stages of disease ensue. The acute phase is marked variably by either no symptoms or alternatively by malaise,

local inflammation, gastrointestinal symptoms, and lymphadenopathy. The second phase, typically occurring approximately 3 months after initial inoculation, may last for years and is an asymptomatic period. During this time serological test results for trypanosomiasis become positive. The third or chronic stage affects approximately one third of patients and usually begins 10-20 years following the original reduvid bite. This phase is characterized by gastrointestinal, cardiac, and neurological manifestations. Approximately 10% of patients with chronic Chagas' disease develop a predominately sensory neuropathy.

Most patients with neuropathy complain of paresthesia in the distal lower limbs. On examination, distal hypesthesia and hyporeflexia are found, usually limited to the lower limbs, occasionally involving all four extremities, and rarely only in the distal upper limbs. Electrophysiological findings include low-amplitude sensory and motor responses, reduced NCVs, and distal neurogenic motor unit potential changes by EMG. Sural nerve biopsy demonstrates decreased density of large and small myelinated fibers, axonal clusters indicating regeneration, and on teased fiber preparations, paranodal and segmental demyclination (Sica et al. 1995). Although both itraconazole and allopurinol have shown to improve electrocardiographic abnormalities in Chagas' disease, there is little information regarding the efficacy of such therapy for the neuropathy (Apt et al. 2003).

Chapter 83
Disorders of the Autonomic Nervous System

Christopher J. Mathias

The autonomic nervous system supplies and influences virtually every organ in the body (Figure 83.1). Its effector (efferent) component consists of two major divisions, the sympathetic and parasympathetic nervous systems, whose activity is influenced by several factors: afferent signals from different parts of the body, neurons in the spinal cord, and cerebral centers, mainly in the hypothalamus and brainstem. Autonomic dysfunction may result from lesions in one or more areas of the central or peripheral nervous system. This may result in a generalized disorder, either restricted to the autonomic nervous system (as in primary autonomic failure [PAF]) or involving other neurological systems (as in multiple system atrophy [MSA] or Shy-Drager syndrome) (sec also Chapter 77), Autonomic impairment may complicate disease processes affecting multiple organs (as in diabetes mcllitus or systemic amyloidosis) or may be localized. The latter may cause varying effects: minimal symptoms (in Horner's syndrome); considerable discomfort, which may be socially unacceptable (in gustatory sweating); and even life-threatening episodes (in carotid sinus hypersensitivity). The clinical problems in autonomic disorders, although often caused by failure, may result from the reverse; examples are increased activity causing hyperhid rosis or hypertension, which may occur in tetanus, Guillam-Barre syndrome, or high spinal cord lesions.

BASIC NEUROANATOMICAI., NEUROPHYSIOLOGY AL, AND NEUROCHEMICAL PRINCIPLES

The afferent pathways influencing the autonomic nervous system consist of virtually every sensory pathway (Figutc 83.2), as observed in the autonomic control of blood pressure. The major baroreccptor afferent: in the carotid sinus and aortic arch relay information to the brain through cranial nerves IX (glossopharyngeal) and X (vagal), Receptors in the heart and lungs (cardiopulmonary baroreceprors), skin, muscle, and viscera also influence blood pressure. Their role may be unmasked in tetraplegic patients with cervical cord transection above the spinal sympathetic outflow, in whom the peripheral sympathetic and cranial parasympathetic nervous systems function independently of the brain.

The major cerebral centers concerned with autonomic regulation include the insula, amygdala, hypothalamus, midbrain (Fdinger-Westphal nucleus and locus ceruleus), and brainstem (nucleus tractus solitaries and vagal nuclei). There is evidence in humans, using a combination of ncuroimaging and physiological studies, that other cerebral areas influence the central autonomic network (Critchley etal. 2000, 2001a).

The parasympathetic outflow consists of cranial and sacral efferents. Cranial efferents accompany cranial nerves III, VI, IX, and X and supply the eye, lacrimal and salivary glands, heart and lungs, and gastrointestinal tract with associated structures, down to the level of the colon. The sacral outflow supplies the urinary tract and bladder, the large bowel, and the reproductive system. Cerebral and spinal parasympathetic nuclei have specific control, for example, the Edinger-Westphal nucleus in pupillary control and OnuPs nucleus in the second and third sacral segments in urinary sphincter function. Most parasympathetic ganglia are close to target organs, and acetylcholine is the major transmitter at the ganglia and at postganglionic sites (Figure 83.3).

The sympathetic outflow is connected with major nuclei in the hypothalamus, midbrain, and brainstem and descends through rhe cervical spinal cord, where axons synapse in the intermediolateral cell mass. From the thoracic and upper lumbar spinal segments, myelinated axons emerge in the white rami and synapse in the paravertebral ganglia, which are some distance from the target organs. The major ganglionic transmitter is acetylcholine. Postganglionic fibers, which are unmyelinated, rejoin the mixed nerve through the gtay rami and innervate

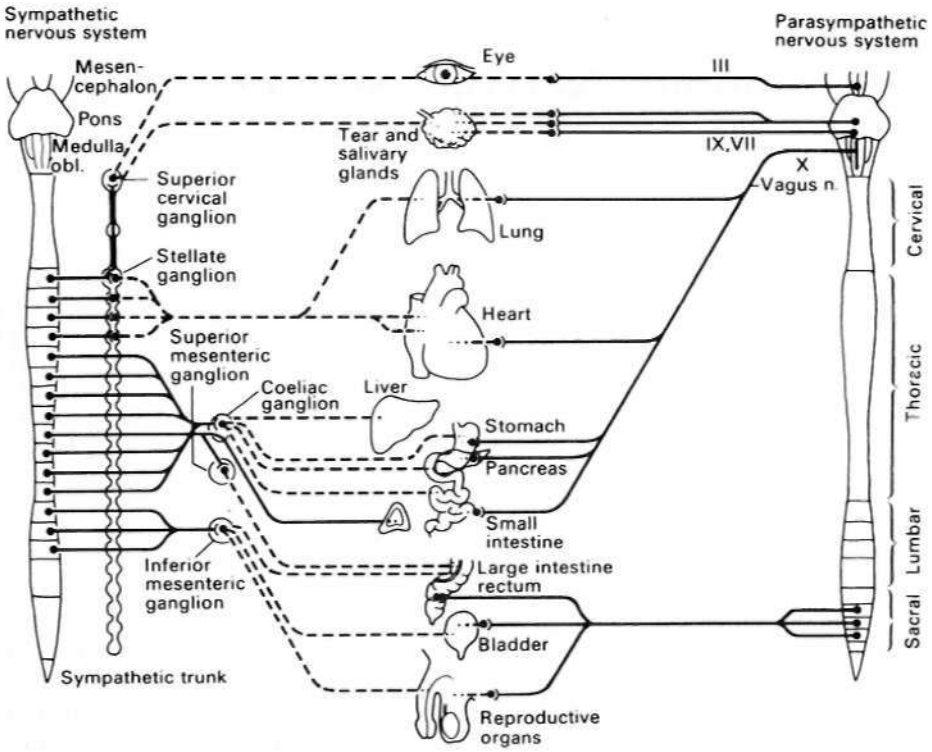

FIGURE 83.1 Parasympathetic and sympathetic innervation of major organs. (n. = nerve; obl. = oblongata.) (Reprinted with permission from Janig, W. 1987, "Autonomic nervous system," in *Human Physiology*, 2nd ed, eds R. F. Schmidt & G. Thews, Springer, Berlin, p. 333.)

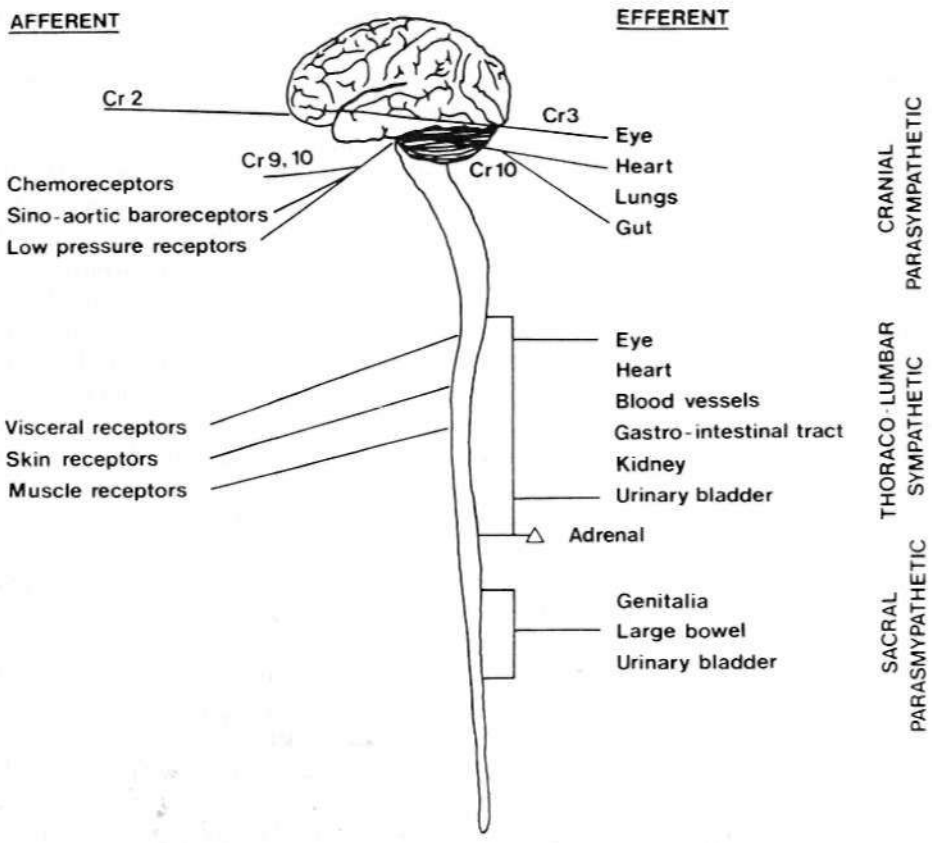

FIGURE 83.2 Schema to indicate the major afferent components that influence parasympathetic and sympathetic afferent activity. (Cr = cranial nerve.)

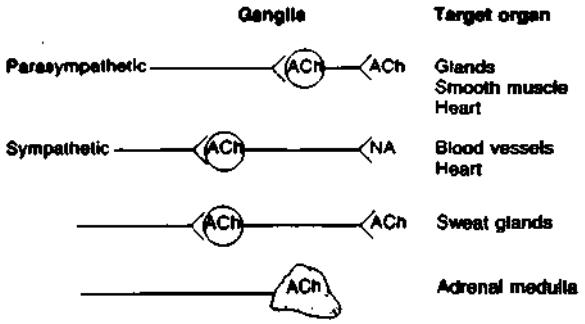

FIGURE 83.3 Outline of the major transmitters at autonomic ganglia and postganglionic sites on target organs. Ganglionic blockade at nicotinic receptors with hexamethonium prevents both parasympathetic and sympathetic activation. Atropine, however, only acts on muscarinic receptors at postganglionic parasympathetic and sympathetic cholinergic sites. (ACh = acetylcholine; NA = noradrenaline.)

target organs except for the adrenal medulla, which has only a preganglionic supply. The neurotransmitter at postganglionic sites is predominantly noradrenaline, although sympathetic cholinergic fibers (with acetylcholine as the transmitter) supply sweat glands.

There arc complex pathways in neurotransmitter formation, release, and function, as illustrated with the catecholamines (Figure 83.4). Many neurons have multiple neurotransmitters, which may be nonadrencrgic and noncholinergic. For example, vasoactive intestinal polypeptide is co-secreted with acetylcholine, which explains the inability of atropine to block all the effects of parasympathetic stimulation, whereas neuropeptide Y may be released with noradrenaline, thus accounting for the fact that or-adrenoceptor blockers may not completely prevent the effects of sympathetic neural stimulation. The availability of specific agonists and antagonists should help dissect the interactions of numerous peptides, amino acids, and amines at multiple sites in response to different stimuli. Despite the multiplicity of neurotransmitters and neuromodulators, however, the autonomic nervous system selectively controls responses in specific regional vascular territories and organs, making it a highly complex but precisely regulated and integrated system.

CLASSIFICATION

Autonomic disorders can be broadly divided into primary, in which no cause has been determined, and secondary (Table 83.1), which are due to specific diseases (such as

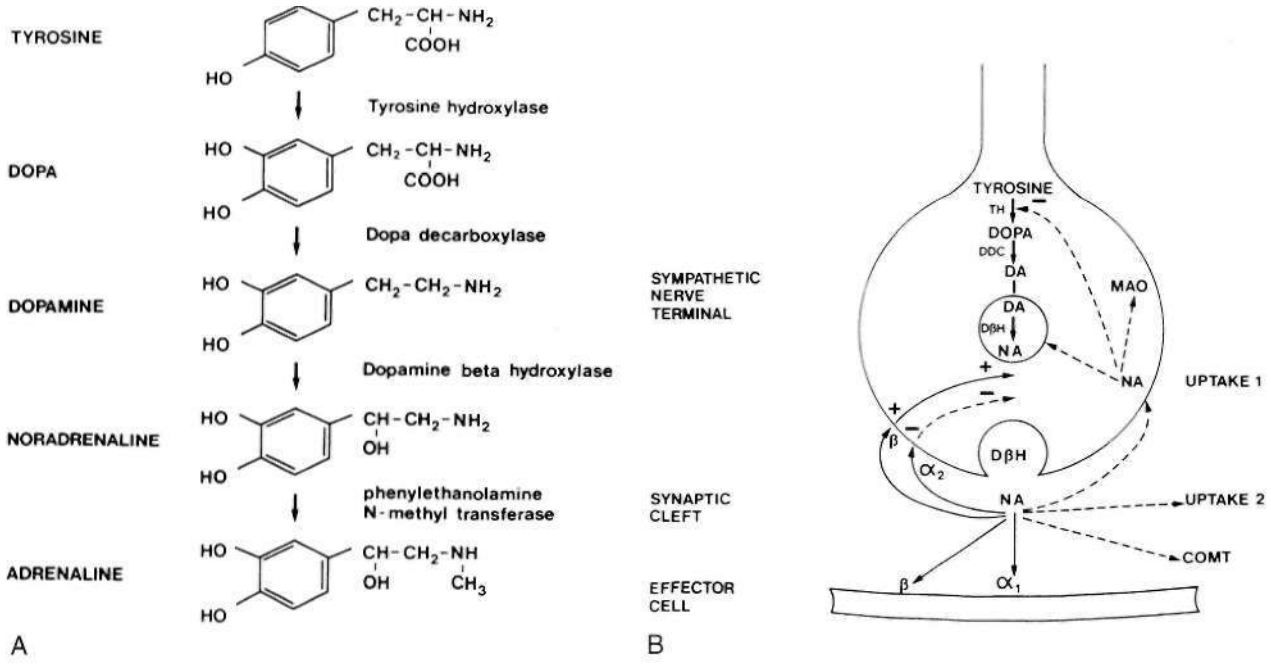

FIGURE 83.4 (A) Outline of biosynthetic stages and enzymes involved in the formation of noradrenaline and adrenaline from tyrosine. IB) Schema of some pathways in the formation, release, and metabolism of noradrenaline from sympathetic nerve terminals. Tyrosine is converted into dihydroxyphenylalanine (DOPA) by tyrosine hydroxylase (TH). DOPA is converted into dopamine (DA) by dopa decarboxylase (DDC). In the vesicles, DA is converted into noradrenaline (NA) by dopamine /J-hydroxylase *(DfiH).* Nerve impulses release both *D0U* and NA into the synaptic cleft by exocytosis. NA acts ptedominantly on a_t-adrenoceptors but has actions on /S-adrenoceptors on the effector cell of target organs. It also has presynaptic adrenoceptor effects. Those acting ono^-adrcnoceptors inhibit NA release; those on ^-adrenoceptors stimulate NA release. NA may be taken up by a neuronal process (uptake 1) into the cytosol, where it may inhibit further formation of DOPA through the rate-limiting enzyme TH. NA may be taken into vesicles or mct.ibolr/.cd by-monoamine oxidase (MAO) in the mitochondria, NA may be taken up by a higher-capacity but lower-affinity extra neuronal process (uptake 2) into peripheral tissues, such as vascular and cardiac muscle and certain glands. NA is also metabolized by catechol-O-methyl transferase (COMT). Thus NA measured in plasma is the overspill not affected by these numerous processes.

Table 83.1: Classification of disorders resulting in autonomic dysfunction

- Primary (etiology unknown)
  - Ai utL' **.in..!** subacute d;. ••.nmnii 'ini.r.
    - Pure cholinergic dysautonomia
    - Pure pandysautonomia
    - Pan dysautonomia with neurological features
  - Chronic autonomic failure syndromes
    - Pure autonomic failure
    - Multiple system atrophy [Shy-Drager syndrome'
    - Autonomic failure with Parkinson's disease
- Secondary
  - Congenital
    - Nerve growth factor deficiency
  - Hereditary
    - Autosomal dominant trait
      - Familial amyloid neuropathy
      - Porphyria
    - Autosomal recessive trait
      - Familial dysautonomia (Riley-Day syndrome)
      - Dopamine ^-hydroxylase deficiency
      - Aromatic l-amino acid decarboxylase deficiency
    - X-linked recessive
      - Fabry's disease
  - Metabolic diseases
    - Diabetes mellitus
    - **Chronic renal failure**
    - Chrome liver disease
    - Vitamin B_u deficiency
    - Alcohol-induced
  - Inflammatory
    - Guillain-Barre syndrome
    - Transverse myelitis
  - Infections
    - Bacterial: tetanus
    - Viral: human immunodeficiency virus
    - Parasitic: *Trypanosoma cntzi;* Chagas' disease
    - Prion: fatal familial insomnia
  - Neoplasia
    - Brain tumors, especially of third ventricle or posterior fossa
    - Paraneoplastic, to include adenocarcinomas: lung, pancreas, and Lambert-Eaton syndrome
  - Connective tissue disotdets
    - Rheumatoid arthritis
    - Systemic lupus erythematosus
    - Mixed connective tissue disease
  - Surgery
    - Regional sympathectomy: upper limb and splanchnic denervation
    - Vagotomy and drainage procedures: "dumping" syndrome
    - **Organ transplantation: hcatt, kidney**
  - **Trauma**
    - Spinal cord transection
  - Miscellaneous
    - Subatachnoid hemorrhage
    - Syringobulbia and syringomyelia
- Neutally mediated syncope
  - Vasovagal syncope
  - Carotid sinus hypersensitivity
  - Micturition syncope
  - Cough syncope
  - Swallow syncope
  - Associated with glossopharyngeal neuralgia

Table 83.2: Drugs, chemicals, poisons, and toxins causing auroni imif d\ -.Inn.. . . .I

- Decreasing sympathetic activity
  - Centrally acting
    - Clonidine
    - Mcthyldopa
    - Moxonidine
    - Reserpine
    - Barbiturates
    - Anesthetics
  - Peripherally acting
    - Sympathetic nerve ending (guanethidinc, bethanidine)
    - **or-Adrcnoccptor blockade {phcnoxybcni'.aminc}**
    - ^-Adrenoceptor blockade (propranolol)
- Increasing sympathetic activity
- Amphetamines
  - Releasing noradrenaline (tyramine)
  - Uptake blockers (imipramine)
  - Monoamine oxidase inhibitors (tranylcypromine)
  - *fi*-Adrenoceptor stimulants (isoprenaline)
- Decreasing parasympathetic activity
  - Antidepressants (imiptamine)
  - Tranquilizers (phenothiazines)
  - Antidysrhythmics (disopyramide)
  - Anticholinergics (atropine, propantheline bromide, be nztt opine)
  - Toxins (hotuhnum)
- Increasing parasympathetic activity
  - Cholinomimetics (carbachol, bethanechol, pilocarpine, mushroom poisoning)
  - Anticholinesterases
    - Reversible carbamate inhibitots (pyridostigmine, neostigmine)
    - Organophosphorous inhibitors (pa rath ion, sarin)
- Miscellaneous
  - Alcohol, thiamine (vitamin B|) deficiency
  - Vincristine, perhexiline malcate
  - Thallium, arsenic, mercury
  - Mercury poisoning (pink disease)
  - Ciguatera toxicity
  - Jellyfish and marine animal venoms
  - First dose of certain drugs (prazosin, captopril)
  - Withdrawal of chronically used drugs (clonidine, opiates, alcohol)

diabetes mellitus) or for which there are strong associations, as with Holmes-Adit: syndrome or aging. Drugs arc a major cause of autonomic dysfunction, acting at single or multiple sites (Tabic 83,2), In neutally mediated syncope, there is an intermittent autonomic abnormality-, as occurs in vasovagal syncope and carotid sinus hypersensitivity. Tabic 83.3 provides examples of autonomic disorders in which localized deficits affect specific organs.

Primary Autonomic Failure

Disorders of primary autonomic failure are those in which autonomic failure is of unknown etiology. Most arc chronic autonomic failure syndromes.

Tabic 83.3: Examples of localised autonomic disorders

Homer's syndrome
Holmes-Adie pupil
Crocodile tears (Bogorad's syndrome)
Gustatory sweating (Frey's syndrome)
Reflex sympathetic dystrophy
Idiopathic palmar or axillary hyperhidrosis
Chagas' disease *(Trypanosomiasis cruzi)**
Surgical procedures
Sympathectomy (regional)
Vagotomy and gastric drainage procedures in "dumping" syndrome
Organ transplantation (heart, lungs)

'Listed here because it specifically targets intrinsic cholinergic plexuses in the heart and gut.

Surgery also may cause other localized disorders, such as Frey's syndrome (after parotid surgery).

Table 83.4: Some of the clinical manifestations in primary chronic autonomic failure

Cardiovascular: postural (orthostatic) hypotension
Sudomotor: anhidrosis, heat intolerance
Gastrointestinal: constipation, occasionally diarrhea, oropharyngeal dysphagia
Renal and urinary bladder: nocturia, frequency, urgency, retention, incontinence
Sexual: erectile and ejaeulatory failure in the male
Ocular anisocoria, Horner's syndrome
Respiratory: stridor, involuntary inspiratory gasps, apneic episodes
Other neurological deficits: parkinsonian and cerebellar or pyramidal features

Chronic Autonomic failure

These patients often have both sympathetic and parasympathetic failure {Table 83.4). Clinically they fall into three major categories (Figure 83.5). Patients with autonomic failure alone and no other neurological features have PAH. This group encompasses *idiopathic orthostatic hypotension* (without other neurological defects), a term that does not indicate the possible autonomic involvement of sweat glands, pupils, and urinary bladder, bowel, and sexual function. When primary chronic autonomic failure is associated with other neurological abnormalities and without a defined cause or association, the term *Shy-Drager syndrome* was used after the first neuropathologic.il description and linkage between orthostatic hypotension and neurological abnormalities. *MSA* is now used synonymously with *Shy-Drager syndrome.* At a consensus meeting of international experts, MSA was defined as a "sporadic, progressive disorder characterized by autonomic dysfunction, parkinsonism, and ataxia in any combination'[1] (SchatZ et al. 1996, Gtlman et al. 1998). There are three major clinical forms of MSA, based on the additional neurological features. The presence of parkinsonian features is associated with stria tonigral degeneration and loss of pigmented cells in the substantia nigra and locus eeruleus; this is the *parkinsonian* ot *striatonigrat degeneration form.* There may be cerebellar manifestations, with or without pyramidal signs, and association with atrophy of the cerebellum, olives, and pons (the *cerebellar* or *olivopontocerebellar atrophy form).* Many patients, especially as the disease progresses, have a combination of extrapyramidal, cerebellar, and pyramidal manifestations *(mixed* or *multiple form).*

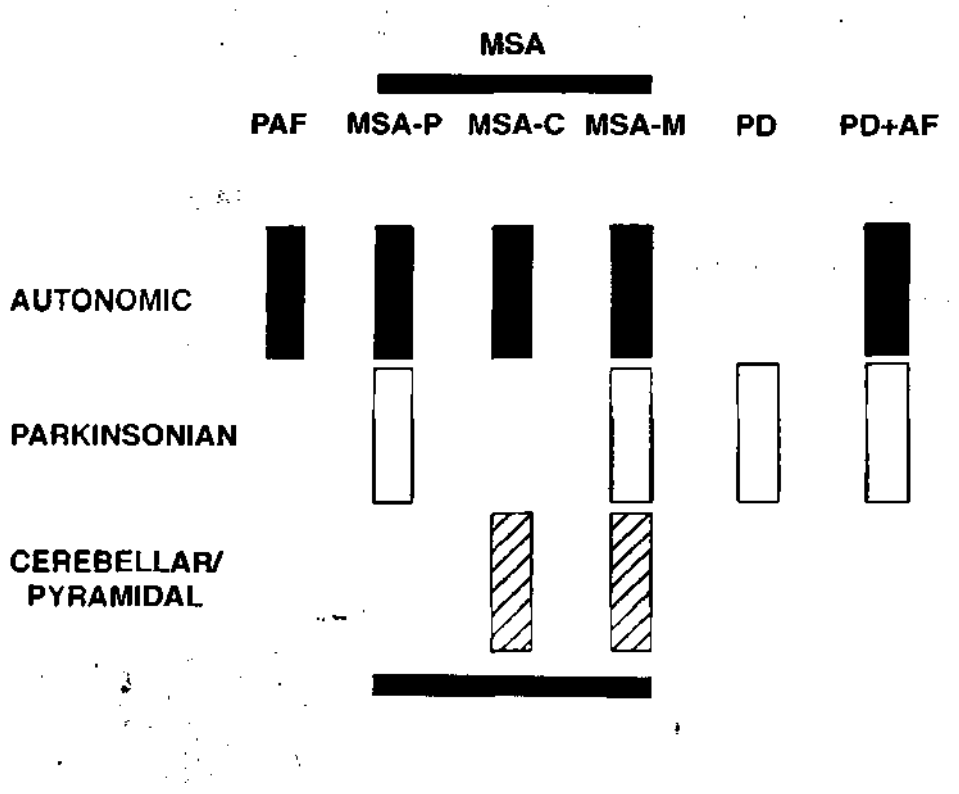

FIGURE 83.5 Schematic representation of the major clinical features of primary chronic autonomic failure syndromes. These include pure auronomic failure (PAF) and the three major neurological forms of multiple system atrophy (MSA): the parkinsonian form (MSA-P, synonymous with striatonigral degeneration), the cerebellar form (MSA-C, synonymous with olivopontocerebellar atrophy), and the mixed lorm (MSA-M, with both features). Also included are Parkinson's disease (PD) and the tarer subgroup with Parkinson's disease and autonomic failure (PD+AF). (Modified with permission from Mathias, C.J. 1997, "Autonomic disorders and their recognition," N *Engl] Med,* vol. 10, p. 721.)

In our autonomic units, which serves as a national referral centers, approximately 20% of patients have the parkinsonian form, 20% have the cerebellar form, and 60% have the multiple form. This distribution probably varies, depending on referral patterns, the special interests of the hospital, early consideration of the diagnosis, and the presence of an autonomic unit.

Extrapyramidal features may predate autonomic failure in the parkinsonian form of MSA, which may be difficult to differentiate from idiopathic Parkinson's disease, especially in the early stages. This problem has been highlighted in postmortem studies, in which 7-22% of patients who were thought to have idiopathic Parkinson's disease actually had MSA. Separating the two disorders is important because the prognosis is considerably poorer for patients with MSA, and the occurrence and nature of complications and the management of the conditions differ (Mathias and Williams 1994; Wcnning et al. 1994, 1997). There are some differences in the extrapyramidal features between MSA and Parkinson's disease (Quinn and Marsdcn 1993), but these may not be clinically valuable, especially in individual subjects in the early stages of the diseases. Although many patients with MSA do not respond favorably to L-dopa or experience substantial side effects, such as postural hypotension, a proportion with the parkinsonian form have a benefit, especially- in the early stages (Colosimo et al. 1995), as do the majority with idiopathic Parkinson's disease. Differentiation of the two groups is important for drug trials and interventional studies (e.g., as with substantia nigra implantation) because those with MSA arc unlikely to show a favorable response.

There is accumulating evidence of autonomic nervous system involvement in idiopathic Parkinson's disease. However, the extent and degree of autonomic dysfunction vary and appear to depend on factors that include age and duration of disease (Mathias 1998). There is a smaller group with apparent idiopathic Parkinson's disease in whom substantial cardiovascular autonomic failure may occur, often as a late complication (Goldstein et al. 2002). These patients usually are elderly and have been successfully treated with L-dopa and other antiparkinsonian drugs for many years. They thus differ clinically from those who have the parkinsonian forms of MSA. It is not clear if they ate a Special group with idiopathic Parkinson's disease who arc vulnerable to autonomic degeneration ot their autonomic failure is associated with old age, chronic drug therapy, or a combination of such factors.

In the different parkinsonian syndromes (other than MSA) the extent and degree of autonomic dysfunction relates to the underlying diagnosis. Cardiovascular autonomic failure is an exclusionary feature in progressive supranuclear palsy (Kimher et al. 2001). In dementia with Lewy bodies, orthostatic hypotension and autonomic failure may be severe and an early manifestation, even before the onset of parkinsonian features (Lamer et al. 2000; Hishikawa et al. 2000). Autonomic deficits have been described in patients with the Guam parkinsonian dementia complex, the Machado-Joseph syndrome (Kazura et a I. 2000), and Wilson's disease {Bhattacharyaetal, 2002; Meenakshi-Sundarametal. 2002).

In chronic primary autonomic failure syndromes, a common feature accounting for sympathetic dysfunction is loss of small sympathetic cells in the intetmediolateral cell column of the thoracic and lumbar spinal cord (Figure 83.6). In PAF, for which limited neuropathological data are available, there also is substantial neuronal cell loss in the paravertebral sympathetic ganglia (Matthews 2002). Some of the surviving ganglionic neurons in the paravertebral ganglia show Lewy bodies that are not found in MSA; these

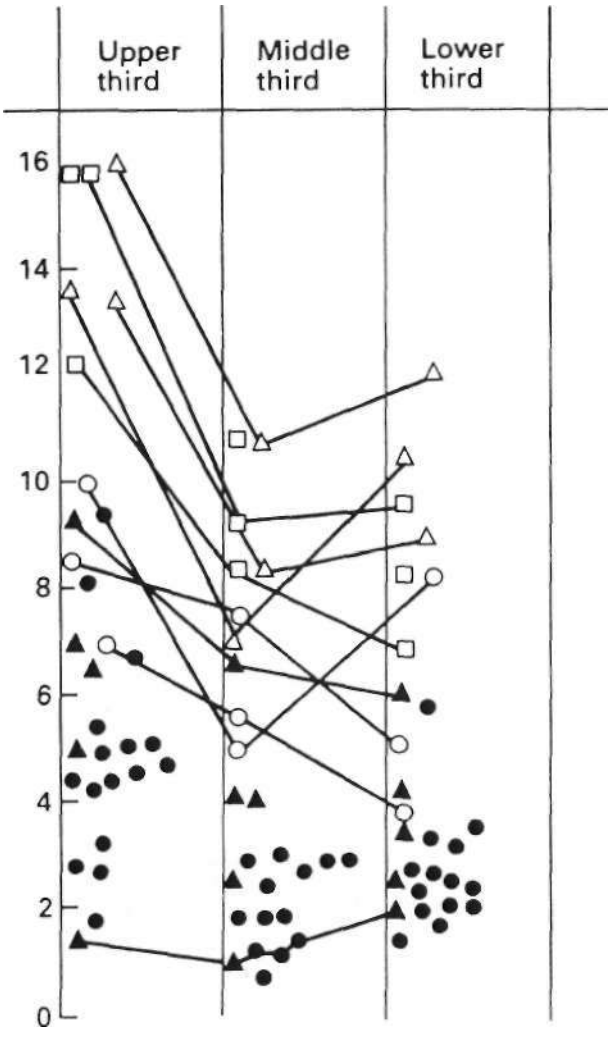

FIGURE 83.6 Cell counts in intermediolateral horns of upper, middle, and lower thoracic spinal cord. Figures indicate mean number of cells in ;i single lateral horn and 20-mm sections in control specimens. These include three patients with Parkinson's disease without autonomic failure (A), three patients with multiple system atrophy without autonomic failure (O), 16 patients with autonomic failure (•), and five patients with autonomic failure showing Lewy bodies in the brainstem (A). (Reprinted with permission from Oppenheimer, D. R., et al. 1980, "Lateral horn cells in progressive autonomic failure," / *Neurol Set,* vol. 46, pp. 393-404.)

include "eosinophilic bodies" of bi/.arre serpiginous form, now regarded as intraneuritic Lewy bodies. The absence of additional neurological features and the available biochemical and hormonal evidence, which excludes central cerebral involvement (Kimber et al. 1997b; Mathias and Polinsky 1999), are consistent with a peripheral sympathetic lesion in PAF. In MSA, the evidence points to predominantly cerebral autonomic lesions. In addition, there is cell loss in the intermediolateral cell column of the thoracic and lumbar spinal cord. A further feature is the involvement of neurons in the margins of the ventral horn ol the second ami ihiol ^ural segments (Omif's nucleus), which innervate the voluntary sphincters of the urinary bladder and anus. These nuclei arc spared in motor neuron diseases, which suggests that they are more likely to be parasympathetic than somatic neurons. It is not known if these cell groups are affected in PAF. In MSA, neurons of sympathetic ganglia usually are not severely reduced in number and do not exhibit major abnormalities, apart from a relative lack of Nissl material, which suggests partial denervation atrophy of long-standing duration.

In MSA, neuropathologies! studies indicate widespread abnormalities in the brain (Daniel 2002). In the parkinsonian form, the proportion of brainstem and cerebellum to whole brain is normal, unlike in the cerebellar form. In the parkinsonian form, the putamen is shrunken with gray-green discoloration, and in severe forms, there is a cribriform appearance. Atrophy and discoloration of the caudate nucleus and pallidum are less common. The substantia nigra shows decreased pigmentation. There is pallor of the locus ceruleus. In the cerebellar form, the pons and the middle cerebellar peduncles are reduced, with atrophy of the folia. On microscopy, there is cell loss and gliosis in the parkinsonian forms, particularly in the putamen, and especially in the posterior two thirds and dorsolateral regions, although this may be more widespread. Similar changes also occur in the caudate nucleus and globus pallidus but to a lesser extent than in the putamen. In the zona compacta of the substantia nigra, there is degeneration of pigmented nerve cells, as in the locus ceruleus. In the cerebellar form, the neuropathological changes may be indistinguishable from those with familial forms of olivopontocerebellar atrophy. There is cell loss in the cerebellum, olives, and pons. Purkinje's cell nerve loss is often focal, rarely complete, and not accompanied by basket cell loss and thus different from cerebellar anoxic damage, in which both cell groups arc vulnerable.

The parkinsonian forms of MSA show features indicative of striatonigral degeneration, while those with the less common cerebellar form show olivopontocerebellar degeneration. Despite characteristic pathological changes in one or the other system in the two forms, there is often widespread involvement ncuropathologically, consistent with in vivo findings using positron-emission tomography (PET) (Rinne et al. 1995). As the disease progresses, there is likely to be an increasing degree of cell loss and gliosis,

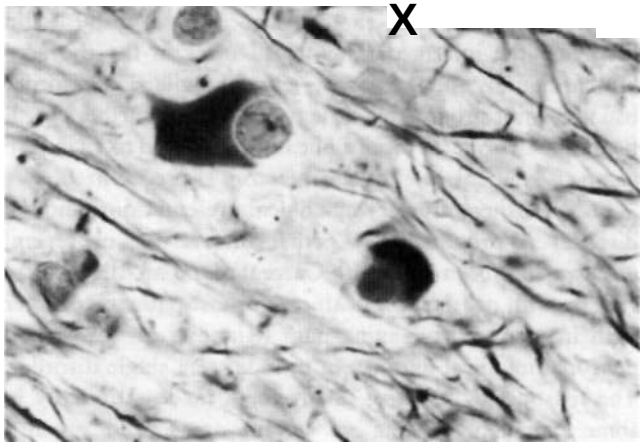

FIGURE 83.7 Photomicrograph showing appearance of oligodendrocyte glial cytoplasmic inclusions with modified Bielschowsky's silver impregnation and immunocytochemistry for cr-tubulin (frontal cortex, x 1250). (Reprinted with permission from Daniel, S. E. 2002, "The neuropathology and neuroehetnistry of multiple system atrophy," in *Autonomic Failure. A Textbook of Clinical Disorders of the Autonomic Nervous System*, 4th ed, eds C. J. Mathias Sc R. Bannister, Oxford University Press, Oxford, pp. 321-328.)

which probably accounts for the varying pathological descriptions provided over the years.

A key feature in MSA has been the presence of glial intraneuronal cytoplasmic nuclei inclusions (Papp and Lantos 1994) (Figure 83.7). These stain with antibodies against ubiquitin, a- and ^-tubulin, and r, thereby indicating a site of origin from cytoskeletal proteins. In MSA, they are present in large numbers and provide a pathological hallmark for the definition of the condition (Daniel 2002). They are also present in previously considered unaffected areas of the brain. Inclusions similar to those in MSA have been described in progressive supranuclear palsy, corticobasal degeneration, and familial olivopontocerebellar atrophy. However, in these conditions they arc rare, require careful search, and have distinct differences in T profile. In MSA, cr-synuclein is present in inclusions and appears different from that of dementia with Lewy bodies and Parkinson's disease (Campbell et al. 2001). These differences may contribute further ro our understanding of MSA and other parkinsonian syndromes.

In MSA, a number of additional sites may be involved. These include degeneration of the thalamus and vestibular complex. There is a reduction of Edinger-Westphal neurons. Cell loss in the hypothalamus is minimal but with an apparent depletion of various catecholamines and neurotransmitters, which may account for the neuroendocrine abnormalities and impairment of hypothalamic function reported. There often is atrophy of the dorsal motor nucleus of the vagus. Despite laryngeal dysfunction being common, cell loss has not been documented in the nucleus atnbiguus, which suggests a central biochemical deficit or more peripheral involvement or both.

In summary, in PAF, the evidence favors a distal lesion involving the intermcdiolateral cell mass in the thoracolumbar regions and the paravertebral ganglia. The disorder usually is not progressive. It is probable that further classification will occur in those clinically considered to have PAF as precise deficits or etiological factors are recognized.

In MSA, there are varying clinical presentations, and the disorder is progressive. Whether this is one or several diseases has been debated. Current data on the clinical course, with overlapping features in most patients together with in vivo neuroimaging data (Rinne et al. 1995) and neuropathological data, seem to indicate a single disorder. The reasons for selective involvement (at least initially in some patients), sparing of certain areas, and possible interaction with genetic and environmental factors remain to be determined.

Acute and Subacute Dysautonamias

In the Guillain-Barre syndrome, a variety of autonomic disorders have been described, from hyperactivity to primary autonomic failure. These disorders can result in marked cardiovascular changes, from hypertension and tachycardia to hypotension and bradycardia. There arc differences between the axonal and myelinated forms of the Guillain-Barre syndrome (Asahina ct al. 2001). Autonomic disturbances contribute to both morbidity and mortality.

Acute and subacute dysautonomias are rarer causes of primary autonomic failure. The precise reasons are unclear and may include viral infections, with immunological damage as a contributory factor. Two case reports have indicated a beneficial response to the intravenous administration of immunoglobulin, which favors an immunological etiology (Hcafiek! ct al. 1996; Smit et al. 1997). There are three clinical forms. In pure cholinergic dysautonomia, parasympathetic and sympathetic cholinergic pathways are impaired, resulting in alacrima, xerostomia, dysphagia, large bowel atony, detrusor muscle dysfunction, and, in men, erectile failure; anhidrosis also occurs. Thus only the cholinergic system is affected. There is a response to cholinomimetic agents, such as bethanechol, indicating preservation of postsynaptic cholinergic receptor function and suggesting a presynaptic lesion. In the other forms with pandysautonomia, the parasympathetic and sympathetic nervous systems are impaired. In some patients, there are no other neurological features, whereas in others, there may be additional neurological lesions, often involving peripheral nerves. These lesions have been demonstrated on sural nerve biopsy, which shows a reduction in the numbers of both myelinated and unmyelinated fibers.

Secondary Autonomic Dysfunction

The pathological changes of secondary autonomic dysfunction depend on the causative or associated disease or disorder. A brief description of some of the changes is provided in the following sections, based on the probable site of lesion within the nervous system,

Cerebral

Autonomic failure may result from specific lesions, especially in the brainstem. Posterior fossa tumors and syringobulbia may cause postural hypotension by ischemia or destruction of brainstem cardiovascular centers. Dcmyelination or plaque formation in multiple sclerosis may cause a variety of autonomic defects of cerebral origin, although it is difficult to exclude a spinal contribution (Thomaides et al. 1993; Kcselbrener et al. 2000). Autonomic failure in elderly patients may be largely central, due to widespread neuronal degeneration, although peripheral neural and target organ deficits may contribute.

Certain cerebral disorders cause a pathological increase in autonomic activity. In bulbar poliomyelitis, hypertension has been associated with damage in the lateral medulla. In cerebral tumors, distortion or ischemia of specific pressor areas, which have been defined experimentally and termed *Cusbing-sensitive areas,* may raise blood pressure by increasing sympathetic activity. This may account for the symptoms in a patient of Penfield, who had a tumor of the third ventricle and was thought to have diencephalic autonomic epilepsy. Similar mechanisms may also account for increased sympathetic activity, hypertension, and cardiac dysrhythmias associated with subarachnoid hemorrhage, although the local effects of various chemicals from extravasated blood also may influence cerebral centers. In tetanus, hypertension may result from increased sensitivity of brainstem centers through retrograde spread of tetanus toxin along the nerve fibers. In fatal familial insomnia, a prion disease predominantly involving the thalamus, there are abnormalities of autonomic function. These include increases in blood pressure, heart rate, lacrimation, salivation, sweating, and body temperature, along with altered hormonal arcadian rhythms in the presence of intact target organ function (Cortelli et al. 1997).

Spinal Cord

Damage to the spinal cord by trauma, transverse myelitis, syringomyelia, or spinal cord tumors may disturb or sever connections between the brain and the thoracolumbar sympathetic and sacral parasympathetic outflow. Spinal reflexes through unaffected areas in the cord below the lesion may be activated, resulting in abnormal peripheral autonomic activity.

Peripheral

Peripheral autonomic dysfunction is associated with a wide range of diseases and syndromes. It may involve a specific afferent pathway, as in carotid sinus hypersensitivity. The

lesion may involve efferent pathways only, as in dopamine ri hydroxylase (Dblli Jilkiuk}, which selectively causes deficiency of noradrenaline and adrenaline, with elevation of the precursor dopamine and preservation of other transmitters in sympathetic nerve terminals (Mathias and Bannister 2002a). In a brother and sister with this disorder, genetic studies indicated an autosomal recessive transmission. DBH genes have been identified on chromosome 9, linked to 9q34, and do not have any obvious deletions in this disorder, thus raising the likelihood of point mutations, recently have been described (Kim et al. 2002). In the Eaton-Lambert syndrome, the cholinergic system is primarily affected. In diabetes mellitus, different autonomic pathways may be affected as the disease progresses; the cardiac parasympathetic nerve is often involved first, with sympathetic dysfunction occurring later. There may be associated involvement of specific components of peripheral nerves in certain disorders. One of these is nerve growth factor deficiency, which results in the deficiency of DBH, the sensory neuropeptides, substance P, and calcitonin gene-related peptide. Another such disorder is the Riley-Day syndrome (familial dysautonomia), with mutation of the *IKAP* gene (Anderson ct al. 2001); pathological changes occur in both dorsal root and sympathetic ganglia.

In amyloidosis, deposits in the heart, blood vessels, and adrenal glands (causing adrenocortical deficiency) may compound autonomic dysfunction and thus increase the severity of orthostatic hypotension. There is increasing evidence of differences in autonomic dysfunction in the various mutations, resulting in familial amyloid polyneuropathy. Deposition of abnormal protein in autonomic nerves can affect cardiovascular, sudomotor, gut, bladder, and sexual function. The heart also may be affected directly, by amyloid deposition.

Autonomic dysfunction may complicate malignancies, including as a paraneoplastic syndrome (Waterman 2001), in which it is often not possible to determine the site of the lesion. Acquired immunodeficiency syndrome is associated with several autonomic abnormalities. Pheoehromoeytoma occasionally may be part of multiple endocrine neoplasia (such as Sipplc's syndrome) or may be associated with neurofibromatosis and other neuroectodermal syndromes (tuberous sclerosis, von Hippel-I.indau disease, and Sturgc-Weber syndrome). Carotid body tumors, ganglioneuromas, and neuroblastomas also arise from neuroectodermal tissue but arc less likely to result in abnormal catecholamine secretion.

Neurally Mediated Syncope

Neurally mediated syncope is a disorder in which there is intermittent dysfunction affecting the autonomic nervous system. This dysfunction results in bradycardia due to increased parasympathetic cardiac activity and hypotension due to withdrawal of sympathetic vasoconstrictor tone. It probably accounts for a substantial proportion of recurrent syncope and prcsyncope, in which a cardiac, nonautonomic neurological or metabolic cause has been excluded (Mathias ct al. 2001a). In the young, a common cause is vasovagal syncope. In elderly patients, carotid sinus hypersensitivity is increasingly recognized. Rarer causes include those associated with neoplasia affecting the glossopharyngeal nerve.

Situational syncope occurs in weigh differs; other examples are during micturition, defecation, or even laughing. There is an association between syncope and the first dose of certain drugs (prazosin and acetylcholinesterase inhibitors).

Drugs, Chemicals, and Toxins

Drugs, chemicals, and toxins may act by interfering with, or stimulating, sympathetic or parasympathetic activity (Tonkin and Hrewin 2002) (see Table S3.2). A minor side effect of a drug may unmask or worsen autonomic deficiency; an example is postural hypotension, which is usually enhanced by L-dopa in the parkinsonian and mixed forms of MSA. Drugs administered locally, such as the beta blocker timolol (ocular drops), the u^-agonist xytometazoline, and the «-agonist phenylephrine (intranasally), may enter the systemic circulation and have deleterious effects.

Alcohol may impair autonomic function cither directly, by causing a neuropathy, or through associated deficiencies, such as that of vitamin Bi (thiamine). The withdrawal of drugs, such as alcohol, opiates, and clonidine, especially when used in high doses chronically, may result in the reverse (sympathetic overactivity), with increased sweating, hypertension, and piloerection.

Vincristine is directly neurotoxic and may cause an .i-,-,tK lated autonomic neuropathy, as with pethexiline m.il eatc, an antianginal agent. The latter is mainly associated with a metabolic deficit, which slows its degradation. Thallium, arsenic, and mercury increase autonomic activity by mechanisms that are unclear. Botulism mainly results in cholinergic deficits, but there may be associated sympathetic involvement in severe cases. Consumption of reef fish containing ciguatera toxin may cause bradycardia through increased vagal tone, which can be reversed by atropine.

Localized Autonomic Disorders

In Horner's syndrome (see Table 83.3), the sympathetic fibers to the pupil, upper eyelid (the nonstriated portion of the levator palpebrae superioris, or Mtiller's muscle), facial sweat glands, and facial blood vessels are affected by lesions that could be in the brain (hemorrhage), spinal cord (trauma), or periphery (neoplasms affecting the cervical ganglia, as in Pancoast's syndrome). When only the eye is

involved, the lesion lies within the distribution of the internal carotid artery because the sympathetic nerves accompanying the external carotid artery arc intact, thus sparing the facial sweat glands and vessels (Raeder's syndrome).

Holmes-Adie pupil is a benign condition, usually seen in women, and is characterized by a dilated pupil that is sluggishly responsive to tight. The iris musculature is supersensitive to locally applied cholinomimetics, such as dilute mcthacholine or pilocarpine Hie pathologic change is thought to involve the parasympathetic ciliary ganglia. When the condition is associated with absent tendon reflexes, the term *Holmes-Adie syndrome* is used. The lesion is thought to involve the dorsal root ganglia, which accounts for the absent H wave on electrophysiological testing. Some patients have sudomotor abnormalities (Ross's syndrome), cardiovascular autonomic deficits, diarrhea, or a dry, chronic cough (Kimbcr ct al. 1998).

In the chronic form of Chagas' disease (after infection with *Trypanosoma cruzi),* there is fibrosis in the heart and damage to the sinus node and conducting system. The esophagus and colon often are involved after ganglionitis and destruction of Meissner's and Auerbach's plexuses, thus causing dilatation of the esophagus, stomach, or large bowel. In congenital megacolon (Hirschsprung's disease), parasympathetic ganglion cells from the intramural (Auerbach's) plexus are absent in localized segments of the rectum and sigmoid colon, often with sympathetic aplasia, and cause colonic narrowing with proximal distention.

Increased lamination due to an abnormal gustolacrimal reflex (crocodile tears or Bogorad's syndrome) results from cross-inncrvation of the lacrimal and salivary glands. It may be acquired after Bell's palsy (with the lesion at, or proximal, to the geniculate ganglion) or after surgery to the greater superficial petrosal nerve (which contains fibers to the lacrimal gland and the submandibular and sublingual salivary glands). It also may occur after damage to the lesser superficial petrosal nerve, which supplies the parotid glands. If bilateral, the disorder is usually congenital. A similar situation may occur in gustatory sweating, in which parasympathetic fibers to the salivary glands reinnervate the sweat glands that normally have a sympathetic cholinergic supply (auriculotemporal or Frey's syndrome).

Sympathetic nerve damage may occur win limb or brachial plexus injuries and be either pre- or postganglionic. Severe pain (causalgia) may result from abnormal connections between the efferent sympathetic nerves and somatosensory afferent nerves. Similar changes may occur in post-traumatic reflex sympathetic dystrophy (Sudeck's atrophy). The precise role of the sympathetic nervous system in such disorders is unclear (Kimber et al. 1997a) and is relevant to their management (Schott 1998).

Transplantation of organs such as the heart and kidneys leaves them bereft of their autonomic nervous supply. After cardiac transplantation, upregulation of ^-adrenoceptors may increase sensitivity to endogenous or exogenous catecholamines and could increase the risk from cardiac dysrhythmia. Renal function after transplantation does not appear to be impaired, although nocturnal polyuria may be attributed to lack of sympathetic control of tubular function. Re innervation may occur.

Clinical Features

Patients with primary chronic autonomic failure are usually middle-aged or elderly. There is a male predominance. Increased awareness of such disorders and earlier referral for autonomic investigation have resulted in recognition of a number of younger subjects, some in their mid-30s. A family history is unusual. Only two families with autonomic failure and additional neurological abnormalities have been reported, although from the descriptions available they were unlikeh to have VISA. In MSA, there is no evidence that genetic, environmental, or occupational risk factors contribute.

In secondary autonomic failure, the age of onset depends on the associated or causative disorder. Some may present at birth, as in Riley-Day syndrome (familial dysautonomia), which is transmitted as an autosomal recessive trait and usually affects siblings rather than successive generations. Riley-Day syndrome occurs mainly in Ashkenazi Jews, in whom there is a high prevalence of consanguinity. Patients with 1)B11 deficiency syndrome have autonomic problems from childhood. In familial amyloid polyneuropathy, the presenting features usually occur in adulthood. Patients with insulin-dependent diabetes of long duration may develop an autonomic neuropathy.

In vasovagal syncope there often is a strong family history, especially in those in whom the disease presents when they are teenagers (Mathias et al. 1998); whether environmental factors contribute remains unclear (Mathias etal. 2000).

Cardiovascular System

Hypotension. The symptoms from postural (orthostatic) hypotension often provide the first clue and are usually the reason for patients' requesting medical advice (Mathias et al. 1999). They mainly result from cerebral hypoperfusion (Table 83.5). Dizziness and visual disturbances (such as blurred VISUM'.. gra\ ing our, blacking out, or tunnel vision) may precede loss of consciousness. These occur on the patient's assuming the upright posture, especially when getting out of bed in the morning (Table *S3.6).* Food, alcohol, exercise, and a raised environmental temperature usually enhance symptoms. Straining during micturition and bowel movements, which often are affected in autonomic disorders, may induce attacks. Many recognize the association between postural change and the early symptoms of cerebral hypoperfusion and either sit down,

Table 83.5: Symptoms that result from postural (orthostatic) hypotension and impaired perfusion of organs

Cerebral hypoperfusion
Dizziness
Vision disturbances
blurred vision, color defects, scotoma, tunnel, graying out, blacking out
Loss of consciousness
Impaired cognition
Muscle hypoperfusion
Paraecrvical and suboccipital ("coat-hanger"] ache
Lower back or buttock ache
Calf claudication
Cardiac hypoperfusion: angina pectoris
Spinal cord hypoperfusion
Renal hypoperfusion: oliguria
Nonspecific: weakness, lethargy, fatigue, falls

lie flat, or assume curious postures, such as squatting or stooping. Occasionally, the blood pressure may fall precipitously, and syncope may occur rapidly, as in a drop attack. Loss of consciousness may result in injury. Seizures due to cerebral anoxia may occur in some patients. Postural hypotension can be considerably aggravated by drugs (such as i.-dopa) that normally cause minimal or no change in blood pressure. In diabetic patients with an autonomic neuropathy, administration of insulin, eithet by reducing blood volume through increasing transcapillary albumin escape or by vasodilatory effects, occasionally may exacerbate postural hypotension.

The fall in blood pressure and symptoms during postural change may vary considerably (Figures 83.8 and 83.9). Many patients tolerate an extremely low cerebral perfusion pressure without symptoms, presumably because of improved cerebrovascular autoregulation. This may explain why some patients' symptoms arc worse in the early stages of their disorder, as in those with high spinal cotd injuries, who later tolerate head-up postural change despite a similar fall in blood pressure. Some may hyperventilate, which should be discouraged because it further reduces cerebral perfusion thtough cerebral vasoconstriction. Symptomatic tolerance appears to develop with repeated head-up tilt and exposute to hypotension. Patients with spinal injuries soon learn that activation of skeletal muscle spasms or urinary bladdet contraction ttiggets spinal reflexes, and they use this to help reduce the postural fall in blood pressure. In eldetly patients, a relatively small fall in blood pressure may induce cerebral ischemia, especially in the presence of cerebrovascular insufficiency due to atheroma and stenosis.

Table 83.6: Factors influencing postural (orthostatic) hypotension

Speed of positional change
Time of day (worse in die morning)
Prolonged recumbency
Warm environment (hot weather, central heating, hot bath)
Raising intrathoracic pressure by micturition, defecation, or coughing
Food and alcohol ingestion
Water ingestion*
Physical exertion
Maneuvers and positions (bending forward, abdominal compression, leg crossing, squatting, activating calf muscle pump)
Drugs with vasoactive properties (including dopaminergic agents)

*This raises blood pressure in primary autonomic failure.
These maneuvers usually reduce the postural fall in blood pressure, unlike the others.

Postural hypotension, especially when severe, may be accompanied by symptoms of hypoperfusion in other organs. In some patients a troublesome featute is pain in the suboccipital, paraccrvical, and shoulder muscles, in a "coat-hanger" distribution. This differs from other types of neck pain, including cervical spondylitis, because it is associated with the upright position and is relieved on the patient's assuming the horizontal position. It is probably due to postural hypotension causing ischemia in neck muscles that need to be kept tonically active to maintain the head uptight. It has been described in primary autonomic failure (Bleasdale-Barr and Mathias 1998) and high spinal cord injuries (Cariga et al. 2002a). Neck and shouldct ache in a coat-hanger distribution specifically related to a postural fall in blood pressure is common; the mechanisms are unclear. Angina pectoris may occasionally occur, even in young patients with apparently normal coronary arteries. There may be symptoms suggestive of spinal cord ischemia during standing.

Hypotension and syncope may occut during events unrelated to postural change, as in neurally mediated syncope. A common cause, especially in young and otherwise healthy individuals with apparently normal autonomic reflexes, is vasovagal syncope, when both heart rate and blood pressure fall rapidly (Figure 83.10) because of increased vagal activity and sympathetic withdrawal. I car, sometimes induced by venipuncture, and assumption of the upright position, especially on a tilt table, may provoke such a response. A variant, more common in wartime, is DaCosta's syndrome (soldier's heart or neurocirculatory asthenia), in which dizziness and syncope on effort are accompanied by exhaustion, dyspnea, headache, palpitations, and pain over the heart. The symptoms resemble orthostatic intolerance and syncope that may occur in chronic fatigue syndrome (De Lorenzo et al. 1997).

These disorders differ from carotid sinus hypersensitivity, in which pressure over the carotid sinus due to turning the head or tightening of the collat may induce an attack. This disorder is being increasingly recognized in elderly patients, especially those who present with falls of otherwise unknown etiology (Mcintosh et al. 1993). Maintenance of heart rate alone, by a catdiac demand pacemaker ot atropine, may not prevent hypotension in such patients. Paroxysms of coughing may induce syncope, especially

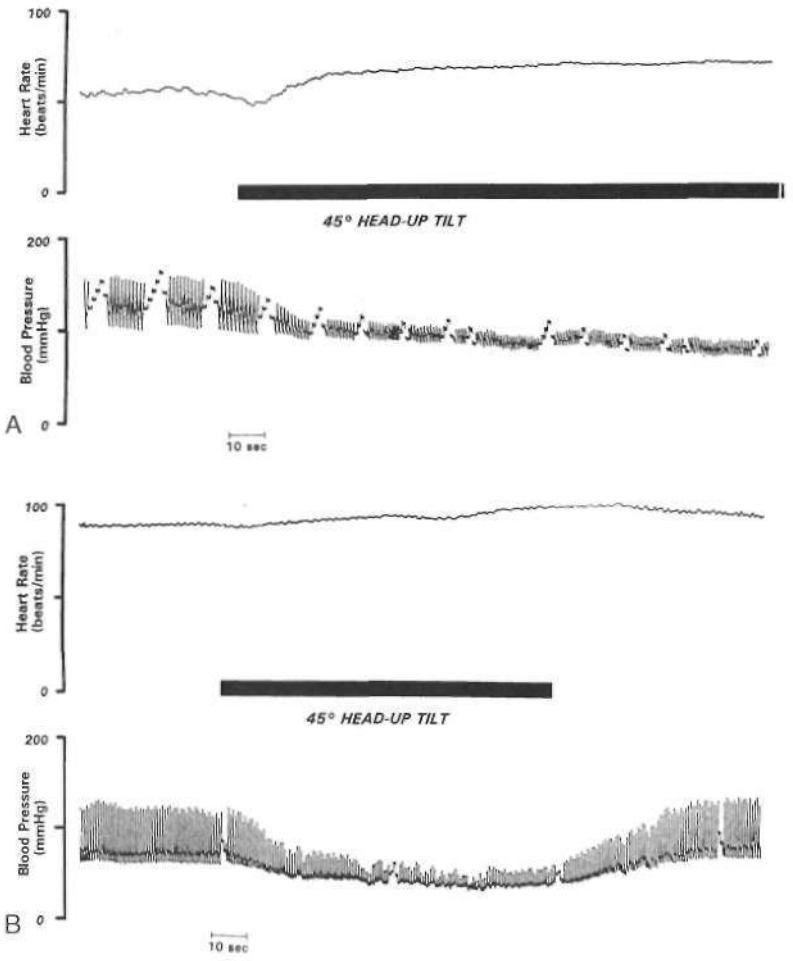

FIGURE 83.8 Blood pressure and heart rate measured by a noninvasive technique (with a Finapres [Ohmeda, BOC Health Care, UK]) in two patients with autonomic failure before, during, and after head-up tilt. (A) Blood pressure falls to low levels, but the patient could maintain head-up tilt with a low blood pressure for 20 minutes with few symptoms. This patient had autonomic failure for many years and could tolerate such levels, unlike the patient in (B), who had to be put back to the horizontal fairly quickly. She developed severe postural hypotension soon after surgery. (Reprinted with permission from Marhias, C. J. 1996, "Disorders affecting autonomic function in parkinsonian patients," Adv Neurol, vol. 69, p. .183.)

in patients with chronic obstructive airway disease. Micturition syncope usually is not accompanied by a detectable autonomic lesion. Hypotension appears to result from the combination of vasodilatation due to warmth or alcohol and straining during micturition. These actions raise intrathoracic pressure and induce a Valsalva maneuver while standing, which is compounded by release of the pressor stimulus arising from a distended bladder.

An increasingly recognised disorder is orthostatic intolerance with tachycardia (a rise of more than 30 heats per min)

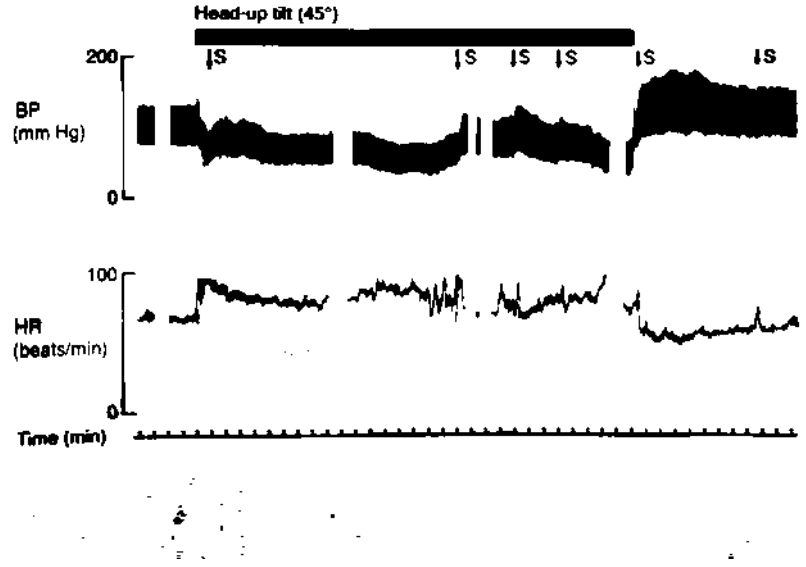

FIGURE S3.9 Inira-arterial recording of blood pressure (BP) and heart rate (HR) in a tetraplegic patient with a complete cervical spinal cord transection above the sympathetic outflow. There is an immediate fall in BP after head-up tilt, followed by a rise in BP during spontaneous skeletal muscle spasms (S). The slow recovery in BP may have been related to the release of renin and the subsequent formation of angiotensin II (measured at hreak-. in the record) because there is minimal or no change in plasma noradrenaline and adrenaline levels excluding significant sympathetic activations in response to postural challenge. On return to the horizontal, there is a BP overshoot. During tilt, heart rate rises due to an intact vagal efferent outflow. (Reprinted with permission from Mathias, C. J. &: Frankel, H. L. 1988, "Cardiovascular control in spinal man," *Annu Rev Physiol,* vol. 50, p. 577.)

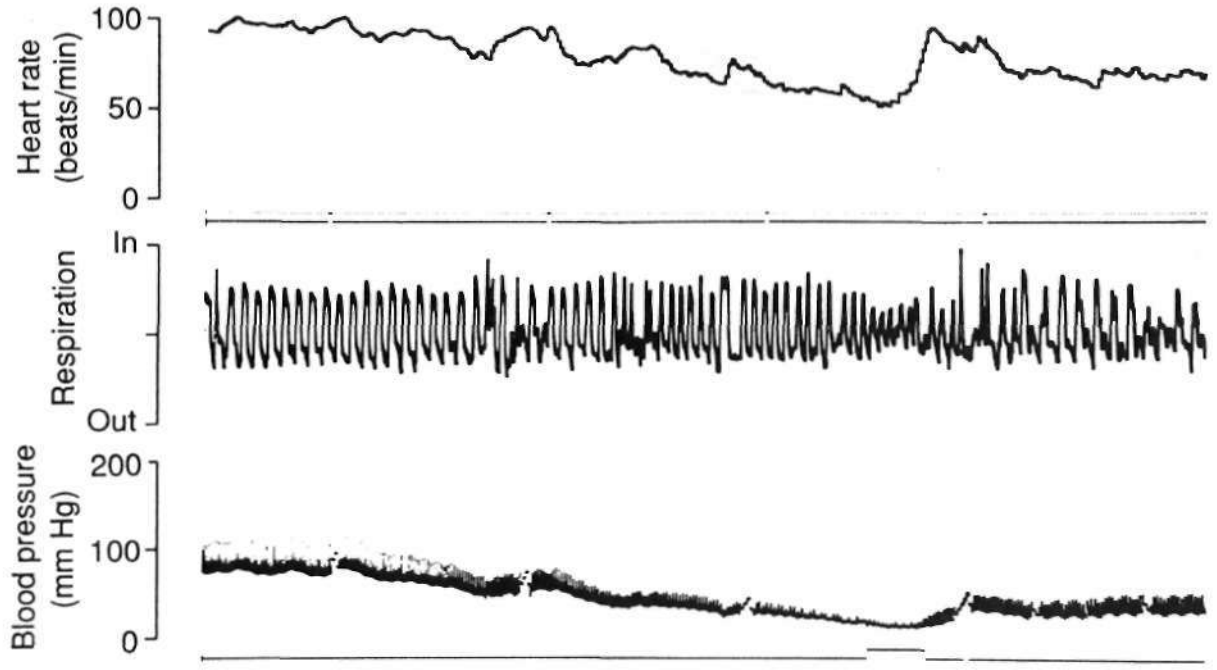

FIGURE 83.10 Blood pressure changes toward the end of a period of head-up tilt in a patient with recurrent episodes of vasovagal syncope. Blond pressure that was previously maintained begins to fall. There is also a fall in heart rate. There are relatively minor changes in respiratory rate, which can be derived from the time signal above it. Each minor dot indicates a second and the bolder mark indicates a minute. The patient was about to faint and was put back to the horizontal (indicated by the elevated time signal below), and then needed 5 degrees of head-down tilt. Blood pressure and heart rate recovered but still remained lower than previously. This patient had no other autonomic abnormalities on detailed testing. Blood pressure was measured noninvasively by the Finapres. (Reprinted with permission from Mathias, G J., & Bannister, *R.* 2002, "Investigation of autonomic disorders," in *Autonomic Failure. A Textbook of Clinical Disorders of the Autonomic Nervous System,* 4th ed, eds G. J. Mathias & R. Bannister, Oxford University Press, Oxford, pp. 169-195.)

on postural challenge, often without a fall in blood pressure (Lower al. 1995; Jacob et al. 2000). Ir commonly occurs in young women, and often disability disproportionate to the observed autonomic abnormality is seen. There may be a relationship to hyperventilation and panic attacks. It is probably a heterogeneous disorder (Khurana 1995). It may result from a partial autonomic neuropathy (Schondorf and Low 1993), has been associated with antibodies to nicotinic acetylcholine receptors (Vernino ct al. 2000), and has been attributed to a norepinephrine transporter defect in a family (Shannon et al. 2000). When the patient is upright, there is pooling in the lower limbs, in contrast to findings in vasovagal syncope (Stewart and Wcldon 2003). Improvement is often seen with beta blockers. Recovery may be spontaneous, but in some patients a variety of treatments are needed.

Hypertension. Hypertension may be sustained in cerebral tumors, subarachnoid hemorrhage, or bulbar poliomyelitis, whereas lability of blood pressure occurs in certain autonomic disorders. Supine hypertension often occurs in primary chronic autonomic failure. The mechanisms are unclear but include impaired baroreflex activity, adrenoceptor supersensitivity, an increase in central blood volume because of a shift from the periphery, and the effects of drugs used to prewm postanal avpotension. 1 leadache may occur. Papilledema, cerebral hemorrhage, aortic dissection, myocardial ischemia, and heart failure are possible but rarely reported complications.

Paroxysmal hypertension may occur in Guillain-Barre syndrome, porphyria, posterior fossa tumors, and pheochromocytoma, often without a precipitating cause. Hypertension in pheochromocytoma is usually associated with autonomous release of catecholamines, with or without other pressor substances from the tumor. In tetanus, hypertension may be precipitated by specific events, such as muscle spasms or tracheal suction. In high spinal cord lesions, contraction of the urinary bladder, irritation of the large bowel, noxious cutaneous stimulation, or skeletal muscle spasms can cause severe hypertension as part of autonomic dysreflexia, with an uninhibited increase in spinal sympathetic nervous activity (Mathias and Fraukel 2002) (Figure 83,11). This is often accompanied by a throbbing or pounding headache,

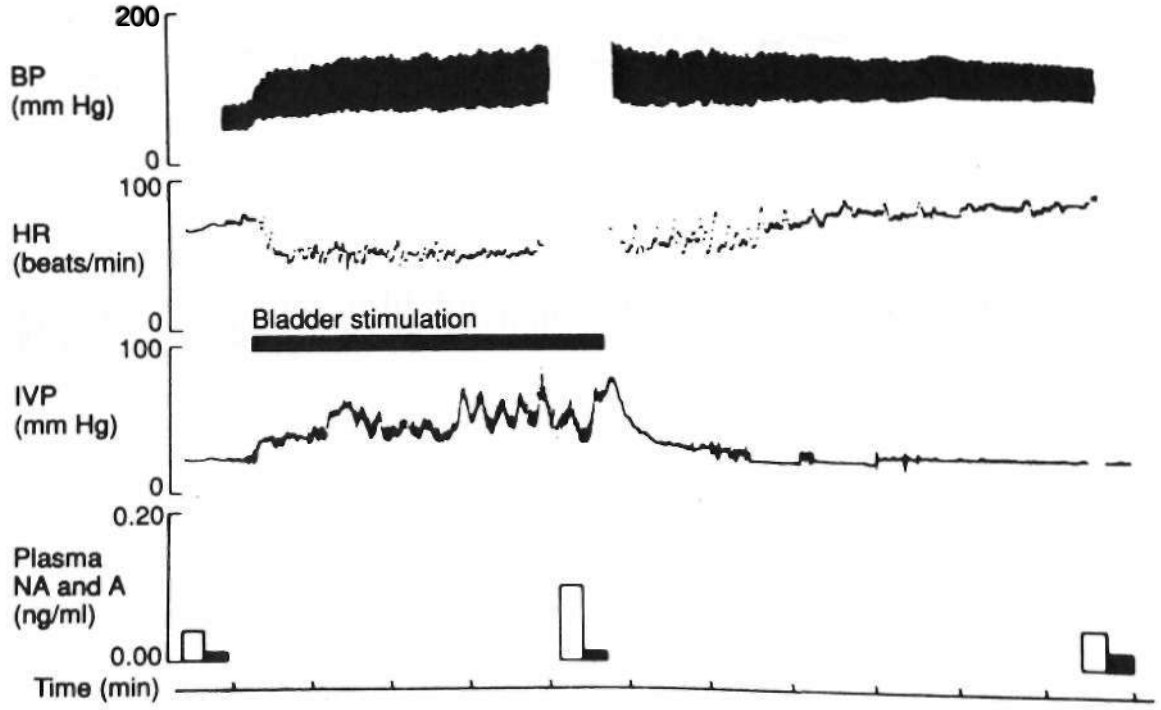

FIGURE 83.11 Blood pressure (BP), heart raw (HR), intravesical pressure (IVP), and plasma noradrenaline (NA, empty histogram), and adrenaline (A, filled histogram) in a tetraplegic patient before, during, and after bladder stimulation (BS) induced by suprapubic percussion of the anterior abdominal wall. A rapid rise in BP is accompanied by a fall in HR, which indicates increased cardiac vagal activity in response to the tise in BP. There is a rise in levels of plasma NA but not of adrenaline, which suggests sympathetic neural but not ad re no medullary activation. (Reprinted with permission from Mathias, C, J. & Frankel, H. L. 1986, "The neurological and hormonal control of blood vessels and heart in spinal man," *J Auton Nerv Syst*, suppl., pp. 457-464.)

bradycardia, sweating and flushing over **the** face and neck, and cold peripheral limbs due to vasoconstriction.

Increased sympathetic nervous activity may initiate or maintain hypertension in renovascular disease (such as renal artery stenosis), in transplant recipients who receive cyclosporine as immunosuppressive therapy, and in pre-eclamptic toxemia (Schobel ct al. 1996).

Cardiac Dysrhythmias. Tachycardia due to increased sympathetic discharge may occur with hypertension in the Guillain-Barre syndrome and in tetanus. In pheochromocytoma, it results from catecholamine release and /i-adrenoceptor stimulation.

Bradycardia (with hypertension) may occur in cerebral tumors and during autonomic dysreflexia in high spinal cord injuries. In the latter, the afferent and vagal efferent components of the baroreflex arc are intact, and the heart slows in an attempt to control the tise in blood pressure. In pheochromocytoma, bradycardia with escape rhythms and atrioventricular dissociation may occur in response to a rapid rise in pressure.

Severe bradycardia can occasionally be a problem if the vagi are intact when there is an inability to increase severe sympathetic activity, as in patients with high cervical cord transection who have diaphragmatic paralysis and need artificial respiration (Table 83.7). The intact vagi arc sensitive to hypoxia, and stimuli such as tracheal suction can induce bradycardia and cardiac arrest (Figure 83,12). Cardiac arrest may also occur in chronically injured tetraplegic patients during general anesthesia, especially when muscle paralysis followed by intubation is performed without parasympathetic blockade (Mathias and Frankel 2002).

In carotid sinus hypersensitivity, bradycardia and syncope may be difficult to distinguish from Stokes-Adams attacks. A cardiac demand pacemaker alone in some patients may not be of benefit because vasodilatation, hypotension, and syncope may occur despite preservation of heart rate.

In diabetes mellitus, the tendency to cardiac vagal neuropathy appears to increase the incidence of cardio-respiratory arrest during anesthesia, for reasons that are unclear. Disorders of cardiac conduction are common in Chagas' disease and may occur in amyloidosis.

Facial Vascular Changes

In autonomic failure, facial pallor usually occurs as blood pressure falls, with prompt restoration of color on the patient's assuming the supine position, when blood

Tabic 83.7: Some of the mechanisms accounting for bradycardia and cardiac arrest in tetraplegic patients with high cervical lesions on artificial respiration and the therapeutic interventions utilized

	Hylioxiti	*Tracheal suet inn*
Normal subjects	Primary response is bradycardia opposed by pulmonary (inflation) vagal reflex, which causes tachycardia.	Increases sympathetic nervous activity, causing tachycardia and raising blood pressure.
Tetraplegic patients	Only causes the primary response, bradycardia, as disconnection from respirator eliminates pulmonary (inflation) reflex.	Sympathetic nervous activity is severely impaired, even at a spinal level in the early stages. Vagal afferent stimulation may lead to unopposed vagal efferent activity.
	Increased vagal cardiac activity	
	Bradycardia and cardiac arrest	Demand pacemaker
Oxygenation	Reconnection to respirator	Atropine

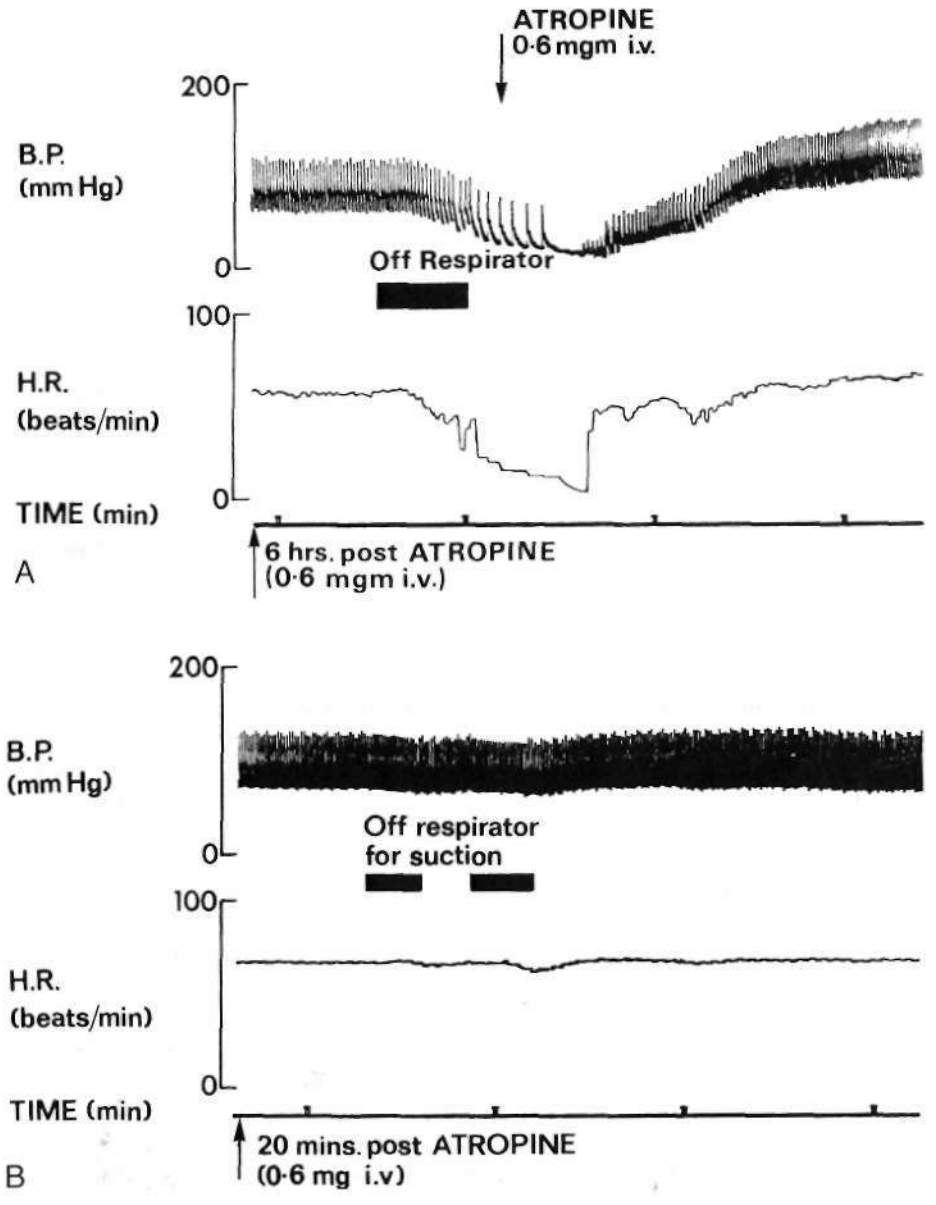

FIGURE 83.12 (A) The effect of disconnecting the respirator (as required for aspirating the airways) on blood pressure (BP) and heart rate (HR) of a recently injured tetraplegic patient (C4-C5 lesion) in spinal shock, *6* hours after the last dose of intravenous atropine. Sinus bradycardia and cardiac arrest (also observed on the electrocardiograph) were reversed by reconnection, intravenous atropine, and external cardiac massage. (Reprinted with permission from Frankel, H. L., Mathias, C. J., & Spalding, J. M. K. 1975, "Mechanisms of reflex cardiac arrest in tetraplegic patients," *Lancet,* vol. ii, p. 1183.) (B) The effect of tracheal suction 20 minutes after atropine. Disconnection from the respirator and tracheal suction did not lower either HR or BP. (Reprinted with permission from Mathias, C. j. [976, "Bradycardia and cardiac arrest during tracheal suction-mechanisms in tetraplegic patients," *Eur) Intensive Care Med,* vol. 2, p, 147.)

pressure rises. Facial pallor may occur during an attack in phcochromocytoma and is usually accompanied by sweating, headache, and hypertension. In the acute phase of high spinal cord lesions, facial vasodilatation may be accompanied by nasal congestion (Gutttnann's sign). The latter also may occur in patients taking (^-adrenoceptor blockers or sympatholytics, such as phenoxy ben/a mine, guanethidine, and reserpinc. In chronic tetraplegia, hypertension during autonomic dysreflexia is often accompanied by flushing and sweating over the face and neck. The mechanisms are unknown. In Harlequin syndrome, there is vasodilatation and anhidrosis on one side of the face due to sympathetic impairment, with apparent sparing of the pupils, although abnormalities may be unmasked with pharmacological testing (Drummond 2002). The signs favor a lesion that spares the first thoracic segment (from which oculomotor fibers often leave) and involves preganglionic fibers of the second **and** third thoracic roots, although the lesion usually is not identified.

Sweating

Anhidrosis or hypohidrosis is common in primary autonomic failure and is usually noticed during exposure to warm temperatutes. The eccrine glands, which are mainly **conc< rned *w* Ith :rill[X':.iHii'f** ivgul::r.' **'ti,** arc **prccniiiinantly** involved, whereas the apocrine glands, which are on the palms and soles and are influenced by circulating substances, including catecholamines, may remain functional. Occasionally, localized hypevhidrns-.s nun occur, which is probably a compensatory response to diminished activity elsewhere rather than a response to denervation hypersensitivity in an incomplete lesion.

Anhidrosis may be coiii;cnii;il wuhoi:: other feature (Cevoli et al. 2002) or may be an integral component of some of the hereditary sensory and autonomic neuropathies (Houlden et al. 2001; Indo 2002), such as congenital insensitivity to pain with anhidrosis (type IV).

Localized or generalized anhidrosis, sometimes with hypethidrosis, may be associated with Holmes-Adie syndrome (Ross's syndrome).

A band of hyperhidrosis above the lesion often occurs in patients with spinal cord injuries, with anhidrosis below the lesion. During autonomic dysreflexia in such patients, however, sweating usually occurs, but mainly over the face and neck. Facial and truncal hyperhidrosis may occur in Parkinson's disease. Hyperhidrosis may occur intermittently in pheochromocytoma. Generalized hyperhidrosis may accompany hypertension in tetanus and may be the major manifestation in infants with mercury poisoning (acrodynia or pink disease).

Localized hyperhidrosis caused by food (gustatory sweating) can be socially distressing and may occur in diabetes mellitus or after trauma or surgery, as a result of aberrant connections between nerve fibers supplying the salivary and sweat glands (Figure 83.13).

Minimally invasive thoracic endoscopic techniques for sympathectomy are being increasingly used because of their success in reducing axillary and palmar hyperhidrosis, but their use may be complicated by abnormalities of sweating in other sites. Approximately one half of patients may develop compensatory hyperhidrosis, usually of the trunk and lower limbs, that may be troublesome; the mechanisms are unclear.

Temperature Regulation

Hypothermia may occur in hypothalamic disorders and in elderly patients, in whom such lesions have been postulated. It usually is not a problem in primary autonomic failure. In patients with high spinal injuries, especially in the early phases, the combination of absent shivering thermogenesis and the inability to prevent heat loss by vasoconstriction can readily result in hypothermia. I lypothermia may be missed if only oral temperature is recorded without a low-reading thermometer (Figure 83.14).

Hyperpyrexia may be a problem in patients with anhidrosis who are exposed to high temperatures. Heat also increases vasodilatation and often enhances postural hypotension.

Gastrointestinal System

Xerostomia usually occurs in acute dysautonomias and especially in pure cholinergic dysautonomia. Dysphagia may be present due to impairment of esophageal function because the lower two thirds of the esophagus contains smooth muscle with autonomic innervation. Large bowel atony may occur, A barium meal should be avoided because it may solidify in the colon and require surgical removal. Dysphagia is unusual in PAF. It often occurs in the later stages of MSA. In primary autonomic failure, constipation is common. In secondary autonomic disorders, a wide variety of gastrointestinal manifestations may occur. The esophagus is often involved in Chagas' disease, with achalasia and megaesophagus causing vomiting. Gastroparesis in diabetes mellitus and amyloidosis may cause food stasis and vomiting. The tevcrse, increased gastric motility, is common in primary autonomic failure, but the relationship between postprandial hypotension and "dumping" is unclear. Paralytic ileus usually occurs in the early phases after spinal cord lesions and can cause abdominal distention and meteorism, which reduces mobility of the diaphragm, the major respiratory muscle in those with high lesions. In such patients, the vagus is intact and probably hyperactive, which may account for the tendency to increased gastric acid production, peptic ulceration, and gastrointestinal bleeding.

Constipation usually occurs in patients with sacral parasympathetic impairment. Diarrhea may occur, as in

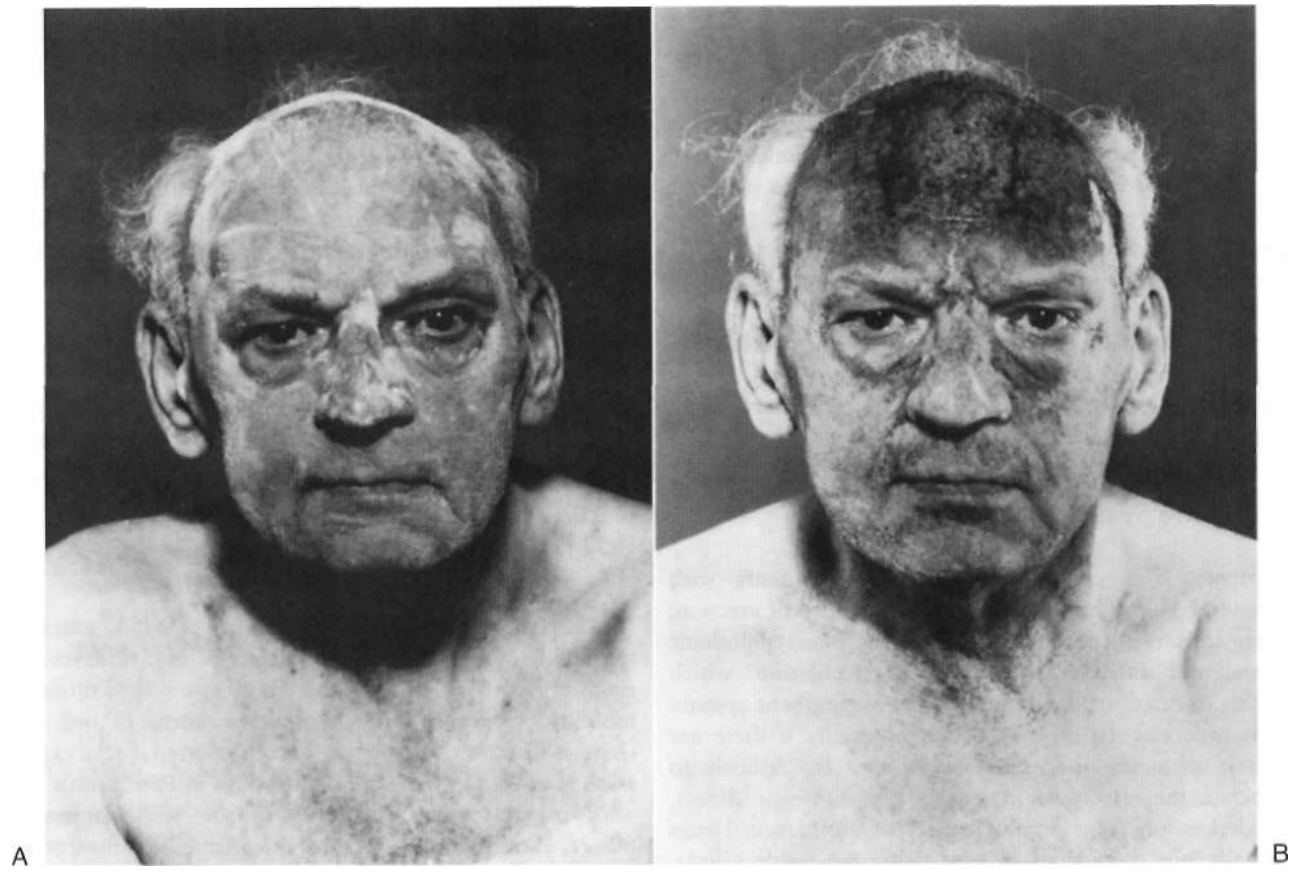

FIGURE 83.13 Sequential photographs showing the effects of quinazarin red (pale powder) before (A) and after (B) gustatory sweating induced by a cheese sandwich. There was profound sweating over the head and face.

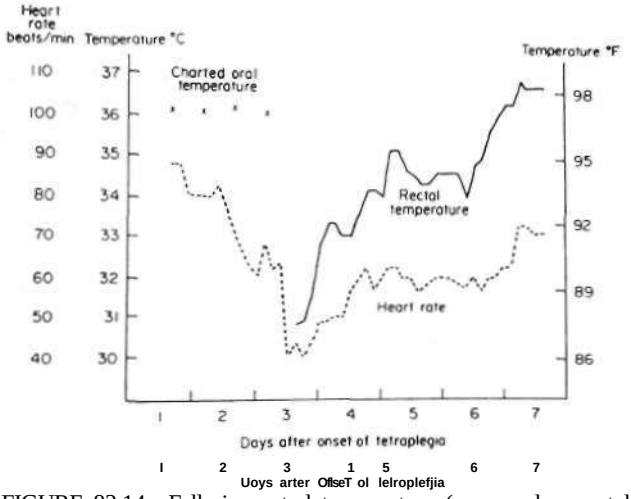

FIGURE 83.14 Falls in central temperature (measured as rectal temperature, *continuous line)* and heart rate *{interrupted line)* in a recently injured tetraplegic patient in a temperate climate, Measurements of oral temperature missed the hypothermia, which should be measured by a low-reading rectal thermometer. The impairment of shivering thermogenesis and the inability to vasoconstrict adequately predispose these patients to hypothermia, (Reprinted with permission ftom Pledger, G. *1962,* "Disorders of temperature regulation in acute traumatic paraplegia," / *Hone Joint Surg jBrj,* vol. 44, p. 110.)

diabetes mellitus, for reasons that are often unclear and include incomplete digestion, altered bowel flora, or abnormal motility.

Kidneys and Urinary Tract

Nocturia is common in primary autonomic failure and probably is the result of recumbency itself rather than abnormal circadian rhythms. Factors such as redistribution of blood from the peripheral into the central compartment, alteration in release of hormones that influence salt and water handling (e.g., renin, aldosterone, and atrial natriuretic peptide), and postural changes in renal hemodynamics may contribute. Nocturia may cause an overnight weight loss greater than 1 kg, resulting in a reduction in extracellular fluid volume, a lower morning blood pressure, and an increased tendency to postural symptoms that may incapacitate some patients until late morning (Mathias 2001).

Involvement of the urinary bladder may result in frequency, urgency, incontinence, or retention. Loss of sacral parasympathetic function, as in the early phase of spinal cord injury, causes an atonic bladder with urinary retention, whereas recovery of isolated spinal cord function results in a neurogenic bladder. With training, there is often controlled bladder emptying. Dyssynergia, however,

with detrusor contraction but not sphincter relaxation, may cause episodes of autonomic dysreflexia resulting in hypertension and, at times, urinary reflux that predisposes patients to renal damage, especially in the presence of a urinary tract infection. In older patients with primary autonomic failure, urinary symptoms initially may be attributed to prostatic hypertrophy in men or to pelvic muscle weakness, especially in muciparous women. Surgery usually is of no benefit. The use of drugs with anticholinergic effects may unmask urinary bladder dysfunction in autonomic failure,

Urinary infection is common when the bladder is involved. Some patients, including those with spinal injuries, are prone to urinary calculi, especially when immobility increases calcium excretion.

Reproductive System

Impotence is a common complaint in patients with autonomic failure and may result from failure of erection, which appears to depend mainly on the parasympathetic system, and difficulty in or lack of ejaculation, which appears to be controlled largely by the sympathetic system, Retrograde ejaculation may occur, especially if there are urinary sphincter abnormalities. It may be difficult to dissociate the effects of increasing age, systemic illness, and depression from organic causes of impotence. Drugs normally not considered to have autonomic side effects, such as thiazides used in the treatment of hypertension, may cause impotence. Priapism due to abnormal spinal reflexes may occur in patients with spinal cord lesions.

In women, autonomic impairment itself does not directly affect reproductive function. Menstrual disorders, if present, are usually due to an underlying disorder. Conception and successful vaginal delivery have been recorded in patients with high spinal cord transection and with primary autonomic failure.

Eye and Lacrimal Glands

The nonstriated component of the levator palpebra superions (Miiller's muscle) is innervated by sympathetic fibers, and mild ptosis is part of Horner's syndrome. If the lesion is bilateral, as in high spinal cord transection, this is difficult to detect,

A variety[7] of pupillary abnormalities may occur: miosis in Horner's syndrome, dilated myotonic pupils in Holmes-Adie syndrome, and small, irregular pupils in Argyll-Robertson syndrome due to syphilitic *{Treponema pallidum)* infection. Symptoms directly relating to the eye are usually minimal in such disorders. Drugs with anticholinergic effects may cause blurred vision due to cycloplegia; they also may raise intraocular pressure and cause glaucoma.

Impaired lacrimal production occasionally occurs in primary autonomic failure, sometimes as part of sicca or Sjogren's syndrome, along with diminished salivary secretion. Excessive and inappropriate lacrimation occurs in crocodile tears syndrome (gustolacrimal reflex).

Respiratory System

In MSA, episodes of apnea may occur in the later stages of the disorder. These are probably due to involvement of brainstem respiratory centers. Inspiratory stridor and snoring may result from weakness of the cricoarytenoid muscles, the main latyngeal abductors. In certain disorders, reflexes from the respiratory tract may cause profound cardiovascular disturbances. Tracheal suction in curarized patients with tetanus receiving artificial ventilation may result in severe hypertension and tachycardia, whereas in patients with high cervical cord transaction, bradycardia and cardiac arrest may occur.

Additional Neurological Involvement

In the parkinsonian and mixed forms of MSA, extrapyramidal manifestations consist mainly of bradykinesia and rigidity with minimal tremor; this causes difficulties in mobility, especially while the patient turns in bed and changes direction. Speech may become slurred, facial expression is affected to a lesser degree than in Parkinson's disease. In idiopathic Parkinson's disease with autonomic failure, extrapyramidal features often have been present for a long period and remain responsive to L-dopa therapy even after the additional features of autonomic dysfunction occur.

In the cerebellar form of MSA, cerebellar features predominate, with an ataxic gait, an intention tremor, cerebellar speech, and nystagmus. Ataxia may he difficult to separate from, or may be compounded by, the unsteadiness caused by postural hypotension. There also may be pyramidal involvement, with increased tone and exaggerated tendon reflexes with extensor plantar responses. A varying combination of extrapyramidal, cerebellar, and pyramidal features occurs in the mixed form of MSA, Sensory deficits are uncommon in MSA, although nerve conduction studies indicate a mixed sensorimotor axonal neuropathy (Pramstaller et al. 1995).

Patients with secondary autonomic failure have the neurological features that are part of, or a complication of, the primary disease. In diabetes mellitus, a somatic neuropathy often coexists with, or precedes, the autonomic neuropathy.

Psychological and Psychiatric Disturbances

In primary autonomic failure, dementia is unusual. In patients with MSA, detailed testing of cognitive function shows deficits in visuospatial organization and visiiomotor ability that arc similar to observations in Parkinson's disease (Monza et al, 1998; Pillon et al, 1995). Most patients with MSA arc not depressed, despite their disabilities and the probable deficit in central cnrecholamine levels; overall

they have a normal affective state, especially when comparisons are made with patients with Parkinson's disease (Pillonct al. 1995).

In PAF there is no psychological disorder, but the absent autonomic responses may result in subtle deficits. These patients appear less emotional than normal subjects and are less anxious when compared with similarly disabled patients with idiopathic Parkinson's disease without autonomic failure (Cntchlc^ et al. 2001b). In normal subjects, fear conditioning and perceptual awareness of a threat stimulus are associated with increased amygdala and insula activity; in PAF there is diminished conditioning related activity in both these areas (Critchley et al. 2002). Anxiety and tremulousness may occur in secondary disorders, as in pheochromocytoma. Psychological factors may contribute to vasovagal syncope (also called emotional syncope) and essential hypcrhidrosis. Frank psychiatric disturbances may complicate other conditions, such as porphyria.

Investigation

Investigation depends on the presenting problem and the primary or secondary disorder. The major aims of investigation are as follows:

- To determine whether autonomic function is normal or abnormal. Screening investigations often are restricted to a particular system, such as the cardiovascular system.
- To assess (if an abnormality has been observed) the degree of autonomic dysfunction, with an emphasis on the site of the lesion and the functional deficit.
- To ascertain whethet the abnormalities are of the primary or secondary variety because further investigations, prognosis, and management depend on the diagnostic category. In some disorders, as in generalized autonomic dysfunction, extensive investigation of various systems may be required (Table 83.8) (Mathias and Bannister 2002b).

The cardiovascular system provides an example of how investigations have been specifically designed to determine and elucidate the deficit, the site of the lesion, and the extent to which associated hormonal abnormalities contribute. As in the investigation of other systems, there has been an emphasis on developing noninvasive techniques that are safe and reliable and can be used for screening and repeated testing as well as for determining disease progrcs sion and the effects of therapy. Different laboratories that test autonomic function arc unlikely to have similar equipment and an identical set of procedures, despite attempts to standardize such approaches. High specificity and sensitiviry of the tests, although desirable, may not be practical in a global setting, especially because the findings often must be considered in the context of a wide variety of factors, including the patient's ability to cooperate in testing. The effect of drugs is another confounding factor, Significantly, the results must be linked with the relevant clinical symptoms and signs. These difficulties mainly arise- in patients with mild or moderate disease with questionable autonomic involvement, however, and are not usually relevant in patients with definite abnormalities.

Table 83.8: Outline of investigations in autonomic failure

- Cardiovascular
  - Physiological
    - Head-up tilt (60 degrees); standing; Valsalva maneuver
    - Pressor stimuli (isometric exercise, cold pressor, mental arithmetic)
    - Heart rate responses to deep breathing, hyperventilation, standing, head-up tilt, 30:15 R-R interval ratio
    - Liquid meal challenge
    - Exercise testing
    - Carotid sinus massage
  - Biochemical: plasma noradrenaline: supine and head-up tilt or standing; urinary catecholamines; plasma renin activity and aldosterone
  - Pharmacological
    - Noradrenaline: a-adrenoceptors, vascular
    - Isoprenaline: /(-adrenoceptors, vascular and cardiac
    - Tyramine: pressor and noradrenaline response
    - Edrophonium: noradrenaline response
    - Atropine: parasympathetic cardiac blockade
- Endocrine
  - Pharmacological
    - clonidme: plasma noradrenaline suppression serum and hormone growth stimulation
- Sudomotor
  - Central regulation thermoregulatory sweat test
  - Swi u gin rid response (<> intradermal acetylcholine, quantitative sudomotor axon reflex test (Q-SART), localized sweat test
  - Sympathetic skm response
- Gastrointestinal: barium studies, video-cine-fluoroscopy, endoscopy, gastric emptying Studies
- Renal function and urinary tract
  - Day and night urine volumes and sodium/potassium excretion
  - Urodynamic studies, intravenous urography, ulrrasound examination, sphincter electromyography
- Sexual function
  - Penile plethysmography
  - Intraeavernosal papaverine
- Respiratory
  - Laryngoscopy
  - Sleep studies to assess apnea and oxygen desaturation
- Eye
  - Sehirmer's test
  - Pupil function, pharmacological and physiological

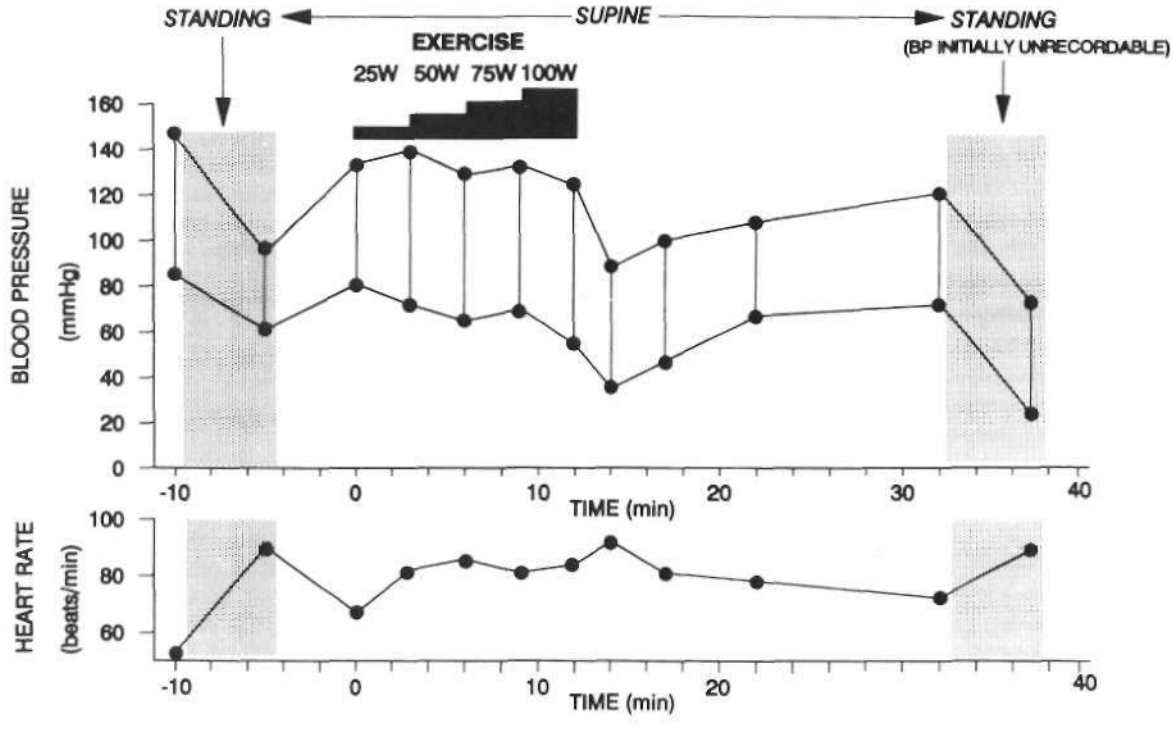
Cardiovascular System

A postural fall in blood pressure, especially if consistently more than 20 mm Ilg systolic or less in the presence of symptoms warrants further investigation. Head-up tilt is often used as the postural stimulus, especially when the neurological deficit or severe hypotension makes it difficult for the patient to stand. In some patients, postural hypotension may be unmasked by exercise (Smith and Mathias 1995) because vasodilatation in skeletal muscle is not appropriately counteracted by autonomic reflexes (Figure 8.3.15). Food ingestion also may be a provoking factor, presumably as a result of splanchnic vasodilatation not compensated for in other regions (Figure 83.16). There may be considerable variability in the basal supine levels and the postural fall in blood pressure; the greatest changes often occur in the morning and after a meal and physical exertion. Other, non-ncurogenic causes of postural hypotension must be considered (Table 8.3.9). The same may occur with drugs that cause vasodilatation, even if this is only a side effect of the agent.

Both blood pressure and heart rate can be accurately measured using noninvasive techniques, many of which are automated and provide a printout at preset intervals. Intermittenl ambulator) blood piTwio ami I'.IMII r.ilc recordings over a 24-hour period using small computerized devices are of particular value, especially in the home, for determining the effects of various stimuli in daily life (Figure 8.3.17), They may be of value in determining the beneficial effects of therapy in different situations. Beat-by-beat measurement of blood pressure and heart rate is essential in neurally mediated syncope (see Figure 83.14). This is especially so during carotid sinus massage, when the changes in blood pressure often are rapid, would be missed because of the slow response time of most noninvasive sphygmomanometers, and may be independent of changes in heart rate (Figure 83.18). The Finapres or Portapres machines enable noninvasive and beat-by-beat blood pressure and heart rate recordings with a finger cuff and provide a reliable measure of changes in blood pressure.

Screening investigations help determine the site and extent of the cardiovascular autonomic abnormality. Responses to the Valsalva maneuver, during which intrathoracic pressute is taiscd, depend on the integrity of the entire baroreflex pathway (Figure 83.19). Changes in heart rate alone, even in the absence of intra-arterial recording, provide a useful guide. In some patients, however, mouth pressure may increase without a corresponding



FIGURF. S3.15 Wood pressure (BP) and heart rate responses in a patient with pure autonomic failure while lying and standing, before and after exercise. The stippled area indicates the periods of standing. There was a fall in blood pressure on standing. Exercise was performed on a bicycle ergometer in the supine position, and unlike normal subjects, in whom there is a rise in blood pressure, there was little or no change. When exercise was stopped, blood pressure fell even while the patient was supine; after standing 20 minutes later, the blood pressure was initially unrecordable and the patient was near syncope. The observations were consistent with the patient's symptoms because he felt faint, not during exercise but on stopping exercise, i Reprinted with permission from Smith, G. D, P., Bannister, R., & Mathias, C.J. 1993, "Posr-exercise dizziness as the sole presenting symptom of autonomic failure,'[7] *Br Heart I,* vol. *69,* p. 359.)

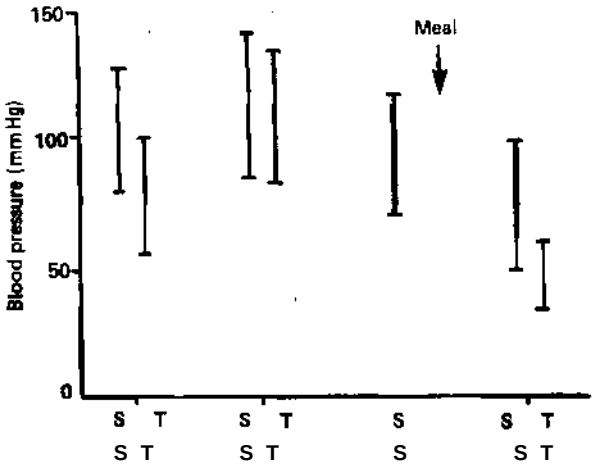


FIGURE 83.16 Systolic and diastolic blood pressure in a patient with multiple -.ysn-in atrophy while supine (S) and after 45-dcgree head-up tilt (T) on three occasions. On the first two, food intake was not controlled. The patient had nor eaten on the second occasion, however, when the postural blood pressure fall was negligible. On the third, supine blood pressure was measured while the patient was fasting and 45 minutes after the meal, Postprandial tilt caused a considerable fall in blood pressure, and the patient had to he returned to the horizontal within 3 minutes. (From Mathias, C. J., Holly, E., Armstrong, E., ct al. 1991, "The influence of food on postural hypotension in three groups with chronic autonomic failure: Clinical and therapeutic implications," / *Neurol Neurosurg Psychiatry*, vol. 54, p. 726.)

increase in intrathoracic pressure, resulting in a falsely abnormal response. Stimuli that raise blood pressure, such as isometric exercise (by sustained hand grip for 3 minutes), **;heC(ilil pi\-,,i>r K-,i** iinirHTsnu; Hie h.md m ice slush for 90 seconds), and mental atithmetic (using serial —7 or -17 subtraction), activate different afferent or central pathways, which then stimulate the sympathetic outflow. The heart rate responses to postural change, deep breathing (sinus arrhythmia), and hyperventilation provide further evidence of the integrity of cardiac vagal efferent pathways. Additional investigations may be needed to determine factors causing or contributing to postural hypotension and syncope. These include determining the responses to carotid sinus massage, food ingestion, and exercise. For patients with suspected carotid sinus hypersensitivity, resuscitation facilities should be available because carotid massage may cause profound bradycardia or cardiac arrest with hypotension. Hypotension only may occur with the subject upright, presumably because of the greater dependence on sympathetic tone, which is withdrawn after carotid sinus stimulation. To assess postprandial hypotension, the cardiovascular responses to a balanced liquid meal containing carbohydrate, protein, and fat arc determined while the patient is supine, with comparisons of the blood pressure response to head-up tilt before the meal and 45 minutes later. To evaluate exercise-induced hypotension, responses are obtained duting graded incremental supine exercise using a bicycle ergometer with measurement of postural responses before and after exercise (see Figure S3.15).

Table 83.9: Examples of non-neurogenic causes of postural hypotension

Low intravascular volume	
Blood/plasma loss	Hemorrhage
	Burns
	Hemodialysis
Fluid/electrolyte loss	Inadequate intake (anorexia nervosa)
	Vomiting
	Diarrhea (including losses from ileostomy)
	Renal/endocrine
	Salt-losing nephropathy
	Adrenal insufficiency (Addison's disease)
	Diabetes insipidus
	Diuretics
Vasodilatation	Drugs (glyceryl trinitrate)
	Alcohol
	Heat
	Pyrexia
	Hyperbradykinism
	Systemic mastocytosis
	Extensive varicose veins
	Systemic mastocytosis
Cardiac impairment	
Myocardial	Cardiomyopathy
Impaired ventricular filling	Atrial myxoma
	Constrictive pericarditis
Impaired output	Aortic stenosis

Note: In patients with autonomic failure or in those taking drugs that impair autonomic function, these disorders enhance postural hypotension considerably.

In patients with PAF, the supine basal level of plasma noradrenaline is low (suggesting a distal lesion) compared with those with MSA, in whom supine levels are often within the normal range (Figure 83.20), The reasons for the normal supine levels in MSA are unclear and may include the central nature of the disorder and impairment of noradrenaline clearance mechanisms in the periphery, In both groups, however, there is an attenuation or lack of rise in plasma noradrenaline levels during head-up tilt, which indicates impairment of sympathetic neural activity. In patients with high spinal cord lesions, basal plasma noradrenaline and adrenaline levels are low and do not rise with postural change. There is, however, a rise (but only moderately above the basal levels of normal subjects) during severe hypertension accompanying autonomic dysreflexia, which differentiates these patients from those with paroxysmal hyper tension due to a pheochromocytoma, in which plasma noradrenaline or adrenaline levels arc usually greatly elevated.

Extremely low or undetectable levels of plasma noradri'ualinc and adrenaline with delated plaMiia dopamine levels occur in sympathetic failure caused by deficiency of the enzyme DBH, which converts dopamine into noradrenaline. Plasma levels of this enzvme ate undetectable,

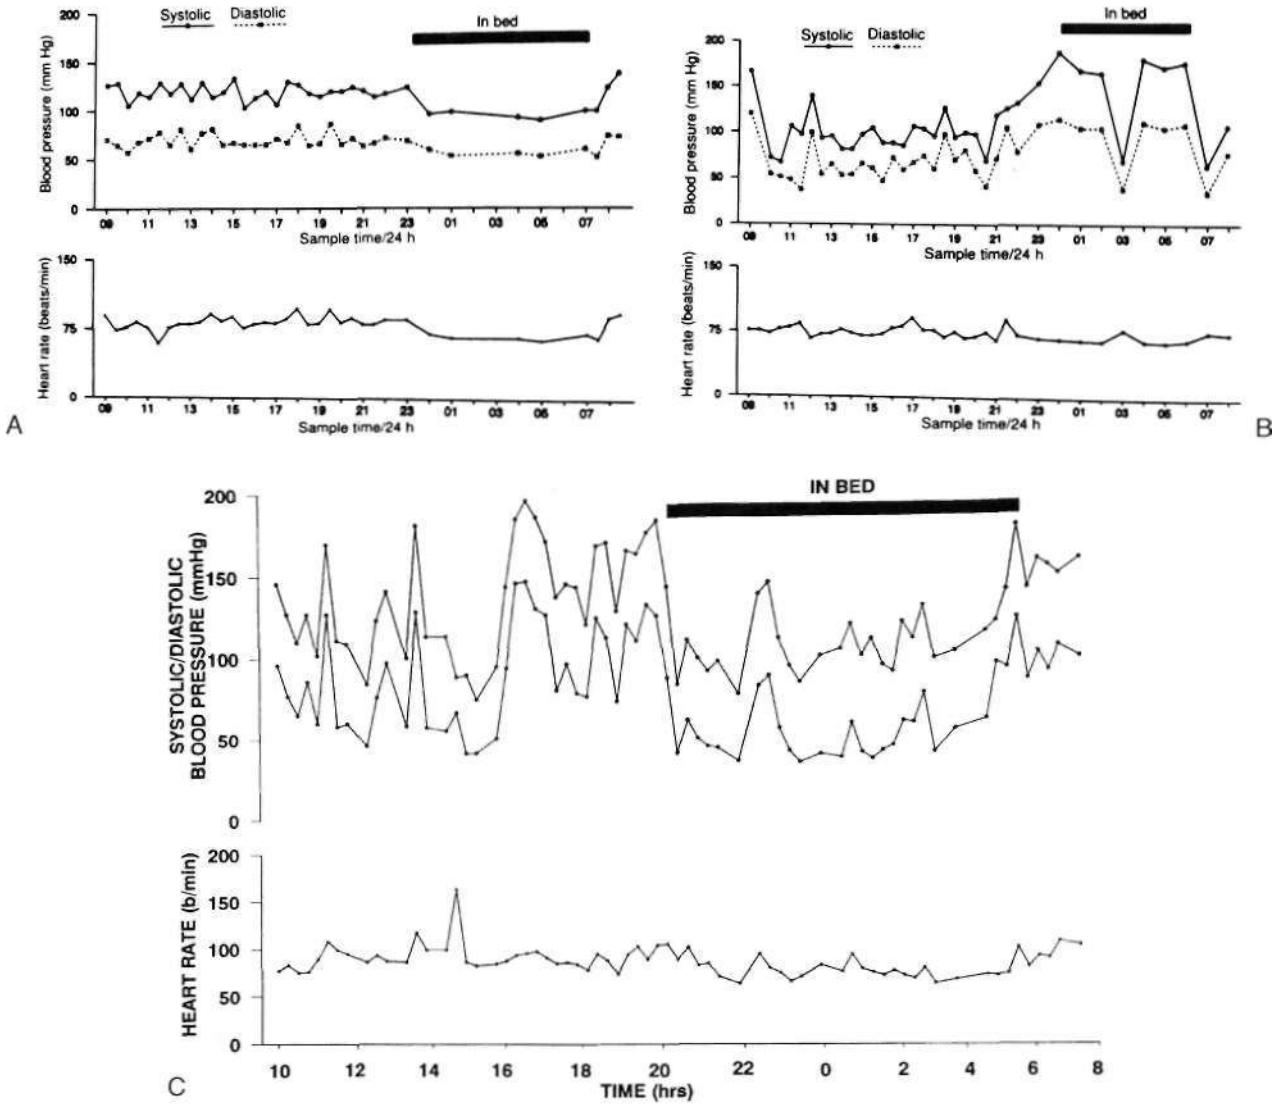

FIGURE S3.17 1 wenry-tour-hour noninvasive ambulatory blood pressure profile showing systolic and diastolic blood pressure and heart rate at intervals throughout the day and night. (A) Changes in a normal subject who did not have postural hypotension; there was a fall in blood pressure on sleeping. |B) Marked fluctuations in blood pressure in a patient with pure autonomic failure. The marked falls were usually the result of postural changes, either sitting or standing. Supine blood pressure, particularly at night, was elevated. Rising to micturate caused a marked fall in blood pressure (at 0300 hours). There was a reversal of the normal diurnal change in blood pressure. There were relatively small changes in heart rate considering the marked fluctuations in blood pressure. (Reprinted with permission from Mathias, C.J. & Bannister, R. 2002, "Investigation of autonomic disorders," in *Autonomic Failure. A Textbook of Clinical Disorders of* Vcri/oiM *.System*, 4th ed, eds C.J. Mathias & R. Bannister, Oxford University Press, Oxford, pp. 169-135.) (C) Changes in a patient with the Riley-Day syndrome (familial dysautonomia). The profile emphasizes the marked variability in blood pressure, with both hypotension and, at times, extreme hypertension. (Reprinted with permission from Mathias, C. J, 1996, "Disorders of the autonomic nervous system in childhood," in *Principles of Child Neurology*, ed B. Berg, McGraw-Hill, New York, p. 413.)

but this may occur in 10% of normal individuals and is not diagnostic of the disorder. Immunohistochemical studies confirm the absence of the enzyme in tissues such as skin.

Measurement of plasma renin activity and plasma aldosterone levels is useful in certain patients. In Addison's disease and adrenocortical failure, basal plasma renin levels are markedly elevated, whereas plasma aldosterone levels are low or absent. In diabetic autonomic neuropathy, there may be low levels of both plasma renin and aldosterone, which contribute to hyperkalemia.

Muscle and skin sympathetic nervous activity can be recorded directly by percutaneous insertion of tungsten microelcctrodes into the peroneal or median nerves. Muscle sympathetic activity is closely linked to the baroreccptor reflex, with a clear relationship to changes in blood pressure and discharge frequency. In patients with high spinal cord transection, there is reduced neural activity in

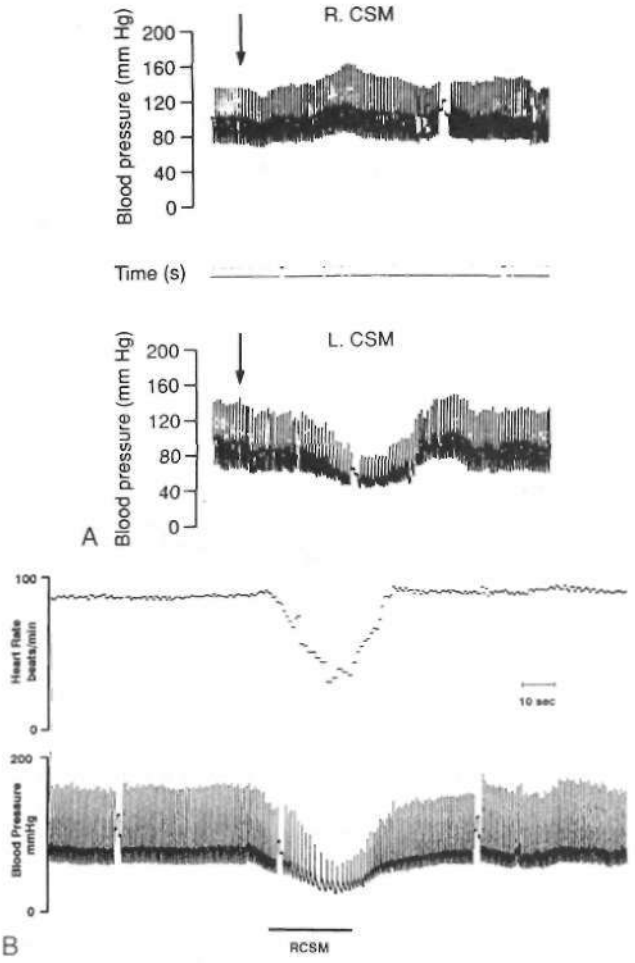

FIGURE 83.18 (A) Continuous noninvasive recording of finger arterial blood pressure (Finapres) before, during, and after carotid sinus massage on the right (R. CSM) and left (L. CSM). The fine dots indicate the time marker in seconds. The arrow indicates when stimulation began. Stimulation on the right for 10 seconds did not lower blood pressure .uid heart rate. On the left, carotid sinus massage caused a substantial fall in both systolic and diastolic blood pressure, during which the patient telt lightheaded and had graying out of visum. There was only a modest fall in heart rate. The syncopal attacks were abolished by left carotid sinus denervation, (Reprinted with permission from Mathias, C. J., Armstrong, E., Browse, N,, et a!., 1991, "Value of non-invasive continuous blood pressure monitoring in the detection of carotid sinus hypersensitivity," *Clin Auton Res,* vol. 2, p. 157,) (B) Continuous blood pressure and hean rate measured noninvasively (by Finapres) in a patient with falls of unknown etiology. Left carotid sinus massage caused a fall in both heart rate and blood pressure. The findings indicate the mixed (cardio-inhihitory and vasodepressor) form of carotid sinus hypersensitivity. (Reprinted with permission from Marhias, C. J. 2000, "Autonomic dysfunction," in *Oxford Textbook of Geriatric Medicine,* 2nd cd, ed J. Grimley-Evans, Oxford University Press, Oxford, pp. 833-852.)

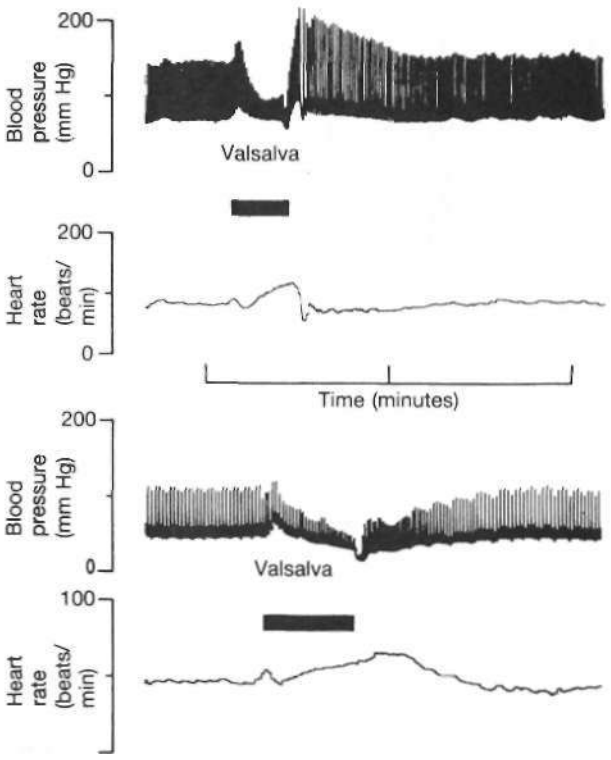

FIGURE 83.19 Blood pressure (BP) and heart rate (HR) before and during the Valsalva maneuver. In the upper trace, tin-expiratory pressure is maintained at 40 mm Hg in a subject with intact sympathetic reflexes. The fall in BP is accompanied by a rise in HR. The fall in BP is due to the reduction in venous return, which then stimulates sympathetic activity. RP then partially recovers. After release of intrathoracic pressure, there is a HP overshoot and the HR falls below the pre-Valsalva level. In rhe lower mice, in a patient with impaired autonomic function, raising intrathoracic pressure lowered BP substantially, with no BP recovery. Note that the HR scale differs from that of a normal subject. After release of intrathoracic pressure, there was no BP overshoot or immediate fall in HR below basal levels. BP slowly returned to pre-Valsalva levels. (Reprinted with permission from Mathias, C. J. & Bannister, R. 2002, "Investigation of autonomic disorders," in *Autonomic Failure. A Textbook of Clinical Disorders of the Autonomic Nervous System,* 4th ed, eds G. [. Mathias &: R, Bannister, Oxford University Press, Oxford.)

the basal state compared with that in normal subjects, This is consistent with their low plasma noradrenaline and blood pressure levels, presumably because of the lack of transmission of tonic brainstem sympathetic activity. Increased firing occurs in patients with Guillain-Barre syndrome, in association with hypertension and tachycardia. These microneurographic approaches have aided our understanding of the pathophysiological processes but are of limited clinical application, especially in the investigation of autonomic failure.

Pharmacological approaches help in determining the degree of sensitivity of different receptors and the functional integrity of sympathetic nerves and the cardiac vagi. 'i he pressor response to infusion oi noradrenaline provides a measure of a-adrenoceptor sensitivity; it is usually greater in patients with postganglionic sympathetic lesions. The hypotensive response to isoprenaline is related to /J.-adreno-receptor-mediated vasodilatation and is greater in the absence of corrective sympathetic reflexes. The heart rate

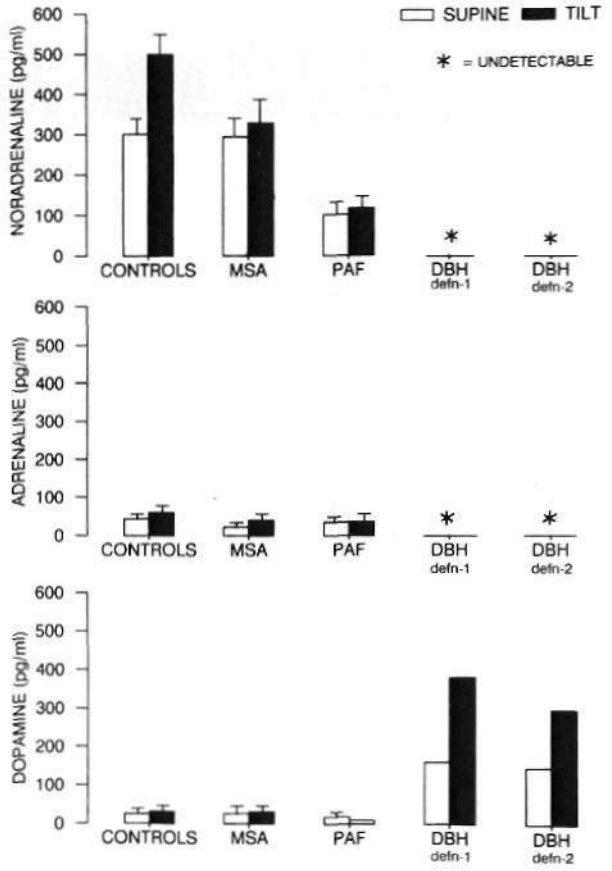

FIGURE 83.20 Plasma noradrenaline, adrenaline, and dopamine levels (measured by high-pressure liquid chromatography) in normal subjects (controls) and patients with multiple system atrophy (MSA, Shy-Drager syndrome) and pure autonomic failure (PAF), along with two patients with dopamine β-hydroxylase deficiency (DBH). Measurements were taken while patients were supine and after head-up tilt to 45 degrees for 10 minutes. The asterisk indicates levels below the detection limit, which are less than 5 pg/mL for noradrenaline and adrenaline and less than 20 pg/mL for dopamine. Bars indicate ± standard error of means. (Reprinted with permission from Mathias, C. J., & Bannister, R. 2002, "Investigation of autonomic disorders," in *Autonomic Failure. A Textbook of Clinical Disorders of the Autonomic Nervous System*, 4th ed, eds C. J. Mathias & R. Bannister, Oxford University Press, Oxford, pp. 169-195.)

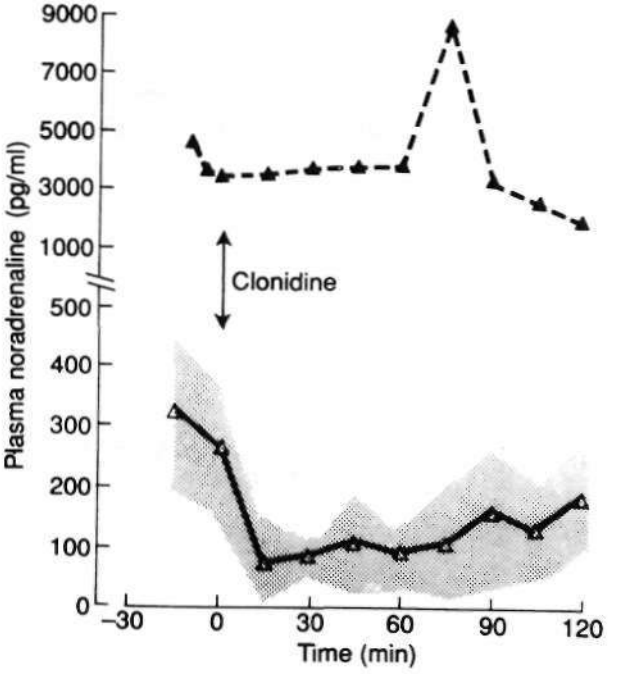

FIGURE 83.21 Plasma noradrenaline levels in a patient with a pheochromocytoma (interrupted line) and in a group of patients with essential hypertension (continuous line) before and after intravenous clonidine, administration of which is indicated by an arrow (2 mg/kg over 10 minutes). Plasma noradrenaline levels fell rapidly in the patients with essential hypertension after clonidine and remained low over the period of observation. The stippled area indicates the ± standard error of means. Plasma noradrenaline levels are considerably higher in the patient with pheochromocytoma and are not affected by clonidine. (Reprinted with permission from Mathias, C. J. & Bannister, R. 2002, "Investigation of autonomic disorders," in *Autonomic Failure. A Textbook of Clinical Disorders of the Autonomic Nervous System*, 4th ed, eds C. J. Mathias & R. Bannister, Oxford University Press, Oxford, pp. 169-195.)

response provides an indicator of β_1-adrenoceptor sensitivity, although the fall in blood pressure may increase heart rate through withdrawal of vagal tone, if intact. A rise in heart rate with atropine (usually up to 105 beats per minute with 1800 mg intravenously) indicates preservation of cardiac parasympathetic activity. In primary autonomic failure, there is usually an impaired or absent response. The pressor and noradrenaline responses to infused tyramine provide a measure of the store of noradrenaline in sympathetic nerve endings.

Certain pharmacological challenges, as with the α_2-adrenoceptor agonist clonidine, can provide information in different disorders. In some patients, basal plasma noradrenaline levels may be elevated due to stress and other factors; in these situations, the central sympatholytic actions of this agent result in a reduction in plasma noradrenaline levels. This suppression does not occur when autonomous secretion occurs, as in pheochromocytoma (Figure 83.21). Another central action of clonidine through the hypothalamus and anterior pituitary is stimulation of growth hormone release. The rise in serum growth hormone levels that occurs in normal subjects is also observed in patients with PAF who have distal autonomic lesions (Figure 83.22A). There is no response in patients with MSA, however, in whom the lesions are central (Kimber et al. 1997b); this is not due to an inability to release growth hormone, as there is a response to L-dopa (Kimber et al. 1999). Thus the growth hormone response to neuropharmacological challenge with clonidine separates the two disorders, MSA and PAF. The clonidine–growth hormone test may also aid in distinguishing parkinsonian forms of MSA from idiopathic Parkinson's disease (Figure 83.22B) (Kimber et al. 1997b).

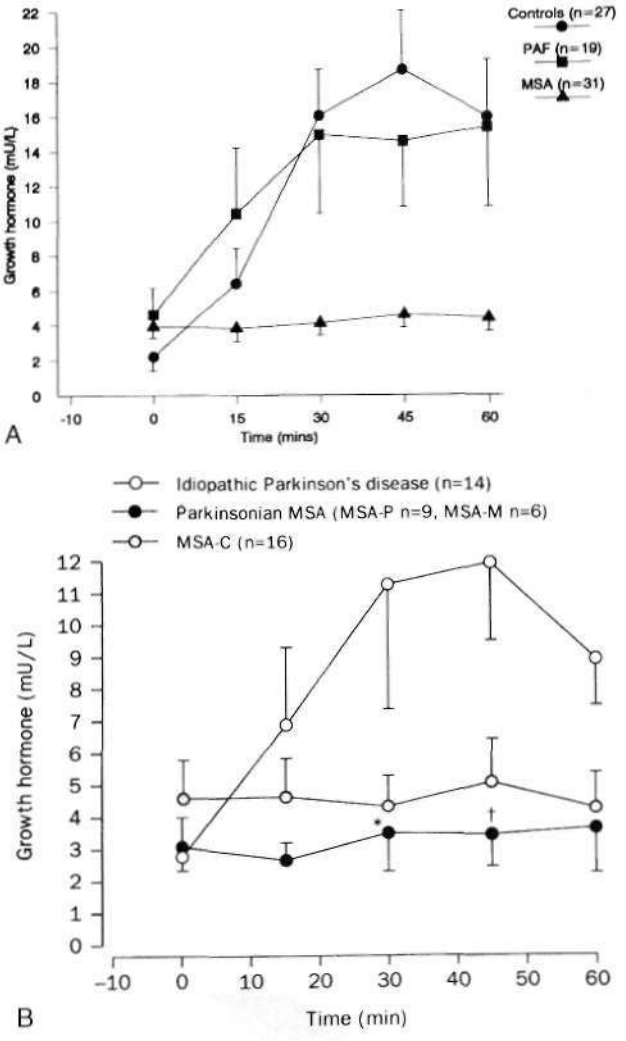

FIGURE 83.22 (A) Serum growth hormone (GH) concentrations before (0) and at 15-minute intervals for 60 minutes after clomdine (2 ug/kg per minute) in normal subjects (controls) and in patients with pure autonomic failure (I'AK) and multiple system atrophy (MSA). GH concentrations rise in control subjects and in patients with PAF with a peripheral lesion; there is no rise in patients with MSA with a central lesion, (B) Lack of serum GH response to clonidinc in the two forms of MSA (the cerebellar form [MSA-C1 and the parkinsonian form [MSA-P]) in contrast to patients with idiopathic Parkinson's disease with no autonomic deficit, in whom there is a significant rise in GH levels, (MSA-M = mixed form.) (Reprinted with permission from Kimber, J. R., Watson, L., &£ Mathias, C. J. I 997, "Distinction of idiopathic Parkinson's disease from multiple system atrophy by stimulation of growth hormone release with clonidine," *Lancet,* vol. 349, p. 1877.)

Many techniques using the advances of modern technology arc being applied to the study of cardiovascular autonomic function in humans. These include techniques for the noninvasive measurement of cardiac function and blood flow in various regions (Puvi-Rajasingham et al. 1997; Chandler and Mathias 2002). A variety of computer and spectral analytic techniques assess cardiovascular function (Parati et al. 2002) and measure total body and regional noradrenaline spillover in regions such as the heart, splanchnic and renal circulations, and the brain (Lambert et al. 1997). Radionuclide [^{121}Ijmetaiodoben/yl-guanidine is used to image sympathetic nerves in the heart (Mantysaari et al. 1996), and PET scanning (using 6-|'^{K}F]fluorodopamine) is used to visualize sympathetic innervation of cardiac tissue (Goldstein et al. 1997). These techniques have a role in the clinical research setting, and in due course some of them may be applied to the routine investigation of cardiovascular autonomic function.

In the majority of autonomic disorders affecting the circulation, physiological testing using head-up postural challenge, a scries of pressor tests, the Valsalva maneuver, deep breathing, and hyperventilation is often adequate for screening purposes. Depending on the disorder, additional tests may be needed, such as food and exercise challenge, carotid sinus massage, and appropriate biochemical and pharmacological studies.

Sweating

The thermoregulatory sweating response is tested by elevating body temperature by 10C, with either a heat cradle or hot water bottles and a space blanket. This tests the integrity of central pathways, from the hypothalamus to the sweat glands. Sweating is assessed using powders, such as quina/arin or Ponceau red, which turn a vivid red on exposure to moisture. In autonomic failure, the thermoregulatory sweating response is lost, and additional tests are needed to distinguish between central and peripheral lesions. In postganglionic lesions, the sudomotor and pilomotor response to intradermal acetylcholine is lost. Various measures can be used, including the quantitative sudomotor axon reflex test. Intradermal pilocarpine assesses the function of sweat glands directly. In DBH deficiency syndrome, sympathetic cholinergic function and sweating is preserved, providing a clue to selective impairment of sympathetic noradrenergic function. In gustatory sweating, spicy foods, cheese, or substances containing tyramine arc ingested to provoke sweating.

The sympathetic skin response (SSR) measures electrical potentials from electrodes on the foot and hand and may provide a measure of sympathetic cholinergic activity to sweat glands. The SSR can be induced by stimuli that arc physiological (inspiratory gasps, loud noise, or touch) or electrical (median nerve stimulation). The response is usually absent in axonal neuropathies but present in demyelinating disorders. Despite numerous reports on the SSR in various disorders, there have been limited observations on factors that influence it and few studies in adequate numbers of patients with clearly defined autonomic disorders. In peripheral disorders, such as PAF and pure cholinergic dysautonomia (Figure 83.23), the SSR is a reliable marker of sympathetic cholinergic function. However, this reliability depends on the use of the presence or absence of the response, rather than latency and amplitude, which are highly variable (Magnifico et al. 199b'),

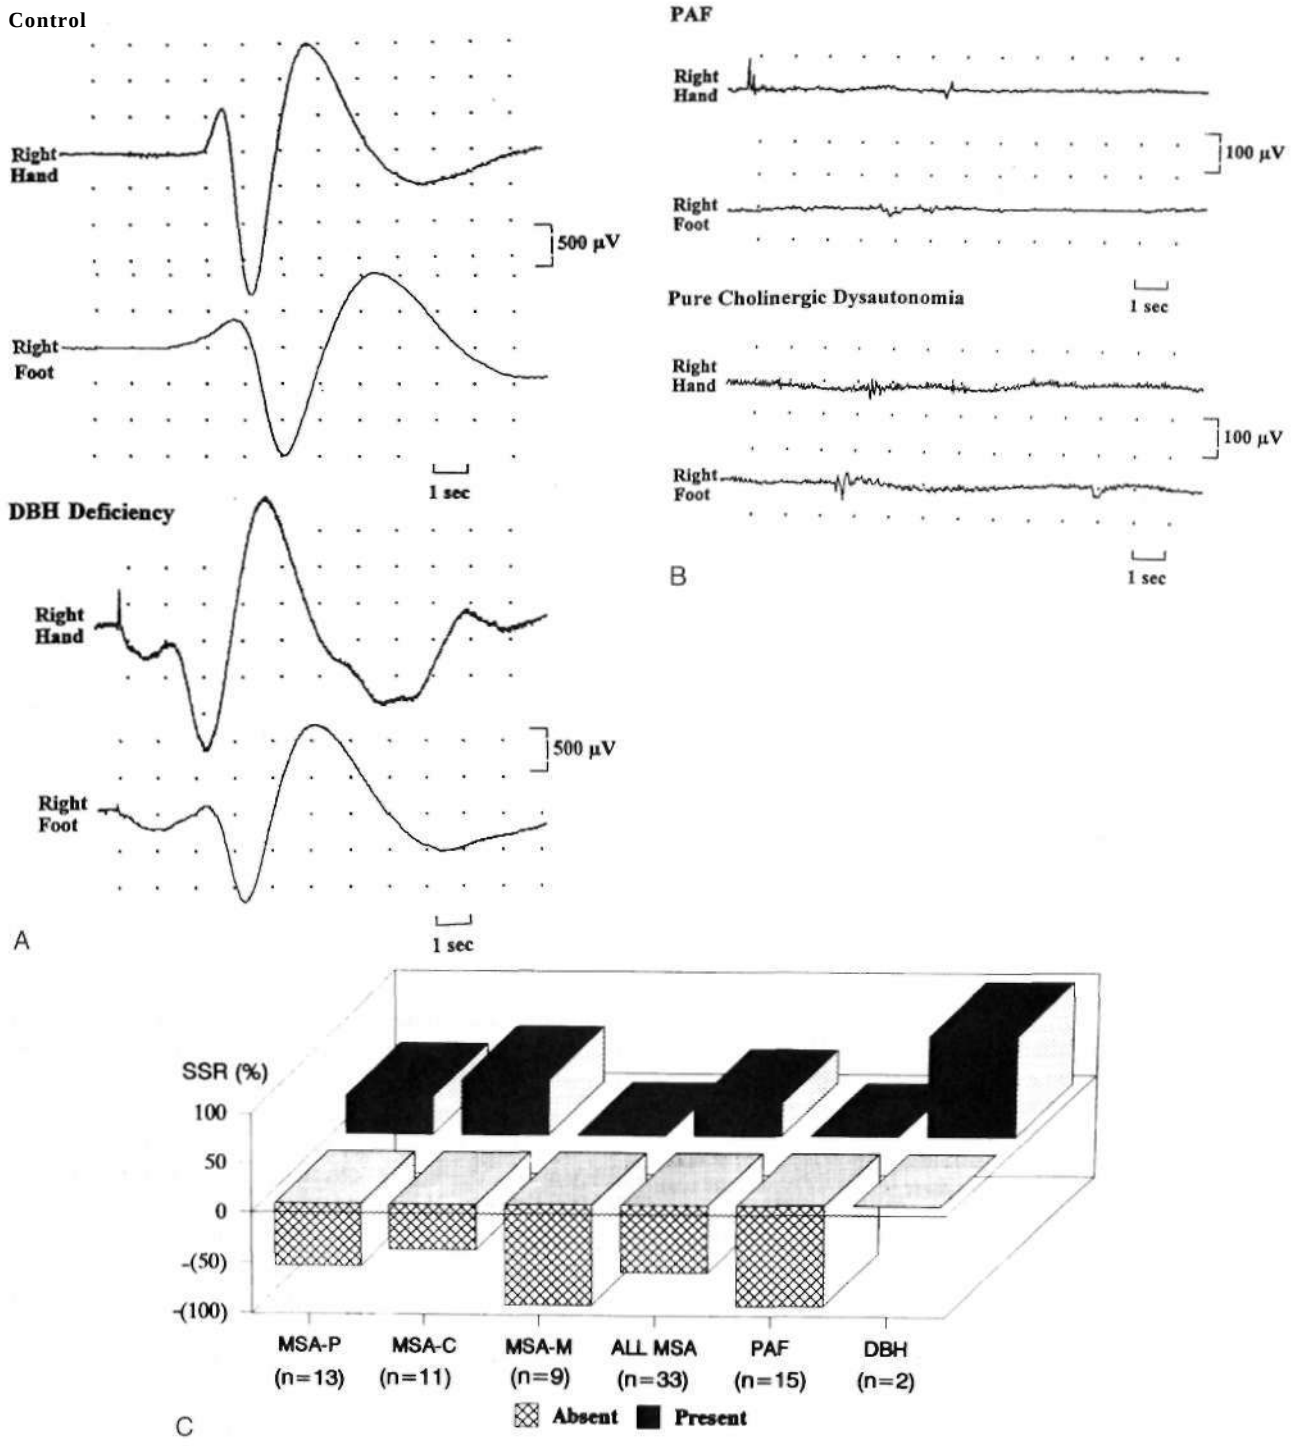

FIGURE 83.23 (A) The sympathetic skin response (in microvolts) from the right hand and right foot of a normal subject (control) and a patient with dopamine ^-hydroxylase (DBH) deficiency. (B) The sympathetic skin response could not be recorded in two patients, one with pure autonomic failure (PAF) and the other with pure cholinergic dysautonomia. (Reprinted with permission from Magnifico, F., Misra, V. P., Murray, N. M, F., & Mathias, C. J. 1 998, "The sympathetic skin response in peripheta autonomic failure—Evaluation in pure autonomic failure, pure cholinergic dysautonomy and dopaminc-heta-hydroxylase deficiency," *Clin Auton* fies, vol. 8, pp. 133-138.) (C) Presence or absence of the sympathetic skin response (SSR) in *ii* patients with multiple system atrophy (MSA), 15 patients with PAF, and two siblings with DBH deficiency. The SSR (as occurs in normal subjects) was present in the two patients with DBH deficiency who had adrenergic failure but preserved cholinergic function; it was absent in all patients with PAF with a peripheral sympathetic lesion. A proportion of patients (up to 30%) with the parkinsonian (MSA-P) and cerebellar (MSA-C) forms had preservation of the SSR despite postural hypotension and definite sympathetic adrenergic failure. (MSA-M = mixed form.) (Data from Magnifico, F., Misra, V. P., Murray, N. M. F., & Mathias, C. J. 1997, "The laboratory detection of autonomic dysfunction in multiple system atrophy—The role of the sympathetic skin response," *Neurology,* vol. 48, **suppl.,** p. A 190.)

The value of the SSR in central autonomic disorders requires further definition. In MSA with confirmed sympathetic adrenergic failure, up to one third of patients with the parkinsonian or cerebellar forms had a recordable SSR (see Figure 83.23C). This makes it unlikely that the SSR would be a valuable discriminatory test in separating MSA from idiopathic Parkinson's disease (without autonomic failure), especially in the early stages (Magnifico et al. 1997).

Gastrointestinal Tract

Video-cine-fluoroscopy is of value in assessing swallowing and the presence of oropharyngeal dysphagia (higure 83.24). This is especially useful in patients with MSA, who in the later stages develop difficulties in deglutition, which appear to enhance the tendency to aspiration pneumonia. A barium swallow, meal, and follow-through are helpful in patients suspected of having upper gastrointestinal disorders, although alternative investigation by endoscopy provides the opportunity for biopsy. Esophageal manometry is of value in disorders of motility and esophagogastric function. Several methods (radioisotope methods and scintigraphic scanning) are available to determine gastric motility noninvasively. When bacterial overgrowth is a suspected cause of diarrhea, a therapeutic trial with broad-spectrum antibiotics, such as neomycin or tetracycline, may be used along with investigations such as jejunal aspiration and the [^{M}C|glycocholate test. *Helicobacter pylori* infection occurs commonly in patients with MSA and PAL and may contribute to gastric dysfunction (Maule et al. 2002). Small bowel manometry and telemetric devices are of value in separating myopathic from neuropathic disorders of the gut. The measurement of transit time and proctological function tests ate used to investigate lower bowel disorders causing diarrhea, constipation, and fecal incontinence.

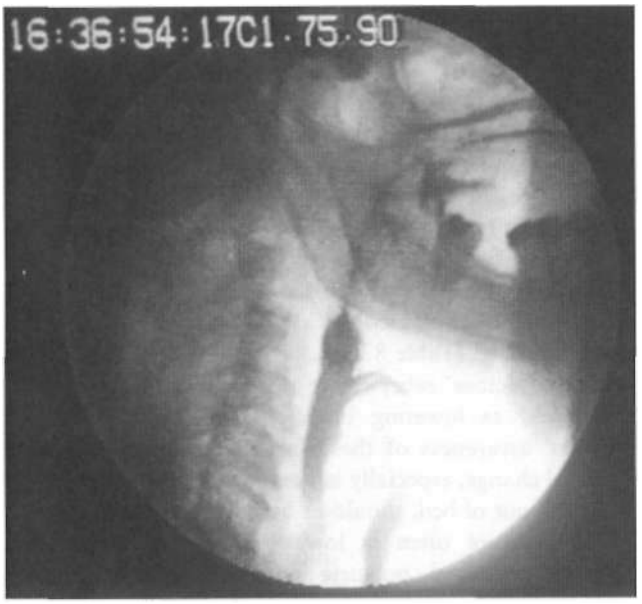

FIGURE 83.24 Still frame from video-cine-fluoroscopic examinatinn in .: p.iiK'iu with oropharyngeal •,lv,ph.u-:.i '.hows penetration of the larynx by contrast medium, indicating the potential to lead to tracheal aspiration. (Reprinted with permission from Mathias, C. J. 1996, "Gastrointestinal dysfunction in multiple system atrophy," *Sernin Neurol*, vol. 16, p. 251.)

Urinary Tract

Nocturnal polyuria can be assessed by separate day and night measurement of urine volume. Measurements of urine osmolarity and the concentrations of sodium and potassium may be helpful. When the urinary bladder is involved, an intravenous pyclogram and micturating cystometrogram may be needed. Urodynamic measurements are valuable in defining the function of the bladder musculature and sphincter mechanisms. They may differentiate idiopathic Parkinson's disease from MSA; in the former, detrusor hyper-reflexia may be present, whereas in MSA, there is usually a combination of both detrusor hyper-reflexia and stress incontinence due to a weak urethral sphincter. Measurement of postmicturition residual volume (e.g., by ultrasound) is of particular importance. It may be high when the bladder is involved, .is in MSA, and may result in urinary infection, which should be detected early and promptly treated. There arc some groups, such as patients with spinal cord lesions, to whom particular care must be provided because recurrent infections, along with calculi, may result in renal failure.

Urethral sphincter electromyography provides an analysis of motor units affected when there is neuronal degeneration of OnuPs nucleus in the sacral cord. This results in sphincter denervation with subsequent reinnervation. Electromyography indicates an increase in amplitude and duration of individual motor units, which are often polyphasic. This combination of denervation and reinnervation is often present in the various forms of MSA unlike idiopathic Parkinson's disease without autonomic involvement (Palace et al. 1997), Similar changes occur in the anal sphincter.

Respiratory System

Respiratory rate and arterial blood gases should be measured to determine the degree of hypoxia, especially during sleep in patients with apneic episodes. Indirect and direct laryngoscopy detect laryngeal abductor paresis.

Eye

Various pharmacological preparations administered locally help determine the degree of sympathetic or parasympathetic involvement of pupils. Lacrimal secretion can be tested by Scfiirmer's test, and damage from deficient

secretion can be assessed using rose bengal instillation followed by slit-lamp examination.

Miscellaneous

A range of additional investigations may be needed to ill [• iiiiiii- the i-niiM' (it die disorder or ;lssi >L ialri.1 i "Hip nations. Computed tomographic scans and magnetic resonance imaging of the brain help in assessing basal ganglia and cerebellar and brainstem involvement in the primary autonomic failure syndromes, especially in MSA (Schrag et al. 2000). PET scanning has provided valuable information in central disorders, such as MSA (Oilman et al. 1996; Rinne et al. 1995). Brainstem auditory evoked responses are often abnormal in MSA but normal in PAF. In suspected peripheral nerve involvement, electrophysiological studies together with sural nerve biopsy are indicated. In amyloidosis, a rectal or renal biopsy may be diagnostic; the latter is indicated if there is renal involvement. To exclude adrenal insufficiency, a short or long Synacthcn test should be performed.

In patients with localized lesions, specific investigations to determine the cause may be warranted. In Horner's syndrome, for example, this may include a computed tomographic or MRI scan of the brain to exclude a midbrain or medullary hemorrhage, bronchoscopy and radiography to exclude an apical bronchial neoplasm, and carotid artery angiography to assess lesions of the internal carotid artery.

PROGNOSIS

In primary autonomic failure, the prognosis depends on the diagnostic category, the degree of autonomic impairment, and the ability to prevent complications. In patients with acute and subacute dysautonomias, complete recovery may occur, although mild or substantial residual autonomic deficits often persist. In chronic autonomic failure syndromes, there are differences in prognosis. Subjects with PAH survive for many years, often with a virtually normal life expectancy, despite the disabilities resulting from autonomic failure. The disorder is usually not progressive, but dysfunction may increase with age, with coincidental illnesses (such as diarrhea), or with use of drugs with vasodilator properties. For patients with MSA, the prognosis is poorer, with a mean life expectancy of around 9 years (Wcnning et al. 1994), although there is considerable individual \ana', mil. 1 a. lias vach a-, rrspa .ilur;, umiplica tions, difficulties with swallowing, and increasing motor deficits contribute to mortality. With improved awareness of these complications and the ability to prevent life-threatening events, survival of patients with MSA is likely to increase.

For patients with secondary autonomic dysfunction, the prognosis depends largely on the associated disorder. With some (e.g., subarachnoid hemorrhage and brain tumors), the primary pathological process often dominates the outcome. In other disorders, such as tetanus, the complications arising from autonomic dysfunction may play a key role in determining morbidity and mortality. In conditions such as diabetes mcllitus (Gcrritscn et al. 2001) and familial amyloid polyneuropathy, autonomic impairment worsens the overall prognosis.

In the subgroups with rarer isolated disorders, there arc considerable differences in prognosis. Patients with specific acetylcholine receptor abnormalities may have severe complications, whereas those with DISH deficiency seem to manage despite severe postural hypotension.

In certain localized disorders, such as Horner's syndrome, the prognosis depends on the initiating cause; in others, such as Chagas' disease, the outcome is determined by complications, such as those arising from cardiac involvement,

MANAGEMENT

Management depends on the autonomic abnormalities and their functional deficits, the associated clinical condition, and the degree of disability. In this section major principles of management relating to autonomic deficits are discussed.

Cardiovascular System

Postural Hypotension

Postural hyporension may cause considerable disability, with the potential risk of serious injury, blood pressure maintenance is dependent, especially in the absence of sympathetic control, on the output of the heart; on tone in resistance and capacitance vessels, which is influenced by various pressor and depressor hormones present systemically or locally; and on intravascular fluid volume. Because no single drug can effectively mimic the actions of the sympathetic nervous system, a multipronged approach combining nonpharmacological and pharmacological measures is needed (Table 83.10).

Many factors other than postural change are now recognized as lowering blood pressure, and increasing patients' awareness of these factors is important. Rapid postural change, especially in the morning when the patient is getting out of bed, should be avoided because the supine blood pressure often is lowest at this time, probably because nocturnal polyuria reduces extracellular fluid volume. Prolonged bed rest and recumbency may contribute even in healthy individuals Perhonen et al. 2001) and can considerably worsen postural hypotension in patients with sympathetic failure. Head-up tilt at night is beneficial and appears to reduce salt and water loss by stimulating the renin-angiotensin-aldosterone system or by

Tabic 83.10: Summary outline of non pharmacological and . 11. i rii..-.. illogical iiiiMvaiv. in 11 ii m.uiagi incnl til poslural hypotension due to neurogenic failure*

Nonpharmacological measures
- To be avoided
  - Sudden hcrtd-up postural change (especially on waking)
  - Prolonged recumbency
  - Straining during micturition and bowel movement
  - High environmental temperature (including hot baths)
  - Severe exertion
  - Large meals (especially with refined carbohydrate)
  - Alcohol
  - Drugs with vasodepressor properties
- To be inttoduced
  - 1 lead-up tilt during sleep
  - Small frequent meals
  - 1 iigh salr intake
  - Judicious exercise (including swimming)
  - Body positions and maneuvers
- To be considered
  - Elastic stockings
  - Abdominal binders
  - Positive-gravity suits
  - Water ingestion

I'll anna co logical
- Startet drug: fludrocortisone
- Sympathomimetics: ephedrinc or midodrine
- Specific targeting: octreotide, desmopressin, or erythropoietin

[&]lt should be emphasized that non-neurogenic factors (such as fluid loss due to vomiting or diarrhea) may substantially worsen postural hypotension. (Adapted with permission from Mar bias, C. J. & ICimber, j. R. 1998, "Treatment of postural hypotension," / *Neurol Neurosurg Psychiatry,* vol. *65,* pp. 285-289.)
'Mathias, C. J, 2000, "A 21st century water cure," *lancet,* vol. 356, pp. 1046-1048.

activating other hormonal, neural, or local renal hemodynamic mechanisms, which reduce recumbency-induced diuresis. In some, head-up tilt may be impractical or the degree of tilt achieved inadequate. In these patients, nocturnal polyuria and nocturia can be reduced with the antidiuretic agent desmopressin (Mathias and Young 2003). Straining during micturition and bowel movement can lower blood pressure further by inducing the Valsalva maneuver. In toilets in small enclosed areas, this is dangerous because the person cannot fall to the floor and thereby recover blood pressure and consciousness. In hot weather, the elevation of body temperature because of impairment of thermoregulatory mechanisms, such as sweating, may increase vasodilatation and worsen postural hypotension. Ingestion of alcohol or large meals, especially those containing a high carbohydrate content, may cause postprandial hypotension and aggravate postural hypotension. Various physical maneuvers (Wieling ct al. 1993), such as leg crossing, squatting, sitting in the knee-chest position, and abdominal compression, arc of value in reducing postural hypotension (Figure 83.25),

A number of devices have been used to prevent venous pooling during standing. These include elastic stockings for the lower limbs, abdominal binders, and, in extreme cases, positive-gravity suits. Each has its limitations and may increase susceptibility to postural hypotension when not in use. In patients with amyloidosis and accompanying hypoalbuminemia, positive-gravity suits may be the last resort because it is virtually impossible to maintain intravascular volume in these patients without causing tissue edema.

Ingestion of 500 mL of water raises blood pressure substantially in patients with primary autonomic failure; this may be of value although the ensuing diuresis may be troublesome, especially in patients with MSA who have associated bladder disturbances (Cariga and Mathias 2001; Shannon et al. 2002),

Drugs often are needed to help sustain blood pressure (Table 83.11). The major mechanisms by which they act include constticting blood vessels, increasing cardiac output, preventing vasodilatation, and retaining salt and water. It should be recognized that enhanced responses usually occur to pressor and vasodepressor agents; the former may result in severe hypertension, especially when rhc patient is supine, and vasodepressor substances may cause marked hypotension. There arc exceptions; patients with infiltration of blood vessels due to amyloidosis may not exhibit supersensitivity, despite a peripheral autonomic neuropathy. With increasing awareness of the precise biochemical deficit in some patients, agents can be given that bypass deficient enzyme systems and result in appropriate neurotransmitter replacement (Figure 83.26). An example is in DBH deficiency, in which the amino acid L-rhreo-3,4-dihydroxyphenylserine is directly converted by do pa-decarboxylase into noradrenaline (Figure 83.27). Whether this occurs intra- or extraneuronally (or both) is unclear. Its potential value in the management of postural hypotension in primary chronic autonomic failure remains to be determined (Mathias et al. 2001b).

A valuable starter drug, especially in mild postural hypotension, is fludrocortisone in a dose of 0.1 or 0.2 mg at night. There is no evidence of a mineralocorricoid deficiency in primary autonomic failure, and low-dose fludrocortisone probably acts by reducing the inability to retain salt and water, especially when recumbent, and by increasing the sensitivity of blood vessels to pressor substances. In the doses used, it is less likely to induce side effects such as ankle edema and hypokalemia. If nocturnal polyuria is not reduced by head-up tilt, fludrocortisone can be effectively combined with desmopressin, a vasopressin-2 receptor agonist with potent antidiuretic but minimal direct pressor activity. Five to 40 mg intranasally or 100-400 mg orally at night reduces the diuresis but, when used without fludrocortisone, does not prevent nocturnal natriuresis. These drugs have been used mainly in patients with primary chronic autonomic failure (Mathias and Young 2003). Patients with PAF require smaller doses (usually 5-10 mg only) because they appear to be more sensitive to the drug than are patients with

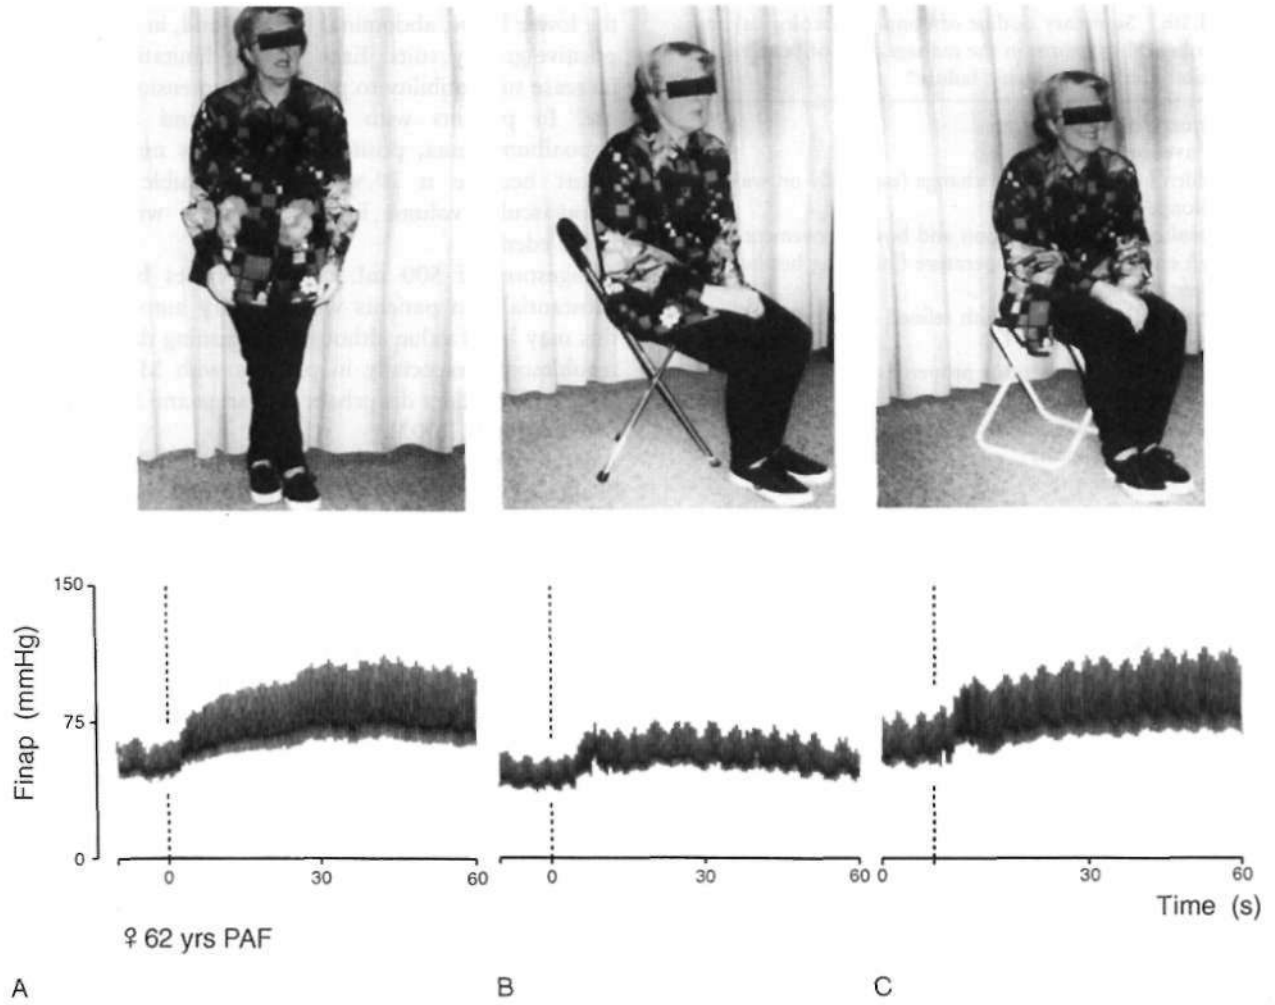

FIGURE 83.25 The effect of standing in a crossed-leg position with leg muscle contraction (A), sitting on a derby chair (B), and sitting in a fishing chair (C) on finger arterial blood pressure in a patient with postural hypotension. Postural symptoms wetc present while the patient was standing and disappeared while the patient had crossed legs. Sitting on a derby chair did not completely relieve the patient's symptoms. Note the greater increment in blood pressure while the patient was standing with crossed legs and leg muscle contractions or sitting on the fishing chair compared with sitting on a derby chair. (Reprinted with permission from Smit, A. A. J., Hardjowijono, M A,, 6c Wieling, W. *1997,* "Are portable folding chairs useful to combat orthostatic hypotension?" *Ann Neurol,* vol. 42, pp. 975-978.)

MSA. The plasma sodium concentration must be monitored to exclude hyponatremia and water intoxication. These can he reversed by stopping the drug and withholding water, hut a diuresis then ensues, which may enhance postural hypotension.

A number of drugs that mimic the activity oi noradrenaline, either directly or indirectly, have been used. Ephedrine acts both directly and indirectly and is of value in central and incomplete autonomic lesions, including MSA. In severe peripheral sympathetic lesions (as in PAF), it may have minimal or no effects. A dose of 15 mg three times daily initially, with an increase to 30 or 45 mg three times daily, can be used, although central side effects limit use of the higher doses. Drugs that act directly on or-adrenoceptors are of value, especially in patients with peripheral lesions. These drugs often act mainly on resistance vessels, with the potential risk of deleterious arterial constriction, especially in elderly patients and in those with peripheral vascular disease. A well-studied example is midodrine, which is converted to the active metabolite, desglymidodrinc (Low ct al. 1997). The ergot alkaloid dihydroergotamine acts predominantly on venous capacitance vessels, but its effects ate limited by its poor absorption; high oral doses (5-10 mg three times daily) may be needed.

Other therapeutic attempts to raise blood pressure have concentrated on pre- and postsynaptic a2⁻ad$^{rcn(>(;cP^{r<,r}}$ mechanisms. They have limited application in practice. Clonidine is mainly an (^-adrenoceptor agonist, which predominantly lowers blood pressure through its central effects by reducing sympathetic outflow. It also has peripheral actions on postsynaptic (^-adrenoceptors, which may raise blood pressure in the presence of pressor supersensitivity. These peripheral vasoconstrictor effects

Table 83.11: Outline of the major actions by which a variety of drugs may reduce postural hypotension

Reducing salt loss or plasma volume expansion:
  mineralocorticoids (fludrocortisone)
Reducing nocturnal polyuria: VVrecepror agonists (desmopressin)
Vasoconstriction, sympathetic
  Directly
    On resistance vessels (midodrinc, phenylephrine, noradrenaline, clonidine)
    On capacitance vessels (dihydroergoramine)
  Indirectly (ephedrine, tyraminc with monoamine oxidase inhibitors, yohimbine)
    Prodrug (t.-dihydroxyphcnylserine)
Vasoconstrictor, nonsympathomimetic: Vpreceptor agents (terli press in)
Preventing vasodilatation
  Prostaglandin synthetase inhibitors (indomethacin, flurbiprofen) .
  Dopamine receptor blockade (metoclopramide, dompetidone)
  ^-Adrenoceptor blockade (propranolol)
Preventing postprandial hypotension
  Adenosine receptor blockade (caffeine)
  Peptide release inhibitors (somatostatin analogue: octreotide)
Increasing cardiac output
  Beta blockers with intrinsic sympathomimetic activity (pindolol, xamoterol)
  Dopamine agonist (ibopnmine!
Increasing red cell mass: erythropoietin

probably account for its modest success in severe, distal sympathetic lesions. Yohimbine blocks presynaptic ^-adrenoceptors, which normally suppress release of noradrenaline and should theoretically be of benefit in incomplete sympathetic lesions, as observed in single-dose studies.

Supine hypertension is not uncommon in autonomic failure and may be worsened by treatment. It may occasionally result in cerebral hemorrhage, aortic dissection, myocardial ischemia, or cardiac failure. This may be a greater problem with certain drug combinations, such as tyramine (which releases noradrenaline) and monoamine oxidase inhibitors (such as tranylcypromine and moclobemide), which prolong its actions. Supine hypertension may increase symptoms of cerebral ischemia during subsequent postural change, probably through an unfavorable resetting of cerebral autoregulatory mechanisms. To prevent these problems, head-up tilt, omission of the evening dose of vasopressor agents, a prebedtimc snack to induce postprandial hypotension, and even nocturnal use of short-acting vasodilatates have been suggested.

One approach to overcoming the problems with blood pressure variability is to use a subcutaneous infusion pump, (as in the control of hyperglycemia with insulin in diabetes mellitus), and a short-acting but effective vasoconstrictor, such as noradrenaline. A pilot study with such a device had been successful, but there were a number of practical problems, including the accurate monitoring of blood pressure without an intra-arterial catheter. Some of these problems have been overcome (Oldenburg ct al, 2001), and this approach may be of benefit to the patient with severe hypotension that is refractory to the combination of ncmpharmacological and conventional drug therapy.

Other therapeutic approaches in postural hypotension include prevention of vasodilatation. Prostaglandin synthetase inhibitors, such as indomethacin and flurbiprofen, have been used with some success and may act by blocking vasodilatory prostaglandins, by causing salt and water

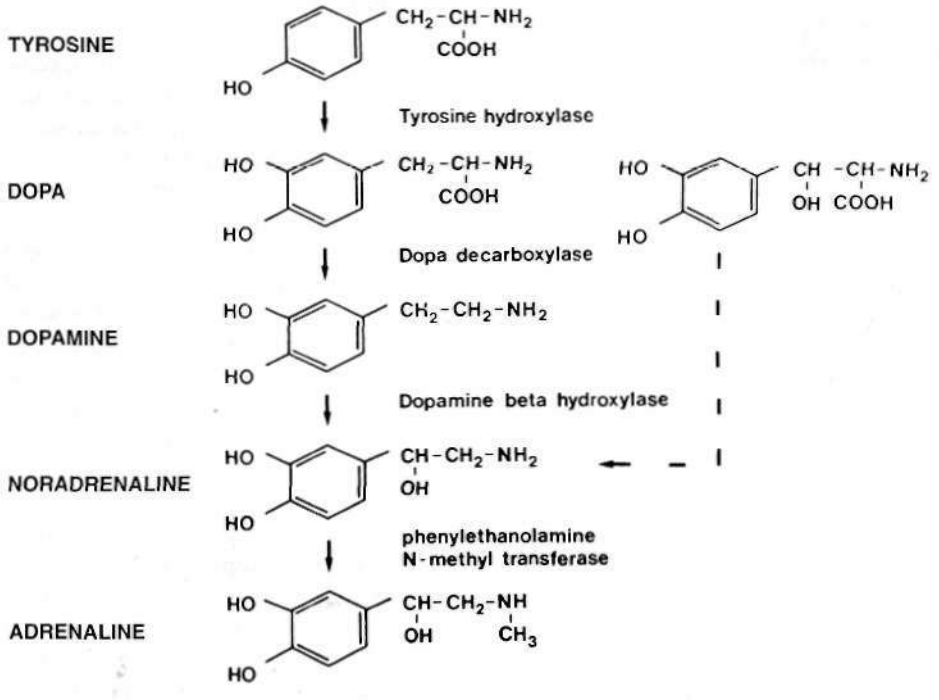

FIGURE 83,26 Biosynthetic pathway for noradrenaline synthesis and the structure of L-threo-3,4-dihydroxyphenylserine (DOPA) alongside. The enzyme dopa-decarboxylase, which is present both intra- and extraneuronally, converts it to noradrenaline, thus bypassing the hydroxylanon step, which depends on dopamine *ft* hydroxylase.

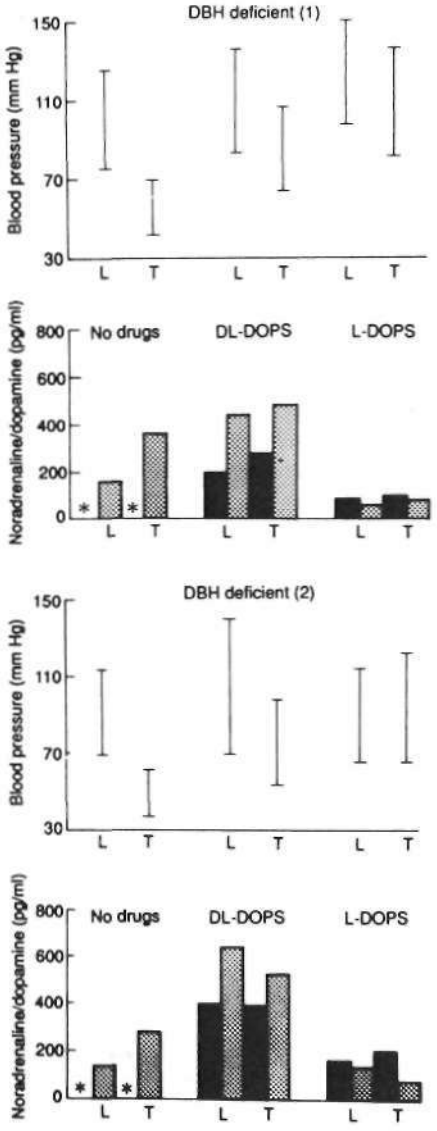

FIGURE 83.27 Blood pressure (systolic and diastolic) while the patient is lying flat (I.) and during head-up tilt (T) in two siMings with dopamine ^-hydroxylase (DBH) deficiency (1 and 2) before and during treatment with m,-dihydro\yphenvlserine (DL-DOPS) and i.-DOPS. Plasma noradrenaline *(histogram)* and dopamine *(stippled histogram)* levels ate indicated before and during head-up rilt. Plasma noradrenaline was undetectable (asterisk <5 pgftnL) in both while the patient is not taking drugs. (Reprinted with permission from Mathias, C. J,, Bannister, R., Cortelli, P., et al. 1990, "Clinical autonomic and therapeutic observations in two siblings willi [Kwt lira I hypotension and sympathetic failure due to an inability to synthesize noradrenaline from dopamine because of a deficiency of dopamine beta-hydroxylase," *Q] Med,* vol. 75, p. 617.)

retention through their renal effects, or both. They have potentially serious side effects, however, such as gastrointestinal ulceration and hemorrhage. The dopamine antagonists metoclopramide and domperidone are occasionally of value when an excess of dopamine is a contributing factor. Whether preventing the vasodilator effects of nitric oxide will be of value remains speculative (Kimber et al. 2001).

£-Adrenoceptor blockers, such as propranolol, may be successful when postural hypotension accompanies tachycardia; the combination of blocking of ^-adrenoceptor vasodilatation and /$J_r$adrenoceptor-induced tachycardia may account for the benefit. Certain ^-adrenoceptor blockers, such as pindolol, with a high degree of intrinsic sympathomimetic activity, may increase cardiac output and through this, or other less well-understood mechanisms, raise blood pressure. Complications such as cardiac failure may occur. Use of another agent with similar properties, xamorerol, has bad limited success, and it has been withdrawn because of deleterious effects. The dopamine agonist ibopaminc has been used in a few patients only with varying success.

Various therapeutic approaches have been used to reduce severe postprandial hypotension. Caffeine has been advocated and may act by blocking vasodilatory adenosine receptors. A dose of 250 mg, present in two cups of coffee, may be of benefit. The prodrug I.-d ill ydrnxy phenyl serine, presumably through adrenoceptor-induced vasoconstriction, reduces postprandial hypotension in primary autonomic failure (Freeman et al. 1996; Mathias et al. 2001). The somatostatin analogue octreotide, which inhibits release of a variety of gastrointestinal tract peptides, including those with vasodilatory properties, has been successfully used to prevent postprandial hypotension; it also may partly reduce postural and exercise-induced hypotension (Smith and Mathias 1995). The need for subcutaneous administration is a drawback. It does not appeat to enhance nocturnal (supine) hypertension (Alam et al. 1995). The development of an oral preparation will be a substantial advance in therapy.

Other strategies must be used in patients with specific disorders causing syncope. In vasovagal syncope, management consists of various nonpharmacological approaches that include salt and fluid repletion (Cooper and Haitisworth 2002; Wieling et al. 2002), lower limb exercises, sympathetic activation techniques, antipooling measures, and maneuvers to introduce, especially in the presyncopal phase (van Dijk et al. 2000); in some a cardiac demand pacemaker (Benditt 1999) and drugs to raise blood pressure may be needed. In carotid sinus hypersensitivity, a cardiac demand pacemaker may be of benefit in the cardioinhibitory form; in the mixed and vasodepressor forms, rhe use of vasopressor drugs and even carotid sinus denervation may be necessary. Bradycardia in patients with high spinal cord injuries who are receiving mechanical ventilation may require a combination of atropine, oxygen, and, if necessary, a temporary demand pacemaker (Mathias and l-'rankel 2002). Tachypacing with an implanted cardiac pacemaker is of no benefit in the management of postural hypotension (except in the rare situation when bradycardia also occurs), because raising the heart rate without

increasing venous return (which is impaired because of pooling due to sympathetic vasoconstrictor failure) docs not elevate cardiac output and therefore does not raise blood pressure.

Hypertension

Hypertension due to increased sympathetic nervous activity occurs in patients with tetanus, Guillain-Barre syndrome, porphyria, certain cerebral rumors, and subarachnoid hemorrhage. It usually responds to propranolol and other •••••. mpntluilytk and .imihypi r tensive as^nls. In patient-, \\:*V.* high spinal cord injuries, it is important to look for the precipitating cause of autonomic dysreflexia (Table 83.12) and tectify it. A range of drugs, based on knowledge of the pathophysiological mechanisms, has been used to prevent or reduce hypertension in these patients (Table 83.13).

V<,"r'i7/;i,'.L,' *I')i>in-il!ri:<*

In idiopathic hyperhidrosis, pharmacological approaches may be beneficial. In hypcrhidrosis over the palms and soles, local astringents containing glutaraldchyde and antiperspirants containing aluminum salts may reduce sweating. Anticholinergics, such as propantheline bromide, and topical applications of hyoscine hydrobromide, may help. Low-dose clonidine may be of benefit, especially in those in whom there is a central or emotional component; in some patients, behavioral psychotherapy may provide relief. Minimally invasive (thoracic endoscopic) sympathectomy often is successful in reducing or abolishing palmar hyperhidrosis, but there is a high incidence of compensatory hyperhidrosis (Adar 1997), which in some may be more distressing than the original symptoms. In gustatory sweating, avoidance of foods that induce attacks may help. Botulinum toxin has been used to treat axillary, palmar (Naumann et a). 1997), and gustatory (Schulze-Bonhage et al. 1996; Tugnoli et a!. 2002) hyperhidrosis.

Table 83.12: Some causes of autonomic dysreflexia in patients with high spinal cord injuries

Cutaneous
- Pressure sores
- Burns
- Infected ingrowing toenails

Skeletal muscle
- Spasms, especially in limbs with contractures

Abdominal viscera
- Ureter
  - Calculus
- Urinary bladder
  - **Distention** by Nocked catheter
  - Infection
  - **Discoordinatcd con tract ion**
  - Irritation by catheter, calculus, or bladder washout
- Rectum/anus
  - Fecal retention
  - Anal fissure
  - Enema ta
- Uterus
  - **Contraction during pregnancy**
  - Menstruation occasionally
- Gastrointestinal organs
  - Gastric ulceration
  - Appendicitis
  - Cholecystitis, cholelithiasis

Miscellaneous
- Fractures of bones
- Urethral abscess
- Vaginal dilation
- **Ejaculation**
- Intrathecal neostigmine or electrical stimulation to **induce ejaculation**

Table 83.13: Drugs used in autonomic dysreflexia with their major site of action

Afferent: Topical lignocaine
Spinal cord
- Clonidine
- Reserpine
- Spinal anesthetics

Sympathetic efferent
- Ganglia: hcxamethonium
- Nerve Terminals: guanethidinc
- <i - A d ren occ p to rs: phen ox y ben za m i ue

Target organ
- Blood vessels: glyceryl trinitrate
- Sweat glands: propantheline bromide

Note; Drugs such as clonidine may act at multiple sites. Some must be given at specific sites, such as lignocaine into the bladder, if this is the source of the stimulus causing autonomic dysreflexia.

Thermo regula turn

hi hypothermia, the standard management ot slowly warming patients, preferably with a space blanket and warm drinks, is recommended. In hyperpyrexia, cold drinks, tepid sponging, a fan to increase heat loss by convection, and, if possible, an air-conditioned environment are helpful; immersion in ice-cold water is occasionally necessary.

Gastrointestinal System

Xerostomia may be helped by artificial saliva. Achalasia of the esophagus may require surgery or dilatation. Patients with MSA who have oropharyngeal dysphagia need advice on the type and quantity of food to be ingested; if there is severe dysfunction and a risk of tracheal aspiration, a feeding gastrostomy may be necessary. Metoclopramide and domperidone increase gastric emptying and may be useful in gastroparesis. The prokinctic drug cisapride, which acts through intrinsic cholinergic plexuses, and the macrolide erythromycin, which stimulates motilin receptors, may be of

value. In paralytic ileus, nasogastric suction with intravenous feeding is necessary. Peptic ulceration, as occurs in the early stages after high spinal cord injury, can be prevented by the prophylactic use of histamine H^-antagonists (such as cimetidine and ranitidine) or proton-pump inhibitors (such as omeprazole). In those with diarrhea, broad-spectrum antibiotics (neomycin or tetracycline) may be the initial step before codeine phosphate or other opiate-based antidiarrheal agents are used. The somatostatin analogue, octreotide, may reduce diarrhea in some patients with amyloidosis and diabetic autonomic neuropathy. Aperients and laxatives, together with a high-fiber diet, are often needed in patients with constipation.

Urinary Tract

In outflow tract obstruction, procedures that include prostatectomy, transurethral resection, or sphincterotomy may be needed. Surgical procedures often worsen incontinence in MSA. Bladder dysfunction may be helped by drugs that influence detrusor muscle activity (such as the anticholinergic, oxyburynin) or sphincter malfunction (e.g., alpha blockers phenoxybenzamine and prazosin). Side effects may be enhanced in patients with generalized autonomic failure. Intermittent or indwelling catheterization may be necessary. The urine should be checked often to detect infection. Nocturnal polyuria in chronic primary autonomic failure is often helped by desmopressin; it is also of value in other disorders, such as multiple sclerosis, in which nocturia may occur. Women often have difficulties with urinary drainage, even by catheterization, and the use of urinary diversion procedures, such as an ileal conduit, is occasionally necessary.

Reproductive System

Erectile failure in men may be helped by suction devices. an implanted prosthesis, or a variety of pharmacological approaches, including local instillation (intracavernosal or urethral) or oral administration of drugs (e.g., sildenafil) (Hussain et al. 2001). In DBH deficiency, difficulty in ejaculation is improved by treatment with L-dihydroxyphenylserine. In patients with spinal cord injuries, elcctroejaculatory procedures followed by artificial insemination have been successful. Pregnant women with high spinal injuries may develop severe hypertension with cardiac dysrhythmias and eclampsia during uterine contractions and delivery. This is best managed by spinal anesthesia, which reduces spinal sympathetic discharge and permits a normal delivery.

Respiratory System

A tracheostomy may be necessary if inspiratory stridor is due to laryngeal abductor paresis and there is evidence of oxygen desaturation, especially at night (Harcourt et al. 1996), In those with periodic apneic episodes, timed or triggered bilevel positive airway pressure ventilation may be useful.

Eye

In alacrima, tear substitutes such as hypromellose eye drops arc of value.

Neurological Deficits

In the parkinsonian forms of MSA, a trial of i.-dopa is indicated because some patients show a response, especially in the early stages of the disease. It may, however, cause or enhance postural hypotension. The monoamine oxidasc-B inhibitor, selegiline, has been used in combination with L-dopa, although there is no evidence that it delays progression of MSA; it may worsen postural hypotension. Postural hypotension also may occur with selegiline treatment in patients with idiopathic Parkinson's disease who do not have autonomic failure; the mechanisms that lower blood pressure may include the central effects of its metabolite, methylamphetamine (Churchyard et al. 1997). There is no effective pharmacotherapy for cerebellar deficits in MSA. Supportive therapy using disability aids must be provided. The family and community must be involved in overall care. Various therapies have been reputed to influence diabetic autonomic neuropathy (Manzella et al. 2001). There is limited evidence that transplantation of the pancreas in diabetes mellirus or of the liver in familial amyloid neuropathy favorably influences the neuropathy in these otherwise relentlessly progressive disorders.

Chapter 84
Disorders of Neuromuscular Transmission

Donald B. Sanders and James F. Howard, Jr.

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is the most common primary disorder ol lU'iirniinisciihr Transmission. An acquired immunological abnormality is the usual cause, but some cases result from genetic abnormalities at the neuromuscular junction. Much has been learned about the pathophysiology and immunopathology of MG during the past 20 years. What was once a relatively obscure condition of interest primarily to neurologists is now the best characterized and understood autoimmune disease. A wide range of potentially effective treatments are available, many of which have implications for the treatment of other auto immune disorders. This chapter is based on the authors' experience with more than 1500 patients with MG seen with out colleagues over a period of 25 years.

Epidemiology

[• pi d c n iio logical studies have shown a trend for an increasing prevalence of and a falling death rate attributed to MG over the past 50 years. The primary factor for both appears to be an increased life span after diagnosis. The current prevalence in the United States is estimated to be 20 per 100,000 population—between 53,000 and 60,000 discs Phillip-, 2()i)i). I'uvaiisi' VIG is often undiagnosed the true incidence is probably higher. Women are affected more in the second and third decades and men in the sixth decade. As the population ages, the average age at onset has increased correspondingly. Men are now more often affected than women, and the majority of patients with MG in the United States are older than 50 years of age.

Clinical Presentation

Patients seek medical attention for specific muscle weakness or dysfunction. Although tbey may also have fatigue, it is not usually the major or presenting complaint. Ptosis or diplopia was the initial symptom in two thirds of our patients; almost all had both within 2 years of disease onset. Difficulty chewing, swallowing, or talking was the initial symptom in one sixth of patients and limb weakness in one tenth. The initial weakness was rarely limited to single muscle groups, such as neck or finger extensors, hip flexors, or ankle dorsiflexors.

Weakness typically fluctuates during the day, usually being least in the morning and wotse as the day progresses, especially after prolonged use of affected muscles. Ocular symptoms typically become worse while the patient is reading, watching television, or driving, especially in bright sunlight. Many patients find that dark glasses reduce diplopia and hide drooping eyelids. Jaw muscle weakness typically becomes worse during prolonged chewing, especially of tough meats or chewy candy.

Careful questioning often reveals evidence of earlier, unrecognized myasthenic manifestations, such as frequent purchases of new- eyeglasses to correct blurred vision, avoidance of foods that became difficult to chew or swallow, or cessation of activities that require prolonged use of specific muscles, such as singing. Friends may have noted a sleepy or sad facial appearance caused by ptosis or facial weakness.

The course of MG is variable but usually progressive. In our experience, weakness remains restricted to the ocular muscles in approximately 10% of patients, although others have reported lack ol spread *u:* more than 10",:. The rest have progressive weakness during the first 2 years that

ultimately involves oropharyngeal and limb muscles. Maximum weakness occurs during the first year in two thirds of patients. Before corticosteroids were used for treatment, approximately one third of patients had spontaneous improvement, one third had progressive disease, and one third died of the disease. Periods of spontaneous improvement occur early in the course but are rarely permanent. Symptoms typically fluctuate over a relatively short period and then become more severe (active stage). Left untreated, the active stage is followed by an inactive stage, in which fluctuations in strength still occur but are attributable to fatigue, intercurrent illness, or other identifiable factors. After 15-20 years, untreated weakness becomes fixed, and the most severely involved muscles are often atrophic (burnt-out stage). Factors that worsen myasthenic symptoms are emotional upset, systemic illness (especially viral respiratory infections), hypothyroidism or hyperthyroidism, pregnancy, the menstrual cycle, drugs affecting neuromuscular transmission (see Drugs That Adversely Affect Myasthenia Gravis and the Lambert-Eaton Myasthenic Syndrome, later in this chapter), and fever.

The diagnosis is often delayed for months or even years. The unusual distribution and fluctuating weakness of MG often suggest psychiatric illness. Conversely, ptosis, diplopia, and oropharyngeal symptoms suggest intracranial pathologic conditions and often lead to unnecessary cranial imaging studies or arteriography.

Physical Findings

The examination must be performed in a manner that will detect variable weakness in specific muscle groups. Strength should be assessed repetitively during maximum effort and again after brief periods of rest. Performance on such tests fluctuates in diseases other than MG, especially if testing causes pain. The strength fluctuations of MG arc best shown by tests of ocular and oropharyngeal muscle function because these muscles are less likely to be affected by other factors. However, the weakness in MG does not always vary over short time intervals, which makes the differential diagnosis difficult, especially if edrophonium (Tensilon) does not improve the weakness.

Ocular Muscles

Most patients with MG have weakness of ocular muscles (Table 84.1). Asymmetrical weakness of several muscles in both eyes is typical. The pattern of weakness is not characteristic of lesions of one or more nerves, and the pupillary responses are normal. Weakness occurs most often and is usually most severe in the medial rectus muscles. Ptosis is usually asymmetrical and varies during sustained activity. To compensate for ptosis, the frontalis muscle may be chronically contracted, producing a worried or surprised look. Unilateral frontalis contraction is a clue that the lid elevators are weak on that side. This also may be the only visible evidence of facial weakness. Patients with ocular muscle weakness usually have weakness of eye closure.

Oropharyngeal Muscles

Oropharyngeal muscle weakness causes changes in the voice, difficulty chewing and swallowing, inadequate maintenance of the upper airway, and altered facial appearance. The voice may be nasal, especially after prolonged talking, and liquids may escape through the nose when swallowing because of palatal muscle weakness. Weakness of the laryngeal muscles causes hoarseness. This can also be shown by asking the patient to make a high-pitched "eeeee" sound. Difficulty swallowing is detected from a history of choking or clearing of the throat or coughing after eating.

Myasthenic patients, particularly those with severe or long-standing disease, may have a characteristic facial appearance, as seen in Figure 84.1. At rest, the corners of the mouth droop downward, making the patient appear depressed. Attempts to smile often produce contraction of the medial portion of the upper lip and a horizontal contraction of the corners of the mouth without the natural upward curling, which gives the appearance of a snarl.

Jaw weakness can be shown by manually opening the jaw against resistance, which is not possible in normal people. The patient may support a weak jaw with the thumb under the chin, the middle finger curled under the nose or lower lip, and the index finger extended up the cheek, producing a studious or attentive appearance.

The strength of eye closure is usually diminished and may be the only residual weakness after treatment.

Table 84.1: Ocular findings in myasthenia gravis (MG)

Weakness usually involves one or more ocular muscles without overt pupillary abnormality.
Weakness is typically variable, fluctuating, and fatigahle.
Ptosis that shifts from one eye to the other is virtually pathognomonic of MG.
With limited ocular excursion, saccades are superfast, producing ocular "quiver."
Afrer downgaze, upgaze produces lid overshoot ("lid twitch").
Pseudo-internuclear ophthalmoplegia-limited adduction is present, with nystagmoid jerks in abducting ryi-.
In asymmetrical ptosis, covering the eye with the ptotic lid may relieve contraction of the opposite frontalis.
Passively lifting a ptotic lid may cause the opposite lid to fall,
Edrophonium may improve only one of several weak ocular muscles; others may actually become weaker.
Edrophonium may relieve asymmetric ptosis and produce retraction of the opposite lid from frontalis contraction.
The opposite lid may droop further as the more involved lid strengthens after edrophonium.
Cold applied to the eye may improve lid ptosis.

FIGURE 84.1 The characteristic facial appearance of a woman with moderately severe myasthenia gravis. (A) At rest: Note the bilateral lid ptosis and downward curve of the corners of the mouth, giving the patient a sad appearance. (B) Smiling: The "myasthenic snarl" that results from an upward movement of the medial portion of the upper lip and a horizontal contraction of the corners of the mouth rather than a norma! upward turn. This gives the patient an angry appearance and may be seen even when the patient is attempting to laugh.

Limb Muscles

Weakness may affect any trunk or limb muscle, but some are affected more often than others. Neck flexors arc usually weaker than neck extensors, and the deltoids, triceps, and extensors of the wrist and fingers and ankle dorsiflexors are often weaker than other limb muscles.

Inheritance of Myasthenia Gravis

MG is not transmitted by Mendelian inheritance, but family members of patients are approximately 1000 times more likely i> develop the disease nan -. 1 In- L-I'IKT.;I population. Increased jitter on single-fiber electromyography (SFEMG) has been demonstrated in 33—45% of asymptomatic first-degree family members, and levels of antibodies to the acetylcholine receptor (AChR) arc slightly elevated in up to 50%. These observations suggest that there is a genetically determined predisposition to develop MG.

Pathophysiology of Myasthenia Gravis

The normal neuromuscular junction releases acetylcholine (ACh) from the motor nerve terminal in discrete packages (quanta). The ACh quanta diffuse across the synaptic cleft and bind to receptors on the folded muscle endplate membrane (Figure 84.2). Stimulation of the motot nerve causes muscle contraction by the release of ACh quanta that depolarize the muscle endplate region and then the muscle membrane.

In acquired MG, the postsynaptic muscle membrane is distorted and simplified, having lost its normal folded shape (see Figure 84.2). The concentration of AChRs on the muscle endplate membrane is reduced, and antibodies and complement ate attached to the membrane. ACh is released normally, but its effect on the postsynaptic membtane is reduced. The postjunctional membrane is less sensitive to applied ACh, and the probability that any nerve impulse will cause a muscle action potential is reduced.

Several lines of evidence indicate that MG results from an autoimmune attack on the postsynaptic muscle membrane that impairs neuromuscular transmission (Tabic 84,2).

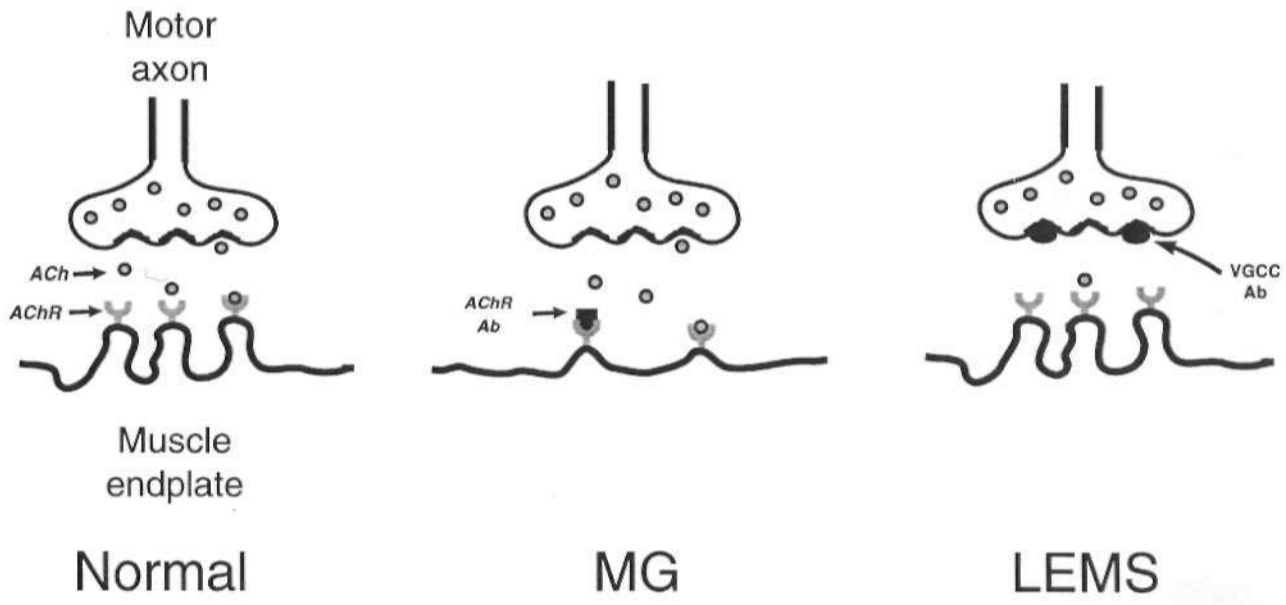

FIGURE 84.2 The neuromuscular junction. In acquired myasthenia gravis (MG), the muscle endplate membrane is simplified and the normal folded pattern is lost. Acetykholine (ACh) receptors (AChR) are lost from the tips of the folds and antibodies (AChR Ab) are attached to the postsynaptic membrane. In Lambert-Eaton myasthenic syndrome (LEMS), antibodies against the voltage-gated calcium channel (VGCC Ab) on the netve terminal interfere with release of ACh.

Autoantibodies in MG

Sttiational antibodies (StrAbs), which react with contractile elements of skeletal muscle, were the first autoantibodies discovered in patients with MG. These antibodies are not pathogenic. They are found in more than 90% of patients with MG and thymoma, and in one third of patients with thymoma who do not have MG. One third of patients with MG without thymoma also have these antibodies; they are seen more often in older patients and in those with more severe disease. The antibody titer does not correlate with disease severity. StrAb levels arc also elevated in patients with autoimmune liver disease and rarely in patients with Lambert-Eaton myasthenic syndrome (LEMS) and in patients with primary lung cancer.

Table 84.2: Evidence that myasthenia gravis (MG) is an immune-media ted disease of the acetylcholine receptor (AChR) complex

Patients with MG have an increased incidence of other presumed or known immune-mediated diseases, such as rheumatoid arthritis.
A transitory neonatal form of the disease occurs in myasthenia and other immune-mediated diseases.
The 1 11, A bnplorypi's ih.ir are common in patients with MG are also common in patients with other autoimmune diseases.
The weakness in MG improves after removal of lymph by thoracic duct drainage and worsens utter rein fusion of a high-molecular-wcight protein fraction from the lymph, probably immunoglobulin G (IgG).
Immunosuppressive treatment, including plasma exchange, produces improvement in most patients with MG.
An animal model of MG can be produced by immunization with purified AChR protein.
Antibodies against human AChR are found in the serum of most patients with MG.
IgG and complement components arc attached to the postsynaptic endplate membrane in myasthenic muscle.
Myasthenic serum or IgG produces abnormal neuromuscular transmission when injected into animals.

StrAb levels are rarely, if ever, elevated in patients with MG in the absence of AChR antibodies and arc therefore of questionable value in confirming the diagnosis of MG. The main clinical value of StrAbs is in predicting thymoma: 60% of patients with MG with onset before age 50 who have elevated StrAb levels have thymoma. Changes in the StrAb titer have been associated with tumor recurrence. However, these antibodies may disappear in patients with persistent thymoma, and they may reappear after thymectomy and immunotherapy without tumor recurrence. Thus they do not consistently indicate the persistence or recurrence of tumor.

We have found antibodies to the AChR in 80% of patients with generalized MG and in more than one half of patients with ocular myasthenia. The assay for these antibodies is a major diagnostic test for MG, and they are only rarely found in the absence of MG (see Antibodies against Acetylcholine Receptors, later in this chapter).

The role of serum antibodies against AChRs in the pathophysiology of MG is not fully understood. Although antibody concentrations are usually higher in patients with more severe disease, these values vary widely among patients, and as many as 25% of patients are seronegative.

Even seronegative patients show improvement aftet plasma exchange, and the neuromuscular abnormality can be transferred to animals by injecting setum from seronegative patients. The antibodies responsible for the neuromuscular abnormality may not always be those that ate measured, and the serum antibody concentration may not refleci the amotini ot antibody attached ro the muscle endplate.

Antititin antibodies have an association with MG similar to that for StrAbs: They are found only in patients with AChR antibodies with late-onset disease ot thymoma (Somnier and Engel 2002). No clinical role for these antibodies has been identified.

Antibodies to muscle-specific receptor rytosinc kinase have recently been desctibed in patients with generalized MG who are seronegative for AChR antibodies (see Seronegative Myasthenia Gravis, later in this chapter).

It is hypothesized that the predominant involvement of ocular muscles in MG is due to the presence of antibodies specific for the y-subunit of the AChR, which is found in adult extraocular muscle. However, the levatot palpebrae, which has a different AChR subumt composition, is as involved clinically as other ocular muscles, and y-subunits have been found even in normal limb muscle.

Autoantibodies to the AChR ate T cell dependent. T lymphocytes also play a pivotal role in the initiation and maintenance of the autoimmune response against the AChR complex, although the precise mechanism by which this occurs is not fully understood. T cells are activated through the T-cell receptor by majot histocompatibility complex (MHC) class II molecules bound with antigenic peptide. The role of HLA linkage has not been fully elucidated. In some instances, certain MHC molecules (e.g., HLA-DRW3, -B8, and -A1) predispose the individual to MG whereas other molecules may provide resistance to disease. CD4^ T cells that tegulate the production of AChR antibodies are found in increased numbers in patienrs with MG. The a-subunit of AChR contains the majority of T-cell recognition sites. These recognition sites are different from those of the main immunogenic region that are recognised by binding antibodies. Sensitization to $CD4^+$ T cells spreads across the AChR complex with disease duration. This ptobably accounts for the large and varied antibody tepertoire of the myasthenic patient. Universal epitopes on the AChR complex tecognize large numbers of CD4' T cells and are expressed in the majority of patients with MG. These drive the synthesis of AChR antibody production (Conti-Fine et al. 1997).

The Thymus in Myasthenia Gravis

The primary abnormaliry in MG appears to be a breakdown in immune tolerance toward self-antigens. The thymus gland plays a role in the induction of tolerance to self-antigens. It contains all the necessary elements for the pathogenesis of MG: myoid cells that express the AChR antigen, antigen-ptesenting cells, and immunocompetent T cells. Cultured thymic myoid cells express transcripts that encode fot AChR subunits. It is likely that the expression of these subunits serves as an anrigen for the auto sensitization of the patient against the AChR. Thymic abnormalities are associated with MG. Ten percent of patients with MG have a thymic tumor, and 70% have hyperplastic changes (germinal centers) that indicate an active immune response.

Almost 20% of our patients with MG whose symptoms began between the ages of 30 and 60 had thymoma; the incidence of thymoma was much lower when symptoms began after age 60. Most thymic tumors in patients with MG arc benign, well-differentiated, and encapsulated and can he reiivv. ed completely at surgery (see Thymectomy, later in this chapter).

Diagnostic Ptocedures

Edrophonium Chloride (Tensilon) Test

Weakness caused by abnormal neuromuscular transmission characteristically improves aftet intravenous administration of edrophonium chloride (Tensilon). This response forms the basis of the Tensilon test, in which strength is examined before and after injection of the drug. Except when examining ocular and pharyngeal muscle function, the clinician must rely on the patient to exert maximum effort before and after drug administration to assess its effect. For this reason, the test is most reliable when the patient has ptosis, discernible limitation of eye movements, or nasal speech.

Results of the Tensilon test are found to be positive in more than 90% of patients with MG. Howevet, improved sttcngth after edrophonium is not unique to MG. For example, it may also be seen in motor neuron disease, in which neuromuscular Transmission is abnormal because of rapidly progressive denervation. We have also seen improved eye movements after edrophonium in patients with lesions of the ocular motor nerves.

The ideal dose of edrophonium cannot be predetermined. A single fixed dose, such as 10 mg, may be too much in some patients and cause increased weakness. Thus an incremental dosing schedule is recommended. A dose of 2 mg is injected intravenously, and the response is monitored for 60 seconds. Subsequent injections are 3 and 5 mg. If improvement is seen within 60 seconds after any dose, no further injections arc given. Ten milligrams of edrophonium does not weaken normal muscle, and the occurrence of weakness afrer its injection indicates a neuropathy or neuromuscular ttansmission defect. The total dose of edrophonium in children is 0.15 mg/kg administered incrementally. Subcutaneous administration can be used in newborns and infants, but the response may be delayed for 2-5 minutes.

Some clinicians administer edrophonium in a blinded or double-blinded fashion to improve objectivity. This is not needed when the end point is well defined, such as relief of ptosis.

Some patients whose MG docs not respond to intravenous edrophonium may show a response to intramuscular neostigmine, which has a longer duration of action. Intramuscular neostigmine is particularly useful in infants and children whose response to intravenous edrophonium maybe too brief for adequate observation. In some patients, a therapeutic trial of oral pyridostigmine (Mcstinon) for several days may produce improvement that cannot be recognized after a single dose of edrophonium or neostigmine.

Techniques that show a more objective effect of cholincsterase (ChE) inhibitors on ocular muscles include electromyography (EMG) of the ocular muscles, tonometry, oculography, and Lancaster red-green tests of ocular motility. These tests increase sensitivity but are nonspecific and may yield false-positive results.

Antibodies d^iiitut Acetylcholine Receptors

Eighty percent of our patients with acquired generalized myasthenia and 55% with ocular myasthenia have serum antibodies that bind human AChRs (Figure 84.3). The serum concentration of AChR Abs varies widely among patients with similar weakness and cannot be used to predict the severity of disease in individual patients. Approximately 10% of patients who lack binding antibodies have antibodies that modulate the turnover of AChR in tissue culture. The concentration of binding antibodies may be low at symptom onset and rise later. Repeat studies are appropriate when initial values arc normal. In general, finding AChR-binding antibodies in a patient with compatible clinical features confirms the diagnosis of MG, but normal concentrations do not exclude the diagnosis. AChR-binding antibody concentrations may be elevated rarely in patients with systemic lupus erythematosus, inflammatory neuropathy, amyotrophic lateral sclerosis, rheumatoid arthritis who are taking D-penicillamine, and thymoma without MG and in normal relatives of patients with MG.

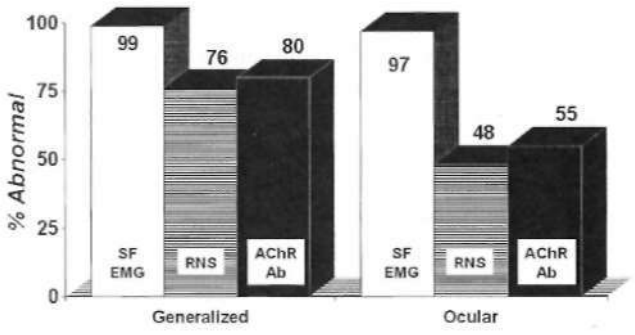

FIGURE 84.3 Comparison of abnormalities demonstrated by single-fiber electromyography (SFEMG), repetitive nerve stimulation of hand and shoulder muscles (RNS), and serum acetylcholine receptor antibody levels (AChR Ah) in 550 patients with acquired i'.nnT.ili/.rd or ocular myasthenia gravis (D. B. Sanders, J. M, Masscy, and J. F. Howard, unpublished observations).

Virtually all patients with MG and thymoma have elevated concentrations of AChR-binding antibodies, and many have high concentrations of AChR-modulating, AChR-blocking, and antistriatcd muscle antibodies as well. However, many patients with MG without thymoma also have high concentrations of these antibodies, and these serological findings cannot be used to predict the presence of thymoma.

E lectromyogrctph y

The following arc Practice Recommendations of the American Association of Electrodiagnostic Medicine regarding the use of EMG in MG (AAEM Quality Assurance Committee 2001):

Repetitive nerve stimulation (RNS) of a nerve supplying a symptomatic muscle should be performed. Abnormality in MG is considered to be a reproducible 10% decrement in amplitude when the first stimulus is compared to the fourth or fifth, which is found in at least one muscle. Anticholinesterase medications should be withheld 12 hours before testing, if this can be done safely.

If results of RNS are normal and there is a high suspicion of a neuromuscular junction (NMJ) disorder, SFEMG of at least one symptomatic muscle should be performed. If results of SFEMG of one muscle arc normal and clinical suspicion for a NMJ disorder is high, a second muscle should be studied.

Option: If the patient has very mild or solely ocular symptoms and it is believed that results of the RNS will be normal or if the discomfort associated with RNS prevents completion of RNS, SFEMG testing may be performed in place of RNS as the initial NMJ test. In laboratories with the capability to perform SFEMG, it may be performed as the initial test for disorders of neuromuscular transmission because it is more sensitive than RNS. Routine needle EMG and nerve conduction studies may be necessary to exclude disorders other than MG or Lambert-Fa ton myasthenic syndrome.

The decremented response to RNS is seen more often in proximal muscles, such as the facial muscles, biceps, deltoid, and trapezius, rather than in hand muscles. We have found a significant decrement to RNS in cither a hand or shoulder muscle in (i I % of patients with MG.

SFEMG {see Chapter 36B) is the most sensitive clinical test of neuromuscular transmission and shows increased jitter in some muscles in almost all patients with MG (Trontelj et al. 2002). Jitter is greatest in weak muscles but is often seen even in muscles with normal strength. Patients with mild or purely ocular muscle weakness may have increased jitter only in facial muscles. Studies to detenu in e whether jitter in limb muscles predicts the development of generalized myasthenia in patients with purely ocular weakness show that at least one half of patients with persistent ocular myasthenia have increased jitter in the limb (Weinberg et al. *1999;* Rostedt et al. 2000). Therefore increased jitter in a limb muscle does not predict the subsequent development of generalized myasthenia, and no threshold jitter value predicts the development of generalized weakness.

Increased jitter is a nonspecific sign of abnormal neuromuscular transmission and can occur in other motor unit diseases. Therefore when jitter is increased, EMG should be performed to exclude neuronopathy, neuropathy, and myopathy. The presence of normal jitter in a weak muscle excludes abnormal neuromuscular transmission as the cause of weakness.

Ocular Cooling

Improvement in lid ptosis after the eye is cooled with an ice pack has been proposed as a simple, fast, and relatively sensitive technique to differentiate myasthenic from nonmyasthenic eyelid ptosis i.Golnik el al. IVSJS*). '['bis test is used as an alternative to the Tensilon test in the clinical evaluation of ocular MG; however, its specificity has not been fully determined.

Comparison of Diagnostic Techniques

The Tensilon test is often diagnostic in patients with ptosis ot ophthalmoparesis, but it is less useful when othet muscles are weak. An elevated serum AChR-binding antibody level vittually ensures the diagnosis of MG, but a normal level does not exclude it. RNS confirms impaired neuromuscular transmission but is not specific to MG and is often normal in patients with mild or purely ocular disease. SFEMG demonstrates abnotmal neuromuscular transmission in almost all patients with MG, but abnormal test results can occur when other motot unit disorders cause defects in neuromuscular transmission. A normal SFEMG test result in a weak muscle excludes the diagnosis of MG.

Other Diagnostic Procedures

Patients in whom MG is diagnosed should have thyroid function tests and a chest-imaging study (computed tomography or magnetic resonance imaging) to assess possible thymoma. A skin test for tuberculosis should be done if the use of immunosuppression is contemplated.

Treatment

Controlled clinical trials for any medical or surgical treatment of MG are rare. Al! recommended regimens are empirical, and experts disagree on treatments of choice. Treatment decisions should be based on knowledge of the ptedicted coutsc of disease in each patient and the ptedictcd response to a specific treatment. Treatment goals must be individualized according to the severity of disease, the patient's age and gender, and degree of functional impairment. Successful treatment of MG tcquires close medical supervision and long-term follow-up. Return of weakness after a period of improvement should be considered an indication of further progression that requires reassessment of current treatment and evaluation for underlying systemic disease ot thymoma,

Cholinesterase inhibitors

ChE inhibitors retard the enzymatic hydrolysis of ACh at cholinergic synapses so that ACh accumulates at the neuromuscular junction and its effect is prolonged, (hi. inhibitors produce considerable improvement in some patients and little to none in others. They have a major role as a diagnostic test and as early, symptomatic treatment in most patients. They are used as adjunctive therapy in most patients undergoing more definitive tteatment. ChE inhibitors alone may provide adequate chronic treatment in some patients, but the response usually becomes less with chronic use,

Pyridostigmine bromide (Mestinon) and neostigmine bromide (Prostigmin) are the most commonly used ChE inhibitors. Pyridostigmine is generally preferred because it has a lower incidence of gastrointestinal side effects and longer duration of action. The initial oral dose in adults is 30-60 mg every 4-8 hours. The equivalent dose of neostigmine is 7.5-15,0 mg. In infants and children, the initial oral dose of pyridostigmine is 1.0 mg/kg and that of neostigmine is 0,3 mg/kg. Equivalent dosages of these drugs are listed in Table 84.3. Pyridostigmine is available as a syrup (60 mg/5 mL) for children or for nasogastric tube administration in patients with impaired swallowing. A timed-release tablet of pyridostigmine (Mestinon Timespan, 180 mg) is useful as a bedtime dose for patients who are too weak to swallow in the morning. Irs absorption is erratic, leading to possible overdosage and underdosage, and it should not be used during waking hours. Even at night, it is sometimes preferable for the patient to awaken at the appropriate dosing intervals and take the regular tablet. Neostigmine and pyridostigmine can be administered by nasal spray or nebulizer to patients who cannot tolerate or swallow oral medications.

No fixed dosage schedule suits all patients. The need fot ChE inhibitors varies from day to day and during the same day. Different muscles respond differently; with any dose, some muscles get stronger, others do not change, and still

Tabic 84.3: Equivalent doses of anticholinesterase drugs

	Route and dose (mg)			
Drug	*Oral*	*Intramuscular*	*Intravenous*	*Syrup*

Neostigmine me thy (sulfate (Prostigmin methylsulfate)	1.3		0.5	
Pyridostigmine bromide (Mestinon bromide)	60	2.0	0.7	60 mg/5 ml.
Mestinon Timespan	90-180			
Ambenonium chloride (Mytelase chloride)	5			

Note: These values are approximations only. Appropriate doses should be determined for each patient based on the clinical response.

others become weaker. The drug schedule should be titrated to produce an optimal response in muscles causing the greatest disability. Patients with oropharyngeal weakness need doses timed to provide optimal strength duting meals. Ideally, the effect of each dose should last until time for the next, without significant underdosing or overdosing at any time. In practice, this is not possible. Attempts to eliminate all weakness by increasing the dose or shortening the interval causes overdose at the time of peak effect. Different muscles show different dose-response curves, so that some become stronger while others become weaker. We aim to keep the dose low enough to provide definite improvement in the most important muscle gtoups within 30-45 minutes, and we expect the effect to wear off before the next dose. This minimizes the possibility that the dose will be increased to the point of causing cholinergic weakness. The practice of giving edrophonium at the time when pyridostigmine has its maximal effect, to determine if the patient will respond to greater dosages of ChE inhibitors, is not without danger. Acute overdosage may cause cholinergic weakness of respiratory muscles and apnea.

Adverse effects of ChE inhibitors result from ACh accumulation at muscatinic teceptors on smooth muscle and autonomic glands and at nicotinic receptors of skeletal muscle. Central nervous system side effects are rarely seen with the doses used to treat MG. Gastrointestinal complaints are common: queasiness, nausea, vomiting, abdominal cramps, loose stools, and diarrhea. Increased bronchial and oral secretions are a serious problem in patients with swallowing or respiratory insufficiency. Symptoms of muscarinic overdosage may indicate that nicotinic overdose (weakness) is also occurring. Gastrointestinal side effects can be suppressed with lopetamide hydrochloride (Imodium), propantheline bromide (Pro-Banthine), glycopyrrolate (Robinul), and diphenoxylate hydrochloride with atropine (Lomotil). Some of these drugs produce weakness at high dosages.

Bromism, presenting as acute psychosis, is a rare complication in patients taking latge amounts of pyridostigmine bromide. The diagnosis of bromide intoxication can be confirmed by ditect measurement of the serum bromide level. Some patients are allergic to bromide and develop a rash even at modest doses.

Thymectomy

Although thymectomy is widely used as a treatment for autoimmune MG, it has never been demonstrated to be effective in a prospective, controlled study. Based on a review of existing studies, the Quality Standards Subcommittee of the American Academy of Neurology concluded dial ;\LIIC:H-, with ,VK who underwent thymectomy were twice as likely to have a medication-free remission, 1.6 times as likely to become asymptomatic, and 1.7 times as likely to show improvement (Gronscth and Barohn 2000). The following practice recommendation was made:

> For patients with non thymoma to us autoimmune MG, thymectomy is recommended as an option to increase the probability of remission ot improvement.

Wc recommend thymectomy for most patients with MG whose symptoms begin before age 60. The response is relatively unpredictable, and significant impairment may continue for months or years after surgery. The best responses to thymectomy are seen in young people, especially women, early in the course of their disease, but improvement can occur even aftet many years of symptoms. In our experience, patients with disease onset after age 60 rarely show substantial improvement after thymectomy, but others have reported improvement after thymectomy even in older patients. In our experience, the response in patients with thymomas is not as good as that in patients without thymomas; however, others have reported good responses after removal of the tumor and the thymus (Schrager et al. 2002). Although thymectomy is not generally recommended for patients with purely ocular myasthenia, these patients also may show a good response after thymectomy (Schrager et al. 2002), and we do recommend it in cettain circumstances, particularly in young patients with relatively recent onset of myasthenia. The major advantage of thymectomy is its potential to induce a sustained, drug-free remission. Another advantage is to rule out or remove a thymoma.

Out preferred surgical approach is ttansthotacic; the sternum is split and the ametior mediastinum is explored.

Transcervical and endoscopic approaches have less postoperative morbidity but do not allow sufficient exposure for total removal of the thymus and are not recommended when there is a thymoma. However, it has not been demonstrated that the extent of removal of the thymus determines outcome, and until there has been a prospective study comparing different thymectomy techniques, the value of different surgical approaches will not be clear. In our experience, the operative morbidity from transthoracic thymectomy is very low when patients are optimally prepared with plasma exchange or immunosuppression and skilled postoperative management is provided. Extubation is usually accomplished within hours after surgery, and patients may be discharged to home as early as the second or third postoperative day.

Repeat thymectomy provides significant improvement in some patients with chronic, refractory disease and should be considered when there is concern that all thymic tissue was not removed at prior surgery and when a good response to the original surgery is followed by later relapse,

Thymectomy may be followed by improvement, even in seronegative patients. We do not base the decision to perform thymectomy on the presence or level of AChR antibodies.

Corticosteroids

Marked improvement or complete relief of symptoms occurs in more than 75% of patients treated with prednisone, and some improvement occurs in most of the rest. Much of the improvement occurs in the first *6-H* weeks, but strength may increase to become total remission in the months that follow. The best responses occur in patients with recent onset of symptoms, but patients with chronic disease also may show improvement. The severity of disease does not predici the ultimate improvement. Patients with thymoma show an excellent response to prednisone before or after removal of the tumor.

We have found that the most predictable response to prednisone occurs when treatment begins with a daily dose of 1.5-2.0 mg/kg per day (Bedlack and Sanders 2002). This dose is given until sustained improvement occurs, which is usually within 2 weeks, and is then changed to an alternate-day schedule, beginning with 100-120 nig. This dose is gradually decreased over many months to the lowest dose necessary to maintain improvement, which is usually less than 20 mg every other day. The rate of decrease must be individualized: For patients who have a prompt, complete response to prednisone the alternate-day dose can be reduced by 20 mg each month until the dose is 60 mg. The dose can then be reduced by 10 mg each month until it is 20 mg and then by 5 mg every 3 months to a minimal dose of 10 mg every other day. If any weakness returns as the prednisone dose is reduced, further reductions are usually followed by even greater weakness. At this point, the prednisone dose should be increased and another immunosuppressant should be added or both. Most patients who have a good response to prednisone become \u\ik if tin- dni.L; is Mopped bin may maintain strength with very low dosages (5-10 mg every other day). For this reason, we do not reduce the dose further than this unless another immunosuppressant is also being given. Others recommend discontinuing prednisone if the patient is doing well after 2 years. In our experience, weakness ultimately returns if this is done.

Approximately one third of patients become wcaket temporarily after prednisone treatment is started, usually within the first 7-10 days and lasting for up to 6 days. This worsening usually can be managed with ChE inhibitors. In patients with oropharyngeal weakness or respiratory insufficiency, we use plasma exchange before prednisone is begun to prevent or reduce the severity of corticosteroid-induced exacerbations and to produce a more rapid response. Because high-dose prednisone may exacerbate weakness, patients with oropharyngeal or respiratory involvement should be hospitalized to start this treatment. Once improvement begins, subsequent corticosteroid-induccd exacerbations are unusual.

An alternative approach is to begin treatment with 20 mg per day of prednisone and increase the dose in 10-mg increments every 1 to 2 weeks until improvement begins. The dose is maintained constant until improvement is maximum, then decreased as above. This protocol may reduce the frequency or severity of corticosteroid-induced exacerbations, but exacerbations still may occur, and the Lici.qv.ihi' iv.pmiM In ;his iv;;:iih':i is k-,- piVikl:i/>'-.-. A similar dose schedule is often used in purely ocular myasthenia. Complete resolution of ocular symptoms is achieved in most patients with ocular myasthenia after treatment with prednisone; early immunotherapy also may reduce the proportion of patients who develop generalized MG.

The major disadvantages of chronic corticosteroid therapy are the side effects. Hypercorticism occurs in approximately one half the patients treated with the suggested regimen. The severity and frequency of adverse reactions increase when high daily doses are continued for more than 1 month. Fortunately, this is rarely necessary, especially if plasma exchange is begun at the same time as prednisone. Most side effects begin resolving as the dose of prednisone is tapered and become minimal at doses of less than 20 mg every other day. Side effects are minimized when patients use a low-fat, low-sodium diet and take supplemental calcium. Postmenopausal women should also take supplementary vitamin D. Patients with peptic ulcer disease or symptoms of gastritis need H_2 antagonists. Prednisone should not be given to people who have untreated tuberculosis,

Prednisone with azathioprine, cyclosporinc, mycophenolate, or other immunosuppressant drugs may produce more benefit than either drug alone (see next section, Immunosuppressant Drugs).

We have seen improvement in several patients with prednisolone treatment when equivalent doses of prednisone did not produce improvement or side effects.

Immunosuppressant Drugs

Several immunosuppressant drugs are effective in MG {Table 84.4). Azathioprinc is the drug used most often. It reverses symptoms in most patients, but the effect is delayed by 4-8 months. The initial dose is 50 mg daily, which is increased in increments of 50 mg per day every 7 days to a total dose of 150-200 mg per day. Improvement is maintained as long as the drug is given, but symptoms almost always recur 2-3 months after the drug is discontinued or the dose is reduced below therapeutic levels. Patients whose MG does not improve with corticosteroids may have a response to azathioprine, and the reverse is also true. Some have a better response to treatment with both drugs than to either alone. Because the response to azathioprine is delayed, both drugs may he started simultaneously with the intent of rapidly tapering the dose of prednisone when azathioprine becomes effective.

A prospective, randomized study showed that the addition of azathioprine to prednisolone significantly reduced the dose of prednisolone required to maintain remission and reduced the number of treatment failures (Palace et al. 1998).

A severe allergic reaction, with flu-like symptoms and possibly a tash, occurs within 2 weeks after azathioprine is started in 15-20% of patients; this reaction requires that the drug be stopped. It is not clear whether this teaction is product specific or related to the active ingredient in the compound. Othet patients may have mild, dose-dependent side effects that can be reversed by dose reductions but do not require stopping of treatment. Gasttointestinal irritation can be minimized by using divided doses after meals or by dose reduction. Leukopenia and even pancytopenia can occur any time during treatment but are not common. To guard against these, the blood count must be monitored every week during the first month, each month for a year, and every *l>-6* months thereafter. If the peripheral white blood cell (WBC) count falls to less than 3500 cells/mm\ the dose should be temporarily reduced and then gradually increased after the "WBC count rises above this level. WBC counts less than 1000 cells/mm require that the drug be temporarily discontinued. Serum transaminase concentrations may be slightly elevated, but clinical liver toxicity is rare. We discontinue treatment if transaminase concentrations exceed twice the upper limit of normal and restart the drug at lower doses when values become normal. Rare occurrences of azathioprine-induced pancreatitis arc reported, but the cost effectiveness of monitoring serum amylase concentrations has not been established, because azathioprine is potentially mutagenic, women of child-beating age should practice adequate contraception.

Table 84.4: Immunosuppressant drugs in myasthenia gravis

Azathioprine
- Onset action: 4—*8* months
- Common side effects: allergic reaction ("flu-like syndrome")
- Less common side effects: hepatic toxicity, leukopenia

Cyclosporine
- Onset action: 2-3 months
- Common side effects: renal toxicity, hypertension, multiple potential drag interactions

Cycli iphosphamidc
- Onset action: variable
- Common side effects: leukopenia, hair loss, cystitis

Mycophenolate mofetil
- Onser action: *2-A* weeks
- Common side effects: diarrhea, mild leukopenia

Cyclosporine (CYA) is a potent immunosuppressant that inhibits predominantly T-lymphocyte-dependent immune responses. Retrospective analyses have reported improvement in most patients taking CYA, with or without corticosteroids (Ciafaloni et al. 2000). We begin CYA at a daily dose of 5-6 mg/kg, given in two divided doses 12 hours apart. Trough serum levels of CYA should be measured after 1 month when tissues have become saturated. The dose is then adjusted to produce a trough serum CYA concentration of 75—150 ng/mL. Serum creatinine should be measured monthly and the dose adjusted to maintain a creatinine level of less than 150% of pre treatment values. Thereafter, serum creatinine should be measured at least every 2-3 months and more often after any new medications are begun. Blood pressure should also be monitored at least monthly until the maintenance CYA dose has been determined.

Renal toxicity and hypertension are the important adverse reactions of CYA. Many medications interact with CYA and must be avoided or used with caution. If the creatinine or blood pressure begins to rise, the clinician should determine whethet any contra indicated medications have recently been started.

Most patients with MG improve 1-2 months after Uvnuninl with I YA is -.'a I U.vl, arid r:u Milium iniprowr.H'in is achieved after 6 months or longer. As with azathioprine, prednisone *iv*,\\ be started at the same tunc, and thr iluse is decreased when CYA becomes effective. After the maximal response is achieved, the CYA dose is gradually reduced to the minimum that maintains improvement. The annual cost of a daily dose of 300 mg of CYA is about $6000, including blood tests,

Cyclophosphamide given intravenously in monthly pulsed doses has been used effectively in severe, generalized MG that is refractory to other therapy (de leo et al. 2002; Drachman et al. 2002). The initial dose was 500 mg/m , which was subsequently titrated according to changes in strength and to reduce side effects. Cyclophosphamide can also be given orally, at a dose of 150-200 mg per day to a total of 5-10 g, as required to relieve symptoms. Alopecia is

the major side effect. Cystitis, leukopenia, nausea, vomiting, anorexia, and discoloration of the nails and skin occur less often.

Mycophenolate mofetil (MM) (CellCept) selectively inhibits the proliferation of B- and T-lymphocyte clones responding to antigenic stimulation. It also suppresses the formation of antibodies active in complement-dependent lysis and antibody-dependent, cell-mediated cytotoxicity. A potential role for MM as a corticosteroid-sparmg agent and as adjunctive therapy in refractory MG has recently been reported in an open-label pilot study (Ciafaloni et al. 2001) and in a few case reports and retrospective scries. The usual dose is 2 g per day, in divided doses 12 hours apart, at a cost of $4500-4800 per year. Improvement has been reported as early as 2 weeks and is usually seen within 2 months in responding patients. The most common side effect is diarrhea, which can usually be managed by altering the dose schedule. The risk of leukopenia requires periodic blood counts, especially after therapy is begun. MM does not inhibit production of interleukin-1 and interleukin-2 as does CYA, and the two drugs have been used synergistically in other conditions. A controlled, randomized multicenter trial is underway to establish efficacy in MG and the optimal dosage. We currently consider using MM in patients with refractory MG and as a corticosteroid-spa ring agent when azathioprine has produced intolerable side effects or has not been effective.

The use of immunosuppressants in MG is usually a long-term commitment: few patients maintain improvement with these agents unless they are continued at effective doses. Life-threatening infections are an impottant risk in all immunosuppressed patients, but in our experience, this risk is limited in MG. The long-term risk of malignancy has not been established, but there are no reports of an increased incidence of malignancy in patients with MG who are receiving immunosuppressive therapy.

Plasma Exchange

Almost all patients with acquired MG show temporary improvement after plasma exchange. It is used as a short-term intervention for patients with sudden worsening of myasthenic symptoms for any reason; to rapidly improve strength before surgery, concomitantly with starting high dose corticosteroids; and as a chronic intermittent treatment for patients whose MG is refractory to all other treatments. The need for plasma exchange and the timing of use are determined by the clinical response in individual patients.

A typical protocol of plasma exchange is to remove 2-3 liters of plasma three times a week until improvement plateaus, usually after five to six exchanges. Improvement usually begins after the second or third exchange. Maximum improvement may be reached as early as the first exchange or as late as the fourteenth. Improvement lasts for weeks or months and then the effect is lost unless the exchange is followed by thymectomy or immunosuppressive therapy. Most patients who have a response to the first course have a response again to subsequent courses. Repeated exchanges do not produce a cumulative benefit and should not be used as chronic maintenance therapy unless other treatments have failed or are contraindicated.

Adverse reactions to plasma exchange include transitory cardiac arrhythmias, nausea, lightheadedness, chills, obscured vision, and pedal edema. The major complications are related to the route of access. Peripheral venipuncture should be used whenever possible to minimize the risk of thromboses, thrombophlebitis, and subacute bacterial endocarditis, as well as pneumothorax and brachial plexus injury when subclavian lines, arteriovenous shunts, or grafts are placed for vascular access. A flulike illness has been reported in patients with reduced immunoglobulin levels.

Intravenous Immunoglobulin

Many groups have reported a favorable response to high-dose (2 g/kg infused over 2-5 days) intravenous immunoglobulin (IVIG), although no adequate prospective, controlled trial has been done. The precise mechanism(s) of action in MG are not known. In general, there appears to be modulation of the inhibitory pathways or down-regulation of production of antibodies against AChR.

Improvement occurs in 50-100% of patients, usually beginning within 1 week and lasting for several weeks or months. Common adverse effects of IVIG are related to the rate of infusion and include headaches, chills, and fever. These reactions can be reduced by giving acetaminophen or aspirin with diphenhydramine (Benadryl) before each infusion.

Severe reactions, such as alopecia, aseptic meningitis, leukopenia, and retinal necrosis, are rare but have been reported in patients receiving IVIG for diseases other than MG. Renal failure may occur in patients with impaired renal function. Vascular-type headaches are often sufficiently severe to limit the use of IVIG, but we find that these headaches can be managed by administration of oral acetaminophen 1 g and ibuprofen 600 mg or intravenous dihydroergotamine before and immediately after the IVIG infusion. Recent reports of vascular occlusion have been reported in patients receiving IVIG. Cerebrovascular and myocardial infarction have occurred, but the mechanism for this is not known, and it is unclear if it is related to the infusion rate, the immunoglobulin concentration of by-products, or the osmolality of the preparation. Pre-existing arteriosclerosis appears to be a prerequisite for the occurrence of strokes or heart attacks. IVIG is contraindicated in patients with selective immunoglobulin (Ig)A deficiency because they may develop anaphylaxis to the IgA in IVIG preparations. IgA levels may be measured in all patients before IVIG therapy is started to detect this condition. Human immunodeficiency virus is not known to

be transmitted by IVIG, but the transmission of non-A, non-B hepatitis by IVIG has been reported. IVIG preparations are now prepared from donors shown to be without these viral infections, and the preparations are pasteurized. Although contamination of human blood products by donors having Creutzfeldt-Jakob disease has been reported, there is no reported case of transmission of this disease by blood products.

The indications for IVIG are similar to those for plasma exchange. IVIG is an effective alternative to plasma exchange, especially in patients with poor vascular access or when plasma exchange is not available. As with plasma exchange, IVIG should not be used as chronic therapy unless other treatments are contraindicated or have been ineffective.

Miscellaneous Treatments

Splenectomy, splenic radiation, and total body or total lymphoid irradiation have been used in a small number of patients who did not show improvement with all other forms of immunotherapy. Ammopyndines facilitate transmitter release at central and peripheral synapses. 4-Aminopyridine produces significant and sometimes dramatic improvement in acquired MG, congenital myasthenia, I.EMS, and botulism, especially when given with pyridostigmine. Confusion and seizures are the side effects that limit its use. 3,4-Diaminopyridinc (DAP) has similar peripheral effects with less central toxicity but is available only under a treatment-use investigational new drug application (see Treatment of Lambert-Eaton Myasthenic Syndrome, later in this chapter).

Ephedrine has been used in patients with congenital myasthenia and in patients with acquired myasthenia in whom ChE inhibitors alone are not effective, but it is not currently available in the United States. Terbutaiine (Brethine, Breathaire, Bricanyl), a /3-adrcnergic agonist, has also been used in this fashion. These agents are associated with a significant risk of arrhythmia, hypotension, and pulmonary edema and should be used with great caution.

Single case reports indicate that MG improves **after** treatment with rituximab (Zaja et al. 2000) and tacrolimus (Evoli et al. 2002). Further observations are necessary to determine the value of these immunosuppressants in MG.

Association of Myasthenia Gravis with Other Diseases

MG is often associated with other immune-mediated diseases, especially hyperthyroidism and rheumatoid arthritis. Seizures have been reported to occur more often in children wirh MG. One fifth of our myasthenic patients have another disease: 7% have diabetes mellitus before corticosteroid treatment, 6% have thyroid di sease, 3% have nonthymus neoplasm, and less than 2% have rheumatoid arthritis. Occurrences of MG related to human immunodeficiency virus and after allogeneic bone marrow transplantation suggest that the relationship may be more than coincidental.

Treatment of Associated Diseases

The effect of concomitant diseases and their treatment on myasthenic symptoms is an important consideration. Thyroid disease should be vigorously treated; both hypo- and hyperthyroidism adversely affect myasthenic weakness. Intercurrent infections require immediate attention because they exacerbate MG and can be life threatening in patients who are immunos up pressed.

Drugs rhar cause neuromuscular blockade must be used with caution. Many antibiotics fall into that category. Ophthalmic preparations of bera blockers and aminoglycoside antibiotics may cause worsening of ocular symptoms. D-PerucUlarnine should not be used because it can induce or exacerbate MG. If corticosteroids are needed to treat concomitant illness, tin- potential adverse and benefitul effects on MG must be anticipated and explained to the patient.

Patients treated with interferon-cr develop several autoantibodies and autoimmune diseases including MG. MG has been reported to develop in patients during interferon-«-2b treatment for malignancy and chronic active hepatitis C. In some individuals treated with inrerferon-a, the presentation of MG has been fulminant with myasthenic crisis. The mechanism is not well understood, but it is recognized that the expression of interferon-^ at motor endplates of transgenic mice results in generalized weakness and abnormal NMJ function that improve with cholinesterase inhibitors. Such studies suggest that the expression of interferon-}/ at motor endplates in these transgenic mice provokes an autoimmune humoral response, similar to that which occurs in human MG.

Patients with neuromuscular disease, such as MG or I.EMS, are at risk of systemic side effects, including dysphagia and respiratory compromise, from typical doses of botulinum toxin, which should be injected with great caution.

Annual immunization against influenza is recommended for all patients with MG, and immunization against pneumococcus is recommended in at-risk patients before prednisone or other immunosuppressive drugs are given. Inactivated polio vaccine rather than attenuated live oral polio vaccine should be used in people who are immunocompromised or in children who have household contacts with immunocompromised individuals. The Centers for Disease Control and Prevention reports that those taking less than 2 mg/kg per day of prednisone or evcry-other-day prednisone are not at risk.

Treatment Plan

We use the following protocols to treat patients with MG.

Ocular Myasthenia. Most patients are given CliE inhibitors. li the response is unsatisfactory, prednisone is added, cither in increments or high daily doses. Thymectomy may be considered in young patients with relatively recent onset of ocular weakness that persists despite treatment with ChE inhibitors in an effort to reduce the possibility that the disease will become generalized and ultimately require long-term medications. Patients with ocular myasthenia who develop weakness in muscles other than the ocular or periocular muscles are moved to the generalized myasthenia treatment protocol.

Generalized Myasthenia, Onset before Age 60. Thymectomy is offered to all patients. High-dose daily prednisone, plasma exchange, or both are used preoperatively in patients with oropharyngeal or respiratory muscle weakness to minimize the risks of surgery. If disabling weakness recurs or persists after thymectomy or if continual improvement is not seen 12 months after surgery, immunosuppression with high-dose daily prednisone, a/.athioprinc, cyclosporine, or MM is recommended (see Immunosuppressant Drugs, earlier in this chapter).

Generalized Myasthenia, Onset after Age 60. Life expectancy and concurrent illness are important considerations in developing a treatment plan. The initial treatment is usually ChE inhibitors. If the response is unsatisfactory, we add azathioprinc in patients who can tolerate a delay before a response is seen, ff treatment with azathioprine is unsatisfactory, high-dose daily prednisone is added or cyclosporine or MM is substituted for azathioprine. If a rapid response is needed, we use high-dose daily prednisone as the first drug, with or without plasma exchange or IVIG. Azathioptinc may be started at the same time, and the prednisone dose can be reduced or even discontinued after the maximum response has been obtained.

Thymoma. Thymectomy is indicated in all patients with thymoma. The patients are pretreated with high-dose daily prednisone, with or without plasma exchange, until maximal improvement is attained.

Postopetative radiation is used if tumor tesection is incomplete or if the tumor has spread beyond the thymic capsule. Medical treatment is then the same as for patients without thymoma.

Elderly patients with small tumors, who are not good candidates for surgery because of other health problems, may be treated medically while tumor size is monitored radiologically.

Juvenile Myasthenia Gravis. The onset of immune-mediated MG before age 20 is referred to as *juvenile myasthenia gravis* (Andrews and Sanders 2002). The pathophysiology is the same as that in adults.

In our experience, 20% of children with juvenile MG and almost 50% of those with onset before puberty are seronegative {see Seronegative Myasthenia Gravis, in the next section). The female-to-male ratio in children is 3:1 compared with almost 1:1 in adult-onset disease. Thymomas are rare in this age group, but the few that we have seen were malignant.

When myasthenic symptoms begin in childhood, it is important to determine whether the patient has acquired autoimmune MG or a genetic form that does not respond to immunotherapy (see Genetic Myasthenic Syndromes, later in this chapter). Because the absence of AChR antibodies does not distinguish these conditions, a therapeutic trial of plasma exchange or IVIG may be indicated. Those who definitely show improvement arc candidates for thymectomy or immunotherapy, but failure to respond does not exclude autoimmune MG.

Treatment decisions in childten with autoimmune MG arc more difficult because the rate of spontaneous remission is high. We recommend ChE inhibitors alone in prepubertal children who are not disabled by weakness. If these drugs do not prevent disability or progressive weakness, we proceed to thymectomy. Removal of the thymus in infants or children does not have a deleterious effect on subsequent immunological development.

Children with postpuberal onset of disease are treated the same as adults.

Seronegative Myasthenia Gravis. One fourth of patients with acquired, presumably immune-mediated MG do not have detectable scrum antibodies against AChRs (Sanders et al. 1997). Seronegative patients are more likely than seropositive patients to be male and to have milder disease, ocular MG, and fewer thymomas; they are less likely to have thymic hyperplasia and more likely to have thymic atrophy. In seronegative patients, the diagnosis is based on the clinical presentation, the response to ChE inhibitors, and electromyographic findings. Genetic myasthenia must be considered in all childhood-onset seronegative MG. The treatment of seronegative MG is the same as that for seropositive MG. The absence of AChR antibodies docs not necessarily mean that an unsatisfactory response to immunosuppression, plasma exchange, or thymectomy is expected.

Antibodies to muscle-specific receptor tyrosine kinase have recent l v been reported n; ,U least Id",, nt p,molts with ;>,rivtalized seronegative MG (Hoch et al. 2001; Scuderi et al. 2002). Many of these patients have scvete ocular and bulbar weakness, which is resistant to many forms of therapy. In such patients, we have seen sustained and significant improvement after plasma exchange and immunosuppression with cyclosporine MM and prednisone (Sanders et al. 2003). Detection of muscle-specific receptor tyrosine kinase antibodies will be an important tool in diagnosing MG in patients who do not have detectable antibodies to the AChR.

Special Situations

Myasthenic or Cholinergic Crisis, Myasthenic crisis is respiratory failure from myasthenic weakness. Patients in

myasthenic crisis who previously h.nl well compensated respiratory function usually have had a definable precipitating event, such as infection, surgery, or rapid tapering of immunosuppressive therapy (Bedlack and Sanders 2000). Cholinergic crisis is rcspitatory failure from an overdose of ChE inhibitors. It was more common before the introduction of immunosuppressive therapy, when very large dosages of ChE inhibitors were used. Respiratory failure of any cause is a medical emergency and requires prompt intubation and ventilatory support.

In theory, it should be easy to determine if a patient is weak because of too little ot too much ChE inhibitor, but in practice this is often difficult. Administration of edrophonium si ion kl distinguish overdose from underdose, hut its use in myasthenic crisis is dangerous unless the patient is already intubated and ventilated. Also, an apprehensive patient in myasthenic crisis usually cannot cooperate with the test. Further, edrophonium may make some muscles stronger and others weaker. Serial measurements of forced vital capacity and blood gases do not predict which patients with MG will need mechanical ventilation. The safest approach to crisis is to admit the patient to an intensive care unit, discontinue all ChE inhibitors, and support ventilation. ChE inhibitors should be resumed at low doses and the dose should be slowly increased as needed.

Respiratory assistance is needed when the patient cannot maintain an inspitatory force of more than —20 cm ETO, when tidal volume is less than 4-5 mL/kg body weight and maximum breathing capacity is less than three times the tidal volume, or when the forced vital capacity is less than 15 mL/kg body weight. A mask and breathing bag can be used in an emergency situation, but ttacheal intubation should quickly be done with a low-pressure, high-compliance cuffed endotracheal tube. A volume-controlled respirator set to provide tidal volumes of 400-500 mL and automatic sighing every 10-15 minutes is preferred. The pressure of the tube cuff should be checked often and the tube position verified daily by chest radiographs. Assisted respiration is used when the patient's own respiratory efforts can trigger the respirator. An oxygen-enriched atmosphere is used only when arterial blood oxygen values fall to less than 70 mm Hg. The inspired gas must be humidified to at least 80% at 37"C to prevent drying of the tracheobronchial tree. Tracheal secretions should be removed periodically using aseptic aspiration techniques. Low-pressure, high-compliance endotracheal tubes may be tolerated for long periods and usually obviate the need for tracheostomy. When respitatory strength improves, weaning from the respirator should he started for 2 or 3 minutes at a time and increased as tolerated. Extubation should be considered when the patient has an inspiratory pressure greater than —20 cm H_20 and an expiratory pressure greater than .35^10 cm H_20. The tidal volume should exceed 5 mL/kg, which usually corresponds to a vital capacity of at least 1000 mL. If the patient complains of fatigue or shortness of breath, extubation should be deferred even if these values and the results of blood gas measurements are normal.

Prevention and aggressive treatment of medical complications offer the best opportunity to improve the outcome of myasthenic crisis.

Anesthetic Management. The stress of surgery and some drugs used perioperatively may worsen myasthenic weakness. As a rule, local or spinal anesthesia is ptcferred over inhalation anesthesia. Neuromuscular blocking agents should be used sparingly, if at all. Adequate muscle relaxation usually can be produced by inhalation anesthetic-agents alone. The required dose of depolarizing blocking agents may be greater than that needed in nonmyasthenic patients, but low doses of nondepolarizing agents cause pronounced and long-lasting blockade that requires prolonged postoperative assisted respiration.

Pregnancy. Myasthenia in women may improve, worsen, or remain unchanged during pregnancy. Eirst trimester worsening is more common in first pregnancies, whereas third-trimester worsening and postpartum exacerbations are more common in subsequent pregnancies. Therapeutic abortion is rarely, if ever, needed because of MG, and the incidence of spontaneous abortion is not increased (Abel 2002). Oral ChE inhibitors are first-line treatment during pregnancy. The use of inttavenous ChE inhibitors is contraindicated because they may produce uterine conrtactions. Prednisone is the immunosuppressive agent of choice. Adverse outcomes in children born to myasthenic mothers taking high-dose prednisone throughout pregnancy have not been reported. We do not use cytotoxic drugs during pregnancy because of their theoretical potential mutagenic effects. Others feel these agents can be used safely during pregnancy. Plasmapheresis or IVIG has been used when immediate, albeit temporary, improvement is needed.

Labor and delivery are usually normal, and cesarean section is needed only for obstetrical indications. Regional anesthesia is preferred for delivery or cesarean section, Magnesium sulfate should not be used to manage preeclampsia because of its neuromuscular blocking effects. Barbiturates usually provide adequate treatment. In our experience, breast-feeding is not a problem, despite the theoretical risk of passing maternal AChR antibodies to the newborn.

The serum concentrations of AChR antibodies in the mother and her newborn arc similar. It is also likely that the fetus of an affected mother has an elevated concentration of AChR antibodies. Decreased fetal movement suggests the diagnosis of intrauterine myasthenia. Affected newborns may have arthrogryposis multiplex congenita because of decreased intrauterine movement, and decreased fetal movement is considered an indication fot plasmapheresis or IVIG. Birth of a child with arthrogryposis should prompt a search for MG in the mother.

Transitory Neonatal Myasthenia. A transitory form of MG affects 10-20% of newborns whose mothers have

immune-mediated MG (Andrews and Sanders 2002). The severity of symptoms in the newborn does not correlate with the severity of symptoms in the mother. The maternal antibody level correlates with the frequency and severity of transitory neonatal myasthenia, and it occurs only rarely in infants of seronegative mothers. If an affected mother delivers an infant with transitory neonatal myasthenia, her subsequent infants are likely to be similarly affected. Affected newborns are hypotonic and feed poorly during the first 3 days. In some newborns, symptoms may be delayed for 1-2 days. Symptoms usually last less than 2 weeks but may continue for as long as 12 weeks. Neonatal antibodies have a half-life of 2-3 weeks and are not detected after 5 months. This time course is consistent with the duration of clinical weakness. Passive transfer of maternal antibodies to the newborn does not fully explain the clinical syndrome of transitory neonatal myasthenia. The mechanism by which some newborns develop weakness and others, with equally high antibody concentrations do not, is uncertain.

All children of myasthenic mothers should be assessed for transitory neonatal myasthenia. The diagnosis is established by administration of edrophonium or RNS. Affected newborns require symptomatic treatment with ChE inhibitors if swallowing or breathing is impaired. Plasma exchange should be considered in newborns with respiratory weakness.

u-Petiidllaniitw-Induced Myasthenia Gravis. D-Penieillamine is used to treat rheumatoid arthritis, Wilson's disease, and cystinuria. Rarely patients treated with o-penicillamine for several months develop a myasthenic syndrome that disappears when the drug is stopped, n-Pen icil I a mine-induced myasthenia is usually mild and is often restricted to the ocular muscles. The diagnosis is often difficult because weakness may not be recognized when there is severe arthritis. The diagnosis is established by the response to ChE inhibitors, characteristic electromyographic abnormalities, and serum AChR antibodies. It is likely that n-penicillaminc stimulates or enhances an immunological reaction against the NMJ. The myasthenic response induced by D-pcnicillamine usually remits 1 year after the drug is stopped. ChE inhibitors usually relieve the symptoms. If myasthenic symptoms persist after D-penicillamine is stopped, the patient should be treated for acquired MG.

The Future. The future of treatment of MG lies in the elucidation of the molecular immunology of the anti-AChR response, with the goal of developing a rational treatment that cures the abnormality in the immune system. The simplistic understandings of T-cell and B-cell function and the myasthenic autoimmune response have not explained the pathophysiology. A more detailed understanding of the mechanisms of synaptogenesis and the molecular basis of autoimmunity is necessary to develop rational, directed therapies that target the specific autoimmune responses while minimally affecting the host.

Genetic Myasthenic Syndromes

Genetic forms of myasthenia arc not immune mediated. They are a heterogeneous group of disorders caused by several abnormalities of neuromuscular transmission (Engel 2002). Some have characteristic physiological or histological features. Symptoms are typically present at birth or early childhood but can be delayed until young adult life. Abnormal neuromuscular transmission is confirmed by the response to edrophonium chloride and characteristic electromyographic findings.

The onset of myasthenic symptoms at birth is always genetic, with the exception of the transitory neonatal form. All generic forms of myasthenia are known or presumed to be transmitted by autosomal recessive inheritance, except slow-channel syndrome, which is transmitted by autosomal dominant inheritance. Myasthenia that begins in infancy or childhood may be genetic or acquired.

Congenital Myasthenia

Congenital myasthenia is a clinical term that encompasses several generic neuromuscular defects. Overall, there is a 2:1 male predominance. Children with congenital myasthenia develop ophthalmoparesis and ptosis during infancy. Mild facial paresis may be present as well. Ophthalmoplegia is often incomplete at onset but progresses to complete paralysis during infancy or childhood. Some children develop generalized fatigue and weakness, but limb weakness is usually mild compared with ophthalmoplegia. Respiratory distress is unusual.

Congenital myasthenia should he suspected in any newborn or infant with ptosis or ophthalmoparesis. Subcutaneous injection of edrophonium usually produces a transitory improvement in ocular motility. A dccremental response to RNS is found in some limb muscles, but it may be necessary to test proximal or facial muscles if hand muscles show a normal response. SFEMG shows increased litter.

ChE inhibitors improve limb muscle weakness in many forms of congenital genetic myasthenia and may be effective even when edrophonium is not. Ocular muscle weakness is less responsive ro ChE inhibitors. The weakness in some children responds to DAP (Harper et al. 2000), which is only available as an investigational new drug in the United States (see Treatment of Lambert-Eaton Myasthenic Syndrome, later in this chapter).

Congenita! Myasthenic Syndrome with Episodic Apnea (Familial infantile Myasthenia)

This condition has characteristic clinical and electrophysiological features that differ from those of other congenital myasthenic syndromes. Generalized hypotonia is present at birth, and the neonatal course is complicated by repeated episodes of life-threatening apnea and feeding difficulty.

Assisted ventilation is often required. Arthrogryposis may be present. Ocular muscle function is usually normal. Within weeks after birth, the child becomes stronger and ultimately breathes unassisted. However, episodes of life-threatening apnea occur repeatedly throughout infancy and childhood and even into adult life. There is often a history of sudden infant death syndrome in siblings, and the correct diagnosis may not be suspected until a second affected child is born.

Administration of edrophonium usually improves both weakness and respiratory distress. A decremental response to RNS is usually present in weak muscles but may be demonstrated in strong muscles only after the muscle is exhausted by several minutes of RNS. Abnormal resynthesis and repackaging of ACh in the motor nerve has been shown in some patients.

ChE inhibitors improve strength in most affected children, but sudden episodes of respiratory distress occur with intercurrent illness. As the patients get older, weakness improves, attacks of respiratory distress occur less often, and the need for medication decreases. In children from : il families with this syndrome, we have seen sustained symptomatic improvement when DAP is given with pyridostigmine.

Slow-Channel Congenital Myasthenic Syndrome

This syndrome may be difficult to distinguish from acquired MG because the onset of symptoms may be delayed until adult life. The disease is transmitted by autosomal dominant inheritance, and a family history of similar illness often is obtained.

Slow-channel congenital myasthenic syndrome is rare. Onset of symptoms always occurs after infancy and may present as late as the third decade. Slowly progressive weakness selectively involves the arm, leg, neck, and facial muscles. Unlike other myasthenic syndromes, atrophy of symptomatic muscles is expected.

RNS shows a decremental response. Repetitive discharges are seen after nerve stimulation, similar to those seen in ChE inhibitor toxicity or congenital deficiency of endplatc acetylcholinesterase. The underlying defect is prolonged open time of the ACh channel.

ChE inhibitors, thymectomy, and immunosuppression are not effective treatment. Quinidine sulfate and fluoxetine may improve strength in this condition (Harper et al. 2002).

Lambert-Eaton Myasthenic Syndrome

LEMS is a presynaptic abnormality of ACh release that was first described in association with malignancy, usually small cell lung cancer (SCLC). The probable mechanism in most, ii in it all,]\n inn v is .in iiniinn';: incdiak'd pi occss directed against the voltage-gated calcium channels (VGCCs) on nerve terminals (see Figure 84.2). LEMS usually begins after age 40 but has been reported in children. Males and females are affected equally. Approximately one half of patients with LEMS have an underlying malignancy; 80% of these have SCLC. The cancer may be discovered years before or after the symptoms of LEMS begin,

Weakness of proximal muscles, especially in the legs, is the major symptom. The weak muscles may ache and are occasionally tender. Oropharyngeal and ocular muscles may be mildly affected but not to the degree seen in MG. The weakness demonstrated on examination is usually relatively mild compared to the severity of symptoms. Strength may improve initially after exercise and then weaken with sustained activity. Administration of edrophonium chloride does not improve strength to the degree seen in MG. Tendon reflexes are reduced or absent but arc often enhanced by repeated muscle contraction or repeated tapping of the tendon. Dry mouth is a common symptom of autonomic dysfunction; other features are impotence and postural hypotension.

LEMS may be first discovered when prolonged paralysis follows the use of neuromuscular blocking agents during surgery. Clinical worsening has been described after administration of aminoglycoside antibiotics, magnesium, calcium-channel blockers, and todinated intravenous contrast agents.

Although LEMS and MG are both immune-mediated disorders of neuromuscular transmission, their clinical features are quite distinct. The weakness in LEMS is not usually life threatening and more closely resembles cachexia, polymyositis, or a paraneoplastic neuromuscular disease.

Diagnostic Procedures

The diagnosis of I.F.MS is confirmed by EMG (see Chapter 36B). The characteristic findings are decreased size of compound muscle action potentials (CMAPs) with further size reduction in response to RNS at frequencies between 1 **and** 5 Hz, doubling of CMAP size in response to repetitive stimulation at 20-50 Hz, and a transitory increase in CMAP size after brief maximum voluntary contraction. Virtually all patients with LEMS have a decrementing response to 3-Hz stimulation in a hand or foot muscle, and almost all have low-amplitude CMAPs in some muscle (Tim et al. 2000). Facilitation of more than 100% is not seen in all muscles; several muscles may need to examined to demonstrate this important finding. Abnormalities of these measurements may be partially masked by low muscle temperature; thus hand and foot muscles should be warmed. In proximal muscles, the CMAP amplitude is normal, there is usually a decrementing pattern, and the amount of facilitation is less than in distal muscles.

When LEMS and MG are difficult to distinguish by cluneal features and electrophysiology, the presence of elevated concentrations of AChR or VGCC antibodies or

lung cancer clarifies the diagnosis. Sometimes, the diagnosis is defined only by the response to treatment or the course of disease.

Immunopatkology of Lambert-Eaton Myasthenic Syndrome

Patients with LEMS, like those with MG, have an increased incidence of other immune-mediated diseases. Those who do not have cancer often have serum organ-specific auto-antibodies, further confirming that LEMS is immune mediated. In LEMS, the motor nerve **terminal** active zone particles, which represent the VGCCs, are disorganized in appearance and reduced in number. Similar changes are seen in recipient mice who are injected with IgG from pa lie ins with 1.1'.MS. 1 he mechanism is probably cross-linking of the VGCCs by antibodies.

SCLC cells are of neuroectodermal origin and contain high concentrations of VGCCs. Calcium influx into these cells is inhibited by LEMS IgG, and antibodies to the VGCC are found in the sera of almost all patients with LEMS, and in 10% of those with SCLC who do not have LEMS. VGCC antibody titers do not correlate with disease severity among individuals, but the antibody levels may fall as the disease resolves in patients receiving immunosuppression. These observations suggest that SCLC cells induce VGCC antibodies that react with the VGCCs of peripheral nerves and cause LEMS. In patients with LEMS who do not have SCLC, the VGCC antibodies are produced as part of a more general immune-mediated disease.

Treatment of Lambert-F.aton Myasthenic Syndrome

Once the diagnosis of LEMS is established, an extensive search for underlying malignancy, especially SCLC, is mandatory. Chronic smokers should undergo bron-choscopy or a positron-emission tomography scan if chest imaging studies are normal. Initial ttcatment is focused on the underlying malignancy, and weakness may improve after effective cancer therapy. In some parients, no further ttcatment is needed for the neuromuscular defect. If tumor is not found, the search for occult malignancy should be repeated periodically, especially during the first 2 years after onset of symptoms. The frequency of reevaluation is determined by the patient's cancer risk factors.

Therapy is railored to the individual based on the severity of weakness, underlying disease, life expectancy, and response to previous treatment. The treatment plan in the following paragraphs is a general guide that should be modified to suit specific situations.

ChE inhibitors may relieve weakness in occasional patients with LEMS. Pyridostigmine 30-60 mg every 6 hours should be tried for several days. In some patients, the major benefit is relief of dry mouth.

Guanidine hydrochloride increases the release of ACh and produces temporary improvement in strength in many patients with LEMS. Guanidine is started at an oral dose of 5-10 mg/kg daily, divided into three doses 4-6 hours apart; the dose may be increased to a maximum of 30 mg/kg per day. Bone marrow depression may occur with doses as low as 500 mg per day. The dose should not be incteased more often than every 3 days because the maximum response may be delayed for 2-3 days. The therapeutic response is enhanced by giving pyridostigmine (30-60 mg every 4-6 hours). In addition to bone marrow depression, side effects seen at higher doses include renal tubular acidosis, chronic interstitial nephritis, cardiac arrhythmia, hepatic toxicity, pancreatic dysfunction, paresthesias, ataxia, confusion, and alterations of mood. Monthly blood counts are recom-mended for any patient receiving guanidine.

Oral DAP 5-25 nig three to four times a day improves strength and autonomic symptoms in most patients with LEMS (Sanders et al. 2000; Tim ct al. 2000). Like guanidine, DAP facilitates release of ACh from motor nerve terminals. The response to DAP is enhanced by the concomitant use of pyridostigmine 30-60 mg three or four times a day. Side effects usually are negligible. Transient perioral and digital paresthesias occur with doses greater than 10-15 mg. Doses of 100 mg per day may cause seizures. Cramps and diarrhea may occur when DAP is given with pyridostigmine and can be minimized by reducing the dose of pyridostigmine. DAP is a safe and effective treatment for LEMS but is not available for general clinical use in the United States. It can he obtained for individual patients upon submission of a treatment-use investigational new drug application by the administering physician. Information on the application process can be obtained from Jacobus Pharmaceutical Co., Princeton, N'J (fax: 609-799-1176).

Both plasma exchange and IVTG provide transitory improvement in some patients with LEMS (Tim ct al. 2000), but the results arc usually not as good as in patients w ah MG.

if these treatments are not effective, it must be determined whether weakness is sufficiently severe to warrant immu-notherapy with prednisone, azathioprine, or cyclosporine. hi patients with severe weakness, plasma exchange or 1VIG may be used first and prednisone and azathioprine added after improvement begins. Repeated courses of treatment may be needed to maintain improvement,

The long-term prognosis for patients with LEMS is variable. In patients with cancer, it is determined by the response to cancer therapy. In patients without cancer, treatment with immunosuppression produces improvement in many patients, but most require substantial and con-tinuing doses of immunosuppressive medications {Maddison ct al. 2001).

The weakness of LEMS may be worse when the ambient temperature is elevated or when **the** patient is febrile. Patient-, should avoid hot shower•> or baths, svstenuc illness of any sort may cause transient worsening of weakness in patients with LEMS.

Drugs That Adversely Affect Myasthenia Gravis and the Lambert-Eaton Myasthenic Syndrome

Drugs that compromise neuromuscular transmission make patients with MG or LEMS weaker. Categorically, four clinical situations are encountered in which these drugs produce a worsening of neuromuscular function. First, there are the direct and augmented deleterious effects of the drug on synaptic transmission in an otherwise apparently normal individual; second, there is a drug-induced disturbance of the immune system that results in the development of MG; third, there is the unmasking of subclinical MG or the worsening of muscle strength in patients with disorders of neuromuscular transmission {MG, LEMS, and botulism); and fourth, those with delayed recovery of strength, particularly respiratory function, after general anesthesia during which neuromuscular blocking agents ma\ or may not have been used.

Pre-existing circumstances such as altered drug clearance due to renal or hepatic disease, concomitant drug administration, electrolyte disturbances, or direct toxicity may predispose the patient to neuromuscular weakness in the first situation. An example would be the patient with chronic renal failure, undergoing a surgical procedure during which a neuromuscular blocking agent and an aminoglycoside antibiotic were given. The second situation is most commonly encountered in n-penicillamine-induced MG. There are a few reports of similar occurrences in patients receiving tiopronin, pyrirhioxine, hydantoin drugs, trimethadione, and possibly chloroquine. In the third situation, failure of the neuromuscular manifestations to resolve after the drug is discontinued implies that the disorder was subclinical and unmasked by the pharmacological agent. This has been seen in previously asymptomatic patients given D-penicillamine in whom MG did not resolve when the drug was discontinued.

Drugs that affect neuromuscular transmission may act presynaptically by reducing ACh release due to local anesthetic-like activity on the nerve terminal or impairing calcium flux into the nerve terminal or by a hemicholinium effect (impaired resynthesis of ACh in the nerve). Drugs may act postsynapticsHy, with curare-like blockade of ACh receptors or potentiation of depolarizing or nondepolarizing neuromuscular blocking agents. In some instances there may be varying degrees of pre- and postsynaptic blockade.

The effects of competitive neuromuscular blocking agents, such as d-tubocurarine and pancuronium, art- exaggerated and prolonged in patients with MG or l.b.MS. Depolarizing agents, such as succinylcholine, also must be used with caution. Some antibiotics, particularly aminoglycosides, antiarrhythmics (quinine, quinidine, and procainamide), and a-adrcnergic blocking drugs, block neuromuscular transmission and increase weakness. Iodinated contrast agents have been reported to produce transitory worsening in patients with MG and LEMS, possibly because of the calcium-chclating effects of these agents. Ophthalmic beta blocker and tobramycin preparations may unmask or exacerbate myasthenic weakness. Many other drugs have been reported to increase myasthenic weakness in isolated patients. Unfortunately, many of these reports are merely anecdotal, often involving isolated cases of patients with increased weakness while using a particular drug. There have been only a few comprehensive in vitro studies of the effects of various drugs on animal or human neuromuscular transmission. The potential adverse effects of these medications must be taken into consideration when the clinician decides which drugs to use. All patients with MG and i KV1S should be observed foi clinical worsening after any new medication is started.

Although ir ˙s desirable to avoid drugs thai are known to impair neuromuscular transmission, this is not always possible. We find it useful to place a list of potentially hazardous drugs on the front of the hospital chart of patients with MG and LEMS (Table 84.5).

Tnhk' S4„S; Drug alert for patients with myasthenia gravis (MG) or Lambert-Eaton myasthenic syndrome

1. Interferon-a, hotulimim toxin, and o-peuicillamine should never be used in myasthenic patients.
2. The following drugs produce worsening of myasthenic weakness in most patients who receive them. Use with caution and monitor patient for exacerbation of myasthenic symptoms,
   - Succinylcholine, (f-tubocutarine, or other neuromuscular-blocking agents
   - Quinine, quinidine, and procainamide
   - Aminoglycoside antibiotics, particularly gentamicin, kanamycin, neomycin, and streptomycin
   - Beta blockers (systemic and oculat preparations): propranolol, timolol maleatc eyedrops
   - Calcium-channel blockers
   - Magnesium salts (including laxatives and antacids with high M(;"' concentrations)
   - Iodinated contrast agents
3. Many other drugs are reported to exacerbate the weakness in some patients with MG. All patients with MG should be observed for increased \vcak:v-.s whenever .'. nnv medie.˙'i<>u is •a.iru-d. \n up in Jau- ivkri ;;LV document loi s.idi .id verse interactions is maintained on the web site of the Myasthenia Gravis Foundation of America (www.myasthenia.org/drugs/refercnce.htm).

BOTULISM

Botulism is caused by a toxin produced by the anaerobic bacterium, *Clostridium hotulinum,* that blocks the release of ACh from the motor nerve terminal (Cherington 2002). The result is a long-lasting, severe muscle paralysis. Of eight types of botulinum toxins, types A and B cause most occurrences of botulism in the United States. Type E is transmitted in seafood. Intoxication usually follows ingestion of contaminated foods that were inadequately sterilized. Neuromuscular symptoms usually begin 12-36 hours after ingestion of contaminated food. Not all

people who ingest the contaminated food become symptomatic. Nausea and vomiting are the first symptoms of food-borne botulism, and the neuromuscular symptoms begin 12-36 hours after exposure.

The most common form of botulism in the United States is wound botulism, which occurs predominantly in drug abusers after subcutaneous injection of heroin. *Clostridium* bacteria colonize the injection site and release toxin that produces local and patchy systemic weakness.

Clinical Features

The major symptoms of botulism arc blurred vision, dysphagia, and dysarthria. Pupillary responses to light are impaired, and tendon reflexes arc variably reduced. The weakness progresses for several days and then reaches a plateau. Fatal respiratory paralysis may occur rapidly. Most patients have evidence of autonomic dysfunction, such as dry mouth, constipation, or urinary retention. Results of the Tensilon test are positive in only approximately one third of patients and do not distinguish botulism from other causes of neuromuscular blockade. The diagnosis of wound botulism is confirmed by wound cultures and serum assay for Botulinum toxin.

Infant botulism results from the growth of C. *botulinum* in the infant gastrointestinal tract and the elaboration of small quantities of toxin over a prolonged period (Jones 2002). Symptoms of constipation, lethargy, poor suck, and weak cry usually begin at approximately 4 months of age. Examination reveals weakness of the limb and oropharyngeal muscles, poorly reactive pupils, and hypoactivc tendon reflexes. Most patients require ventilatory support. The diagnosis of infant botulism is confirmed by demonstration of botulinum toxin in the stool or by isolation of C. *botulinum* from stool culture.

Electromyographic Findings in Botulism

Electrophysiological abnormalities in botulism tend to evolve with time and may not be present early in the disease. The electromyographic findings in botulism include the following:

- Reduced CMAP amplitude in at least two muscles
- At least 20% facilitation of CMAP amplitude during tetanic stimulation
- Persistence of facilitation for at least 2 minutes after activation
- No postactivation exhaustion

Not all patients with botulism meet the first criterion. If none of these criteria is met, the diagnosis of botulism is unlikely. If all four are met, only hypermagnesemia is in the differential diagnosis.

SFFMG demonstrates markedly increased jitter and blocking, and results have been abnormal in all reported patients with food-borne or wound botulism. Jitter and blocking may decrease as the firing rate increases, but this is not a consistent finding.

Treatment

[reatment .;nnsists of bivaleni (type A and U) or trivalenl (A, B, and E) antitoxin. Antibiotic therapy is not effective because the symptoms are caused by the ingestion of toxin rather than organisms. Otherwise, treatment is supportive; respiratory assistance is given when necessary. ChF, inhibitors are not beneficial; use of guanidine or DAP may improve strength but not respiratory function. Recovery takes many months but usually is complete.

The use of botulinum A toxin for the treatment of focal dystonia has resulted in focal or regional weakness after injection of the toxin. Such adverse events have included diplopia, dysphagia, urinary incontinence, focal weakness, brachial plexoparhy, and the unmasking of neuromuscular weakness due to LEMS and amyotrophic lateral sclerosis. SFEMG has demonstrated abnormal neuromuscular transmission in muscles remote from the site of injection, which persists for many months.

OTHER CAUSES OE ABNORMAL NEUROMUSCULAR TRANSMISSION

The NMJ is uniquely sensitive to the effects of neurotoxins and other disorders of the motor unit (Howard 2002). Unlike the blood-brain barrier that protects the brain and spinal cord and the blood-nerve barrier that protects peripheral nerve, there are no barriers to protect the NMJ from these agents. Envenomation is the most common cause of NMJ neurotoxicity worldwide. All forms of NMJ neurotoxicity are characterized by progressive, typically symmetrical muscle weakness. Muscles of eye movement or the eyelids are most often involved as well as the muscles of neck flexion and the pectoral and pelvic girdles. In more severe situations, bulbar or respiratory muscles are also involved. Cognition and sensation are usually spared unless other parts of the nervous system arc also involved. Muscle stretch reflexes are often preserved or only minimally diminished, particularly during the early phases of illness, but may be lost if muscle weakness is severe,

Venom toxicity at the NMJ occurs by four mechanisms: (1) an initial augmentation of ACh release with subsequent depletion of neurotransmitter, (2) facilitation of ACh release without subsequent depletion of neurotransmitter, (3) depletion of ACh release, and (4) blockade of the postjunctional ACh receptor. Most biological toxins of animal origin either facilitate the release of

neurotransmitter From the presynaptic nerve terminal or block the ACh receptor.

Examples of arthropod venoms that affect the NMJ are those of the funnel web and black widow spiders (latrodectism). Each produces marked facilitation of neurotransmitter release by depolarization of the presynaptic nerve terminal and increasing Ca^{2+} influx into the nerve KTiii.:i.il. 'I ick ;vi!-.ilvv-. results from *a* neurotoxin [hat blocks receptor function postsynaptieally. Envenomation by snakebite occurs primarily from the *Elapidae* and *Hydrophiodae* species. Snake toxins may act cither presynaptically or postsynaptieally. Presynaptic ^-neurotoxins (/^bungarotoxin, norexm, and taipn\iuj inhibit the normal release of ACh. Often, there is an initial augmentation of ACh release, followed by presynaptic depletion of neurotransmitter. These tend to be more potent than postsynaptic toxins. Postsynaptic W-neurotoxins produce a curare-mimetic, nondepolarizing neuromuscular block that is variably reversible. Most venoms contain both types of neurotoxins although one type may predominate in n given venom. Marine neurotoxins affecting the NMJ arc rare and come primarily from poisonous fish (stonustoxin), a few mollusks (conotoxins), and perhaps dinoflagellates. Most marine intoxications occur as the result of ingestion. Unique to some marine toxins is the fact that there is an increase in the concentration of toxin through successive predatory transvection up the food chain {Howard 2002).

Neuromuscular transmission may be abnormal in diseases of the motor unit that do not primarily affect the NMJ. For example, patients with amyotrophic lateral sclerosis may have fluctuating weakness that responds to ChE inhibitors, an abnormal decrements1 response to RNS, and increased jitter and blocking on SFEMG. Features that can be attributed to abnormal neuromuscular transmission also are reported in syringomyelia, poliomyelitis, peripheral neuropathy, and inflammatory myopathy.

Chapter 85
Disorders of Skeletal Muscle

Anthony A. Amato and Michael H. Brooke

Disorders of skeletal muscle encompass several illnesses that cause weakness, pain, and fatigue in any combination. They vary from the protean symptoms of aches, cramps, and pains thai often dcf\ any explanation to the muscular dystrophies, which are readily recognized on clinical grounds. 'I'll- disorder^ wilh primary iiivnlvemciu "I die anterior horn cells (e.g., amyotrophic lateral sclerosis and the spinal muscular atrophies), neuromuscular junction disorders (myasthenia gravis, Lambert-Eaton syndrome, **and** congenital myasthenia), and certain polyneuropathies (e.g., chronic inflammatory demyelinating polyneuropathy) can cause similar symptoms and may be difficult to differentiate on clinical grounds from primary disorders of muscle. Some definitions are worth reviewing. *Myopathy* refers ro an abnormality of the muscle and has no other connotation. *Muscular dystrophies* are genetic myopathies, usually caused by a disturbance of a structural protein. *Myositis* implies an inflammatory disorder, and the term is usually reserved for disorders in which muscle histological preparations show an inflammatory response. The *myotonias* are diseases in which die normal coiuraculu process is distorted by the occurrence of involuntary, persistent muscle activity accompanied by abnormal repetitive electrical discharges, which may occur after percussion or voluntary contraction. *Metabolic myopathics,* in this context, refer mainly to abnormalities of muscle biochemistry that impair energy production. In a general medical context, *metabolic myopathy* is often synonymous with *endocrine myopathy. Congenital myopathies* are a group of genetic disorders with structural disturbances of the muscle cell that usually present at birth or during childhood. Many of these are relatively nonprogressive. Some myopathies with similar structural **features** may have a later onset, even into adult life (e.g., myofibrillar myopathy, central nuclear myopathy, and nemaline myopathy) and have a progressive course.

Striated muscle is the tissue that converts chemical energy into mechanical energy. The component processes include (1) excitation and contraction occurring in the muscle membranes, (2) the contractile mechanism, (3) structural supporting elements that allow muscle to withstand mechanical stress, and (4) the energy system that supports the activity and integrity of the other three systems. Logically, myopathies should be categorized according to the part of the system involved. This was previously impossible because the molecular basis of muscle activity was unknown. Recent advances in knowledge allow an attempt to classification along these lines.

Abnormalities in the membrane ion channels involved in muscle excitation are referred to as *channelopathies* and cause several forms of myotonia and periodic paralysis. The complex of proteins, which include dystrophin, the sarcoglycan proteins, and laminin, constitutes a vital structural mechanism linking the contractile proteins with the extracellular supporting structures. Defects in these proteins are found in many forms of muscular dystrophy. Although knowledge is still incomplete, it seems reasonable to modify the classic description of the myopathies to incorporate this new information. In the sections that follow, diseases are described under the heading of their known molecular defect, where possible; the classic appellation appears parenthetically. Before the description of the individual disorders is provided, the techniques used in the clinical evaluation of patients are briefly reviewed.

MUSCLE BIOl'SY

The technique of muscle biopsy is nor difficult, I tidcr local anesthesia, a small incision is made over the muscle, and with careful dissection, a small strip of muscle is removed. Needle biopsies may be used in some situations.

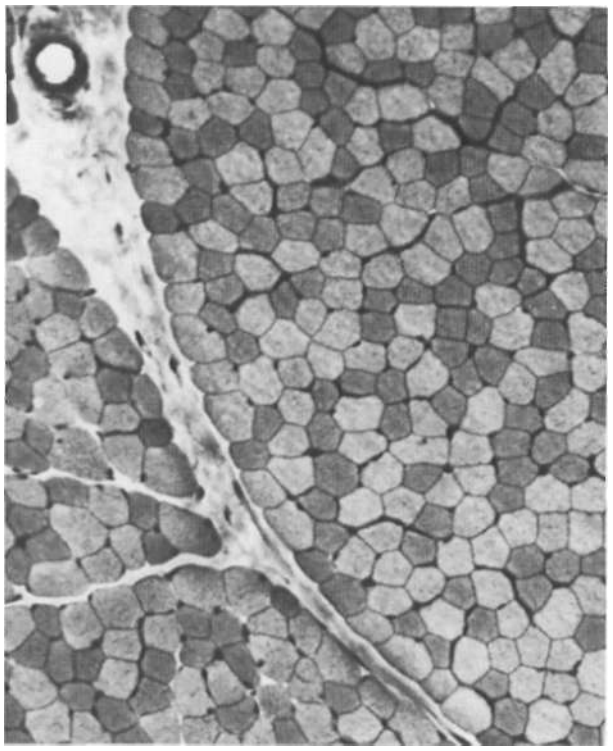

FIGURE 85.1 Normal muscle biopsy. The fibers are roughly equal in size, the nuclei are peripherally situated, and the fibers are tightly apposed to each other with no fibrous tissue separating them. (Verhoeff-Van Gieson stain.)

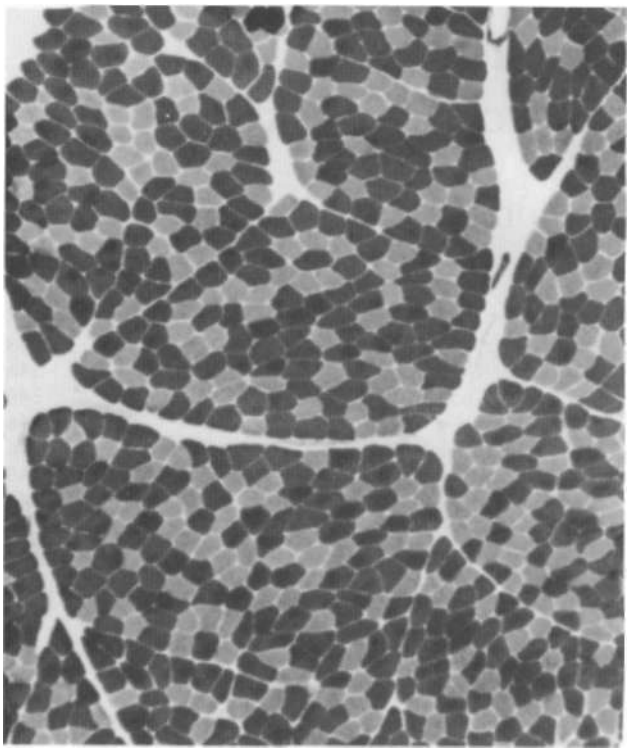

FIGURE 85.2 Normal muscle biopsy. Myosin adenosine triphosphatase stain at pH 9.4 demonstrates the relative proportions in the size of type 1 (light) and type 2 (dark) fibers. The muscle fibers belonging to one motor unit innervated by the same anterior horn cell are uniform in type, implying that there are fast and slow anterior horn cells. In addition, subsets of fiber rypes have been described, namely types 2A, 2B, and 2C The metabolism of type 2A fibers is more oxidative than that of type 2B fibers. The type 2C fiber is present in fetal muscle.

Histochemical studies of frozen sections are essential for proper interpretation. On transverse section, the fibers of normal muscle are roughly of equal size and have an average diameter of approximately 60 pm (Figure 85.1}. The muscle fibers of infants and young children are proportionately smaller. Each fiber consists of hundreds of myofibrils separated by an intermyofibrillar network containing aqueous sarcoplasm, mitochondria, and the sarcoplasmic reticulum with the associated transverse tubular system. A thin layer of connective tissue (the endomysium) surrounds each muscle fiber. The fibers are grouped into fascicles by strands of connective tissue, the perimysium, which separates the fascicles. Groups of fascicles are collected into muscle bellies surrounded by epimysium.

Situated at the periphery of the fibers are the sarcolemmal nuclei. The fibers are of different types. The simplest division is into type 1 and type 2 fibers, best demonstrated with the histochemical reaction tor myosin adenosine triphosphatase (ATPase) (Figure 85.2), The type 1 and type 2 fillers are roughly equivalent to slow and fast fibers or to oxidative and glycolytic fibers in human muscle. The inrermyofibrillar network pattern is best demonstrated with the histochemical reactions for oxidative enzymes, such as reduced nicotinamide adenine dinucleotide dehydrogenase. A regular network is seen extending across the whole fiber. In addition to routine stains with hematoxylin-cosin, modified Gomori-trichrome, myosin ATPasc, and nicotinamide adenine dinucleotide dehydrogenase, other special stains may be used to demonstrate fat (Sudan black or oil red O), complex carbohydrates (periodic acid-Schiff), amyloid (Congo red.i, or specific enzymes (e.g., phosphorylasc, lactate dehydrogenase, succinic dehydrogenase, and cytochrome oxidase). Immunoeytochcmical techniques are used to demonstrate the location and integrity of structural proteins, such as dystrophin, or to characterize the cell types in biopsies with inflammatory changes.

Changes of Denervation

When the muscle loses its nerve supply, the muscle fiber atrophies, often resulting in the fiber being squeezed into the spaces between normal fibers and assuming an angulated appearance (Figure 85.3). Scattered angulated fibers arc seen early in denervation. Sometimes, picturesque changes in the intermyofibrillar network occur, as in the *target fiber*, which characterize denervation and rein nervation. This is a three-zone fiber, on which the intermediate zone stains darker and the central "bull's-eye" stains much lighter than normal tissue (Figure 85.4). Often, a denervated fiber may

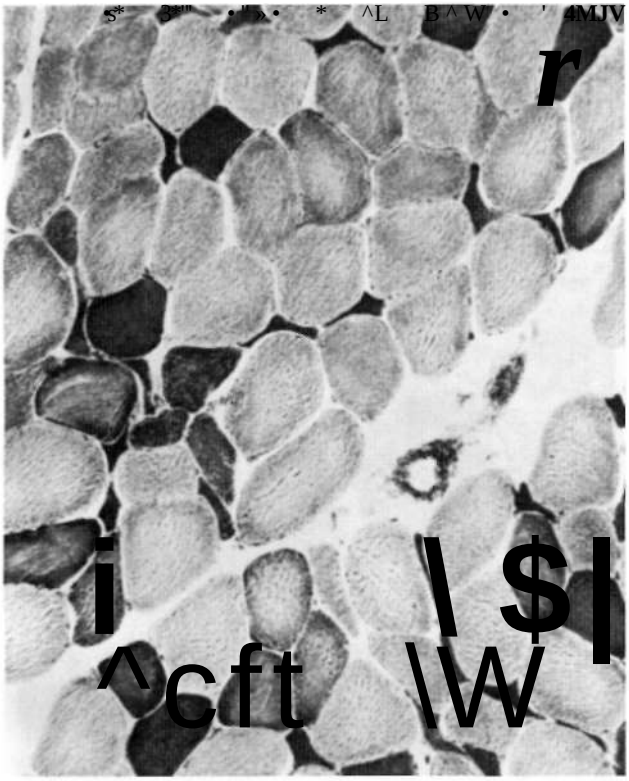

FIGURE 8S.3 Denervation. Notice the small, dark, angulated fibers demonstrated with this oxidative enzyme reaction, (Nicotinamide adenine dinucleotide dehydrogenase stain.)

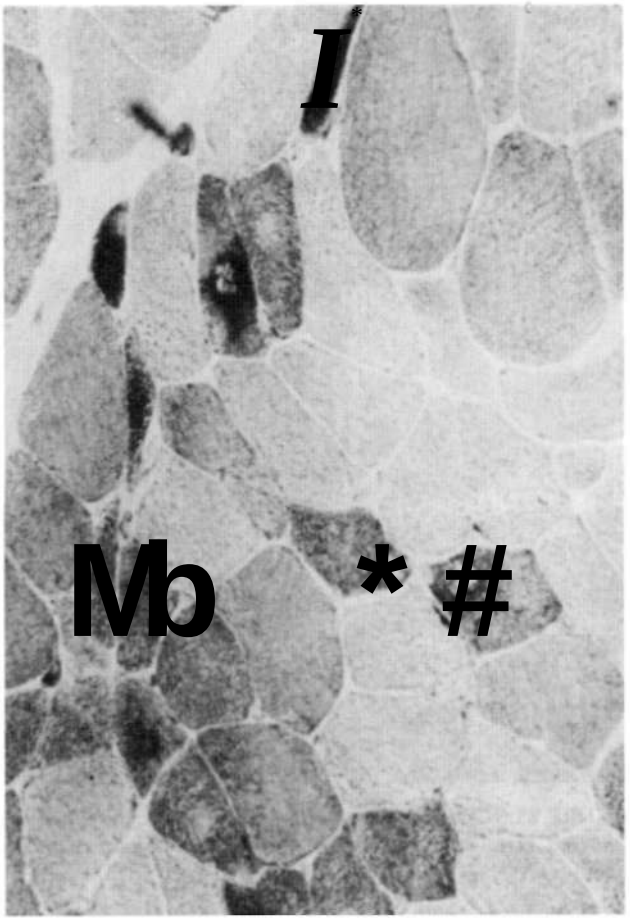

FIGURE. *HSA* Denervation. Target fibers. (Nicotinamide adenine d[nucleotide dehydrogenase stain.)

be reinnervatcd by a neighboring nerve twig, which results in two or more contiguous fibers being supplied from the same anterior horn cell. If that nerve twig then undergoes degeneration, instead of one small, angulated fiber being produced, a small group of atrophic fibers are produced. Small-group atrophy suggests denervation (figure 85.5). When the process continues, large-group or geographical atrophy occurs, in which entire fascicles may become atrophic. In addition to the change in size, the fiber types are redistributed. Normally, there is a random distribution of types 1 and 2 muscle fiber types, sometimes incorrectly called a *checkerboard* or *mosaic pattern.* The same process of denervation and reinnervation results in larger and larger groups of contiguous fibers being supplied by the same nerve. Because all fibers supplied by the same nerve arc of lhe same fiber lype. the normal mosaic pattern is replaced by groups of type 1 fibers next to groups of type 2 fibers. This **fiber** type grouping is pathognomonic of reinnervation (Figure 85.6). When long-standing denervation is present, the atrophic muscle fibers almost disappear, leaving small clumps of pyknotic nuclei in their place.

Myopathic Changes

The pathological changes associated with diseases of muscle have much greater variation than those associated with denervation. The type of change depends on the type of muscle disease. The normal peripherally placed nuclei may migrate toward the center of the fiber. In normal muscle, up to 2% of fibers have central nuclei. The presence of more numerous central nuclei usually indicates a myopathic, often dystrophic, process. In the myotonic dystrophies and limb-girdle muscular dystrophies (LGMDs), internal nuclei are numerous. Occasionally, internal nuclei are seen in some chronic denervating conditions (e.g., 1 LI veil lie spinal muscular atrophy). Necrosis of muscle fibers, in which the fiber appears liquefied and later presents as a focus of phagocytosis, is seen in many myopathies. These changes almost always represent an active degenerative process, such as myoglobinuria, toxic myopathies, inflammatory myopathies, metabolic myopathies, and dystrophies. Fiber-size variation with large fibers and small fibers intermingling in a random pattern often occurs in primary muscle diseases. It is sometimes the only indication of the pathological process. Fiber splitting often accompanies muscle fiber hypertrophy. Split fibers can be recognized in transverse section because of a thin fibrous septum, often associated with a nucleus that crosses part of the way but not all the way across the fiber, A detailed

lHK .1 'Rl\ tf.S.d (linmic denervation and rcimuTvarioii. liisir.nl <. it the usual mosaic pattern of the uvo fiber types, the fibers arc clumped together, with groups of one type appearing next to groups of the other type. (Myosin adenosine triphosphatase stain, pH 9,4.)

study of serial transverse section may reveal more split fibers than a single section. Fiber splitting is particularly visible in dystrophic conditions, such .is LCi.VlD. 1: is rare in Duchenne's muscular dystrophy (DMD) and Becker's muscular dystrophy (BMD) and is usually not seen in acquired myopathics, such as polymyositis.

Many myopathies arc characterized by degeneration and regeneration of fibers. The regenerating fibets often become basophilic and the myonuclei enlarge as a result of **the** accumulation of RNA needed for protein synthesis. Fiber basophilia is a sign of an active regenerating myopathy. It is particularly characteristic of DMD, in which small basophilic groups of fibers may be prominent. Cellular responses include inflammatory reactions around blood vessels, which characterize the collagen vascular diseases and dermatomyositis. Endomysial inflammation with invasion of non-necrotic muscle fibers is seen in inclusion body myositis and polymyositis. Inflammatory cellular responses may be pronounced in dystrophics, particularly facioscapulohumeral muscular dystrophy and dysferlinopathies. Kven the so-called congenital inflammatory myopathics are actually forms of congenital muscular dystrophy (CMD).

In normal muscle, a very thin layer of connective tissue surrounds and separates the individual muscle fibers. In dyslrnplik ennd:; lulls, r hi, ki.-i I cu; ol [his layer (nr.i--.Llr fibrosis) may be pronounced. In DMD and some congenital dystrophies, muscle fibrosis gives the muscle a hard, gritty texture. In the inflammatory myopathies, a loose edematous separation of fibers may be seen, but fibrosis is not characteristic of the active disease phase, except when it is associated with systemic scletosis.

Changes in the inrramyofibrillar network pattern are common in myopathic disorders. Moth-eaten, whorled changes to the intermyofibrillar network arc seen in LGMD and facioscapulohumeral dystrophy (FSHD) (Figure 85.7). The intermyofihrillar network loses its orderly arrangement and becomes swirled, resembling the current in an eddying stream. Ringbmden (ringed fibers, snake coil fibers) are due to the peripheral reorientation of myofibrils in a circular direction. These changes, although not specific, occur more often in myopathies.

Other Changes

Selective fiber type changes are important. Type 2 fiber atrophy is one of the more common muscle abnormalities {Figure 85.8). This change, particularly if it is limited to type 2B fibers, is a nonspecific change that indicates muscle disuse. If muscle is examined some weeks after a limb is put into a cast, selective atrophy of type 2 fibers is noted. Many

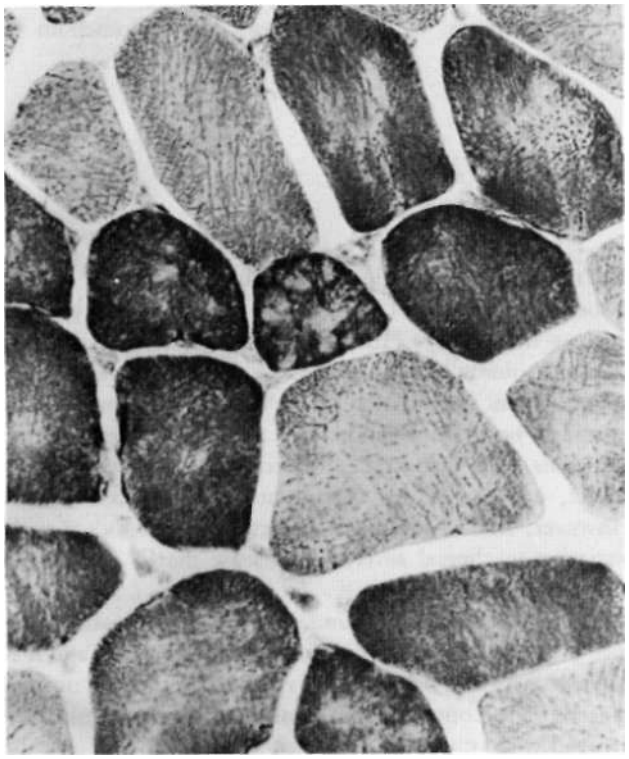

FIGURE 85.7 Myopathy. Moth-eaten, whorled fibers. The intramvofibnllnr network pattern is distorted, and some areas lack the proper stain, (Nicotinamide adenine dinucleotidc dehydrogenase stain.)

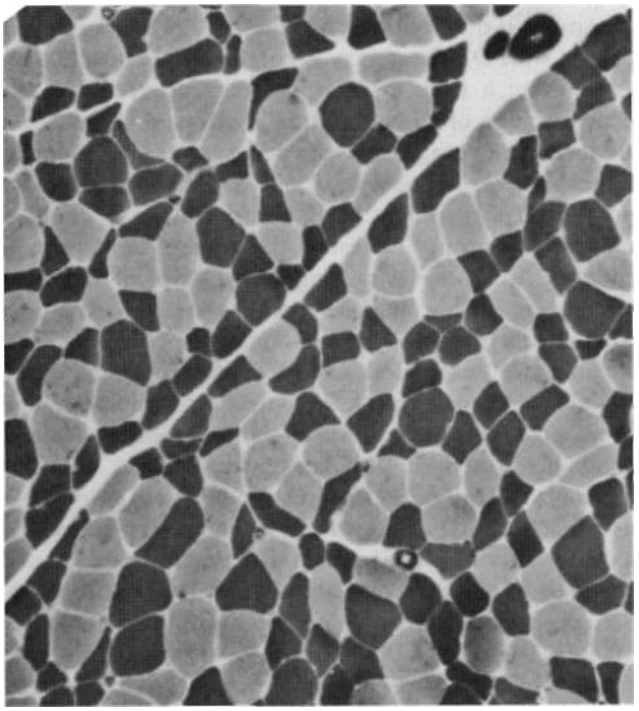

FIGURE 85.8 Type 2 fiber atrophy is a common change resulting from a number of different conditions affecting muscle contraction. (Myosin adenosine triphosphatase stain.)

chronic systemic illnesses tend to produce type 2 atrophy. It is associated with rheumatoid arthritis, nonspecific collagen vascular diseases, cancer (hence the name *cachectic atrophy),* mental retardation in children, and pyramidal tract disease. Type 2 fiber atrophy is regarded as a nonspecific result of anything less than robust good health.

Type 1 fiber atrophy has greater specificity. It is seen in some congenital nonprogressive myopathies, such as nemaline myopathy and congenital fiber type disproportion, and is characteristic of myotonic dystrophy. It can be seen in rheumatoid arthritis. Changes in the proportion of fibers in the biopsy are quite separate from changes in the fiber size. The name *fiher type predominance* has been given to a change in the relative numbers of a particular fiber type. Type 1 fiher predominance is a normal finding in the gastrocnemius and deltoid muscles. It is also the hallmark of congenital myopathies and many eatly-onset dystrophies. Type 2 fiber predominance is seen in the lateral head of the quadriceps muscle. Type 2 predominance is seen occasionally in juvenile spinal muscular atrophy and motor neuron disease, but type 1 predominance is more common in chronic denervating-reinnervating conditions.

Some histological changes ate pathognomonic. Perifascicular atrophy, in which the atrophic fibers are more numerous around the edge of the muscle fascicles, is the hallmark of dermatomyositis. Several metabolic myopathies are characterized by the presence of lipid vacuoles (carnitine deficiency} or abnormal pockets of glycogen (glycogen storage disorders). Several enzyme defects, such as phosphorylase deficiency, phosphofructokinase (1'EK) deficiency, lactate dehydrogenase (LDH) deficiency, and myoadenylatc deaminase deficiency, are detected with the appropriate histochemica! stains. The interpretation of a muscle biopsy should include a description of the morphological and histochemical changes and the association of these changes with a particular diagnosis. Characteristic histological changes are seen in infantile spinal muscular atrophy, dermatomyositis, inclusion body myositis, congenital nonprogressive myopathies, congenital fiber type disproportion, myotubular myopathy, lipid storage myopathies, acid maltase deficiency, and phosphorylase deficiency. Immunocytochemical staining of dystrophin and many other sarcolemmal and myofibcr proteins can distinguish several muscular dystrophies from each other. Although not disease specific, characteristic pathological changes differentiate chronic denervation from acute simple denervation.

IMMUNOCYTOCHEMICAL STUDIES

The availability of commercially produced antibodies has allowed missing proteins to be identified in muscle biopsy

specimens. If the DNA blood studies are unremarkable in a patient with DMD, as may occur with a point mutation rather than a large deletion, the diagnosis rests on the demonstration of no or abnormal dystrophin in the tissue. All the sarcoglycan proteins arc demonstrated using similar techniques. A deficiency of one or more sarcoglycan proteins is increasingly being recognized as a cause of muscular dystrophy. Because the sarcoglycans form a complex, when one is missing, all or some of the other sarcoglycan proteins may be absent as well. ar-Sarcoglycan is especially prone to be abnormal, which makes it a suitable and economical screening tool. The laminin «2 chain (merosin) is absent in some forms of CMD, and absence of nuclear membrane staining with anticmerin antibodies is seen in X-linked Emery-Dreifuss muscular dystrophy (EDMD). Dystroglycan staining can help recognize other LGMDs. Histochemical studies may be used to look for various proteins, such as desmin, ubiquitin, and amyloid. In addition, biopsy material may provide information aboiil intlaimtiarory cell types and iheu affinity for markers, such as CD8 and CD4, which identify cells involved in cytotoxic or humoral mechanisms of inflammation. Antibodies to the membrane attack complex may demonstrate the cells marked for destruction by the immune process, such as the vascular endothelium in dermatomyositis.

SI'ICIfK DISORDERS

Muscular Dystrophies

The muscular dystrophies are a group of hereditary muscle disorders (Table 85.1). They occur at all ages and with all degrees of severity. Historically, they were classified on clinical grounds and recognized by distinct clinical appearances. Recent information on molecular abnormalities has provided both clarification and additional questions for clinicians. The distinct clinical entities, such as BMD or DMD, are caused by distinct molecular abnormalities. However, similar molecular defects may produce a wide variation in clinical severity of disease that is not always easily explained.

For the most part, the underlying molecular abnormalities in the dystrophics involve structural proteins, and it is useful to review these proteins as they occur in normal muscle. The contractile ptoteins, actin and myosin, are arrayed with othet ptoteins, such as troponin, to form the

Table 85.1: Molecular defects of muscular dystrophies

Disease	*Chromosome*	*Protein*
DMD/BMD	Xp21	Dystrophin
fh\:n	Xq28	Emerin
Myotonic dystrophy	19ql3.2	Myotonin protein kinase
Myotonic dystrophy type 2/PROMM	3q	7.NF9
FSHD	4q35	³
Oculopharyngeal dystrophy	14q	Poiyalanine binding protein 2 (PABP2)
Bethlem myopathy I	21q22.3	Collagen type VI (or-1 or *a-2* subunits)
Billikm nv upatlr. *1*	2q37	Collagen type VI *{a-6* subunit}
LGMD IA	5q22-31	Myotilin
I.(AID Mi Willi L.irilio;i.L:liy.':in::>s. . . . . I Joniin.iiii [:)\II)	lqll-12	Nuclear lannn A/C
LGMD 1C	3p25	Caveolin-3
LGMD 2A	L5ql5	Calpain-3
LGMD 2B/Miyoshi's myopathy	2pl3	Dysferlin
IGMD2C	13ql3	y-Sarcoglycan
LGMD 2D	17q21	a-Sarcoglycan
LGMD 2E	4q12	^-Sarcoglycan
i(AID *n*	5q33	<S-Sarcoglycan

LGMD 211	9q31-q33	TK1M32
LGMD 21	19ql3.3	Fukunn-rclated protein, *FKRP1*
Congenital muscular dystrophy (CMD)		
Merosin-negative classic type	6q21-22	Merosin (a-2 subunit)
Merosin-positive integrin deficiency	12ql3	*a-1* Integrin
Merosin-positivc I-'IIRP deficiency	I9ql3.3	Fukutin-related protein, *FKRl'l*
Fukuyama type	9q31-33	LnkLIT n
Walker-War burg syndrome	•):\l ;i ;.;	?
Muscle-eye-bra in disease	Ip32-p34	POMGnTl
CMD with rij;id spine syndrome	lp35-36	Selenoprotein 1

DMD = Duchenne's muscular dystrophy; BMD = Becker's muscular dystrophy; EDMD = Emery-Dreifuss muscular dystrophy; PROMM = proximal myotonic myopathy; FSHD = facioscapulohumeral muscular dystrophy; LGMD = limb-girdle muscular dystrophy; POMGnTl =0-mannose-^-l,2-N-acetylglucosaminlyl transferase; ZNE9 = zinc finger 9.

familiar thick and thin filaments of the sarcomere. The reaction between actin and myosin results in realignment between the two molecules. In the sliding filament model, the thick and thin filaments form an array that slides back and forth.

The contractile proteins are connected to the "outside" of the cell by a complex of proteins that ultimately links to the basal lamina. The first step in this connection is the protein *dystrophin,* which is located on the cytoplasmic face of the muscle membrane. This large protein (427 kD) is coded by a gene on the short arm of the X chromosome. Dystrophin is related to spectrin and other structural proteins and consists of two ends separated by a long, flexible, rod-like region. The amino rerminus binds to the acmi molecule, and the carboxvl tern-.inns, which is rich in cysteine, links dystrophin to a a implex oi glycoproteins 1:1 the sarcolemma. Two of these, the dystroglycans, form a direct link between dystrophin and part of the laminin molecule, which is on the extracellular surface of the muscle membrane. or-Dystroglycan is a 156-kD prorein located outside the membrane and linked to the laminin «2 chain. It also connects with ^S-dystroglycan, which is a 43-kD transmembrane component of the complex and is linked with dystrophin. The other glycoproteins are the sarcoglycans; four have been identified and are labeled alphabetically a-sarcoglycan (50 kD), ^-sarcoglycan (43 kD), y-sarcoglycan (35 kD), and <5-sarcoglycan *{35* kD). They span the sarcolemma I membrane, but their relationship to the dystroglycans and their precise function is uncertain. The sarcoglycans are coded on different autosomal chromosomes; none is on the X chromosome. The a_2 chain of laminin (merosin) provides the anchor to the extracellular matrix because it is through the globular domain portion of the molecule that a-dystroglycan attaches to laminin. Merosin also binds to *afHD* integrin, a protein complex located on the sarcolemma membrane. Dystrophin, the sarcoglycans, rbe dystroglycans, and merosin appear ro function as a unit in stabilizing the muscle membrane. Together, these proteins arc referred as the dystrophin-glycoprotein complex. The complex may serve to propagate the force of contraction from the inside to the outside of the fiber to prevent membrane disruption.

Other sarcolemmal proteins not directly linked to the dystrophin-glycoprotein complex are also affected in some forms of muscular dystrophies (e.g., dysferlin and caveolin-3). Also, sarcomeric proteins (e.g., myotilin, titin, and telethon in), important in stabilizing the contractile apparatus, are mutated in certain dystrophies. Mutations of the muscle-specific calcium-dependent protease (calpain-3) gene are responsible for the majority of non-dystrophin/sarcogly can-re la ted LGMDs. In addition, secretary enzymes (e.g., O - ma nn os e- £-1,2 -N-acety Igluc os amin y 1 transferase, fukutin, and fukutin-related protein), which probably play a role in glucosylation of a-dystroglycan and other import proteins, arc responsible for some forms of CMD. Mutations in genes encoding for nuclear envelope proteins, emerin and lamin A/C, arc the causes of X-Iinked and autosomal dominant EDMD, respectively.

Dystrophin Deficiency (Duchenne's Muscular Dystrophy, Becker's Muscular Dystrophy, and Atypical Forms)

An absence or deficiency of dystrophin is implicated in two disorders lhai cause progressive destruction ol muscle. I he responsible gene is located on the short arm of the X chromosome at locus Xp21. It is an extremely large gene, comprising more than 2.5 million base pairs and 79 exons or coding regions. Approximately two thirds of cases are associated with a detectable deletion or duplication of segments within the gene. The others are presumably due to point mutations too small to be detected using standard techniques. There are "hot spots"' for these gene deletions, notably between exons 43 and 52 and particularly between exons 44 and 49 (Nobile et al. 1997). Whether the deletion is in frame or out of frame (see Chapter 44) determines whether dystrophin is absent from the muscle or present in a reduced, altered form. This has clinical significance because the former is usually associated with the severe (Duchenne's) form of muscular dystrophy (DMD), whereas the latter may cause the milder (Becker's) variant (BMD), in which the abnormal dystrophin preserves enough function to slow down the progress of the illness. The DNA code is read by triplet base pairs (bp). This *reading frame* must be maintained throughout the length of the gene to produce dystrophin. If a deletion removes a multiple of 3 bp, the reading frame may be intact upstream and downstream but may make limited sense, as if the sentence "You cannot cat the cat" were changed to "You not eat the cat," and some modified dystrophin may be formed. This is often the situation in the mild form (BMD) of dystrophin deficiency. In the severe form (DMD), the reading frame is destroyed, as if a deletion resulted in the sentence "Yoc ann ote att hec at." Exceptions to this rule exist, and frameshift deletions are associated with the milder form of the disease, particularly at the 5' end of the gene in exons 3 to 7 (Muntoni et al. 1994).

The prevalence rate of DMD in the general population is approximately 3 per 100,000, and the incidence among liveborn males is 1 per 3500. BMD is approximately one tenth as common. Although the inheritance is clearly X-linked recessive, almost one third of cases are sporadic, presumably due to spontaneous mutations occurring in either the child's or the mother's ovum.

It is easy to imagine that an absence of dystrophin would severely impair the integrity of the sarcolemmal membrane. Attention was previously focused on this membrane because of electron microscopic evidence thar it contains breaches associated with wedge-shaped areas of destruction in the subadjacent muscle cell. It is assumed that the absence of a supporting protein renders the membrane susceptible to mechanical damage. This presumably means that molecules, such as calcium, would have unlimited

access to the fiber interior and would initiate a chain of destructive processes, producing muscle fiber necrosis. The process would then involve continuing degeneration, with repeated attempts to regenerate on the part of the surviving satellite cells. Eventually, this process results in severe muscle fiber loss and replacement of muscle fibers with fibrous tissue.

Several animals have been found to have dystrophin deficiency; the better known include the *mdx* mouse and a dog model. The mouse model is unusual because the animals appear relatively normal, except for an early phase when inflammatory changes are noted in the muscle. In dogs, dystrophin deficiency is associated with progressive clinical weakness, and dystrophic muscle pathological changes, thus making this animal suitable for the evaluation of potential treatment.

Ducbenne's Muscular Dystrophy. Boys with DMD are usually normal at birth. The early clumsiness seen in all toddlers persists into the second year when walking begins. The children is noted to place one hand on the knee to assume an upright position when rising from the floor *(Gou/er's maneuver).* It is often at this stage that the calf muscles are found to be rather firm and rubbery (pseudo-hypertrophy) (l-'igure *#5.9).* Within 2 to 3 years, parents notice that the child does not run properly and is never able to jump clear off the floor with both feet. In the absence of therapy, tightness is noted in muscles that cross two joints in the legs. The iliotibial bands and the Achilles heel cords are usually the first to become tight. This is particularly noticeable in boys who habitually walk on their toes.

A period of apparent improvement may be seen between 2 and *(•>* years of age as the child gains motor skills. This represents the child's natural development, which has not yet been outpaced by the muscle weakness. By 5 or 6 years of age, stair climbing becomes labored, and the railing is used to pull upward. At the age of 6 or 7, sudden falls begin to occur, at first, when the child is hurrying or is knocked off balance by playmates. The fall is quite spectacular; the knees collapse abruptly and the child drops like a stone to the ground. At approximately 8 to 10 years of age, affected children cease to climb stairs or stand up from the floor. barlicr, affected boys began using a wheelchair and lost the ability to walk at approximately *9* years of age. Now, with prednisone therapy, bracing, reconstructive surgery, and physiotherapy, the average age of wheelchair confinement is 12.2 years. The true natural history of DMD is difficult to ascertain because many physicians and parents put considerable effort into keeping the children straight and the limbs supple.

Contractures of the hips, knees, and ankles become severe when the relatively untreated child spends much of the day in the wheelchair. The hips and knees become contracted to 90 degrees, and the feet turn downward and inward in an exaggerated position of equinovarus. It is very difficult to get normal shoes that fit and impossible for the child to sleep except in one position: usually with the knees propped up with pillows and slightly turned on one side. I [andling children at this stage becomes difficult, and back pain and limb pain almost always accompany this severe stage of muscular dystrophy. The development of severe scoliosis compromises respiratory function.

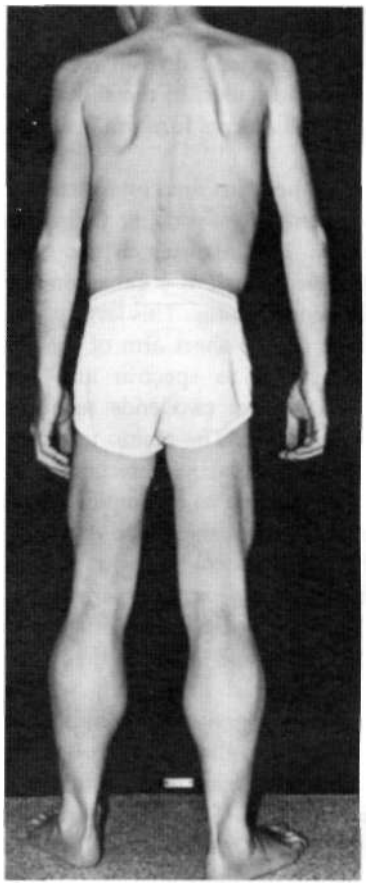

FIGURE 85.9 Duche Line's muscular dystrophy. Calf and thigh hypertrophy in an ambulatory 8-year-old patient.

The cardiac involvement is characterized by degeneration and fibrosis of the posterolateral wall of the left ventricle. Besides the abnormal electrocardiogram (ECG) that is seen at an early age in DMD, valve motion, wall thickness, and wall motion are also abnormal as revealed by echocardiograms. Death occurs due to cither respiratory failure or the catdiomyopathy that is relatively resistant to treatment.

I lie simplest tot to *a>* it inn the diagnosis is a blood DNA study that demonstrates a deletion in the dystrophin gene. In the 30% of patients in whom a deletion is not detected, a muscle biopsy is necessary to establish the absence of dystrophin. Three antibodies are available: Dys 1 for the rod region of the protein, Dys 2 for the carboxyl-terminal end, and Dys 3 for the amino-terminal end. Absence of the amino-terminal end, the end that binds with actin, is associated with more severe phenotypes. In DMD, the protein is absent and no staining is seen, whereas in BMD the stain is reduced, irregular, and fragmented. Approximately

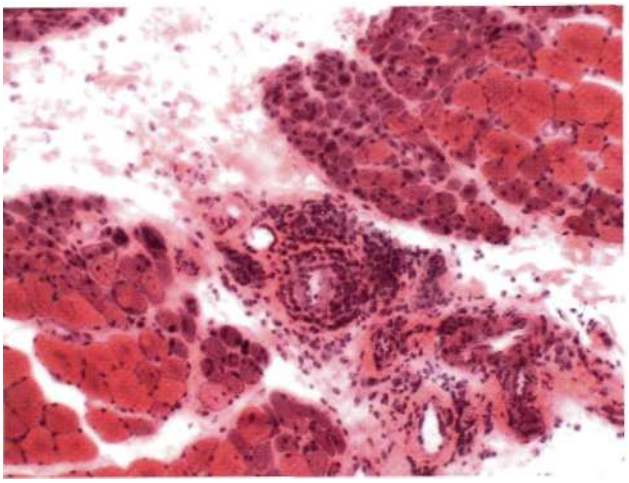

PLATE 85.1 Dermatomyositis. Muscle biopsy demonstrates perifascicular atrophy. Inflammatory cells when present are located around blood vessels (i.e., perivascular) and arc located primarily in the perimysial connective tissue as opposed to the endomysium as seen in polymyositis and inclusion body myositis.

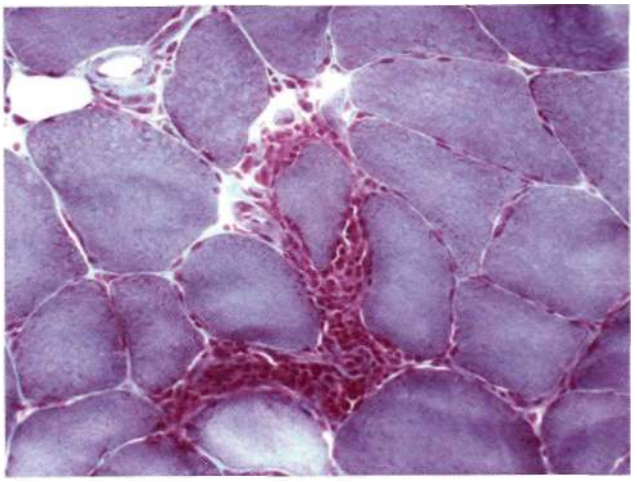

PLATE 8S.II Polymyositis. Mononuclear inflammatory cells composed of cytotoxic T-cells and macrophages surround and invade non-necrotic muscle in the endomysium.

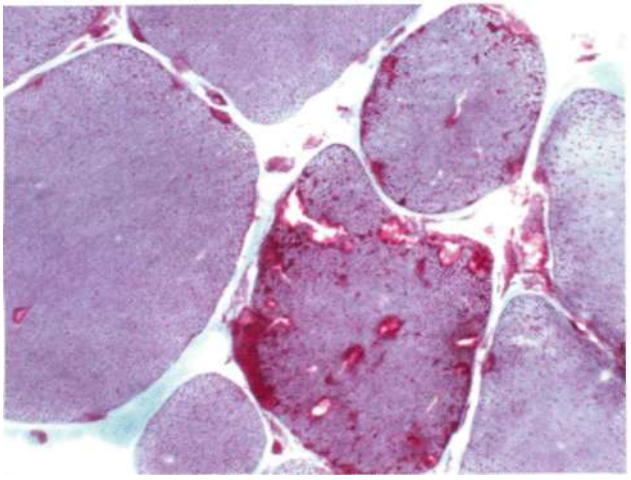

PLATE 85.ITI Inclusion body myositis. Scattered muscle fibers contain one or more rimmed vacuoles. (Hematoxylin-eosin stain)

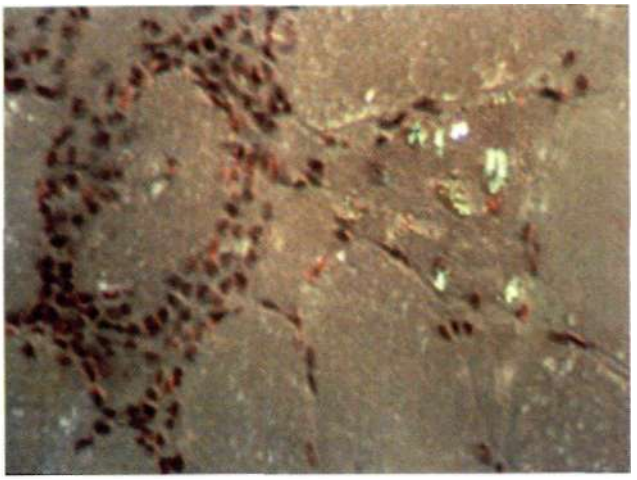

PLATE 85.IV Inclusion body myositis. Abnormal amyloid deposition can be seen in vacuolated muscle fibers. (Congo red stain)

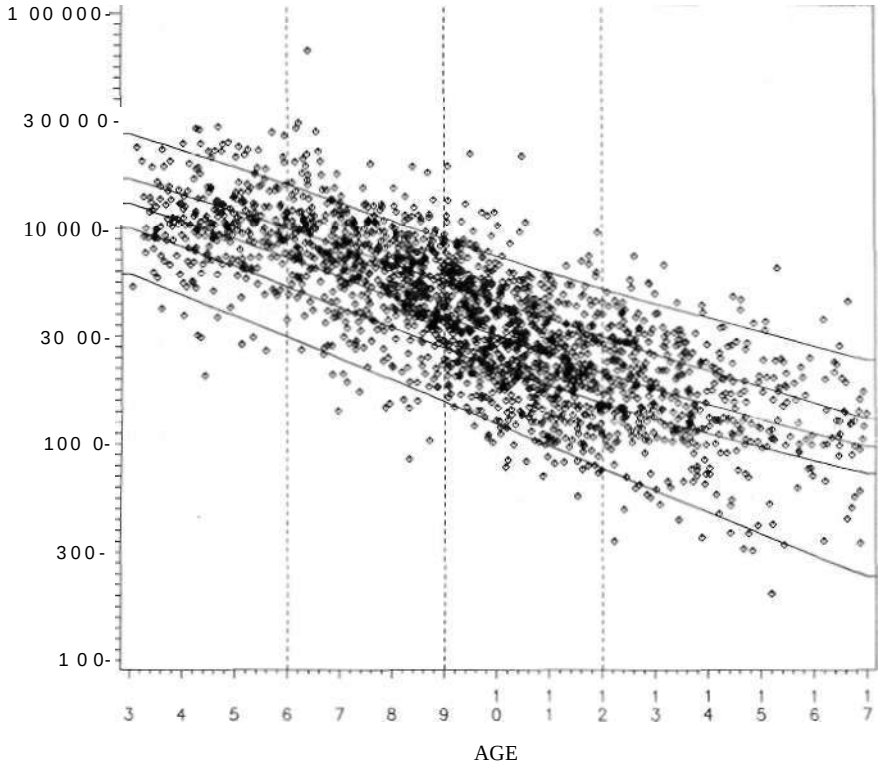

FIGURE 85.10 Duchenne's muscular dystrophy: change in scrum creatine kinase (CK) level with age. This is a scattergr.ini of scrum CK levels in individual patients. The lines represent the fifth, twenty-fifth, fiftieth, seventy-fifth, and ninety-fifth percentiles.

1 % of fibers demonstrate a rim of dystrophin. These are the revertant fibers, in which either the gene has undergone another mutation, putting the coding sequence back in frame, or alternative splicing of messenger RNA has occurred spontaneously, allowing for translation of some abnormal dystrophin. Where doubt exists, immu no blotting may show a decreased amount of dystrophin in the tissue.

The serum concentration of creatine kinase (CK) is markedly elevated to greater than 10,000 mU/mL. The elcctromyogram (EMG) shows myopathic changes (set-Chapter 36B), and the muscle biopsy shows muscle fiber necrosis, phagocytosis, variation in the size of fibers, fibrosis, groups of basophilic regenerating fibers, and opaque or hypercontracted fibers (hyaline fibers) (figures 85.10, 85.11, and 85.12).

Treatment

Physical Therapy. The primary aim of physical therapy is to keep the joints as loose as possible. Early on, the iliotibial bands and the heel cords are the tightest. Later, contractures of the elbow, wrist, and finger add to functional disability. Physical therapy is usually started at 3–4 years of age, when parents are taught to stretch the child's heel cords, hip flexors, and iliotibial bands on a daily basis. The goal of passive stretching of joints is not to increase the range of motion but, rather, to prevent further development of contractures. This should be carefully explained to parents because they may be discouraged to see no improvement in the tightness, even after many-months of therapy. The use of a night splint is important at an early age. The splint is a plastic shell molded around the

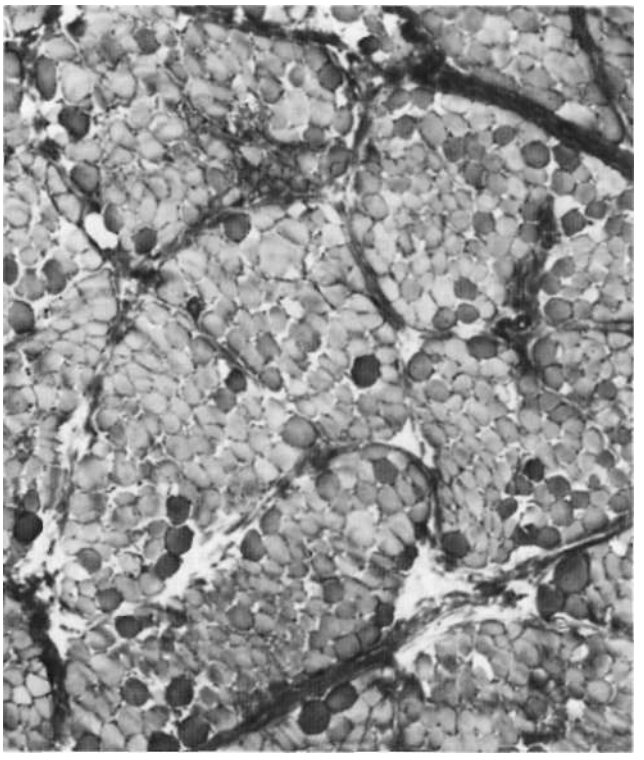

FIGURE 85.11 Duchenne's muscular dystrophy: muscle biopsy. The fibers are of variable size and separared by connective tissue. Large, heavily stained opaque fibers are noted. (Vcrhocff-Vnn Gieson stain.)

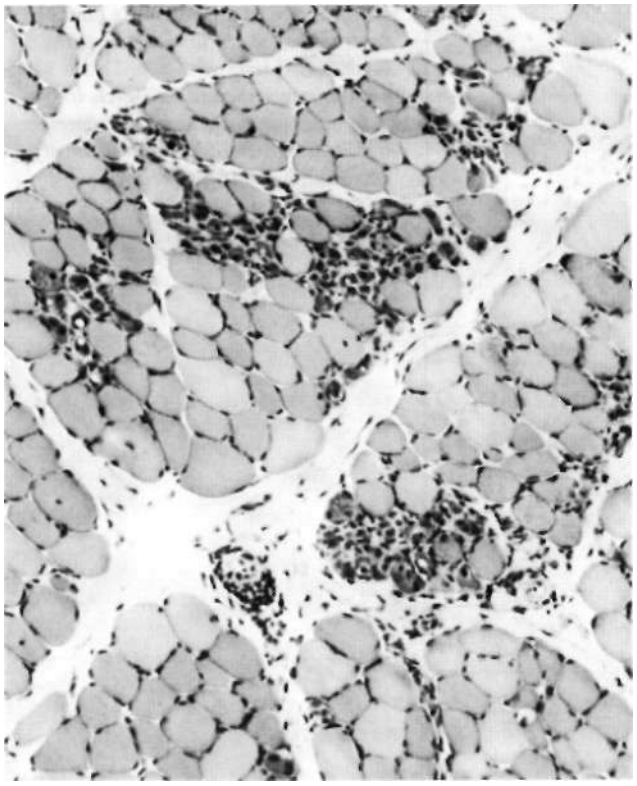

FIGURE 85.12 Duchenne's muscular dystrophy. Groups of small, basophilic (darkly staining) fillers are scattered in the biopsy. (Hematoxylin-eosin stain.)

lower part of the leg to maintain the foot at a right angle to the leg. Ankle contractures almost never occur in boys who use the splints regularly. Unfortunately, some boys, particularly those 6 years of age or older, cannot tolerate the splints. Parents often ask about an active exercise program. Such programs are largely unnecessary in a young child, who is running around to the best of his ability. By the time a child finds walking difficult or is in a wheelchair, muscle weakness is severe, and exercise does not effectively increase muscle strength.

Bracing. The appropriate use of bracing can delay progression to wheelchair use by 2 years. Weakness of the quadriceps is a major factor responsible for the inability to stand or walk. Such weakness causes the knee to collapse when even slightly flexed; the only stable position is in hyperextension. The boy is then reluctant to bend the knee in walking and may remain rooted to the ground, unable to move the feet. The addition of a long-leg brace (knee-foot orthosis) helps solve this problem. This device stabilizes the knee and prevents it from flexing. The child walks stiff-legged but does not have the same problem with falling. In general, the time for bracing is when the child has stopped climbing stairs, has difficulty arising from the floor, and falls daily. An indication for bracing seen on examination is a knee extensor muscle that is unable to straighten the knee against gravity. Parents often complain that the weight of the brace makes walking difficult. This is incorrccr. The brace basically functions as a pendulum, and slight elevation of the hip is sufficient to bring the leg forward. The disadvantage of a lightweight, plastic knee-foot orthosis is the difficulty in keeping the foot straight. In contrast, the high-top boot worn with a double-upright brace provides excellent stability, but is heavier. The choice between plastic and metal often comes down to personal preference of the patient or physician.

Surgery. Reconstructive surgery of the leg is often combined with bracing. The two are often performed during the same hospital admission. The purpose of leg surgery is to keep the leg extended and remove contractures of the iliotibial bands and hip flexors. Shortening of the iliotibial bands is associated with a stance in which the boy's legs are widely abducted. Because the long-leg brace is used like a pendulum, if the foot is widely abducted, the child cannot swing the leg forward. The only effect of lifting the hip in this case is that the leg tries to swing inward toward the midline. This is impossible because the abduction is due to the resistance of the iliotibial band contractures. A simple way to maintain function in the leg is to perform percutaneous tenotomies of the Achilles tendons, knee flexors, hip flexors, and iliotibial bands. This procedure often allows a child, who is becoming increasingly dependent on a wheelchair, to resume walking.

The modern techniques of spinal stabilization are used increasingly in boys with DMD and progressive scoliosis. Spinal surgery is now well accepted by patients and families because of the extreme discomfort and respiratory problems associated with severe scoliosis. This has had a positive impact on the management of late stages of disease. Surgery should be considered in patients with 35 degrees or more of scoliosis and significant discomfort. To reduce the risk of surgery, forced vital capacity should be greater than 35% of predicted. Noninvasive positive pressure ventilatory assistance is often used prophylactically in such patients.

Pharmacological Treatment. Prednisone is the only drug that improves muscle strength and function. Although the duration of its effect is uncertain, it seems to be at least 3 years. The synthetic steroid deflazacort has a similar therapeutic effect and approximately one half the side effects. It is available in Europe and Central and South America but not in the United States. The use of corticosteroids in DMD is increasing. The best time to initiate therapy is uncertain. Corticosteroids may be viewed as agents that can "buy time" for the patient until some better treatment comes along. In this light, we usually delay treatment until 5 years of age, just before the expected decline in strength, but at a stage when the muscles are relatively well preserved.

Gene Therapy. In theory, the treatment and cure of DMD would be a matter of replacing the defective gene early in life. The muscle wasting is caused by the lack of dystrophin, not by the presence of a toxic gene product. The possibility of replacing old muscle with new is enticing and has occupied scientists for the last decade. The first attempt

was to use normal myoblasts grown from muscle of a normal donor. These were then injected into the muscle with the hope that they would fuse with the dystrophic muscle and carry the normal gene with them. Although dystrophin was expressed in some of the muscle fibers, the percentage was so low that no clinical effect was detected. The reasons are many: The injected cells diffuse only a short distance, they are prone to rejection, and the surviving muscle proves resistant to fusion with these myoblasts. Attempts to uivimnvill ilic.se drawbacks an ongoing. Inn .11 iliis 11 me, myoblast transfer is only a future possibility.

A more promising approach is the effort to develop a vector inro which the dystrophin gene can be inserted and can then carry the gene into the muscle. Several problems must be overcome. The large size of the gene makes insert inn into the usual vectors difficult. An abbreviated version of the full gene may be satisfactory. Such truncated genes occur naturally and cause only mild BMD phenotypes. The gene will have to work in conjunction with a promoter that allows dystrophin production to be limited to the muscle. The viral vector must also have been proved to be safe. This necessitates removal of most or all of the viral genes. At present, the adenovirus is the best candidate from which a vector might be developed, but other viruses, such as retroviruses, are also being considered. Initial animal experiments have given some encouragement to this approach, and initial human studies have been performed.

Another possibility is upregulation of utrophin, a dystrophin-I ike protein found near the endplatc. Animal studies suggest both functional and pathological improvement if the amount of utrophin can be increased in the dystrophin-deficient animal. This finding is reinforced by the fact that utrophin is increased in patients with dystrophin deficiency. It is much easier to upregulate a mile ili.u .liiv.uh e\isls than II is lt> inlrodnet :i [mvii',11 ;:nu' to which the individual has had no prior exposure. It may also be possible to upregulate utrophin levels pharmacologically. Indeed, one of the effects of corticosteroids on cultured dystrophic cells is to increase utrophin levels.

Becker's Muscular Dystrophy. BMD shares all the characteristics of the severe form but has a milder course. The first signs of weakness usually appear in the first decade, although the onset of symptoms is sometimes delayed until the fourth decade or later. The muscular hypertrophy, contractures, and pattern of weakness are similar to that seen in DMD. Boys with BMD, however, continue to walk independently past 15 years of age and may not have to use a wheelchair until they are at least in their twenties, A common complaint in teenagers with **BMD** is leg cramps and other muscle pains, which arc often associated with exercise and arc more severe than those in ll.MH. Many p.iii.ns li.ne ;i cardiomyopathy thai car. be more disabling than the weakness. Cardiac transplantation has been very successful in some patients with this dilated cardiomyopathy form of the illness.

Serum CK concentrations are elevated but not as high as in DMD. The EMG demonstrates myopathic features. These abnormalities are nonspecific, and diagnosis requires demonstration of a mutation in the dystrophin gene or reduced quantity or size of dystrophin on muscle biopsy. Immunostaining of muscle tissue with Dys 1, Dys 2, and Dys 3 antibodies will usually demonstrate an abnormal staining pane 111, Definitive diagnosis often requires quantitation of the dystrophin in the muscle with immunobiot (Western blor) studies.

Because patients do not have much trouble in the first few years, aggressive physiotherapy, surgical reconstruction, and night splints are less often needed. Patients with BMD are less prone to development of kyphoscoliosis, perhaps because they are not confined to a wheelchair until after the spine has become fully mature. We have used corticosteroids only occasionally in patients with 15ML). The stabilizing effect of corticosteroids is less noticeable when the disease course is already fairly stable. In every other respect, including bracing and genetic counseling, BMD and DMD can be treated the same.

Other Pbcnotypes Associated with Dystrophinoparhy. With the development of genetic testing and dystrophin analysis, it is becoming clear that dystrophin deficiency is associated with several phenotypes. In one family, males with dystrophin deficiency were asymptomatic (Morrone et al. 1997). Dystrophin deficiency has been associated with very mild late-onset weakness, exercise intolerance, muscle cramps, and myoglobinuria (Figarella-Branger et al. 1997), Female carriers may have a phenotype similar to that of DMD due to symmetrical inactivation of the X chromosome (lyonization), may manifest symptoms and signs suggestive of LGMD (manifesting carriers), or may have a dilated cardiomyopathy.

It is impractical to perform genetic testing on ali patients with neuromuscular complaints. However, the combination of cramps, mild weakness, an elevated serum CK concentration, and large calf muscles warrants analysis of dystrophin and its associated proteins. Genotype-phenotypc correlations are inexact, but abnormalities in the amino-tcrmmal and the earboxyl-terminal domains of dystrophin arc associated with more severe phenotypes. Alterations in the rod domain are more variable and may be associated with a mild phenotype. In-frame deletions and insertions are associated with much more benign phenotypes than out-of-frame alterations.

Genetic Counseling. Because DMD is an X-linked recessive disorder, the carrier state of all women at risk should be ascertained. Up to 30% of cases may be sporadic, due to new mutations or deletions. The percentage of new cases that are sporadic appears to be increasing, perhaps because genetic counseling is widely available and women who are carriers decide nor to have children.

Most female carriers arc asymptomatic but approximately 8% manifest weakness and have a clinical phenotype similar to that of BMD. Manifesting carriers usually have an elevated serum CK level and myopathic changes on an EMG. Muscle biopsy usually demonstrates a mosaic pattern or patchy staining of dystrophin on the sarcolemma. However, these laboratory tests and muscle biopsy are not sensitive enough for the identification of carriers among asymptomatic females, and genetic studies ate required.

Genetic analysis of all potential carriers is advisable. When the disease is associated with a deletion of the dystrophin gene, carrier detection is available in many-genetics laboratories that have the ability to identify the presence of a mutant gene over the background contributed by the normal allele. This involves an analysis of the gene "dosage," comparing two normal alleles that have a double dose against a deleted allele and a normal allele that have a single dose (Voskova-Goldman et al. 1997). Thus current diagnosis of carrier status when a deletion has been identified in a proband is based on an analysis of a gene dosage. Unfortunately, situations exist in which a mutation is identified in a boy with "sporadic" DMD but not in the mother and yet the mother is still a carrier. This is due to germlinc mosaicism in which the mutation in the mother lies only in her oocytes. The recurrence rare of DMD has been estimated to be as high as 14% in such situations.

For women who are shown to be carriers of a dystrophin gene mutation it is possible to offer reproductive management techniques to avoid the birth of affected children. Prenatal diagnosis using amniotic cells or chorionic villus biopsies can identify an affected fetus with the mutated gene, and, more important, fetuses that are unaffected. In vitro fertilization followed by gamete in vitro cell sampling is also available, although it is expensive and not always successful. In families in whom the disease is associated with a point mutation too small to detect, carrier detection relies on demonstrating that the woman carries the same X chromosome as the affected individual. This necessitates linkage studies, which become reliable only if there are enough occurrences in the family and enough family members to provide reliable linkage. Research is decreasing the proportion of probands in whom no mutation can be detected (currently about 5%).

Other Limb-Girdle Dystrophies

One of the most important recent developments in muscle disease has been a better understanding of the LGMDs. Before the advent of modern neuromuscular diagnostic techniques, juvenile nr **.ii.iull ousel pseudi Htiynpathk** spinal muscular atrophy was included in this group of conditions. Despite separation of patients with these conditions, the LGMD group of disorders defied classification until the availability of molecular genetic testing. Weakness was generally proximal, but other features were disparate. In some patients inheritance was dominant and in others recessive. Some had more hip than shoulder weakness and others had the reverse. The onset of illness could be mild in late life; other patients had severe and early onset. It was generally recognized that the tetm LGMD encompassed several different disorders. The first discovery was that a defect in one of the sarcoglycans caused a severe form of dystrophy that occurred in a North African family. Since that time, many entities have been delineated that are characterized by defects in different structural and other proteins. These include, among others, the sarcoglycans, the *txi* chain of laminin (merosin), caveolin-3, and calpain-3. LGMDs transmitted by autosomal dominant inheritance are designated LGMD type 1 and those transmitted by autosomal recessive inheritance as LGMD type 2, Subclassification with an alphabetical letter characterizes distinct genetic forms of LGMD 1 and LGMD 2. In the following sections the known protein abnormalities and other forms of LGMD are discussed. As a group, their prevalence probably approaches 1 per 100,000 (van der Kooi ct al. 1996). The autosomal recessive LGMDs are more common than the autosomal dominant LGMDs.

Autosomal Dominant LGMDs (LGMD 1)

LGMD 1A (Myotilin Deficiency). LGMD 1A presents during the second and third decades with proximal arm weakness greater than leg weakness. Some patients have distal arm and leg weakness as well as facial and pharyngeal weakness. Serum CK concentrations can be normal or moderately elevated. Rimmed vacuoles within muscle fibers are seen on histological preparations.

LGMD 1A has been linked to mutations in the myotilin gene located on chromosome 5q22.3-31.3. Myotilin is a sarcomeric protein that is present at the Z-disc. The protein is probably important in myofibrillogenesis and stabilization of the Z-disc and sarcomere.

LGMD IB (Lamin A/C Deficiency). LGMD IB is allelic with the disorder previously reported as autosomal dominant EDMD. Limb-girdle weakness is the presenting feature in some patients, whereas humeral-peroncal weakness and early contractions are the initial features in others. Gardiomyopathy and severe conduction defects and arrhythmias may occur with or without skeletal muscle involvement. Sudden death due to fatal arrhythmias is common, and pacemakers are often needed. Scrum (K concentrations may be normal or elevated 25-fold. Muscle histological pteparations show dystrophic features and rare rimmed vacuoles.

The disorder is associated with mutations in the lamin .V(s;euc located on chromosome Iql 1-21. Lamins A and C are produced by alternative splicing of the lamin A/C messenger RNA (mRNA) transcript. Lamin A/C is an inter mediate-sized filament located on the nucleoplasmic surface of the inner nuclear membrane where it interacts with lamin-associated proteins, including emerin, the

protein associated with X-linkcd EDMD. Lamin A/C may also bind to heterochromatin. Normal immunostaining of the nuclear membrane with antiemerin antibodies helps distinguish this myopathy from X-linked FJDMD. Examination by electron microscopy shows alterations in myonuclei including the loss of peripheral heterochromatin, altered interchromatin texture, and fewer than normal numbers of nuclear pores.

LGMD 1C (Caveolin-3 Deficiency). LGMD 1C is a rare myopathy characterized by childhood onset of proximal weakness greater in the legs than in the arms and exertional myalgia. Progression is variable. The clinical phenotype associated with caveolin-3 mutations is heterogeneous, Some families have distal weakness, and others have the syndrome of *autosomal dominant rippling muscle disease* (Betz et al. 2001; Vogerd et al. 2001). Serum CK conccntniiions arc increased to 3-25 times greater than normal. Some patients have increased serum CK concentrations and no weakness.

LGMD 1C is caused by mutations in the gene encoding for caveolin-3 on chromosome 3p25. Caveolins are scaffolding proteins that interact with lipids and other proteins in caveolae, which are flask-shaped invaginations of the sarcolemmal membrane. Immunostaining of muscle tissue demonstrates a reduction of caveolin-3 along the sarcolemma. Electron microscopic examination reveals a decreased density of caveolae on the muscle membrane as well.

LGMD 2A (Calpain-3 Deficiency). A careful scries of studies conducted over a decade documented the existence of a form of autosomal recessive LGMD in an inbred population on Reunion Island in the Indian Ocean (Fardeau et al. 1996). The gene for LGMD 2A was localized to chromosome 15 and associated with a mutation in the gene for muscle-specific calcium-activated neutral protease (CANP-3 or calpain-3). Cases have been since described throughout the world, and LGMD 2A is estimated to account for as many as 20-26% of dystrophies in patients with normal dystrophin and sarcoglycan. The underlying pathophysiological process is uncertain. CANP-3 is not a structural protein but an enzyme that binds to titin. It may have a regulatory role in the modulation and control of transcription factors and thereby affect gene expression.

The onset is in childhood or early adult life. Most patients have a mild to moderately progressive disease course with loss of ambulation in adult life. In mote severe forms, weakness first occurs in the hips and then in the shoulders. The facial muscles and the neck flexors and extensors are strong. Scapular winging, different from that seen in FSHD, is characterized by a jutting backward-of the whole medial scapular border. The posterior thigh muscles arc affected more severely than the knee extensors, and the rectus abdominis muscles seem to be affected early. The serum concentration of CK is markedly elevated early and then decreases and may normalize later on. Treatment is not available, but it seems reasonable to apply the same principles used in treatment of dystrophin deficiency.

LGMD 2D (Dysferlin Deficiency). Mutations in the gene encoding for dysferlin on chromosome 2p13 lead to at least two phenotypes. One is a limb-girdle pattern of weakness (LGMD 2B), and the other is weakness and atrophy of the calf muscles (Miyoshi's myopathy}. Some patients have earlier involvement of the anterior tibial muscles. Dysferlinopathies account for only 1% of the LGMDs but 60% of the distal myopathies. From another perspective, 80% of patients with dysferlinopathy have a distal myopathy, 8% have LGMD, and 6% have only asymptomatic elevations of serum CK concentrations.

The dysferlinopathies typically present in adolescence or early adult life. Progression is usually slow but can be variable. Some lose the ability to walk in the second decade whereas others walk until late in life. Clinical variability in the pattern of weakness and disease progression exists within the same family.

Serum CK concentrations are elevated to 35-200 times normal. Muscle histological preparations show dystrophic features in severely affected muscles and nonspecific myopathic features in less affected muscles. The occasional finding of endomysial or perivascular inflammation may lead to an incorrect diagnosis of polymyositis. However, unlike polymyositis, the inflammatory cells do not invade non-nccrotic muscle fibers. A helpful immunohistological feature is the demonstration of a membrane attack complex on the sarcolemma of non-necrotic muscle fibers. This feature is also seen in other dystrophies with secondary inflammatory changes (e.g., FSHD) but not in primary inflammatory myopathies (i.e., polymyositis, dermatomyositis, or inclusion body myositis) {Spuler and Engel 1998). Diagnosis can be confirmed with immunostaining and immunoblot.

Dysferlin localizes to the sarcolemmal membrane but does not directly interact with dystrophin or the sarcoglycans. Its function is unknown, but it may be important for membrane fusion.

LGMD *2C, 2D, 2E, and 2F (Sarcoglycan Deficiencies).* Four sarxoglycans expressed in muscle arc associated with different forms of autosomal recessive LGMD 2. LGMD 2C, 2D, 2E, and 2F are caused by mutations in the genes for ^-sarcoglycan, a-sarcoglycan, ^-sarcoglycan, and *8*-sarcoglycan, respectively. The gene for a-sarcoglycan lies on chromosome 17, that for ^-sarcoglycan on chromosome 4, that for ^-sarcoglycan on chromosome 13, and that for 5-sarcoglycan on chromosome 5. The original cases of severe childhood autosomal recessive muscular dystrophy, although described as ff-sarcoglycan deficiency, were linked to chromosome 13, the locus of y-sarcoglycan rather than of-sarcoglycan. This illustrates one pitfall in the diagnostic testing for LGMD 2. The sarcoglycans are tightly knit, and when one is absent, the others may also be missing. This is particularly true of

or-sareoglycan, making it both useful and misleading as a screening tool. An absence of a-sarcoglycan is an indication to search for the abnormal gene associated with each sarcoglycanopathy.

Large population studies are not yet available, but surveys of muscle biopsies suggest that the sarcoglycanopathies account for more than 107o of patients with an LGMD syndrome and the presence of dystrophin (Duggan et al. 1997). Of these, a-sarcoglycanopathies account for *6%* of cases, ^-sarcoglycanopathies for 3%, *y-surco*-glycanopathies for 1%, and S-sarcoglycanopathics for less than 1%. However, in North Africa, sarcoglycan deficiencies are estimated to account for up to 50% of muscular dystrophies.

All sarcoglycanoparhies have the same features at onset: trunk and limb weakness, a serum CK concentration of 1000 lU/liter and higher, and calf hypertrophy. Facial strength is good, and cardiac findings are not prominent, A deficiency of y-sarcoglycan best mimics DMD in seventy of weakness and progressive loss of ambulation, *a*-Sarcoglycan and ^-sarcoglycan deficiencies are variable and may be severe or mild (Dincer et al. 1997). In some, the onset of weakness is delayed until adult life, and patients are able to function without severe disability, despite proximal weakness. Although the sarcoglycanopathies may resemble dystrophin deficiency, there is not enough information about corticosteroid treatment to make a specific recommendation for treatment.

LGMD *2G (Teletbonin Deficiency).* This rare form of muscular dystrophy may be associated with either proximal or distal weakness (Morcira et al. 1997), Mean age of onset is 12.5 years. Legs are affected more than arms, and the quadriceps and anterior tibial muscles show significant weakness. Serum CK concentrations are elevated to 3-17 times normal. Muscle histological preparations demonstrate dystrophic features, and rimmed vacuoles within muscle fibers are often seen.

LGMD 2G has been linked to mutations in the gene encoding for telethonin on chromosome 17ql 1-12. Telethonin is abundant at the sarcomere where it may interact with the large sarcomeric proteins titin and myosin. Abnormal telethonin may disrupt normal myofibrillogenesis.

IXiMD Hi. This disorder has been reported in several families of Manitoba Hutterite origin (Weiler et al. 1998). The age of onset is 8-27 years, and ambulation is not lost until the fourth decade. Serum CK concentrations range from 250 to more than 3000 lU/liter. The EMG shows a myopathic pattern. The genetic defect is believed to be a mutation in the gene that encodes for E3-ubiquitin ligase (also known as *TRIM32)* located on chromosome 9q31-' q33 (Frosk et al. 2002).

LGMD 21. This rare LGMD was initially described in a large consanguineous Tunisian family (Dris et al. 2000). Subsequently, the clinical, laboratory, and genetic features of 17 affected kinships have been reported (Brockington et al. 2002). Phcnotypic variation is considerable. The age of onset ranges from birth to the fourth decade. The clinical course can be similar to that of a CMD or mild BMD. Severe cardiomyopathy may develop. Scrum CK concentrations are elevated to 10-30 times normal in children but may be normal in adults.

The LGMD 21 gene was linked to chromosome 19ql3.3, where mutations in the gene that encodes for FKRP were identified (Brockington et al. 2002). Mutations in this gene were also found in some patients with CMD with normal mcrosin (CMD type 1C). FKRP is a glycosy I transferase, and its deficiency is associated with abnormal glycosylation of a-dystroglycan.

Congenital Muscular Dystrophies. The CMDs are a group of disorders that usually present at birth as severe hypotonia and weakness of the trunk and limbs. All are inherited as autosomal recessive traits and produce some degree of central nervous system (CNS) dysfunction. Contractures of the joints are prominent, particularly at the ankles, knees, and hips. Mental retardation may be present, and, in many infants, a magnetic resonance imaging (MR!) scan shows a striking increase in the T2-weigh ted signal in the cerebral white matter. Several forms of CMD have been characterized clinically and genetically. The besr characterized forms are classic or occidental CMD, Fukuyama type congenital muscular dystrophy (FGMD), Walker-Warburg syndrome, and muscle-eye-brain disease of Santa vuori. The classic form of CMD (CMD type!) is the most common type of CMD in the Western Hemisphere. It is genetically heterogeneous. Approximately one half of occurrences of CMD type 1 are associated with deficiency of merosin or »$_2$⁻kiminin. Other forms of CMD type 1 with normal or secondary deficiency of merosin have been linked to mutations in intcgrin and FKRP.

Laminin a_2 (Merosin} Deficiency. Laminin a_2 is one of a large family of glycosylated proteins located in the basement membrane. Laminin is composed of three dissimilar chains: «2, j9i, and y_t. The amino termini separate to form a crosslike structure and the other end of the molecule attaches to the dystroglycan complex. In the human, laminin *a*^ is coded by a gene on chromosome *6.* Laminin «i is found in muscle as well as skin and peripheral nerves.

The essential features of merosinopathy are severe weakness of the trunk and limbs and hypotonia at birth. The extraocular and facial muscles are usually spared. Contractures of the feet and hips are prominent. Intelligence is often normal, and the incidence of epilepsy is 12-20%. MRI of the brain often reveals increased signal in the white matter on T2-wcighted images. White matter abnormalities may also be seen on computed tomography (CT) scans of the brain. For the most part, affected children are severely disabled, and many arc dependent for life.

Milder forms have a delayed onset and produce milder weakness (Tan et al. 1997). Absence of the protein causes a severe myopathy, but symptoms arc less severe in patients

with partial deficiencies, similar to the situation for dystrophin deficiency. The diagnosis relies on showing alterations of muscle merosin. Antibodies to merosin are commercially available, but some antibodies fail to show the abnormality if part of the laminin a_2 chain is present. The use of at least two different antibodies is advantageous. Skin biopsy can be used for diagnosis because merosin is expressed in the skin. The final diagnosis relies on DNA testing of the gene because merosin may be reduced secondarily in other myopathies with membrane instability.

Merosin is absent in one half of patients with classic CMD. Serum CK concentrations are elevated as in all diseases with muscle membrane instability. The EMG shows myopathic changes and slowed nerve conduction velocities, the latter arising from abnormalities in laminin *ai* expression in the peripheral nerve.

Other Forms of Classic CMD Type 1. Some children with phenotypes identical to that of CMD type 1 have no abnormality in the laminin *ai* gene (Figure 85.13). Muscle symptoms are milder, and sufficient function may be regained with time to support independent walking. These myopathies progress more slowly than merosin-negativc CMD, and many patients survive to adult life.

FIGURE 85.13 Congenital muscular dystrophy (classic type). This hoy also had weakness and contractures of the limbs. His illness was relatively static.

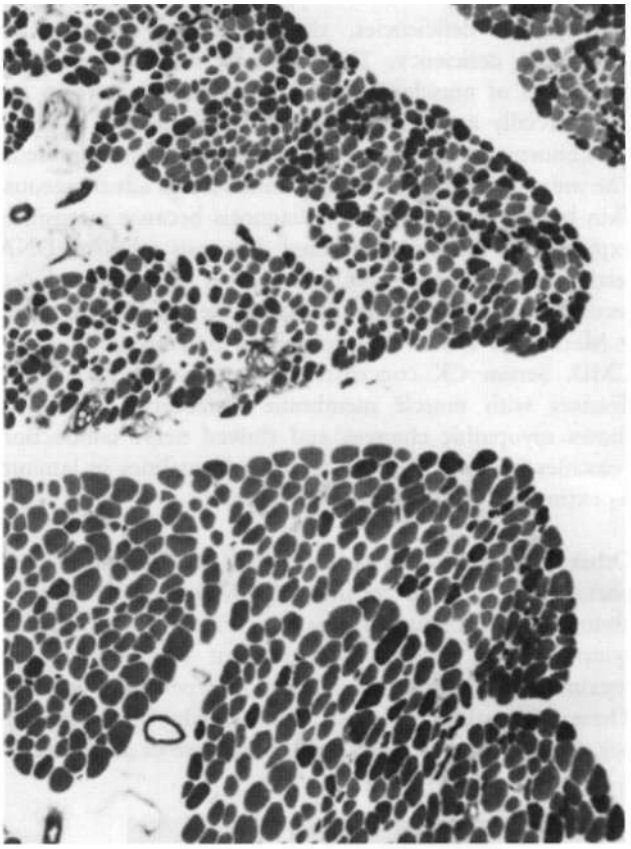
CMD type IB has been linked to mutations in the gene that encodes for the *a-7* subunit of a-7/*lD mtegrin. Integrin is a sarcolemmal protein that binds to merosin and is probably important for the structural integrity of the muscle membrane. CMD type IC with normal merosin is reported in patients with mutations in FKRP (Brockington et al. 2002). Mutations that involve this protein are described in LGMD 21. A range of severity of disease is associated with FKRP-associatcd myopathies as with the dystrophinopathies, sarcoglycanopathies, and mcrosinop-athies. FKRP is thought to play a role in glycosylation of other proteins, a-Dystroglycan, which binds merosin, is normally heavily glycosylated. FKRP mutations impair the normal glycosylation of tf-dystroglycan, which may result in instability of the muscle membrane.

Fukuyama Type Congenital Muscular Dystrophy. FCMD, like other CMDs, is inherited as an autosomal recessive disease. The myopathy is linked to mutations in the gene that encodes for fukutin i oca ted on chromosome 9q3T33. Secondary loss of laminin ot_2 and a-dystroglycan may be seen. Fukutin is an enzyme associated with the Golgi complex and is thought to participate in the glycosylation of other proteins. a-Dystroglyean is heavily glycosylated and a mutation in fukutin probably results in abnormal glycosyla-tion of ar-dystroglycan (and perhaps other important proteins), thereby altering the normal three-dimensional structure of the protein and the integrity of the glycoprotein-dystrophin complex. This complex is also expressed in the CNS and probably accounts for the CNS manifestations associated with FCMD.

Affected newborns usually have normal strength. Some are floppy, and joint contractures of the hip, knee, and ankles are present in 70% by 3 months of age. Mental retardation is often so severe that speech never develops. Convulsions, either major motor seizures or staring spells, are common (Figure 85.14). A curious finding noted on clinical examination is asymmetry of the skull. "Weakness is diffuse, sometimes involving the face and neck, and is often disabling, so that the child never walks. Affected children are completely dependent and never attain any degree of un-supervised activity. The muscle disease is moderately or slowly progressive, and survival into early adult life is common.

The serum CK concentration is usually markedly elevated. Muscle histological preparations show dystrophic changes, with variability in the si/.e of fibers and fibrosis. Internal nuclei are common, and there is diminished immunostaining with or-dystroglycan antibodies, which easily distinguishes this disorder from any of the congenital nonprogressive myopathies. As with other congenital dystrophies, muscle histological preparations may show features suggestive of neurogenic atrophy, with the fiber size changes being nonrandom and some fascicles contain-ing much smaller fibers than others. However, this nonrandom change differs from denervation atrophy, in

FIGURE 85.14 Fukuyama type congenital muscular dystrophy. This girl was severely retarded, had many seizures, and demonstrated marked contractures of the limbs. She was too weak to support her own weight. The disease was nonprogressive. Her two hrothers also had the same illness,



FIGURF. 85.15 A biopsy from a patient with Fukuyama type congenital muscular dystrophy. In addition to the variability in fiber size and the type 1 fiber predominance with fibrosis, notice the nonrandom distribution of atrophy. The fascicle in the lower part of the picture contains larger fibers than that in the upper part, (Myosin adenosine triphosphatase stain, pll 9.4.)

which there is a random variability in fiber size within individual fascicles {Figure 85,15).

'I l,i.- IMOM sinking brain change vrii mi MRI and til' scans is the presence of white matter abnormalities, particularly in the frontal area (Figure 85.16). This change seldom extends to the genu of the corpus callosum and the medial subependymal regions along the trigones and occipital horns are spared. With time, the abnormalities disappear in sequence from the occipital to the frontal region in a fashion resembling the progression of normal myelination. Occasionally, marked pallor of the myelin in the centrum semiovale is noted, together with mild gliosis or edema. At postmortem examination, several malformations of gyral formation are found, such as agyria, pachygyria, and microgyria. The cortex may have a cobblestone appearance. Lamination of the gray matter is absent. Other associated malformations are heterotopia in the brainstem and basal meninges, cerebellar micropolygyria, ventricular dilatation, enlarged cortical sulci, and aqueductal stenosis.

Walker-Warburg Syndrome and Muscle-Eye-Brain Disease. Walker-Warburg syndrome and muscle-cye-brain disease are characterized by the combination of muscular dystrophy, lisencephaly, cerebellar malformations, and severe retinal and eye malformations. Both disorders are more severe than FCMD. Walker-Warburg syndrome is a catastrophic disease, with death occurring within the first 2 years of life. The eye changes are more severe in Walker-Warburg syndrome than in muscle-eye-brain disease. Characteristic findings are microphthalmia, colobomas, congenital cataracts and glaucoma, corneal opacities, retinal dysplasia and nonattachment, hypoplastic vitreous, and optic atrophy. In muscle-cye-brain disease, high myopia and possibly a preretinal membrane or gliosis occurs, but severe structural eye abnormalities are not seen.

The CNS findings are different, and MRI is a useful technique to separate the two entities (van der Knaap et al. 1997). MRI scans in Walker-Warburg syndrome show various combinations of hydrocephalus, aqueductal stenosis, cerebellar and pontine hypoplasia with a small posterior vermis, Dandy-Walker malformations, and agyric or pachygyric cobblestone cortex. Tl-weighted images show a diffuse decreased white matter signal; T2-weightcd images show myelination defects. In muscle-eye-brain disease, the cortical changes are milder and the white matter changes more focal.

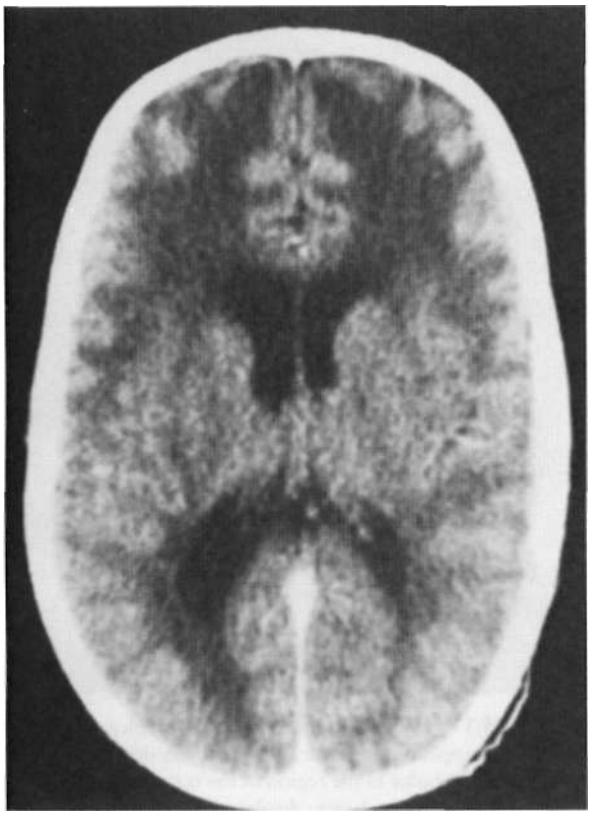


FIGURE 85.16 Computed tomographic scan of the head of a patient with Fukuyama type congenital muscular dystrophy demonstrating lucencies in the white matter, particularly toward the frontal poles.

It is not certain if Walker-Warburg syndrome and FCMD are genetically distinct. Both were linked to chromosome 9q31-q33 in one kinship. Muscle-eye-brain disease is caused by mutations in the gene that encodes for O-mannose jS-l,2-N-acctylglucosaminyl transferase located on chromosome lp3.

Other Congenital Muscular Dystrophies

Ullrich's Congenital Muscular Dystrophy. Ullrich's CMD (also known as atonic-sclerotic dystrophy) is associated with neonatal weakness, multiple contractures, and distal hyperlaxity. Marked protrusion of the calcanei in the feet is seen in affected children. The clinical course is static or slowly progressive. Serum CK concentrations are normal to slightly elevated. Mutations in subumts of collagen type VI have been reported, suggesting that this condition is allelic to Bethlem myopathy (Camacho Vanegas et al. 2001).

Congenital Muscular Dystrophy with Rigid Spine Syndrome. Infantile hypotonia and weakness are the initial symptoms. Motor milestones are delayed. Mobility cil the spine is reduced, and many children develop scoliosis and contractures at the knees and elbows,

Serum CK concentrations are normal or moderately elevated. Muscle histological preparations show type 1 predominance, increased internal nuclei, and nonspecific myopathic features. In some kinships, the myopathy is linked to mutations in the selenoprotein N1 gene located on chromosome lp3 (Moghadaszadeh et al. 2001). Other myopathic disorders, such as F.DMD, may be associated with the rigid spine syndrome.

Other Regional Forms of Muscular Dystrophies

X-Linked Emery-Dreifuss Dystrophy (Emerin Deficiency). The most common form of EDMD is inherited as an X-linked recessive disease. **The gene *(STA)* is** located at Xq2S and encodes for emerin. Emerin localizes to the inner nuclear membrane from which it projects into the nucleoplasm (Manilal et al. 1996). Emerin belongs to a family of lamin-associatcd structural proteins that are important in the organizing of the nuclear membrane and its attachment to hetcrochromatin.

EDMD is characterized by wasting and weakness of the upper arms, shoulders, and anterior compartment muscles of the legs. Contractures of the elbows, the posterior neck, the pataspinal muscles, and the Achilles tendon occur early in its course. Severe elbow contractures occur during childhood. F.DMD is slowly progressive. The weakness spreads to involve other muscles, especially the hip. Cardiac complications are common. Conduction block caused by atrial paralysis results in sudden, unexpected death. The atria become electrically inexcitable, and the heart responds only to ventricular pacing. Ventricular myocardial disease with ventricular failure also occurs. Sudden death may occur in female carriers because they develop the cardiac abnormalities at a later age. The severity of cardiopathy in men and women increases with age.

The clinical picture of EDMD is distinctive, and the diagnosis can be confirmed by DNA studies. The diagnosis may also be made from a skin biopsy if emerin is absent from nuclei in the skin. Results of muscle biopsy and electro-myography simply confirm that the disease is myopathic. The CK concentrations may be elevated. An ECG should he obtained annually for every patient with EDMD. An ECG is recommended for family members at risk because of the possibility of isolated cardiac involvement.

Analysis and treatment of the cardiac problems are the most pertinent aspects of therapy. Most patients with EDMD need a cardiac pacemaker at a relatively early age, and some need treatment for congestive cardiac failure due to ventricular failure. Because the atrial block is sudden, unpredictable, and fatal, early use of a pacemaker is recommended. The pacemaker does not retard the devel-opment of **the** cardiomyopathy and only protects against the complications of conduction block. Female carriers should be screened with an ECG beginning at 35 years of age.

Facioscapulohumeral Dystrophy. FSHD is inherited as an autosomal dominant trait. Its prevalence is 1-2 per 100,000 population. The responsible gene has been localized to chromosome 4q35 in many, but not all, families. The genetic abnormality is a deletion in a 3.3-kb repeating sequence. Digestion with the endonuclcase £coRI produces a fragment that is shorter than 34 kb in most families with FSHD compared with a length of more than 40 kb in normal individuals. In the past, the results were clouded by the existence of an identical sequence, unrelated to the disease, on chromosome 10. The problem has since been resolved, and DNA testing is reliable (Upadhyaya et al. 1997), although a few patients with the same phenotype show no abnormality in the chromosome 4q sequence. The severity of the illness bears a relationship to the size of the deletion: the largest deletions tend to be associated with severe illness. The phenomenon of *anticipation,* in which age at onset is younger and severity of illness is more severe with successive generations, occurs in FSHD. This suggests a dynamic mutation as in myotonic dystrophy. A puzzling feature of the abnormal chromosome 4q region is that it docs not seem to contain any actual genes. This suggests that the responsible gene is slightly removed from the deleted area but that it is influenced by the changes in its neighboring environment *(position effect variegation)* (Fisher and Upadhyaya 1997).

The severity of FSHD varies even within the same family. Some patients may have only mild facial weakness whereas others have total paralysis of the face and severe weakness of other muscles causing wheelchair confinement during childhood. The most common time of presentation is during adolescence. Facial weakness is expressed as difficulty in blowing up balloons or drinking through a straw. Affected children may sleep with the sclera of the eyes showing through partially opened lids. Facial expression is relatively preserved, but the smile is often flattened and transverse, as opposed to the usual upward curve. When the patient attempts to whistle, the lips move awkwardly and have a peculiar pucker (Figure 85.17). The mouth also may have a pouting quality, the so-called *boucbe de tapir.*

Weakness of the shoulder muscles affects scapular fixation. When the arms are outstretched in front, the scapulae jut backward (winging), with the inferomedial corner pointing backward. Deltoid muscle strength is well preserved even late in the disease course, and the distal part of the muscle is often pseudohypertrophic. The biceps and triceps muscles arc often weak. The forearm muscles are less involved (leading to a Popeye appearance), although a discrepancy between the stronger wrist flexors and weaker wrist extensors is often used to support the diagnosis. The muscles of the legs are involved in FSHD. Weakness of the hip flexor muscles and of the quadriceps is common, and the ankle dorsiflexors are often weak, whereas strength is preserved in the plantar flexors. The ankle dorsiflexors arc-often involved early and footdrop may be the presenting

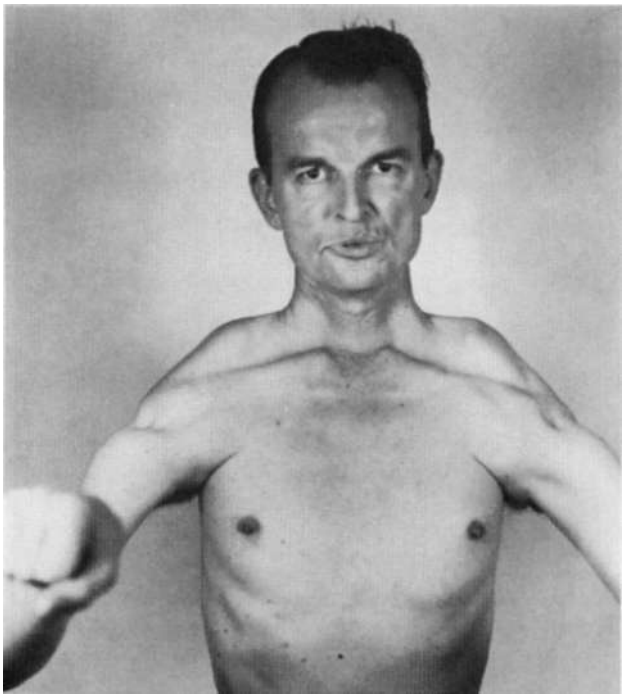

FIGURE 85.17 Facioscapulohumeral dystrophy. Notice the characteristic appearance of the shoulders, the downward-sloping clavicles, and the bulge in the region of the trapezius muscle, which is due to the scapula being displaced upward on attempted elevation of the arms. The patient also is attempting to purse his lips.

feature, blending FSHD with the scapuloperoneal syndromes. Asymmetry of weakness is common, often leading the inexperienced clinician to doubt the diagnosis of muscular dystrophy and to consider a peripheral nerve lesion, such as a lesion of the long thoracic nerve of Bell.

The most severe form of FSHD occurs in infancy. Such babies have severe weakness. The face has no move men I and remains passive and expressionless. Weakness of the limbs, although it conforms to the general pattern of FSHD, is so severe that the ability to walk is lost by 9 or 10 years of age. A striking feature is the extreme lumbosacral lordosis seen when the child walks or stands. This initially disappears on sitting, indicating that a compensatory mechanism :•, u.scJ to maintain balance. Deafness and Coats' disease, an oxidative vascular degeneration of the retina, arc associated abnormalities.

The diagnosis can be established reliably by DNA studies. The serum CK concentration is elevated, muscle histological preparations shows myopathic features, sometimes with scattered inflammatory foci (Figure 85.18). The EMG shows myopathic potentials (see Chapter 36R).

The treatment of FSHD is supportive. Scapular stabilization may be beneficial if the arms cannot be raised above the head (Twyman et al. 1996). This is especially true when deltoid function is preserved, and the patient is ambulatory. Because of the general severity of their weakness, wheelchair-confined patients do not find the problems in

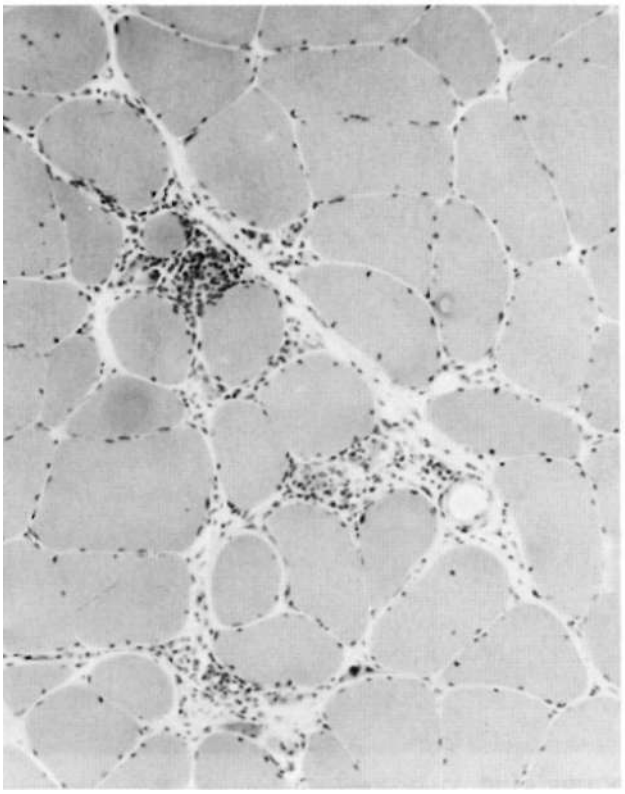

FIGURE 85.18 Facioscapulohumeral dystrophy. Cellular inflammatory responses are rioted in the biopsies from many patients with this illness. These are more often associated with necrotic fibers than with blood vessels. (Hemaroxylin-eosin stain,)

shoulder movements to be out of proportion to the rest of the muscular weakness. Such patients find a forearm orthosis or ball-bearing feeder device to be useful. An ankle-foot orthosis may be helpful for ambulatory patients with a footdrop. Surgical transposition of the posterior tibial tendon to the dorsum of the foot is useful in patients who have a marked intorsion of the foot when walking. The posterior tibial muscle remains relatively unaffected until very late in the illness. The posterior tibial tendon, in addition to its action of inversion, also dorsiflcxcs the foot. If the anterior tibial group is severely weak, overactivity of the posterior tibial muscle may be seen in an attempt to dorsiflex the foot and allow the toes to clear the ground. This causes marked inversion of the foot while walking and may lead to callus formation on the outer border of the foot. It also may make *in* ankle-foot orthosis impossible to use. Surgical transposition of the posterior tibial tendon to the dorsum of the foot can be an effective reconstructive procedure, which may prolong walking. Prednisone has been tried in some patients, but the results arc generally not beneficial, unless there is significant inflammation in the muscle biopsy.

Scapuloperoneal Syndromes. Weakness of the muscles of the shoulder and of the anterior compartment of the lower leg arc early symptoms of several diseases. Some forms of scapuloperoneal dystrophy are related to FSHD, but others have no linkage to the FSHD site on chromosome 4q35. Further studies are needed in a larger population of patients with this symptom complex. As in FSHD, in the scapuloperoneal syndrome a discrepancy between the weak ankle dorsiflexors and the strong plantar flexors is seen. However, facial weakness is only minor. Results of histopathological studies, electromyography, and other laboratory tests are identical to those seen in FSHD in some patients (Milanov and Ishpekova 1997). Scapulo-peroneal muscular dystrophy may be inherited as an autosomal dominant trait, although an X-linked recessive pattern also has been described. The importance of investigating this syndrome is that some congenital non-progressive diseases, such as ncmaline myopathy, may present with a scapuloperoneal distribution of weakness. It is therefore important to confirm the diagnosis with the appropriate tests in any patient with a scapuloperoneal syndrome. The only useful treatment is the application of ankle-foot orthoses, which may improve the patient's function by correcting the footdrop.

Oculopharyngeal Muscular Dystrophy. Oculopharyngeal muscular dystrophy (OPMD) is worldwide in distribution, hut prevalence rates are higher in Quebec, Uruguay, Germany, and the Spanish-American populations of Colorado, New Mexico, and Arizona. Isolated occurrences in families are described throughout the rest of the world. It is inherited as an autosomal dominant trait with almost complete penetrance. The genetic abnormality is mutations in the gene encoding for poly (A) binding protein 2 (PAR2) located on chromosome 14ql 1.2-13 (Brais et al. 1998). PAB2 is a nuclear protein involved in messenger RNA polyadenylation. The mechanisms by which mutations in this gene cause OPMD have not been established.

OPMD usually begins in the fifth or sixth decade, but onset can be in the foutth decade. Eye muscle weakness and ptosis are the initial features. The ptosis may initially be asymmetrical, but eventually both lids become severely ptotic, and all eye movements arc diminished (Figure 85.19), The severity of extraocular palsies is varied, but ptosis is a constant feature. Difficulty with swallowing occurs concomitant with or shortly after the development of ocular symptoms. At first, saliva pools in the pharynx, but swallowing eventually becomes impossible. Facial weakness is common, and proximal limb weakness is common in the late stages. Death may occur from starvation, but the terminal event is often pneumonia initiated by aspiration of secretions. Although symptoms may be severe, long-term survival is expected when nutritional status is maintained.

Initial laboratory tests should be used to exclude othet causes of ocular weakness such as myasthenia gravis (see Chapter 82). The definitive diagnosis relies on DNA testing of the genetic abnormality. Muscle biopsy reveals a random

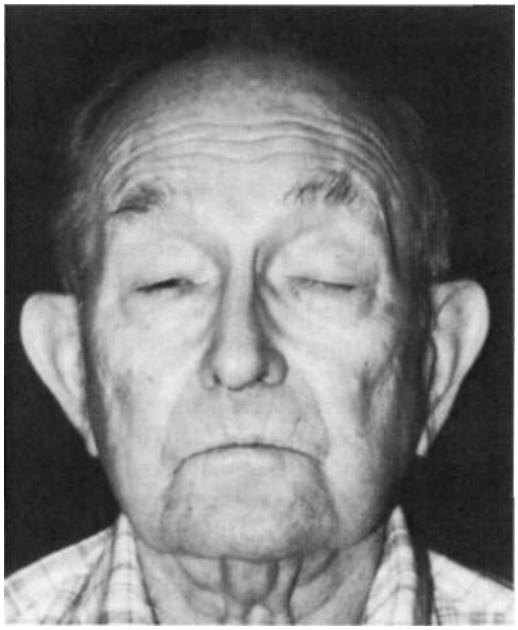

FIGURE 85.19 Oculopharyngeal dystrophy. The facial appearance of a patient who has ptosis and paralyzed eye movements.

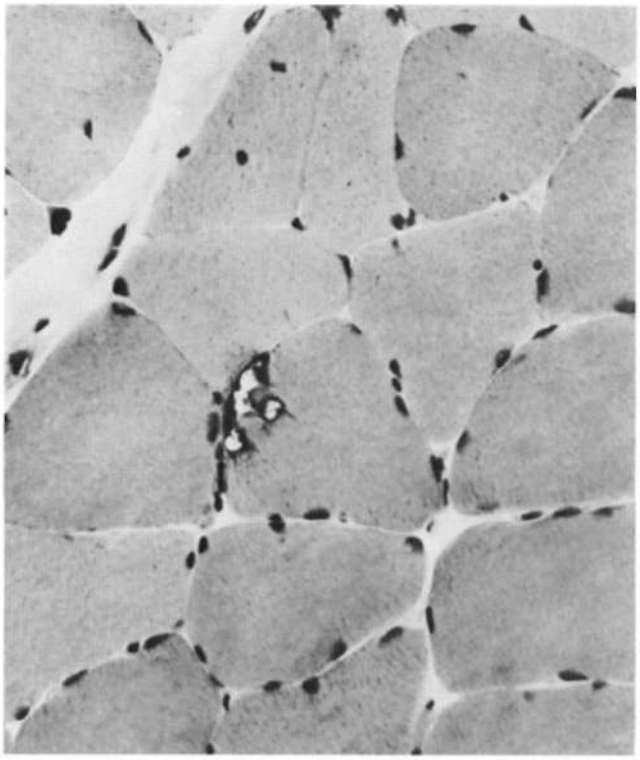

FIGURE 85.20 Oculopharyngeal dystrophy. Rimmed vacuoles are commonly seen in this illness. (Hematoxylin-eosin stain.)

variation in the size of the fibers, necrotic fibers, some fibrosis, and occasional internal nuclei. In addition, autophagic vacuoles (rimmed vacuoles) and intranuclear fibrillary inclusion bodies arc noted (Figure 85.20), which are features common to OCPD, inclusion body myositis, and several hereditary distal myopathies/dystrophies.

The presence of small (8-10 nm) intranuclear tubulofilamerits that appear as palisading filamentous inclusions is a hallmark of OCPD. The filaments are unbranched and may be stacked side by side or may occur in tangles. In addition, abnormal mitochondria and nemaline rods are seen in pharyngeal muscles.

Treatment is supportive. Dysphagia is first treated by a soft diet; the next step is pureed foods, and eventually a gastrostomy is needed. Surgical correction of ptosis is often successful.

Distal Muscular Dystrophies/Distal Myopathies

Several muscle dystrophies have a predominant distal pattern of weakness (Sapcrstein ct al. 2001), Such myopathies are often misdiagnosed as hereditary or acquired neuropalilies in evrr .is motor :u-.iron disease. Mild elevations in the serum CK concentration can be seen in rapidly progressive neuropathic disorders, but concentrations greater than .S00 IU/L should suggest a myopathic process. However, the serum CK concentration may be normal in some distal myopathics and cannot be used to exclude a myopathy. An EMG is useful in distinguishing a distal myopathy from a neutopathic disorder, and repetitive nerve stimulation can be used to exclude rare instances of distal weakness from myasthenia gravis. Other myopathic disorders with a distal pattern of weakness include myotonic dystrophy type *1*, inclusion body myositis, and certain forms of congenital myopathy {e.g., myofibrillar myopathy). The age at onset, inheritance pattern, histopathological features, and pattern of weakness are most useful in distinguishing the distal myopathies from each other.

Treatment of distal myopathy is largely symptomatic. A cock-up splint helps preserve hand function when wrist-drop is present, and an ankle-foot orthosis is used to correct footdrop.

Miyoshi's Myopathy. This disorder was first described in Japan but affects many ethnic groups. The disease has been linked to mutations in the gene encoding the sarcotemmal protein, dysferlin, located on chromosome 2pl2-14, The same gene is responsible for LGMD 2B. Both phenotypes may exist in the same family. Some members have a distal myopathy, usually affecting the gastrocnemius muscle but sometimes predominantly involving the anterior compartment of the leg, and others have a proximal myopathy. Muscle histological preparations show dystrophic changes without autophagic vacuoles.

Welandcr's Myopathy. Welander's myopathy was initially described in Scandinavia, where it is relatively common. It is inherited as an autosomal dominant trait. The initial symptoms begin between 40 and 60 years of age. Weakness begins in the hands and later causes footdrop.

The distal distribution suggests a neuropathy, but laboratory tests show little evidence of denervation, which favors i myopathy. Careful evaluation may show mild distal hypesthesia and temperature sensation loss associated with some loss of small myelinated fibers. Muscle histological preparations show myopathic features and the rimmed vacuoles that are charactetistic of other distal myopathies. The serum CK concentration is normal or slightly elevated.

Markesbery-Griggs-Udd Myopathy. Markesbery-Griggs-Udd myopathy is transmitted as an autosomal dominant trait. The disorder has been linked to mutations in the gene that encodes for titin on chromosome 2q31-33 (Hackman et al, 2002). Titin is a giant sarcomeric protein that serves as a ligand for calpain-3. Mutations in titin are also associated with a dilated cardiomyopathy.

The myopathy is characterized by footdrop due to weakness in the anterior tibial muscles. Onset is typically after 35 years of age. Eventually, wristdrop and fingerdrop develop because of extensor compartment weakness of the forearms. Proximal limb muscles are rarely involved. The serum CK concentration is normal or slightly elevated. Milsck- histology demonstrates myopathic features and rimmed vacuoles.

Nonaka's Myopathy, Autosomal Recessive Hereditary Inclusion Body Myopathy. This early adult-onset distal myopathy was first described in Japan. Similar patients were described as having an autosomal recessive hereditary inclusion body myopathy (IBM) (Sivakumar et al, 1996). The clinical phenotype is similar to that of Markeshery-Griggs-Udd myopathy. Weakness initially involves the anterior tibial muscles in the legs and extensor muscles of the forearm. It is inherited as an autosomal recessive trait, and the onset is before 30 years of age. Muscle histological preparations show rimmed vacuoles as in Markesbery-Griggs-Udd myopathy and Welander's myopathy. Electron microscopy reveals 15- to 18nm tubular filaments typical of inclusion body myositis. However, unlike *inclusion body myositis,* a significant inflammatory process is not seen. Kinships with Nonaka's myopathy and those with autosomal tecessive inclusion body myopathy were subsequently shown to be allelic.

Heteditary IBM may be heterogeneous. The form of quadriceps-sparing myopathy first described in Iranian Jews (Argov et al. 1997) and now recognized in many other genetic backgrounds is due to a mutation in the gene encoding for UDP-N-acctylglueosamine 2-epimerase/N-acetylmannosamine kinase on chromosome 9pl-ql (Eisenberg et al. 2001).

Laing's Distal Myopathy. A distinct autosomal dominant distal myopathy is characterized by weakness of the anterior tibial muscle groups and the neck flexors (I.aing et al. 1995). Onset is in childhood or early adult life. Scrum CK concentrations are normal or slightly elevated and the EMG shows a myopathic pattern. Unlike Markesbcry-Gnggs-Udd myopathy and Nonaka's myopa thy/hereditary IBM, muscle histological examination does not reveal rimmed vacuoles. The exact gene has not been identified, but linkage studies indicate that the gene is located on chromosome 14ql I.

Myotonic Dystrophies

Myotonic Dystrophy Type 1

Myotonic dystrophy type 1 (DM 1) is characterized by muscle wasting and weakness, myotonia, and multisystem abnormalities. It is inherited as an autosomal dominant trait. The incidence is 1 per 8000 live births The disorder is caused by mutations in ijir y.uu that ..nioiKs In: myotonic dystrophy protein kinase (DMPK) located on chromosome I9q13.3. The mutation occurs in an untranslated region of the gene. This region normally contains 5-30 repeating sequences of three nucleotides (CTG trinucleotide repeats). In DM 1, there are up to several thousand CTG repeats.

The size of the expansion correlates with severity of disease. Newborns with severe congenital myotonic dystrophy have very large expansions (>750 repeats). Mothers with more than 100 repeats are at greater risk of having a child with the severe infantile form than are mothers with a smaller expansion. Anticipation is explained by the tendency of the triplet repeat expansion to gtow with each mciosis in the female. The reverse is sometimes true of patients with paternally inherited disease, when the expansion may be reduced and the clinical state may return to normal or be very mild. Variation in the degree of gene expansion among different tissues of the body further complicates genotype-phenotype correlation.

The gene product is ubiquitously expressed in muscle and other tissues, such as the lens in the eye. Different studies have localized DMPK to the neuromuscular junction and myotendinous junction, the sarcolemma, and the perinuclear region. In experimental animals, DMPK affects the voltage-gated sodium channels in skeletal but not cardiac muscle, thereby decreasing the peak sodium current. Other experiments indicated a higher intracellular calcium concentration in cells with a flux abnormality in the l.-type calcium channel. However, the expansion is not in the coding region of the gene, and other experiments with knockout mice or with mice that overexpress the protein show no marked abnormality in muscle or in other systems. This has suggested that the mutation alters the expression of adjacent genes (Thornton et al. 1997). Studies have shown that the transcribed DMPK mRNA is directly toxic and causes abnotmal splicing of mRNA transcripts, including those of the muscle chloride ion channel (Mankodi et al. 2002), dysfunction of which is probably responsible for the myotonia.

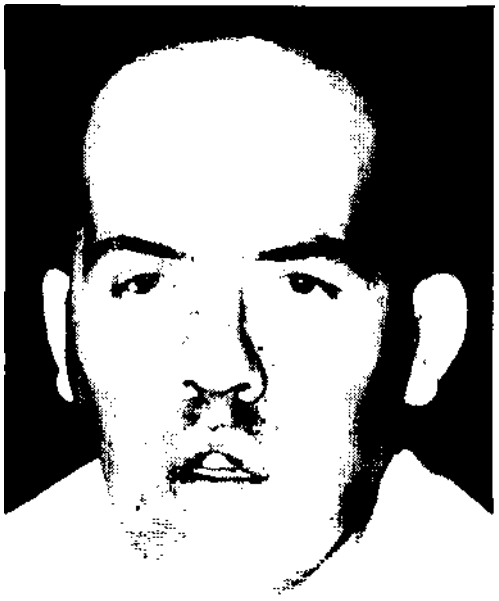

FIGURE 85.21 Myotonic dystrophy type 1, The facial appearance includes ptosis, hollowing of die masseter and temple?„ and facial weakness.

Once considered, DM 1 is readily diagnosed. However, the diagnosis is often missed because patients often present with what appears to be an unrelated problem. Patients may be referred for evaluation of mental retardation, present in the emergency room with fractures, or appear on the ward because they did not recuperate after cholecystectomy. The severity of DM 1 ranges from no symptoms, early cataracts, or mild weakness in some adults to profound mental retardation and severe weakness in children,

The more typical picture is hand weakness and often footdrop beginning in early adolescence. DM 1 is one of the forms of dystrophy that affects distal muscles more severely than proximal muscles. The sternocleidomastoid muscles are often atrophic and poorly defined. A rather long face with a mournful expression is accentuated by hollowing of the temples due to masscter and temporalis atrophy. In fully developed disease, the eyes are hooded due to ptosis, and the mouth is slack and often tented (Figure 85.21). Weakness is not limited to distal muscles; shoulder, hip, and leg weakness may be prominent

Repeated falls arc common in middle age. With time, weakness becomes sevete and myotonia may be lost. Absence of myotonia of the small muscles of the hand and pronounced myotonia of the deltoid or forearm muscles are common in advanced disease. The voice may be hollow and echoing, suggesting palatal weakness. Facial weakness makes consonants difficult to pronounce. Dysphagia is common but is usually a minor complaint. Recurrent dislocation of the jaw may occur, particularly when the mouth is widely opened, as in biting an apple.

Myotonia is demonstrated either by sharp percussion of the muscle with a reflex hammer or after firm voluntary contraction. Fither maneuver elicits a sustained, involuntary contraction of the muscle, which fades slowly over a matter of seconds. Percussion of the thenar eminence is a popular way of eliciting myotonia. It produces a sharp abduction of the thumb and a firm contraction of the thenar eminence, which gradually relaxes and allows the thumb to return to the resting position. Percussion myotonia is often easier to demonstrate by percussing the posterior muscles of the forearm. The normal response to forearm percussion is also a brisk contraction of the finger extensors or the wtist extensors, but the wrist or fingers then fall into the resting position without delay. In the patient with myotonia, the fingers extend sharply and subsequently drift downward toward the normal position. The wrist may remain extended for some seconds. Patients seldom complain spontaneously about myotonia except in cold climates. When questioned, they may admit to difficulty releasing a key after it has been firmly grasped or letting go of a hammer or vacuum cleaner, particularly in cold weather.

Cardiac disease is a well-known complication of DM 1. Advances in both molecular techniques and cardiological investigations have helped to provide a better understanding of the conduction disturbances and tachyarrhythmias that occur in more than one half of patients with advanced DM 1. They correlate in severity with both skeletal muscle disease and molecular defect in some studies. Clinical evidence of a generalized cardiomyopathy is unusual. Radionuclide .studies of cardiac function after relatively mild exercise may show outward ballooning of the ventricular wall and a deceased ventricular ejection fraction. The rate of progression varies widely between individuals. Sudden death can be caused by ventricular arrhythmias or by complete heart block and can occur at an early stage of disease. A familial tendency for cardiac complications exists. The histopathological examination shows fibrosis (primarily in the conducting system and sinoatrial node), myocyte hypertrophy, and fatty infiltration (Phillips and Harper 1997). Examination by electron microscopy shows prominent I-bands and myofibrillar degeneration. The role of other genes or the normal myotonic dystrophy allele in myotonic heart disease has not been determined. Myotonic dystrophy should be considered in patients who present with suspected arrhythmia or conduction block. Suggestions for management include an annual cardiac history and a 12-lead ECG with use of 24-hour Holtcr monitoring if necessary.

Excessive daytime somnolence is common (Damian et al. 2001). It may be mistaken for narcolepsy and is accompanied by a disturbed nighttime sleep pattern. The cause is an abnormal central ventilatory response, with an absence of the usual hyperpnea ptoduced by an increasing carbon dioxide concentration. This is associated with an abnormal sensitivity to barbiturates, morphine, and other drugs that depress the ventilatory drive. The risk of respiratory

complications Willi die use ui ;;ener.il ancsriclics is ahllnsl 10% (Marhieu et al. 1937). Anesthesiologists should be made aware of the possibility of complications with these drugs.

Several other organs are commonly involved in DM 1. Cataracts are almost universally seen by slit-lamp examination. Multihued specks (Christmas tree cataracts) are usually found in the anterior and posterior subcapsular zones. Disturbances of endocrine function involve the thyroid gland, pancreas, hypothalamus, and gonads. Testicular atrophy, with disappearance of the seminiferous tubules, leads to progressive infertility in males. Females may develop the tendency for habitual abortion and have menstrual irregularities. Although the incidence of clinical diabetes mellitus is probably not increased, abnormal results on glucose tolerance tests are common. The elevation of glucose concentrations late in the test is probably caused by an overproduction of insulin caused by an abnormal resistance of the insulin receptor. Involvement of smooth muscle accounts for cholecystitis and symptoms referable to gallbladder function, mild dysphagia, constipation, and urinary tract dysfunction.

DNA analysis is the definitive test for myotonic dystrophy. Genetic counseling should be offered to patients with clinical disease and all individuals at risk. Prenatal diagnosis is reliable and uses chorionic villus biopsies or cultured amniotic cells. A curious problem that makes genetic counseling less effective is that some people with advanced disease pay little attention to it. Denial of illness is distinctly different in patients with DM 1 compared with those with other muscle diseases. Many affected family members do not seem to know they have the illness despite being seen in the muscle clinic.

An EMG is useful and shows not only myopathic features but also myotonic discharges (see Chaptet 36B). The muscle histological preparations in fully developed disease are markedly abnormal (Figures 85.22 and 85.23). Fiber size is variable, and fibrosis is present. Internal nuclei and ringed fibers are abundant. These fibers are characterized by small bundles of myofibrils oriented at 90 degrees to the majority of fibers, rather like a thread wrapped around a stick. Other laboratory studies are less helpful. Scrum CK concentrations are often elevated. Some patients have low concentrations of immunoglobulin G. Abnormalities seen on brain MRI scans include cerebral atrophy, increased white matter signals on T2-weighted images, and thickening of the ctanial vault (Miaux et al. 1997). These seem to have little significance.

Supportive treatment includes the use of ankle-foot orthoses to treat footdrop. In theory, hand splints should increase hand function, but most patients prefer not to use

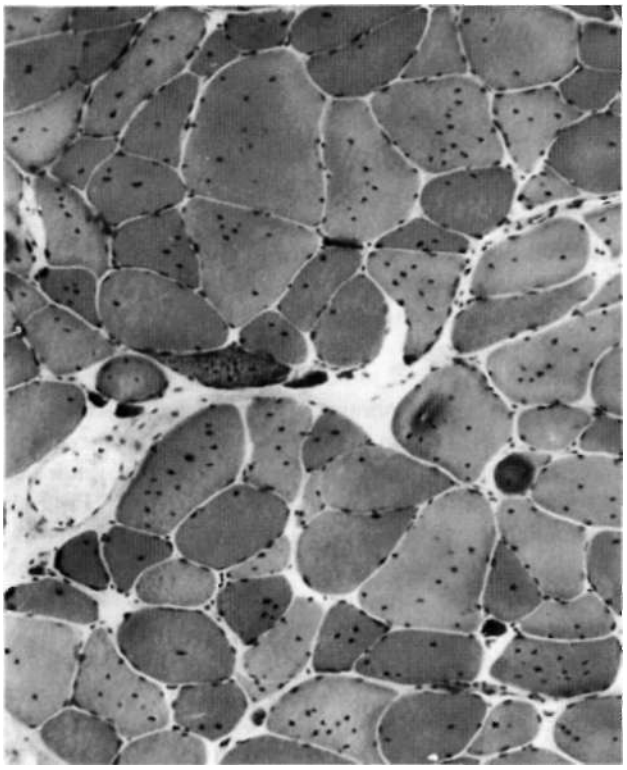

FIGURE 85.22 Myotonic dystrophy type 1. There are numerous internal nuclei, some scattered pyknotic nuclear clumps, and marked variability in the size of fibers. One ring fiber can he identified by its circular, dark-staining appearance. (Hematoxylin-eosin stain.)

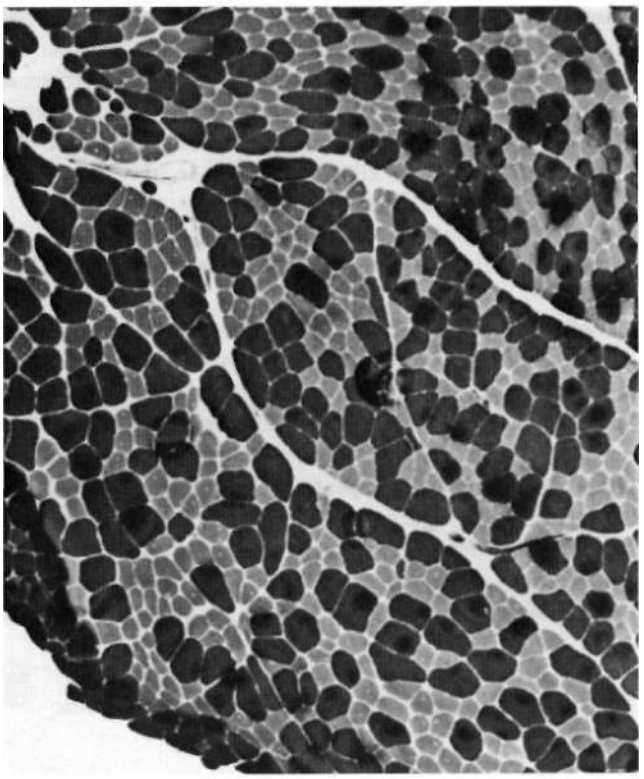

FIGURE 85.23 Myotonic dystrophy type 1. This myosin adenosine triphosphatase stain at pH 9.4 demonstrates that the majority of type I hhers are small. 1 vpe I fiber airopliy is noted in early disease and is obscured as the disease becomes more severe.

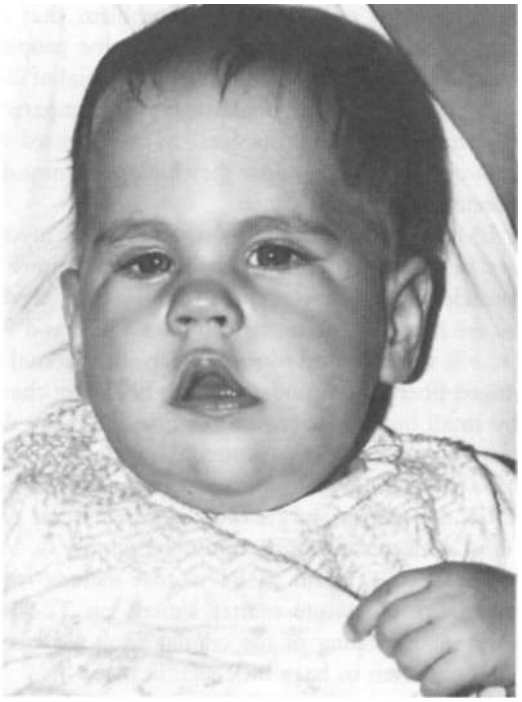

FIGURE 85.24 Infantile myotonic dystrophy. I'll is child is severely retarded and has a marked inverted-V mouth.

them. Breathing exercises and postural drainage can help ward off the respiratory infections often seen in advanced myotonia. Quinine, phenytoin, procainamide, mexiletine, acetazolamide, and even prednisone can be used to treat myotonia. However, most patients with DM 1 are bothered more by weakness than by myotonia and do not use the drugs. Modafinil at 200—400 mg per day improves hypersomnolence (Damian et al. 2001).

Congenita! Myotonic Dystrophy

Congenital myotonic dystrophy expresses itscl f in newborns of myotonic mothers. Extreme hypotonia, respiratory insufficiency, facial paralysis, failure to thrive, and feeding difficulty are the main features. Recurrent respiratory infections that develop into pneumonia are common. Other features are the appearance of the an inverted V or "shark mouth" (Figure 85.24), clubfeet, and severe mental retardation. Affected newborns have a large increase in the trinucleotide repeat region. This occurs with maternal transmission, particularly if the mother has a sizable expansion.

Myotonic Dystrophy Type 2 or Proximal Myotonic Myopathy

Whereas DM I has a predilection for the distal muscles, patients with proximal myotonic myopathy have greater stiffness, pain, and weakness in proximal than in distal muscles (Moxley 1996). Transmission is also by autosomal dominant inheritance. Cataracts are part of the phenotype but gonadal atrophy and cardiac conduction defects are much less common than in DM 1. Hyperinteusc areas on T2-weighted MRI scans in the cerebral white matter and progressive deafness have been reported.

The initial complaints—muscle stiffness and pain—usually begin in adult life. The stiffness is a sense of having a tight muscle that causes reluctance to move. It commonly affects the thighs and may be asymmetrical. Grip myotonia is noted, and the relaxation phase is jerky. The severity of myotonia may vary from day to day, and a "warm-up" phenomenon is noted in which the stiffness disappears after repeated contraction and telaxation. The pain is a sense of discomfort and varies from sharp to a deep visceral ache.

The prognosis is relatively good. Patients with proximal myotonic myopathy do not show the slow decline into helplessness and early cardiorespiratory death so often noted in patients with DM 1. An EMG shows myotonia, but this finding may require a careful search of several muscles. Muscle histological preparations shows features similar to those of DM 1. The serum CK concentration may be elevated.

The genetic defect has been localized to mutations in the gene that encodes for zinc finger 9 *{ZNF9)* on chromosome 3q21 (Liquori et al. 2001). The mutations are expanded CCTG repeats in intron 1. As with DM 1 the expanded repeat probably leads to the expression of a toxic pre-mRNA that impairs the splicing of other mRNA species, including those of ion channels,

Channelopathies (See Also Chapter 70)

The clinical disorders associated with abnormalities in ion channels range from myotonic syndromes to periodic paralyses (Kleopa and Barchi 2002). The classification of channelopathies has been revised based on molecular pathological changes. Ion channels control the passage of ions across cell membranes and shift ions between cell compartments. The ion channel proteins are cell membrane-associated and ate responsible for electrophysiological phenomena such as the muscle action potential. Electrical potentials across the cell membrane (voltage-gated) or ligands such as glutamate serve to open or close channels. The amino acid sequences in segments of ion channel proteins are conserved segments that arc remarkably similar across a wide range of species. It is logical to assume that the conserved segments are vital to normal function. Some mutations are presumably lethal; others produce intermittent symptoms (e.g., the periodic paralyses).

Ion Channels

The calcium channel in muscle is made up of five subunits: *a-1, a-1, f}, y,* and *S. a-* is the most important and forms

the ion pore across the membrane; The type of *a-1* subunit determines the sensitivity of the calcium channel. In muscle, the <*-] subunit is sensitive to dihydropyridines, such as nifedipine, and is called an I.-type channel because of its long open time. The subunit is formed from four similar transmembrane regions (domains D1-D4), each made up of six membrane spanning proteins (S1-S6) that are all linked in scries by "loops" that extend into the cytoplasm or extracellular space. S4 is rich in positively charged amino acids. It is highly charged and may confer voltage sensitivity to the channel. Calcium-channel abnormalities are associated with several neurological disorders, including hypokalemic periodic paralysis (Kleopa and Barchi 2002).

The calcium channel on the sarcoplasmic reticulum is the ryanodine receptor, which controls the flux of calcium from the sarcoplasmic reticulum into the cytoplasm. It plays an important role in the activation of the contractile mechanism, and malfunction causes malignant hyperthermia. Ryanodine receptors are made of four identical subunits, each of which is approximately 550 kD. The alkaloid ryanodine inhibits the receptor at high concentrations and potentially activates it at low concentrations. *RYR1* is the receptor type in muscle. The ryanodine receptor interacts with an L-type calcium channel. Mutations in the ryanodine receptor arc associated with central core myopathy and malignant hyperthermia.

The sodium channel has a composition similar to that of the calcium channel. The a-subunit, a 260-kD protein, confers the sodium channel activity with four domains, composed of six membrane-spanning proteins. The S4 segment is highly charged and may respond to voltage changes. Sodium channel gene mutations arc the most common cause of hypetkalemic periodic paralysis and paramyotonia congenita (Kleopa and Barchi 2002). Hypokalemic periodic paralysis in some families is linked to mutations in the sodium channel (Bulman ct al. 1999; Sternberg ct al. 2001).

Defects in the chloride channel arc associated with both autosomal dominant and recessive myotonia congenita. The structure of the chloride channel is different from those of the calcium and sodium channels. It is a homotetramer, in which each unit contains approximately 1000 amino acids.

The potassium channels are the most ubiquitous and diverse group of voltage-gated ion channels (Kleopa and Barchi 2002). They are composed of monotetramcrs or hete rote trainers with font *a* subunits. Mutations in voltage-gated K^{+1} channel genes are associated with hypokalemic periodic paralysis and Anderson's syndrome (Abbott et al 2001; Plaster etal 2001).

Calcium-Channel Abnormalities (Familial Hypokalemic Periodic Paralysis)

Familial hypokalemic periodic paralysis is inherited as an autosomal dominant trait. Most affected families have mutations on chromosome lq31-32 in the gene that encodes for the *a-1* subunit of the dihydropyridine-sensitive calcium channel. The voltage-sensitive S4 segment of domains 2 and 4 is presumed to be affected. Two common mutations account for most cases. In both, histidine is substituted for arginine: one at position 528 and the other at 1239. Each mutation is found in about one half of patients. The Arg^{2M} mutation is associated with incomplete penetrance of the disease in women, which accounts for the male preponderance in this disorder. The same mutation may also result in incomplete penetrance in males (Sillen et al. 1997).

In the attack, the paralyzed muscle is inexcitable either by stimulation or by the application of calcium on isolated muscle strips. The normal response to calcium can be restored by stripping the muscle of its sarcolemmal membrane, which allows the application of calcium to cause a local contraction of the underlying myofibrils. Studies on intact intercostal muscle fibers from patients with hypokalemic periodic paralysis indicate that the resting membrane potential of muscle fibers is depolarized by approximately 5-15 mV compared with the normal value of -85 mV. Further reductions of the external potassium concentration depolari/.e the fibers to 51) mV and render them inexcitable. Factors that lower the serum potassium concentration provoke attacks of weakness. During an attack, the serum potassium concentration may fall as low as 1.5 mEq/liter, but weakness is noted at higher concentrations. Unexplained findings are (1) the elevated intracellular sodium concentration in resting fibers, (2) the restoration of membrane stability by removal of sodium from the medium, and (3) the fact that the sodium channel is not blocked by tetrodotoxin, unlike in normal muscle.

The onset of familial hypokalemic periodic paralysis is usually in the second decade. Age of onset may be earlier, and the hypokalemia is more severe in the Argl239His mutation (Fouad et al. 1997). The attack begins with a sensation of heaviness or aching in the legs or back. This gradually increases and is associated with weakness of the proximal muscles. Distal weakness also develops. During severe attacks, the patient cannot get up from bed or even raise the head off the pillow. Respiration is not usually compromised, although respiratory function may be mildly decreased. At the height of weakness, the muscle is electrically and mechanically inexcitable, and reflexes are lost. The muscles feel swollen and may be firm to palpation. Attacks usually last for several hours, even up to a day, and strength returns as quickly as it left. A mild residual weakness is slow to clear. Sometimes permanent weakness ensues, associated with a vacuolar myopathy. Attacks vary in seventy and frequency and may occur as often as several times a week, but usually they are separated by weeks to months. Because a shift in the potassium concentration occurs during attacks, provoking factors include heavy exercise followed by a period of sleep or rest, a heavy carbohydrate load, or other causes of increased insulin

secretion. Most attacks occur in the morning hours on waking, probably because movement of ions, such as potassium, across the muscle membrane happens during sleep. Epinephrine, norepinephrine, and corticosteroids may provoke attacks. The greatest incidence of attacks is in the third and fourth decades, and a spontaneous reduction in the frequency of attacks is noted at later ages.

A fall in the concentration of serum potassium is usual, but not constant, during an attack. Weakness may commence at a potassium concentration at the low end of normal and may be profound by the time the serum potassium concentration reaches 2.0-2.5 mEq/liter. ECG changes include bradycardia, prolongation of the PR and QT intervals, and flattening of the T wave associated with prominent U waves. During profound paralysis, motor nerve stimulation may demonstrate reduced amplitudes or absent compound muscle action potentials. An EMG of paralyzed muscles shows an absence of electrical activity. The short exercise test can be helpful between attacks. Baseline ulnar compound muscle action potentials (CMAPs) are recorded, and then the patient is instructed to exercise the muscle for 5 minutes. CMAPs arc recorded at 1-minute intervals during the exercise period and for 25 minutes after exercise. About 50% of patients demonstrate an increment of the CMAP amplitude during exercise followed by a significant decrement after exercise. The test is not specific to the subtype of channelopathy because results arc positive in hypokalemic periodic paralysis, hyperkalemic periodic paralysis, paramyotonia congenita, and myotonia congenita.

The preferred method of diagnosis is genetic testing. Muscle histological preparations may be normal or show minor myopathic changes. A few vacuoles within fibers are ;i common feature, especially when permanent weakness is present. Tubular aggregates may be noted in hypokalemic periodic paralysis caused by sodium channel mutations (Sternberg et al. 2001).

The acute attack is treated with 5-10 g of oral potassium. The dose is repeated in 1 hour if the first dose is ineffective. Potassium administration can only be used in patients with normal renal function. Acetazolamide is used for prophylaxis. It produces a mild metabolic acidosis that may influence the potassium shifts that occur during an attack. Dichlorphenamide, another carbonic anhydrase inhibitor, may be effective as well. Adverse effects of acetazolamide therapy are tingling in the digits and a tendency for kidney stone formation. Hypersensitivity reactions may also occur. Triamterene and spironolactone arc used as adjunctive therapy as arc low-sodium or low-carbohydrate diets.

Secondary Hypokalemic Paralysis

An established association exists between periodic paralysis and thyrotoxicosis, especially in Asian populations. This predisposition is inherited as an autosomal dominant trait, but many cases are sporadic and men are affected more commonly than women. Kidney or adrenal failure may be associated with changes in serum potassium concentrations. A more common form of weakness caused by low potassium levels occurs in patients taking potassium-depleting diuretics. Other compounds, such as licorice, have been implicated in attacks of weakness associated with potassium loss. Renal tubular acidosis secondary to genetic defects in the kidney and secondary renal tubular acidosis secondary to inhalant abuse (e.g., toluene) are also causes of hypokalemia and paralysis.

Sodium-Channel Abnormalities (Potassium-Sensitive Periodic Paralysis, Hyperkalemic Periodic Paralysis, Paramyotonia Congenita, Myotonia Huctuans, and Hypokalemic Periodic Paralysis Type 2)

The combination of potassium-sensitive periodic paralysis and myotonia is associated with mutations in the or-subuuit of the sodium channel. The responsible gene is located on chromosome 17q. The association of decreased electrical activity, paralysis, and hyperactivity[7] (paramyotonia) was recognized even in early descriptions of these disorders. Molecular studies partially explain the relationship. Normal sodium channel activity depends on a complicated series of activation and deactivation processes that opens the pores to allow the passage of sodium while simultaneously protecting the cell against inadvertent excess sodium flux. The channel may exist in the closed, open, and inactivated state. The domain IV S3 segment is believed to have a dominant role in the recovery of inactivated channels, whereas the S4 segment is concerned with deactivation and inactivation of the open channel (fi et al. 1996). Mutations of the sodium channel may impair fast inactivation of the sodium channel or shift the voltage for channel opening to hyperpolarization. However, mutations within the domain II1-IV linker that cause myotonia, with or without weakness, do not impair slow inactivation.

Muscle is slightly depolarized during a paralytic attack. Intracellular potassium concentrations are elevated as are the contents of sodium, water, and chloride. The spontaneous muscle activity of intercostal muscle in vitro is increased even in normal physiological saline. Increasing the external concentration of potassium gradually depolarizes the cells and is associated with increased sodium conductance. Tetrodotoxin reverses the increased sodium conductance, implying that this sodium channel function is not affected. Cultured myotubes from patients with potassium-sensitive periodic paralysis were used to examine the sodium currents. Raising the potassium concentration in the media results in an increased open time or slowed inactivation of the sodium channel associated with sustained depolarization,

In paramyotonia, when intact intercostal muscle fibers were cooled, the resting membrane potential was reduced from approximately -80 to —40 mV, at which point the fibers were inexcitable. As the muscle cools, it passes

through a phase of hypercxcitability. Inexorability is prevented by tetrodotoxin, which blocks the sodium channels. The clinical features reflect the physiological findings.

The predominant symptom of hyperkalemic periodic paralysis is weakness provoked by potassium exposure. Myotonia may be present but is not a complaint. The features of paramyotonia congenita, an allelic disease, are different. Muscle stiffness is the predominant symptom and bouts of weakness arc mild and provoked by cold exposure. In some families, the distinction is clear, and in others the symptoms arc mixed.

Hyperkalemic Periodic Paralysis. Potassium-sensitive periodic paralysis is inherited as an autosomal dominant trait, with strong penetrance, that affects both genders. Onset may occur during infancy or early childhood. The infant's cry suddenly becomes altered or unusual, or the child may be found lying quietly in the crib. An unusual stare may develop, particularly on cold exposure. The first attack commonly occurs in the first few weeks of school because of enforced sitting. By adolescence, the attacks are fairly well characterized. Rest after exercise provokes an attack, and weakness develops quite rapidly, often within minutes. The weakness is milder than that in hypokalemic periodic paralysis, and the attacks are shorter in duration. The attack may be aborted by exercise early in the course, but many prefer inn [<> do so because an .muck is mild .ind followed by a period of relative freedom from symptoms. In addition to rest after exercise, other provocative factors include exposure to cold, anesthesia, and sleep. Patients often avoid fruit juices that contain high concentrations of potassium. Many patients differentiate two kinds of attacks, light and heavy. A light attack is characterized by a feeling of fatigue and mild weakness that usually disappears in less than 1 hour. A heavy attack may be associated with severe paralysis to the point where the patient is unable to arise from the chair or the bed. The frequency of attacks varies from two or three mild attacks a day to heavy attacks months apart. Residual weakness may be noted into middle age and beyond.

Paramyotonia Congenita. In addition to weakness, hyperkalemic periodic paralysis may be associated with a form of myotonia that involves the muscles of the face, eyes, tongue, and hands. Paramyotonia of the face may be noted by stiffness of the expression, narrowing of the palpebral fissures, or dimpling of the chin due to contraction of the mentalis muscle. Unlike the myotonia in myotonic dystrophy, paramyotonia is often accentuated by repeated exercise (myotonia paradoxical. Patients complain of aching or stiffness. A clinical test for paradoxical paramyotonia is repealed forced closure ol the eyes. After each repetition, difficulty with relaxation is accentuated until eventually the eyes cannot open. Exposure to cold not only w[r]orsens myotonia but produces muscle weakness in this condition. The same symptoms may be noted spontaneously when patients arc swallowing ice cream or going out into winter weather. A useful test is to soak a small towel in ice water and lay it over the patient's eyes for 2 minutes. Eyelid myotonia is demonstrated by asking the patient to look upward for a few seconds and then look down. The eyelids remain up, baring the sclera above the iris. When muscle is sufficiently chilled, the paramyotonia disappears, and the muscle is flaccid and paralyzed. The weakness may far outlast the cold exposure, and the muscle may not regain full use for hours after warming. Strong voluntary contraction may be associated with a long-lasting decrease in strength, which is not clearly caused by increased myotonia. Immersing the forearm in ice water may also cause weakness that was not seen on initial examination.

Diagnosis of the different types of potassium-sensitive conditions relics on demonstration of the genetic defects. The disorder is suspected when bouts of weakness are associated with a high concentration of serum potassium. In paramyotonia electromyographic examination of resting muscles at room temperature shows myotonic discharges that are present on percussion or with movement of the needle. More remarkable is the finding of spontaneous activity on cooling of the limb. Low-amplitude fibrillation potentials appear as the muscle is cooled and arc most intense when muscle temperature is around 30°C. This spontaneous activity completely disappears as cooling continues. In contrast to myotonia, during the delayed muscle relaxation of paramyotonia, electtical activity of the muscle is not prominent. EMG studies are also useful in demonstrating the worsening of the myotonic discharges with exposure to cold or to potassium. Because exercise may worsen symptoms, a brief exercise test as described in the section on hypokalemic periodic paralysis can be performed.

The EGG may show the changes of hyperkalemia, and the serum CK concentration may be elevated during or after an attack. Provocative testing may be dangerous and is best avoided.

Muscle histological preparations in patients with fixed paralysis may show tubular aggregates. Other myopathic features include internal nuclei, vacuoles, and fibrosis. In paramyotonia congenita, muscle histological preparations show variability in the size of fibers, internal nuclei, and occasional vacuoles.

Acute attacks usually do not require treatment because they are mild and brief. Patients learn to eat a candy bar or drink a sweet drink to ward off an attack. If weakness is more severe, intravenous administration of calcium gluconate has been recommended. Intravenous administration of sodium chloride sometimes may abort an attack. Maintenance therapy with dichlorphenamide or acetazolamide may be helpful. The combination of hydrochlorothiazide with potassium may be effective, although the reason is not clear. Mexiletine, a drug related to lidocaine and

tocainide, blocks the sodium channel. It may provide relief to patients with myotonia. It can be started at a dose of 200 mg three times per day. Most patients who derive benefit receive relatively low doses.

Myotonia Fluctuans. Myotonia fluctuans is a dominantly inherited disorder of the sodium channel. It is characterized by muscle stiffness exacerbated by exercise or potassium ingestion. The onset in adolescence is characterized by bouts of stiffness. The stiffness affects extraocular, bulbar, or limb muscles. It improves by loosening up the limb, as in myotonia congenita, but muscles become stiff after or during exercise. Unlike in paramyotonia congenita, weakness is not a part of the disorder. Abnormalities in exon 22 and in exon 14 of the sodium channel gene arc thought to be responsible. Mexiletine and acetazolamidc are effective therapeutic agents.

Secondary Hyperkalemic Periodic Paralysis. Hyperkalemia may cause weakness in disorders other than familial hyperkalemic periodic paralysis. The difference between secondary hyperkalemic periodic paralysis and genetic hyperkalemic periodic paralysis is that higher concentrations of potassium are required to cause weakness in secondary hyperkalemic periodic paralysis. Renal failure and potassium-retaining diuretics are causes of secondary hyperkalemic periodic paralysis.

Hypokalemic Periodic Paralysis Type 2, Hypokalemic periodic paralysis is caused by mutation in the muscle sodium channel gene (type 2) rather the calcium channel (type 1) in approximately 9% of patients (Kleopa and Barchi 2002). Clinical differences that help to distinguish patients with periodic paralysis type 2 from those with type 1 are that the former are more likely to suffer severe myalgias after paralytic attacks, to show tubular aggregates rather than vacuoles histologically, and to show disease worsening with acetazolamide therapy.

Andersen's Syndrome. The constellation of periodic paralysis, cardiac dysrhythmias, and dysmorphic features have been termed *Andersen's syndrome* (Sansone et al. 1997). The disorder is inherited in an autosomal dominant fashion and caused by mutations in the potassium channel gene *(KCNJ2)* located on chromosome 17q2.'5 (Plaster et al. 2001). The onset of paralysis may begin in early childhood or be delayed until the second decade. Attacks ate associated with both high and low serum potassium concentrations. Affected family members often have dysmorphic features that include wide-spaced eyes, low-set ears, a small chin, clinodactyly of the fifth finger, and syndactyly of the toes. Permanent muscle weakness is a featute in some patients.

The syndrome is important to recognize because of the high rate of cardiac involvement. This varies from prolongation of the QT interval through ventricular tachycardia to fatal cardiac arrest. The risk of cardiac complications is sufficiently high that provocative hypokalemic or hyperkalemic testing is not warranted. Some members of affected families have only fragments of the syndrome {e.g., clinodactyly or an abnormal QT interval), and a full pedigree evaluation is necessary.

Myotonia Congenita. Two forms of myotonia congenita are recognized; one is transmitted as an autosomal dominant and the other as an autosomal recessive trait. Both are associated with abnormalities in the gene for the chloride channel on chromosome 7q35. Introducing the gene tor the iinir.mt chloride channel ir.ro n cell system abolishes the chloride current and deranges the normal function of the chloride channel (Fahlke et al. 1997). Chlotidc conductance is also reduced in the patient's muscle, and the membrane resistance is greater than normal. The action potential in a normal muscle cell is associated with an outflow of potassium, which may accumulate in the transverse tubules simply because the physical structure of the tubule docs not favor easy diffusion. Ordinarily, this does not present a problem because the chloride conductance is so large that the relatively ftce passage of chloride ions negates the effect of any small change in potassium. If chloride conductance is impeded, the increase in potassium concentration in the transverse tubules may lead to enough depolarization to activate the sodium channels again and hence lead to repetitive electrical discharge of the membrane, producing electrical and clinical myotonia.

The dominant disease was originally described by Thomsen among members of his own family. It is usually milder than the recessive form described by Becker, in which weakness develops. The pattern of inheritance is sometimes difficult to determine in patients with sporadic disease because other family members with the abnormal mutation may be asymptomatic or have only mild involvement. This necessitates a thorough evaluation of the family with appropriate genetic testing.

On initial examination, especially if the patient has been sitting in the waiting room for some time, apparent weakness is observed because a severely myotonic muscle cannot be used with full voluntary power. With repetitive activity, the muscle loosens up, and the strength usually returns to normal. This is particularly true of the proximal limb muscles. Symptoms are described in a rather stereotyped way. After resting, the muscles are stiff and difficult to move. When the patient arises from a chair, muscles move en bloc, giving a stiff, wooden appearance, rather like the rusted Tin Man in *The Wizard of Oz.* As movement continues, the patients can walk freely and finally can run with ease. Myotonia is exacerbated by cold. All the muscles of the body are involved, and although it is most noticeable in the limbs, myotonia also can be found in the face and the tongue. In addition, particularly in the recessive form, muscular hypertrophy may be pronounced.

In myotonia congenita, the EMG shows well-marked myotonia with none of the associated dystrophic features of myotonic dystrophy. The muscle biopsy may demonstrate an absence of type 2B fibers; no explanation for the finding has been noted. Muscle biopsy also may reveal some increase in the size of fibers and internal nuclei and other mild, nonspecific changes.

Unlike patients with myotonic dystrophy, those with myotonia congenita may be quite disabled by myotonia. Treatment with mexiletine is worth trying and may provide dramatic relief in some patients. Older medicines include quinine, procainamide, and phenytoin,

Metabolic Myopathies

Any disturbance in the biochemical pathways that support adenosine triphosphatase (ATP) levels in muscle inevitably ••(.•suits m exercise intolerance. One common symptom is muscle fatigue, a sense that the muscle will no longer perform in a normal fashion. This is true fatigue and not simply a feeling of tiredness or weariness. It may be difficult for the patient to describe the fatigue in terms that the physician can understand because it is nothing like the sensations experienced by a healthy person after strenuous exercise. The fatigue has an unpleasant quality and is described in terms of a barrier through which the patient cannot break. Other symptoms include muscle pain and sometimes muscle cramps. The normal fatigue of strenuous exercise is painless. Muscle pain after strenuous exercise (e.g., the next day) is almost universal in the untrained individual, but pain during exercise suggests a disturbance of muscle function.

Normally functioning muscle has a series of safety mechanisms that prevent exercise to the point of muscle destruction. In the metabolic muscle diseases, maintenance of ATP levels is impaired, and the protective mechanism that functions in the normal person is absent. When a patient with a metabolic myopathy exercises, muscle pain develops followed by a muscle contracture in which the muscle is hard, swollen, and tender. This reflects destruction of the muscle and may be associated with the release of myoglobin into the blood and urine. This is sometimes noticed as a change in the color of the urine, which may resemble weak lea or to'.;, hinsnie, IIIIIM.1I' pain, contractures, and myoglobinuria are increasingly severe effects of the biochemical defect. Every effort should be made to prevent the development of myoglobinuria, which is associated with the potential complication of renal tubular necrosis. Although the final results are similar in many of the diseases, the metabolic myopathics can be grouped into three major categories: disorders of carbohydrate metabolism, disorders of lipid metabolism, and disorder-. nt mitochondrial function. Finally, some conditions, in theory, should disturb pathways for ATP maintenance but do not seem to cause any exercise intolerance. Tissues in which ATP is completely depleted are dead tissues. The muscle seldom reaches this critical state in the metabolic myopathies. Instead, most of the support pathways are overworked and unwelcome by-products are produced, which arc probably responsible for the symptoms.

Disorders of Carbohydrate Metabolism

Myophosphorylase Deficiency. Intramuscular carbohydrate stores play an important part in providing the energy source during the early stage of exercise, before the compensatory mechanisms of an increased supply of blood-borne metabolites and increased lipid metabolism catch up with the added demand. The first of the biochemical disorders to be recognized was a disorder of carbohydrate metabolism called *myophosphorylase deficiency* (McArdle's disease). In 1952, McArdle noted that a young man who presented with exercise intolerance experienced pain and tightness of his muscles on forced exercise. Ischemic forearm exercise caused a painful contracture of the muscle within minutes. Insertion of an electromyography needle showed no electrical activity, thereby differentiating this contracture from a muscle cramp, McArdle commented that the phenomenon resembled the reaction of a fish muscle poisoned by iodoacetate, *a* compound that blocks glycolysis. Subsequent studies showed the defect to be an absence of myophosphorylase activity, encoded by a gene on chromosome 1 lq13. Phosphorylase exists in two forms: phosphorylase a, the active tetramer, and phosphorylase b, an inactive dimer. Conversion of the inactive form to the active form is catalyzed by phosphorylase b kinase, which itself is activated by a protein kinase under the control of cyclic adenosine monophosphate (AMP). Any abnormality of this cascade of reactions results in an absence of phosphorylase activity. Both phosphorylase a and phosphorylase b kinase deficiencies are known to cause exercise intolerance, and both conditions appear to be inherited as autosomal recessive traits.

Symptoms are noted during the first 10 years of life but are recognized only in retrospect. As children, patients may complain of being tired and unable to keep up with their playmates. The typical symptoms appear in adolescence. Fatigue and pain begin within the first few minutes of exercise, particularly if it is strenuous. The sensation of hitting a barrier is noted, which causes activity to slow down. It exercise is continued, pain develops within the muscle, which at first is deep and aching but gives way to the rapid development of a painful tightening of the muscle. When the muscle is examined, it is hard and contracted, and any attempt to straighten it results in great pain. The muscle contracture may last for several hours and can be differentiated from a muscle cramp by two characteristics: the EMG is electrically silent, and the duration of the contracture is far longer than that of a physiological cramp, which disappears after a few minutes at most.

Another aspect of McArdie's disease is the development of the second-wind phenomenon. If, with the onset of fatigue, the patient slows down but does not stop, the abnormal sensation may disappear, and thereafter the muscle may function more normally. By gradually increasing the level of exercise again, the patient may be able to break through the barrier and may then be able to exercise at an adequate level for long periods of time. This second-wind phenomenon, which is similar to the phenomenon normally experienced by distance runners, may be marked in patients with phosphorylase deficiency. It probably is associated with a change in the blood supply in the muscle and with an intrinsic change in the muscle's metabolism. The second-wind phenomenon usually is associated with a rise in *fatty* acid use and may be blocked by nicotinic acid.

Unusual forms of phosphorylase deficiency have been described. One was seen in an infant girl who died of respiratory failure. Phosphorylase deficiency also has been noted in an occasional patient with proximal weakness, who has neither cramps nor fatigue. Oil examination, the patients have neither wasting nor detectable weakness but may be reluctant to exert full force during muscle strength testing because of the possibility of exacerbating muscle pain.

A simple diagnostic clinical test is the exercise forearm test (previously called *ischemic exercise test).* A butterfly needle is inserted in the antecubital vein, and baseline lactic acid and ammonia concentrations ate obtained. The patient then opens and closes the hand repeatedly and as fast as possible for 1 minute. Importantly, an ischemic arm is not required for the test. In fact, ischemic exercise is contra-indicated because it may lead to myoglobinuria. Scrum lactic acid and ammonia levels are obtained at 1, 2, 3, and 5 minutes aftet the exercise. The notmal response is a three to fourfold rise in lactic acid and ammonia. In deficiencies of phosphorylase, phosphorylase h kinase, phosphoIycerate mutase, phosphoglycerate kinase, lactate dehydrogenase, and enolase, ammonia concentrations rise but not lactic acid concentrations. The ammonia assay is imperative to ensure that the patient performed sufficient exercise. A rise in lactic acid without a rise in ammonia is seen in myoadenylate deaminase deficiency.

Light microscopic examination of the muscle biopsy specimen may show an increase in glycogen in subsarco-lemmal blebs. Muscle fiber necrosis also may be noted. Results with routine histological stains are entirely normal. However, staining for myophosphorylase is absent, and biochemical assay of enzyme activity on the muscle biopsy is significantly reduced.

Phosphofructokinase Deficiency. PFK is the enzyme that converts fructose 6-phosphate to fructose 1,6-diphosphate and is a step in the glycolytic chain downstream from that activated by phosphorylase. The reaction is rate limiting for glycolysis. PFK deficiency is inherited as an autosomal recessive trait, the gene is on chromosome 1, and hcterozygotes have dec teased hut not absent levels of enzyme activity.

PFK deficiency is an autosomal recessive disorder with clinical features almost identical to those of phosphorylase deficiency, although the second-wind phenomenon is uncommon. Most attacks are associated with nausea, vomiting, and muscle pain. Thete may also he mild hemo-lytic anemia and gallbladder pigment stones, with increased concentrations of bilirubin and increased reticulocyte counts due to deficiency of red blood cell PFK. PFK, like phosphorylase, is a tetramer of different su bun its, M and R. Muscle PFK is composed of identical M subunits, wheteas the enzyme in the red blood cell comprises both M and R types. In PFK deficiency, the M subunit is missing, resulting in absence of muscle PFK and impairment of the PFK in the red blood cell because the R subunit is still preserved.

Phosphoglycerate Kinase Deficiency. Phosphoglycerate kinase is involved in another step in the glycolytic pathway. Muscle deficiency produces a predictable picture very similar to that of phosphorylase deficiency. Venous lactate concentrations does not rise after exercise, as would be expected. The muscle histological preparation is normal, as is the glycogen concentration. Phosphoglycerate kinase is a single polypeptide, and many different point mutations of this enzyme have been described, most of which produce abnormalities in the red blood cell, with hemolytic anemia, mental retardation, and seizures. The gene is on chromo-some Xql3; hence the inheritance is an X-linked recessive trait.

Phosphoglycerate Mutase Deficiency. Phosphoglycetate mutase exists as a dimer wirh M and B subunits. The predominant form in normal muscle is MM, A small amount of residual activity may be present in muscle as a result of the existence of the BB form. Patients with an absence of the enzyme have attacks of muscle pain and myoglobinuria and, in one case, typical attacks of gouty arthritis. The high uric acid level may be associated with overactivity' of the adenylate kinase-adenylate deaminase reaction, which is seen in many metabolic disorders and produces uric acid as its end product. Exercise testing shows some elevation of lactate, but not to the concentra-tions usually seen in the other disorders of glycogen metabolism. Incremental bicycle ergometry in one patient was said to show a normal rise in lactate and a normal $V02_{m\cdot nx}$ and heart rate, which are difficult to explain. The responsible gene is located at chromosome 7pl2-13.

Lactate Dehydrogenase Deficiency. l.DH deficiency is as.socL.itI'd wall I'M'iviM.' iniiili.Taiuv, Lunelle, and myo dobinuria. Some differences exist in the laboratory studies between LDH deficiency and the other disotdcrs discussed here. In most muscle diseases, muscle LDH and serum CK concentrations fluctuate together. This disorder shows a marked discrepancy between the high concentrations of CK

and the low concentrations of LDH. Furthermore, because the action of LDH in exercise is to convert pyruvate to lactate, large amounts of pyruvate are produced even though no lactate is produced after ischemic forearm exercise. The gene is at chromosome 1 lp 15.4.

/i-F.nolasc Deficiency. A single patient has been reported with exercise intolerance, myalgias, and episodic elevated blood concentrations of serum CK caused by a muration in the gene that codes for /3-enolase.

Treatment of the Glycolytic Disorders. No effective treatment for glycolytic disorders is available. The patient should be counseled to avoid situations that might precipitate myoglobinuria. Attempts have been made to bypass the metabolic block by using glucose or fructose. Sublingual administration of isoproterenol has been tried without benefit. Administration of branched-chain amino acids and a protein-enriched diet has been suggested, but these regimens are no more effective than a well-balanced diet. One maneuver that can be adopted is to develop the patient's awareness of the second-wind phenomenon. Graded exercise on a treadmill can be used to train the patient to recognize how to slow down with the first onset of symptoms and then resume exercise in small increments. This training is best accomplished in an exercise physiology-laboratory.

Disorders of Lipid Metabolism

Carnitine Palmitoyl Transferase Deficiency. The synthesis of ATP from the oxidation of fatty acids is accomplished by as complex a system as that in glycolysis. Although fatty acids are not used at the beginning of exercise, they become increasingly important after 20-30 minutes of endurance exercise$_s$ and after 1 hour, they represent the major energy supply. Consequently, defects in lipid metabolism cause symptoms after sustained activity. Carnitine palmitoyl transferase (CPT) is the enzyme that links carnitine to long-chain fatty acids, which is necessary to transport the fatty acid across the mitochondrial membrane from outside to inside (CPT-I). It is also responsible for unhooking carnitine when the complex reaches the inside (CPT-II). CPT-II deficiency is one of the more common biochemical abnormalities in muscle. The disorder is inherited as an autosomal recessive rrair.

Typically, the patient with CPT deficiency is a young adult male who experiences his first bout of weakness and myoglobinuria after strenuous exercise, such as mountain climbing or playing several sets of tennis. In retrospect, patients[1] brief episodes of muscle pain were often experienced as children, but these were dismissed as growing pains or ordinary muscle cramps. Episodes of myoglobinuria are more likely when exercise is performed in the fasting state when there is greater dependence on fatty acids for energy. Several patients with this illness first experienced symptoms during military training when undertaking a forced march with a full backpack before breakfast. Attacks of myoglobinuria in CPT deficiency are often more severe than those occurring in disorders of glycolysis and have a greater tendency to cause renal damage. This may occur because the symptoms come on so rapidly in glycolytic disorders that cessation of exercise immediately returns the muscle to its resting condition. In disorders of lipid metabolism, the patient is often far away from home and must out of necessity use muscles that have already been damaged. In addition, muscles still depend on fatty acid metabolism even after work ends. Respiratory-paralysis may rarely accompany a severe attack.

Patients with CPT deficiency often notice that stamina depends on diet and carry a candy bar to be eaten during exercise. Others know that exercise in a fasting state is far more difficult for them. Despite these limitations, most patients with CPT deficiency are quite athletic. Usually, however, they are weight Sifters or sprinters rather than marathon runners. Both activities draw on carbohydrate energy supplies and use glycolytic fibers, not the oxidative fibers. Results of muscle examination are normal, and many patients are muscular, perhaps because their favorite exercise is weight lifting.

In general, routine laboratory studies are unrevealing. The serum CK concentration may be normal and muscle histological preparations arc normal unless the patient has had a recent attack of muscle damage. Biochemical analysis of the muscle biopsy reveals the deficiency of CPT. Analysis for CPT is not routine and must be requested. The respiratory exchange ratio (RER) is a useful screening test. The ratio of carbon dioxide produced to oxygen consumed indicates the type of fuel being used by the patient. In a normal individual at rest, the RER is apptoximately 0.8 because fatty acids are rhe predominant source of fuel at rest. In CPT deficiency, the RER is seldom much below 1.0, even with the patient at complete rest. It may be worthwhile to obtain incremental bicycle ergometry results because, in addition to the RER, the $Vo2_{max}$ and W_{m3X} also can be determined. Values for both are likely to he decreased. The maximum heart rate is normal, indicating full effort. Forearm exercise testing is not useful in CPT deficiency because the test stresses glycolytic pathways.

Patients with CPT deficiency should be cautioned to avoid any situation that provokes muscle pain and puts them at risk for myoglobinuria. The physiological effect of fasting should be explained, and the patient should be warned not to attempt exercise under such conditions. The use of glucose tablets or candy bars during exercise may raise exercise tolerance slightly. If myoglobinuria is noted, the patient should be admitted to the hospital, and renal function monitored. Forced alkaline diuresis may be helpful to prevent acute tubular necrosis. All exercise should be discontinued, and the patient should be restricted to bed rest until serum CK concentrations return to normal and renal function is normal.

Carnitine Deficiency Myopathy, Carnitine is an important compound in intermediary metabolism. It influences the balance between free coenzyme A (CoA) and acylated CoA in the mitochondria and is used to transfer long-chain fatty acids across the mitochondrial membrane under the action of the enzyme CPT, Carnitine supplied by the diet usually is supplemented by carnitine synthesized in the liver and kidney, which is transported to and then actively taken up by the muscle. Many metabolic processes produce acyl-CoA, which may then be employed in useful metabolic pathways, degraded by the liver, or excreted by the kidneys. The formation of acylcarnitinc is often a step in these processes, enabling the transport of fatty and organic acids across membranes, such as the mitochondrial membrane. However, an excess of acyl-CoA may cause a wide variety of damage, because it inhibits reactions as diverse as the oxidation of pyruvate, steps in the tricarboxylic acid cycle, and gluconcogencsis.

An adequate amount of carnitine is necessary for normal function. The adequacy of the carnitine supply can be judged from its absolute value and the percentage of free (nonaeylated) carnitine. If free carnitine is absent, carnitine deficiency exists, no matter how much total carnitine is present. Because 98% of the body carnitine is in muscle, it is not surprising that carnitine deficiency is associated with neuromuscular disease. In most patients with carnitine deficiency, the loss of free carnitine is due to a defect in some other enzyme system that results in an overproduction of organic acids or a defect in acyl-CoA disposal. Causes of secondary carnitine deficiency include multiple acyl-CoA dehydrogenase deficiencies, resulting in an overabundance of organic acids, which then bind the available carnitine; propionyl-CoA carboxylase deficiency; methylmalonyl-CoA mutase deficiency; and a number of mitochondrial disorders. Hemodialysis, cirrhosis, pregnancy, Reye's syndrome, valproate therapy, and renal Fanconi's syndrome also deplete cai nitinc stores. In must Ic carnitine deficiency, serum concentrations of carnitine are often normal, but both total and free carnitine concentrations are reduced in the muscle. In systemic catnitine deficiency, muscle carnitine, liver carnitine, and serum carnitine concentrations arc all decreased.

The most common clinical picture in patients with carnitine deficiency of the muscle is a slowly progressive weakness on which sudden exacerbations or a fluctuating course are superimposed. Fatigue and exercise-related pains have been described but usually do not constitute major complaints; myoglobinuria is almost never a problem. The weakness is usually proximal, and the symptoms begin during childhood or early teenage life. In addition to the limb and some trunk weakness, facial and bulbar weakness has been described.

Systemic carnitine deficiency may ptcscnt in infancy and childhood, when the muscular weakness occurs in association with an encephalopathy crises resembling Reye's Syndrome, fhe initial symptom ;r the e:icer»fMlop.i:hy usually is protracted vomiting, followed by changing levels of consciousness, culminating in coma. Hypoglycemia usually occurs and is associated with evidence of liver damage, an enlarged, tender liver, and increased serum concentrations of hepatic enzymes. Hypothrombinemia, hyperammonemia, and excess lipid in the liver arc common. Fasting may exacerbate the symptoms of carnitine deficiency, because the body becomes dependent on fatty acids.

The EMC appears myopathic but has no specific findings that suggest the diagnosis of carnitine deficiency. The disorder may be suspected with a muscle biopsy because of the accumulation of lipid droplets in muscle fibers (Figure 85.25), but the biochemical measurement of carnitine, both free and total, is necessary to establish the diagnosis. An abnormal value should initiate the search for the underlying defect.

Treatment of carnitine deficiency by replacing L-carnitine is not uniformly successful. Approximately 2-4 g per day have been given to adults in divided doses, with the equivalent of 100 mg/kg in infants and children. No serious adverse effects are seen, although patients find i-carnitine unpleasant to take because of accompanying nausea and a fishy odor of the sweat. Some patients show dramatic improvement, while others feel no change at all. The

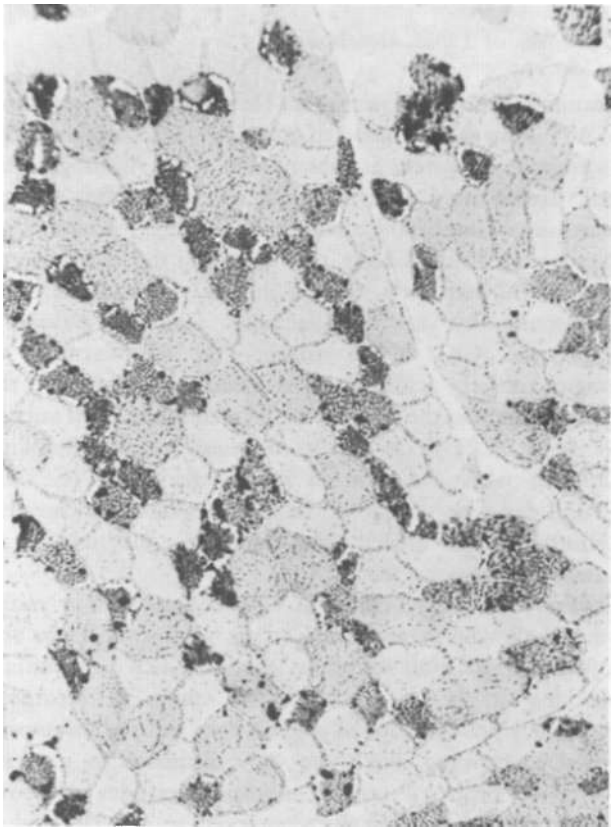

FIGURE 85,25 Carnitine deficiency. This lipid stain demonstrates deposition of fat in muscle fibers.

efficacy of other treatment is equally variable. One patient showed a response to riboflavin in high doses and others to ptcdmsone. Dietary manipulations, such as reducing the amount of long-chain fatty acids in the diet and supplying a medium-chain triglyceride diet, are successful in some patients.

Disorder of Abnormal Nucleotide Metabolism: Myoadenylate Deaminase Deficiency

Approximately 1-2% of the population has a deficiency of the enzyme myoadenylate deaminase (AMP deaminase [AMPDA]). The disorder is inherited as an autosomal recessive trait. The enzyme plays a role in supporting ATI[3] levels by acting in conjunction with adenylate kinase. Adenylate kinase converts two molecules of adenosine diphosphate to one each of ATP and AMP. Adenylate deaminase then converts AMP to inosine monophosphate with production of ammonia. This reaction is used when muscle is stressed.

Early studies suggested that AMPDA deficiency caused myalgia. However, most people with AMPDA deficiency are asymptomatic and show no signs of exercise intolerance. A deficiency of the enzyme has been described in almost every condition from congenital hypotonia to amyotrophic lateral sclerosis. The poor correlation between the enzyme defect and clinical symptoms makes it difficult to know how to interpret the entity.

Muscle histology is normal. The histochemical reaction for AMPDA is absent. On the forearm exercise test, patients with AMPDA deficiency produce normal amounts of lactate but little or no ammonia and hypoxanthine, both of which are by-products of the AMPDA reaction.

Mitochondrial Myopathies

A group of disorders known as the *mitochondrial myopathies* are caused by several different defects in respiratory chain function. The group includes Kearns-Sayre syndrome (KSS), other disorders of oxidative muscle metabolism with exercise intolerance, myoclonus epilepsy with ragged-red fibers (MERRF), and mitochondrial encephalopathy associated with lactic acidosis and stroke-like episodes (M FI .AS). Most of these patients present with CNS dysfunction and are discussed in Chapter 69,

The final products of fatty acid metabolism and glycolysis ate the two carbon fragments that enter the tricarboxylic acid cycle and are further oxidized in the mitochondrial respiratory chain. Major disturbances in mitochondrial function produce severe multisystem disease (brain, heart, kidney, and skeletal muscle). Less severe disturbances may primarily affect skeletal muscle and cause exercise intolerance. Under normal conditions, the rate of riilOi.lniridi:.'.l o\id.uion is coupk'd to the need for A I 1'. II ATP turnover is rapid, mitochondrial oxidation is turned on, with the resulting consumption of oxygen and other metabolites. When ATI' turnover is minimal, mitochondrial oxidation is relatively quiescent. The body's response to the increased demands of exercise {and increased iimochon • drial oxidation) is predictable. The higher oxygen consumption necessitates augmented delivery of oxygen to the muscle, evidenced by vasodilatation, tachycardia, and increased cardiac output and respiration. The heat generation that accompanies this oxidation results in sweating. These are the normal accompaniments of vigorous exercise. When mitochondrial function is impaired, maintaining \ IP levels al resi ma; require thai mitochondrial oxidation is fully turned on. In this situation, the patient at rest may experience all the symptoms that normally accompany vigorous exercise. In addition, because the oxidative mechanisms are insufficient to cope with the demand for ATP, anaerobic mechanisms are required, resulting in lactic acidosis.

Severe mitochondrial diseases can be detected at rest. High resting serum lactate concentrations are evidence of defective mitochondrial function after hyperthyroidism or intoxication with poisons (e.g., dinitrophenol) that uncouple mitochondria) oxidation are excluded. Incremental bicycle ergometry is the most useful test in patients whose disease is less severe. Increasing the workload even to low levels results in an excessive rise in pulse rate and oxygen consumption with a low W_{max}. This discrepancy between normal $Vo_{2m\cdot lx}$, normal heart rate, and a very low $W_{m;ix}$ is characteristic of the illness. If bicycle ergometry is nor available, incremental forearm exercise may demonstrate excessive lactate production for the levels of work needed. If the disorder is suspected from the clinical history and the results of exercise testing, a muscle biopsy should be carried out to confirm the diagnosis.

Histochemical analysis of affected muscle usually shows ragged-red fibers whereas unaffected muscle in the same patient may be normal. Abnormal mitochondria sometimes are seen on electron microscopic examination (Figure 85.26). Ragged-red fibers also arc seen in other diseases and in normal aging, although not in such quantities. The biopsy specimen may reveal scattered fibers that lack cytochrome oxidase. Even though the typical clinical picture associated with ragged-red fibers in the muscle makes the diagnosis apparent in many patients, some have few pathological changes and even normal biochemical values. Assay of mitochondrial enzyme activity and mutational analysis of the mitochondria] DNA can be performed to confirm the diagnosis.

r>uk. lieinn .'.I c\ .illi.il n in of tiie eymehninie eh.nn cm localize the defect. However, analysis of mitochondrial oxidation requires relatively large amounts of muscle. The introduction of noninvasive techniques to monitor muscle metabolism has had a major impact on the analysis of mitochondrial disorders, although it is perhaps less useful in the diagnosis of these conditions. Magnetic resonance spectroscopy of P compounds permits the analysis of

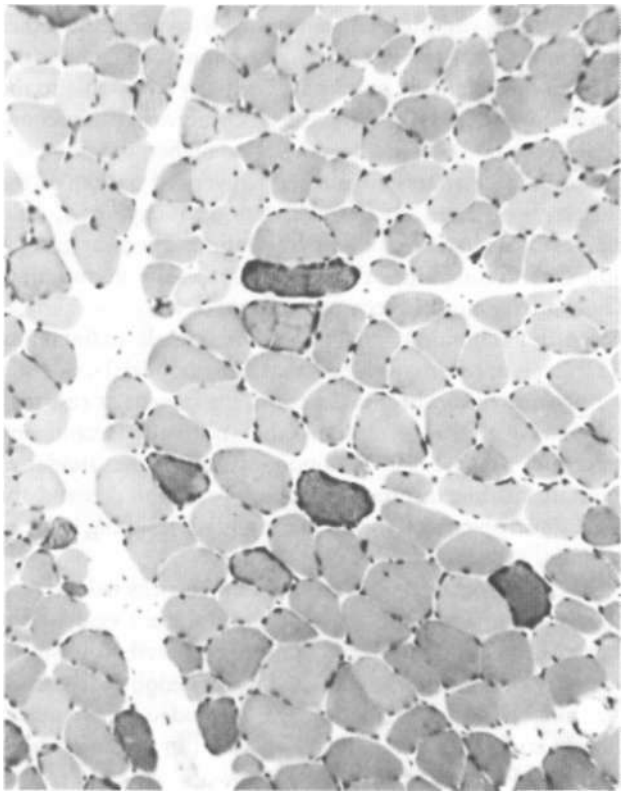

FIGURE 85.26 Kcarns-Sayrc syndrome. Typical appearance of the ragged-red fibers seen in the biopsy. (Modified Gomori trichrome stain.)

ATP, creatine phosphate, inorganic phosphate, and pH in muscle. In mitochondrial disorders, there is a rapid fall in concentrations of creatine phosphate and an abnormal accumulation of inorganic phosphates. Equally important, there is a delay in the recovery of phosphocreatine concentrations to normal after exercise. These techniques can be used to evaluate the effects of treatment in a way that invasive procedures, such .is muscle biopsy, cannot.

The treatment of most mitochondrial disorders is limited to the treatment of lactic acidosis when it occurs. A "cocktail" of compounds, including riboflavin, ubiquinone, vitamin C, menadione, coenzyme Q 10, and niacin has been popular, but its efficacy is unproven.

Myoclonic Epilepsy and Ragged-Red Fibers

The complete spectrum of MERRF includes myoclonus, generalized seizures (myoclonic and tonic-clonic), ataxia, dementia, sensorineural hearing loss, optic atrophy, and muscular weakness and atrophy. Weakness and atrophy are usually more prominent in proximal muscles. In addition, some patients have a generalized sensorimotor polyneuropathy along with high arched feet (pes cavus). The disorder can begin in childhood or adult life, Although the course and severity are often progressive, these can vary even within the same family. Cardiac-muscle is also affected, and patients can develop arrhythmias or heart failure. Patients with MERRF can develop life-threatening hypoventilation associated with surgery, sedation, or intercurrent infection.

Serum CK concentrations can be normal or mildly elevated. Serum lactate concentrations also are often elevated. An electroencephalogram may demonstrate generalized slowing of the background activity as well as bursts of spikes and slow waves. A MRI or CT scan of the brain reveals cerebral and cerebellar atrophy.

There is non-Mendclian maternal inheritance of MERRF. Approximately 80% of affected patients have a point mutation at nucleotide position 8344 of the mitochondrial genome, resulting in an A to G transition in the tRNA ^ gene. Other mutations in this gene (positions 8356 and 8366), in the $tRNA^{\wedge 11}$ gene (the gene most commonly mutated in MELAS; see later), and in the gene for tRNA ^{*r} also have been reported in patients with MERRF. MERRF may also be due to multiple mitochondrial DNA (mtDNA) deletions. The mitochondrial tRNA gene mutations impair the translation of mtDNA-encoded respiratory chain proteins. Decreased activity of complexes I and IV have been demonstrated. Mutations can be demonstrated by polymerase chain reaction of nit DNA in leukocytes or muscle specimens, but abnormal mtllXA is seen more often in muscle.

Mitochondrial Myopathy, Lactic Acidosis, and Strokes

MELAS is characterized by biochemical or morphological evidence of mitochondrial abnormalities, high lactate concentrations in the serum or cerebrospinal fluid (CSF), and strokelike episodes. The disorder usually manifests in childhood, but rare occurrences with onset as late as in the eighth decade have been reported. Most patients present with recurrent migraine-type headaches, hemiparesis, hemianopsia, or cortical blindness. These attacks may be provoked by exercise or intercurrent infection. Some patients develop progressive dementia after repeated attacks. Proximal muscle weakness is present in the majority of patients along with exercise intolerance. Many patients have short stature. Some patients also develop myoclonus, seizures, or ataxia.

Serum CK concentrations may be normal or elevated. Lactate concentrations are elevated in the serum and CSF in the majority of patients. Cortical atrophy and focal low signal abnormalities are evident on CT and MRI scans of the brain. Muscle biopsies are indistinguishable from those with othet mitochondrial myopathies as described earlier. Defects in complex I, III, IV, and V activities have been demonstrated in muscle specimens.

MELAS is inherited maternally in a non-Mcndelian pattern. The majority of cases are caused by an mtDNA mutation, .in A in *C,* substitution in the gene encoding tor $tRNA^{1""}$ at nucleotide position 3243. Mutations have also

been identified at other positions in the $tRNA^{Ltm}$ gene, as well as in the genes for $tRNA^{Val}$, $tRNA^{Cys}$, and ND.5 of complex 1 and in cytochrome *b* of complex III.

Mitochondrial Myopathies Associated with Recurrent Myoglobinuria

Mitochondrial myopathy may present as recurrent myoglobinuria beginning in infancy or early adult life. Laboratory and histopathological features are indistinguishable from those of other mitochondrial myopathies but serve to exclude more common causes of myoglobinuria, such as CPT deficiency, a glycogen storage disease, or a mild form of muscular dystrophy.

This is a genetically heterogeneous group of disorders. Multiple mtDNA deletions were demonstrated in two brothers with presumed autosomal recessive inheritance. In addition, point mutations in $tRNA^{pl,t}$ have been found in kinships with maternal inheritance of recurrent myoglobinuria, and micro deletions within the gene encoding for cytochrome oxidase III (COX III) have been reported in patients with sporadic disease. Other instances of exercise intolerance and recurrent myoglobinuria have been ascribed to mutations in the mtDNA genes encoding for subunit 4 of reduced nicotinamide adenosine dinucleotide (NADH) dehydrogenase (ND4) and cytochrome *b*.

Kear?is-Sayre Syndrome

KSS is characterized by the clinical triad of progressive external ophthalmoplegia (PEO), retinitis pigmentosa, and heart block with onset usually before age 20. Mild proximal weakness of the arms and legs may be apparent. KSS is also associated with other defects including short stature, sensorineural hearing loss, dementia, ataxia, depressed ventilatory drive, and multiple endocrinopathies.

The serum CK level is typically normal; however, lactate and pyruvate concentrations may be elevated. The CSF protein level is usually increased. The ECG reveals conduction defects. Muscle biopsy specimens demonstrate ragged-red fibers on Gomori-trichrome stain. The number of ragged-red fibers and COX-negative fibers correlate with the percentage of mitochondria with large deletions.

Single large mtDNA deletions of varying sizes (ranging from 1.3 to 8.8 kb) can be seen m most patients with KSS. mtDNA deletions may be present in leukocytes and other tissues, but the sensitivity is much lower than that seen in muscle. The large deletions usually involve several tRNA genes, thus impairing the adequate translation of rntDNA-encoded proteins.

Progressive External Ophthalmoplegia

Patients present with ptosis and ophthalmoparesis with or without limb weakness. Unlike in KSS, they typically do not have pigmentary retinopathy, cardiac conduction defects, or other systemic manifestations (e.g., endocrinopathies). Patients with PEO can develop hypoventilation in response to sedatives and anesthetic agents. Patients with mtDNA deletions often have dysphagia in addition to the extraocular weakness related to cricopharyngeal achalasia.

Serum CK, serum lactate, and CSF lactate concentrations can be normal or elevated. The CSF protein level may be increased. In contrast to classic KSS, the ECG does not demonstrate cardiac conduction defects. Muscle pathological changes are indistinguishable from those with KSS.

This is genetically a very heterogeneous disorder (Hirano and Di Mauro 2001). There are autosomal dominant and maternally inherited forms of PEO that are genetically distinguished from the sporadic subtype. Some patients with sporadic PEO have single large mtDNA deletions indistinguishable from those seen in KSS. This could represent a partial expression of KSS. Importantly, these deletions are felt to be sporadic in occurrence and not inheritable. Point mutations have been demonstrated within various mitochondrial tRNA (Leu, lie, Asn, and Trp) genes in several kinships with maternal inheritance of PEO. In addition, multiple mtDNA deletions have been described in a few kinships with autosomal dominant inheritance.

The molecular defects are suspected to lie in nuclear genes involved in regulating the mitochondrial genome. Autosomal dominant PEO appears to be genetically heterogeneous, because the disorder has been localized to mutations in the genes encoding for adenine nucleotide translocator 1 (ANTJ) on chromosome 4q34-q35, *Twinkle* on chromosome 10q23.3-q24.3, and *polymerase gamma* on chromosome 15q22-q26. ANT1 is responsible for transporting adenosine triphosphate across the inner mitochondrial membrane, whereas Twinkle and polymerase gamma are involved in mitochondrial DNA replication.

Mitochondrial DNA Depletion Syndrome

The severity of muscle weakness in this syndrome can vary. Fatal infantile myopathy is a severe early-onset form characterized by generalized hypotonia and weakness at birth. Weakness is progressive, leading to feeding difficulties, respiratory failure, and death usually within the first year of life. Some infants develop ptosis and ophthalmoplegia. A subclinical neuropathy is often is evident on examination. Deep tendon reflexes are diminished or absent.

There is also a benign form of infantile myopathy that early on can resemble the fatal form of myopathy. Generalized hypotonia and weakness and respiratory and feeding difficulties begin in infancy or early childhood. Although ventilatory assistance may be required, muscle strength often improves during the first year of life. Motor

milestones may be delayed but are usually attained, and occasionally children can appear normal by 2 or 3 years of age. Affected individuals can have a normal life expectancy, but some die in the first two decades of life.

Serum CK levels can be normal or elevated, as can the serum lactate level. The associated renal tubular defect results in glycosuria, proteinuria, and aminoaciduria. MRI of the brain may reveal cerebral atrophy and patchy areas of hypomyclination of subcortical white matter. Muscle biopsies demonstrate ragged-red fibers, foci of intense NADH and succinic dehydrogenase staining, and many COX-negative fibers. Biochemical assay of skeletal muscle tissue of affected patients shows that COX activity is greatly diminished or absent.

Inheritance of this disorder is autosomal recessive and is associated with a quantitative defect in mtDNA. Several different mutations of nuclear genes (e.g., thymidine kinase gene) important in regulation of the mitochondrial genome are felt to be responsible for mtDNA depiction (Saad et al. 2001). The severity of the depletion cot relates with the clinical severity of the disorder. As much as a *99%* reduction in mtDNA is present in the fatal infantile myopathy form of the disease, whereas the more benign myopathy has been demonstrated to have a smaller depletion (36-88%) of mtDNA.

Congenital Myopathies

Occasionally children exhibit a lack of tone at birth or shortly thereafter. In some children, this hypotonia is accompanied by obvious weakness of the limbs, and the baby lies immobile in the crib. Such children usually have one of the spinal muscular atrophies or a metabolic disorder (e.g., a mitochondrial myopathy), or, rarely, the cause may be a toxic substance (e.g., botulism). Other babies move the limbs, if not normally, at least through their full range of movement, and do so spontaneously. Determining muscle strength in a baby is difficult; however, when no obvious weakness is discernible, the babies are said to have congenital hypotonia. One of the most common causes of congenital hypotonia is damage to the CNS. As such children grow older, the hypotonia is often replaced by increased tone and an associated delay in intellectual development. This cerebral hypotonia is not due to any primary abnormality in the muscle but presumably accompanies .i disturbance ol roilc\ turn-. Selective atroph) of type 2 muscle fibers may be noted on biopsy, a change that is not indicative of a primary disease of the muscle but is secondary to the cerebral lesion.

Babies with benign congenital hypotonia do not show any neurological abnormality other than hypotonia. Tendon reflexes are preserved or slightly diminished. Results of muscle biopsy and electromyography are normal, and serum CK concentrations are appropriate to the child's age. As time progresses, the children gain tone, and normal motor development ensues. In teenage life, these children may not be star high school athletes, but, nevertheless, in general, their neuromuscular function is normal. The only treatment necessary in all these conditions is encouragement of the child to participate in play therapy, with the aim of increasing motor activity. A referral to an occupational therapist accomplishes this.

Central Core Disease

Centtal core disease was the first of the congenital nonprogressive myopathies to be described. The disease is inherited as an autosomal dominant trait, although sporadic cases occur. The faulty gene is on chromosome I9q13.1. The illness is associated with a mutation of the ryanodine receptor and is allelic to one form of hereditary malignant hyperthermia. Malignant hyperthermia and central core disease certainly coexist in some families; however, tin[1] association is not always clear.

The newborn with central core disease may be floppy and may have congenital hip dislocation. As the child grows older, motor milestones are delayed, and, at an age when children should be running easily, affected children are often ungainly and clumsy. The family soon recognizes that the weakness is not getting worse. Strength, although less than normal, usually is nor impaired enough to cause severe disability. As in other similar disorders, the child may be slender and short of stature. Examination reveals diffuse weakness of the limbs and mild facial and neck weakness. Deep tendon reflexes often are diminished but are sometimes normal. Skeletal abnormalities, such as pes cavus, a long face, and a high-arched palate, arc associated. For both central core disease and nemaline myopathy, a severe and disabling form may be seen with respiratory failure. The pathological changes in muscle do not appear to be any different, but the patient may be confined to a wheelchair, scarcely able to move the arms or legs, and have profound kyphoscoliosis. In this type of central core disease, surgical stabilization of the hack may be helpful, although the lack of respiratory reserve may prevent surgery.

The EMC shows nonspecific myopathic changes in central core disease. The scrum CK level is usually normal, although mild elevation may be seen. The muscle biopsy is diagnostic. On cross-section the muscle shows a combination of type 1 fiber predominance with central cores, an area in the muscle fiber where the central myofibrils are in disarray, and many of the oxidative histochemical reactions and the periodic acid-Schiff stain demonstrate an unstained central core (Figure 85.27).

No specific treatment for central core disease is available, although bracing may be needed to correct a deformity, such as a footdtop. Any family in whom central core disease has been found should be advised about the possibility of malignant hyperthermia because this is a potentially fatal complication,

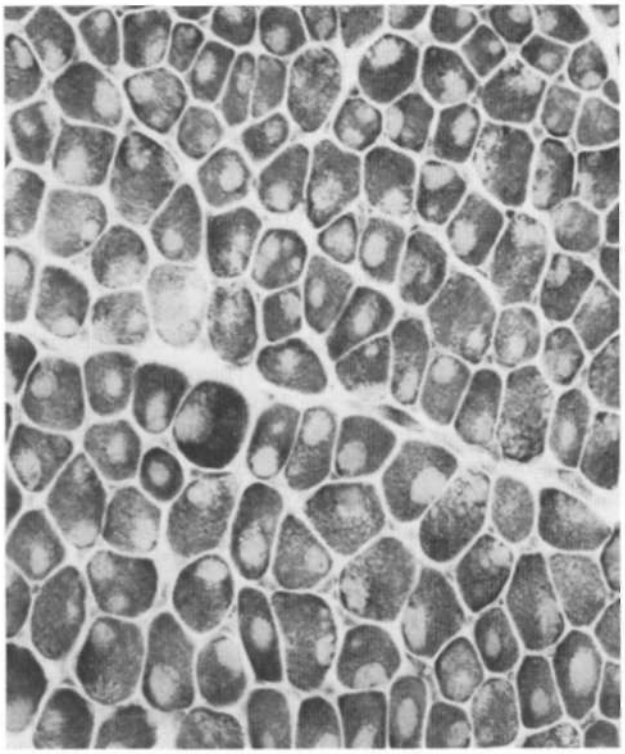

FIGURE 85.27 Central tore disease. The unstained area in most of the fibers is characteristic of this illness. (Nicotinamide adenine dinucleotide dchydrogenase-tetrazolium reductase stain.)

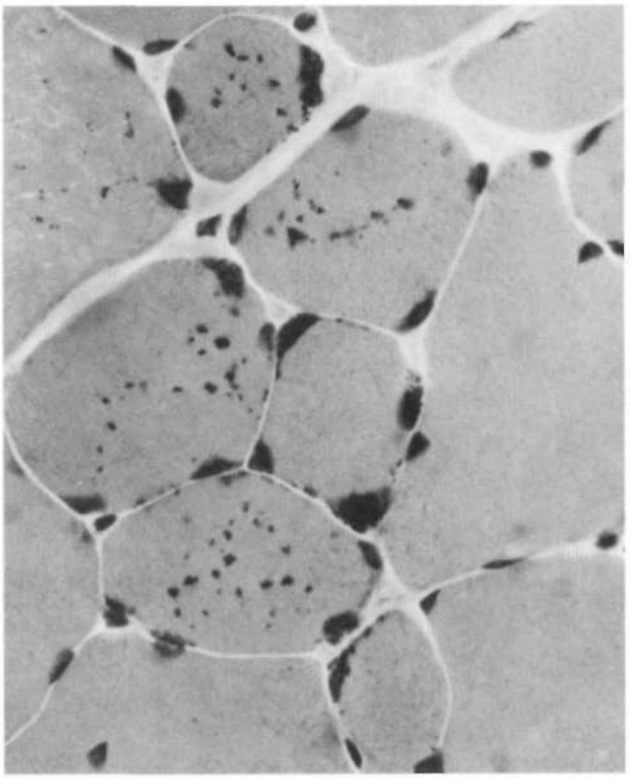

FIGURE 85.28 Nemaline myopathy. Although better demonstrated with the electron microscope, nemaline rods are also noted with histochemical reactions. The granular appearance of these fibers is due to the presence of many rods. (Modified Gomori trichrome stain.)

Nemaline Myopathy

The diagnosis of nemaline myopathy is based on the presence of small, todlike particles in the muscle fibers. They arc usually found with the modified trichrome stain (figure 85.28), hut they are most accurately characterized on electron microscopic examination. They originate in the Z-disc and exhibit structural continuity with the thin filaments. They have a regular structure, presenting as a tetragonal filamentous array when cut transversely and exhihiting periodic lines both perpendicular and parallel to the long axis. Major constituents of the rods include or-actin, desmin, and nebulin, proteins normally present in the Z line.

The disorder is genetically heterogeneic. Autosomal dominant nemaline myopathy has been linked to mutations in the gene for a-tropo myosin on chromosome Iq21-q23 (Laing et al. 1995) and for *fi*-tropomyosin on chromosome 9p13. Autosomal recessive nemaline myopathy has been associated with mutations in the genes that code for nebulin on chromosome 2q21.2-q22 and troponin T on chromosome 19q13 (Johnston er al. 2000). Both autosomal dominant and recessive occurrences have been described with mutations in cv-actin on chtomosome lq42.1.

The clinical picture of nemaline myopathy is heterogeneous (Ryan et al. 2001). The most common presentation is early hypotonia, followed by a diffuse weakness of the arms and legs, mild weakness of the face and othct bulbar muscles, and a dysmorphic appearance. The face is long and narrow, and the jaw may be either prognathous or abnormally short. The feet and palate are often high arched, and kyphoscoliosis is common as the children grow older. The disorder is considered nonprogressive, although some patients become weaker later in life. In some patients, respiratory failure out of proportion to the general weakness may ensue. Cardiomyopathy may be associated. A severe infantile variety is fatal. Such newborns have profound hypotonia and respiratory failure. Another form may have its onset in early adult life and present with a mild proximal weakness. No specific treatment fot nemaline myopathy is available. Bracing and surgery may be recommended when necessary.

In nemaline myopathy, the EMG demonstrates the nonspecific myopathic changes. Serum CK concentrations may be normal or elevated. The muscle biopsy specimen, in addition to demonstrating nemaline rods, often shows type 1 fiber predominance, selective atrophy of the type 1 fibers, and deficiency of type 2B fiber. Electron microscopic studies show the characteristic rods (Figure 85.29). These are seen most often in the cytoplasm, but intranuclear rods

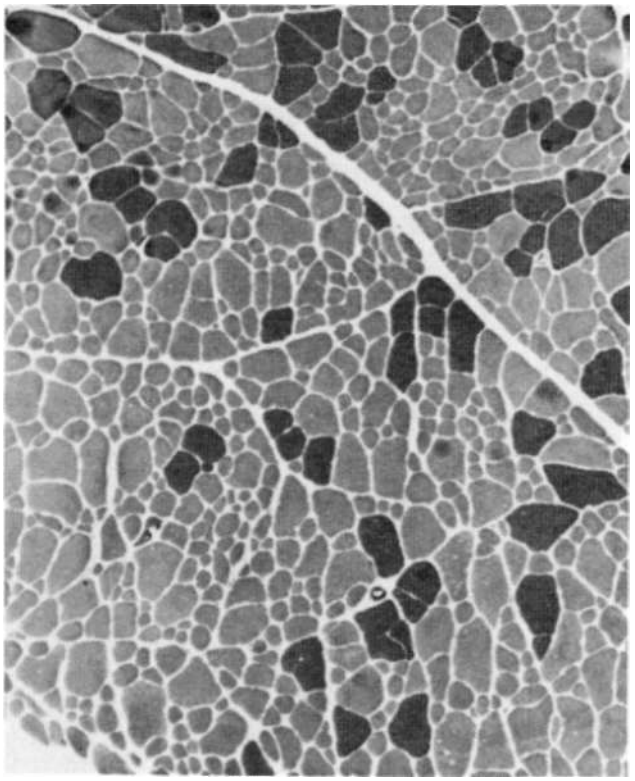

FIGURE 85.29 Nemaline myopathy. As in central tore disease, nemaline myopathy shows predominance and atrophy of type J fibers. Note that the very smallest fibers in this biopsy are all type 1. (Myosin adenosine triphosphatase stain, pH 9.4.)

also have been noted and are associated with the severe infantile form (Goebel and Warlo 1997),

Centronuclear or Myotubular Myopathy

The term *centronuclear* or *myotubular myopathy* (MTM) was used i" identify a group of diseases in whieh the pathological finding was the ptesence of fibers with central nuclei, which were thought to resemble the myotube stage in the development of muscle. The best known form is a severe infantile illness that is often fatal, the hallmarks of which are extraocular, facial, and limb weakness, often with respiratory failure. The gene locus has been identified to be the long ar:r. of the X chromosome ;;t Xi]_!iv i'lie sictie has been identified and is known as the *MTM1* gene. It encodes for myotuhularin, a protein with a tyrosine phosphatase domain (I.aporte et al. 1997). There appears to be another related gene on the X chromosome, *MTMR1,* and two other genes, *MTMR2* and *MTMR3,* on autosomes. Perhaps changes in the last two account for the occurrence of the autosomally inherited variety of illness, some of which are dominant and some recessive. The relationship between the gene product and the disease has not yet been elucidated. Mild and intermediate forms do exist. Large deletions of the gene have not been described, but missense and nonsense mutations and point deletions have been found in a number of families with X-linked disease,

The severe infantile variety of myotubular myopathy is inherited as an X-linked recessive disorder. It usually presents as severe hypotonia and respiratory distress. The disorder is usually fatal due to respiratory failure during the first few months. The weakness is severe and includes weakness of the facial and neck muscles as well as the extraocular muscles. Ptosis has not been as pronounced, but the eyes may appear puffy. The ribs are thin, and there are contractures at the hips and less often at the knees and ankles. Intermediate and milder forms of the illness are known. These vary among adults who have extraocular weakness, facial weakness, and mild difficulty with limb strength and adolescents who have more severe weakness and lose the ability to walk in early to middle adult life.

In the autosomal dominant form of myotubular myopathy, the illness is milder and occurs later in life. This form is less common than the severe X-linked form. Ptosis, extraocular weakness, and facial weakness are noted, and moderate limb weakness causes some disability, Equinovarus deformity of the feet has been noted. The autosomal recessive variety, which is also less common, seems to be intermediate in severity between the other varieties. Reports of electrical or clinical seizures were prominent in the early literature but have not been emphasized recently.

Laboratory studies show normal or slightly elevated serum CK levels. The EMG demonstrates marked muscle membrane instability in the torm ol fibrillation potentials, positive sharp waves, complex repetitive discharges, and occasionally even myotonic discharges. The only other congenital myopathy that usually has such prominent abnormal spontaneous and insertional activity on the EMG is myofibrillar myopathy.

The muscle biopsy has characteristic features. With routine hemaroxylin-eosin or tricbrome staining, variability in the size of fibers, most of which are small, is seen. In the center ot many of these fibers is a large, plump nucleus, resembling the myotube stage of muscle development. With the oxidative enzyme reaction, main ol the libers have a darkly staining central spot. Almost all the fibers have a palt siaining area, with tin ATPase reaction ihat runs through the middle of the fiber. Although this looks superficially like a core, most central cores are not visible with an ATPase stain. When viewed in longitudinal section, the fiber has a long central area containing nuclei interspaced with mitochondria-rich cytoplasm. Some features of the biopsy resemble those of other congenital disorders, with type 1 fiber predominance and often type 1 fiber atrophy. The biopsy findings in the X-linked recessive-illness appear similar. Although the muscle fibers superficially resemble myotubes, they arc in fact quite different, hence the preferred term *centronuclear myopathy.* The

differentiation into well-marked histochemical fiber types and the cytoarchitecture of the fiber more closely resemble those of the adult fiber. Two fetai cytoskeletal proteins (vimentin and desmin), which are found in fetal myotubes, have been demonstrated in fibers from patients with myotubular myopathy by immunocytochemical studies. The electroencephalogram has been reported on occasion to show a paroxysmal disturbance.

Treatment of the milder forms of myotubular myopathy includes respiratory support where indicated, treatment of any concurrent seizure disorder, and general supportive measures. Treatment of the severe infantile form must be considered in association with the very poor prognosis. The decision whether to provide life support for these children is a difficult one. Most die within the first 2 years.

Congenital Fiber-Type Disproportion

Affected children arc floppy at birth, with varying degrees of weakness. The weakness is diffuse, usually involving the face and neck. Sometimes in early childhood, there is an improvement in strength, although whether this represents a lessening of the disease or the child's natural growth is not certain. Conttactutes, particularly of the Achilles tendons, and congenital hip dislocation are commonly seen. Respiratory complications are common during the first 2 years of life, when the disease can be quite severe. As the children grow older, they remain weak and are short, with low weight. Accompanying the illness are various deformities of the feet, a high-arched palate, and kyphoscoliosis.

In congenital fiber-type disproportion, the EMG shows myopathic potentials but no evidence of muscle membrane instability (i.e., no fibrillation potentials or positive sharp waves). The serum CK level may be normal to slightly elevated. The muscle biopsy is diagnostic. The biopsy specimen in congenital fiber-type disproportion is characterized by a marked disproportion between the size of type 2 and type 1 fibers, with type 1 fiber atrophy and predominance. Originally, it was suggested that biopsy specimens in which the mean diameter of the type 1 fibers was 15% smaller than that of the type 2 fibers were indicative of the disorder. This assumption was a mistake, leading to the inclusion of patients with many different illnesses, such as CMD and FSHD. The diagnosis should only be made when the discrepancy between the type 1 and type 2 fibers is greater than 45% and when more than 75% of the fibers are type 1 (Figure 85.30). The reason for this discrepancy in fiber size is unknown.

The illness is inherited as an autosomal dominant trait in approximately 40% of reported cases. There is considerable debate in the literature on the specificity of this disorder, and many believe it to be a nonspecific biopsy finding. It is possible that this disorder represents nemaline myopathy without rods, a view that is strengthened by the fact that both rods and cores are inconsistently present in biopsy specimens from patients with both of these disorders. Only the appropriate DNA studies in the future will settle this question.

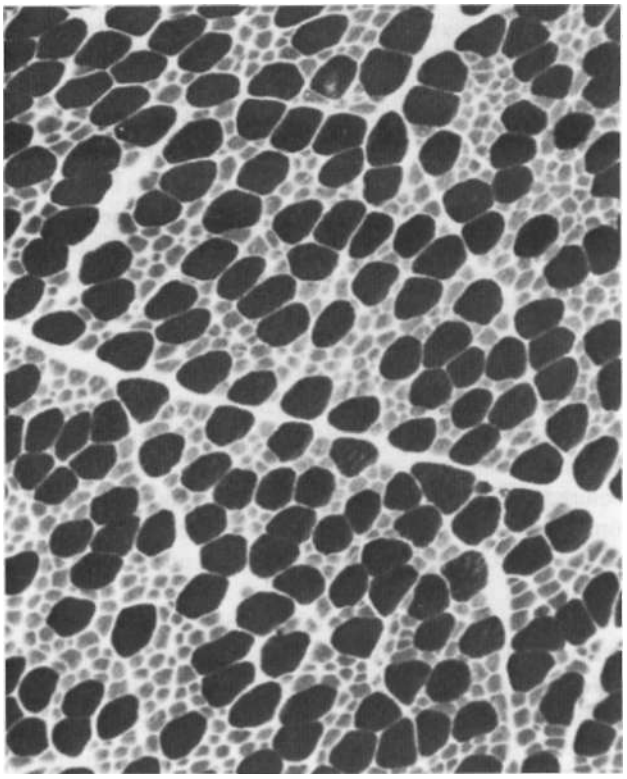

FIGURE 85.30 Congenital fiber-type disproportion. The diagnosis should not be made unless there is a clear discrepancy between hypertrophic type 2 fibers and atrophic type 1 fibers, as demonstrated in this picture. (Myosin adenosine triphosphatase stain, pH 9.4.)

Myofibrillar Myopathy

Myofibrillar myopathy (MFM) is characterized by the pathological finding of myofibrillar disruption on electron microscopic examination and excessive desmin accumulation in muscle fibers on immunostains (DeBleecker et al. 1996; Amato et al. 1998). Desmin is not the only protein that accumulates in this disorder; thus *myofibrillar myopathy* is the preferred term. This myopathy has been reported in the literature as desmin storage myopathy, desmin myopathy, familial desminopathy, spheroid body myopathy, cytoplasmic body myopathy, Mallory body myopathy, familial cardiomyopathy with subsarcolemmal vermiform deposits, myopathy with intrasarcoplasmic accumulation of dense granulofilamentous material, and hereditary IBM with early respiratory failure (Amato et al. 1998). In addition, some patients in whom other forms of distal myopathy were previously diagnosed

(e.g., Markesbery-Griggs-Udd distal myopathy) may actually have MFM.

A wide spectrum of clinical phenotypes exists {Amato et al. 1998). Most patients develop weakness between 25 and 45 years of age, but onset can occur in infancy or late .idnh life. Hither cardiac or skeletal muscles can be involved and dominate the clinical picture. Limb weakness can be predominantly distal and affect cither the arms or the legs. In other patients, proximal muscles are involved more than distal muscles. Facial and pharyngeal muscles can also be affected. Some patients have a facioscapulohumeral or scapuloperoneal distribution of weakness.

The cardiomyopathy may manifest as arrhythmias or conduction defects as well as congestive heart failure. Pacemaker insertion or cardiac transplantation may be required. Severe respiratory muscle weakness can also complicate MFM, In addition, there are rare reports of smooth muscle invohvmen! li'.uliiiy to intestinal pscudo obstruction.

The serum CK concentration is normal or only slightly increased. The ECG may demonstrate conduction defects or arrhythmia. An echocardiogram may reveal a dilated or hypertrophic cardiomyopathy. The EMG demonstrates markedly increased insertional and spontaneous activity with fibrillation potentials, positive sharp waves, and myotonic discharges. Motor units have myopathic morphological features and arc recruited early.

Muscle biopsies demonstrate variability in fiber size, increased central nuclei, and occasionally type 1 fiber predominance (Amato et al. 1998), Muscle fibers with rimmed vacuoles may also he evident. There are two major types of lesions seen on light and electron microscopic examination: hyaline structures and nonhyaline lesions. The hyaline structures are cytoplasmic granular inclusions that are typically eosinophilic on hematoxylin-eosiu stain and dark blue-green or occasionally red on modified-Gomori-trichrome stain. They appear as cytoplasmic bodies, spheroid bodies, or Mallory bodies on electron microscopic examination. The nonhyaline lesions appear as dark green areas of amorphous material on Gomori-trichromc stain. On electron microscopic examination, these nonhyaline lesions correspond to foci of myofibrillar destruction and consist of disrupted myofilaments, Z-disc-derived bodies, dappled dense structures of Z-disc origin, and streaming of the Z-disc.

Immunohistochemical examination reveals that both the hyaline and nonhyaline lesions contain desmin and numerous other proteins (Detileecker et al. 1996; Nakano et al. 1996). Immunohistochemical examination also reveals that the nonhyaline lesions react strongly for desmin, dystrophin, gelsohn, the N terminus of ^-amyloid precursor protein, and neural cell adhesion molecule (NCAM). However, the nonhyaline lesions arc depleted of actin, or-actinin, myosin, and less consistently of titin and nebulin. In contrast, the hyaline structures are composed of compacted and degraded remnants of thick and thin filaments and react to actin, a-actinin, and myosin in addition to dystrophin, gelsolin, and the N terminus of /^-amyloid precursor protein; they do not react to NCAM and react variably to desmin. Both types of lesions also react for *ciB*-crystallin, <*x-l* antichymotrypsin, and ubiquitin and can be congophilic. Interestingly, abnormal muscle fibers also abnormally express several cyclin-dependent kinases in the cytoplasm, including CDC2, CDK2, CDK4, and CDK7.

The pathogenesis of MFM is probably multifactorial, given the heterogeneous nature of the disorder. In most familial cases autosomal dominant inheritance is seen, although autosomal recessive or X-linkcd inheritance is possible in some families. Mutations in the desmin gene located on chromosome 2q.35 have been identified in several families with autosomal dominant myofibrillar myopathy as well as in a few occurrences of sporadic diseasi'. In addition, a homozygous or hemizygous mutation involving a 21-bp deletion in the first exon of the desmin gene was reported in a patient with presumed autosomal recessive inheritance of MFM. Mutations in the aB-crystallin gene on chromosome llq21-23 have been demonstrated in other patients. <*B-crystallin possesses molecular chaperone activity and is felt to interact with desmin in the assembly of the intermediate filament network. Some patients have no identifiable mutations in either the desmin or orB-cry stall in genes. The mechanism by which abnormal desmin or aB-crystallin leads to muscle cell destruction is not known.

Inflammatory Myopathies

Inflammatory eel hilar changes are sec: m tie muscle biopsies from patients with a wide range of myopathies and dystrophies. In many of these instances, the changes are presumed to be due to some other underlying disorder, hi the inflammatory myopathics, the basic disease is believed to be an abnormality of the immune system ot a direct infection of the muscle itself. Polymyositis and dermatomyositis are examples of abnormalities of the immune system, whereas the various forms of viral, bacterial, and parasitic infection of the muscle represent infections of the muscle. Pathological involvement of the muscle also may be seen in other autoimmune diseases, such as rheumatoid arthritis. Such involvement often is overshadowed by the primary condition.

Polymyositis and dermatomyositis, together with inclusion body myositis, represent the three most common inflammatory diseases seen by the clinician (Amato and Barohn 1997). Dermatomyositis and polymyositis both have an autoimmune basis, but the basic mechanism is very different. In dermatomyositis, the illness is the result of a humoral attack on the muscle capillaries, whereas in polymyositis the muscle fibers are under attack by cytotoxic T cells.

As in all autoimmune illnesses, the membrane-associated proteins, which are determined by the major

histocompatibility complex (MHC), play an important role. These molecules may act as antigens if they find theit way into an animal or human with a different characteristic type, In humans, the MHC system is equated with HLA typing. Class 1 antigens (HI.A-A, HLA-B, and HLA-C) are present on the membranes of virtually all ceils. Class 2 antigens (HLA-DR) are not so widespread and are limited predominantly to the lymphorcticular system, vascular endothelium, and some epithelia. For a cell to be the target of an attack from a cytotoxic T cell, the two cells must share the I II A class 1 molecule. The reactions in which CD4 cells participate require class 2 molecules to he shared. There is a predominance of B8 and DR3 antigens in patients with myositis. Although muscle normally expresses class 1 HLA molecules, class 2 expression may be induced under the influence of cytokines or other abnormal situations, T cells may be typed by means of a series of surface markers (CD markers) to determine whether they are cytotoxic, helper, inducer, and so forth. Because CD8 cells are involved in cytotoxic mechanisms, analysis of the type of cell involved in the cellular response is one way to determine whether the primary process is due re cellular or humoral factors.

Dermatomyos'ttis

Dermatomyositis is an illness in which weakness is associated with a characteristic skin rash. It is the common form of myositis occurting in childhood through middle adult life. The rash usually occurs with onset of muscle weakness, although it may develop during the course of the disease. It is characteristically a purplish discoloration of the skin over the cheeks and eyelids. It often has a butterfly distribution and blanches on pressure. Another area that may he affected is a V-shaped distribution on the chest below the neck. The rash may spread widely over the body and be associated with edema of the skin, which often becomes sealy and weeping. The skin over the elbows, knees, and knuckles is particularly prone to development of a reddened, indurated appearance (Gottron's sign and papules). Because the hallmark of the disease is the capillary abnormality, it may he helpful to use a hand lens to examine the skin around the nail beds. There small hemorrhages and looped, dilatated, and sometimes thrombosed capillaries often may be combined with avascular areas. The cuticle is discolored. In chronic, long-standing det ma tomyositis of childhood, the skin changes may be more disabling than the muscle weakness. In the terminal stage, the skin may be a shiny, fragile, shell-like covering that cracks at the slightest movement. Soft tissue calcification also is seen in some patients as die disease progresses; it usually occurs late in the illness and is not necessarily an indication of active disease,

The weakness is symmetrical and affects the proximal more than distal muscles of the arms and legs. Muscle pain is noted in one third of patients. The illness often follows a relapsing-remitting course, although occasionally it is clearly monophasic even to the point of recovering spontaneously without treatment.

Tissues other than muscle may also be involved, as mentioned later m the section on polymyositis, with lung, heart, and gastrointestinal findings being not uncommon.

Diagnosis, Serum CK concentrations are usually elevated in dermatomyositis but can be normal early or in patients whose disease has a very indolent course. Serum CK levels do not necessarily reflect activity of the disease. Thus one can see a clinical exacerbation unaccompanied by marked changes in serum CK concentrations in patients whose illness appears quiescent and who have a moderately elevated serum CK level. The CK concentrations may rise several weeks before a clinical relapse occurs.

The FMG demonstrates a combination of myopathic features together with indications of muscle hyperirritabiliry. Thus small polyphasic motor unit action potentials often are associated with increased insertional activity, fibrillation potentials, positive sharp waves, and complex repetitive discharges.

The characteristic histological feature of muscle biopsy specimens is perifascicular atrophy {a crust of small fibers surrounding a core of more normal-sized fibers deeper in the fascicle) (Figure 85.31). This feature is seen only in dennatomyositis and in overlap syndromes (see later).

FIGURE 85,31 Dermatomyositis. Perifascicular atrophy. (Myosin adenosine triphosphatase stain, pH 9.4.)

In addition, many fibets arc undergoing changes of degeneration and necrosis that cause them to lose the staining characteristics with many of the enzyme reactions. Importantly, perifascicular atrophy is an uncommon finding (occurring in less than 10% of biopsies in the authots' experience), particularly in adults and in patients who underwent biopsy early in the course of their illness. Before perifascicular atrophy develops, the expression of the membrane attack complex and immunoglobulins is seen in capillaries and small blood vessels, and MHC class 1 exptession is seen on petifascicular muscle fibers. Inflammatory infiltrates can he scant if present at all. When present, the inflammatory cells are located around blood vessels (perivascular inflammation) and in the perimysial connective tissue father than in the endomysium (Plate 85.1). Further evidence for humoral rather than cytotoxic factors is found in the relative preponderance of B and CD4 (helper) cells rather than CDS (cytotoxic cells) in the inflammatory reaction associated with the blood vessels. With advancing disease, the capillaries arc destroyed and the muscle undergoes changes that resemble microinfarction. The fibers atound the edge of the fascicles ate particularly affected (perifascicular atrophy) because this area constitutes the watershed region in terms of blood supply. Unlike polymyositis and inclusion body myositis, endomysial inflammation with invasion of non-necrotic muscle fibers by macrophages is not seen in dermatomyositis. Electton microscopic examination reveals tubuloreticular inclusions in endothelial cells, another early histopathological abnormality that precedes perifascicular atrophy.

Unfortunately, many patients with dermatomyositis haveless definite changes. Scattered fiber necrosis and phagocytosis, associated with some degtcc of perivascular cuffing, should always lead to the suspicion of detmatomyositis. When the cellular responses are only associated with the muscle fibets themselves, the diagnosis is less certain because some fotms of muscular dysttophy and other illnesses are associated with inflammatory responses around the muscle fibers.

Blood tests also provide evidence of an altered immune state with the development of unusual antibodies. These fall into different categories, depending on the type of antigen. One set is ditected against the tRNA synthetases (anti-synthctases), and, of these, the Jo-1 antibody against histidyl tRNA synthetase seems to be particularly imporlant because ol us .issnei.un >n will', ntcrstuial lung disease. It is present in more than 20% of patients with dermatomyositis and is relatively specific to this disease group. A seties of antibodies specific to myositis have also been found. Of these, atiti-Mi-2 seems to be specific to dermatomyositis, but the low rate of its occurrence makes it only moderately useful as a diagnostic test. Test results for antinuclear antibody and rheumatoid factors may be positive, particularly when evidence of other collagen vascular diseases is noted.

Polymyositis

Polymyositis is an acute or subacute illness that occuts mainly in adults. Occurrences of polymyositis occurring in infants and children are most likely to represent muscular dystrophies with inflammation. Polymyositis is tare (with an incidence of less than 5-10 per 1,000,000 population) and is less common than dermatomyositis and inclusion body myositis. It is most common in the 40- to 60-year-old population and occurs slightly more often in women than in men, as do other autoimmune diseases. There is nothing very characteristic about the weakness. One would expect an inflammatory disorder of the muscle to cause severe pain, but this is not the case with polymyositis. Although there may be an aching, tender quality to the muscles in approximately one half of patients with polymyositis, the more severe the pain is, the less likely is the diagnosis of polymyositis. There are often systemic symptoms at onset, such as malaise, fever, and anorexia. Sometimes, the illness is preceded by a viral prodrome, but such events are common enough in the general population that the it association with the onset of polymyositis may be no more than coincidental.

The neuromuscular examination tevcals little that allows the clinician to make a specific diagnosis. The weakness is genetally diffusely proximal rather than the specific distribution seen in the muscular dystrophies. Usually when patients have severe proximal weakness {e.g., Medical Research Council grade 4 or less), a good examination will detect distal weakness as well in a patient with polymyositis. If a patient has severe proximal weakness in the absence of any distal weakness, an LGMD should be suspected. Fye muscles and bulbar muscles usually arc not involved, but dysphagia associated with altered pharyngeal and esophageal motility may be seen, particularly in the overlap syndromes, in which polymyositis is associated with other rhrum.uological diseases, such as scleroderma. Occasionally, the muscles may be sore to palpation and have a slightly nodular, grainy feel. Tendon reflexes generally are decreased or absent in established disease bin nay he increased early n the course ol the condition.

Muscle is not the only tissue involved in inflammatory myopathies. Vascular abnormalities, such as Raynaud's phenomenon, occur in the overlap syndromes. Catdiac involvement ranges from conduction defects ro congestive heart failure due to an inflammatoty cardiomyopathy. Interstitial pneumonitis and fibrosis may cause a nonproductive cough and respiratory distress. Chest radiographs show changes in the majority of patients with patchy consolidation, particularly subplcural, and peribronchovascular thickening. The changes arc reversible with treatment (Mino ct al. 1997). Gastric and esophageal emptying may also be delayed in the illness, indicating an abnormality in the smooth muscle of the upper gastrointestinal tract.

The natutal history of polymyositis and dermatomyositis is not well defined. Attempts have been made to

characterize these disorders, but there has been no clear agreement on what diagnostic criteria can be used. The situation is complicated by the fact that most clinicians believe that these myositides should be treated with corticosteroids or immunosuppression; therefore the course of the untreated illness will never be discovered. When the disease is relentlessly progressive, death usually occurs from inanition, intercurrent infection, or cardiac and respiratory failure, often complicated by the side effects of corticosteroid therapy. The course commonly relapses and remits, especially when the disease is treated with immunosuppressants or corticosteroids. It is difficult to determine the mortality rate of rhe illness; some studies have placed this at 15-30%, In a study of 69 patients the 5-year survival rate was 66%, which is not very reassuring (Maugars ct al. 1996). A substantial number of patients have profound disability even though the illness is "burned out." The morbidity and mortality associated with high-dose immunosuppressive therapy, particularly corticosteroids, have to be considered in the prognosis of the disease.

Diagnostic studies for polymyositis are similar to those for dermatomyositis and include scrum CK concentrations, serum antibodies, and an EMC with muscle biopsy as the mainstay. Serum CK concentrations may be markedly elevated during the course of the illness. Anti-Jo-1 antibodies are found in one fifth of patients.

Polymyositis is a cell-mediated disorder, the immune attack being directed against some unknown antigen(s) on the muscle fibers. The inflammatory cells are predominantly composed of T lymphocytes (more CDS than CD4) and macrophages. The cytotoxic T cells are seen to surround and invade non-necrotic muscle fibers (Plate 85.0). Pcrifascicular atrophy and deposition of immunoglobulin or complement on small blood vessels are not seen.

The major unsolved question is how the immune system becomes activated. Viral mechanisms have long been suspected of playing a part in polymyositis and dermatomyositis. Coxsackie B virus has been implicated in both animals and humans as a cause of an acute myositis, and indirect evidence of Coxsackie B infection is found in a number of patients with polymyositis or dermatomyositis. Coxsackie B is a member of the same class of virus as the encephalomyocarditis virus (KMCV), another virus causing myositis. These picornaviruses have a shell made up of several coat proteins. The sequence of amino acids in a region of one of these proteins is very similar to the sequence in an enzyme (histidyl tRNA synthetase, the antigen to the Jo-1 antibody) present in many patients with polymyositis and to sequences in the myosin light chain. The coat protein of EMCV demonstrates additional homology with the myosin heavy chain. The induction of polymyositis might be due to infection with one of the picornaviruses, such as Coxsackie B or EMCV, which might induce the formation of an antibody against these viruses. However, al! this remains speculative, and supporting evidence is lacking at present. Polymyositis is more common in patients infected with the human immunodeficiency virus, which may infect the muscle tissue, directly damaging the vascular endothelium and releasing cytokines. Cytokines may then induce abnormal MHC expression and render the muscle tissue susceptible to destruction.

Dermatomyositis and Polymyositis Associated with Other Collagen Vascular Diseases (Overlap Syndromes)

lupus erythematosus, mixed connective tissue disease, systemic sclerosis, rheumatoid arthritis, and Sjogren's syndrome all may have weakness as a facet of the disease complex. The overlap syndromes are those in which features of all these illnesses coexist with an inflammatory myopathy. 1 he cluneal, laboratory, and histological features are otherwise typical of dermatomyositis or polymyositis.

Polymyositis or Dermatomyositis Associated with Neoplasia. A relationship between malignancy and polymyositis and, more particularly, dermatomyositis, has long been suspected. At one time, it was believed that the incidence of neoplasia in patients with dermatomyositis was approximately 50%, but subsequent studies showed that the incidence was much less, probably in the neighborhood of 10-20% overall. In elderly patients, particularly those with dermatomyositis, the incidence of an associated neoplasm is higher, reaching 100% in some series. The type of neoplasm is usually a carcinoma. The breast, lung, ovary, and stomach have been commonly affected. The incidence of carcinoma may simply represent the normal incidence in the particular population of patients referred, but in some series, the incidence has exceeded by many times that seen in the control population. In practical terms, it is wise to carry out a rectal and vaginal examination and obtain a chest radiograph, mammogram, pelvic ultrasound or CT scan, hematological studies, and a test for occult blood in the stools in any patient with adult-onset polymyositis or dermatomyositis.

Treatment of Dermatomyositis and Polymyositis. There have been no good double-blind trials of corticosteroid treatment in the myositides. In the therapeutic trials that have been conducted, the critctia on which the diagnosis was made in the different studies were quite varied. Nevertheless, there is general agreement that polymyositis and dermatomyositis should be treated with corticosteroids or some other form of immunosuppression or a combination of these (Amato and Barohn 1997).

Daily administration of prednisone may be used in the early stages of the disease in doses of up to 1.5 mg/kg or with a usual maximum of 100 mg. After 2-4 weeks the prednisone regimen can usually be switched to alternate day therapy (e.g., 100 mg every other day). In extremely weak patients or those with systemic involvement, a slower taper by 10 mg per week to an alternate day regimen (i.e., taking 10 weeks to taper to a dose of 100 mg every other

day) is recommended. When significant improvement has occurred, the prednisone dose can then be decreased by 5 mg every 2-3 weeks. Once the patient's dose is reduced to 20 mg every other day, further reduction continues in steps of 2.5 mg. If symptoms recur, it may be necessary to return to a higher dose of prednisone. If rhere is no response after 8-12 weeks, the clinician should seriously consider some oilier form nl treatment. The development ol significant side effects may influence use of this regimen. Side effects may be minimized in some patients by careful attention to diet and consumption of a high-potassium diet, salt restriction, use of Hi-receptor blockers, and use of adjunctive calcium.

A recent development is the use of high-dose intravenous pooled human immunoglobulin (IVIG) (2 g/kg per day over 2-5 days). In a controlled, double-blind trial of IVIG, patients with dermatomyositis showed improvement in functional ability and strength. IVIG was administered every month, with a total dose of 2 g/kg spread over a period of 2 days. The improvement was noted by the second or third treatment in most patients. Whether the improvement will be sustained over years is uncertain, The treatment itself poses some hazard and is extremely expensive. Thrombotic events may be seen in some patients. Common complications include vasomotor symptoms, headache, rash, leukopenia, and fever. Almost one half of patients have some minor adverse event. In our experience, IVIG is not very effective in polymyositis.

Most neurologists use azathioprine as their second-line agent of choice. Unfortunately, it often takes 9 months or longer to see an effect from azathioprine. It is tolerated easily by most patients in otal doses of 1.5-2.0 mg/kg per day. Before treatment is begun, a baseline complete blood count, platelet count, and livet function studies are obtained. Therapy often is initiated with a low dose (e.g., 50 mg per day in an adult). The dose then is increased gradually with monitoring of the blood studies. With an effective dose (usually 2.0-3.0 mg/kg), the white blood cell count may be reduced to around 4000, and the total lymphocyte count to approximately 750 cells/mL. An abnormal decrease in platelets to less than 150,000/ml. or a total neutrophil count of less than 1000/mL is an indication for reducing the dosage or stopping the drug temporarily. Blood studies should be obtained twice a week at first. After a stable dose has been attained, blood studies can be obtained weekly and then monthly. Liver function tests (aspartate aminotransferase [AST], alanine aminotransferase [ALT|, and y-glutamy I transferase [GGT|) should be performed monthly at the beginning of treatment. It is important to monitor the GGT concentration because it is specific for the liver, whereas AST and ALT concentrations can be elevated due to the underlying muscle disease. An idiosyncratic response to azathioprine is seen in some patients. This consists of severe gastrointestinal distress, with nausea and vomiting associated with fever and some elevation of the liver function test values. The response disappears when the drug is withdrawn. If it is not certain that such an episode is due to azathioprine, a test dose of 25 mg can be given, which usually causes the symptoms to recur within 1 hour or so. There are advantages to combining prednisone and azathioprine therapy because a lower dose of both drugs may be used in the combination than when each is used alone.

We prefer methotrexate as the second-line agent of choice rathet than azathioprine because it appears to wotk much faster (e.g., within 2-3 months). Methotrexate is usually administered orally at a dose of 7.5 mg per week and gradually increased as necessary up to 20 mg per week. If higher doses (up to 35 mg per week) are required, we .uln. . . .stei methotrexate intramuscularly or intravenously. Patients should be given folate at the same time.

Methotrexate can cause interstitial pulmonary fibrosis. For this reason, it is important to obtain measurements of anti-Jo-1 antibodies and pulmonary function tests for patients with inflammatory myopathies because of the associated risk nl M:\TS1III.I1 lur.;; dise • -•• \\ U;i myositis. We would avoid methotrexate in patients with interstitial lung disease. Methotrexate is also associated with hepatotoxicity and bone marrow suppression. As with azathioprine it is important to monitor results of complete blood counts and liver function tests in patients receiving methotrexate. Cyclophosphamide and mycophcnolate are also used.

Inclusion Body Myositis

This is the most common myopathy in patients older than 50 years of age and only rarely does it occur in anyone younger than 50. Unlike dermatomyositis, polymyositis, and other autoimmune disorders, inclusion body myositis is much more common in men than in women. The disease weakens the distal muscles of the arms and legs. The deep finger flexors (particularly of the ulnar two fingers), including the flexor pollicis longus and wrist flexors, are affected quite early and are almost always more involved than the wrist and finger extensors (Amato et al. 1996). In the legs there is early involvement of the quadriceps and anterior tibial muscles. Profound atrophy can be seen in the flexor forearms and quadriceps. Muscle atrophy and weakness arc often asymmetrical and may lead to an erroneous diagnosis of motor neuron disease (Dabby et al. 2001). However, unlike amyotrophic lateral sclerosis, there is no significant atrophy of the hand intrinsic muscles, fasciculations are absent, and deep tendon reflexes are normal or red need. The progression is gradual but relentless, and disability may be severe. Facial weakness and dysphagia may be found in approximately one third of patients. Muscle vvutis are absent. Sometimes the sporadic form occurs in a familial setting (Sivakumar et al. 1997; Amato and Shebert 1998). Thete are extremely rare cases of familial inclusion body myositis that should not be confused with hereditary inclusion body myopathies.

The disease generally has a chronic progressive course and is relatively unresponsive to prednisone and other immunosuppressive (e.g., methotrexate) and immunomodulating (e.g., IVIG) therapies (Griggs et al. 1995). Indeed, this is one of the criteria by which the diagnosis may be suspected. It is tempting to embark on a therapeutic trial when the inflammatory reaction is marked, hut the side effects of cotticosteroids and other immunosuppressive/ immunomodulating therapies in the elderly population are not to be taken lightly, particularly in the absence of any objective improvement with these agents in several double-blind, placebo-controlled trials.

The diagnosis of IBM should he suspected on the basis of the clinical history and examination and can usually be confirmed by muscle biopsy. The serum CK concentration may be normal or only mildly elevated (<10 times upper limit of normal). The EMG demonstrates fibrillation potentials and positive sharp waves. There is a mixture of small and large polyphasic motor unit potentials. These large motor units may represent a neurogenic process or remodeling of the motor unit that can be seen in a chronic myopathy

The muscle biopsy demonstrates endomysial inflammation, increased variation in fiber si/e with fiber hypertrophy, and macrophage invasion of non-necrotic muscle fibers similar to those seen in polymyositis. In addition, characteristic "rimmed" vacuoles may be profuse. On light microscopic examination, the structures have a sharply-demarcated vacuole, around which is a rim of altered tissue that stains red with trichrome stain and bluish-purple with hematoxylin-eosin (Plate 85.III). There are also inclusion bodies and eosinophilic inclusions in the nuclei and sometimes also in the cytoplasm adjacent to nuclei. Amyloid deposits arc seen in the vacuolated muscle fibers with Congo red and other stains (Plate 85,1V). Klectron microscopic examination demonstrates the presence of cytoplasmic and nuclear tubulofilamentous structures. The filaments are paired and twisted together and often are stacked in parallel arrays. They are 15-21 nm in diameter, with an inner diameter of 3–6 nm. There may also be orher paired helical filaments that are 6-10 nm thick. The paired helical filaments may now be detected with light microscopy using a commercial antibody (Askanas el al. $l^{l}J$"(.).

Unfortunately, because of sampling error the biopsy is not definitively diagnostic 20-30% of the time. When the muscle shows only a cellular reaction, the diagnosis may be considered if the clinical picture is typical (Griggs ct al. 1995; Amato et al. 1996). The absence of rimmed vacuole inclusions can lead to the misdiagnosis of polymyositis if the clinician is not attuned to the distinct differences in the clinical pattern of muscle weakness seen in inclusion body myositis and polymyositis.

Besides the presence of amyloid in vacuolated muscle fibers, there are also curious similarities to the changes seen in the brain in Alzheimer's disease. Investigation of the muscle using antibodies or probes against several proteins (including ^-amyloid, amyloid precutsor protein, prion protein, ubiquitin, o^{r}-antichymotrypsin, neuronal microtubule-associated protein, and *r)* has shown all of these to be associated with the vacuoles. Ubiquitin and a hyperphosphorylatcd form of T decorate the larger filaments, whereas /^-amyloid is in the smaller paired helical filaments and associated with more amorphous structures. The possibility that inclusion body myositis is also a disease with an abnormality in protein processing has been considered. An interesting and unexplained finding is that there is a protein in the muscle that binds single-stranded DNA and localizes to the nucleus and the vacuoles.

An increased number of deletions of mitochondrial DNA have also been found in patients with inclusion body myositis compared with normal age-matched control subjects. This is probably reflected in the increased number of cytochrome oxidase-ncgative fibers and ragged-red fibers noted on the muscle biopsy. The findings do not cast any light on the etiology of the illness, which shares no clinical features with the mitochondrial disorders (Moslemi et al. 1997).

Despite the fact that the histological hallmark of the disease is the inclusion body, the most abundant change in the biopsy from inclusion body myositis is the invasion of muscle fibers by $CD8^{+}$ cytotoxic cells, suggesting a cell-mediated cytotoxicity with an immune basis. This is reinforced by the presence of the necessary MHC class I antigens on the invaded muscle fibers. On the other hand, a study of patients treated with prednisone showed that although the cellular reaction was lessened, the patient's condition worsened along with the vacuolar changes, suggesting that the cellular response might be secondary (Barohn et al. 1995). Direct transfer of the /i-amyloid protein precursor gene into cultured muscle cells reproduced some of the changes seen in inclusion body myositis.

Other Inflammatory Conditions

Muscle often shows subclinical involvement in chronic granulomatous diseases, such as sarcoidosis and tuberculosis. Bacterial infection (pyomyositis) is rare outside of tropical countries, although it has been recorded. The organism involved is often *Staphylococcus aureus,* and sometimes *Streptococcus,* Usually, the large muscle groups, such as those of the thigh, are the sites of infection. The muscle is hot, painful, and swollen, and any movement exacerbates pain. Parasitic infections of muscles include those due to trichinosis, cysticercosis, and toxoplasmosis. In trichinosis, general symptoms of malaise and fever are associated with muscle pains and stiffness. There may be periorbital edema, and the jaw muscles commonly are involved. Laboratory studies include muscle biopsy, which may show evidence of hypersensitivity, such as eosinophilia and hypergammaglobulinemia. Treatment with thiobendazole has been recommended. Myopathies associated with

the retroviruses, such as human immunodeficiency virus, are discussed elsewhere {see Chapter 59E).

Polymyalgia Rheumatica

Polymyalgia rheumatica is an illness characterized by severe muscle pain. The clinician should be cautious about the indiscriminate use of this diagnosis without full investigation because of two major implications: the high incidence of temporal arteritis and the effectiveness of corticosteroid therapy. The diagnosis should be limited to those with the typical picture, including an increased erythrocyte sedimentation rate, and not used as an explanation for various aches, cramps, and pains. Women arc affected more commonly than are men, and the disorder is rare in patients younger than 55 years. The patient develops muscle stiffness and pain and a feeling that the **muscles** have "set." The arms are involved more commonly than the legs. Manipulation of the limb exacerbates the pain. The symptoms are particularly prominent in the morning when the patient arises and lessen as the patient loosens up. These symptoms may be associated with chronic malaise, pyrexia, **night** sweats, and weight loss. On examination, there are no specific muscle abnormalities other than soreness. There may be tenderness over the temples, reflecting temporal arteritis. The incidence of biopsy-positive temporal arteritis is about 20-30%.

The erythrocyte sedimentation rate is elevated (often more than 70 mm per hour), and this should be considered an essential part of the diagnosis of polymyalgia rheumatica. There may be a mild hypochromic anemia. Otherwise, results of laboratory studies arc generally normal. There is no elevation of the serum CK concentration, the EMG may be normal, and the muscle biopsy specimen may show type 2 fiber atrophy, a nonspecific finding that is not helpful in the diagnosis.

Polymyalgia rheumatica may be self-limiting but may take years to resolve. For this reason, prednisone and the nonsteroidal ami-inflammatory drugs have been recommended as a treatment. The response to prednisone may be quite dramatic, with resolution of symptoms in hours to days. For the most part, the doses can be lower than those used in other inflammatory autoimmune diseases. It is possible to commence with 30-50 mg of prednisone daily in an adult and maintain this dose for 2 months before a gradual decrease. Maintenance with a low dose of corticosteroids is often necessary for 2 years, and even then, only 24% of the patients were able to stop treatment in one prospective study.

Chapter 86
Neurological Problems of the Newborn

Alan Hi

Increased survival of premature newborns as a result of improved obstetrical care and especially of the treatment of neonatal respiratory disease has focused attention on the morbidity and mortality resulting from neurological complications. Rational management of neurological problems in newborns must be based on sound principles of basic science, human and experimental pathological conditions, and phyMoJot'K..il and Imiuiciiik.il mechanisms.

Advances in fetal assessment, especially the use of real-time ultrasound (US) scanning, have increased awareness of the prenatal origin of many neurological abnormalities detected in the newborn. In many instances, methods of fetal assessment allow a limited neurological examination of the fetus. Intrauterine intervention for prevention of brain injury may be considered the primary objective for optimal management of neurological disorders that manifest in the newborn. Optimal management demands expertise from many disciplines, including obstetrics, neonatology, genetics, neurology, and neurosurgery. A cooperative team effort often is the most effective approach to neurological problems in neonates, especially when difficult ethical decisions are involved.

In this chapter, the practical aspects of diagnosis and management of relatively common neurological problems of the newborn encountered by practicing neurologists are reviewed.

GENERAL PRINCIPLES Of INVESTIGATION AND MANAGEMENT

The importance of a detailed history and neurological examination for the assessment of the newborn with neurological problems cannot be overemphasized. Although the genetal framework of the neurological examination used in older children is applicable ro the newborn, observations must be interpreted on the basis of known maturational changes at different gesrational ages. The ev.imin.it ion •dion'J not he prolonged unnecessarilj, especially in premature infants, because even routine handling may contribute to hypoxemia, hypertension, and h\ pott usion.

Neurological examination is often limited by associated systemic illness and the use of complex life support systems, especially in premature infants. Therefore, considerable attention has been focused on determining the role of adjunctive noninvasive neurodiagnostic techniques for the assessment of neurological injury at varying gestational ages. At the present time, most neurodiagnostic

investigations performed in older children and adults also have clinical applications in newborns.

NEONATAL SEIZURES

Seizures in newborns are rarely idiopathic and may be considered to be the most common feature of significant neurological disease in the newborn. Prompt recognition is essential because seizures are often caused by serious underlying diseases that require treatment and because they may interfere with supportive care, such as ventilation and feeding. Experimental studies have shown a decrease in brain glucose concentration during prolonged seizures, an increase in brain lactate concentration, and excessive release of excitatory amino acids, which may interfere with DNA synthesis and subsequently with glial proliferation, differentiation, and myelination (Holmes et al. 1999). Although the implications of these experiments for the human newborn are not entirely clear, their relevance is suggested by in vivo studies with magnetic resonance spectroscopy, which have demonstrated an association between abnormally low phosphocreatine to inorganic phosphate ratios during seizures and long-term neurological sequelae.

Diagnosis

Table 86.1 summarizes the common types of neonatal seizures. These seizure types are not specific for cause, but some are seen more often with certain underlying conditions. Tonic seizures, which may represent decerebrate posturing, occur in up to 50% of prcmatute newborns with severe intraventricular hemorrhage (IVH). Focal clonic seizures in the term newborn are most commonly associated with focal cerebral infarction or traumatic injury, such as cerebral contusion (Mizrahi and Kellaway 1998).

Differentiation of Seizures from Nonconvulsive Movements

Simultaneous monitoring with an electroencephalogram (EEG) and video display in newborns with movements suggestive of "subtle seizures" have not shown consistent electrographic discharges concomitant with the movement. This suggests that the abnormal movements may be nonictal brainstem release phenomena rather than seizures. Similarly, tonic extensor posturing in newborns with severe IVH is not usually accompanied by epileptiform discharges and responds poorly to anticonvulsant therapy. Myoclonic seizures, which may evolve inro infantile spasms, often have a dismal outcome and must be distinguished from benign neonatal sleep myoclonus, which occurs in healthy newborns.

Jirteriness, an exaggerated startle response, is often confused with clonic seizures, especially because **both** jitteriness and clonic seizures occur in conditions such as hypoxic-ischemic or metabolic encephalopathies and in drug withdrawal. Jitteriness is distinguished clinically from seizures by the absence of associated ocular movements and the presence of stimulus sensitivity; the predominant movement is tremor that stops when the affected limb is passively flexed.

Determination of the Underlying Cause

Diagnosis of the underlying cause allows specific treatment and a more precise prediction of outcome. Table 86.2 summarizes the major causes of neonatal seizures, their usual times of onset, and prognosis. Seizures are often caused by several factors (e.g., the combination of intracranial hemorrhage, metabolic derangement, and hypoxic-ischemic injury). Benign genetic epilepsies rarely have their onset in the neonatal period; the only example is benign familial neonatal epilepsy, an autosomal dominant trait for which two separate chromosomal loci have been

Table 86.1; Types of neonatal seizures

Neonatal seizure types	*Clinical manifestations*	*Age distribution*
Subtle	Eye deviation, blinking, fixed stare Repetitive mouth and tongue movements Apnea Pedaling, tonic posturing of limbs	Premature and term
Tonic: focal or generalized	Tonic extension of limbs Tonic flexion of upper limbs, extension of legs	Primarily premature
["lonic: multifocal or focal	Multifocal, clonic, synchronous, or asynchronous limb movements Nonordered progression Localized clonic limb movements Consciousness often preserved	Primarily term
Myoclonic: focal, multifocal, or generalized	Single or several synchronous flexion jerks of upper more than lower limbs	Rare

identified on chromosome 20, which encodes for a potassium channel, and on chromosome 8 (Lerche et al. 1999).

Electroencephalography

Electroencephalography, particularly continuous monitoring of an EEG (when available), is a valuable aid in the diagnosis of neonatal seizures, especially in newborns who are paralyzed to assist ventilation and in those with suspected subtle seizures. EEG correlates of neonatal seizures are focal or multifocal spikes or sharp waves and focal monorhythmic discharges. Sharp transients arc normal in premature newborns and should not be confused with seizure activity. Similarly, the trace alternant pattern of quiet sleep in normal term infants, in which normal low-amplitude reactivity is preserved between bursts, must be distinguished from the abnormal burst-suppression pattern, in which long periods of voltage suppression or absence of activity are recorded between bursts of high-voltage spikes and slow waves (Biagioni et al. 1998).

The interictal EEG may have prognostic value. Severe suppression of the background activity, whether or not interrupted by high-amplitude bursts, is associated with an abnormal outcome in more than 90% of patients. In contrast, normal background activity is associated with good outcome.

Management

Neonatal seizures require iirgem Itvaimcni. Once adequate ventilation and perfusion are established, the blood glucose concentration is measured. If the glucose concentration is low, 10% dextrose should be administered in a dose of 2 ml/kg. In the absence of hypoglycemia, immediate treatment with anticonvulsant medications should be started, as outlined in Table 86.3. Studies for other underlying causes should proceed concurrently, and specific treatment should be initiated whenever possible.

Phenobarbital alone controls seizures in most newborns when adequate dosages are administered (up to a maximum of 40 mg/kg loading dose). Phenytoin 20 mg/kg is given if seizures continue (Painter et al. 1999). Fosphcnytoin, which is converted to phenytoin, has not been evaluated extensively in newborns, but initial data suggest that the rate of conversion is identical to that shown for older infants. Thus fosphcnytoin appears to have significant advantages over phenytoin and would be considered preferable to use (Takeoka et al. 1998). Seizures usually respond to intravenous loading doses of phenobarbital and phenytoin. When these drugs fail, other anticonvulsants (diazepam, lorazepam, and primidone) may be effective, but they are not recommended as first-hue drugs.

Phenobarbital may suppress seizures caused by hypocalcemia, and a favorable response does not exclude that diagnosis. Approximately 50% of newborns with hypocalcemia also have hypomagnesemia, which requires specific treatment.

I'yridoxinc deficiency is ,; rare causi ol neonatal seizures and should be considered whenever no other cause is determined. Most infants have an unusual paroxysmal pattern on an EEG with generalized bursts of synchronous high-voltage activity of 1^4 Hz intermixed spikes and sharp waves. The diagnosis of pyridoxine deficiency cannot be excluded on the basis of lack of response to a single latge dose of intravenous pytidoxine with concurrent LEG

Table 86.3: Treatment of neonatal seizures

I. Ensure adequate ventilation and perfusion		
II. Kcgin therapy for specific metabolic disturbances (if present)		
	Acute therapy	Maintenance therapy
Hypoglycemia: glucose {10% solution)	2 m1Ag IV (0.2 g/kg)	Up to 8 mg/kg/min IV
Hypocalcemia: calcium gluconate (5% solution)	4 mL/kg IV (Note: monitor cardiac rhythm)	500 mg/kg/24 hr PO
Hypomagnesemia: magnesium sulfate (50% solution)	0.2 ml/kg IM	0.2 mi/kg/24 hr IM
Pyridoxine deficiency: pyridoxine	50-100 mg IV	100 mgPO daily for 2 wk
III. Begin anticonvulsant therapy		
	Acute therapy	Maintenance therapy (begin 12 hr after loading dose)
Phenoharbital	20 mg/kg IV if necessary, additional 5-25 mg/kg IV in 5 mg/kg aliquots (Note: monitor blood pressure and respiration)	4-6 mg/kg/24 hr 1V/IM/PO
Phenytoin"	2 doses of 10 mg/kg IV, diluted in normal saline (Note: monitor cardiac rate and rhythm)	5-10 mg/kg/24 hr IV
Lorazepam	0.05-0.10 mg/kg IV	

* bos phenytoin may be the preferred form of phenytoin.
IV=intravenous; IM= intramuscular; PO= orally.

recording; rather, large doses (50-100 mg daily) should be given orally for several days.

Duration of Treatment and Outcome

The optimal duration of maintenance therapy for neonatal seizures has not been established. The duration of maintenance treatment for neonatal seizures depends on the risk of recurrence, the underlying cause (see Table 86,3), the neurological examination, and the EEC Phenytoin is usually discontinued when intravenous therapy is stopped, because adequate serum levels are difficult to maintain with oral phenytoin in the newborn. If seizures have stopped and the neurological examination and EEG are normal, phenoharbital may be discontinued before discharge from the hospital. If phenoharbital is continued after discharge, discontinuation should be considered as early as 1 month later based on the neurological status and EEG. Phenoharbital may be discontinued in an infant whose examination is not normal if the EEG does not show epileptiform activity. Concern has been raised about the potential deleterious effects of phenoharbital on brain development, and it is recommended that infants be treated with phenoharbital for the briefest possible time.

HYPOXIC-ISCHEMIC BRAIN INJURY IN THE TERM NEWBORN

Hypoxic-ischemic encephalopathy results from reduced oxygen delivery to the brain and from the excessive ncci:-inilariiin ot nn-rahi iu-v -ndi .-. lactate, free radicals, and excitotoxic amino acids. It is a major cause of morbidity and mortality in both premature and term infants. Hypoxic-ischemic cerebral injury in the premature newborn is discussed subsequently, together with IVH (see Hemorrhagic and Hypoxic-Ischemic Brain Injury in the Ptemature Newborn, later in this chapter). In this section, only hypoxic-ischemic injury in the tctm newborn is discussed. The pathophysiological and biochemical mechanisms that provide a rational approach to the diagnosis and management of neonatal hypoxic-ischemic encephalopathy are reviewed in Chapter 61. Because most hypoxic-ischemic brain injury in term infants occuts antepartum and intrapartum, prevention depends principally on optimal obstettical management, Advances in fetal heart rate monitoring, assessment of fetal movements, and the use of biophysical ptofile and scalp blood gases are helping to reduce the incidence and severity of acute hypoxic-ischemic encephalopathy.

Diagnosis

Because asphyxia is mainly an intrauterine event, a history of matetnal risk factors and abnormalities of labot and delivery must be documented carefully. An accurate history also may provide more precise information about the type of insult, which in turn may suggest a specific pattern of brain injury. The clinical features of hypoxic-ischemic encephalopathy arc determined by the severity, duration, and timing of the insult. Acute total asphyxia may cause disproportionate injury to tbalami, basal ganglia, and brainstem nuclei, whereas prolonged partial asphyxia causes injur) principal!) to cerebral coriev ami >.ii1v<>nic;i! white matter (Roland et al. 1998).

Table 86.4: Neuropathologies] patterns of neonatal hypoxic-ischemic brain injury and clinical correlation

Pattern of injury	*Neuropathoiogical injury*	*Clinical features in neonatal period*
vliviivi-]K-LI><:LI1 IUVUKK	Cerebral and cerebellar cortex thalamus, brainstem nuclei	Premature and term: coma, seizures, hypotonia, oculomotor abnormalities, abnormal sucking, swallowing
M.iiir, njannonitus	Thalamus, basal ganglia	Term > premature: unknown
Parasagittal	Cerebral cortex, subcortical white matter in parasagittal regions	Term: proximal limb weakness, upper > lower
Periventricular leukomalacia	Periventricular white matter	Premature: unknown (probably lower limb weakness)
Foe a l/mu I ti focal	Unilateral or bilarcral cerebral cortex and subcortical white matter	Premature and term: variable hemiparesis/ quadriparesis, stereotyped, nonhabituating reflex responses

The initial features of severe asphyxia are depressed level of consciousness, periodic breathing (due lo bihu-r.il hemisphere dysfunction}, hypotonia, and seizures. An apparent increase in alertness may occur between 12 and 24 hours, but seizures worsen and apnea may be noted. Between 24 and 72 hours of age, the level of consciousness deteriorates and brainstem abnormalities may become prominent. This timing corresponds to the development of maximum intracranial pressure. Specific patterns of weakness related to the distribution of neuronal injury may become evident (Table 86.4). After 72 hours, infants who survive show continued (although diminishing) stupor, abnormal tone, and brainstem dysfunction with disturbances of sucking and swallowing. The temporal profile of clinical features of severe hypoxic-ischemic encephalopathy in the term newborn are summatized in Table 86.5.

The classification of hypoxic-ischemic encephalopathy into mild, moderate, and severe is useful for prediction of outcome. Mild encephalopathy is characterized by increased irritability, exaggerated Moro and tendon reflexes, and sympathetic overreactivity. Recovery is usually complete within 2 days, and there are no long-term sequelae. Moderate encephalopathy with lethargy, hypotonia, diminished reflexes, and seizures is associated with a 20—40% risk of abnormal outcome. Infants with severe encephalopathy with coma, flaccid muscle tone, brainstem and autonomic dysfunction, seizures, and possible increased intracranial pressure cither die or survive with severe neurological abnormalities.

Electroencephalography and Cortical Evoked Responses

Hypoxic-ischemic encephalopathy is the single most important cause of seizures in term and premature newborns. Seizures associated with modetate or severe encephalopathy begin during the first 24 hours after the original insult and ate nototiously difficult to control. The pattern of background activity on the bL\G may have prognostic implications. Thus infants with a normal EEC 1 week after the initial insult usually have a favorable outcome,

Table 86.5: Clinical features of severe hypoxic-ischemic encephalopathy

Clinical features	*Time after insult*			
	0-12 br	*J 2-24 h;r*	*24-72 br*	*72 br*
Seizures	++	4-4-4-	4-4-	±
Increased intracranial pressure (full-term)		±	+++	
Stupor/coma	+++	++	+++	1
\pnea	+ (periodic breathing)	+ +	4-4-4-	1
Abnormal pupil/oculomotor responses		±	4-4-	
! 1; poionia	++4-	++ +	4-4-4-	+-t
Limb weakness	4-4-	4-	+	
Proximal, upper > lower (term)	±	±	±	J_
Hemiparesis	±	±	±	t
Lower limbs (premature)	±	±	±	±
Electroencephalographs features	Amplitude (suppression) frequency	Periodic pattern, ± mu!Itifocal sharp activity	Prominent periodic pattern ± more voltage suppression, isoelectric pattern	

Note: - = absent; ± = possibly present; 4- = present; ++ = more common; ++-J-= most common.

The usefulness of the visual, auditory, and somatosensory evoked responses in the diagnosis and prognosis of hypoxic-ischemic encephalopathy is less well established (see Chapter 36A). Limited data suggest a role for visual evoked responses in the diagnosis of periventricular [eukoninlacia (1'Vl,) and for auditors evoked responses in the diagnosis of brainstem injury.

Metabolic Parameters

Hypoglycemia, hypocalcemia, hyponatremia (inappropriate antidiuretic hormone secretion), and lactic acidosis may contribute to the neurological syndrome of hypoxic-ischemic encephalopathy. Metabolic derangements that are not corrected may worsen the cerebral injury (Hanrahan et al. 1998).

Neuroimaging

Neuroimaging is useful for locating and quantifying cerebral injury. Magnetic resonance imaging (MRI) and computed tomography (CT) in the term newborn (Figures 86.1 and 86.2) and US in the premature newborn are especially valuable. Decreased attenuation on a CT scan performed between 3 and 5 days of age shows the maximum severity of acute hypoxic-ischemic cerebral injury in the term newborn (see Figure 86.1). More precise anatomical delineation of mild brain injury or selective involvement of thalamus and basal ganglia or cerebellum may be assessed more accurately by MRI after the hypoxic-ischemic episode (Rutherford et al. 1998; Aida et al. 1998; Mcrcuri et al. 1 999). More advanced MRI techniques may prove especially useful; e.g., diffusion-weighted MRI may permit earlier diagnosis of injury (Indcr et al. 1999) and volumetric MRI may permit quantitative assessment of cerebral tissue loss,

Several newer techniques that provide insight into functional disturbances of newborn hypoxic-ischemic cerebral injury may have important implications for management. Positron-emission tomography, single-photon emission computed tomography, and near-infrared spectroscopy show disturbances of cerebral perfusion. Magnetic resonance spectroscopy shows decreased brain levels of high-energy phosphates in asphyxiated infants.

Management

Optimal management begins in utero by measures to prevent hypoxic-ischemic injury. Fetuses at risk must be identified early, monitored serially (discussed earlier), and considered for cesarean delivery when signs of fetal distress persist. An asphyxiated newborn requires immediate treatment to prevent additional hypoxic-ischemic cerebral injury. This includes close attention to ventilation, perfusion, blood glucose concentrations, control of seizures, and

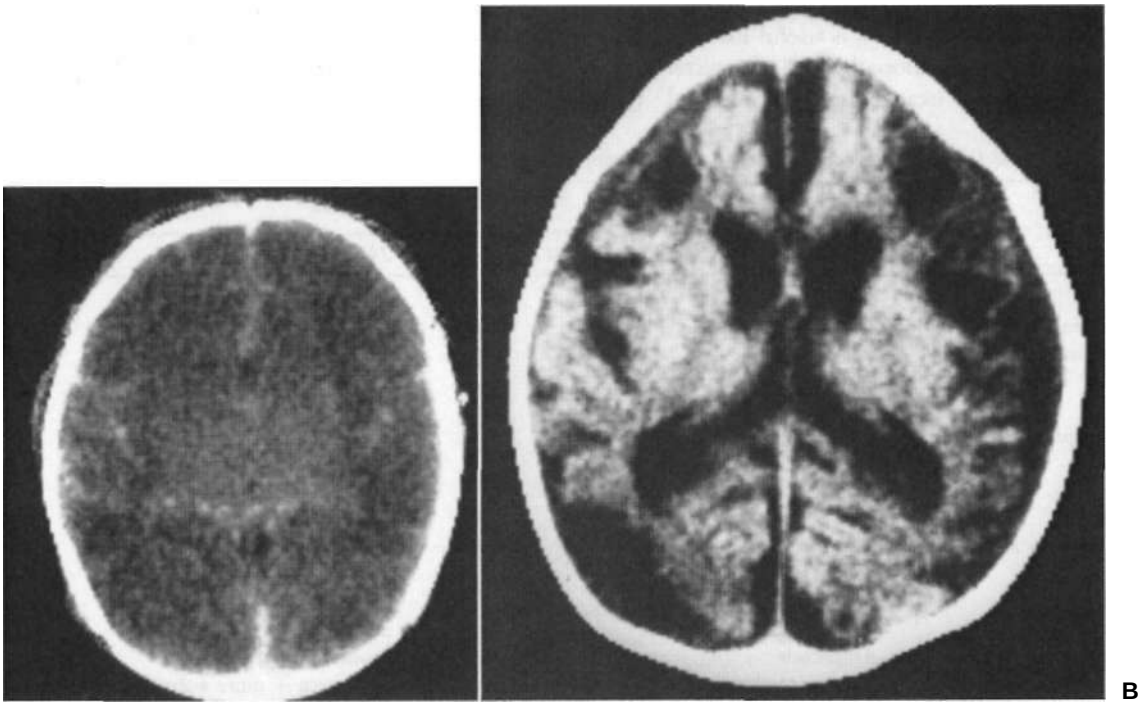

FIGURE 86.1 Computed tomographic scans of severely asphyxiated term newborn, (A) Sean at 3 days of age demonstrates diffuse low attenuation. (B) Scan at 5 months demonstrates wide sulci and enlarged ventricles consistent with severe generalized atrophy.

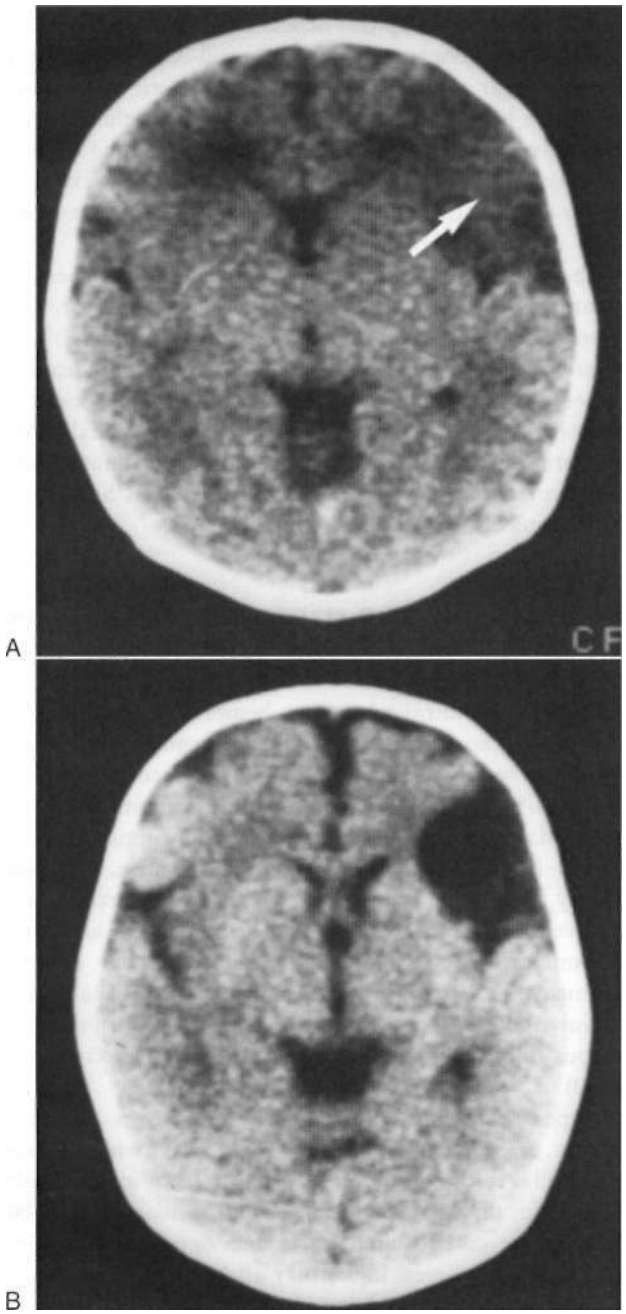

FIGURE 86.2 Computed tomographic scans demonstrate evolution of focal ischemic lesion in term infant who presented with focal seizures. (A) Scan at 3 days of age. Note low tissue attenuation in distribution of left middle cerebral artery *(arrow).* (B) Scan at 2 months of age. Note marked tissue loss in this region.

maintenance of perfusion and function of other affected organs, including the heart, liver, kidneys, and gastrointestinal tract.

Maintenance of Adequate Ventilation

Maintenance of adequate ventilation and avoidance of hypoxemia and hypercapnia are critical to outcome. Recognition of hypoxemia and hypercapnia has been facilitated by the availability of continuous transcutaneous oxygen and carbon dioxide monitoring. Significant hypoxemia occur in thi[1] premature newborn during routine care, such as suctioning or venipuncture; minimal handling is recommended. Persistent pos:n;ilal hypoxemia is caused by the respiratory distress syndrome in premature newborns and by persistent fetal circulation and pulmonary hypertension in term newborns. Overcorrection of hypoxemia should he avoided because hypcroxemia may cause chronic lung injury and retrolental fibroplasia as well as ponrosubicular necrosis, a specific pattern of selective neuronal necrosis involving principally the hippocampal and pontine neurons, I iypcrcapnia is deleterious because it worsens intracellular acidosis, impairs cerebrovascular autoregulation, or does both, with development of a pressure-passive cerebral circulation. The potential effects of hypocapnia on cerebral blood flow in the newborn have not been established. Experimental and human data do not support the use of hyperventilation in asphyxiated newborns, except perhaps in those with persistent fetal circulation.

Maintenance of Adequate Perfusion

The maintenance of adequate perfusion is critical to prevent further cerebral ischemia. Management of perfusion must be based on knowledge of normal systemic arterial blood pressure levels in the newborn at all gestational ages. Systemic hypotension must be avoided because cerebral blood flow is not autoregulated in asphyxiated newborns and reflects systemic blood pressure in a pressure-passive manner. Transitory myocardial ischemia, a common cause of hypotension in asphyxiated newborns, may respond to inotropic agents such as dopamine. Other important causes of systemic hypotension that may result in decreased cerebral perfusion are patent ductus arteriosus and recurrent apneic spells with bradycardia. Because of the pressure-passive relationship between the systemic and cerebral circulations, systemic hypertension must be avoided also, especially in the premature infant, in whom the presence of vulnerable germinal matrix capillaries predisposes to the development of 1VH.

Hyperviscosity due to polycythemia (venous hematocrit *>65%)* may further impair cerebral perfusion in asphyxiated newborns, especially in those who are small for gestational age. Jitteriness, apnea, poor feeding, and seizures are concomitant neurological features in approximately 40% of these newborns. Partial exchange transfusion with plasma is indicated in ail symptomatic newborns with polycythemia and perhaps also in those who are asymptomatic.

Prevention of Metabolic Derangements

Fluid overload is an important consideration in the maintenance of metabolic homeostasis. Inapptopriate

antidiuretic hormone secretion is common during the first 3 days after a severe hypoxic-ischemic episode and may lead to hypo-osmolality and hyponatremia, which in turn increase brain water content (cerebral edema) and seizures. The role of glucose supplementation in the management of **the asphyxiated** newborn is unclear. We recommend maintaining blood glucose concentrations in the normal r:iii.!!i'.

Control of Brain Swelling

The contribution of brain swelling to neurological outcome in terra newborns with hypoxic-ischemic encephalopathy is controversial. Experimental data from animals and human newborns suggest that brain swelling with increased intracranial pressure is a consequence of tissue necrosis rather than a cause of brain damage in scvete hypoxic-ischemic encephalopathy, and it is not associated with transtentorial or transmagnal herniation. Clinical evidence of increased intracranial pressure, a bulging anterior fontanelle, is most evident between 36 and 72 hours after the initial asphyxial episode. Mannitol reduces intracranial pressure in asphyxiated newborns, but its beneficial effect on outcome is not proven. Surveillance of intracranial pressure by palpation of the anterior fontanelle or by noninvasive monitoring with the Ladd monitor may have prognostic value. Elevated intracranial pressures 36-72 hours after the asphyxial episode correlate with extensive low attenuation of tissue on CT scans and a poor outcome.

Prognosis

Severe hypoxic-ischemic encephalopathy causes widespread injury. The resulting clinical features are microcephaly, mental retardation, seizures, and spastic quadnparesis (see Chapter 67). Less severe encephalopathies mainly injure the parasagittal regions, causing shoulder weakness. Involvement of tbalami and basal ganglia is often associated with choreoathetosis and dystonic cctebral palsy, which may be delayed in onset. Unilateral focal lesions result principally in hemiplegia.

Selected aspects of the neurological syndrome and neurodiagnostic studies are helpful in determining outcome in lupoxK ischemic encephalopathy (Table 86.6). Because most instances of hypoxic-ischemic encephalopathy begin before birth, assessment of fetal well-being in utero is useful. Apgar scores at I and 5 minutes are notoriously unreliable because of interobscrver variability, the effects of drugs given to the mother before delivery, and the stress of delivery, which may be reversible. In contrast, low extended Apgar scores after 10 minutes, may suggest that a major prior insult has occurred.

The severity and duration of hypoxic-ischemic encephalopathy is the single most useful prognostic factor. Our experience indicates that newborns who may have sustained intrapartum asphyxia but do not develop features of neonatal encephalopathy will not have major long-term neurological morbidity. The features of encephalopathy that are most predictive are its seventy and duration and the occurrence of seizures. Abnormalities on US, CT, and MRI scans also predict poor outcome.

Tabic 86.6: Prognostic factors in hypoxic ischemic encephalopathy in term infants

Neonatal encephalopathy: severity and duration (>J-7 days)
Presence of seizures
Presence of brain swelling
Electroencephalography: isoelectric, suppressed background, hurst-suppression
Radiological investigations: computed tomography, ultrasound, magnetic resonance imaging.

HEMORRHAGIC AND HYPOXIC-ISCHEMIC BRAIN INJURY IN THE PREMATURE NEWBORN

Periventricular-intraventricular hemorrhage (PIVH) is reported in approximately 20% of premature newborns with birth weight less than 1.500 g. PIVH occurs on the first day in 50% of affected premature newborns and before the fourth day in 90%. PIVH originates from rupture of small vessels in the subependymal germinal matrix. Approximately 80% of germinal matrix hemorrhages extend into the ventricular system. Severe hemorrhages are often accompanied by hemorrhagic lesions in the cerebral patenchyma. Parenchymal hemorrhages are usually unilateral and are considered to result from hemorrhagic venous infarction in the periventricular region (Volpe 2000).

Hypoxic-ischemic injury in the premature newborn affects predominantly the periventricular white matter bilaterally, resulting in PVL. This pattern of injury results in spastic diplegia, quadtiplcgia, or visual impairment because the corticospinal tracts and optic radiations are involved. More severe injury may affect the cerebral cortex, resulting in microcephaly and cognitive impaitment.

Diagnosis

The high incidence of PIVH in premature infants has led to the routine use of US scanning at 3-4 days in all newborns of less than 32 weeks' gestation. CT or MRI and US scans are informative, bur US is generally considered to be the technique of choice because it can be performed noninvasively in the intensive care nursery and there is no ionizing radiation involved. CT and MRI remain the techniques of choice for demonstration of epidural, subdural, and subarachnoid hemorrhage as well as most inttaccrcbral and posterior fossa hemorrhages.

PIVH can be predicted on the basis of clinical features in only 50% of patients in whom the hemorrhages have extended from the germinal matrix into the ventricular system. The spectrum of clinical features associated with PIVH ranges from an asymptomatic state, through stepwise neurological deterioration over several days, to rapid catastrophic deterioration characterized by coma, apnea, generalized tonic seizures, brainstem disturbances, and flaccid quadriparesis. Severe hemorrhage may be associated with the systemic abnormalities, which include metabolic acidosis, hypotension, bradycardia, and abnormal glucose and water homeostasis. Bloody or xanthochromic cerebrospinal fluid (CSF) from lumbar puncture also suggests PIVH.

CT scans have limited value in assessing acute hypoxic-ischemic cerebral injury in premature newborns because the immature brain has a high water content and low tissue attenuation is a normal feature. PVI. may be suggested on routine US scans in premature newborns by increased echogenicity in the periventricular regions during the first days of life and subsequent cyst formation in the same areas after the first several weeks (Figure 86,3). The ability to distinguish between hemotrhagic and ischemic injury (Figure 86.4} and to reliably identify mild or diffuse injury in the white matter with US is limited. MRI performed at term shows increased signal in cerebral white matter on T2-weighted images. Diffusion-weigh ted MRI may demonstrate diffuse white matter injury-even earlier than conventional MRI (Indcr et al. *1999).* After the neonatal period, PVL can be demonstrated by CT or MRI.

Pathogenesis and Management

Table 86.7 summarizes the current concepts of pathogenesis and management of PIVI I. Fluctuations of cerebral blood flow are a major factor in the pathogenesis of PIVH.

The primary management strategy for PIVH is prevention. Ideally, this is accomplished by preventing premature delivery. If premature delivery cannot be prevented, several strategies have been proposed, directed against the known intravascular, vascular, and extravascular mechanisms of hemorrhage. Muscle paralysis with pancuronium bromide in ventilated premature newborns has an established role in reducing the incidence and severity of PIVH by stabilizing fluctuations of cerebral blood flow. The role of other agents is less well established. Phenobarbital may dampen fluctuations of systemic blood pressure and cerebral blood flow and may have other cellular neuroprotective effects. However, one important study reported an increased incidence of PIVH in infants treated with phenobarbital. Indomethacin inhibits prostaglandin synthesis, thereby regulating cerebral blood flow. It prevents PIVH in animal models, but its efficacy in humans is inconclusive. Two other agents. •: itatnin I' and ethamsylnre, may hold promise for preventing PIVH, but the data are insufficient to recommend their routine use (see Table 86.7).

After PIVH has occurred, treatment is focused on preventing extension of hemorrhage, which occurs in 20-40% of patients, and preventing further hypoxic-ischemic cerebral injury. Severe 1VH may decrease circulating blood

FIGURE 86..1 Cystic periventricular leukomalacia. Parasagittal ultrasound scan performed 5 weeks after intraventricular hemorrhage and hypoxic-ischemic insult. Note cystic lesion *(arrow).*

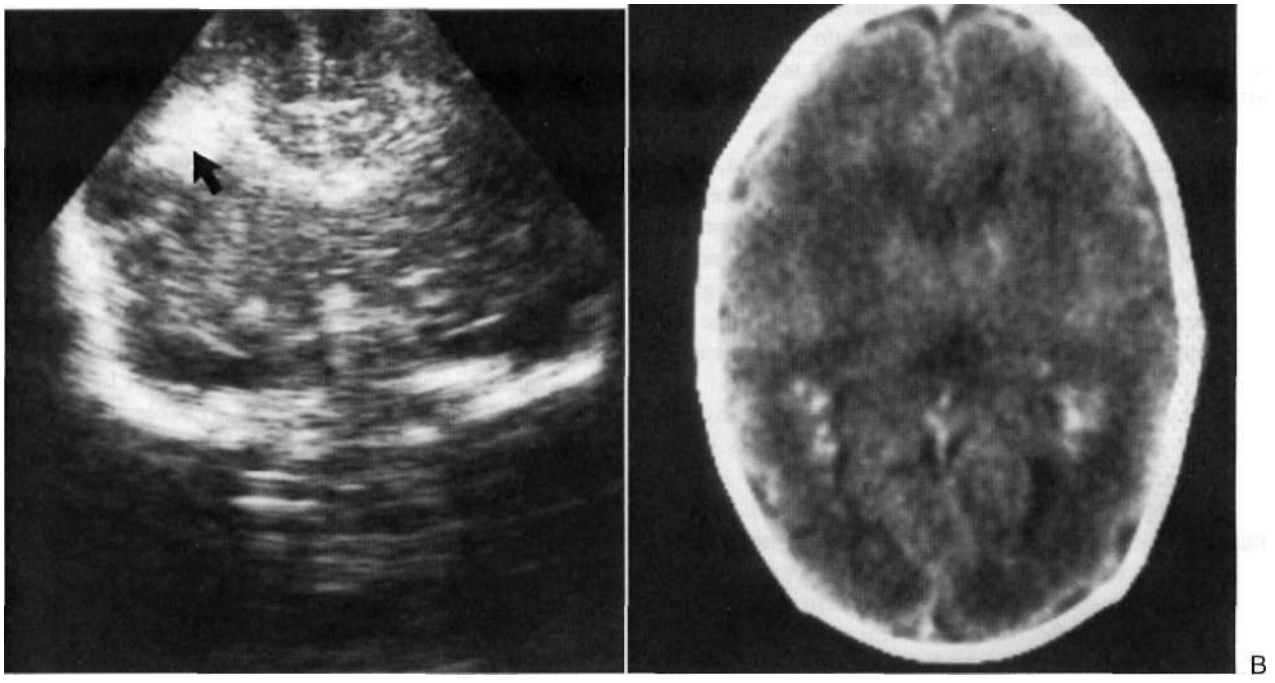

FIGURE 86.4 Hemorrhagic and nonhemorrhagic periventricular leukomalacia. (A) Ultrasound (US) scan demonstrates increased echoes in periventricular region *(arrow).* (B) In a computed tomographic scan performed at the same time, however, note the absence of hemorrhage in regions corresponding to increased echoes on the US scan. This illustrates that echogenicity on US examination does not distinguish between ischemic and hemorrhagic injury.

volume sufficiently to cause systemic hypotension that needs to be corrected by blood transfusion.

Serial US scans and measurements of head circumference are needed in every newborn with PIVH for early diagnosis of the development of posthemorrhagic hydrocephalus (Figure *86.5).* This complication is caused by arachnoiditis in the posterior fossa, by aqueductal obstruction, or by both. Significant ventriculomegaly may precede measurable

Table 86.7: Pathogenesis and management of periventricular-intraventricular hemorrhage

Pathogenesis	*Management*
Intravascular factors	
Fluctuating cerebral blood flow	Paralysis of ventilated preterm infants with pancuronium bromide
Increases in cerebral blood How	Avoidance of systemic hypertension associated with routine handling and rapid volume expansion, exchange transfusions, colloid infusions, seizures, pneumothorax

increases in head circumference. Factors that influence the management of posthemorrhagic hydrocephalus are the rate of progression, ventricular size, and intracranial pressure. In approximately 50% of premature newborns with posthemorrhagic hydrocephalus, vemrieulomegaly arrests or resolves spontaneously without intervention, usually within 4 weeks (see Figure *86.5).* In the other 50%, dilatation progresses beyond 4 weeks and requires intervention. However, rapid ventricular enlargement with clinical evidence of increased intracranial pressure requires intervention before 4 weeks of age. The definitive treatment is placement of a ventriculoperironeal shunt, but temporary measures are often needed. These measures include CSF drainage by serial lumbar punctures, external ventriculostomy, placement of a ventricular catheter with subcutaneous reservoir or subgalcal shunt, and administration of drugs that reduce CSF production, such as osmotic agents (isosorbide and glycerol) and carbonic anhydrase inhibitors and diuretics (acetazolamide and furosemidc). In infants with rapidly progressive hydrocephalus, placement of a ventriculoperitoneal shunt is often indicated, despite the morbidity associated with shunt placement in small, premature infants.

Prognosis

The prognosis after PIVH relates to the severity of hemorrhage and to the concomitant hypoxic-ischemic cerebral injury. Germinal matrix hemorrhage alone is rarely a cause of significant neurological morbidity. The prognosis after blood is found in the ventricles is relatively good unless ventricular dilatation occurs. Newborns with severe ventricular dilatation and intraparenchymal hemorrhage may die in the neonatal period, and most survivors develop posthemorrhagic hydrocephalus. Prognosis does not always correlate with the severity of PIVH and posthemorrhagic hydrocephalus; hypoxic-ischemic parenchymal injury, principally PVL, is the other important variable that cannot be overlooked. However, PVL may be more difficult to document radio logically (Ment ct al. 1999).

INTRAVENTRICULAR HEMORRHAGE IN THE TERM NEWBORN

Although IVH is considered to be primarily a lesion of the premature newborn, it has been reported to occur in approximately 3.5% of healthy term newborns. The pathogenesis of major IVH in term newborns is similar to that in premature infants in that hypoxia and trauma are relevant factors in approximately 50% of infants. However, traumatic delivery may be relatively more significant, presumably causing increased cerebral venous pressure and alrered cerebrovascular autoregulation. I-ml lu-: i in n\-. tin[1] s:;cs u1 origir. <i IVI I an more variable in the term newborn and include residual germinal matrix (2%), choroid plexus (1.1%), vascular malformations, tumor, or hemorrhagic venous infarction of the thalamus (Roland et al. 1998). IVH from the latter usually presents somewhat later, at several days or weeks of age.

The diagnosis and management of IVH and its complications in the term newborn are similar to those described for premature newborns. IVH may be suspected clinically and confirmed by ncuroimaging.

The prognosis for IVH in the term newborn may be worse than that for premature newborns, in whom less

severe lesions comprise the majority of cases. Long-term neurological sequelae are reported in more than 50% of infants and are related principally to associated parenchymal damage and to the underlying etiology, especially trauma and hypoxic-ischemic insult. Approximately 50% of term newborns with IVH develop posthemorrhagic hydrocephalus, which requires the placement of a ventriculoperitoneal shunt and an additional 20% develop ventricular dilation, which arrests or resolves spontaneously.

INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Bacterial infections of the central nervous system (CNS) in the newborn include bacterial meningitis, epidural and subdural empyema, and brain abscess.

Neonatal Meningitis

Bacterial meningitis is more common in premature than in full-term infants and generally has a two-fold pattern of illness: "early-onset" disease within the first days of life caused by group B streptococcus, *Escherichia colt,* and *Listeria monocytogenes* acquired from an infected birth canal and "late-onset" disease after several days, which may be acquired from the mother or other contacts in the environment and may be caused by the organisms listed above, as well as by *Staphylococcus* or *Pseudomonas aeruginosa.* Maternal genital infection with group B streptococcus (which is usually asymptomatic) and maternal urinary tract infection during the weeks before delivery are considered to be particularly high-risk situations. Because as many as 20-30% of cases of neonatal sepsis are complicated by meningitis and because early diagnosis and treatment are critical to prevent morbidity and monthly, mniba: puncture must be performed .is soon .is a newborn appears sick; one cannot wait for the typical cliuiL.d Icaraics nt meningitis, such as a bulging tontanellc, neck retraction, seizures, irritability, pallor, and poor feeding. The characteristic CSF ptofile is pleocytosis, increased protein concentration, decreased glucose concentration, and identification of the otganism by Gram's stain and culture. Laboratory techniques that allow rapid detection of bacterial antigens also may be useful (e.g., Immunoelectrophoresis, latex agglutination, and radioimmunoassays). Valuable supporting data regarding the probable bacterial etiology may be derived from isolanon of an organism from body fluids other than CSF.

Management

In an attempt to prevent neonatal meningitis, the American College of Obstetrics and Gynecology and the American Academy of Pediatrics recommend intravenous administration of ampicillin during labor for mothers with rectal or genital cultures positive for group B streptococcus or other major risk factors for neonatal sepsis {Schrag et al. 2000). The initial empiric treatment of a neonate with bacterial meningitis of unknown cause is a combination of ampicillin, an aminoglycoside such as gentamicin, and possibly cefotaxime administered intravenously. The precise dosage varies according to the body weight and postnatal age of the affected infant. The optimal selection of antibiotics is determined when definitive bacteriological diagnosis is known and by the resistances of the infecting organism. Repeated sampling of CSF is required to ensure response to treatment. Parenteral antibiotic treatment is usually maintained for 21 days or at least 2 weeks after sterilization of CSF. A repeat CSF examination should be performed 48 hours after discontinuation of antibiotic therapy.

In addition to antimicrobial therapy, supportive measures such as maintenance of fluid and electrolyte balance and control of blood pressure and blood gases are essential. Because the syndrome of inappropriate antidiuretic hormone secretion is common, fluids should be restricted to 30-40 ml./kg per day during the first few days of illness. Seizures are a common complicarion and should be treated with pbenobarbital, phenytoin, or both (see Table 86.2). Serial measurements of head circumference and cranial US scans permit early diagnosis of the complications of ventriculitis, hydtocephalus, and subdural effusion.

Ventriculitis commonly causes hydrocephalus, either durine the acute phase ol the illness or subsequently {Figure 86.6). Meningitic hydrocephalus is treated by external ventricular drainage, often with a reservoir for intermittent draining of CSF, instillation of antibiotics in selected infants if active infection is present, or both. Most newborns require a permanent ventriculoperitoneal shunt after the infection has been eradicated.

Cerebral abscess is a rare complication of neonatal meningitis. It occurs most often with *Citrobacter* infection but may also occur after other virulent gram-negative infections or rarely, gram-positive organisms. Abscess should be suspected when newborns with increased intracranial pressure respond poorly to treatment. Diagnosis is confirmed by brain imaging. The duration of antibiotic therapy is prolonged, and surgical exploration and drainage are usually considered to be the treatments of choice. The mortality is approximately 15%, and survivors often have major neurological impairment.

Prognosis

The important variables that determine mortality are the type of infecting organism and the gestational age of the infant. Mortality is reportedly between 20-30% and is highest for gram-negative infections. Permanent

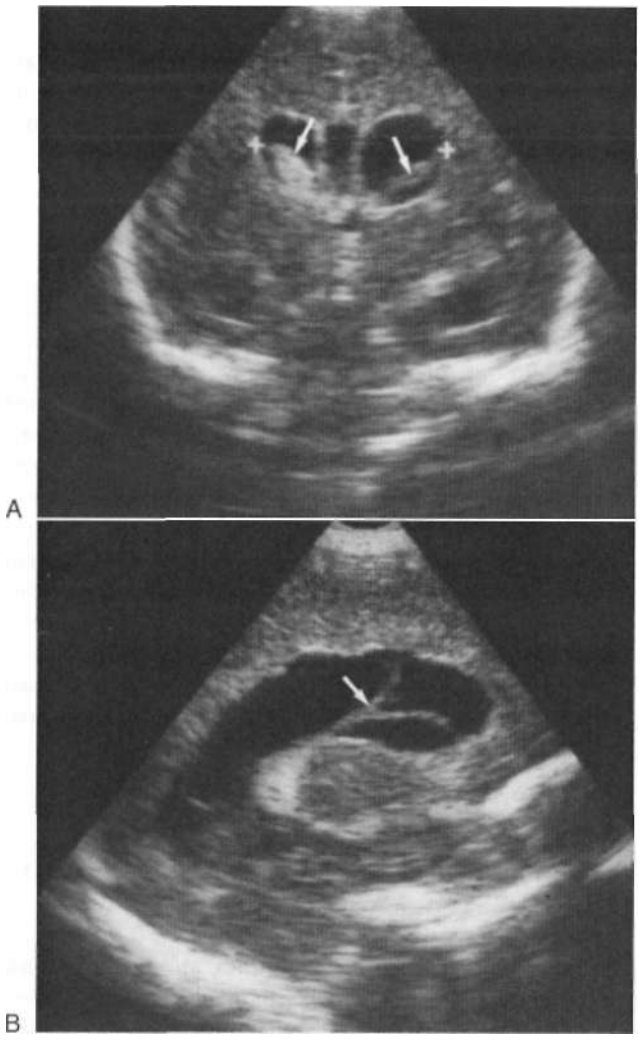

FIGURE 86.fi Ultrasound scans of newborn infant with bacterial meningitis and ventriculitis. Note intraventricular strands in both (A) coronal and (B) parasagittal images *[arrows).*

neurological sequelae occur in 30-50% of survivors and include hydrocephalus, cerebral palsy, epilepsy, intellectual deficits, and deafness.

Viral and Parasitic Infections

Viral, protozoan *{Toxoplasma gondii),* and fungal infections occur in the newborn. The acronym TORCH is used as a reminder of the major nonbacterial neonatal infections: toxoplasmosis, others (such as syphilis), rubella, cytomegalovirus (CMV), and /jcrpes simplex. All of the TORCH infections occur during pregnancy by transplacental inoculation, except for herpes simplex, which usually is contracted by passage of the fetus through an infected birth canal. Although most newborns with 1 OIU 1 I syndromes have clinical features of disease during the first month of life, symptoms can be delayed until later infancy and childhood.

Congenital Rubella

Although the incidence of congenital rubella infection has diminished markedly since widespread use of the rubella vaccination, it remains a significant problem in many parts of the world (Zerr et al. 2001; Reef et al. 2002) The congenital rubella syndrome occurs when the fetus is infected before 20 weeks' gestation. The clinical features in the newborn include low birth weight, jaundice, hepatosplenomegaly, petechial rash, congenital heart disease, cataracts, sensorineural deafness, microcephaly, bone lesions, and thrombocytopenia. Less severely affected infants appear normal at birth and later show features of neurological and ocular defects, deafness, and congenital heart disease. Infected infants arc highly infectious, may shed virus for several years, and must be considered a hazard to nonimmune women. Diagnosis is confirmed by culture of virus (throat swab and urine) and demonstration of rubella-specific immunoglobulin M (IgM) in neonatal plasma. Neuroimaging may reveal periventricular calcifications, subependymal cysts, or PVL. The only effective management is prevention by universal immunization. Antiviral treatment is unavailable. Infants who survive may develop progressive sensorineural hearing loss, behavioral •nunriou.i. prob-Mm, *y.um* ih failure, or Jialv;,'-, mellitus later in childhood.

Cytomegalovirus

CMV infection is the most common congenital viral infection and results cither from primary maternal infection or from reactivation of virus in the mother. Almost all newborns with congenital CMV infection are asymptomatic. The fewer than 10% who arc symptomatic have hepatosplenomegaly, jaundice, perechiac, microcephaly with periventricular calcifications, and chorioretinitis and are blind. In symptomatic infants, virus can be cultured from throat swabs or urine, and CMV-specific IgM is present in serum. Urine culture results are also positive in asymptomatic infants. Preliminary data suggest that specific therapy with a 3-month course of ganciclovir may provide clinical benefits for symptomatic newborns. However, further evaluation is required, because most of the brain injury occurs in urero. Supportive therapy involves control of seizures.

Most asymptomatic newborns with congenital CMV infection develop normally. However, a percentage develop impaired intellectual function, deafness, microcephaly, chorioretinitis, ataxia, and seizures. The mortality in symptomatic newborns is 20-30%, and most survivors have multiple, severe neurological sequelae (Boppana et al. 1997).

Herpes Simplex

Neonatal herpes simplex infection is acquired during passage through an infected birth canal in the vast majority of newborns. The incidence of this infection in the newborn is increasing, which reflects the high prevalence of herpes infection in adults in the United States, reported to be between 20 and 60%. It may present as localized oral, cutaneous, or ophthalmic disease; localized disease of the CNS, such as meningitis; or disseminated disease with hepatosplcnomegaly, severe disseminated intravascular coagulation, renal failure, and meningoencephalitis. Any infant with CSF suggestive of encephalitis should be considered to have herpes simplex infection until proven otherwise. Intranuclcat inclusions may be detected in vesicular fluid, CSF, or conjunctival scrapings. A throat swab, as well as urine and stool samples, should be cultured. Negative culture results do not exclude the diagnosis. Studies of the CSF usually are consistent with vir.ii meningoencephalitis, and diagnosis may be established quickly using polymerase chain reaction (sec Chapter 59B). Polymerase chain reaction assay is the best technique to identify the virus rapidly in the CSF. CT or MRI, especially diffusion-weighted MRI, is useful for delineating the extent and severity of brain injury. In term newborns a 14-day course of acyclovir (30 mg/kg per day given in evenly divided doses every 8 hours) should be started even before the results of cultures are known. Dosage should be reduced in premature infants and infants who have impaired renal function. Acyclovir may improve outcome but is not as effective as in postnatally acquired infection (Kesson2001).

Toxoplasmosis

Toxoplasmosis is a parasitic infection that is acquired transplacental^ and affects principally the CNS and the eye in the newborn. The result is extensive necrosis and calcification of the cerebral cortex and periventricular tissue. Cerebral injury in the periaqueductal region obstructs CSF flow and causes hydrocephalus. Cataracts and microphthalmia are the main eye abnormalities. Other organs that may be involved are the liver, bone marrow, lungs, muscles, and myocardium.

Antibody screening for neonatal infection may suggest congenital toxoplasmosis, but test results for *Toxoplasma*-specific Ig.Vl often are negative (Pinon et al. 2001). Examination of the CSF may show lymphocytosis, high protein content, and trophozoites. Diffuse intracerebral calcifications may be seen on skull radiography, CT, and US.

Spiramycin, pyrimethamine, and sulfadiazine with folinic acid are used to treat the infected mother and her infant during the first year (Foulon ct al, 2000). Specific doses and regimens are beyond the scope of this discussion. In severe meningoencephalitis, the use of corticosteroids may be considered. Approximately one third of infected infants are symptomatic, and their mortality is 25%. Most survivors have significant neurological sequelae. In contrast, asymptomatic newborns have a good prognosis.

Human Immunodeficiency Virus

The number of newborns who are seropositive for human immunodeficiency virus (HIV) is increasing. Transmission may occur in urero, during labor and delivery, or postnatally by breast-feeding. The vast majority of infected newborns are asymptomatic but later develop opportunistic systemic infections (e.g., CMV or *P>teumocystis)* and dementia with cerebral atrophy and acquired microencephaly caused by viral infection of the brain (Tardieu 1998). The management of HIV-infected women to prevent maternal-infant transmission is beyond the scope of this discussion. Studies have shown that the risk of transmission may be reduced by a program of prenatal, perinatal, and postnatal therapy with zidovudine and may be decreased further by elective cesarean section and avoidance of breast-feeding (Mofenson 1999; Gibb and Tess 1999).

MECHANICAL TRAUMA TO EXTRACRANIAL, CENTRAL, AND PERIPHERAL NERVOUS SYSTEM STRUCTURES

The occurrence of traumatic injuries at birth has been greatly reduced by improvements in obstetrical management. This section discusses the diagnosis and management of traumatic injury according to its anatomical location.

Intracranial Hemorrhage

Othet types of intracranial hemorrhage, such as primary subarachnoid, epidural, subdural, and intracerebcllar hemorrhage, are usually associated with traumatic delivery or a bleeding diathesis and occur less commonly than PIVH (Figure 86.7). Subdural hemorrhage occurs in both ptemature and term newborns and results from laceration of major veins and sinuses. It is often related to excessive molding of the head. CT is the investigational technique of choice for diagnosis of subdural hemorrhage. Convexity subdural hematoma, especially if associated with midline shift, may require decompression by craniotomy or subdural tap. Subarachnoid hemorrhage can also be of venous origin but is usually self-limited, originating from small vessels in the leptomeningeal plexus or bridging veins within the subarachnoid space. Infants may be asymptomatic with minor subarachnoid hemorrhage or present with seizures. Diagnosis may be suspected on the basis of uniformly blood-stained or xanthochromic CSF and

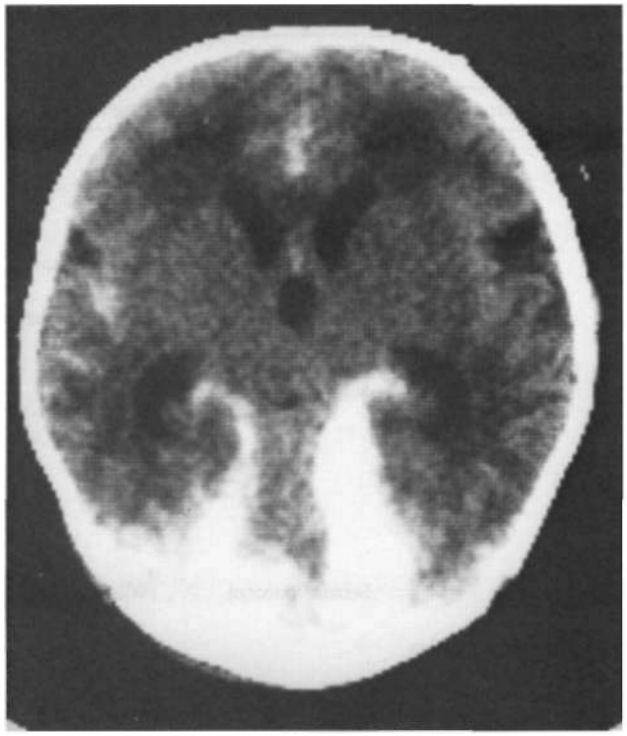

FIGURE 86.7 Computed tomographic scan of posterior fossa hemorrhage (intracercbcllar and subdural).

confirmed by CT scans. In the absence of severe trauma or major hypoxic-ischemic injury, normal outcome is seen in *90%* of patients. Table 86.8 summarizes the clinical features, management, and outcome of these types of intracranial hemorrhage.

Extracranial Hemorrhage

Extracranial hemorrhage is classified according to the tissue planes involved. Caput succedaneum is superficial bleeding between the skin and the epicranial aponeurosis, subgaleal hemorrhage is located between the aponeurosis and the periosteum of the skull, and cephalhematoma occurs in the deepest plane between the periosteum and cranial bones. The major clinical features and the usual outcome for extracranial hemorrhages are summarized in Table 86.9.

Skull Fractures

Skull fractures may be linear or depressed. Linear skull fractures usually are parietal in location. Rony continuity is lost without depression. Depressed skull fractures are called *ping-pong fractures* because the bone buckles inward without loss of continuity, like a depression in a ping-pong ball. Occipital diastasis is not an actual fracture but rather a traumatic separation of the squamous and lateral parts of the occipital bones that is usually associated with breech delivery.

Depressed skull fractures may be suspected clinically by palpation of the skull, but a CT scan is needed to visualize the relation of the depressed bone to the cerebral surface. CT scans are useful also to show a linear fracture beneath a cephalhematoma. Occipital diastasis may be associated with posterior fossa subdural hemorrhage, cerebellar contusion, and brainstem compression without hemorrhage or contusion. The importance of recognizing fractures and diastases is that they alert the physician to the possibility of a more serious intracranial disorder.

In the absence of intracranial lesions, treatment is required only when a depressed fracture impinges on the brain. Spontaneous elevation of the bone may occur with skull molding. Nonsurgical methods for elevation are digital pressure or use of a breast pump or an obstetrical vacuum extractor. Surgical intervention usually is reserved for complicated fractures with extradural or subdural blood clot or bone fragments. A leptomeningeal cyst may develop at the site of a skull fracture. This unusual complication may be identified by transillumination of the region or radiographical evidence of a widening bony defect ("a growing fracture").

Spinal Cord Injury

Spinal cord injury is uncommon. It is caused by excessive **torsion** or traction. Injuries associated with breech delivery (75%) involve principally the lower cervical and upper thoracic regions, whereas injuries after vertex delivery more commonly involve the upper cervical and midcervical cord. Injuries of the lower thoracic and lumbar spinal cord arc even less common and are usually related to vascular occlusion due to umbilical artery catheterization or air embolus from peripheral intravenous injection.

The neurological features reflect the segmental level of the lesion. Newborns with high cervical lesions are often stillborn or die quickly from respiratory failure in the absence of rapid ventilatory support. Lower cervical, upper thoracic lesions cause urinary retention, hypotonia, weakness, and arcflcxia of all limbs, evolving subsequently to spastic paraplegia or quadriplegia. Cord injuries are distinguished from neuromuscular disorders and brain injuries by the demonstration of a distinct sensory level of response to pinprick, **urinary retention,** and **a** patulous anus. Autonomic dysfunction may cause wide fluctuations of body temperature.

Spinal cord injury of fetuses in the breech position can be minimized by cesarean delivery of all fetuses with a hyperextended head. Unfortunately, cesarean section does not entirely eliminate the risk because some fetuses sustain injuries in utero, perhaps caused by vertebral artery (KVIUSLMM. (ord injury after vertex deliver;, ma; be a rare complication of forceps rotation. The diagnosis of spinal

ICP — intracranial pressure.

cord injury is made on the basis of the clinical features. Ultrasonography, radiography, and MR] of the spine are sometimes indicated to exclude surgically correctable lesions such as spinal dysraphism or extramedullar}' compression. Because the cord injury is a tear or inrrnparenchyma] hemorrhage, surgical decompress inn and laminectomy generally are not helpful. Supportive management consists of adequate ventilation and prevention of urinary tract infection, decubitus ulcers, and contractures. High-dose corticosteroids have not been used in controlled trials in spinal cord injury in the newborn age group.

Traumatic Injury to the Peripheral Nervous System

b a rial Paralysis

facial paralysis occurs more commonly in utcro by compression of the facial nerve against the bony sacral

Table 86.9: Clinical features and outcome of extracranial hemorrhage

	Must common location	*Increases after birth*	*Crosses suture lines*	*Marked jcute blood loss*	*Usual outcome*
Caput succedaneum	Vertex	No	Yes	***So***	Resolves in first days of life
Subgaleal hemorrhage	Wide spread entire scalp	Yes	Yes	Yes	Resolves in 2-3 wks
Cephalhematoma	Unilateral parietal	Yes	No	\n	May calcify Resolves in weeks ro months

Note: Extracranial hemorrhage rarely requires intervention, except for subgaleal hemorrhage, in which the amount of acute blood loss may cause shock. Urgent blood transfusion and surveillance for hyperbilirubinemia are sometimes needed. Cephalhematoma is often associated with skull fracture, but does not require treatment.

promontory than by the pressure of forceps blades during delivery. The clinical features are a unilateral widened p.il|v'-•ml '⁚-MIIV i-111 Hinvni-d nasili.iln.i' told with the infant at rest and inability to close the eye completely or grimace when crying. Facial paralysis must be distinguished from *asymmetrical crying fades* resulting from congenital aplasia of the depressor angularis oris muscle.

Facial palsy is managed by the use of artificial tears and taping the affected eye closed at night to prevent corneal injury. Most cases resolve within weeks or months.

Brachial Plexus Injury

Brachial plexus injury occurs in 0.5-2,6 per 1000 live term births. The injury almost always occurs in large newborns who are difficult to deliver (Figure 86.8). The upper roots of the brachial plexus are involved most commonly (Erb's palsy). In other instances, lesions may involve the lower nerve roots down to the first thoracic root (Klumpke's palsy). Approximately 5% of instances are associated with diaphragmatic paralysis caused by injury of the third to fifth cervical roots. Such paralysis may result in tachypnea and hypoventilation, with consequent cyanosis and hypercapnia. Brachial plexus injury also may be associated with Horner's syndrome, a fractured clavicle or humerus, subluxation of the shoulder or cervical spine, cervical cord injury, and facial palsy.

The neurological features of brachial plexus injury may be deduced from an understanding of the function of the involved cervical roots. Thus involvement of the upper cervical roots results in loss of shoulder abduction and external rotation and of elbow flexion and supination, with variable impairment of wrist and finger extension (see Figure 86.8). Absence of the biceps reflex on the affected side and an impaired abduction phase of the Moro reflex are demonstrable. With involvement of the lower roots, paralysis extends to intrinsic hand muscles and includes an absent gtasp reflex. Horner's syndrome occurs in one third of such patients. Deficits of motot function and reflexes are usually more striking than are sensory deficits.

fn the majority of infants, diagnosis is based primarily on careful neurological examination and may be confirmed if necessary by showing electromyographica! evidence of denervation 2-3 weeks after the injury (Sundholm et al. 1998). Clinical suspicion of diaphragmatic paralysis should be confirmed by either fluoroscopy or US scanning. This complication necessitates careful surveillance of respiratory status and perhaps ventilatory support or surgical plication of the affected diaphragm. Other traumatic or bony lesions should be excluded by radiography of the cervical spine, clavicles, and humerus.

Management

The affected arm is usually painful and should be immobilized across the upper abdomen for 7-10 days. Passive range-of-motion exercises are then initiated to prevail contractures. Supportive wrisl splints are important. The value of electrical stimulation techniques is controversial. Prognosis relates largely to the severity of the injury and to the time of onset and rate of initial improvement. Evidence of improved arm function within 2 weeks is a favorable prognostic sign. As many as 88% of infants recover by 4 months and 92% by 12 months. Mirgical reconstruction ol the plexus e.g., nerve grafts and neuroma excision) should be considered in infants with no evidence of spontaneous recovery at 4 months (Strombeck etal. 2000).

FIGURE S6.R Brachial plexus injury in newborn. Upper extremity held adducted, internally rotated, and pronated. Note "waiter's tip" position of affected wrist and fingers,

EFFECTS OF DRUGS AND TOXINS

Exposure of the fetus to medications and toxins may have profound adverse effects on the function of the newborn's central and peripheral nervous systems. These effects may lit' dn idrti :iro;ui'.> mio [/lost- that are teratogenic and those that cause passive addiction. It is often difficult to distinguish between the adverse effects of a specific agent and those associated with confounding influences, such as intrauterine undernutrition, infection, genetic factors, and toxicity of other medications or exogenous substances.

Table 86.10 lists the major adverse effects of the most commonly used ncuroactive agents taken during pregnancy. Prevention is the most important aspect ol management, and women of childbearing age must be advised of the risks to the fetus of noxious agents before conception because the risk of malformations is greatest during the early weeks of gestation.

Teratogenic Effects and Intrauterine Growth Retardation

Congenital malformations and intrauterine growth retardation often are associated. In general, maternal alcohol abuse causes growth retardation and intellectual deficits, whereas anticonvulsant drugs cause congenital heart disease and cleft lip and palate. Exposure to valproate during the first weeks of gestation is associated with a 5% risk of neural tube defects. This risk may be diminished to some degree by preconceptional and periconceptional maternal folate supplementation. Because neural tube defects originate very early during pregnancy (5-6 weeks' gestation), folate administered after confirmation of pregnancy is not helpful in this regard. Distinct syndtomes of growth retardation, developmental delay, dysmorphism, and distal limb abnormalities arc attributed to fetal exposure to phenvtoin (Figure 86.9), barbiturates, alcohol, trimethadione, and valproate (Report of Quality Standards Subcommittee 1998; Kaneko et al, 1999).

Microcephaly and mental retardation arc the most disturbing teratogenic effects attributed to fetal exposure to toxins. Microcephaly occurs in approximately 40% of infants who arc passively addicted to heroin.

Risk of Intracranial Hemorrhage

A hemorrhagic diathesis caused by reduced levels of vitamin K-dependent clotting factors (factors II, VII, IX, and X) may occur in newborns of mothers treated with phenytoin, barbiturates, and primidone; cither prothrombin or partial thromboplastin times are prolonged. Severe bleeding may take place in the skin and internal organs. All newborns exposed to anticonvulsant drugs during pregnancy should be treated with inttavenous vitamin K immediately after delivery, and those with abnormal clotting factors should be given fresh fro/en plasma. Exchange transfusion is indicated if the newborn has hemorrhagic disease.

Passive Addiction and Withdrawal Syndrome

Passive addiction occurs in 60-90% of newborns of mothers using neuroactive drugs (i.e., drugs that affect the CNS during pregnancy). The clinical features of

addiction and withdrawal are similar for most drugs, but the time of withdrawal differs according to the half-life of elimination for the specific drug. Withdrawal symptoms usually start on the first day with heroin, alcohol, short-acting barbiturates, diazepam, tricyclic antidepressants, hydroxyzine, propoxyphene, and pentazocine; at 2-3 days of age with methadone and cocaine; as laic as 7 days of age with longer-acting barbitutates; and at up to 21 days of age with chlordiazepoxide.

The initial features of withdrawal reflect CNS over-activity: jitteriness, irritability, disturbed sleep-wake patterns, shrill cry, and frantic sucking. These may be accompanied In gastrointestinal dislurbaiRvs, MICII as poor feeding, vomiting, and diarrhea, and less commonly by sneezing, tachypnea, and excessive sweating. Fever and seizures are uncommon manifestations of the neonatal withdrawal syndrome (see the exceptions listed in Table 86.10] and suggest the possibility of sepsis or other serious neonatal disorders.

The withdrawal syndrome associated with long-acting barbiturates and hydroxyzine may persist for several weeks. Newborns withdrawing from heroin often appear to recover initially, but latet experience a significant worsening of symptoms that may persist for as long as 6 months.

Effective management requires early diagnosis. Attention is focused on management of respiratory complications, infection, dehydration, and metabolic derangements. In addition, severe and persistent irritability, vomiting, and diarrhea may require treatment with tincture of opium, paregoric, phenobarbital, chlorpromazine, or diazepam.

Tincture of opium (0.4 mg/mL of morphine equivalent) may be given at a dose of 0.1 mL/kg and increased as needed every 3-4 hours by 0.05- to 0.10-mI. increments. The usual dose is 0.2-0.5 mL every 3-4 hours. Other options are oral paregoric (0.8-2.0 ml./kg per day, given in six to eight divided doses) and chlorpromazine (2-3 mg/kg per day given in four divided doses), which effectively control both the CNS and gastrointestinal symptoms. Paregoric contains camphor, which is a stimulant and may have adverse effects in premature infants. Chlorpromazine may cause extra-pyramidal disorders and a lowered seizure threshold. Treatment must be continued for several weeks and tapered gradually to avoid recurrence of symptoms.

Phenobarbital (loading dose of 20 mg/kg, followed by a maintenance dose of 5 mg/kg per day) or diazepam (0.5-1.0 mg intramuscularly every 8 hours! controls only the CNS abnormalities but ii"cs not relieve the gastro-intestinal symptoms. These drugs also cause sedation that may worsen feeding problems. Therefore tincture of opium should be used first and phenobarbital added if CNS abnormalities are not controlled by the narcotic agent alone, which is a distinctly unusual situation.

Chapter 87
Neurological Problems of Pregnancy

D. Malcolm Shaner

Diseases of the nervous system develop and continue despite pregnancy. The good neurologist maintains a broad perspective, balancing the needs of the woman, her fetus, and her loved ones. Insofar as this audience creates an atmosphere for performance, the clinician may feel like a stage character prompted by cues from scattered, incomplete, and occasionally contradictory findings reported in the literature. Still, neurologists who enjoy drama find gratification in caring for the pregnant woman with neurological disease.

NEUROLOGICAL COMPLICATIONS OF CONTRACEPTION

The neurologist can help to plan *a* pregnancy in a woman with pre-existing neurological disease. The expected burden of the woman's neurological disease must be balanced against her perceived need for procreation. Asking her to consider the effect of a child on her life and how the child might be affected by her illness can be beneficial. For instance, a patient who is wheelchair-bound with spinal muscular atrophy or muscular dystrophy may have difficulty with breathing during the later stages of pregnancy, may need cesarean section to deliver the baby, and may have great difficulty lifting the baby as it grows. The neurologist may discuss prenatal genetic testing with women affected by inherited neurological disease. Many-women welcome the neurologist's uninvolved opinion.

Women who decide against pregnancy and use oral contraceptives should be informed that agents containing more than 80 ug of esrrogen are linked to increased incidence of stroke. Information on rhe use of agents containing less than 50 fig of estrogen in nondiabetic, nou hypertensive patients indicates that these agents pose no additional risk or at most a true relative tisk of ischemic stroke of no more than 2,5. Given the very low annual incidence of ischemic stroke in the normal population of women aged 15-44 of approximately 11.3 per 100,000, this small or nonexistent added risk can be considered safe. When women taking this dose smoke cigarettes, the risk of hemorrhagic stroke increases the odds ratio to 3.64 with a 95% confidence interval of 0.95-13.87. Stroke in pregnancy and the puerpenum is discussed later.

Some neurologists advise their female epileptic patients taking microsomal enzyme-inducing anticonvulsants to increase the dose of estrogen in their contraceptives to at least 50 pg. Although this adjustment increases contraceptive effectiveness, the efficacy of the regimen is untested. The result is that barrier, spermicidal, or other contraceptive measures often are recommended for use simultaneously or exclusively. Valproic acid does not induce microsomal enzymes significantly, but there are no studies confirming !,ick n! ilnm iiueracdor with estrogen contraception,

Anticonvulsants do not affect the efficacy or dose of medroxyprogesterone. Medroxyprogesterone may be the contraceptive of choice in women with seizure disorders (Kaunitz 2000). Unwanted pregnancies with levonorgestrel

use have occurred in women taking phenytoin and in women taking carbamazepinc. Some authors advise against the use of levonorgestrcl in patients taking liver enzyme-inducing drugs of any kind, including enzyme-inducing anticonvulsants.

Some neurologists recommend that hormonal contraceptives not be used in women with activated protein C resistance. Estrogen-containing oral contraceptive agents may worsen chronic inflammatory demyelinating polyneuropathy (CIDP), unmask systemic lupus erythematosus, worsen migraine, and produce chorea in patients with antiphospholipid antibody syndrome. The heightened risk of cerebral venous thrombosis (CVT) in women taking oral contraceptive agents increases with prothrombin or factor V gene mutations.

ETHICAL CONSIDERATIONS

Partially settled and unresolved ethical difficulties complicate care of the gravid woman with neurological disease. These problems arc rooted in the occasionally conflicting goals of therapy between mother and fetus. In nearly every instance, physicians juggle responsibilities toward a pregnant woman and the unborn child. In complex situations, multiple interested parties may demand a determining say including the husband, the father (if not the same as the husband), the family, the state, legal representatives, and political and religious groups.

When the neurologist diagnoses maternal death by neurological criteria, a decision must be made whether to conlinue medic;;l inicrvnirious for the sake of a viable or marginally viable fetus. There is no consensus as to the conditions under which such medical intervention must be offered. Physicians sometimes turn to the ethically appropriate surrogate(s) (sometimes one for the mother and one tor the fetus) to discuss the foreseeable possible futures and to ask the surrogate to make a decision with regard to offered medical therapies. A model for this procedure, which the Ethics, Law, and Humanities Committee of the American Academy of Neurology Committee, recommended for affirmation, can be obtained though the Council on Ethical Affairs of the California Medical Association (Council on Ethical Affairs 2002). In some states, the physician helps to select surrogates. In others, a statute-driven "hierarchy" exists. Some states prohibit an appropriate surrogate from permitting the termination of pregnancy for an incapacitated patient but not when the patient is dead. Advising pregnant women to execute advance directives for medical care seems an unlikely and incomplete solution.

HEADACHE

Headache during pregnancy is common. Usually a patient visits the neurologist to receive reassurance that no serious medical problem is apparent. Of the headaches that occur during pregnancy, benign tension headaches are seen most often (sec Chapter 75), There is no known association with hormones and, specifically, no association with the hormonal changes of pregnancy. Treatment for mild headaches often includes behavioral therapy, adequate rest, moist heat, massage, exercise, avoidance of triggering factors, and use of acetaminophen. For severe headaches, the use of a tricyclic antidepressant, such as amitriptyline or nortriptyline, may be helpful. No evidence of embryopathy has been reported with amitriptyline, and preschool children exposed m utero to tricyclic antidepressants have notmal global IQs, language, and behavioral development. When significant comorbid depression is treated, fluoxetine may also be helpful,

Approximately 80% of women with migraine clearly show improvement during pregnancy, but 15% continue to have headaches and in 5% headaches worsen. The prognosis for women with migraine without aura is better than that for women with migtaine with aura. For women anticipating pregnancy, the physician may consider the discontinuation or reduction in dose of all migraine medications because of possible fetal damage. Vigorous treatmen r with behavioral therapy, moist heat, and the judicious use of acetaminophen or opioid preparations can be considered. Migraine usually lessens during the second and third trimesters. The diagnosis of complicated migraine, or de novo migraine with aura, should be made during pregnancy only after a thorough consideration of other diagnoses.

Pregnancy complicates usual migraine therapy. Ergotamine and dihydroergotamine are associated with high rates of fetal malformation and are contra indicated. Eor newer drugs, such as sumatriptan, data are incomplete, and theit general use cannot be advised. Limited information compiled by the makers of sumatriptan and a small prospective study suggest a low teratogenic potential. This news has provoked some authors to suggest that prescription of sumatriptan may be acceptable in pregnant women who suffer physiologically and psychologically disabling migraine, whose headaches respond to sumatriptan, and in whom safer medications have failed (Von Wald 2002). Valproic acid causes fetal ma 1 format ions. During pregnancy, the use of valproic acid to treat headache eithet abortively or prophylactically should be avoided.

There are rare descriptions of fetal toxicity with propranolol, atenolol, and other beta blockers but not with metoprolol. Although often safe during pregnancy, these drugs usually are discontinued or usage is reduced to the lowest effective dose. When physician and patient are convinced that prophylactic therapy is required, the benefit of metoprolol, propranolol, or verapamil may outweigh risks. Incomplete data are available for lithium usage in humans. In animals, lithium is teratogenic. Use during pregnancy to treat headache should be avoided. Naproxen sodium is relatively safe throughout pregnancy but safest

when used during the first two trimesters. Metoclopramidc, acetaminophen, and meperidine do not increase fetal risk and may be of benefit.

In general, the breast-feeding woman with migraine should avoid ergotamine and lithium. Sumatriptan, antidepressants, and neuroleptics can be used cautiously.

LEG MUSCLE CRAMPS

Between 5 and 30% of pregnant women experience painful leg cramps, which do not adversely affect the fetus and are not dangerous but can be very bothersome to the patient. The condition resolves rapidly postpartum. Typically, cramps occur in the morning or evening during the last trimester of pregnancy. Changes in the ionic concentrations of potassium, magnesium, sodium, and calcium may be important in the pathogenesis. Magnesium lactate or magnesium citrate tablets (122 mg in the morning and 244 mg in the evening) relieve or considerably lessen symptoms in approximately 80% of patients. Placebo is similarly effective in 40%. Some physicians report successful therapy with oral calcium carbonate or gluconate 500 mg three or four times daily. Passive stretch and massage are helpful for the acute cramp,

RESTLESS I.ECS

Unpleasant paresthesias (desctibed as creeping, crawling, aching, or fidgetiness) localized deep within both legs affect 10-27% of pregnant women. Usually they begin 30 minutes after the patient lies down and are reported mainly in the last trimester. An irresistible desire to move the legs accompanies the discomfort,

Approximately 80% of patients complaining of restless legs experience periodic movements of sleep {see Chapter 74). These are stcteotyped flexion movements of the legs during non-rapid eye movement sleep, which may awaken the patient, leading to sleep loss and excessive daytime somnolence. Caffeine ingestion, uremia, alcohol use, iron deficiency, hypothyroidism, vitamin deficiency, rheumatoid arthritis, peripheral neuropathy, and medications are important, if only occasional, associated factors.

Folic acid 500 mg daily may be of benefit in treating restless legs during pregnancy. Anecdotal reports suggest a benefit from vitamin E, vitamin C, and magnesium supplements. Electric vibrators, stretching, walking, decreased activity, and massage also may be helpful. For severe restless legs during pregnancy, i.-dopa/carbidopa 25 mg/100 mg may be preferable to several other dopamine agonist medication-; sliowr. to *he* effective in nonpregnant patents. A single dose before bedtime, increasing to efficacy or the use of several doses through the night has been anecdotally reported to be helpful. Advantages of the use of the L-dopa/carbidopa combination include its demonstrated clinical effectiveness for both restless legs and periodic movements of sleep and its low teratogenic potential.

MYASTHENIA GRAVIS

Fertility is unaffected by myasthenia gravis, and oral contraceptive agents do not weaken the patient with myasthenia gravis. No single study offers certainty with regard to the cumulative risk that pregnancy causes in the patient with known myasthenia gravis. Pregnancy did not worsen the long-term outcome of patients with myasthenia gravis in one small prospective Italian study (Batocchi et al. 1999). Patient conditions may remain stable, improve, worsen, or both improve and worsen at different stages of pregnancy. Approximately two thirds of patients report some worsening at some time during pregnancy or the puerperium. The puerperium and first trimester are times of greatest risk. The course of myasthenia gravis for a future pregnancy cannot be predicted from the course of previous pregnancies.

The effect of thymectomy on myasthenia gravis usually is delayed. The potential mother can be advised that the procedure may be helpful for a pregnancy beginning approximately 1 year after surgery. Generally, the woman who may become pregnant is best served when the physician uses drugs other than azathioprine and cyclosporine, Azathioprine is teratogenic, and the safety of cyclosporinc during gestation is uncertain.

Myasthenia gravis docs not influence the contractile strength of the smooth muscle of the uterus, the incidence of postpartum hemorrhage, or the occurrence of toxemia. Usually, the course of labor and delivery is unaffected. Premature labor may be more common in women widi myasthenia gravis but varies considerably among studies.

The medical therapy of myasthenia gravis changes little with pregnancy. Anticholinesterase agents including edrophonium (Tensilon) and plasmapheresis arc relatively safe, Rapid drug metabolism during pregnancy may require increasing the rate or dose of anticholinesterase drugs. Corticosteroids may increase the risk of gestational diabetes and preeclampsia. Abortion does not lessen the manifestations of myasthenia gravis. Although human immunoglobulin has been used safely during pregnancy, the number of patients studied is small.

Regional anesthesia is preferred for cesarean section. When the patient is taking anticholmestetase agents, the metabolism of procaine is slowed and poorly predictable. In those patients, lidocaine is favored for local anesthesia, Neuromuscular blocking agents, such as curariform drugs, must be avoided, because they may have a greatly prolonged effect in patients with myasthenia gravis. The use of magnesium sulfate as a tocolytic agent or as a treatment for preeclampsia may precipitate a myasthenic crisis and is contraindicated.

When the pregnant woman with myasthenia gravis develops the rare complication of immunologically mediated thrombocytopenia, intravenous immunoglobulin may be helpful before delivery to increase the platelet count to greater than 50 x 10^9/litcr (Ellison 2000).

Perinatal mortality increases to 6-8% for infants of women with myasthenia gravis, which is approximately five times that of the normal population. Approximately 2% of these are stillborn. Transient neonatal myasthenia affects 10-20% of infants born to women with myasthenia gravis. Most infants who develop transient myasthenia gtavis do so within the first day, but weakness may begin up to 4 days after delivery and usually resolves within 3-6 weeks. Neonates must be observed carefully for at least 4 days. An imperfect correlation has been observed between maternal levels "I ai....cetylcholine receptor antibodies and the likelihood that the neonate will develop transient myasthenia gravis. Intrauterine exposure to these receptor antibodies rarely may result in arthrogryposis.

Breast-feeding poses no significant difficulty, although there is evidence that the antiacetylcholine receptor antibodies do pass to the baby in the breast milk. Cyclosporine and azathioprine are secreted in breast milk; they should be avoided because of theit tisk of immunosuppression and riimorigcnic potential. Corticosteroids also are secreted into breast milk but in small amounts. Large doses of anticholinesterase drugs taken by the mother may lead to gastrointestinal upset in the breast-fed newborn.

DISORDERS OF MUSCLE

Myotonic Dystrophy

Pregnancy is uncommon in women who have advanced myotonic dystrophy, probably because of progressive ovarian failure. Before the development of advanced disease, there is no significant reduction in fertility. For women who are able to conceive, pregnancy can be hazardous for both mother and fetus. Myotonic weakness often worsens during the second half of pregnancy. Congestive heart failure is reported. Ineffective uterine contractions, premature labor, and breech presentation often complicate labor. Tocolysis may result in aggravation of myotonia. Oxytocin can stimulate the myotonic uterus to produce increased contractions. Myotonic dystrophy complicates obstetric anesthesia, and regional anesthesia is preferred. Patients with myotonic dystrophy are unduly sensitive to respiratory suppression with pentobarbital. After delivery, hypotonic uterine dysfunction results in an increased risk of retained placenta and postpartum hemorrhage. One half of the children bom to women with myotonic dystrophy inherit the disordet. Anticipation due to an increased number of triplet repeats (see Chapter 44) is responsible for the syndrome of congenital myotonic dystrophy in the neonate (see Chapter 85). Many neonates are hypotonic, and high rates of morbidity are reported. Fetal myotonic dystrophy may affect fetal swallowing, causing polyhydramnios. Prenatal diagnostic testing with amniocentesis or chorionic villus biopsy is available.

Inflammatory Myopathy

Pregnancy worsens or activates polymyositis and derma tomyositis. Manifestations of collagen vascular disease commonly associated with myositis may complicate pregnancy. More than one half of fetuses die, but surviving infants thrive. Immunosuppressive treatment is advised for gravid women.

Neuropathy

Bell's Palsy

Facial nerve palsy is three to four times more common during pregnancy and the puerperium. A retrospective chart review found the prognosis for recovery of facial nerve function to be worse when facial palsy occurs during pregnancy (Gillman 2002). Some researchers found an increased incidence of toxemia in patients with gestational facial palsy. Herpes simplex virus type 1 is implicated as the cause of most facial palsies and varicella-zoster far less often. Pharmacological therapy of Bell's palsy during pregnancy remains controversial. Prednisone 1 mg/kg for 5 days, tapering rapidly over a total 10-day course when begun within 3 days of onset of facial weakness, may be effective in improving the prognosis in nongravid adults. Simultaneous administration of acyclovit 400 mg five times daily for 10 days is more effective than prednisone alone in a similar population. This combination of drugs has not been tested adequately during pregnancy, but individually the drugs pose low risk. Patching of the eye and lubricating eye drops may help prevent corneal irritation (see Chapter 76).

('iirptil 'Ittimcl .Si udronut

Approximately one in five pregnant women reports nocturnal hand paresthesias, primarily during the last trimester, often associated with peripheral edema. Excessive weight gain and fluid retention increase the occurrence of these complaints. This irritation can be expected to disappear spontaneously within weeks after parturition. During pregnancy, conservative therapy is indicated. Splinting of the wrist in the neutral position at night is helpful. Additionally, some physicians inject corticosteroids into the carpal tunnel. When hand muscles supplied by the median nerve weaken, surgical decompression using fiberoptic techniques is indicated.

Meralgia Paresthetica

The expanding ahdominal wall and the increased lordosis of pregnancy stretch the lateral femoral cutaneous nerve to the thigh as it penetrates the tensor fascia lata or at the inguinal ligament. This unilateral or bilateral affliction of late pregnancy resolves within 3 months postpartum.

Acute Polyradiculoneuropathy (Guillain-Barre Syndrome)

Pregnancy does not affect the incidence or course of acute polyradiculoneuropathy. Usually, infants of a mother without complications are born healthy. Some authors recommend fluid loading before plasmapheresis to prevent hypotension. Others suggest avoidance of tocolytics in the presence of autonomic instability. Intravenous human immunoglobulin has been used safely during pregnancy, but the number of patients who received this therapy and were srudied remains small.

Chronic Inflammatory Demyelinating Polyneuropathy

CIDP is three times more likely ro relapse during the last trimester and puerperium than in the absence of pregnancy. Infants are unaffected. Corticosteroids, plasmapheresis, and intravenous immunoglobulin are used to treat exacerbations during pregnancy. Oral contraceptives can worsen CIDP.

Charcot-Marie-Tooth Disease Type 1

Small studies indicate that Charcot-Marie-Tooth disease type 1 worsens in approximately one half of affected women during pregnancy. The magnitude of the effect of pregnancy on this disease remains unclear. Risk is less when weakness begins in adulthood. After delivery, this deterioration improves in one third of patients and becomes persistently progressive in two thirds of patients. The course and outcome of pregnancy are unaffected. Epidural anesthesia for labor has been used safely.

Gestational Polyneuropathy

Distal symmetrical neuropathy affects malnourished women. Presumably, thiamine and possibly other nutrients are deficient in these patienrs. The acute presentation of symmetrical neuropathy and Wernicke's encephalopathy (see later) in the third and fourth months may be due to the thiamine deficiency associated with hyperemesis gravidarum.

Maternal Obstetric Palsy

Peripheral nerves are occasionally the objects of intrapartum compressive trauma by the fetal head, the application of forceps, and improperly positioned leg holders. Craniopelvic disproportion, dystocia, prolonged labor, and primigravida status contribute to these injuries.

Unilateral lumbosacral (L4, L5, and rarely SI) plexus injury is most common. The fetal brow strikes the nerves as they cross the posterior brim of the true pelvis. The associated sensory deficir usually involves more widespread sensory loss than that due to peroneal neuropathy. Peroneal nerve injuries often are caused when the nerve is compressed between a leg holder and the fibular bead. Less common obstetric palsies include those of the femoral and obturator nerves.

Most maternal obstetric palsies are neuroapraxic and resolve **willnn** (> WIVKS. 1:I iutii:v **pnr.i)i iki;.-..** women **with** recurrent craniopelvic disproportion, dystocia, or axonal degeneration with their initial neuropathy are candidates for cesarean delivery. Otherwise, a cautious trial of labor may be prudent.

WERNICKE'S ENCEPHALOPATHY

More than three fourths of women experience nausea and vomiting during pregnancy, most commonly between 6 and 16 weeks' gestation. When vomiting becomes severe enough to result in weight loss or metabolic derangement requiring intravenous therapy, the term *hyperemesis gravidarum* is applied. Commonly, hyperemesis is isolated and idiopathic. Molar pregnancy, hyperthyroidism, and hepatitis are differential diagnostic considerations. Studies on treatment with vitamin B_6 (pyridoxine) 10 mg three times per day for 5 days showed little benefit, but enthusiasts continue to recommend this treatment, sometimes with ginger (Niebyl 2002).

Apathy, drowsiness, memory loss, catatonia, ophthalmoplegia, nystagmus, ataxia, optic neuritis, and papilledema may result, typically between 14 and 20 weeks" gestation, and are described as features of Wernicke's encephalopathy (see Chapter 63). This condition is sometimes associated with gestational polyneuropathy and central pontine myclinolysis. Exacerbating factors include persistence of the hyperemesis over at least 3 weeks and the administration of intravenous glucose without other nutrients. Death or severe morbidity results when this condition is not treated. In a small study, only one half of women with this condition delivered normal children.

The amount and duration of parenteral thiamine supplementation that are required is unknown and must be titrated to the clinical state. Generally, parenreral therapy for at least 1 week is recommended or until a normal diet can be resumed. Despite therapy, some women continue to have ataxia and visual difficulties months to years afterward. Several authors suggest treating any patient with prolonged nausea and vomiting with oral thiamine 100 mg daily.

CHOREA GRAVIDARUM

Chorea of any cause beginning in pregnancy is chorea gravidarum. Historically, rheumatic heart disease (often fatal) was associated with most cases. Rheumatic heart disease has virtually disappeared. Today, the disease linked most strongly with this condition is the antiphospholipid antibody syndrome, with or without systemic lupus erythematosus. Additional etiologies include tardive dyskinesia due to neuroleptics, hyperthyroidism, Wilson's disease, vascular disease, other hypercoagulable states, and a variety of intoxications.

Chorea commonly presents during the second to fifth months of pregnancy and uncommonly may begin postpartum. Subtle, sometimes severe, cognitive change may accompany the chorea. Usually, this condition resolves spontaneously within weeks to months, often shortly after delivery. Choice of therapy tor this often benign condition depends on the severity of the disorder and other accompanying clinical manifestations. Expectant observation, cautious use of haloperidol, and use of corticosteroids have been successful. Oral contraceptives also have been associated with the appearance of chorea. The mechanism by which pregnancy and oral contraceptives cause chorea is unknown. Chorea may recur in subsequent pregnancies.

MULTIPLE SCLEROSIS

Uncomplicated multiple sclerosis has no apparent effect on fertility, pregnancy, labor, delivery, the rate of spontaneous abortions, congenital malformations, or stillbirths. The approximately 13% reduction in pregnancy rate among women with multiple sclerosis noted in one study may resell Iron: plusioi] di-,abilil\ and from iviimtii deciding not to have children. Oral contraceptive agents do not affect the incidence of multiple sclerosis (Hernan et al. 2000).

Despite several careful studies, the effect of pregnancy on the course of multiple sclerosis remains controversial. Small, prospective analyses challenge the long-held conclusion that multiple sclerosis worsens overall as a result of pregnancy. Some authors suggest that pregnancy has either a beneficial effect or no significant effect on disease course. Larger, retrospective studies describe a decrease in the exacerbation rate of multiple sclerosis during the last trimester and an increased rale during the 6 months after parturition. Glatiramer acetate, interferon-/3-1a, and interferon-^-lb have not been studied adequately during pregnancy. Until information is available regarding safety, these medications should be discontinued before an anticipated pregnancy. Mitoxantrone causes fetal damage in animals. Mitoxantrone should not be used during pregnancy and only with contraceptives in fertile women.

Management strategies for multiple sclerosis must be adapted to the individual pregnant patient. Anecdotal reports detail the success of plasmapheresis in a pregnant woman with rapidly progressive multiple sclerosis and in another woman with Devic's syndrome. Clinical improvement has been associated with the use of intravenous immunoglobulin in a few case studies. Short-term courses of corticosteroids during pregnancy seem safe, but baclofen and tizanidinc have not been well studied.

TUMORS

Primary Brain Neoplasms

Brain tumors of all types occur during pregnancy, but only at 38% of the rate expected in nonpregnant women of fertile age. Diminished fertility in women with these tumors may explain this reduction, because pregnancy probably does not protect against the development of neoplasms. Studies show increased numbers of abortions before the symptoms of tumor appear. Whether pregnancy worsens morbidity and mortality in women with brain tumors is not known, hut certain tumors grow more rapidly during pregnancy. Meningiomas have estrogen receptors, which may explain the enlargement usually seen during pregnancy. The rate at which spinal hemangiomas rupture inert .sis with the duration of gestation, Symptoms ol meningioma, vascular tumors, and acoustic neuromas may remit postpartum due to tumor shrinkage.

Gestational brain tumors tend to present at different stages dependent on tumor type: gliomas usually present problems during the first trimester, meningiomas during and after the second trimester, and vascular tumors in the third trimester.

Malignant tumors or tumors threatening compression of vital brain structures usually require surgery during pregnancy. Surgery for some benign tumors can wait several weeks postpartum to observe for spontaneous improvements. Babies of most women with brain tumors arc delivered by cesarean section. Vaginal delivery is reserved for patients whose tumor would not pose a threat of herniation with the shifts of intracranial pressure associated with labor. Pregnancy interruption is considered when increased intracranial pressure, vision loss, or uncontrolled seizures develop as a result of the tumor.

Administration of corticosteroids commonly lessens symptoms of brain tumors (see Chapter 58), but fetal hypoadrenalism may result from their use. Physicians usually defer potentially teratogenic chemotherapy until after delivery. Cranial radiation therapy during pregnancy may be helpful to the mother, but no dose of radiation can be considered completely safe for the fetus. The fetus usually is seriously affected when it receives doses greater than 0.1 Gy (10 rads), which may cause growth retardation, microcephaly, and eye malformations. The fetus may be affected by lower amounts of radiation, particularly early in gestation. Researchers

estimate that in utero exposure to 0.01-0.02 Gy of radiation increases the incidence of leukemia by 1 case per 6000 exposed children. Estimates of the fetal dose during radiation for brain tumors range from 0.03-0.06 Gy. One study suggests that alternative positioning of the patient may reduce fetal exposure to as little as 0.003 Gy when a dose of 30 Gy is delivered to the brain (Magnc 2001).

Pituitary Tumors

Women with untreated hyperprolactinemia often are anovulatory and infertile. Treatment with dopamine agonists restores ovulation in 90% of patients. During pregnancy, medical therapy focuses on preventing complications of tumor growth. Bromocriptine reduces prolactinoma size usually within 6 weeks to 6 months. Although this drug has not been demonstrated to have teratogenic potential, some authors recommend discontinuation of the medication unless it is clearly needed during pregnancy. Bromocriptine suppresses lactation. Puerperal maternal hypertension, seizures, stroke, and cerebral angiopathy have been reported anecdotally with its use. Data on other dopamine agonists during pregnancy are limited. The normal pituitaty gland and most pituitary tumors grow during pregnancy. The woman with a pituitary microadenoma (<I0 mm I may be reassured that fewer than 5% of these tumors grow enough to become symptomatic. The risk for a macroadenoma becoming symptomatic tanges from 16 to 36% but is considerably less for patients who receive radiation or surgical therapy before pregnancy. Commonly, physicians advise women with macroadenomas to have transsphenoidal surgery before attempting pregnancy or to receive bromocriptine therapy during pregnancy. Visual fields and acuity can be checked monthly. Monitoring of prolactin levels is not helpful. Magnetic resonance imaging (MRI) is indicated after delivery and should be performed if symptoms are increasing. For the woman in whom a symptomatic macroprolactinoma is diagnosed during pregnancy, therapeutic options include bromocriptine therapy, pregnancy termination, or surgery.

Usually, women with pituitary tumors deliver vaginally. Studies have not demonstrated tumor growth associated with breast-feeding. Pituitary apoplexy may present within days, weeks, or occasionally years after delivery. Uncommonly, a pituitary mass presenting in late pregnancy, or up to 1 year postpartum, may be lymphocytic hypophysitis.

Choriocarcinoma

Cerebral metastases are a common manifestation of this rare tumor of trophoblastic origin. The tumor metastasizes first to the lung and then from lung to brain. This often happens months after a molar pregnancy or abortion. Approximately 15% of tumors follow normal pregnancies, but most are discovered after pregnancies characterized by spontaneous abortion or by vaginal bleeding, premature labor, and an enlarged uterus due to a molar pregnancy. Women with such cerebral metastases present with seizures, hemorrhage, Infarction, or gradually progressive deficits. Tumor may invade the sacral plexus, cauda equina, or spinal canal. A ratio of serum to cerebrospinal fluid chorionic gonadotropin less than 60 suggests the presence of choriocarcinoma brain metastasis. Chemotherapy, radiation, and surgery have yielded successful results when the diagnosis is made early.

Idiopathic Intracranial Hypertension (Pseudotumor Cerebri) {see Chapter 65)

Idiopathic intracranial hypertension (IIH) usually worsens with pregnancy. Some authors advise a delay in pregnancy until all signs and symptoms of pre-existing 11H abate. Termination of pregnancy is of unknown value and is not indicated. Healthy babies usually result tegardless of whether IIH begins before or during pregnancy,

Commonly, IIH develops during the fourteenth gestational week and disappears after 1-3 months, but it sometimes persists until the early puerperium. Typically, these women are obese and gain weight rapidly with pregnancy. Brain imaging is normal or may show slitlike ventricles. Protein levels may be slightly low in otherwise normal spinal fluid.

Frequent checks of optic fundi, visual acuity, and visual fields are recommended to monitor the condition and the results of treatment. Initial cerebrospinal fluid pressures that exceed 350 mm H2O usually indicate more severe disease. Careful studies of the effectiveness of treatment arc unavailable. Most physicians advise moderation in diet to reduce weight gain. Two-week courses of corticosteroids, most commonly dexamethasone or prednisone, may be added for vision loss. Four to six serial lumbar punctures can be performed, sometimes weekly, before optic nerve sheath fenestration or lumbopentoneal shunt is considered.

The use of acetazolamide remains controversial; human studies are inadequate to determine its efficacy or teratogenic potential. Nevertheless, acetazolamide has been used to treat IIH during many pregnancies productive of healthy infants. Some physicians recommend restricting its use until after 20 weeks' gestation.

Headaches may be improved by acetaminophen with or without codeine. More aggressive therapy usually is reserved for vision loss. Adequate pain control during labor may decrease expected rises in intracranial pressure.

Usually, these patients can undergo vaginal delivery with epidural analgesia. Recurrence of IIH in a subsequent pregnancy is unusual.

EPILEPSY AND ITS TREATMENTS

Maternal Considerations

Women with epilepsy have approximately 15% fewer children than expected. Reasons offered for this decrease in fertility include social effects of epilepsy, menstrual irregularity, the effect of some antiepileptic medications on the ovaries, and an effect of seizures oil reproductive hormones.

The effect of pregnancy on seizure occurrence can be predicted from the control of epilepsy during the 9 months preceding gestation. The fewer seizures there are in the 9 mn:uhs (•:••:in- ₍-:>iKY-iruii. -In- Im'.iT ihe risk of wors ening during the pregnancy. Women who have at least one seizure in a month can be expected to have mote seizures during pregnancy. Women who have less than one seizure in 9 months usually do not experience an increase in seizure rate during pregnancy.

Most studies suggest that approximately one fourth of women experience an increase in seizure rate during gestation, which may result from lowered levels of circulating unhound antiepileptic drugs (AEDs). Pregnancy alters protein binding of many AEDs and increases the volume of distribution and metabolism of many drugs. However, even when blood levels of drugs are maintained adequate!;.. .ip^iiixiiirrrb I!)',',', ◁] women can expect worsened seizure control during pregnancy. During labor, approximately 1-2% of epileptic women have a convulsive seizure, and another 1-2% have a seizure within 24 hours of delivery. Other factors that may contribute to an increase in seizure rate include hormonal changes, sleep deprivation, mild chronic respiratory alkalosis, the use of folic acid supplements, and emotional factors. Seizure type did not play a role in some studies, but in othets, partial complex epilepsy worsened more often during gestation,

Convulsive seizures during pregnancy can result in blunt trauma to the mothct. Trauma is the leading nonobstetric cause of maternal death in women with epilepsy, but its incidence is ven low .

Controversy continues over whether seizures increase risks for developing eclampsia, preeclampsia, blood loss, placental abruption, and premature labor. For studies that claim increased risk, these risks are calculated to be approximately 1.5-3.0 times the risk of women without epilepsy. These reports have been based largely on retrospective and registry studies. The limited prospective data suggest that women with epilepsy have no or minimal additional risk for these complications.

Fetal Considerations

Nearly 90% of epileptic women deliver healthy, normal babies, but risks of miscarriage, stillbirth, prematurity, developmental delay, and major malformations are increased in epileptic mothers. Maternal seizures; AEDs; and socioeconomic, genetic, and psychological aspects of epilepsy affect outcome.

Although AEDs may cause significant problems for the fetus, the consensus among neurologists has been that maternal seizures probably are more dangerous. Convulsive seizures cause fetal hypoxia and acidosis and are associated with the potential for blunt trauma to the fetus and placenta (Holmes et al. 2001). Fetal heart rate slows during and for up to 20 minutes after a maternal convulsion, which suggests the presence of fetal asphyxia. The child of an epileptic mother experiencing convulsions during gestation is twice as likely to develop epilepsy as the child of a woman with epilepsy who does not have a convulsive seizure during gestation,

In previous studies, the rate of major birth defects in the general population has been estimated to be approximately 2.0—4.8%, depending on the population studied and methodology used. The risk of birth defects increases for infants of women with epilepsy to a rate of 3.5-6.0%, independent of the effect of medication. In general, use of a single AED increases the risk of congenital malformations to 4-8%. Researchers found a 5.5% incidence of malformations with two anticonvulsant drugs, 11 % with three anticonvulsant drugs, and 23% with four AEDs.

Data from a large study add to our knowledge of the influence of gestational seizures and the diagnosis of maternal epilepsy on fetal malformation (Holmes et al, 2001). In a prospective study, investigatots screened 128,049 singleton pregnancies in nondiabetic, English-speaking patients at delivery between 1986-1993. They physically examined 414 children of epileptic mothers and 508 control subjects and reported the incidence of major malformations (structural abnormalities of surgical, medical, or cosmetic importance not including microcephaly, growth retardation, or hypoplasia) to be 1.8% in their normal, control population. With one AED (phenytoin, carbamazepine, or phenobarbital), this rate rises to 3,4-5.2% and with two or more to 8.6%. Some women with a history of seizures did not take anticonvulsants during pregnancy and had a rate of major malformation statistically the same as the control population at 0%. Women who suffered seizures during the first trimester and were taking their .lnlkniivukiiil drugs **k.ul** .1 rale **◁ii nujoi malli** iriiiation of 7.4-7.8%, This carefully gathered information challenges the notion that the diagnosis of maternal epilepsy itself contributes to major malformation of the fetus and lays blame for teratogenesis squarely on the use of AF.Ds. Pregnant women may be reassured that current data do not indicate risk of malformation to their fetus Iron-, an uncomplicated seizure during the first trimester.

AEDs exert their most serious effects during the first 2.5 months of gestation. Changes in medication must be made before or during the first trimester to be maximally useful. The neural tube closes between 3 and 4 weeks. Cleft lip and palate occur with exposure before 5 and 10 weeks, respectively, where.is congenital heart disease due to anticonvulsant exposure occurs before 6 weeks' gestation.

Studies disagree on whether the anomalies caused by phenytoin and carbamazepine are dose dependent. Valproic acid increases the risk of neural tube defects and other malformations 3- to 20-fold, to approximately 1-2%, and *as* teratogenic effect ^ are dim[1] related. (.arkiala/cp-.iie also is associated with neural tube defects, with an incidence of 0.5-1.0%. A syndrome described initially as *fetal hydantoin syndrome*—including midfacial hypoplasia, long upper lip, low birth weight, cleft lip and palate, digital hypoplasia, and nail dysplasia—occurs with carbamazepine, primidone, and valproic acid and is more accurately called *fetal anticonvulsant syndrome.* Some minor anomalies usually disappear during the first years of life. Investigators speculate that midfacial hypoplasia associated with hypoplasia of the facial bones could be a marker for cognitive dysfunction. Trimethadione has such a high teratogenic potential that its use during pregnancy is contraindicated, and it should not be used in women who might become pregnant.

Adequate human studies of newer anticonvulsant drugs during pregnancy are lacking. The teratogenic potential of gabapentin, vigabatrin, tiagabine, zonisamidc, lamotriginc, topiramate, clobazam, levetiracetam, and oxcarbazepine is known incompletely. At this time, the physician may consider reevaluating the need for these anticonvulsants in a patient planning pregnancy or substituting an agent whose potential for risk is known,

Common Advice and Management Strategy

The need for AED therapy should be reevaluated before conception. Monotherapy at the lowest effective dose is preferred. Warning the patient about the effects of sleep deprivation and noncompliance with the drug regimen may be helpful when paired with a thorough description of the potential consequences of seizures and benefits of AEDs. AED levels can be monitored more often during gestation and the postpartum period and dosage adjusted as indicated. Women with a family history of neural tube defects probably should be weaned from valproic acid or carbamazepine, particularly if there is a suitable substitute,

Pregnant women with epilepsy who are already taking AEDs when seen by the neurologist should be managed on an individual basis. During pregnancy and particularly after the period of organogenesis has passed, changes in medications are likely to cause more harm than good.

Women who take folic acid supplements before and during pregnancy lower their risk of delivering a child with major malformations. The use of folic acid has become routine, but recommendations vary. The Department of Health in the United Kingdom and the Centers for Disease Control and Prevention in the United States have recommended, respectively, 5 and 4 mg of folic acid daily for women who have had a child with a neural tube defect and 0.4 mg for all other women planning pregnancy. Anticonvulsants inhibit the absorption of folic acid. Occasionally, folic acid lowers levels of anticonvulsants. Some authors suggest that 5 mg of folic acid be given daily to women treated with valproic acid or carbamazepine. Others recommend 2-4 mg daily for all women with epilepsy who are taking anticonvulsants, beginning as long as 3 months before conception until 12 weeks' gestation.

In one study, women taking AEDs and a multiple vitamin supplement containing folic acid had no teduction in the risk to their infants of developing cardiovascular defects, oral clefts, or urinary tract defects compared with women who took no supplements (Hernandez-Diaz 2000).

Eor patients taking AEDs during pregnancy, a second-trimester high-resolution ultrasound evaluation helps to exclude spina bifida aperta, cardiac anomalies, and limb defects. When results of the ultrasound scan are inconclusive, amniocentesis can be considered and tv-feroprorein and acetylcholinesterase levels obtained.

A deficiency of vitamin K-dependenr clotting factors occurs in some neonates born to women who take phenobarbital, primidone, carbamazepine, ethosuximide, or phenytoin. Although rarely reported, neonatal intracerebral hemorrhage may be attributable to this vitamin K deficiency. In an attempt to lower this risk, physicians prescribe oral vitamin Ki 10-20 mg daily beginning 2-4 weeks before expected delivery and until birth. Often, the neonate receives a single 1- to 2-mg intramuscular injection of vitamin K| immediately after delivery. The American Academy of Pediatrics has recommended that physicians inject every newborn with 1 mg of vitamin K_L intramuscularly. When hemorrhage occurs, fresh-frozen plasma corrects the hemorrhagic state acutely. When the expectant mother who is taking AEDs presents in labor without having received vitamin K, supplements, some authors recommend administration of 10 mg of intravenous vitamin K| to the mother during labor, 2 mg to the neonate immediately postpartum, and fresh-frozen plasma if needed on the basis of fetal cord coagulation studies. Despite this sage advice, a study by Kaaja (2002) could not support the hypothesis that maternal enzyme-inducing AEDs increase the risk for bleeding in offspring, yet the author endorses antenatal administration of vitamin K in selected women taking AEDs during pregnancy.

Occasionally, seizures occur for the first time during pregnancy. Pregnancy has little effect on the use of diagnostic examinations and treatment considerations. The most common causes of seizures during child bearing years include idiopathic epilepsy, trauma, congenital defects, neoplasms, meningitis, intracerebral hemorrhage,

and drug or alcohol toxicity. In addition, pregnancy predisposes women to certain epileptogenic conditions, such as eclampsia, water intoxication, thrombotic thrombocytopenic purpura, sinus or cortical venous thrombosis, and amniotic fluid embolus. Common iatrogenic causes of epilepsy include hyponatremia due to intravenous fluid infusion during the intrapartum period, and the use of epidural or parenteral anesthetics.

A single first-onset seizure resolving within minutes usually can be managed acutely without anticonvulsants. Once the physician determines the cause for the seizure and whether further seizures are likely, the need for anticonvulsant medication can be reviewed.

There arc no special considerations during pregnancy when potentially fatal generalized convulsive status epilepticus is treated. The choice of initial anticonvulsant regimen remains controversial. Physicians agree that use of a specific treatment regimen they arc familiar with and prompt application generally assure the best chance of success. Monotherapy with phenobarbital or lorazepam and combined therapies with phenytoin are effective.

Anticonvulsants are secreted in breast milk and ingested by the infant. Sedation and hypcrirritability are reported. Infants may show withdrawal reactions from phenobarbital after lactational exposure. The World Ilea lib Organization Working Group on Human Lactation and the American Academy of Pediatrics disagree on the safety of breast milk containing ethosuximide, which may cause hypercxcitability and poor suckling. Known health benefits of breast milk probably outweigh potential suhtle and theoretical effects of AEDs on the nervous system. Zonisamide, lamotrigine, and oxcarbazepine arc classified as unsafe to use during breast-feeding, whereas the safety of other newer AEDs remains uncertain.

CEREBROVASCULAR DISEASE

Arteriovenous Malformations

The risk of repeat hemorrhage from a *previously ruptured arteriovenous malformation* (AVM) generally outweighs the risk from surgical excision or an obliterative procedure. Usually, surgical excision can be performed shortly after the diagnosis and before pregnancy is considered. When proton beam irradiation is performed, some authorities advise the woman to wait 2 years before conception. The decision about whether an *unruptured AVM* should be observed, i'\i i-i-ii, c:i::vili/i-ii. or ir:-.idiaii-d rem.lins control **ersial. No** specific therapeutic course can be recommended for patients planning pregnancy.

The risk of hemorrhage from an AVM (whether unruptured or previously ruptured) rises from a low point during childhood and teenage years to a higher risk during childhearing years. Whether pregnancy poses an additional risk remains uncertain. The best retrospective review suggests that risk of hemorrhage during pregnancy resulting from an unruptured AVM may be as low as *3.5"/o.* This is probably no different from the risk to nonpregnant women with unruptured AVMs. Multiple pregnancies do not increase the rate of hemorrhage. In the past, physicians routinely advised women with an AVM, previously ruptured or not, to avoid pregnancy. This conclusion might have been expected from information available from early retrospective studies that 87% of AVMs rupture during pregnancy and that 25-30% of initial tuptures are fatal. Subsequent analysis has contradicted these dismal estimates. Still, we have no prospective studies. The clinician must exercise caution in interpreting this information.

Women whose AVM is repaired surgically can undergo vaginal delivery. Physicians usually perform cesarean section for incompletely repaired or partially treated previously ruptured AVMs. Epidural anesthesia is preferred.

Intracranial Hemorrhage

Women presenting with pregnancy-associated stroke are as likely to have an infarct as an intracerebral hemorrhage. Compared with the nonpregnant state, intracerehral hemorrhage occurs 2.5 times more often during pregnancy and almost 30 times more often during the 6 weeks postpartum. Up to 44% of these hemorrhages are associated with eclampsia and preeclampsia. In France, nearly one half of women with intracerehral hemorrhage associated with eclampsia die. Additional diagnostic considerations include bleeding diatheses, cocaine toxicity, bacterial endocarditis, sickle cell disease, and metastatic choriocarcinoma. In approximately one third of patients who have intracerebral hemorrhage, no specific cause is uncovered.

Subarachnoid hemorrhage is a common cause of nonobstetric maternal death. Hemorrhage from aneurysms and vascular malformations account for 25-35% of intracranial hemorrhages. Management strategies are generally the same as those applied outside of pregnancy. Definitive therapy for AVMs may usually he postponed until after delivery, whereas surgery or obliterative therapy for an aneurysm usually is urgent. The effects of some treatment agents for subarachnoid hemorrhage, such as nimodipine, on the human fetus have not been studied well. However, the potentially fatal consequences of the vasospasm associated with subarachnoid hemorrhage make their use reasonable during pregnancy.

Anticonvulsants, specifically phenytoin, are unnecessary and ineffective in nongravid patients who have had an intracranial hemorrhage hut have not had a seizure. Data during pregnancy are unavailable. Anticonvulsants probably are best reserved for women whose hemorrhage may herniate if intracranial pressure rises with a seizure or after the first convulsion.

Although many physicians recommend cesarean section for patients with gestational intracranial hemorrhage, mode of delivery did not affect outcome in the studies available. Vaginal delivety can be performed with epidural anesthesia.

Ischemic Stroke

Most women who have a stroke before gestation complete uneventful pregnancies with excellent outcomes. Women in whom emboligenic cardiac disease, systemic lupus erythematosus, antiphospholipid antibody syndrome, or other coagulopathies are diagnosed have the added risk tor stroke during pregnancy associated with those conditions. Stroke during one pregnancy by itself is not a risk factor for stroke in subsequent pregnancies.

MRI can be used selectively to scan the brain and the venous and arterial circulations and is useful during pregnancy. No study or clinical observation has detailed harmful effects on mother or child, but detailed longitudinal studies on children exposed in utero to MRI are lacking.

Two-dimensional echocardiography may be the test of greatest importance when a woman with gestational stroke is evaluated. Computed tomography and selective angiography are associated with a small risk to the fetus and must be performed with adequate shielding and hydration. Magnetic resonance angiography may help in the diagnosis of aneurysm, AVM, arteritis, venous thrombosis, or vasospasm, because it is important to avoid radiation wherever possible.

One woman in every 10,000-20,000 deliveries has a stroke. During pregnancy, the risk of cerebral infarction does not exceed the risk in age-matched fertile control subjects, but during the 6 weeks postpartum, the risk is approximately nine times that of the risk of nonpregnant women. Cesarean delivery and gestational hypertension place women at increased risk for stroke.

Eclampsia and preeclampsia are associated with approximately one fourth of pregnancy-related infarcts in the United States and approximately one half of such infarcts in France. In 25-35% of patients, the cause remains unclear. In the remainder, the stroke is symptomatic of a systemic illness, including premature atherosclerosis, hypertension, cardiac disease, hyperlipidemia, diabetes, arterial dissection, Takayasu's disease, vasculitis, antiphospholipid antibody syndrome, systemic lupus erythematosus, sickle cell disease, thrombotic thrombocytopenic purpura, cerebral venous thrombosis, coagulopathies, tobacco, cocaine, and other drug use. Etiologies of stroke unique to pregnancy include chotiocarcinoma, postpartum cerebral angiopathy, and postpartum cardiomyopathy. Stroke during labor or shortly after vaginal delivery may result from an amniotic fluid embolus.

Aspirin at a low dose (60-150 mg per day) has been used throughout pregnancy and is demonstrably safe in the second and third trimesters. No longitudinal studies have confirmed the efficacy of aspirin in the prevention of stroke during pregnancy. The safety and efficacy of clopidogrel and ticlopidine are unknown during pregnancy, and their use in this situation has not been advised.

Cardiac Disease

Prosthetic heart valves are associated with embolization; rates depend on whether the valves are aortic, mitral, bioprosthetic, or mechanical. Mechanical valves have the highest rate, Bioprosthetic valves are associated with better pregnancy outcomes, but some researchers postulate that gestation accelerates the natural rate of calcification and degeneration of these prostheses, ultimately leading to valve failure. We lack convincing studies that demonstrate an effect of pregnancy on these valves.

Attempts to resolve the most pressing issue of anticoagulation in women with mechanical hcatt valves have been unsatisfactory. Risk of thromboembolism of some mechanical valve prostheses during pregnancy has been reported to be 25-35%, much higher than the annual risk m the nonpregnant state of about 1.25-5.4%. In the nonpregnant state, target values for warfarin therapy and the use of aspirin 80-100 mg per day vary, depending on whether the valves are caged ball, tilting disk, or bileaflet. Aortic or mitral valvular location, the presence of atria! fibrillation, left atrial size, or thrombus, and previous thromboembolic episodes also influence some recommendations for anticoagulation (Stein 2001), Conflicting data and incomplete studies impede attempts to ttanslate these recommendations for the pregnant patient.

Warfarin is teratogenic, with maximal effect during the first 6-12 weeks of gestation, and is associated with a high rate of fetal loss, congenital malformations, and mental and physical disability. Physicians postulate that serious complications of warfarin use during the second and third trimesters are caused by microhemorrhages within the brain. Included among these are dorsal midline dysplasia such as corpus callosum dysgcncsis/Dandy-Walker malformation or ventral midline dysplasia with optic atrophy, mental retardation, developmental delay, seizures, and microcephaly. Approximately 30% of living progeny suffer fetal embryopathy. *Fetal warfarin syndrome* includes nasal hypoplasia/stippled epiphyses, limb hypoplasia, low birth weight, hearing loss, and ophthalmic anomalies. One study found that women taking more than 5 mg of wariflrin daily had an increased likelihood of fetal complications—an effect independent of the extent of anticoagulation as measured by the international normalized ratio. Insignificant quantities of warfarin are found in breast milk.

One systematic review and pooling of literature on fetal outcome for women with mechanical heart valves suggests that warfarin embryopathy occurs in 6.4% of live births when warfarin is taken throughout pregnancy (Chan 2000).

A logical therapeutic alternative to warfarin during pregnancy is heparin. Heparin does not cross the placenta and is not associated with teratogenic effects. The substitution of unfractionated heparin for warfarin at or before 6 weeks' gestation eliminates the risk of warfarin embryopathy, but increases the risk of thromboembolic complications over warfarin alone. Regardless of anticoagulant therapy, maternal mortality is approximately 3%, and fetal wastage is 16.3-44.4%. Additional, carefully controlled studies arc needed to clarify the validity of these data.

Some authors recommend that patients with mechanical heart valves who require warfarin be counseled against pregnancy. Others suggest substituting unfractionated or low-molecular-weight heparin (L.V1WH) for warfarin during 6-12 weeks' gestation. Warfarin may then be i . . . >iiikiV w i n disL(>i:lini:.-.[]()ii ol |I:L- h e p a r i n al the thirteenth week. At the middle of the third trimester or at about 36 weeks, warfarin should be discontinued. Heparin may be given optionally until just before early induced labor or cesarian section. Some European experts, based on a belief that the risks of warfarin are overstated, recommend use of warfarin throughout pregnancy (Vcrstracte et al. 2000). In the United States warfarin is categorized by the U.S. Food and Drug Administration as possessing fetal risk "which clearly outweighs any possible benefit to the patient (USFDA Category X)." Complete data on the use of LMWH fot this indication are unavailable.

like unfractionated heparin, LMWH does not cross the placenta and offers additional benefits, including reduced incidence of heparin-induccd thrombocytopenia, osteoporosis, and bleeding complications. No blood test is required to monitor its safety. Relative safety has been demonstrated in small studies that include women with antiphospholipid antibody syndrome and active lupus disease, but clear indications for the use of these preparations are still under investigation. Each vatiety of LMWH has its own therapeutic level and properties. Case reports document thromboembolic complications in women with mechanical valves who receive certain preparations of LMWH during pregnancy.

The incidence of cerebral embolism associated with chronic atrial fibrillation during pregnancy is 2-10%. When atrial fibrillation is associated with cardiac disease, physicians recommend anticoagulation throughout gestation, commonly with high-dose subcutaneous heparin.

Antiphospholipid Antibody Syndrome

Women with circulating antiphospholipid antibodies and without a history of pregnancy loss do not require treatment to prevent stroke during pregnancy. Successful pregnancies without treatment are common. Women with ven high antibody liters, habitual nrst-irimosu-r ahorrion, a single miscarriage in the later trimesters, or a symptomatic antiphospholipid antibody syndrome, particularly with previous stroke, usually receive treatment. Various studies have examined the use of monotherapy or polytherapy in widely ranging doses and combinations of aspirin, prednisone, subcutaneous unfractionated heparin (UFH), intravenous immunoglobulin, and, occasionally, placebo. Studies on LMWH are optimistic, but preliminary. Stroke in these women may occur at doses of heparin sufficient to produce a therapeutic partial thromboplastin time. Some authors advise women seriously ill with symptomatic antiphospholipid antibody syndrome not to become pregnant.

For women with previous thromboembolism, subcutaneous heparin {UFH or LMWH) is recommended, ideally just before conception and throughout pregnancy. Suggested regimens include 10,000 U of unfractionated heparin twice daily with monitoring of partial thromboplastin time, cnoxaparin 40 mg once daily, or dalteparin 5000 U once daily. The dose may be reduced during labor and then continued postpartum usually for 3-7 days.

Women with antiphospholipid antibodies and monosymptomatic habitual pregnancy loss should receive subcutaneous, high-dose UFH, together with low-dose aspirin until 34 weeks' gestation. A combination of low-dose aspirin and LMWH during pregnancy appears to be current practice in the United Kingdom (Shehata et al. 2001) for women with antiphospholipid antibodies and a history of fetal loss after 16 weeks' gestation, intrauterine growth retardation, early-onset preeclampsia, placental abruption, or stillbirth.

Postpartum Stroke

Debate continues over classification of syndromes described as postpartum cerebral angiopathy, delayed peripartum vasculopathy, or postpartum stroke. These patients present with puerperal focal neurologic signs and symptoms and often with headaches and have hypertension without edema or proteinuria. Brain MRI scanning depicts ischemia primarily in the parietooccipital region, and angiography commonly demonstrates vasospasm. The course often is benign, but permanent deficits are reported, When these occurrences include reversible headache, altered sensorium, seizures, or visual loss without hemorrhage, they can be considered to belong in the category of a reversible posterior leukoencephalopathy syndrome. Some researchers believe postpartum stroke is a form of eclampsia/prceclampsia and suggest relaxation of requirements for diagnosis of eclampsia/prceclampsia.

Witlin et al. (2000) provide a case series and describe "postpartum stroke" as an uncommon and unprevcntable complication of pregnancy. After excluding trauma, neoplasm, infection, or eclampsia, they describe women suffering ischemic or hemorrhagic stroke without specific warning. The hemorrhage may follow initial ischemia with injury to the blood vessel walls. In general, these events

were most common around the eighth day after delivery (range 3-35 days) and were associated with cesarean delivery. Seizures in one half of patients, an increase in the mean arterial pressure to 1.5 times above the baseline, and headache herald the onset. Two of 20 patients died of severe intracerebral hemorrhage. Included in this series were patients with cerebral venous thrombosis and a ruptured AVM. The authors postulated that the hypercoagulabte or thrombophilic state of pregnancy may emerge as a major risk factor, perhaps interacting with underlying coagulopathies.

Cerebral Venous Thrombosis

Aseptic thrombosis of the cerebral venous system, in its most obvious clinical state, presents with puerperal headache that worsens over several days, a change in behavior or personality, convulsive seizures, and neurological deficits. The patient may be emotionally regressed, anxious, or lethargic, with mild to obvious neurological signs, and, occasionally, papilledema. Initial symptoms generally begin 1 day to 4 weeks postpartum and peak in occurrence at "-14 Jus poMpanjm.

CVT has been associated with hypcrcoagulable states, infection, sickle cell disease, dehydration, and ulcerative colitis, in addition to gestation. Differential diagnoses include eclampsia, meningitis, and cerebral mass.

Brain MRI scanning with magnetic resonance venography is the initial imaging procedure of choice. Although it detects occlusion of major sinuses with high sensitivity, when smaller veins are involved, detection may be more difficult. The MRI may show multiple small infarcts involving the gray and white matter, sometimes with minor hemorrhage. Selective or digital subtraction angiography may be considered in some patients.

Geographic location influences the frequency of CVT. India reports a high rate of puerperal CVT, estimated at 400-500 per 100,000 births. This high rate is attributed primarily to dehydration and has a predilection for women delivering at home. Incidence in the United States is comparatively low, approximately 9 per 100,000 deliveries.

CVT associated with pregnancy is relatively more benign than that occurring without pregnancy. Researchers in Mexico describe a mortality of approximately 10% for gestational CVT and 33% for CVT not associated with pregnancy. In the United States, estimates of the mortality of CVT from all causes suggest that approximately 1 of 10 patients dies. However, death did not occur in a national survey of 4454 patients with penpartum CVT in the United States. Cesarean section and age oldet than 25 are risk factors for CVT.

Researchers find diminished activity of protein S and antiphospholipid antibodies in women with gestational and puerperal CVT. Occasionally, multiple defects in coagulation are encountered in the same woman. Current theory suggests that levels of proteins, such as C4b-binding protein, increase during pregnancy and the puerperium, creating a hypcrcoagulable state. Some women have conditions that predispose them to hypercoagulation during pregnancy, such as activated protein C resistance (factor V Leiden mutation), protein S deficiency, or antithrombin III antibodies. Homocystinuria (hyperhomocyst|ejinemia) may increase risk.

Heparin anticoagulation may be of benefit, particularly if the patient has concurrent thrombophlebitis in the pelvis and legs. Some observers recommend heparin therapy only when clinical indicators suggest that a poor prognosis is likely. Therapy with antifibrinolytic agents is controversial. Thrombolysis of an occluded dura] sinus with urokinase or with [issue plasminogen activator via selective venography has been used as initial therapy without significant deterioration. Physicians performing this procedure claim therapeutic success, even for some patients with cerebral hemorrhage. Heparin and antifibrinolytic therapies are relatively contraindicatcd when the patient has had an intracranial hemorrhage. Long-term anticonvulsant therapy usually is unnecessary.

ECLAMPTIC ENCEPHALOPATHY

Preeclampsia (toxemia gravidarum) and eclampsia remain the principal causes of maternal perinatal morbidity and death. Edema, proteinuria, and hypertension after 20 weeks' gestation characterize the syndrome of preeclampsia. Epileptic seizures and this preeclamptic triad comprise the syndrome of eclampsia. Defining the terms *preeclampsia* and *eclampsia* in this way simplifies a complex disorder. Important and common manifestations, such as hepatic hemorrhage, disseminated intravascular coagulation, ahruptio placentae, pulmonary edema, papilledema, oliguria, headache, hyper-reflexia, hallucinations, and blindness seem relatively neglected in this definition. Occasionally, eclamptic seizures may precede the clinical triad of preeclampsia. Reasoning that pedal edema is ubiquitous and nonspecific during pregnancy, a consensus group recommended that physicians exclude edema as a criterion for the diagnosis of preeclampsia and concluded that the dyad of hypertension and proteinuria is sufficient, more sensitive, and no less specific (Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy, 2000).

Preeclampsia develops in approximately 4-8% of the pregnancies in prospective studies. Eclampsia accounts for nearly OIK- half of intracranial hemorrhages and nearly one half of cerebral infarcts in pregnancy and puerperium in French hospitals. In the United States, the figures are lower {14 and 24%, respectively). Methodological problems plague these studies, and accurate estimates are difficult to obtain. Neurological symptoms are more likely when the onset of eclampsia is postpartum. Maternal morbidity and

mortality Increase when eclampsia occurs at 32 weeks' gestation.

A specific laboratory test for rhis disorder is lacking, and understanding of the pathogenesis remains incomplete. Conditions considered to place women at added risk for preeclampsia include multifetal gestations, previous preeclampsia, insulin-treated diabetes mellitus, hypercoagulable states, and chronic hypertension. Geneticists have associated preeclampsia with a molecular varianr of the angiotensinogen gene and suggest a possible genetic predisposition. Some authors postulate that damage to the fetal-pi a cental vascular unit {such as defective placentation) may release products toxic to die endothelium, causing diffuse vasospasm and organ injury. Researchers point to soluble fms-like tyrosine kinase 1, a substance produced in toxic amounts by the placenta and implicated in reducing levels of angiogenic trophic factors, vascular endothelial growth factor (VEGF) and placenta! growth factor (P1GF). Lack of these trophic factors may result in the clinical and pathological syndrome of preeclampsia. Short intervals between pregnancies reduce the risk of preeclampsia (Skjaervcn et al. 2002). No theory explains satisfactorily the tendency for preeclampsia or eclampsia to affect primarily young, primigravid women.

At autopsy of patients who died of eclampsia, pathologists find cerebral edema; hypertensive encephalopathy; subarachnoid, subcortical, and petechial hemorrhages; and infarction of multiple areas of the brain and brainstem. The occipital lobes, parietal lobes, and watershed areas are most vulnerable. Although any of these lesions may cause seizures, the patient may not have a seizure. This observation has led to criticism that the definition of eclampsia solely on the basis of a seizure is too restrictive.

Two theories compete to explain the genesis of the cerebral lesions. Elevated blood pressure may overcome protection that is usually provided by the precapillary-arteriolar sphincter. Loss of autoregulation then leads to rupture of fragile capillaries, resulting in ring hemorrhages and thrombosis. Alternatively, diffuse cerebral endothelial dysfunction may precipitate generalized cerebral vasospasm, producing the same pathologic changes.

One review observed that many women in whom preeclampsia or eclampsia was diagnosed had, in retrospect, clinical presentations most consistent with other diseases. These included cerebral arterial infarction, hypertensive encephalopathy, and CVT. Eagerness to diagnose (o\;i:ii.i, '•iiv,ih", ilur :n [In niu. i which tin condition naturally presents, may overestimate its incidence in epidemiological studies. The neurologist must consider alternative diagnoses carefully.

Biuiul pressure elevations consistent!; equal to 140/90 without proteinuria beyond 20 weeks after conception in a woman previously normotensivc is gestational hypertension. Gestational hypertension complicates 6% of pregnancies. Within this group arc women suffering from unrecognized chronic hypertension and transient hypertension of pregnancy. One quarter of them will develop preeclampsia/eclampsia. Transient, mild hypertension does not affect mother or fetus. When the physician discovers end-organ damage associated with gestational hypertension, the patient is managed according to the recommendations for preeclampsia. When proteinuria (>300 mg per 24 hours) accompanies gestational hypertension, physicians may diagnose preeclampsia; although this definition has not been substantiated by research, it is used commonly,

Severe preeclampsia is defined hy the magnitude of blood pressure elevation (usually a systolic pressure of 160 mm Hg or a diastolic pressure of 110 mm Hg on two occasions at least 6 hours apart while the patient is resting in bed), amount of proteinuria (>500 mg of protein per 24 hours or 3+ in random urine samples taken at least 4 hours apart), the presence of end-organ injury, or symptoms of possible end-organ injury (headache, right upper quadrant pain, visual disturbance, or altered sensorium) in a woman with preeclampsia. Approximately 4-14% of women with preeclampsia develop a syndrome called HELLP—an acronym for hemolysis, elevated *liver* enzyme levels, and low platelets. All three components must be present, Hemolysis is detected by an abnormal peripheral blood smear, a bilirubin level of 1.2 mg/dL, or a lactate dehydrogenase level of 600 EU/liter. Liver enzyme levels are considered elevated when aspartate aminotransferase is 2 times normal. A plateler count of less than 100 x 10 /p.L is low. HELLP syndrome is considered a form of severe preeclampsia with a high rate of maternal and fetal injury. Patients complain of malaise, nausea, right upper quadrant pain, and vomiting. Occasionally, HELLP syndrome presents without preeclampsia and is considered a separable clinical entity.

Women in whom preeclampsia is diagnosed and rheir fetuses should receive careful monitoring (ACOG 2002}. When preeclampsia is severe or hypertension is more than mild (systolic pressure of 160 mm Hg or diastolic pressure of 105-110 mm Hg), consensus groups recommend methyldopa and labetalol as appropriate first-line therapies. Hydralazine is used commonly.

Severe preeclampsia, eclampsia, or HELLP syndrome requires definitive therapy. Commonly, women are delivered within 24—48 hours of presentation, and all gestational products must be removed from the utetus by vaginal or cesarean delivery.

Parenteral magnesium sulfate is used extensively to treat symptoms of severe preeclampsia and eclampsia while the woman awaits delivery. In a large clinical trial, women presenting for delivery with hypertension were given either phenytoin or magnesium sulfate. Among the women receiving magnesium sulfate, fewer developed seizures. In a separate analysis of women with eclampsia, magnesium sulfate therapy reduced recurrent seizures better than regimens using cither diazepam or phenytoin. The mechanism of action remains unclear. The most coherent theory

suggests that magnesium sulfate affects the pathogenesis of cerebral disease, resulting in a secondary effect on the seizures rather than functioning as an anticonvulsant itself. Usually, the drug is continued for a day after delivery. AEDs commonly used to prevent and control eclamptic seizures include barbiturates, phenytoin, and benzodiazepines.

For some women, thrombocytopenic purpura and hemolytic-uremic syndrome may be seen with or complicate toxemia and HELLP syndrome. Death and severe neurological disease are common. Survival may be improved with the use of plasma transfusion and plasmapheresis.

Low-dose aspirin thctapy was effective in preventing eclampsia in small trials, but larger studies of women at high risk for preeclampsia showed no benefit for aspirin 60 mg taken daily. French researchers claimed beneficial effects for aspirin 100 mg daily when doses are given by about 17 weeks' gestation. Women whose bleeding time increased were more likely to benefit (Dumont 1999). The combination of aspirin with ketanserin, a selective seroronin-2 receptor blocker, may prevent preeclampsia in women with hypertension diagnosed before 20 weeks' gestation. However, consensus opinion has not endorsed the use of aspirin with or without ketanserin to prevent preeclampsia,
